Alkylating agents	Mechlorethamine (Mustargen)	Hodgkin's lymphoma Lymphosarcoma Lung cancer Chronic leukemia	Nausea and vomiting Leukopenia Thrombocytopenia Hyperuricemia	Maintain good hydration. Alkalinize urine. Administer antiemetics prior to chemotherapy. Monitor WBC, uric acid. Assess for infection.
	Busulfan (Myleran)	Chronic myelogenous leukemia	Leukopenia Thrombocytopenia Renal failure Pulmonary fibrosis	Monitor WBCs, BUN. Maintain adequate fluid intake. Assess for infection. Assess lungs for fibrotic (coarse, loud) rales.
	Cyclophosphamide (Cytoxan)	Lymphomas Multiple myeloma Leukemias Adenocarcinoma of lung and breast	Hemorrhagic cystitis Renal failure Alopecia Stomatitis Liver dysfunction	Encourage daily fluid intake of 2–3 L during treatment. Monitor WBCs, BUN, liver enzymes. Teach ways to manage hair loss.
Antimetabolites	Methotrexate	Acute lymphoblastic leukemia Osteosarcoma Gestational trophoblastic carcinoma	Oral and gastrointestinal ulcerations Anorexia and nausea Leukopenia Thrombocytopenia Pancytopenia	Monitor CBC, WBC differential, BUN, uric acid, creatinine. Assess oral mucous membranes; treat ulcers prn. Assess for infection, bleeding.
	5-Fluorouracil (5-FU)	Colon carcinoma Rectal carcinoma Breast carcinoma Gastric carcinoma Pancreatic cancer	Stomatitis Alopecia Nausea and vomiting Gastritis Enteritis Diarrhea Anemia Leukopenia Thrombocytopenia	Monitor CBC with differential, BUN, uric acid. Administer antiemetics prn. Assess for bleeding; check stool occult blood. Evaluate hydration and nutrition status. Teach oral care for stomatitis. Assess for infection. Teach care for hair loss.
Antitumor antibiotics	Doxorubicin (Adriamycin)	Acute lymphoblastic leukemia (ALL) Acute myeloblastic leukemia Neuroblastoma Wilms' tumor Breast, ovarian, thyroid, lung cancer	Stomatitis Alopecia Nausea and vomiting Gastritis Enteritis Diarrhea Anemia Leukopenia Thrombocytopenia Cardiac toxicity	Monitor ECG; assess for arrhythmias, gallops, and congestive heart failure (CHF). Monitor CBC with differential, BUN, uric acid. Administer antiemetics prn. Assess for bleeding; check stool for occult blood. Evaluate hydration and nutrition status. Teach oral care for stomatitis. Assess for infection. Teach care for hair loss.

TABLE 14–10 Classifications of Chemotherapeutic Drugs (*continued*)

Drug Classification	Common Drugs	Target Malignancies	Adverse Effects or Side Effects	Nursing Implications
	Bleomycin (Blenoxane)	Squamous cell carcinoma Lymphosarcoma Reticulum cell sarcoma Testicular carcinoma Hodgkin's lymphoma	Mucocutaneous ulcerations Alopecia Nausea and vomiting Chills and fever Pneumonitis and pulmonary fibrosis	Check for fever 3–6 hours after administration. Have chest x-ray films taken every 2–3 weeks. Assess respiratory status, and check for coarse rales. Evaluate hydration and nutrition status. Teach oral care for stomatitis. Assess for infection. Teach care for hair loss.
Plant alkaloids	Vincristine (Oncovin)	Combination therapy for acute leukemia, Hodgkin's and non-Hodgkin's lymphomas, rhabdomyosarcoma, neuroblastoma, Wilms' tumor	Areflexia Muscle weakness Peripheral neuritis Constipation Paralytic ileus Mild bone marrow Depression	Assess neuromuscular function. Monitor CBC with differential. Evaluate gastrointestinal function. Manage constipation.
	Vinblastine (Velban)	Combination therapy for Hodgkin's lymphoma, lymphocytic and histocytic lymphoma, Kaposi's sarcoma, advanced testicular carcinoma, unresponsive breast cancer	Areflexia Alopecia Nausea and vomiting Bone marrow depression	Assess neuromuscular function. Monitor CBC with differential. Administer antiemetics prn. Teach ways to manage hair loss.
	Etoposide, also called VP-16 (VePesid)	Nonresponsive testicular tumors Small-cell lung cancer	Alopecia Hypotension with rapid infusion	Hydrate adequately before administration. Administer over 60 min. Monitor vital signs every 15 min during administration and every 2–4 hours thereafter. Teach ways to manage hair loss.
	Prednisone	Combination therapy for many tumors Leukemia Lymphoma	Fluid retention Hypertension Steroid diabetes Emotional lability Silent bleeding ulcers Increased risk for infection	Monitor vital signs. Administer diuretics prn. Check blood glucose regularly. Evaluate mental status. Administer oral medications with food. Administer hydrogen ion antagonist drugs (antacids) as ordered. Monitor WBC with differential. Check for signs of systemic infection.
	Diethylstilbestrol (DES)	Advanced breast and prostrate cancers	Fluid retention Feminization Uterine bleeding	Monitor vital signs. Administer diuretics prn as ordered. Explain reason for feminization to men, bleeding to women. Monitor for excessive bleeding.
	Tamoxifen (Nolvadex)	Breast cancer	Hot flashes Nausea and vomiting	Teach ways to manage hot flashes. Explain reason for hot flashes. Administer antiemetics as ordered.
Miscellaneous drugs	Cisplatin (CDDP) (Platinol)	Combination and single therapy for metastatic testicular and ovarian cancers, advanced bladder cancer, head and neck tumors, non-small-cell lung carcinoma, osteogenic sarcoma, neuroblastoma	Bone marrow depression: leukopenia and thrombocytopenia Renal tubular damage Deafness	Monitor WBC with differential and platelets, BUN, creatinine, uric acid. Watch for bleeding. Monitor for signs of infection. Evaluate hearing; check for tinnitus. Ensure that patient is well hydrated before drug is administered. Encourage 2–3 L of fluid intake daily.

textbooks for additional drugs and for new combination therapies as they are developed.

PREPARATION AND ADMINISTRATION Many states and individual hospitals require that personnel be trained and certified to administer chemotherapy. Pharmacists in large hospitals and independent home care agencies usually prepare chemotherapeutic drugs for parenteral administration under specific safety guidelines established by the federal government or the Oncology Nursing Society. In some agencies, nurses both prepare and administer these drugs. Because of the potential carcinogenic effects of chemotherapy drugs, healthcare professionals should wear gloves, a mask, and gown while preparing and administering the drug and disposing of equipment. The nurse must use care when handling excretory products of patients undergoing chemotherapy and teach patients to dispose of their own body fluids safely. Oral medications pose a lesser risk of exposure, but a risk nonetheless, primarily through excretion in the urine.

Chemotherapeutic drugs can be administered orally, such as cyclophosphamide (Cytoxan) and chlorambucil (Leukeran). Other drugs, such as hormones or hormone-blocking agents, may be given intramuscularly. However, many drugs require intravenous infusion or direct injection into intraperitoneal or intrapleural body cavities. Intravenous preparations can be given through large peripheral veins, but the risk of extravasation or irritation to the vein may preclude this method for long-term therapy. Many patients now receive vascular access devices (VADs), especially if their treatment requires several cycles over weeks or months. VADs are also useful for adjunctive parenteral nutrition in the patient who needs continuous intravenous infusions to manage pain or frequent blood drawing to monitor blood counts. Different types of VADs are available:

- Catheters that are inserted nonsurgically by threading them through a large peripheral vein into the vena cava. Called peripherally inserted central catheters (PICCs), they have multiple lumens that facilitate blood drawing. Placement is usually monitored by fluoroscopy.
- Catheters tunneled under the skin on the chest into a major vein, such as the subclavian vein. Hickman or Groshong catheters may be used.
- Surgically implanted ports are placed under the skin with a connected catheter inserted into a major vein. These are accessed by means of a special needle with a 90-degree angle inserted through the skin directly into the rubber dome of the port, which has a hard plastic back to prevent tissue damage.

Figure 14–6 ■ shows examples of different catheters and vascular access ports.

Risk of infection, catheter obstruction, and extravasation are the main problems associated with VADs. Nurses must teach patients and family members to observe for redness, swelling, pain, or exudate at the insertion site, which may indicate infection; to observe for swelling of the neck or skin near the VAD for extravasation and infiltration; and to flush catheters and provide site care (cleaning and dressing changes) on a regular basis. During each encounter with the patient, the nurse always inspects the site; observes for infection, infiltration, and catheter occlusion; and provides site care when necessary.

MANAGEMENT OF PATIENTS RECEIVING CHEMOTHERAPY Nurses help identify and manage toxic effects or side effects of the drugs and provide psychosocial support (ONS, 2013c, 2013e). Careful assessment and monitoring of the patient's manifestations, including appropriate laboratory tests, alert the nurse to the onset of toxicity. Nausea and vomiting, diarrhea, inflammation and ulceration of oral mucous membranes, hair loss, skin changes, anorexia, and fatigue require specific medical and nursing actions (discussed later in this chapter under the appropriate nursing diagnoses). Indicators of organ toxicities, such as nephrotoxicity, neurotoxicity, or cardiac toxicity, must be reported immediately to the physician.

Another aspect of managing patients undergoing chemotherapy is to teach them how to care for access sites and to dispose of used equipment and excretions safely. Nurses teach patients to increase fluid intake to flush out the drugs; to get extra rest, which can both

Figure 14–6 ■ Vascular access devices. *A,* Single- and double-lumen catheters. *B,* Triple-lumen and groshong catheters.

assist therapy and help the patient avoid other illnesses; to identify major complications of their particular drug protocol; to know when to call the physician or emergency medical services; and, if their WBC count is low, to limit their exposure to other people, especially children or those with infections (ONS, 2013g).

During chemotherapy, a number of psychologic issues that can cause moderate to severe emotional distress may arise. The need to plan activities around chemotherapy treatments and their side effects can impair the patient's ability to work, manage a household or care for family members, function sexually, or participate in social and recreational activities (ONS, 2013a). Weight loss and alopecia may prompt feelings of powerlessness and depression. The nurse can assist by carefully evaluating manifestations, providing specific interventions, and allowing patients opportunities to express their fears, concerns, and feelings (ONS, 2013a, 2013c, 2013g). Patients should be encouraged to participate in their care and maintain control over their life as much as possible. Specific interventions will be discussed later in the chapter under the appropriate nursing diagnoses. Table 14–10 includes nursing implications for specific adverse effects of common chemotherapy drugs.

RADIATION THERAPY Still the treatment of choice for some tumors and of some oncologists, radiation may be used to kill the tumor, to reduce its size, to decrease pain, or to relieve obstruction. Lymph nodes and adjacent tissues are irradiated when beginning metastasis is suspected. **Radiation therapy** consists of delivering ionizing radiations of gamma and x-rays in one of two ways:

- *External radiation,* also called *teletherapy*, involves delivery of radiation from a source at some distance from the patient. A relatively uniform dosage is delivered to the tumor.
- *Internal radiation,* also called **brachytherapy**, is a process in which radiation is given inside the body by implanting small amounts of radioactive material directly into a tumor or body cavity while avoiding scattering radiation to the surrounding tissues or organs. This technique allows delivery of high doses of radiation to the tumor while sparing adjacent tissue. Brachytherapy is referred to as internal, interstitial, or intracavitary radiation. The innovation of brachytherapy uses a MammoSite catheter to provide a 5-day accelerated partial breast irradiation and holds promise of reducing the risk of radiation-induced complications.

Lethal injury to DNA is believed to be the primary mechanism by which radiation kills cells, especially cells in faster growing tumors and tissues. As a result, when given over time, radiation can destroy not only rapidly multiplying cancer cells but also rapidly dividing normal cells, such as those of the skin and mucous membranes. A malignant tumor is considered cured when there are no surviving tumor stem cells. The goal of radiation therapy is to achieve maximum tumor control with a minimum of damage to normal tissue.

Implanted or ingested radiation can be dangerous for those living with, taking care of, or treating the patient. Caregivers must use protection by, for example, shielding themselves from the source of radiation, limiting the time of exposure to the patient, increasing the distance from the patient, and using specific safety procedures for handling secretions. Box 14–5 identifies safety principles to be followed by those caring for patients undergoing internal radiation.

Tumors have differing sensitivities to radiation. Tumors that have the greatest number of rapidly proliferating cancer cells usually exhibit the best early response to radiation. The decision to use radiation rather than other modalities is based on balancing the probability of controlling the tumor against the probability of causing complications, such as tissue damage. The decision is usually made via a risk–benefit analysis. Planning for radiation therapy includes assessing the disease site, tumor size, and histologic findings. Treatment schedules vary based on these factors. The patient receiving external radiation may experience skin changes such as blanching, erythema, desquamation, sloughing, or hemorrhage. Ulcerations of mucous membranes may cause severe pain; in addition, oral secretions can decrease, making the patient more vulnerable to infection and dental caries. Gastrointestinal effects include nausea and vomiting, diarrhea, or bleeding. Lungs may develop interstitial exudate, a condition called radiation pneumonia. Occasionally, external radiation therapy may cause fistulas or necrosis of adjacent tissues. Implanted radioactive materials can lead to similar problems; moreover, the excretory products of these patients are usually considered dangerous and require special disposal. See the box on page 358 for nursing care of patients receiving radiation therapy.

BOX 14–5 Safety Principles for Radiation

These recommendations apply to caregivers working with patients receiving internal radiation (brachytherapy).

- Maintain the greatest possible distance from the source of radiation.
- Spend the minimum amount of time close to the radiation source.
- Shield yourself from the radiation with lead gloves and aprons when possible.
- If pregnant, avoid contact with radiation sources.
- If you work routinely near radiation, wear a monitoring device to measure whole-body exposure.
- Avoid direct exposure with radioisotope containers; for example, do not touch the container.
- Keep patients with implanted radioisotopes in a private room with private bath and as far away from other hospitalized individuals as possible.
- Dispose of body fluids of patients with unsealed implanted radioisotopes with special care and in specially marked containers.
- Handle bed linen and clothing with care and according to agency protocol.
- Use long-handled forceps to place any dislodged implants into a lead container.
- Consult with the radiation therapy department for any questions or problems in caring for patients with radioactive implants.

BIOTHERAPY **Biotherapy** modifies the biologic processes that result in malignant cells, primarily through enhancing the person's own immune responses. The development of this therapy was based on the immune surveillance hypothesis. Although it has been established that a competent immune system is the body's most important defense against any disease, the role that various immune cells play in combating different types of malignancies continues to be investigated. Currently, biotherapy is used for both hematologic malignancies, such as lymphoma and hairy-cell leukemia, and solid tumors, such as renal cancer, lung cancer, and melanoma (Fox et al., 2013; Poust et al., 2013).

Tumor immunology has the following applications: detection screening in high-risk groups, differential diagnosis and classification

NURSING CARE OF THE PATIENT

Receiving Radiation Therapy

NURSING RESPONSIBILITIES FOR EITHER EXTERNAL OR INTERNAL RADIATION THERAPY

- Assess and manage any complications, usually in collaboration with the radiation oncologist.
- Assist in documenting the results of the therapy; for example, patients receiving radiation for metastases to the spine will show improved neurologic functioning as tumor size diminishes.
- Provide emotional support, relief of physical and psychologic discomfort, and opportunities to talk about fears and concerns. For some patients, radiation therapy is a last chance for cure or even for relief of physical discomfort.

EXTERNAL RADIATION

Prior to the start of treatments, the treatment area will be specifically located by the radiation oncologist and marked with colored semipermanent ink or tattoos. Treatment is usually given 5 days per week for 15 to 30 minutes per day over 2 to 7 weeks.

Nursing Responsibilities

- Monitor for adverse effects: skin changes, such as blanching, erythema, desquamation, sloughing, or hemorrhage; ulcerations of mucous membranes; nausea and vomiting, diarrhea, or gastrointestinal bleeding (ONS, 2013h, 2013i).
- Assess lungs for rales, which may indicate interstitial exudate. Observe for any dyspnea or changes in respiratory pattern.
- Identify and record any medications that the patient will be taking during the radiation treatment.
- Monitor white blood cell counts and platelet counts for significant decreases (ONS, 2013g).

Health Education for the Patient and Family

- Wash the skin that is marked as the radiation site only with plain water, no soap; do not apply deodorant, lotions, medications, perfume, or talcum powder to the site during the treatment period. Take care not to wash off the treatment marks (ONS, 2013h, 2013i).
- Do not rub, scratch, or scrub treated skin areas. If necessary, use only an electric razor to shave the treated area (ONS, 2013h, 2013i).
- Apply neither heat nor cold (e.g., heating pad or ice pack) to the treatment site.
- Inspect the skin for damage or serious changes, and report these to the radiologist or physician (ONS, 2013h, 2013i).
- Wear loose, soft clothing over the treated area.
- Protect skin from sun exposure during treatment and for at least 1 year after radiation therapy is discontinued. Cover skin with protective clothing during treatment; once radiation is discontinued, use sun-blocking agents with a sun protection factor (SPF) of at least 15 (ONS, 2013h, 2013i).
- External radiation poses no risk to other people for radiation exposure, even with intimate physical contact.
- Be sure to get plenty of rest and eat a balanced diet.

INTERNAL RADIATION

The radiation source, called an implant, is placed into the affected tissue or body cavity and is sealed in tubes, containers, wires, seeds, capsules, or needles. An implant may be temporary or permanent. Internal radiation may be ingested or injected as a solution into the bloodstream or a body cavity or be introduced into the tumor through a catheter. The radioactive substance may transmit rays outside the body or be excreted in body fluids.

Nursing Responsibilities

- Place the patient in a private room.
- Limit visits to 10 to 30 minutes, and have visitors sit at least 6 feet from the patient.
- Monitor for side effects such as burning sensations, excessive perspiration, chills and fever, nausea and vomiting, or diarrhea.
- Assess for fistulas or necrosis of adjacent tissues.

Health Education for the Patient and Family

- While a temporary implant is in place, stay in bed and rest quietly to avoid dislodging the implant.
- For outpatient treatments, avoid close contact with others until treatment has been discontinued.
- If the radiologist indicates the need for such measures, dispose of excretory materials in special containers or in a toilet not used by others.
- Carry out daily activities as able; get extra rest if feeling fatigued.
- Eat a balanced diet; frequent, small meals often are better tolerated.
- Contact the nurse or physician for any concerns or questions after discharge.

of tumor cells, monitoring the course of the disease with early detection of recurrence, and active therapies to halt or limit the disease. The theory underlying tumor immunology is that most tumor cells have a structural appearance recognizable by the immune cells. Tumor-associated antigens exist on tumor cells but not on normal cells. TAAs elicit an immune response that, in an individual with a competent immune system, destroys or inhibits tumor growth. Thus, TAAs can be isolated from serum and used for both diagnosis and various treatment modalities. The PSA is one such TAA currently in successful diagnostic use.

Tumor cells are often in a stage of arrested development (i.e., in the differentiation stage) for the cell type they represent; thus, they express antigens characteristic of that particular stage of development. The immaturity of the cells provides the physician with information about the relative aggressiveness of the cancer.

Another aspect of immunotherapy is the development of monoclonal antibodies that enhance the immune system's ability to fight the cancer. Monoclonal antibodies are developed by inoculating an animal with the tumor antigen and recovering the specific antibodies produced. The antibodies are then given to the person with that cancer to assist in the destruction of the tumor. Monoclonal antibodies are also recreated, or cloned, in the genetic laboratory by recombining DNA to produce the specific antibody. Techniques involving recombinant DNA have been used to combine these antibodies with toxins and drugs that are then delivered selectively to the tumor sites. For example, approximately one-fourth of all women diagnosed with early breast cancer present with tumors that are associated with Her-2/neu receptor overexpression. Overexpression of Her-2/neu results in a high risk of metastasis and poor prognosis, which represents a target for a selective monoclonal antibody therapy with trastuzumab (Herceptin) (Ahmad et al., 2013). Trastuzumab is a monoclonal antibody that inhibits Her-2 by binding to the extracellular portion of the receptor to inhibit initial signal transduction, thus inhibiting growth, proliferation, and angiogenesis. The combination of trastuzumab with chemotherapy has led to a considerable reduction of recurrences and to a significant reduction in breast cancer mortality (Ahmad et al., 2013).

A promising discovery has been the natural killer (NK) cells. These cells are like large granular lymphocytes, but have a cell surface phenotype different from that of T lymphocytes or macrophages.

They have demonstrated a spontaneous cytotoxic effect on some types of cancer cells. They provide a strong resistance to metastasis and secrete cytokines. Combining biotherapy (such as IL-2, IL-12) with chemotherapy results in increased tumor destructive activity and treatment responses (Fox et al., 2013; Poust et al., 2013).

A combination of cytokines, particularly interferon alpha (IFN-α) and interleukin 2 (IL-2), with chemotherapy has been used to treat patients with renal cell, metastatic melanoma, and lung cancer with promising results. Such a combination is referred to as either biochemotherapy or chemoimmunotherapy (Fox et al., 2013; Poust et al., 2013). The rationale for biochemotherapy is based on the independent antitumor activity of both IFN-α and IL-2 against melanoma and their lack of cross-resistance with cytotoxic chemotherapy. Although the precise mechanism of the antitumor effect of biochemotherapy regimens is less understood, two hypotheses have been proposed: (1) Chemotherapy enhances the antitumor effect of biologic agents, and (2) the biologic agents enhance the antitumor cytotoxic effect of chemotherapy.

As promising as these biotherapies or biochemotherapies are, they are accompanied by serious side effects and toxicities (Fox et al., 2013; Poust et al., 2013). IL-2 can cause acute alterations in renal, cardiac, liver, gastrointestinal, and mental functioning. IFN-α causes mental slowing, confusion, and lethargy and, when used in combination with 5-fluorouracil or IL-2, severe flu-like symptoms—chills and fever of 39.4° to 41.1°C (103° to 106°F), nausea, vomiting, diarrhea, anorexia, severe fatigue, and stomatitis—may result. The toxic effects are probably exaggerations of the normal systemic effects that these substances cause when fighting infection. For example, IL-2 is known to raise body temperature substantially in an attempt to create a hostile environment for foreign invaders.

The accompanying box discusses nursing care for patients receiving immunotherapy. For nursing care of specific problems, refer to the appropriate nursing diagnoses later in this chapter.

PHOTODYNAMIC THERAPY Photodynamic therapy (PDT) is a method of treating certain kinds of superficial tumors. It is known by several different names: phototherapy, photoradiation, and photochemotherapy. Patients who have tumors growing on the surface of the bladder, peritoneal cavity, chest wall, pleura, bronchus, or head and neck are candidates for this treatment. The patient is given an intravenous dose of a photosensitizing compound, Photofrin, which is selectively retained in higher concentrations in malignant tissue. This drug is activated by a laser treatment that is started 3 days after the drug injection and administered for 3 days. The drug interacts with oxygen molecules in the tissue to produce a cytotoxic oxygen molecule called singlet oxygen.

At the time of the first intravenous injection, patients are observed for adverse hypersensitivity reactions, such as nausea, chills, and hives. Systemic or long-term toxicities are rare. The main side effects are local skin reactions and temporary photosensitivity, transiently elevated liver enzymes, and inflammatory responses of the tissues being treated, such as peritoneal or pleural tissues.

The major nursing responsibilities associated with PDT are to address the patient and family's anxiety and to educate them in managing side effects. The drug remains in the subcutaneous tissues for 4 to 6 weeks after injection. Any direct or indirect exposure to the sun activates the drug, resulting in a chemical sunburn. Patients are taught to protect themselves from sunlight (even on cloudy days) by covering themselves from head to toe in opaque clothing, including a wide-brimmed hat, gloves, shoes and stockings, and sunglasses with 100% ultraviolet block. Long-term care of treated skin includes moisturizing lotions and protection from trauma or irritation.

BONE MARROW AND PERIPHERAL BLOOD STEM CELL TRANSPLANTATIONS Bone marrow transplantation (BMT), also known as hematopoietic stem cell transplantation (HSCT or SCT), is an accepted treatment to stimulate a nonfunctioning marrow or to replace marrow. BMT is given as an intravenous infusion of bone marrow cells from donor to patient. Most commonly used in leukemias, this therapy is being expanded to include treatment of other cancers including melanoma and testicular cancer. Chapter 33 provides an in-depth discussion of this procedure. Peripheral blood stem cell transplantation (PBSCT) is the process of removing circulating stem cells from the peripheral blood through apheresis and returning these cells to the patient after dose-intensive chemotherapy. PBSCT has fewer side effects, shorter hospitalization, and lower costs compared to BMT.

NURSING CARE OF THE PATIENT

Receiving Immunotherapy

Immunotherapy can consist of various substances used alone, such as IL-2, IL-12, or combination biotherapy, such as IFN-α with 5-fluorouracil. The nurse's role is to enhance the patient's quality of life.

Nursing Responsibilities

- Monitor for side effects: IFN-α may cause mental slowing, confusion, fatigue, and lethargy; combination therapy of 5-fluorouracil or IL-2 and IFN-α may cause severe flu-like symptoms, with chills and fever of 39.4° to 41.1°C (103° to 106°F), nausea, vomiting, diarrhea, anorexia, severe fatigue, and stomatitis; erythropoietin may cause acute hypertension.
- Monitor enzymes and other appropriate biochemical indicators for acute alterations in renal, cardiac, liver, or gastrointestinal functioning, which can be side effects of IL-2.
- Evaluate response to therapy by conducting a thorough evaluation of patients' symptoms.
- Assess patients' coping behaviors and teach new strategies as needed.
- Manage fatigue and depression.
- Encourage self-care and participation in decision making.
- Provide close supervision for patients with altered mental functioning, either by caretakers or frequent nursing visits to the patient's home.
- If patient is unable to manage alone, teach medication administration and care of equipment to caregivers.

Health Education for the Patient and Family

- Minimize symptoms by managing fever and flu-like symptoms: increase fluid intake, take analgesic and antipyretic medications, and maintain bed rest until symptoms abate.
- Seek help for serious problems not managed by usual means, such as dehydration from diarrhea.
- Use correct techniques for providing subcutaneous injections.
- Identify how to work and care for ambulatory pumps when medication is administered through an intercatheter or vascular access device.

COMPLEMENTARY THERAPIES Although advances in cancer treatment have increased 5-year survival rates, cancer reoccurrence and the uncertainty about its cure compels some patients to look for complementary therapies. Complementary therapies are therapies that patients choose as a complement to medical treatment. Common complementary therapies for cancer can be categorized into botanical agents, nutritional supplements, dietary regimens, mind–body modalities, energy healing, spiritual approaches, and miscellaneous therapies. Box 14–6 provides information about complementary therapies.

To provide sensitive nursing care, nurses should be knowledgeable about common complementary therapies. It is important for nurses to provide truthful, nonjudgmental responses to patients' inquiries about complementary therapies. Nurses should encourage patients to report the use of any complementary therapies to their oncologist to prevent potential interactions of those therapies with their medical treatment.

PAIN MANAGEMENT

Pain management is an important component of oncology care and is considered a crucial part of the collaborative treatment plan. Ogboli-Nwasor and colleagues (2013) have estimated that more than 60% of patients with early-stage cancer and up to 95% of patients with advanced cancer experience pain that requires analgesia. There are three main categories of pain syndromes in patients with cancer, and the category influences the type of treatment:

- ***Pain associated with direct tumor involvement*** The most common causes are metastases to bone, nerve compression or infiltration, and involvement of hollow visceral organs.
- ***Pain associated with treatment*** This may include postsurgical incisional or wound pain; peripheral neuropathy, ulceration of mucous membranes, and pain from herpes zoster outbreaks secondary to chemotherapy; and pain in nerve plexuses, muscles, and peripheral nerves from radiation therapy.
- ***Pain from a cause not related to either the cancer or therapy,*** such as diabetic neuropathy.

The goal of pain therapy is to provide relief that allows patients to function as they wish and, in the case of terminally ill patients, to die relatively free of pain. With the emphasis on putting evidence into nursing practice, the Oncology Nursing Society (2013f) conducted a systematic review of cancer pain and concluded that combinations of nonopioids, opioids, and coanalgesics are effective in the management of acute and persistent nociceptive and neuropathic pain that occurs as a result of cancer or cancer treatment. Other therapies include injection of anesthetic drugs into spinal cord or specific nerve plexuses, surgical severing of nerves, radiation to reduce tumor size and pressure, and behavioral approaches. Pharmacologic pain management follows these steps:

1. Conduct careful initial and ongoing assessment of the pain.
2. Evaluate the patient's functional goals.
3. Establish a plan that uses combinations of nonnarcotic drugs (such as aspirin or ibuprofen) with adjuvants (such as corticosteroids or antidepressants).
4. Evaluate the degree of pain relief.
5. Progress to stronger drugs as needed, from mild narcotics such as oxycodone (Percodan) or hydrocodone (Vicodan) to strong narcotics such as morphine or hydromorphone (Dilaudid), and monitor side effects.

BOX 14–6 Common Complementary Therapies for Cancer

Type	Description
Botanical agents	Many people believe that herbs are the most natural and safe plants that can be ingested with the hope that they will cure cancer. The safety for many of these botanical agents has not been proven, especially as a complement to medical treatment. Commonly used botanical agents include echinacea, Essiac, ginseng, green tea, pau d'arco, and Hoxsey.
Nutritional supplements	Chemical compounds that include vitamins, minerals, enzymes, amino acids, and essential fatty acids, or proteins (such as shark cartilage) are believed to have the ability to promote health and help cure cancer. The safety of certain compounds such as vitamins has been established; however, in megadoses, many of the compounds can be toxic and have potential interactions with some therapeutic agents used for cancer such as chemotherapy.
Dietary regimens	The ingestion of only natural substances is believed to have the effect of purifying the body and slowing down the growth of cancer. Popular regimens include the grape diet, the carrot juice diet, and garlic, onions, and liver intake. The effectiveness of these dietary regimens remains to be established.
Mind–body modalities	The harmony of mind and body is believed to facilitate physiologic and psychologic healing. Such modalities include relaxation, meditation, or imagery. Recent research has shown that these modalities helped individuals with cancer adjust to the experience of cancer (Barrows, 2014).
Energy healing	The human body is believed to be an energy field and cancer might be the result of a disturbed energy field. Energy therapies, such as therapeutic touch and healing touch, can affect the energy field of the human body and promote physiologic healing. Therapeutic touch uses the hands on or near the body with the intent to promote healing. Healing touch uses energy healing techniques to heal by restoring the harmony and balance of the body. Clinical practice and research on energy healing have shown positive findings of energy healing in a variety of patients.
Spiritual approaches	Faith in God or a higher power of the universe is believed to help cancer healing. Spiritual approaches include faith healing, prayer to God, prayer groups, and chain prayer. Research has shown that faith in God or a higher power helped individuals with cancer to adjust to the experience of cancer.
Miscellaneous therapies	Aromatherapy has been used for patients with cancer to relieve nausea, vomiting, or retching and to decrease anxiety. However, aromatherapy might not be appropriate for patients who are highly sensitive to strong fragrance. Music, art, and humor therapies have been used to help patients with cancer to reduce anxiety, to express feelings of loss, and to promote optimism.

6. Continue to try combinations and escalate dosages until maximal pain relief balanced with a patient's need to function is achieved.

Medication usually is administered by the oral route as long as this route continues to be effective. Medication is given on a regular time schedule (e.g., every 4 hours) with additional medication prescribed to cover breakthrough pain. When the oral route alone becomes inadequate, the primary narcotic can be administered intramuscularly, subcutaneously, or rectally on an intermittent schedule; continuously by transdermal patches; or intravenously by a continuous drip, usually controlled by an infusion pump. Some newer pumps are portable, deliver medication continuously, and allow patients to control their breakthrough pain with a limited number of boluses.

When narcotic doses are increased gradually, there is no limit to the amount the patient can receive, as long as adverse reactions can be managed. Patients have received up to 4800 mg daily (200 mg per hour) of morphine sulfate with up to six 200- to 400-mg breakthrough doses daily without major ill effects and with good pain control. The body develops tolerance to the sedative after a short period, and most patients are able to tolerate the level of medication needed to control the pain. Other side effects, such as constipation, nausea and vomiting, and itching, can be managed through the usual means and are discussed under the appropriate nursing diagnoses. If the patient has persistent untoward side effects that do not respond to treatment, or if the patient does not get adequate relief from the narcotic, different narcotics and combinations are tried. Morphine sulfate and transdermal fentanyl are the most commonly used drugs for relief of cancer pain (Ogboli-Nwasor et al., 2013; ONS, 2013f). Patients receiving high-dose narcotics should not have the medication abruptly stopped, because withdrawal symptoms will occur. If the drug needs to be stopped, it must be tapered gradually. For more information on pain management, and on alternative therapies in particular, refer to Chapter 9.

●○● NURSING CARE

Nurses face a major challenge in educating patients about preventive measures and lifestyle changes to reduce the risk of cancer. At the same time, patients with cancer must be reassured that they are not responsible for having acquired cancer.

Once a cancer diagnosis is established, nurses help patients recover and support them during the rehabilitation phase. In cases of terminal cancer, nurses provide comfort and facilitate positive growth for the patient and significant others.

Health Promotion

Cancer prevention is the key to reduce the incidence and mortality of cancer. Strategies include smoking cessation, maintaining a healthy weight, and preventing infections (ACS, 2013a). (See Box 3–2 Dietary Guidelines for Health for recommendations to maintain healthy weight and reduce cancer risk.) Recent advances in cancer prevention through vaccines are promising. For example, human papillomavirus (HPV) vaccination holds the hope to eliminate cervical and anal cancers (see Table 3–4 for current HPV vaccination recommendations from the Centers for Disease Control and Prevention [2012]). The Moving Knowledge into Action box presents an opportunity to apply knowledge of current HPV vaccine recommendations for adolescents and young adults.

Moving Knowledge into Action

As a nurse working at a pediatric clinic with girls up to 18 years old, a mother asks you for advice on HPV vaccine for her 10-year-old daughter. To provide optimal care for cancer prevention:

- Identify sources of information to use when planning care.
  - What additional assessment data should you collect?
  - What nursing interventions would be most appropriate to include in the care plan?

Early detection and treatment are considered the most important factors influencing the prognosis of those who have cancer. However, many people do not seek early diagnosis and treatment because of denial, fear and anxiety, stigma, or the absence of specific signs such as pain or weight loss (which usually are late signs). For this reason, screening procedures such as mammograms, PSA tests, occult blood stool tests, and sigmoidoscopies may be lifesaving.

The ACS promotes early cancer detection through promotion of cancer awareness and guidelines for screening procedures. See Table 3–5 for cancer screening recommendations by the ACS. Nurses have a special role in public education and should encourage everyone they come in contact with to schedule cancer checkups and to seek medical attention when they discover signs and symptoms characteristic of cancer (Box 14–7). Encourage people to report to the public health department any known leaking of chemicals or radioactive materials into the water or air and any noted increase in the incidence of cancer, especially of one specific type, in their communities.

For people without symptoms, the ACS recommends incorporating a cancer checkup into periodic health examinations. This general cancer checkup includes health counseling, teaching self-examination techniques when appropriate, and, depending on age and gender, examination for cancers of the thyroid, oral cavity, skin, lymph nodes, testes, and ovaries (ACS, 2013a). If an individual is at increased risk due to heredity, ethnicity, environment, occupation, or lifestyle, special tests or more frequent examinations may be necessary. For example, the ACS recommends that physicians discuss annual low-dose CT scans for lung cancer screening with current or former smokers who have a 30-pack-year or greater smoking history (e.g., people who smoked a pack of cigarettes/day for 30 years) (Wender et al, 2013). Nurses must be familiar with the ACS guidelines so that they can advise patients, their families, and significant others.

BOX 14–7 Cancer Symptoms

Cancer can cause many different symptoms. Some of them are as follows:

- A thickening or lump in the breast or any other part of the body
- A new mole or a change in an existing mole
- A sore that does not heal
- Hoarseness or a cough that does not go away
- Changes in bowel or bladder habits
- Discomfort after eating
- Difficulty swallowing
- Weight gain or loss with no known reason
- Unusual bleeding or discharge
- Feeling weak or very tired.

Assessment

The assessment chapters in this text contain questions about manifestations and risk factors for cancer that involves specific body systems. Examples of appropriate questions to elicit information during a health history assessment follow. They are appropriate for use during the initial interview and at subsequent assessments:

- "What brought you in to see the doctor?" *Asking this question allows patients to tell their story in their own way, which may elicit more information than asking specific questions. The answer should elicit not only data about the signs and symptoms but also fears or concerns. If the cancer was discovered during a routine physical examination or checkup, the patient may have some difficulty accepting the disease, especially if there were no symptoms. For patients who offer insufficient information in response to this open-ended question, more specific questions may be necessary, such as "Did you have pain or any specific physical problems that caused you to seek healthcare?"*
- "Are any other medical conditions or problems troubling you at this time?" *It may be necessary to ask about specific diseases to help the patient focus. For example, "Do you have high blood pressure?" or "Are you having any problems with your lungs?" Information gained from these questions can help you anticipate problems and formulate potential nursing diagnoses related to other diseases that may interact with the cancer.*
- "Describe the kinds of physical problems you are having at this time. Do you have pain? How has your appetite and food intake been? Have you experienced a recent weight change? Tell me how well you are able to carry out your usual daily activities. How has your illness affected your mood or outlook on life?" *For each positive response, ask follow-up questions to narrow down or define the exact nature of the problem. These data help identify what nursing diagnoses should be included in the care plan.*
- "What options has your physician suggested for treating your cancer?" *The answer will indicate patients' knowledge about their treatment and, possibly, their communication with the physician. Often, under the stress of a cancer diagnosis, patients do not hear or understand what the physician is saying and are afraid to ask questions. Lack of knowledge indicates a need to collaborate with the physician to explain the information to the patient so that the patient can absorb and understand it.* If the patient has a good understanding of the treatment plan, discussing how he or she feels about it can be useful in exposing fears, concerns, and emotional responses.
- "What do you expect to happen as a result of this treatment?" *The answer may reveal unrealistic expectations or lack of understanding of consequences of the treatment.*
- "What effects are the disease and/or treatment having on your ability to carry on with your usual daily activities?" *Additional questions may be needed to pinpoint the types of limitations. The response to this question should provide information on the patient's functional status (see Box 14–8). This information can be used to identify the need to collaborate with professionals from other disciplines. For example, if the patient is the sole financial support of the family and is unable to work, a social worker may be able to help with resources; if the patient is extremely weak, referral to a physical therapist may help with energy conservation strategies and strengthening exercises.*
- "Who is available to help you at home and run errands for you? Who can provide transportation for you to get to your appointments or treatments? Who can you rely on to be a good listener when you're sad or to be a comfortable companion? Have you identified someone to make healthcare decisions for you if there is a time when you are unable to make them for yourself?" *When the person with cancer is the one who usually takes care of everyone else, asking for help may be difficult for this person. This information can identify how much support and help the patient has access to. The last question introduces the concept of advanced directives and durable power of attorney regarding healthcare (refer to Chapter 5).*
- "How do you manage your stress or your feelings of discomfort? What helps you feel better? Do you think these measures work well for you?" *The responses to these questions provide information about the patient's coping strategies and may identify maladaptive strategies such as alcohol or drug use. Lack of appropriate coping methods can interfere with the patient's response to treatment and decrease overall quality of life.*

Other assessment questions may be useful at different stages of the patient's illness. For example, if the patient is not expected to survive the cancer, it is important to ask whether the patient has made decisions about last wishes (e.g., for a funeral and burial), whether these have been discussed with significant others, and whether the patient has completed a will.

Physical Assessment

As soon as the patient is admitted to the healthcare service or agency, conduct a complete physical assessment to establish a baseline for subsequent evaluation of later changes (Box 14–9). It is especially important to document the nutritional status of the patient using anthropomorphic measurements (i.e., height, weight, body fat, muscle mass, body mass index, and body composition) and to evaluate laboratory results and note any specific signs and symptoms. Table 14–11 compares the manifestations of good nutrition with those of malnutrition.

It is important to assess the patient's hydration status, especially if the patient is not taking oral food and fluids well or is having bouts

BOX 14–8 Example of an Instrument for Assessing Functional Status for Cancer Patients: Eastern Cooperative Oncology Group (ECOG) Scale

0 Fully active, able to carry out all predisease activities without restriction
1 Restricted in physically strenuous activity, but ambulatory and able to carry out work of a light or sedentary nature, for example, light housework or office work
2 Ambulatory and capable of all self-care, but unable to carry out work activities. Up and about more than 50% of waking hours
3 Capable of only limited self-care, confined to bed or chair 50% or more of waking hours
4 Completely disabled, cannot carry out any self-care, totally confined to bed or chair.

Source: Non-Small Cell Lung Cancer Collaborative Group. (1995). Chemotherapy in nonsmall cell lung cancer: A meta-analysis using updated data on individual patients from 52 randomised clinical trials. *British Medical Journal, 311*(7010), 899–909.

BOX 14–9 Highlights of Nursing Assessments

- ✓ Anthropomorphic measurements (i.e., height, weight, body fat, muscle mass, body mass index, and body composition)
- ✓ Family history
- ✓ Cancer-related or treatment-related symptoms
- ✓ Hydration status
- ✓ Nutrition status
- ✓ Functional status
- ✓ Psychologic and emotional state and coping skills
- ✓ Social and family support
- ✓ Patient's knowledge of cancer and treatment

BOX 14–10 Factors to Consider in Assessing Hydration Status

- Intake and output
- Rapid weight changes
- Skin turgor and moisture
- Venous filling
- Vital sign changes
- Tongue furrows and moisture
- Eyeball softness
- Lung sounds
- Laboratory values

of vomiting. Box 14–10 lists specific assessments for hydration status. Other recommended assessments are discussed under the specific nursing diagnoses that follow. They can also be found in other chapters that address specific body systems affected by the cancer.

Diagnoses, Outcomes, and Interventions

Nursing goals focus on supporting the whole person and providing interventions for specific problems such as pain, poor nutrition, dehydration, fatigue, adverse emotional responses, altered individual and family coping, and the side effects of medical treatment. Nursing care also focuses on improving quality of life by promoting rehabilitation for survivors of cancer and helping those who succumb to the disease maintain their comfort and dignity in the dying process. Because cancer affects the whole family, nursing care includes everyone involved with the patient from the onset of diagnosis through the entire disease and treatment process and the ultimate outcome. Many diagnoses are pertinent to patients with cancer; this section addresses only the most common diagnoses. See the Case Study & Nursing Care Plan on page 370.

Anxiety

Early in the disease process (i.e., during diagnosis and treatment), threats to or changes in health status, physical discomfort, impaired role functioning, or even socioeconomic status can cause psychologic and emotional disturbance, such as fear, anxiety, or hopelessness (Galway et al., 2012). Such psychologic and emotional disturbance may result from the anticipation of pain, disfigurement, or the threat of death. In particular, patients whose coping skills have been poor in the past (e.g., in managing anger) may find themselves at a loss to manage this current crisis. The patient may manifest overt signs of anxiety: trembling, restlessness, irritability, hyperactivity, stimulation of the sympathetic nervous system (increased blood pressure, pulse, respiration, excessive perspiration, pallor), withdrawal, worried facial expressions, and poor eye contact. The patient may report insomnia and feelings of tension and apprehension, or express concerns regarding perceived changes brought about by the disease and fear of future events.

Expected Outcome: Patient will be free of or decrease the level of anxiety related to cancer diagnosis and treatment.

- Carefully assess the patient's level of anxiety (moderate anxiety, severe anxiety, or panic) and the reality of the threats represented in the patient's current situation to ensure personalized nursing intervention. *A patient in panic may need medical intervention with appropriate medications, whereas those with moderate or severe anxiety are often managed by the nurse through counseling and teaching new coping skills* (ONS, 2013a, 2013c).

TABLE 14–11 Signs of Nutritional Status

System	Good Nutrition	Poor Nutrition
General	Alert, energetic, good endurance, psychologically stable Weight within range for height, age, body size	Withdrawn, apathetic, easily fatigued, irritable Over- or underweight
Integumentary	Skin glowing, good turgor, smooth, free of lesions Hair shiny, lustrous, minimal loss	Skin dull, pasty, scaly-dry, bruises, multiple lesions Hair brittle, dull, falls out easily
Head, eyes, ears, nose, and throat	Eyes bright, clear, no fatigue circles Oral mucous membranes pink-red and moist Gums pink, firm Tongue pink, moderately smooth, no swelling	Eyes dull, conjunctiva pale, discoloration under eyes Oral mucous membranes pale Gums red, spongy, and bleed easily Tongue bright to dark red, swollen
Abdomen	Abdomen flat, firm	Abdomen scaphoid (concave), flaccid or distended (ascites)
Musculoskeletal	Firm, well-developed muscles Good posture No skeletal changes	Flaccid muscles, wasted appearance Stooped posture Skeletal malformations
Neurologic	Good attention span, good concentration, astute thought processes Good reflexes	Inattentive, easily distracted, impaired thought processes Paresthesias, reflexes diminished or hyperactive

- Establish a therapeutic relationship by conveying warmth and empathy and listening in a nonjudgmental manner. *A patient who feels safe in the relationship with the nurse more easily expresses feelings and thoughts. The patient will be able to trust the nurse and perhaps be willing to try new behaviors as suggested. The amount of time this relationship may take to develop depends on the patient's current emotional and mental state and the stage of the disease process* (ONS, 2013a, 2013c).
- Encourage the patient to acknowledge and express feelings, no matter how inappropriate they may seem to the patient. *Just by expressing their feelings, patients often can significantly diminish anxiety. Expressing feelings allows the patient to direct energy toward healing and thus has a positive therapeutic effect. Moreover, by acknowledging feelings, especially those the patient considers unacceptable, the patient can lay the groundwork for new coping behaviors* (ONS, 2013a, 2013c).
- Review the coping strategies the patient has used in the past and build on past successful behaviors, introducing new strategies as appropriate. Explain why inappropriate strategies, such as repressing anger or turning to alcohol, are not helpful. *The patient will be more willing to make changes that build on what has already worked in the past. The patient will be more willing to reject inappropriate strategies if he or she is given a persuasive reason why they have not had the desired effect in managing previous crises.*
- Identify resources in the community (such as crisis hotlines and support groups) that can help the patient manage anxiety-producing situations. *The patient may not have support systems available, or the patient's significant others may be having their own difficulties in dealing with the cancer diagnosis. Programs such as "I Can Cope," sponsored by the ACS in most communities, provide education, counseling, and support in a group setting with other cancer patients.*
- Provide specific information for the patient about the disease, its treatment, and what may be expected, especially for those patients with obvious misinformation. *Knowing what is to come gives the patient a sense of control and enables the patient to make decisions. Knowing that every effort will be made to keep the patient as free of pain as possible can do a great deal to relieve anxiety* (Stephenson, 2006).
- Provide a safe, calm, and quiet environment for the patient in panic. Remain with the patient and administer antianxiety medications as ordered. *Staying with the patient and displaying calmness and confidence can protect the patient from injury and prevent further panic. If the panic does not subside with the nurse's presence and support, referral to the physician for medication management may be necessary* (Cramer et al., 2012).
- Use crisis intervention theory to promote growth in the patient and significant others, regardless of the outcome of the disease. *During a major crisis, people can, with assistance, transform the experience from one that causes defeat and despair to one that enhances personal and spiritual growth. If you are not skilled in this area, a referral to an appropriate mental health professional may be helpful to the patient and family.*

Disturbed Body Image

Cancer and cancer treatments frequently result in major physiologic and psychologic body image changes. Loss of a body part (e.g., amputation, prostatectomy, or mastectomy), skin changes and hair loss from chemotherapy or radiation therapy, disfigurement of a body part (e.g., lymphedema in the affected upper and lower extremities), or creation of unnatural openings on the body for elimination (e.g., colostomy or ileostomy) may have a major effect on the person's self-image. The gaunt, wasted appearance of the patient with cachexia or the draining, malodorous lesions that result when cancer breaks through the skin are other significant etiologies of body image disturbance. This may give rise to fear of rejection, which plays a major role in sexual dysfunction. In addition to all of the other challenges the cancer brings about, the patient may undergo major changes in appearance and function. The patient may exhibit a visible physical alteration of some portion of the body, verbalize negative feelings about the body and/or fear of rejection by others, refuse to look at the affected site, and depersonalize the body change or lost part (e.g., by calling the colostomy "that thing").

Expected Outcome: Patient will accept the after-cancer treatment body image.

- Discuss the meaning of the loss or change with the patient. *Doing so helps the nurse discover the best approach for this particular patient and involves the patient more actively in interventions. A small, seemingly trivial loss may have a big impact, especially when viewed in light of the other changes that are occurring in the patient's life. Likewise, a major loss may not be as important as the nurse might imagine. To ensure more appropriate and individualized care, evaluate each situation in terms of the reactions of the specific patient.*
- Observe and evaluate interaction with significant others. *People who are important to the patient may unintentionally reinforce negative feelings about body image; on the other hand, the patient may perceive rejection where none exists.*
- Allow denial, but do not participate in it; for example, if a patient does not want to look at the wound, the nurse may say, "I am going to change the dressing to your breast incision now." *During the initial stage of shock at the loss of a body part, denial is a protective mechanism and should not be challenged, nor should it be promoted. A matter-of-fact approach and an empathetic attitude will go far to facilitate the eventual acceptance of the change.*
- Assist the patient and significant others to cope with the changes in appearance:
  a. Provide a supportive environment.
  b. Encourage the patient and significant others to express feelings about the situation.
  c. Give matter-of-fact responses to questions and concerns.
  d. Identify new coping strategies to resolve feelings.
  e. Enlist family and friends in reaffirming the patient's worth.

  A supportive, safe environment in which feelings are respected and new coping strategies can be tried promotes acceptance, as does reaffirming that the patient's worth is not diminished by any physical changes (ONS, 2013b).
- Teach the patient or significant others to participate in the care of the afflicted body area. Provide support and validation of their efforts. *Active involvement in providing care, such as changing a dressing or emptying a colostomy bag, empowers the patient and/or significant others. This intimate involvement also desensitizes feelings about disfigurement and promotes acceptance. Involving significant others reduces the risk of their rejecting the patient and can promote closeness. Positive reinforcement from the nurse encourages them to continue these behaviors.*
- Teach strategies for minimizing physical changes, such as providing skin care during radiation therapy and dressing to enhance

appearance and minimize change in the body part. *Early intervention can limit the negative side effects of treatment and actually promote recovery. Involving the patient provides an additional way for the patient to be in control of a difficult situation (ONS, 2013h).*

- Teach ways to reduce the alopecia that results from chemotherapy and to enhance appearance until the hair grows back:
  a. Discuss the pattern and timing of hair loss. *This allows the patient to cope with changes and incorporate them into daily activities.*
  b. Encourage wearing cheerful, brightly colored head coverings; assist in color coordinating them with usual clothing. *Attractive head coverings protect the bald head while allowing the patient to feel stylish and well dressed.*
  c. Refer to a good wig shop before hair loss is experienced. *Hair color and texture can be matched to minimize obvious changes in appearance.*
  d. Refer to support programs such as "Look Good . . . Feel Better," which is sponsored by the ACS and the Cosmetic, Toilet, and Fragrance Association Foundation. *A support group can diminish feelings of isolation and provide practical tips for managing problems. For a list of community resources available to patients with cancer, refer to a local phone book.*
  e. Reassure that hair will grow back after chemotherapy is discontinued, but also inform that the color and texture of the new hair may be different. Hair loss has been identified as the most distressing symptom by many patients. *Interventions to reduce that loss can have a significant impact on body image concerns. Moreover, knowing what to expect may decrease anxiety and distress.*

Grieving

Grieving is a response to an actual, anticipated, or perceived loss (Herdman, 2012). Overall, only 50% of people with cancer fully recover, and certain types of cancer have a much higher death rate; thus, the patient with cancer is often confronted with facing death and making preparations for it. This can be a healthy response that allows the patient and family to work through the dying process and achieve growth in the final stage of life. Perceived changes in body image and lifestyle can prompt grieving. The patient or significant others may show sorrow, anger, depression, or withdrawal, expressing distress at the potential loss or verbalizing concern about unfinished life business. (Refer to Chapter 5 for more on nursing care of the patient who is grieving or dying.)

Expected Outcome: Patient will use effective and healthy responses to actual, anticipated or perceived cancer-related losses.

- Use the therapeutic communication skills of active listening, silence, and nonverbal support to provide an open environment for the patient and significant others to discuss their feelings realistically and to express anger or other negative feelings appropriately. *This helps the patient and family to get in touch with feelings and confront the possibility of the loss or death.*
- Answer questions about illness and prognosis honestly, but always encourage hope. *This allows for realistic appraisal of the situation and planning, and it helps combat feelings of hopelessness and depression.*
- Encourage the dying patient to make funeral and burial plans ahead of time and to be sure the will is in order. Make sure the necessary phone numbers can be easily located. *This gives a sense of control and relieves family members of these concerns at a time when the patient is most in need of their support and when they themselves are extremely stressed.*
- Encourage the patient to continue taking part in activities he or she enjoys, including maintaining employment as long as possible. *This gives a sense of continuity of life even in the face of severe losses.*

Risk for Infection

Malnutrition, impaired skin and mucous membrane integrity, tumor necrosis, and suppression of the WBCs from chemotherapy or radiation may contribute to the risk for infection. Anorexia, as well as the disease itself, deprives the body of nutrients needed for healing, while impaired integrity of skin and mucous membranes (a result of chemotherapy and/or radiation therapy) compromises the first lines of defense against microbial invasion. Cells in the center of large or not very vascular tumors may die from malnutrition, eventually eroding through tissues to increase the risk of sepsis. Bone marrow depression due to the effects of certain types of cancers and chemotherapy impairs the body's ability to respond to infection. The patient may exhibit the classic signs of infection: lassitude, fever, anorexia, pain in the affected area, and physical evidence of infection, such as a purulent, draining lesion or wound. If the bone marrow is compromised, the usual signs and symptoms of infection may be absent or reduced.

Expected Outcome: Patient will be free of infections related to cancer or treatment.

- Monitor vital signs. *Fever and sympathetic nervous system responses, such as increased pulse and respiration, are usual early signs of infection. However, severely immunosuppressed patients may be unable to mount a fever; therefore, the absence of fever cannot rule out infection (ONS, 2013g).*
- Monitor WBC counts frequently, especially if the patient is receiving chemotherapy known to cause bone marrow suppression. *This allows the nurse to notify the physician at the first sign of diminishing WBC counts so that corrective action can be taken (ONS, 2013g).*
- Teach the patient to avoid crowds, small children, and people with infections when WBC count is at nadir (lowest point during chemotherapy) and to practice scrupulous personal hygiene. *During periods of leukopenia, the patient may lose immunity to his or her own natural flora. Careful attention to hygiene reduces the risk of infection. Crowds, which promote contact with a greater variety of infectious agents, and friends with minor infections can be very dangerous to people who are immunosuppressed. Small children should be avoided because they often have microbes to which most people are usually immune but which the patient may not be able to resist.*
- Protect skin and mucous membranes from injury. Teach appropriate skin care measures, such as good hygiene, use of a moisturizing lotion to prevent dryness and cracking, frequent changes of position for the bed-bound, and immediate attention to skin breaks or lesions (ONS, 2013g). *Ensuring intact skin strengthens the first line of defense against infection.*
- Encourage the patient to consume a diet high in protein, minerals, and vitamins, especially vitamin C. *Improving nutrition decreases the risk of infection. Vitamin C has been shown to help prevent certain types of infection, such as colds.*

Risk for Injury

In addition to infection, cancer can pose a risk for injury from, for example, obstruction by a large tumor or one located in a limited body space (e.g., in the brain, bowel, or bronchial airways). If the cancer is one that creates ectopic sites of hormones, elevated levels of hormones that are not under the control of the pituitary gland can injure the patient in a variety of ways. Signs of obstruction depend on the organ involved: Bowel obstruction presents with pain, distention, and cessation of bowel activities; obstruction in the brain gives signs of increased intracranial pressure or personality/behavioral change; bronchial obstruction manifests as respiratory distress, cyanosis, and altered arterial blood gases. Ectopic production of parathyroid hormone manifests as high serum calcium levels as well as signs of hypercalcemia; ectopic production of antidiuretic hormone causes fluid retention and manifests as hypertension and peripheral and pulmonary edema.

Expected Outcome: Patient will be free of injuries related to cancer or treatment.

- Assess frequently for signs and symptoms indicating problems with organ obstruction. *Early detection of major problems allows the nurse to seek medical help before the problem evolves into a physiologic crisis.*
- Teach to differentiate minor problems from those of a serious nature. Encourage the patient to consult with the nurse or physician if in doubt or to call 911 if the patient becomes very ill. Box 14–11 provides guidelines to help patients identify serious problems. *Having guidelines for when to call the physician provides an anxiety-reducing safety net for the patient and family and promotes early detection of complications.*
- Monitor laboratory values that may indicate the presence of ectopic functioning and report abnormal findings to physicians immediately. (Refer to Table 14–4 for laboratory indicators of ectopic functions.) *Early detection promotes early medical intervention and prevents serious consequences from the ectopic secretion.* Refer to Chapters 10, 19, and 20 for specific signs and symptoms of electrolyte imbalances and endocrine disorders.

BOX 14–11 When to Call for Help

Instruct the patient or family member to call the nurse or physician if any of the following manifestations are experienced:

- Oral temperature greater than 38.6°C (101.5°F)
- Severe headache; significant increase in pain at usual site, especially if the pain is not relieved by the medication regimen; or severe pain at a new site
- Difficulty breathing
- New bleeding from any site, such as rectal or vaginal bleeding
- Confusion, irritability, or restlessness
- Withdrawal, greatly decreased activity level, or frequent crying
- Verbalizations of deep sadness or a desire to end life
- Changes in body functioning, such as the inability to void or severe diarrhea or constipation
- Changes in eating patterns, such as refusal to eat, extreme hunger, or a significant increase in nausea and vomiting
- Appearance of edema in the extremities or significant increase in edema already present.

Instruct the patient or family member to call 911 in these situations:

- The patient is having much difficulty breathing or if the patient's lips or face have a bluish tinge.
- The patient becomes unconscious or has a convulsion.
- The patient exhibits unmanageable behavior, such as being physically abusive, hurting self, or engaging in uncontrollable activity.

Imbalanced Nutrition: Less Than Body Requirements

The anorexia-cachexia syndrome (described earlier in this chapter) is a common cause of malnutrition in cancer patients. Metabolism increases in response to increased cancer cell production while the cancer's parasitic activity reduces the nutrients available to the body. Loss of appetite, food aversion, nausea and vomiting, and painful oral lesions from chemotherapy or radiation may contribute to impaired nutrition. Tumors of the gastrointestinal tract that affect absorption also contribute to the problem. Manifestations include wasted appearance, considerable weight loss over a relatively short period of time, anthropometric measurements below 85% of standard for fat and muscle tissue, decreases in serum proteins, and negative responses to antigen testing.

Expected Outcome: Patient will restore and maintain balanced nutrition.

- Assess current eating patterns, including usual likes and dislikes, and identify factors that impair food intake. *This allows for a more individualized plan based on needs and preferences.*
- Evaluate degree of malnutrition:
  a. Check laboratory values for total serum protein, serum albumin and globins, total lymphocyte count, serum transferrin, hemoglobin, and hematocrit. *These values represent the laboratory values that are most likely to decrease with malnutrition.*
  b. Calculate nitrogen balance and creatinine-height index. Calculate skeletal muscle mass, and compare findings to normal ranges. *Urinary creatinine is an index of lean body mass and decreases in malnutrition. Lean muscle mass is catabolized for energy in patients with cancer.*
  c. Take anthropometric measurements and compare them to standards: height, weight, elbow breadth, arm circumference, triceps skinfold thickness, and arm muscle mass. *This estimates the degree of wasting; findings below 85% of standard are considered malnutrition.*
- Teach the principles of maintaining good nutrition by using the federal government's MyPlate resources and adapting the diet to medical restrictions and current preferences. *This tailors the food plan to the patient's needs and thereby promotes compliance.*
- Manage problems that interfere with eating:
  a. Encourage eating whatever is appealing and consider adding nutritional supplements such as Ensure Plus or Isocal to diet. *It is better to eat something even if it is not nutritionally balanced.*
  b. Eat small, frequent meals. *These are more easily digested and absorbed and usually better tolerated by the patient with anorexia.*
  c. Encourage to try icy cold foods (such as ice cream) or those that are more highly seasoned if food has no taste. *Chemotherapy and radiation therapy may harm taste buds and prevent distinguishing the taste of foods. Strong seasonings and coldness make food more enjoyable to the patient with diminished taste. However, spicy foods are not recommended for patients with stomatitis.*
  d. Encourage cold and bland semisoft and liquid foods with painful oropharyngeal ulcers; use a nonalcohol anesthetic

mouthwash prior to eating. *These foods are less irritating to sensitive mucous membranes; deadening the pain can make chewing and swallowing easier.*

e. Manage nausea and vomiting by administering antiemetic drugs (around-the-clock medication may be an effective preventive measure). Encourage patient to eat small, frequent, low-fat meals with dry foods such as crackers and toast, to avoid liquids with meals, and to sit upright for an hour after meals. Remove emesis basins, and encourage oral hygiene before eating. *Dry, low-fat foods are more readily tolerated when nauseated. Removing vomiting cues, such as odor and supplies associated with vomiting, can reduce nausea.*

- Teach to supplement meals with nutritional supplements such as Ensure Plus or Isocal and to take multivitamin and mineral tablets with meals. Suggest increasing calories by adding ice cream or frozen yogurt to the liquid supplement or commercial protein-carbohydrate powders to milk or fruit juice. *Because the food intake is usually less than that needed to maintain or gain weight, these supplements can add calories in a manner often tolerated by patients who are ill.*
- Teach to keep a food diary to document daily intake. *If the patient can see how little is being consumed, he or she may eat more. A food diary helps the nurse keep a calorie count and alert the physician if more drastic nutritional measures, such as a feeding tube or parenteral nutrition, need to be instituted.*
- Teach to administer parenteral nutrition via a central line or other VAD. Teach safety measures and care of the VAD, and explain how the pump delivering the solution works. Provide an emergency phone number for help with administration problems. (See Chapter 22 for safety guidelines for administering parenteral nutrition.) *The patient with chronic or terminal cancer requiring parenteral nutrition is usually managed at home, so information on how to manage the entire process may be needed.*

Impaired Tissue Integrity

The most common impairment of tissue integrity occurs in the oral-pharyngeal-esophageal mucous membranes. It is secondary to the effects of some chemotherapeutic drugs and radiation treatment to the head and neck. The oral-pharyngeal-esophageal tissues are lined with cells with a high mitotic turnover rate and are therefore vulnerable to many chemotherapeutic drugs. Leukemias, bone marrow transplants, and herpes viral infections are other etiologic factors in the disruption of oral-pharyngeal-esophageal tissue.

Manifestations of this problem may include the following:

- Small ulcers occur on the tongue and mucous membranes in the mouth and throat.
- Herpes simplex type 1 lesions or vesicles evolve into ulcerations.
- Fungal infections, such as thrush (due to *Candida* infections), are manifested by a white, yellow, or tan coating with dry, red, fissured tissue underneath.
- Red, swollen, friable gums bleed with minimal or no trauma.
- **Xerostomia** is excessive dryness of the mucous membranes (due to chemotherapy or radiation).

Expected Outcome: Tissue integrity will be restored and maintained.

- Carefully assess and evaluate the type of tissue impairment present. Identify possible sources, such as chemotherapy or radiation therapy to head and neck. *This allows the nurse to implement corrective measures appropriate to the type of problem.*
- Implement and teach measures for preventing oropharyngeal infection (ONS, 2013d):
  a. Observe for systemic signs of infection. Be suspicious of any fever that has no apparent cause. *This facilitates early identification of an infection before it spreads.*
  b. Encourage cleaning teeth gently and using a nonalcohol mouthwash several times a day. This can be done after waking up in the morning, after any oral intake, and before bedtime. Soak dentures nightly in hydrogen peroxide and floss gently with waxed floss after meals and bedtime; this measure may be contraindicated for people with leukemia or thrombocytopenia. *Disrupted mucous membranes allow the normal oral bacterial flora into the systemic circulation, which can result in sepsis in the immunocompromised person. Reducing the oral flora by frequent hygiene decreases the risk of infection.*
  c. Culture any oral lesions, and report the problem to the physician. Herpes lesions may not follow a typical pattern in immunosuppressed patients. *Identifying the cause of the infection, whether viral, fungal, or bacterial, allows the physician to prescribe the appropriate treatment.*
- Implement and teach measures for reducing trauma to delicate tissues:
  a. Counteract dry mouth (xerostomia) with lubricating and moisturizing agents, such as Gatorade, sugarless gum, and Blistex. *This protects mucous membranes from infection and trauma.*
  b. Avoid putting sharp instruments in the mouth. Use smooth plastic spoons and forks for eating, especially with a bleeding disorder. Dental work should be done by dental oncologists.
  c. Brush teeth with a very soft toothbrush and obtain a new toothbrush monthly. If gums are friable and bleeding, clean teeth with a soft cloth or toothpaste over finger. Chlorhexidine mouthwash (Peridex) may be used. *This protects gums from trauma and decreases risk of hemorrhage.*
- Administer specific medications as ordered to control infection and/or pain:
  a. Acyclovir is often used to treat viral infections.
  b. Systemic antibiotics are used to treat bacterial infections.
  c. Nystatin or clotrimazole solution for "swish and swallow" or lozenges that dissolve slowly in the mouth are used for fungal infections.
  d. Use viscous Xylocaine or various combination mouthwashes before meals and as needed. These agents reduce pain and inflammation. See Box 14–12 for the ingredients of combination mouthwashes. *Knowing the contents of each mouthwash can prevent hypersensitivity reactions (e.g., to lidocaine) and assist in patient teaching.*

Nursing Interventions for Oncologic Emergencies

In caring for patients with cancer, nurses may encounter a number of emergency situations in which their role may be pivotal to the patient's survival. Most of these emergencies require astute observations, accurate judgments, and rapid action once the problem has been identified. A brief description of the more common **oncologic emergencies** with nursing interventions follows. In all cases, immediate notification of the physician or emergency team is the first step.

BOX 14–12 Combination Mouthwashes for Oropharyngeal Pain Control

KAISER MOUTHWASH
- Nystatin
- Hydrocortisone
- Tetracycline

STANFORD MOUTHWASH
- Nystatin
- Tetracycline
- Lidocaine
- Hydrocortisone

XYLOXYLIN SUSPENSION
- Benylin syrup
- Lidocaine
- Maalox suspension

STOMAFATE SUSPENSION
- Sucralfate
- Sterile water
- Benylin syrup
- Maalox suspension

Pericardial Effusion and Cardiac Tamponade

Malignant pericardial effusion is an accumulation of excess fluid in the pericardial sac that compresses the heart, restricts heart movement, and results in a cardiac tamponade. The signs of cardiac tamponade are caused by compression of the heart, which leads to decreased cardiac output and impaired cardiac function. Signs include hypotension, tachycardia, tachypnea, dyspnea, cyanosis, increased central venous pressure, anxiety, restlessness, and impaired consciousness.

Interventions include the following:

- Start oxygen and alert respiratory therapy for other respiratory support as needed.
- Insert an intravenous catheter if one is not already in place.
- Monitor vital signs and initiate hemodynamic monitoring.
- Prepare vasopressor drugs.
- Bring emergency cart to bedside.
- Set up for and assist the physician with a pericariocentesis (pericardial tap).
- Reassure the patient.

Superior Vena Cava Syndrome

The superior vena cava can be compressed by mediastinal tumors or adjacent thoracic tumors. The most common cause is small-cell or squamous cell lung cancers. Occasionally the problem is caused by thrombus around a central venous catheter that then occludes the vena cava, resulting in obstruction and backup of the blood flowing into the superior vena cava.

Obstruction of the vena cava causes increased venous pressure, venous stasis, and engorgement of veins that are drained by the superior vena cava. Signs and symptoms may develop slowly; facial, periorbital, and arm edema are early signs. As the problem progresses, respiratory distress, dyspnea, cyanosis, tachypnea, and altered consciousness and neurologic deficits may occur. Figure 14–7 ■ illustrates superior vena cava syndrome.

Emergency measures include the following:

- Provide respiratory support with oxygen, and prepare for tracheostomy.

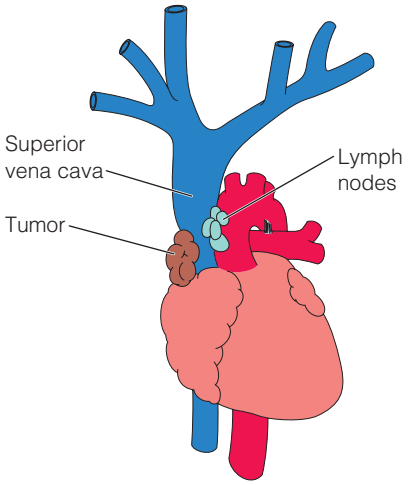

Figure 14–7 ■ Superior vena cava syndrome. The enlargement of a tumor adjacent to the superior vena cava (usually in the lung or mediastinum) compresses that major blood vessel, which leads into the right atrium of the heart. As a result, blood backs up into the venous system behind the obstruction, diminishing blood flow into the heart.

- Monitor vital signs.
- Administer corticosteroids (e.g., dexamethasone) to reduce edema.
- If the disorder is due to a clot, administer antifibrinolytic or anticoagulant drugs as ordered.
- Provide a safe environment, including seizure precautions.

After the emergency is managed, the patient often receives radiation or chemotherapy to reduce the tumor size.

Sepsis and Septic Shock

Tumor necrosis, immune deficiency, antineoplastic therapy, malnutrition, and comorbid conditions can lead to the development of sepsis. Bacteria gain entrance to the blood, grow rapidly, and produce septicemia. Because malignant tumors are more likely to use anaerobic metabolic pathways, the bacteria of tumor sepsis are usually gram negative and damage the body through a combination of bacterial endotoxins and an uncontrolled immune reaction. Gram-negative sepsis progresses to systemic shock and eventually results in multisystem failure.

Signs and symptoms appear in two phases. The first phase is characterized by vasodilation with hypovolemia, high fever, peripheral edema, hypotension, tachycardia, tachypnea, hot flushed skin with creeping mottling beginning in the lower extremities, and anxiety or restlessness. Without treatment, the shock progresses to the second phase, which shows the more classic signs of shock: hypotension, rapid thready pulse, respiratory distress, cyanosis, subnormal temperature, cold clammy skin, decreased urinary output, and altered mentation. Identifying the problem while the patient is still in the hyperdynamic state is crucial to the patient's survival. Refer to Chapter 11 for further discussion of septic shock.

Spinal Cord Compression

Spinal cord compression is most commonly associated with pressure from expanding tumors of the breast, lung, or prostate; lymphoma; or metastatic disease. Spinal cord compression constitutes an

emergency because of the potential for irreversible paraplegia. Back pain is the initial symptom in almost all cases of spinal cord compression. This may progress to leg pain, numbness, paresthesias, and coldness. Later, bowel and bladder dysfunction occur and, finally, neurologic dysfunction progressing from weakness to paralysis. Treatment often consists of radiation or surgical decompression, but early detection is essential. See Chapter 43 for further discussion of spinal cord compression.

Obstructive Uropathy

Patients with intra-abdominal, retroperitoneal, or pelvic malignancies, such as colorectal, prostate, cervical, or bladder cancers, may experience obstruction of the bladder neck or the ureters. Bladder neck obstruction usually manifests as urinary retention, flank pain, hematuria, or persistent urinary tract infections, but ureteral obstruction is not often evident until the patient is in renal failure. See Chapter 28 for further discussion of obstructive uropathy.

Hypercalcemia

Hypercalcemia in patients with cancer results from the excessive ectopic production of parathyroid hormone and is most commonly associated with cancers of the breast, lung, esophagus, thyroid, head, and neck and with multiple myeloma. Bone metastases may also cause hypercalcemia. When the rate of calcium mobilization from the bone exceeds the renal threshold for excretion, serum calcium levels can become dangerously elevated. Patients with hypercalcemia often present with nonspecific symptoms of fatigue, anorexia, nausea, polyuria, and constipation. Neurologic symptoms include muscle weakness, lethargy, apathy, and diminished reflexes. Without treatment, hypercalcemia progresses to alterations in mental status, psychotic behavior, cardiac arrhythmias, seizures, coma, and death (refer to Chapter 10).

Hyperuricemia

Hyperuricemia usually is a complication of rapid necrosis of tumor cells after vigorous chemotherapy for lymphomas and leukemias. Hyperuricemia may be related to increased uric acid production or to the tumor lysis syndrome associated with Burkitt's lymphoma. Uric acid crystals are deposited in the urinary tract, causing renal failure and uremia. Patients with hyperuricemia manifest with nausea, vomiting, lethargy, and oliguria.

Tumor Lysis Syndrome

Tumor lysis syndrome (TLS) is a life-threatening emergency for patients with cancer. TLS is characterized by a combination of two or more metabolic abnormalities, including hyperuricemia, hyperphosphatemia, hyperkalemia, and/or hypocalcemia (McBride & Westervelt, 2012). The syndrome develops because of massive and rapid destruction or death of cancer cells caused by cytotoxic treatment such as chemotherapy, radiation, biologic therapy, hormonal therapy, and surgery. It can occur spontaneously with sudden death of tumor cells. A high incidence of TLS occurs in patients with high-grade lymphomas (Burkitt's lymphoma) and acute lymphocytic leukemia (ALL). Although the incidence of TLS in solid tumors is rare, cases of TLS following chemotherapy have been reported in patients with small-cell lung cancer, breast cancer, neuroblastoma, melanoma, and ovarian cancer.

The major cause of TLS is chemotherapy to tumors with a high proliferative rate, a relatively large tumor burden, and high sensitivity to cytotoxic agents, which leads to massive and rapid cell death. Usually, within a week of initiating chemotherapy, the body no longer can excrete the large amount of metabolic by-products from the cell death, resulting in the release of intracellular contents and metabolic by-products (such as potassium, phosphorus, and nucleic acid) into the bloodstream (McBride & Westervelt, 2012). As a result, a combination of metabolic derangements occurs, including hyperkalemia, hyperuricemia, and hyperphosphatemia with secondary hypocalcemia (McBride & Westervelt, 2012). These metabolic abnormalities put patients at risk for cardiac dysfunction and renal failure.

Manifestations of TLS include nausea, vomiting, lethargy, edema, fluid overload, congestive heart failure, cardiac dysrhythmias, seizures, muscle cramps, tetany, syncope, and possible sudden death (McBride & Westervelt, 2012). Diagnosis of TLS mainly depends on laboratory tests and clinical signs and symptoms.

Prevention is crucial in management of TLS. Patients at risk for TLS include those with bulky chemosensitive cancer such as high-grade lymphomas and acute leukemia, elevated serum uric acid, potassium, phosphorus, and renal deficiency. Preventive and management measures include identifying patients at risk, promoting uric acid excretion, and managing electrolyte imbalances. Allopurinol is administered to inhibit the conversion of nucleic acid to uric acid, and hydration and diuretic therapy is used to promote uric acid and phosphate excretion. An oral phosphate binder such as aluminum hydroxide and sodium polystyrene sulfonate (Kayexalate) are given to promote excretion of phosphate and potassium through the bowel. Hemodialysis may be required to manage electrolyte imbalances unresponsive to standard approaches (McBride & Westervelt, 2012).

Health Education for the Patient

Rehabilitation and Survival

Rehabilitation from cancer not only involves regaining strength, recovering from surgery or chemotherapy, and learning to live with an altered body part or appliance, but also entails recovering from associated psychologic and emotional turmoil.

Rehabilitation centers provide physical therapy, occupational therapy, speech therapy, job retraining, and an opportunity to recuperate before resuming full responsibilities. In addition, many patients go home to convalesce and receive in-home support in the form of nursing supervision, direct care, and teaching. A certified home health aide can provide hygiene and home maintenance. Physical and occupational therapists provide muscle strengthening and mobility training (especially with prostheses), and home safety teaching.

Psychologic rehabilitation of cancer survivors addresses quality-of-life issues. Three "seasons of cancer survival" have been described (Mullan, 1985). The first starts with diagnosis but is dominated by treatment. The second stage is one of extended survival, which occurs when treatment ends and the watchful waiting period begins. This period is characterized by fear of recurrence. Permanent survival is said to begin when the survival period has gone on long enough that the risk of recurrence is small. In this period, the patient has to deal with secondary problems related to health and social issues resulting from the cancer experience. Employment may be a problem, health insurance may be canceled, and life insurance may be difficult to get. Relationships may have suffered from the strain of the illness on significant others and the essential self-focusing required for recovery. Both the patient and significant others may have undergone

CASE STUDY & NURSING CARE PLAN A Patient with Cancer

James Casey, age 72, has a history of chronic obstructive pulmonary disease, previous myocardial infarction, and type 1 diabetes mellitus. He reports that he lost his wife from lung cancer 5 years ago and still "misses her terribly." He describes his bad habits as smoking two packs of cigarettes a day for 52 years (a 104 pack/year smoking history), drinking one to two six-packs of beer a week and one "bourbon and water" a night, and eating "a lot of junk food, like French fries." He states that he quit smoking 2 years ago, when he could no longer walk a block without considerable shortness of breath, and just quit drinking alcohol a few weeks ago at his physician's insistence. Six months ago, he was diagnosed with bladder cancer and underwent two 6-week courses of BCG bladder instillations. His latest report indicates that the tumors have grown back and there is evidence of metastasis to pelvic lymph nodes and his spine. Mr. Casey decides to forego further treatment and to be managed at home with hospice care. He asks his daughter Mary to move in with him to provide care and support during his final months. The daughter accepts; she has been informed of the physical and emotional stress this will entail.

ASSESSMENT

Glynis Jackson, RN, Mr. Casey's hospice case manager, completes a health history and physical examination during her first two visits. She gathers this information over 2 days to conserve his strength and allow more time for Mr. Casey and his daughter to talk about their concerns.

Ms. Jackson notes that Mr. Casey is thin and pale, with a wasted appearance and a strained, worried facial expression. He complains of severe back pain no longer adequately relieved by oxycodone/aspirin (Percodan) and hydrocodone/acetaminophen (Vicodin) alternating every 2 to 4 hours. His vital signs are BP 90/50 mmHg, right arm sitting; apical pulse 102 bpm, regular; respirations 24/min and unlabored; breath sounds clear but diminished in the bases; oral temperature 36°C (96.8°F).

A tunneled Groshong catheter as a VAD is present in the right anterior chest. There is no drainage, redness, or swelling at the site. No medication is currently running via the VAD. Mary reports that his urinary output is adequate. Approximately 200 mL of yellow, cloudy, nonmalodorous urine is present in the urinal at the bedside.

Mr. Casey states that he spends most of his time either in bed or sitting up in a chair in his room. He reports that he has no energy and is unable to walk to the bathroom unassisted, dress himself, or manage his own personal hygiene. Ms. Jackson rates Mr. Casey's functional level at ECOG level 4: capable of only limited self-care, confined to bed or chair 50% or more of waking hours. He tells the nurse that his daughter "is working day and night to help me and is looking awfully tired."

Mary reports that Mr. Casey is eating very poorly, usually eating a small bowl of oatmeal with milk for breakfast and vegetable soup and crackers for lunch, but he wants only fruit juice for dinner. Mr. Casey says that he has no appetite and eats just to please Mary. He does drink at least three to four glasses of water a day plus juice. His fingerstick blood sugars remain within normal range.

His current weight is 120 pounds at 67 inches tall, down from 180 pounds a year ago. He has lost about 30 pounds during the past 2 months.

Available laboratory values from his visit with the physician show the following:

Total protein: 4.1 g/dL (normal range: 6.0 to 8.0 g/dL)

Albumin: 2.2 g/dL (normal range: 3.5 to 5.0 g/dL)

Hemoglobin: 10.2 g/dL (normal range: 13.5 to 18.0 g/dL)

Hematocrit: 30.5% (normal range: 40.0% to 54.0%)

BUN: 30 mg/dL (normal range: 5 to 25 mg/dL, slightly higher in older people)

Creatinine: 2.2 mg/dL (normal range: 0.5 to 1.5 mg/dL).

DIAGNOSES

- *Imbalanced Nutrition: Less Than Body Requirements* related to anorexia and fatigue
- *Risk for Caregiver Role Strain* related to severity of her father's illness and lack of help from other family members
- *Chronic Pain* (malignant) related to progression of disease process
- *Impaired Physical Mobility* related to pain, fatigue, and early neuromuscular impairment
- *Risk for Impaired Skin Integrity* related to impaired physical mobility and undernutrition

EXPECTED OUTCOMES

- Patient will increase oral intake.
- Patient will experience minimal pain for the rest of his life.
- Patient will continue his current activity level.
- Patient will maintain intact skin.
- Patient will continue receiving support and care from his daughter.

PLANNING AND IMPLEMENTATION

- Ask about favorite foods, and ask Mary to include these foods in meals and snacks. Encourage use of a nutritional supplement (e.g., Ensure).
- Refer to home health agency to provide a home health aide to assist with hygiene and household chores.
- Request a volunteer to stay with Mr. Casey twice a week, allowing Mary to attend to outside activities and chores. Encourage Mary to talk with family members about providing additional respite care for Mr. Casey.
- Collaborate with the interprofessional team to establish a pain control program, using the VAD and a CADD-PCA infusion pump with a continuous morphine infusion.
- Teach Mary how to manage the morphine infusion and pump, usual side effects of the morphine infusion and their management, and adverse effects which should be reported to the nurse.
- Instruct Mary to allow ample rest periods for Mr. Casey between activities.
- Order a hospital bed with electronic controls and a bedside commode for Mr. Casey.
- Instruct Mary and the home health aide to inspect skin daily, provide good skin care with emollient lotion after bathing, and report any lesions immediately to the nurse.

EVALUATION

Mr. Casey did increase his oral intake a little, sometimes eating the special treats his daughter prepared and drinking one or two cans of liquid nutritional supplement a day. His daughter was very grateful for the extra help from the home health aide and the volunteer, though she could not bring herself to ask her family for help. She did become more rested and reported that "Dad and I had some wonderful 3:00 a.m. talks when he couldn't sleep."

Mr. Casey's pain was well controlled using the morphine infusion with boluses as needed for breakthrough pain. His skin remained intact and in good condition.

Mary reported that Mr. Casey died peacefully in his sleep, about 2 weeks after hospice care was started. She said spending the last weeks of his life together was a healing experience for both of them.

Clinical Reasoning in Patient Care

1. What other tests could be done to evaluate Mr. Casey's nutritional status?
2. Mr. Casey had severe back pain. What were the possible pathophysiologic reasons for his pain?
3. What medications are available to improve Mr. Casey's appetite? What side effects might they have that would contraindicate these medications for him?
4. If Mr. Casey had developed sepsis, what manifestations would you expect to see? As the nurse making the home visits, what would be your nursing actions, and in what order of priority?

See Evaluating Your Response in Appendix B.

a personal and spiritual growth that ushers in a new and enriching period of their lives.

New self-help groups are emerging in many communities to support others through their "seasons of survival." Many cancer survivors speak to groups about assisting other cancer survivors. Patients and families need to be informed about the resources available through community agencies and survivor support groups.

Continuity of Care

Before the patient is discharged or transferred to a long-term care setting, teach both the patient and significant others or caregivers to manage the patient at home. Discuss problems that may result from the type of cancer and the treatment received, and provide information on how to manage these problems and when to call the physician.

- Teach wound care to the patient with an open wound or draining lesion, and provide a referral to a home health nurse to monitor progress.
- Explain special diets clearly, or refer the patient to a dietitian before discharge.
- Carefully review the physician's instructions with the patient and family, making sure they understand medications to be taken, any other treatments, and when to see the physician for follow-up care.
- Provide or order equipment and supplies needed for home care, especially any specialized bed or equipment to aid mobility and ensure safety in the home.
- For the patient who will need complex care, such as parenteral nutrition, provide a referral to a home health nurse before discharge.

Because the hospital stay is often short, the patient and family will benefit from follow-up phone calls at home for several days. People do not learn well under the stress of going home; give the patient and family a number to call if they have concerns or questions.

Hospice Care

More and more patients with terminal cancer disease are electing to die at home. This decision has been made easier by the increased availability of **hospice** programs. When a patient and family or significant others elect hospice care, they are usually precluding additional hospitalizations other than those required to manage reversible problems.

Many hospice services are connected with an inpatient respite care unit, where the patient can receive 24-hour care for up to several weeks. This source provides the necessary care to the patient if a family member becomes ill or needs to be relieved temporarily of the tremendous burden of caring for a dying loved one. Chapter 5 provides more information on hospice care.

CHAPTER HIGHLIGHTS

- **Cancer is a life-threatening and complicated disease characterized by uncontrolled growth and spread of abnormal cells. Cancer can affect people of any age, gender, ethnicity, or geographic region.**
- Cancer is the second leading cause of death in the United States. The incidence of cancer increases with advancing age. The most commonly seen cancers in women are breast, lung, colorectal, uterine, and thyroid. In men, prostate, lung, colorectal, bladder, and skin melanoma cancers occur most frequently.
- An estimated 5% to 10% of cancers have a hereditary component; therefore it is important to determine patients who have a genetic predisposition. Recurring patterns of cancer within a family may indicate a genetic component, as well as shared environmental exposures, lifestyle, and other nongenetic risk factors.
- **The diagnosis and treatment of cancer is a pivotal, life-changing event that requires immediate and ongoing adjustment to this life-threatening illness. Effective physical and psychosocial adjustment to cancer diagnosis and treatment enhances patients' ability to cope, and improves survival and quality of life.**
- **The goals of cancer treatment are aimed at cure and control of cancer as well as management of cancer-related and treatment-related symptoms.**
- Cancer may be treated through surgery, chemotherapy, radiation therapy, biotherapy, photodynamic therapy, bone marrow and stem cell transplants, hormonal therapy, and complementary therapies. Chemotherapy uses cytotoxic medications to cure or control cancer by interrupting cell metabolism and replication and by interfering with the ability of the malignant cell to synthesize vital enzymes and chemicals.
- Common complementary therapies for cancer include botanical agents, nutritional supplements, dietary regimens, mind–body modalities, spiritual approaches, and miscellaneous therapies.
- **Nurses play a pivotal role in cancer prevention, providing quality patient-centered individualized care for patients with cancer.**
- Managing cancer-related or treatment-related symptoms, such as pain, nausea and vomiting, mucositis, or fatigue, is a major nursing responsibility.
- Managing oncologic emergencies is an important nursing responsibility. Tumor lysis syndrome (TLS) is a life-threatening oncologic emergency for patients with cancer.

TEST YOURSELF NCLEX-RN® REVIEW

1. A patient with a history of colon cancer is informed that cells from the colon tumor have traveled to the liver. Which process should the nurse plan to explain to the patient?
   1. mutation
   2. dysplasia
   3. metastasis
   4. carcinogenesis
2. A patient diagnosed with lung cancer reports having difficulty sleeping and often feels tense. What would be the most appropriate initial nursing intervention?
   1. Offer an antianxiety drug such as Ativan (lorazepam).
   2. Obtain an order for medication for sleep from the physician.
   3. Encourage the patient to express feelings about the cancer diagnosis.
   4. Document the patient's report of difficulty sleeping and tenseness in the chart.
3. A patient is receiving external radiation for treatment of lung cancer. What should the nurse teach the patient to care for the skin in the marked area?
   1. Avoid contact with others.
   2. Cleanse the skin with soapy water.
   3. Apply antibacterial ointment daily.
   4. Avoid rubbing or scratching treated skin areas.
4. A patient is experiencing nausea and vomiting after daily chemotherapy treatments. What should the nurse do to help this patient?
   1. Schedule chemotherapy administration for bedtime.
   2. Provide clear liquids until the chemotherapy is completed.
   3. Keep the patient NPO until daily chemotherapy is completed.
   4. Provide antiemetic medication 30 to 40 minutes prior to each treatment.
5. A patient is experiencing bone marrow depression as a result of chemotherapy. Which assessment should the nurse expect because of this health problem?
   1. alopecia
   2. temperature 38.9°C (102°F)
   3. nausea and vomiting
   4. platelet count of 50,000
6. The nurse instructs a patient with cancer about chemotherapy. Which patient statement indicates that teaching has been effective?
   1. "Chemotherapy stops cancer cells from using body enzymes and chemicals."
   2. "Chemotherapy only uses a single drug to treat cancer because drug resistance is rare."
   3. "Chemotherapy uses drugs that promote the normal growth of cells while killing the cancer cells."
   4. "Chemotherapy is a preferred therapy because it has fewer adverse effects than radiation therapy."
7. A patient is going to begin a course of high-energy radiation to kill cancer cells through the use of a machine to focus a beam of radiation on the body. For which type of radiation therapy should the nurse instruct the patient?
   1. brachytherapy
   2. biochemotherapy
   3. external radiation therapy
   4. internal-beam radiation therapy
8. The nurse is monitoring the uric acid, potassium, phosphorus, and calcium levels for a patient completing the first cycle of chemotherapy. For which complication is the nurse monitoring the patient?
   1. septic shock
   2. tumor lysis syndrome
   3. spinal cord compression
   4. superior vena cava syndrome
9. A patient is going to receive chemotherapeutic medication that affects DNA replication and chromosome duplication. Which phase of the cell cycle is this medication going to affect?
   1. S
   2. M
   3. G_1
   4. G_2
10. The nurse is preparing to instruct a group of patients newly diagnosed with cancer on the role of oncogenes. What should the nurse explain as a characteristic of oncogenes?
    1. They block cell growth.
    2. They are strictly regulated.
    3. They promote cell growth when activated.
    4. They stimulate a complex signaling process.

UNIT

3 Building Clinical Competence

Pathophysiology and Patterns of Health

CLINICAL SCENARIO

Directions: *Read the following clinical scenarios and answer the questions that follow. To complete this exercise successfully, you will utilize not only knowledge of the content in this unit, but also principles related to priority setting and maintaining patient safety.*

You have been assigned to work with the following four patients for the 0700 shift on a medical-surgical unit. Significant data obtained during report is as follows:

- Allen Barber is a 55-year-old patient with diabetes mellitus who is 4 days postoperative abdominal surgery with an inflammation of the incision site. Temperature is 38.3°C (101°F), pulse 94 bpm, respirations 24/min, and blood pressure 138/82 mmHg. The abdominal incision appears red with warmth and edema around the incision. The patient states his pain level is 8 on a pain scale of 0 to 10. Labs and wound cultures have been ordered.
- Tamra Sanders is a 22-year-old patient with Down syndrome. She is admitted in sickle cell crisis with a temperature of 38.9°C (102°F), pulse 90 bpm, respirations 30/min and shallow, and blood pressure of 110/84 mmHg. She is complaining of severe chest pain with shortness of breath. She states her pain scale level is 10 of 10. She has an order to begin morphine PCA.
- Mia Windham is a 26-year-old who was admitted yesterday with a maculopapular rash on her hands and feet that is spreading to her arms and legs. This morning she is complaining of abdominal pain, nausea, and bloody diarrhea. The patient has a history of having a bone marrow transplant 3 months ago as treatment for leukemia.
- Harry Anderson is a 40-year-old in late stages of AIDS. He is confused, incontinent, and is very spastic. He is on seizure precautions. He needs to be turned every 2 hours to prevent pressure sores. He is currently yelling that he needs help.

CLINICAL REASONING

1. Ms. Windham has experienced four episodes of bloody diarrhea within the last 2 hours and now appears to be increasingly lethargic. What additional assessments should the nurse make? What collaborative interventions should be discussed with the healthcare provider?

Priority Setting

2. In what order would you visit these patients after report?
   A. _____
   B. _____
   C. _____
   D. _____

Health Promotion

3. Mr. Anderson has experienced a recent 20-pound weight loss. Because the client is currently confused, the dietitian teaches a family member meal planning for which type of diet?
   A. high protein, high fiber
   B. high protein, high kilocalorie
   C. low fiber, low protein
   D. high carbohydrate, high vitamins

Nursing Process

4. Besides obtaining vital signs, what diagnosis-specific assessment data should be collected for each patient?
   A. _____
   B. _____
   C. _____
   D. _____

5. In what position should the nurse place Ms. Sanders to ease her breathing?
   A. Sims' position
   B. high Fowler's
   C. Trendelenburg
   D. dorsal recumbent

6. Due to diarrhea, Ms. Windham's arterial blood gas results are pH, 7.30; pCO_2, 35 mmHg; pO_2, 90 mmHg; HCO_3^-, 19 mEq/L. How does the nurse correctly interpret these results?
   A. metabolic acidosis
   B. metabolic alkalosis
   C. respiratory acidosis
   D. respiratory alkalosis

Communication

7. The family of the patient in sickle cell crisis asks the nurse how sickle cell disease is transmitted from one family member to another. Which statement by the nurse is the correct response?
   A. "The mother carries the gene for sickle cell disease and passes it to the children."
   B. "The father carries the gene for sickle cell disease and passes it to the children."
   C. "Both parents carry the gene for sickle cell disease and have a 25% chance of children with the disease."
   D. "One parent has the disease and one parent carries the affected gene and they have a 50% chance of passing it to the children."

8. When talking with Ms. Sanders, what communication techniques will you use as a result of her diagnosis of Down syndrome?

Delegation

9. What nursing interventions for each patient can be delegated to a CNA?

A. _____
B. _____
C. _____
D. _____

Interprofessional Care

10. The nurse collaborates with the healthcare provider regarding Mr. Barber's temperature and condition of his incision. Which laboratory studies does the nurse anticipate being ordered?

A. white blood cell count/differential, erythrocyte sedimentation rate, C-reactive protein
B. troponins, metabolic panel for electrolytes, cultures of wound site
C. blood cultures, hematocrit and hemoglobin, blood glucose level
D. complete blood cell count, alkaline phosphatase, urine creatinine, and blood urea nitrogen

Continuity of Care

11. Mr. Barber is being discharged to home following a course of intravenous antibiotics. Which of the following statements made by the patient indicates a need for further discharge instruction?

A. "I can stop the antibiotic pills once I haven't had a fever for two consecutive days."
B. "I'll wash my hands carefully with soap and water before and after I touch my wound."
C. "If I develop a fuzzy growth or white plaques on my tongue, I'll call my healthcare provider."
D. "If I start to develop constipation from my pain medications, I'll increase my fluid intake."

Safety

12. Which of the following parameters are essential for the nurse to monitor every 2 hours or more frequently for Ms. Sanders while receiving PCA morphine? (Select all that apply.)

A. urinary output
B. analgesia level
C. sedation level
D. bowel function
E. oxygen saturation
F. respiratory rate and effort

Quality Improvement

12. The nurse manager of a medical nursing unit performs electronic health record reviews and notes that patients admitted with fluid excess states have unexplainable fluctuations in daily weights recorded. What type of quality improvement measures can be implemented to ensure accuracy of patients' daily weights?

Informatics

13. A nurse documents that the blood pressure of a patient is dropping with the mean arterial pressure <70 mmHg. What term would he or she use to document these findings in the electronic health record?

A. hypertension
B. cardiac output
C. shock
D. blood loss

UNIT

4

Responses to Altered Integumentary Structure and Function

15 Assessing the Integumentary System 377

16 Nursing Care of Patients with Integumentary Disorders 390

17 Nursing Care of Patients with Burns 432

Nutritional–Metabolic Pattern

The structure, functions, and healing of the integument affect and depend on nutritional balance.

15 Assessing the Integumentary System

LEARNING OUTCOMES

1. Describe the anatomy, physiology, and functions of the skin, hair, and nails.
2. Discuss factors that influence skin color.
3. Identify specific topics for a health history interview of the patient with problems involving the skin, hair, or nails.
4. Explain techniques for assessing the skin, hair, and nails.
5. Give examples of genetic disorders of the integumentary system.
6. Differentiate normal variations in assessment findings for the older adult.
7. Identify abnormal findings that may indicate impairment of the integumentary system.

CLINICAL COMPETENCIES

1. Complete a health history of the integumentary system incorporating an appraisal of psychosocial and physiologic issues.
2. Conduct and document a health history for patients who have or are at risk for alterations in the skin, hair, or nails.
3. Conduct and document a physical assessment of the integumentary system demonstrating sensitivity and respect for the diversity of the human experience.
4. Monitor the results of diagnostic tests and communicate abnormal findings within the interprofessional team.

MAJOR CHAPTER CONCEPTS

- Intact structure and function of the integumentary system is vital to the protection of the body's organs from the external environment.
- Manifestations of dysfunction, injury, and disorders affecting the integumentary system may be detected during a general health assessment as well as during focused integumentary assessments.

KEY TERMS

alopecia, *385*
cyanosis, *379*
ecchymosis, *384*
edema, *384*
erythema, *379*
hirsutism, *385*
jaundice, *379*
keratin, *378*
melanin, *378*
pallor, *379*
sebum, *379*
urticaria, *384*
vitiligo, *384*

EQUIPMENT NEEDED

- Disposable gloves
- Ruler (metric to centimeters)
- Flashlight

The skin, hair, and nails make up the integumentary system. The skin, the largest organ of the body, provides an external covering for the body, separating and protecting the body's organs and tissues from the external environment. Functions of the skin, hair, and nails are summarized in Table 15–1.

Anatomy, Physiology, and Functions of the Integumentary System

The Skin

The skin has a total surface area of 15 to 20 square feet and weighs about 9 pounds. It has been estimated that each square inch of skin contains 15 feet of blood vessels, 4 yards of nerves, 650 sweat glands, 100 oil glands, 1500 sensory receptors, and more than 3 million cells that are constantly dying and being replaced. The skin is composed of two regions: the epidermis and the dermis (Figure 15–1 ■). Alterations in the skin increase the risk for many physical and psychologic disorders, including fluid and electrolyte imbalance, altered temperature regulation, infection, delayed wound healing, and altered self-concept.

TABLE 15–1 Functions of the Skin and Its Appendages

Structure	Functions
Epidermis	Protects tissues from physical, chemical, and biologic damage. Prevents water loss and serves as a water-repellent layer. Stores melanin, which protects tissues from harmful effects of the ultraviolet radiation in sunlight. Converts cholesterol molecules to vitamin D when exposed to sunlight. Contains phagocytes, which prevent bacteria from penetrating the skin.
Dermis	Regulates body temperature by dilating and constricting capillaries. Transmits messages via nerve endings to the central nervous system.
Sebaceous (oil) glands	Secrete sebum, which lubricates skin and hair and plays a role in killing bacteria.
Eccrine sweat glands	Regulate body heat by excretion of perspiration.
Apocrine sweat glands	Remnants of sexual scent gland.
Hair	Cushions the scalp. Eyelashes and cilia protect the body from foreign particles. Provides insulation in cold weather.
Nails	Protect the fingers and toes, aid in grasping, and allow for various other activities, such as scratching the skin, picking up small items, peeling an orange, and so on.

THE EPIDERMIS

The epidermis, which is the surface or outermost part of the skin, consists of epithelial cells. The epidermis has either four or five layers, depending on its location; there are five layers over the palms of the hands and the soles of the feet, and four layers over the rest of the body.

The stratum basale is the deepest layer of the epidermis. It contains melanocytes, cells that produce the pigment **melanin**, and keratinocytes, which produce **keratin**. Melanin forms a protective shield to protect the keratinocytes and the nerve endings in the dermis from the damaging effects of ultraviolet light. Melanocyte activity probably accounts for the difference in skin color in humans. Keratin is a fibrous, water-repellent protein that gives the epidermis its tough, protective quality. As keratinocytes mature, they move upward through the epidermal layers, eventually becoming dead cells at the surface of the skin. Millions of these cells are worn off by abrasion

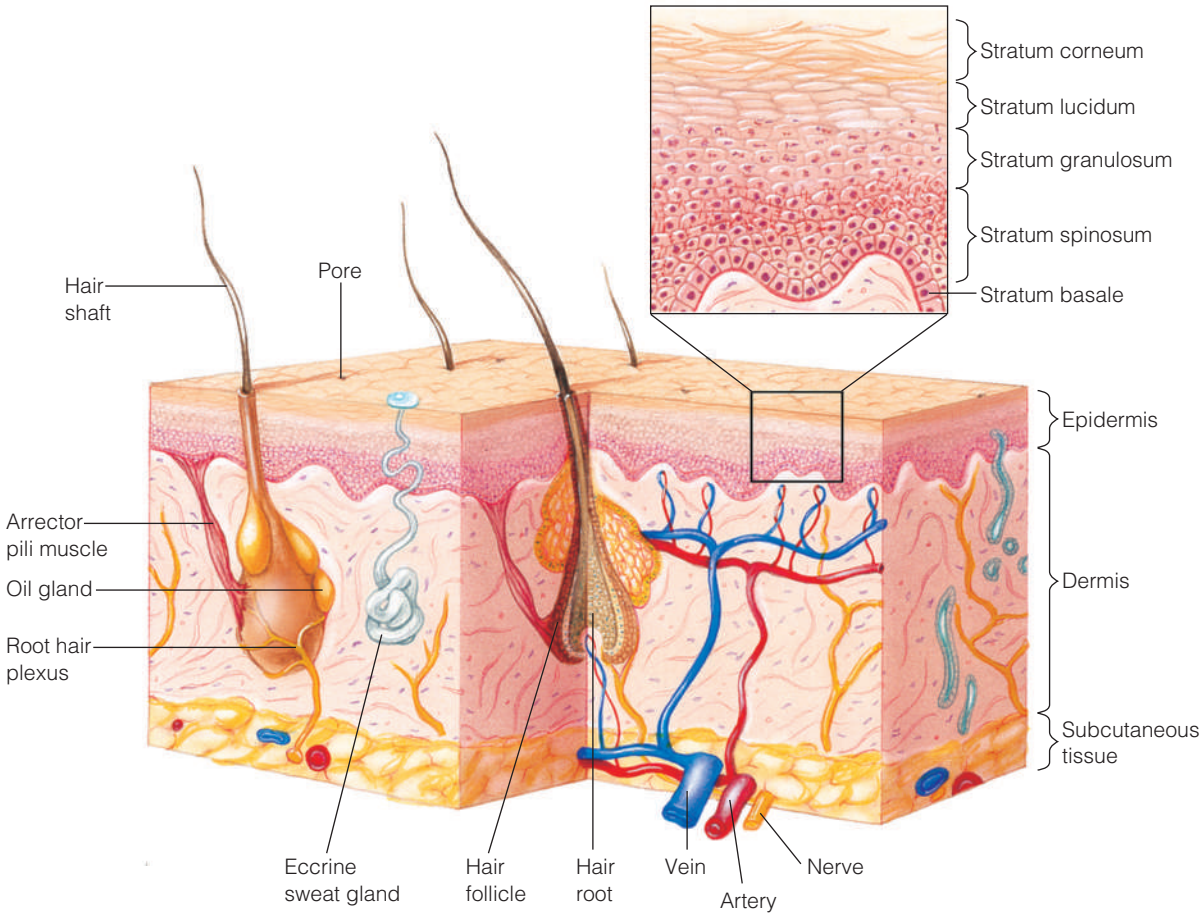

Figure 15–1 ■ Anatomy of the skin.

each day, but millions are simultaneously produced in the stratum basale (also known as stratum germinativum). The next layer of the epidermis is the stratum spinosum. Several cells thick, this layer contains abundant cells that arise from the bone marrow and migrate to the epidermis. Mitosis occurs at this layer, although not as abundantly as in the stratum basale.

The stratum granulosum is only two to three cells thick. The cells of the stratum granulosum contain a glycolipid that slows water loss across the epidermis. Keratinization, a thickening of the cells' plasma membranes, begins in the stratum granulosum. The stratum lucidum is present only in areas of thick skin; it is made up of flattened, dead keratinocytes. The outermost layer of the epidermis, the stratum corneum, is also the thickest, making up about 75% of the epidermis's total thickness. The stratum corneum consists of about 20 to 30 sheets of dead cells filled with keratin fragments arranged in shingles that flake off as dry skin.

THE DERMIS

The dermis is the second, deeper layer of skin. Made of a flexible connective tissue, this layer is richly supplied with blood cells, nerve fibers, and lymphatic vessels. Most of the hair follicles, sebaceous glands, and sweat glands are located in the dermis. The dermis consists of a papillary and a reticular layer. The papillary layer contains capillaries and receptors for pain and touch. The deeper, reticular layer contains blood vessels, sweat and sebaceous glands, deep pressure receptors, and dense bundles of collagen fibers. The regions between these bundles form lines of cleavage in the skin. Surgical incisions parallel to these lines of cleavage heal more easily and with less scarring than incisions or traumatic wounds across cleavage lines.

SUPERFICIAL FASCIA

A layer of subcutaneous tissue called the superficial fascia lies under the dermis. It consists primarily of adipose (fat) tissue and helps the skin adhere to underlying structures.

GLANDS OF THE SKIN

The skin contains sebaceous (oil) glands, sudoriferous (sweat) glands, and ceruminous glands. Each of these types of glands has a different function. Sebaceous glands are found all over the body except on the palms and soles. These glands secrete an oily substance called **sebum**, which usually is ducted into a hair follicle. Sebum softens and lubricates the skin and hair, and decreases water loss from the skin in low humidity. Sebum protects the body from infection by killing bacteria. Hormones, especially androgens, stimulate the secretion of sebum. If a sebaceous gland becomes blocked, a pimple or whitehead appears on the surface of the skin; as the material oxidizes and dries, it forms a blackhead.

There are two types of sweat glands: eccrine and apocrine. Eccrine sweat glands are more numerous on the forehead, palms, and soles. The gland itself is located in the dermis; the duct to the skin rises through the epidermis to open in a pore at the surface. Sweat, the secretion of the eccrine glands, is composed mostly of water, combined with sodium, antibodies, small amounts of metabolic wastes, lactic acid, and vitamin C. The production of sweat is regulated by the sympathetic nervous system and serves to maintain normal body temperature and may occur in response to emotions.

Most apocrine sweat glands are located in the axillary, anal, and genital areas. The secretions from apocrine glands are similar to those of sweat glands, but they also contain fatty acids and proteins. Apocrine glands are a remnant of sexual scent glands. Ceruminous glands, located in the skin of the external ear, are modified apocrine sweat glands. They secrete yellow-brown, waxy cerumen that provides a sticky trap for foreign materials.

SKIN COLOR

Skin color varies among individuals and among people of different races, ranging from a pinkish white to various shades of brown and black. Areas of the skin that are normally exposed to the sun and environment, such as the face and hands, may have a slightly different color from areas that are usually covered with clothing. Special care must be taken when assessing changes in skin color in people with dark skin, such as Blacks, Hispanics, Native Americans, Asians, people of Mediterranean descent, and Whites who are deeply suntanned.

The color of the skin is the result of varying levels of pigmentation. Melanin, a yellow-to-brown pigment, is darker and is produced in greater amounts in individuals with dark skin color than in those with light skin color. Exposure to the sun causes a buildup of melanin and a darkening or tanning of the skin in people with light skin. Carotene, a yellow-to-orange pigment, is found most in areas of the body where the stratum corneum is thickest, such as the palms of the hands. Carotene is more abundant in the skins of individuals of Asian ancestry and, together with melanin, accounts for their golden skin tone. The epidermis in White skin has very little melanin and is almost transparent. Thus, the color of the hemoglobin found in red blood cells (RBCs) circulating through the dermis shows through, lending a pinkish skin tone.

Skin color is influenced by emotions and illnesses. **Erythema**, a reddening of the skin, may occur with embarrassment (blushing), fever, hypertension, or inflammation. Reddening may result from a drug reaction, sunburn, acne rosacea, or other factors. A bluish discoloration of the skin and mucous membranes, called **cyanosis**, results from poor oxygenation of hemoglobin. **Pallor**, or paleness of skin, may occur with shock, fear, or anger or in anemia and hypoxia. **Jaundice** is a yellow-to-orange color visible in the skin and mucous membranes; it is most often the result of a hepatic disorder. Table 15–2 further defines these terms and compares and contrasts skin color changes in people with light and dark skin.

The Hair

Hair is distributed all over the body, except the lips, nipples, parts of the external genitals, the palms of the hands, and the soles of the feet. Hair is produced by a hair bulb, and its root is enclosed in a hair follicle (Figure 15–2 ■). The exposed part, called the shaft, consists mainly of dead cells. Hair follicles extend into the dermis and in some places, such as the scalp, below the dermis. Many factors, including nutrition and hormones, influence hair growth. Hair in various parts of the body has protective functions: The eyebrows and eyelashes protect the eyes, hair in the nose helps keep foreign materials out of the upper respiratory tract, and hair on the head protects the scalp from heat loss and sunlight.

The Nails

A nail is a modified scalelike epidermal structure. Like hair, nails consist mainly of dead cells. The body of the nail rests on the nail

TABLE 15–2 Skin Color Assessment Variations in People with Light and Dark Skin

PALLOR: *A decrease or absence in skin color as the result of a decrease in tissue perfusion; a decrease in shape, size, or amount of RBCs; or absence of melanin (local or generalized).*

Disorder and Cause	Change in Light Skin	Change in Dark Skin
Anemia (decreased or abnormal size and shape of RBCs)	Generalized paleness	Brown skin is dull and has a yellow cast; black skin is dull and has an ashen gray cast
Hemorrhage (decreased amount of circulating RBCs)	Generalized paleness	Brown skin is dull and has a yellow cast; black skin is dull and has an ashen gray cast
Shock (decreased amount of circulating RBCs or decreased perfusion)	Generalized paleness	Brown skin is dull and has a yellow cast; black skin is dull and has an ashen gray cast
Arterial insufficiency (trauma, acute arterial occlusion, or arteriosclerosis)	Local paleness	Dull, ashen gray
Vitiligo (patchy loss of melanocytes)	Patches of white spots, most often found over skin of the face, hands, or groin	Patches of white spots, most often found over skin of the face, hands, or groin
Albinism (total absence of melanin)	White/pink	Tan, cream, or white

CYANOSIS: *A bluish discoloration of the skin and mucous membranes resulting from a local or generalized excess of deoxygenated hemoglobin or a structural defect in the hemoglobin molecule.*

Disorder and Cause	Change in Light Skin	Change in Dark Skin
Acute and chronic disorders of the structure and function of the heart and lungs (arterial insufficiency; exposure to cold, hypothermia)	Dusky blue; color may be generalized or local, depending on cause.	Skin may appear darker, but will be dull; cyanosis is more readily assessed in the nail beds, oral mucous membranes, and conjunctivae

ERYTHEMA: *Redness of the skin or mucous membranes that is the result of dilation and congestion of superficial capillaries.*

Disorder and Cause	Change in Light Skin	Change in Dark Skin
Hyperemia (inflammation, increased body temperature, hot environmental temperature, embarrassment, alcohol ingestion)	Red or bright pink	Difficult to assess; skin may have dark red cast
Carbon monoxide poisoning (carbon monoxide displaces oxygen on the hemoglobin molecule, causing hypoxia, carboxyhemoglobinemia)	Cherry red in face and upper torso	Cherry red lips, oral mucous membranes, and nail beds
Venous stasis (inability of veins to return blood to heart; may result from edema, varicose veins, or pressure)	Dusky red	Difficult to assess

JAUNDICE: *Yellowish discoloration of the skin, mucous membranes, and sclerae of the eyes, caused by increased amounts of bilirubin or other pigments in the blood.*

Disorder and Cause	Change in Light Skin	Change in Dark Skin
Increased serum bilirubin to >2–3 mg/100 mL (liver disease, pancreatic disease, gallbladder disease, hemolysis, such as following blood transfusion, severe burns or infections)	Yellowing of skin follows yellowing of sclerae and mucous membranes; may also be assessed in the fingernails and palms of the hands.	Yellowing is best assessed at the junction of the hard palate and the soft palate or on the palms of the hands. Sclerae may be yellow near the limbus (do not confuse with normal yellow eye pigmentation)
Uremia (retained urochrome pigments in the blood)	Orange-green or gray cast to skin	Difficult to assess; may appear as yellowish green color in the sclera of the eye

bed (Figure 15–3 ■). The proximal visible end of the nail has a white crescent, called a lunula. The sides of the nail are overlapped by skin, called nail folds. The proximal nail fold is thickened and is called the eponychium or cuticle. Nails form a protective coating over the dorsum of each digit on the fingers and toes.

ASSESSING THE INTEGUMENTARY SYSTEM

The structures of the integumentary system are assessed by findings from diagnostic tests, a health assessment interview to collect subjective data, and a physical assessment to collect objective data. See the box that follows the physical assessment information for a documentation sample of an assessment of the integument.

Diagnosis

The results of diagnostic tests of the structure and function of the integumentary system are used to support the diagnosis of a specific injury or disease, to provide information to identify or modify the appropriate medication or treatments used to treat the disease, and to help the interprofessional team monitor a patient's responses to interventions. Some diagnostic tests are conducted to identify bacterial carriers. For example, if patients have repeated bacterial skin infections,

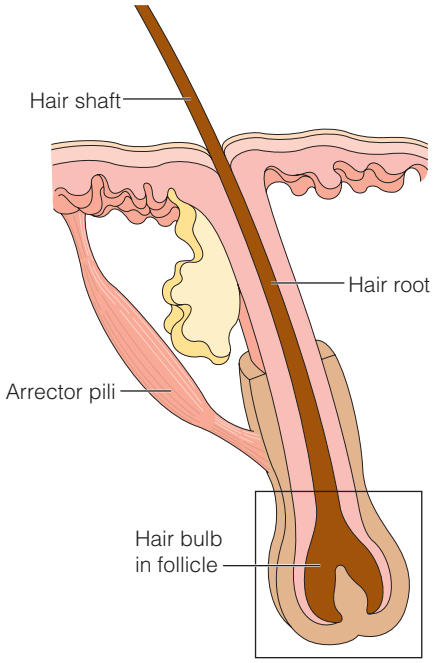

Figure 15–2 ■ Anatomy of a hair follicle.

or if a healthcare unit or agency experiences numerous bacterial infections of patients, nasal cultures may be performed to determine if the patients or the healthcare workers are carriers of the bacteria.

Regardless of the type of diagnostic test, the nurse is responsible for explaining the procedure and any special preparation needed, for assessing for medication use that may affect the outcome of the tests, for supporting the patient during the examination as necessary, for documenting the procedures as appropriate, and for monitoring the results of the tests.

Diagnostic tests to assess the integumentary system are described in the box on page 382. More information is included in the discussion of specific health problems or injuries in Chapters 16 and 17.

Genetic Considerations

When conducting a health assessment interview and physical assessment, the nurse should consider genetic influences on the health of the adult. During the health assessment interview, ask about integumentary disorders or abnormalities in immediate family members and also inquire about their gender. During the physical assessment, assess for any manifestations that indicate a genetic disorder (see the Genetic Considerations box). If data are found that indicate genetic risk factors or alterations, ask about genetic testing and refer for appropriate genetic counseling and evaluation. Chapter 8 provides further information about genetic implications in medical-surgical nursing.

GENETIC CONSIDERATIONS

Examples of Integumentary Disorders

- Oculocutaneous albinism, an autosomal recessive inheritance disorder, causes hypopigmentation (albinism or absence of color) of the skin, hair, and eyes as a result of an inability to synthesize melanin.
- Keloids, which are elevated scars, have a familial tendency and are more commonly found in Blacks.
- Vitiligo, the sudden appearance of white patches on the skin, has a familial tendency.
- Male pattern baldness (the most common cause of baldness in men) is genetically predetermined.
- Hirsutism (excessive hair in women) may be genetically predetermined.
- Blacks may have very dry scalps and dry, fragile hair of genetic origin.
- A family history of skin cancer is a risk factor for skin cancer

Health Assessment Interview

A health assessment interview to determine problems with the integumentary system may be conducted as part of a health screening or complete health assessment, or it may focus on a chief complaint (such as itching or a rash). If the patient has a skin problem, analyze its onset, characteristics and course, severity, precipitating and relieving factors, and note the timing and circumstances of any associated symptoms. For example, ask the patient the following:

- What type of itching have you experienced?
- When did you first notice a change in this mole?
- Did you change to any different kinds of shampoo or other hair products just before you started to lose your hair?

Ask about any change in health, rashes, itching, color changes, dryness or oiliness, growth of or changes in warts or moles, and the presence of lesions. Precipitating causes, such as medications, the use

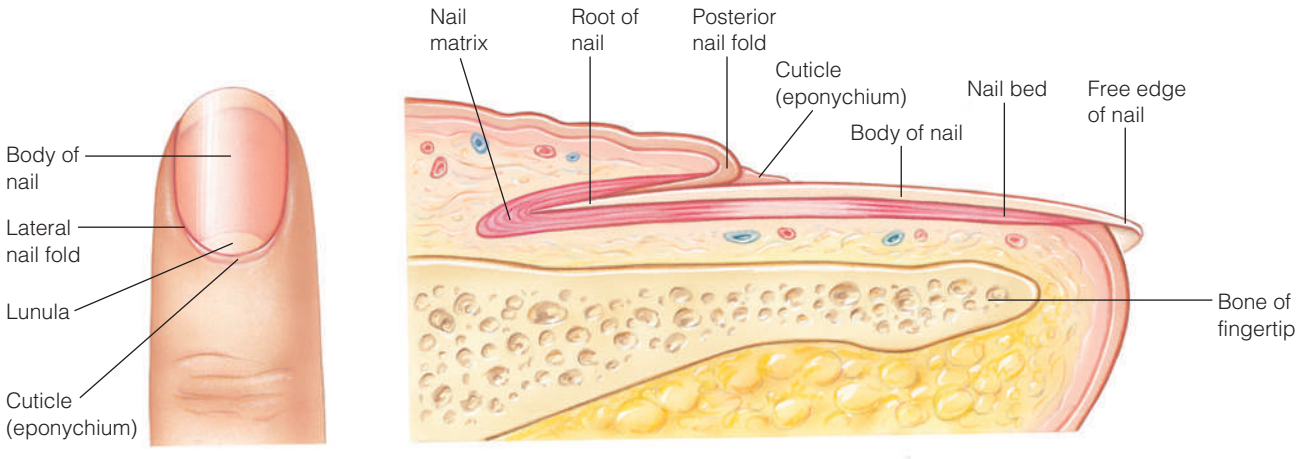

Figure 15–3 ■ Anatomy of a nail.

DIAGNOSTIC TESTS of the Integumentary System

Name of Test	Purpose and Description	Related Nursing Interventions
Biopsy	A punch biopsy is done to differentiate benign lesions from skin cancers. An instrument is used to remove a small section of dermis and subcutaneous fat. Depending on size, the incision may be sutured with a single suture. An incisional biopsy is done to differentiate benign lesions from skin cancers. An incision is made and the skin lesion or tumor is removed for analysis. The incision is closed with sutures.	Apply dressing and provide information about self-care and when to return for suture removal.
Culture	A culture of scrapings from a lesion, from drainage, or of exudate is done to identify fungal, bacterial, or viral skin infections.	Obtain the culture with a sterile Culturette swab and culture tubes. Maintain strict asepsis while obtaining the culture.
Immunofluorescent Slides	Immunofluorescent studies of samples from skin and/or serum may be done to identify IgG antibodies (present in pemphigus vulgaris) and to identify varicella in skin cells (for herpes zoster). Skin or blood samples are placed on a slide and examined microscopically.	No special preparation is necessary.
Oil Slides	Oil slides are used to determine the type of skin infestation present. Scrapings of the lesion are placed on a slide with mineral oil and examined microscopically.	No special preparation is necessary.
Patch Test, Scratch Test	These tests are used to determine a specific allergen. In a patch test, a small amount of the suspected material is placed on the skin under an occlusive bandage. In a scratch test, a needle is used to "scratch" small amounts of potentially allergic materials on the skin surface.	Explain to the patient the need to return in 48 hours to have the patched or scratched areas evaluated.
Potassium Hydroxide (KOH)	A specimen from hair or nails is examined for a fungal infection. The specimen is obtained by placing material from a scraping on a slide, adding a potassium hydroxide solution, and examining it microscopically.	No special preparation is necessary.
Tzanck Smear	This test is used to diagnose herpes infections, but it does not differentiate herpes simplex from herpes zoster. Fluid and cells from the vesicles are obtained, put on a slide, stained, and examined microscopically.	Explain to the patient the need to collect fluid and cells from an open vesicle. Minor discomfort can occur during the incision to open the vesicle.
Wood's Lamp	This test uses an ultraviolet light that causes certain organisms to fluoresce (such as *Pseudomonas* organisms and fungi). The skin is examined under a special lamp.	Explain to the patient that the room is darkened to allow visualization of fluorescence.

of new soaps, skin care agents, cosmetics, pets, travel, stress, or dietary changes, must be explored. In assessing hair problems, ask about any thinning or baldness, excessive hair loss, change in distribution of hair, use of hair care products, diet, and dieting. When assessing nail problems, ask about nail splitting or breakage, discoloration, infection, diet, and exposure to chemicals.

The patient's medical history is important. Questions focus on previous problems, allergies, and lesions. Skin problems may be manifestations of other disorders, such as cardiovascular disease, endocrine disorders, hepatic disease, and hematologic disorders. Occupational and social history may provide cues to skin problems; ask the patient about travel, exposure to toxic substances at work, use of alcohol, and responses to stress. Responses should be documented in the patient's medical record.

Assess the presence of risk factors for skin cancer carefully. These include male gender; age over 50; family history of skin cancer; extended exposure to sunlight; tendency to sunburn; history of sunburn or other skin trauma; light-colored hair or eyes; residence in high altitudes or near the equator; and exposure to radiation, x-rays, coal, tar, or petroleum products. (Risks for skin cancer are further discussed in Chapter 16.) Include specific questions to identify risk factors for malignant melanoma. These include a large number of moles, the presence of atypical moles, a family history of melanoma, prior melanoma, repeated severe sunburns, ease of freckling and sunburning, or inability to tan.

Physical Assessment

Physical assessment of the skin, hair, and nails may be performed either as part of a total assessment or may be a focused assessment of the integument for patients with known or suspected problems. Physical assessment of the skin, hair, and nails is conducted by inspection and palpation. Assess the skin for color, presence of lesions (observable changes from normal skin structure), temperature, texture, moisture, turgor, and presence of edema. Characteristics of lesions to note include location and distribution, color, pattern, edges, size (measure with a ruler in centimeters), elevation, and type of exudate (if present). Common skin lesions of older adults are outlined in Box 15–1;

BOX 15–1 Common Skin Lesions of Older Adults

- *Skin tags:* soft brown or flesh-colored benign papules
- *Keratoses:* horny growths of keratinocytes; may be seborrheic (benign) or actinic (premalignant)
- *Lentigines (liver spots):* brown or black benign macules with a defined border
- *Angiomas (hemangioma):* benign vascular tumors with dilated blood vessels; found in the middle to upper dermis
- *Telangiectases:* single dilated blood vessels, capillaries, or terminal arteries
- *Venous lakes:* small, dark blue, slightly raised benign papules
- *Photoaging:* wrinkling, mottling, pigmented areas, loss of elasticity, benign or malignant lesions

TABLE 15–3 Terminology of Skin Lesions with Associated Disorders

Lesion	Examples of Disorders
Pigmented	Freckle, seborrheic keratosis, nevus, melanoma
Scaly	Psoriasis, dermatitis, xerosis, tinea, actinic keratoses
Pustular	Acne vulgaris, folliculitis, candidiasis
Vesicular	Herpes simplex, herpes zoster, scabies
Nodular	Warts, basal cell carcinoma, acne
Weepy, crusted	Acute contact allergic dermatitis, impetigo
Figurate (shaped) erythema	Urticaria, cellulites
Bullous	Pemphigus, toxic epidermal necrolysis
Pruritic	Xerosis, scabies, pediculosis
Ulcerated	Pressure ulcer, skin cancer, herpes simplex

see the Nursing Care of the Older Adult box for age-related integument changes. Examine the hair for color, texture, quality, and scalp lesions. Determine the shape, color, contour, and condition of the nails. The terminology for skin lesions and examples are outlined in Table 15–3.

The examination should be conducted in a warm, private room. The patient removes all clothing and puts on a gown or drape. The areas to be examined should be fully exposed, but protect the patient's modesty by keeping other areas covered. The patient may be standing, sitting, or lying down at various times of the examination. Don disposable gloves when palpating open lesions, skin surfaces suspicious of infections or infestations, or discharge from lesions of the skin and mucous membranes. A ruler is used to measure the size of lesions. A flashlight is used to better visualize lesions.

SAMPLE DOCUMENTATION

Assessment of the Integumentary System

A 50-year-old man with no history of skin lesions, hair loss, or disorders of the nails. Took antibiotic (azithromycin) for respiratory infection approximately 10 days ago and reports having a fine, raised, red rash on trunk and arms that itched. Nurse practitioner prescribed antihistamine and rash cleared in 3 days. Skin light brown, warm, dry, and elastic. Patches of vitiligo present over dorsum of hands. No lesions or edema noted. Healed scar on lower left abdomen (appendectomy as a young adult). Hair dark brown with gray at the temples, clean. Nails are smooth, hard, and immobile.

NURSING CARE OF THE OLDER ADULT

Age-Related Skin Changes

Age-Related Change	Significance
Epidermis: ↓ thickness and miotic activity	• Skin is more fragile and at greater risk for tears or injury • Delayed wound healing • Hyperkeratoses and skin cancers in sun-exposed areas are more evident
Epidermis: ↑ permeability, ↓ Langerhans cells	• Increased risk of reactions to irritants • Decreased inflammatory response
Epidermis: ↓ number of active melanocytes	• Increased susceptibility to sun exposure
Epidermis: hyperplasia of melanocytes, especially in sun-exposed areas	• Small areas of hyperpigmentation (liver spots) and hypopigmentation (age spots), especially on the hands
Epidermis: ↓ vitamin D production	• Increased risk of osteomalacia, osteoporosis
Epidermis: dermal–epidermal junction flattens	• Increased risk of skin tears, purpura, and pressure ulcers
Dermis: ↓ perfusion	• More susceptible to dry skin • Decreased sensation (pain, touch, temperature, and peripheral vibration) • Increased risk of injury
Dermis: ↓ vasomotor response	• Greater risk of hyperthermia and hypothermia
Dermis: elastic fibers degenerate	• Decreased tone and elasticity, with wrinkle formation
Dermis: proliferation of capillaries	• Cherry hemangiomas are common
Subcutaneous skin layer: thins	• Greater risk of hypothermia • Increased risk of pressure ulcers
Subcutaneous skin layer: adipose tissue is redistributed	• Cellulite forms • Bags over and under the eyes • Double chin forms • Abdominal fat increases • Breasts sag • Skin returns to normal more slowly when pinched (called *tenting*)
Glands: ↓ eccrine and apocrine activity	• Dry skin is common • Absent perspiration

Integumentary Assessments

Technique/Normal Findings	Abnormal Findings
Inspect skin color and note any odors coming from the skin. *Skin color should be even, appropriate to the age and race of the patient, without foul odors.*	• A strong odor of perspiration may indicate poor hygiene and a need for patient teaching. A foul odor may indicate a disorder of the sweat glands. • Pallor and/or cyanosis are seen with exposure to cold and with decreased perfusion and oxygenation. In cyanotic dark-skinned patients, skin loses glow and appears dull. Cyanosis may be more visible in the mucous membranes and nail beds of these patients. • In dark-skinned patients, jaundice may be most apparent in the sclerae of the eyes. • Redness, swelling, and pain are seen with various rashes, inflammations, infections, and burns. First-degree (superficial) burns cause areas of painful erythema and swelling. Red, painful blisters appear in second-degree (partial-thickness) burns, whereas white or blackened areas are common in third-degree (full-thickness) burns. • **Vitiligo**, an abnormal loss of melanin in patches, typically occurs over the face, hands, or groin. Vitiligo is thought to be an autoimmune disorder.
Inspect the skin for lesions and alterations, including calluses, scars, tattoos, and piercings. Include inspection of skin creases and folds. *Skin should be intact without lesions.*	Primary, secondary, and vascular lesions are described and shown in Tables 15–4 through 15–6. • Pearly edged nodules with a central ulcer are seen in basal cell carcinoma. • Scaly, red, fast-growing papules are seen in squamous cell carcinoma. • Dark, asymmetric, multicolored patches (sometimes moles) with irregular edges appear in malignant melanoma. • Circular lesions are usually present in ringworm and in tinea versicolor. • Grouped vesicles may be seen in contact dermatitis. • Linear lesions appear in poison ivy and herpes zoster. • **Urticaria** (hives) appears as patches of pale, itchy wheals in an erythematous area. • In psoriasis, scaly red patches appear on the scalp, knees, back, and genitals. • In herpes zoster, vesicles appear along sensory nerve paths, turn into pustules, and then crust over. • Bruises (**ecchymosis**) are raised bluish or yellowish vascular lesions. Multiple bruises in various stages of healing suggest trauma or abuse.
Palpate skin temperature. *Skin should be warm.*	• Skin is warm and red in inflammation and is generally warm with elevated body temperature. • Decreased blood flow decreases the skin temperature; this may be generalized, as in shock, or localized, as in arteriosclerosis.
Palpate skin texture. *Skin should be smooth.*	• Changes in the texture of the skin may indicate irritation or trauma. • The skin is soft and smooth in hyperthyroidism and coarse in hypothyroidism.
Palpate skin moisture. *Skin should be dry.*	• Excessively dry skin often is present in older adults and patients with hypothyroidism. • Oily skin is common in adolescents and young adults. Oily skin may be a normal finding, or it may accompany a skin disorder such as acne vulgaris. • Excessive perspiration may be associated with shock, fever, increased activity, or anxiety.
Palpate skin turgor. *Skinfold should return rapidly to normal position.*	• Pinch the patient's skin gently over the back of the hand or collarbone. Tenting, in which the skin remains pinched for a few moments before resuming its normal position, is common in older patients who are thin (Figure 15–4 ■). • Skin turgor is decreased in dehydration. It is increased in edema and scleroderma.

Figure 15–4 ■ Tenting in an older patient.

Assess for edema. *No edema should be present.*	• Assess **edema** (accumulation of fluid in the body's tissues) by depressing the patient's skin on the dependent extremities (Figure 15–5 ■). Record findings as follows: 1+ Slight pitting, no obvious distortion 2+ Deeper pit, no obvious distortion 3+ Pit is obvious; extremities are swollen 4+ Pit remains with obvious distortion Record depression rebound time in seconds if present. • Edema is common in cardiovascular disorders, renal failure, trauma, and cirrhosis of the liver. It also may be a side effect of certain drugs.

Integumentary Assessments (*continued*)

Technique/Normal Findings	Abnormal Findings

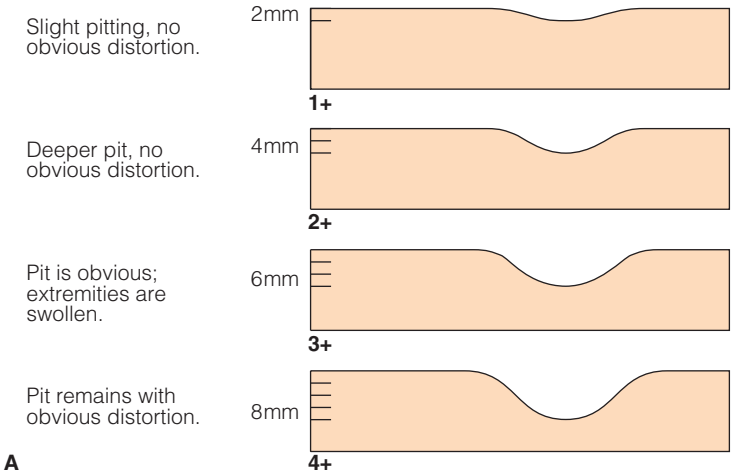

Figure 15–5 ■ A, Degrees of pitting in edema. B, 4+ pitting.
Source: Dr. P. Marazzi/Science Photo Library/Photo Researchers, Inc.

Inspect distribution and quality of hair. *Hair should be evenly distributed for patient's gender.*	• A deviation in the normal hair distribution in the male or female genital area may indicate an endocrine disorder. **Hirsutism** (increased growth of coarse hair, usually on the face and trunk) is seen in Cushing's syndrome, acromegaly, and ovarian dysfunction. **Alopecia** (hair loss) may be related to changes in hormones, chemical or drug treatment, or radiation. In adult males whose hair loss follows the normal male pattern, the cause is usually genetic.
Palpate hair texture. *Hair should be of even texture.*	• Some systemic diseases change the texture of the hair. For instance, hypothyroidism causes the hair to coarsen, whereas hyperthyroidism causes the hair to become fine.
Inspect the scalp for lesions. *There should be no lesions on the scalp.*	• Mild dandruff is normal, but excessive, greasy flakes indicate seborrhea. • Hair loss, pustules, and scales appear on the scalp in tinea capitis (scalp ringworm). • Red, swollen pustules appear around infected hair follicles and are called folliculitis. • Head lice may be seen as oval nits (eggs) adhering to the base of the hair shaft. Head lice are usually accompanied by itching.
Inspect nail curvature. *Nails should not be excessively curved.*	• Clubbing (Figure 15–6 ■), in which the angle of the nail base is greater than 180 degrees, is seen in respiratory disorders, cardiovascular disorders, cirrhosis of the liver, colitis, and thyroid disease. The nail becomes thick, hard, shiny, and curved at the free end.

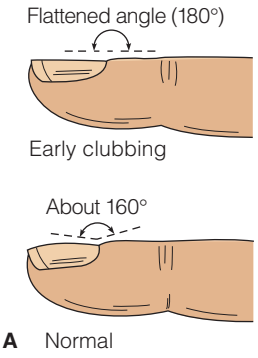

Figure 15–6 ■ A, Assessing clubbing of the nails. B, Hand with nail clubbing.
Source: SPL/Science Source

Inspect the surface of the nails. *Nail surfaces should be smooth and nail folds firm, without redness.*	• The nail folds become inflamed and swollen and the nail loosens in paronychia, an infection of the nails.

(*continued*)

Integumentary Assessments (*continued*)

Technique/Normal Findings	Abnormal Findings
	• Inflammation and transverse rippling of the nail are associated with chronic paronychia and/or eczema. • The nail plate may separate from the nail bed in trauma, psoriasis, and *Pseudomonas* and *Candida* infections. This separation is called onycholysis. • Nail grooves may be caused by inflammation, by planus, or by nail biting. • Nail pitting may be seen with psoriasis. • A transverse groove (Beau's line) may be seen in trachoma and/or acute diseases. • Thin spoon-shaped nails (Figure 15–7 ■) may be seen in anemia.

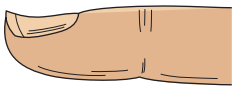

Figure 15–7 ■ Spoon-shaped nails.

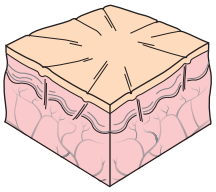
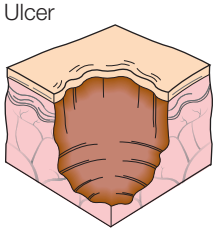
Inspect nail color. *Nail color should be even. Pigmented bands are normally found in more than 90% of African Americans.*	• The sudden appearance of a pigmented band may indicate melanoma in people with light skin. • Yellowish nails are seen in psoriasis and fungal infections. • Dark nails occur with trauma, *Candida* infections, and hyperbilirubinemia. • Blackish-green nails are apparent in injury and in *Pseudomonas* infection. • Red splinter longitudinal hemorrhages may be seen in injury and/or psoriasis.
Inspect nail thickness. *Nails should not be excessively thick.*	• Trauma to the nails usually causes thickening. Other causes of thick nails include psoriasis, fungal infections, and decreased peripheral vascular blood supply. • Thinning of the nails is seen in nutritional deficiencies.

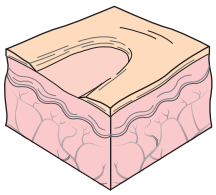
TABLE 15–4 Primary Skin Lesions

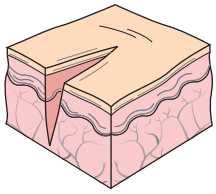
Macule, Patch	Flat, nonpalpable change in skin color. Macules are smaller than 1 cm, with a circumscribed border. Patches are larger than 1 cm and may have an irregular border. **Examples** Macules: freckles, measles, and petechiae. Patches: Mongolian spots, port-wine stains, vitiligo, and chloasma.	Vesicle, Bulla	Elevated, fluid-filled, round- or oval-shaped palpable mass with thin, translucent walls and circumscribed borders. Vesicles are smaller than 0.5 cm; bullae are larger than 0.5 cm. **Examples** Vesicles: herpes simplex/zoster, early chickenpox, poison ivy, and small burn blisters. Bullae: contact dermatitis, friction blisters, and large burn blisters.
Papule, Plaque	Elevated, solid, palpable mass with circumscribed border. Papules are smaller than 0.5 cm; plaques are groups of papules that form lesions larger than 0.5 cm. **Examples** Papules: elevated moles, warts, and lichen planus. Plaques: psoriasis, actinic keratosis, and lichen planus.	Wheal	Elevated, often reddish area with irregular border caused by diffuse fluid in tissues rather than free fluid in a cavity, as in vesicles. Size varies. **Examples** Insect bites and hives (extensive wheals).
Nodule, Tumor	Elevated, solid, hard or soft palpable mass extending deeper into the dermis than a papule. Nodules have circumscribed borders and are 0.5 to 2 cm; tumors may have irregular borders and are larger than 2 cm. **Examples** Nodules: small lipoma, squamous cell carcinoma, fibroma, and intradermal nevi. Tumors: large lipoma, carcinoma, and hemangioma.	Pustule	Elevated, pus-filled vesicle or bulla with circumscribed border. Size varies. **Examples** Acne, impetigo, and carbuncles (large boils).
		Cyst	Elevated, encapsulated, fluid-filled or semi-solid mass originating in the subcutaneous tissue or dermis, usually 1 cm or larger. **Examples** Varieties include sebaceous cysts and epidermoid cysts.

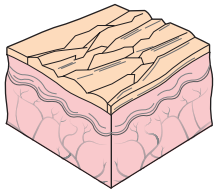
TABLE 15–5 Secondary Skin Lesions

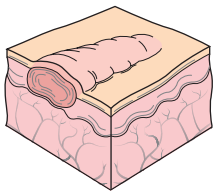


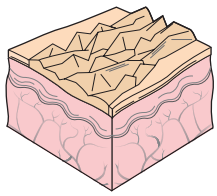


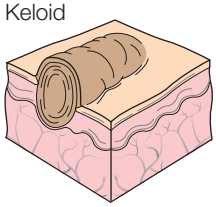


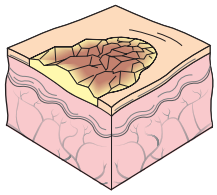


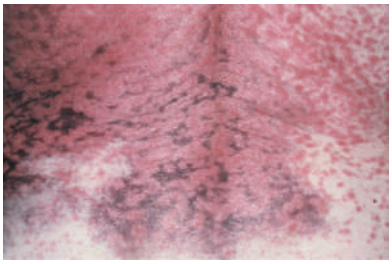












Atrophy 	A translucent, dry, paper-like, sometimes wrinkled skin surface resulting from thinning or wasting of the skin due to loss of collagen and elastin. **Examples** Striae, aged skin.	Ulcer 	Deep, irregularly shaped area of skin loss extending into the dermis or subcutaneous tissue. May bleed. May leave scar. **Examples** Decubitus ulcers (pressure sores), stasis ulcers, chancres.
Erosion 	Wearing away of the superficial epidermis causing a moist, shallow depression. Because erosions do not extend into the dermis, they heal without scarring. **Examples** Scratch marks, ruptured vesicles.	Fissure 	Linear crack with sharp edges, extending into the dermis. **Examples** Cracks at the corners of the mouth or in the hands, athlete's foot.
Lichenification 	Rough, thickened, hardened area of epidermis resulting from chronic irritation such as scratching or rubbing. **Example** Chronic dermatitis.	Scar 	Flat, irregular area of connective tissue left after a lesion or wound has healed. New scars may be red or purple; older scars may be silvery or white. **Examples** Healed surgical wound or injury, healed acne.
Scales 	Shedding flakes of greasy, keratinized skin tissue. Color may be white, gray, or silver. Texture may vary from fine to thick. **Examples** Dry skin, dandruff, psoriasis, and eczema.	Keloid 	Elevated, irregular, darkened area of excess scar tissue caused by excessive collagen formation during healing. Extends beyond the site of the original injury. Higher incidence in people of African descent. **Examples** Keloid from ear piercing or surgery.
Crust 	Dry blood, serum, or pus left on the skin surface when vesicles or pustules burst. Can be red-brown, orange, or yellow. Large crusts that adhere to the skin surface are called scabs. **Examples** Eczema, impetigo, herpes, or scabs following abrasion.		

TABLE 15–6 Vascular Skin Lesions

Spider Angioma		A flat, bright red dot with tiny radiating blood vessels ranging in size from a pinpoint to 2 cm. It blanches with pressure. **Cause** A type of telangiectasis (vascular dilation) caused by elevated estrogen levels, pregnancy, estrogen therapy, vitamin B deficiency, or liver disease, or may not be pathologic. **Localization/Distribution** Most commonly appears on the upper half of the body.
Venous Star		A flat blue lesion with radiating, cascading, or linear veins extending from the center. It ranges in size from 3 to 25 cm. **Cause** A type of telangiectasis (vascular dilation) caused by increased intravenous pressure in superficial veins. **Localization/Distribution** Most commonly appears on the anterior chest and the lower legs near varicose veins.
Petechiae		Flat red or purple rounded "freckles" approximately 1 to 3 mm in diameter. Difficult to detect in dark skin. Do not blanch. **Cause** Minute hemorrhages resulting from fragile capillaries, petechiae are caused by septicemias, liver disease, or vitamin C or K deficiency. They may also be caused by anticoagulant therapy. **Localization/Distribution** Most commonly appear on the dependent surfaces of the body (e.g., back, buttocks). In the patient with dark skin, look for them in the oral mucosa and conjunctivae.
Purpura		Flat, reddish blue, irregularly shaped extensive patches of varying size. **Cause** Bleeding disorders, scurvy, and capillary fragility in the older adult (senile purpura). **Localization/Distribution** May appear anywhere on the body, but are most noiceable on the legs, arms, and backs of hands.
Ecchymosis		A flat, irregularly shaped lesion of varying size with no pulsation. Does not blanch with pressure. In light skin, it begins as bluish purple mark that changes to greenish yellow. In brown skin, it varies from blue to deep purple. In black skin, it appears as a darkened area. **Cause** Release of blood from superficial vessels into surrounding tissue due to trauma, hemophilia, liver disease, or deficiency of vitamin C or K. **Localization/Distribution** Occurs anywhere on the body at the site of trauma or pressure.

CHAPTER HIGHLIGHTS

- Intact structure and function of the integumentary system is vital to the protection of the body's organs from the external environment.
- Manifestations of dysfunction, injury, and disorders affecting the integumentary system may be detected during a general health assessment as well as during focused integumentary assessments.

TEST YOURSELF NCLEX-RN® REVIEW

1. Following a burn involving several layers of a patient's skin, the healed burn area does not grow hair or sweat. When teaching the patient, which layer of the skin should the nurse explain as being burned?
   1. dermis
   2. epidermis
   3. stratum basale
   4. stratum spinosum
2. During an assessment the nurse notes different areas of skin color over the back and chest of a patient who spends time in the sun. What is responsible for this change in skin color?
   1. sebum
   2. melanin
   3. carotene
   4. red blood cells
3. The nurse is preparing to assess a patient's integumentary status. Which technique will the nurse use first?
   1. palpation
   2. inspection
   3. percussion
   4. auscultation
4. A patient's oral body temperature is elevated by 3 degrees. What other assessment finding would be consistent with this body temperature?
   1. pallor
   2. jaundice
   3. cyanosis
   4. erythema
5. The nurse is assessing a patient who is complaining of severe itching. Which question about the itching should the nurse ask the patient during the interview?
   1. "Tell me how this itch feels."
   2. "Have you used a new soap?"
   3. "Why do you keep scratching it?"
   4. "Describe your daily fluid intake."
6. While conducting a skin assessment, the nurse suspects an older patient is experiencing dehydration. What did the nurse most likely assess in this patient?
   1. decreased turgor
   2. pallor or cyanosis
   3. increased moisture
   4. presence of lesions
7. The intravenous access site infiltrated in a patient's right hand. When assessing the degree of edema, the nurse finds obvious pitting and the entire hand is swollen. How should the nurse document this assessment finding?
   1. 1+
   2. 2+
   3. 3+
   4. 4+
8. The nurse assesses rough thickened areas on a patient with chronic dermatitis. What term should the nurse use to document this assessment finding?
   1. ulcers
   2. papules
   3. atrophy
   4. lichenification
9. While assessing the skin of an older patient who is at home, the nurse notices multiple angiomas on the arms and body. What does this finding indicate to the nurse?
   1. aging skin
   2. poor hygiene
   3. caregiver strain
   4. high intake of vitamin A
10. The school nurse, assessing the scalp of a school-age child who is complaining of itching, notices small white eggs on the hair shaft. What should the nurse suspect the child is experiencing?
    1. head lice
    2. head lichens
    3. viral infection
    4. bacterial infection

16 Nursing Care of Patients with Integumentary Disorders

LEARNING OUTCOMES

1. Describe the manifestations, self-care, and nursing care of common skin problems and lesions.
2. Compare and contrast the etiology, pathophysiology, interprofessional care, and nursing care of patients with infections and infestations, inflammatory disorders, and malignancies of the skin.
3. Explain the risk factors for, pathophysiology of, and nursing interventions to prevent and care for pressure ulcers.
4. Discuss surgical options for excision of neoplasms, reconstruction of facial or body structures, and cosmetic procedures.
5. Explain the pathophysiology of selected disorders of the hair and nails.
6. Discuss the nursing implications related to the actions and effects of medications and other treatments for the patient with a disorder of the integumentary system.

CLINICAL COMPETENCIES

1. Assess functional health status of patients with integumentary disorders, and monitor, document, and report abnormal manifestations.
2. Plan and implement evidence-based nursing interventions for patients with pressure ulcers.
3. Consider assessment findings, patient values and beliefs, cultural norms, best practices, and clinical expertise when developing and implementing an individualized plan of care.
4. Apply safe practices during the administration of topical, oral, and injectable medications for the treatment of integumentary disorders.
5. Collaborate with the interprofessional team in the planning and provision of care for patients with integumentary disorders.
6. Implement patient teaching focused on prevention and management of integumentary disorders.
7. Revise the plan of care as needed to provide effective interventions to promote, maintain, or restore functional health status to patients with disorders of the integument.

MAJOR CHAPTER CONCEPTS

- The skin provides the first barrier between the internal and external environments.
- Skin disorders, lesions, and infections can range from mild to life threatening.
- Nursing plays a central role in the treatment and management of skin disorders.

KEY TERMS

acne, *407*
actinic keratosis, *409*
angioma, *393*
basal cell cancer, *410*
carbuncle, *397*
cellulitis, *397*
comedones, *407*
cyst, *392*
dermatitis, *405*
dermatophytoses, *399*
folliculitis, *396*
frostbite, *424*
furuncle, *397*
herpes simplex, *402*
herpes zoster, *402*
keloids, *392*
keratosis, *393*
lichen planus, *409*
malignant melanoma, *414*
nevi, *393*
paronychia, *429*
pemphigus vulgaris, *408*
pressure ulcer, *419*
pruritus, *391*
psoriasis, *393*
scabies, *401*
skin graft, *425*
squamous cell cancer, *411*
xerosis, *391*
warts, *401*

The skin and its accessory structures (the integumentary system) enclose and cover the body, providing protection by serving as a barrier between the internal and external environments. The skin contains receptors for touch and sensation, helps regulate body temperature, and maintains fluid and electrolyte balance. The skin also provides cues to racial and ethnic background, and plays a major role in determining self-concept, roles, and relationships.

Disorders of the integument range from dry skin to life-threatening cancer. Many disorders are treated in an outpatient setting or by self-care. This chapter discusses disorders of the skin, hair, and nails. Chapter 17 discusses the patient with burns. Primary and secondary skin lesions are described and illustrated in Chapter 15, Tables 15–4 and 15–5. The terms introduced in those tables are used throughout this and the next chapter.

Common Skin Problems and Lesions

The disorders discussed in this section are those experienced by a large number of people. Although they are considered minor health problems in terms of healthcare, they may cause major problems for the person experiencing a high level of discomfort and/or chronicity.

THE PATIENT WITH PRURITUS

Pruritus is a subjective itching sensation that produces an urge to scratch. Pruritus may occur in a small, circumscribed area, or it may involve a widespread area; it may or may not be associated with a rash. The itch sensation begins in nerve endings in the skin, is carried to the dorsal horn of the spinal cord, and is then transmitted to the somatosensory cortex in the central nervous system (CNS). Itching may also be perceived by the brain, but not exist on the skin. Scratching is a neurologic reflex that can be controlled in varying degrees by the individual (Huether & McCance, 2011).

Almost anything in the internal or external environment can cause pruritus. Insects, animals, plants, fabrics, metals, medications, allergies, and emotional distress are among the most common causes. Pruritus also may occur as a secondary manifestation of systemic disorders, such as certain types of cancer, diabetes mellitus, liver disease, and renal failure. Although the exact physiology is unknown, heat and prostaglandins are known triggers of pruritus, and pruritus is increased by histamine and morphine.

The pathophysiologic response of pruritus to stimulation or irritation follows a similar pathway, regardless of cause. The irritating agent stimulates receptors in the junction between the epidermis and dermis, and may also trigger the release of histamine and other chemical mediators that either further stimulate or mediate the itch response. The response of the person experiencing the itch is to scratch or rub the affected area. This may irritate the skin and cause further inflammation, which in turn sets off a cycle of increasingly intense itching and scratching, called the *itch–scratch–itch cycle*.

Secondary effects of scratching include skin excoriation, erythema (redness), wheals, changes in pigmentation, and infections. Persistent pruritus may interrupt sleep patterns because the itching sensation is often more intense at night. Long-term pruritus may be debilitating and increases the risk of infection as excoriation occurs.

Management of pruritus focuses on identifying and eliminating its cause and providing medications to relieve the itch. Antihistamines may relieve pruritus in some patients. Tranquilizers provide sedation, which may in turn relieve the emotional stress associated with pruritus; however, eliminating the stressors produces a more successful result. Topical or systemic antibiotics are used to treat the infection resulting from the scratching and excoriation. Topical medications that contain corticosteroids are often used to relieve the pruritus and inflammation. Topical medications may also be administered through therapeutic baths or soaks with agents that relieve pruritus, such as cornstarch and baking soda or coal tar concentrates. Creams containing a topical anesthetic or antibiotic may also be used. Therapeutic baths are discussed in the Medication Administration box on page 392. Table 16–1 lists examples of topical agents used to treat skin disorders.

THE PATIENT WITH DRY SKIN (XEROSIS)

Dry skin, also called **xerosis**, is most often a problem in the older adult. It is the result of a decrease in the activity of sebaceous and sweat glands, which reduces the skin's lubrication and moisture retention abilities. However, dry skin may occur at any age from exposure to environmental heat and low humidity, sunlight, excessive bathing, and a decreased intake of liquids.

Two types of severe dry skin are xeroderma and ichthyosis. Xeroderma is a chronic skin condition characterized by dry, rough skin. Ichthyosis is an inherited dermatologic condition in which the skin is dry, fissured, and hyperkeratotic; the surface of the skin has the appearance of fish scales.

The primary manifestation of dry skin is pruritus. Other manifestations include visible flaking of surface skin and an observable pattern of fine lines over the area. If the skin has been excessively dry and pruritic for a long period, the patient may have secondary skin lesions and lichenification (thickening).

Nursing care focuses on teaching the patient and family how to reduce the dry skin and relieve the pruritus, as outlined in Box 16–1.

TABLE 16–1 Medications Used to Treat Skin Disorders

Type	Use	Examples
Creams	Moisturize the skin	Aquacare, Curel, Nutraderm
Ointments	Lubricate the skin and retard water loss	Aquaphor, Vaseline
Lotions	Moisturize and lubricate the skin	Alpha-Keri, Dermassage, Lubriderm
Anesthetics	Relieve itching	Xylocaine
Antibiotics	Treat infection	Bacitracin, Polysporin, Gentamicin, Silvadene
Corticosteroids	Suppress inflammation and relieve itching	Dexamethasone, Clocortolone, Desonide

MEDICATION ADMINISTRATION

Therapeutic Baths

AGENTS USED IN THERAPEUTIC BATHS

Saline or tap water

Antibacterial agents: potassium permanganate, acetic acid, hexachlorophene

Colloid substances: oatmeal (Aveeno), cornstarch, sodium bicarbonate

Coal tar derivatives (Balnetar, Zetar, Polytar)

Emollients: Alpha Keri, Lubath, mineral oil

Therapeutic baths have a variety of uses in treating skin disorders. Depending on the agent used, therapeutic baths soothe the skin, lower the skin bacteria count, clean and hydrate the skin, loosen scales, and relieve itching.

Nursing Responsibilities

- Ensure that the bath water is at a comfortable temperature that is neither too hot nor too cool, usually 45° to 46°C (110° to 115°F).
- Fill the tub one-third to one-half full.
- Mix the agent well with the water.
- Assist the patient into and out of the tub to prevent falls.
- Dry the patient's skin by blotting with the towel.

Health Education for the Patient and Family

- Use a bath mat in the tub because the medications may cause the tub to become slippery.
- Keep the bathroom warm but adequately ventilated.
- Follow directions carefully for the amount of medication to use in the bath.
- Fill the bath one-third to one-half full of water that is at a comfortable temperature.
- Stay in the bath for 20 to 30 minutes, and immerse the areas to be treated.
- Do not get the bath water in your eyes.
- Dry by blotting (not rubbing) with the towel.
- If the medications cause staining, use old towels or linens.
- If the itching is not relieved or the skin becomes excessively dry, call your healthcare provider.

BOX 16–1 Teaching to Reduce Dry Skin and Relieve Pruritus

- Wash clothing in a mild detergent and rinse twice; do not use fabric softeners.
- Avoid using perfumes and lotions containing alcohol.
- Apply skin lubricants after a bath to help retain moisture.
- Soaps and hot water are drying. Clean the skin with tepid water and either a mild soap or cleansing creams. If soap is used, rinse it off carefully.
- It is not necessary to take a bath every day.
- If bath oils are used, add them to the bath water at the end of the bath (the moist skin is more likely to retain the oil). Use care not to slip in the tub.
- Use a humidifier to humidify the air.
- Apply creams and lotions when the skin is slightly damp after bathing.
- Increase fluid intake.
- Keep nails trimmed short, wear loose clothing, and keep the environment cool.
- A brief application of pressure or cold may relieve pruritus.
- Cotton gloves may be worn at night if scratching during sleep causes skin excoriation.
- Distraction or relaxation techniques may prove helpful.

THE PATIENT WITH BENIGN SKIN LESIONS

The skin is subject to many different types and kinds of benign skin lesions, including cysts, keloids, nevi, angiomas, skin tags, and keratoses. Although these benign lesions are often considered more of a nuisance than an illness, they do require monitoring for an increase in size that interferes with the skin's appearance or function. Most benign skin lesions do not require treatment, although excision or laser surgery may be desired or necessary. Cysts may enlarge, skin tags may become irritated and bleed, nevi may change in appearance, or any of the lesions may cause discomfort with appearance.

Cysts

Cysts of the skin are benign closed sacs in or under the skin surface that are lined with epithelium and contain fluid or a semisolid material. Epidermal inclusion cysts and pilar cysts are the most common types.

Epidermal inclusion cysts may occur anywhere on the body but are most often found on the head and trunk. Although they are painless, they may grow so large that they become irritated by contact with clothing (e.g., if located on the back of the neck) or cause obstruction (e.g., if located on the nose). The cysts contain a semisolid material consisting mainly of keratin. Pilar cysts are found on the scalp and originate from sebaceous glands. They are also painless. Both types of cysts rarely require treatment unless they become large and bothersome.

Keloids

Keloids are elevated, irregularly shaped, progressively enlarging scars. They arise from excessive amounts of collagen in the stratum corneum during scar formation in connective tissue repair. These lesions are more common in young adults and appear within 1 year of the initial trauma.

This abnormal response most often occurs in people of African and Asian descent who sustain burns of the skin, but even seemingly minor trauma can result in keloid formation. There is a familial tendency to develop keloids. Other risk factors for keloid formation include excessive tension on a wound and poor alignment of skin edges following accidental or intentional skin trauma. Certain skin surfaces are also more likely to develop keloids: the chin, ears, shoulders, back, and lower legs.

The excessive scar formation is associated with increased metabolic activity of fibroblasts and increased type III collagen (Figure 16–1 ■). The swollen appearance of the keloids is the result of an excess of extracellular material. The keloids first appear as red, firm, rubbery plaques that persist for several months after the initial trauma. Uncontrolled overgrowth over time causes the keloids

Figure 16–1 ■ Keloids form as a result of deposits of excessive amounts of collagen during scar formation.
Source: Medical-On-Line/Alamy.

to extend beyond the original scar. Eventually, the keloid becomes smooth and hyperpigmented.

Nevi

Nevi, more commonly called *moles*, are flat or raised macules or papules with rounded, well-defined borders (Figure 16–2 ■). Nevi arise from melanocytes during early childhood, with the cells initially accumulating at the junction of the dermis and epidermis. Over time, the cluster of cells moves into the dermis, and the lesion becomes visible. Nevi can occur on any skin surface of the body and may arise as single lesions or in groups. Almost all adults have nevi.

Nevocellular nevi are tan to deep brown, small in size, and grow in groups. Dysplastic nevi are larger than other nevi and may be flat, slightly raised, or appear as lesions with a darker, raised center and irregular border. Dysplastic nevi can transform into malignant lesions (see the later discussion about melanoma). It is important to monitor nevi for changes in size, thickness, color, bleeding, or itching. If any of these changes occur, the person should seek immediate professional assessment.

Figure 16–2 ■ Nevi (moles) arise from melanocytes and are common in all adults.
Source: Pat Watson/Pearson Education.

Angiomas

Angiomas, also called *hemangiomas*, are benign vascular tumors. They appear in the adult in different forms:

- Nevus flammeus (port-wine stain) is a congenital vascular lesion that involves the capillaries. The lesions tend to occur on the upper body or face as macular patches that range from light red to dark purple. These lesions are present at birth and grow proportionately with the child into adulthood.
- Cherry angiomas are small, rounded papules that may occur at any age, but they most commonly arise in the 40s and gradually increase in number. The lesions range in color from bright red to purple. These lesions are often found on the trunk.
- Spider angiomas are dilated superficial arteries. They are common in pregnant women and in patients with hepatic disease. Spider angiomas occur most often on the face, neck, and upper chest. The lesions are usually small, bright red papules with radiating lines.
- Telangiectases are single, dilated capillaries or terminal arteries that appear most often on the cheeks and nose. These lesions are more common in older adults and result from photoaged (aging, sun-damaged) skin. The lesions look like broken veins.
- Venous lakes are small, flat, blue blood vessels. They are seen on the exposed skin of the older adult: the ears, lips, and backs of the hands. They are considered compressible papules.

Skin Tags

Skin tags are soft papules on a pedicle. They can be as small as a pinhead or as large as a pea and are most often found on the front or side of the neck and in the axillae, as well as in areas where clothing (such as underwear) rubs the skin. These lesions have normal skin color and texture.

Keratoses

A **keratosis** is any skin condition in which there is a benign overgrowth and thickening of the cornified epithelium. These lesions most often appear in adults after age 50. *Seborrheic keratoses* appear as superficial flat, smooth, or warty-surfaced growths, 5 to 20 mm in diameter, most often on the face and trunk. The lesions may be tan, waxy yellow, dark brown, or flesh colored, and they often appear greasy. They are most often seen in the older adult and do not appear to be related to damage from sun exposure.

THE PATIENT WITH PSORIASIS

Psoriasis is a chronic immune skin disorder characterized by raised, reddened, round circumscribed plaques covered by silvery white scales (Figure 16–3 ■). There are several different forms, but the most common is plaque psoriasis (psoriasis vulgaris), occurring in about 80% of cases. As with any chronic illness, the skin manifestations may occur and disappear throughout life, with no discernible pattern to the recurrence.

As many as 7.5 million people in the United States have psoriasis; about 20% have moderate to severe forms (Augustin et al., 2011). The incidence of psoriasis is lower in warm, sunny climates. The

Figure 16–3 ■ The characteristic lesions of psoriasis are raised, red, round plaques covered with thick, silvery scales.
Source: olavs/Shutterstock.

average age of onset is in the 30s, but it may occur at any age. Psoriasis occurs more often in Caucasians, and men and women are affected equally. Sunlight, stress, seasonal changes, hormone fluctuations, steroid withdrawal, and certain drugs (such as beta-blockers, lithium, and chloroquine [an antimalarial]) appear to act as triggers to development of the disorder. About one-third of patients have a family history of psoriasis. Trauma to the skin from such events as surgery, sunburn, or excoriation is also a common precipitating factor; lesions that result from trauma are called *Koebner's reaction* (Huether & McCance, 2011).

Pathophysiology

Normally, the keratinocyte (an epidermal cell making up 95% of the epidermis) migrates from the basal cell to the stratum corneum (the outer skin layer) in about 14 days and is sloughed off 14 days later. Psoriatic skin cells, by contrast, have a shorter cycle of growth, completing the journey to the stratum corneum in only 4 to 7 days, a condition called hyperkeratosis. These immature cells produce an abnormal keratin that forms thick, flaky scales at the surface of the skin. The increased cell metabolism stimulates increased vascularity, which contributes to the erythema of the lesions.

Although the exact cause is unknown, there is increasing evidence that a T-lymphocyte–mediated reaction results in the production of chemical messengers that stimulate the growth of keratinocytes and dermal blood vessels. The accompanying inflammation further contributes to plaque formation. The lesions can be found anywhere on the skin but most commonly involve the skin over the elbows, knees, and scalp. Lesions involving the hand and foot are especially problematic for the patient. Initially, the lesions are papules that form into well-defined erythematous plaques with thick, silvery scales. The plaques in darker-skinned people may appear purple.

Manifestations

The characteristic lesions in plaque psoriasis are well-demarcated regions of erythematous plaques that shed thick, silver-gray flakes. Pruritus is common over the psoriatic lesions. If the lesions are located in an intertriginous zone, such as between the toes, under the breasts, or in the perianal region, the psoriatic scales may soften, allowing painful fissures to form. When psoriasis affects the nails, pitting and a yellow or brown discoloration results. The nail may separate from the nail bed, thicken, and crumble. The involved nails, which are more often fingernails than toenails, are at high risk for infection. Psoriatic arthritis is a specific form of arthritis involving not only skin lesions but also inflammation of joints.

●○● INTERPROFESSIONAL CARE

Treatment is based on the type of psoriasis, the extent and location of the lesions, the age of the patient, and the degree of disfigurement or disability.

DIAGNOSIS

Skin biopsy may be done if the patient presents with atypical manifestations, or to differentiate psoriasis from other inflammatory or infectious skin disorders. In addition, an ultrasound may reveal typical psoriatic changes in the stratum corneum and inflammation of the dermis.

MEDICATIONS

A variety of medications and treatments may be prescribed, including topical medications and photochemotherapy. Although there is no cure, treatment decreases the severity and pain of the lesions. Corticosteroids; tar preparations (Balnetar); anthralin (Psoriatec); calcipotriene (Dovonex), a vitamin D derivative; adalimumab (Humira); and tazarotene (Tazorac), a synthetic retinoid, are typically used. Ustekinumab (Stelara), an injectable monoclonal antibody that decreases the immune response, was approved by the FDA in 2009 for severe psoriasis.

Topical corticosteroids decrease inflammation, suppress mitotic activity of psoriatic cells, and delay the movement of keratinocytes to the surface of the skin (thus giving them time to mature and decreasing hyperkeratinosis). The most effective topical corticosteroids are potent preparations that are well absorbed through the skin and are used under an occlusive dressing. Corticosteroids may also be taken systemically or injected directly into the lesions. However, corticosteroids rarely cause a lasting remission and may cause the psoriasis to become unstable. They are therefore used for repeated short periods of treatment and combined with other measures, such as tar preparations, occlusion, or a topical retinoid.

Tar preparations (such as Estar, PsoriGel, and Fototar) suppress mitotic activity and are also anti-inflammatory. Their exact mechanism of action is unknown, but they are effective in removing scales and increasing remission time. Preparations made of coal tar are messy, cause staining, and have an unpleasant odor, but they are an effective form of treatment. Salex shampoo is prescribed for patients with scalp psoriasis to remove plaques and scales. Psorent is a nonprescription cream that is made from coal tar but does not stain or have an odor.

Calcipotriene (Dovonex) has been effective and safe in both the short-term and long-term treatment of psoriasis. It inhibits cell proliferation in the epidermis and facilitates cell differentiation. Although more irritating than calcipotriene, tazarotene gel (Avage, Tazorac) is a topical retinoid that may also be used to treat mild to moderate psoriasis.

Severe psoriasis may be resistant to topical drugs and phototherapy. Medications that impact the inflammatory and immune responses

may be indicated. These can include methotrexate (Rheumatrex, Trexall), cyclosporine (Sandimmune, Neoral), alefacept (Amevive), adalimumab (Humira), ustekinumab (Stelara), etanercept (Enbrel), and infliximab (Remicade).

TREATMENTS

Psoriasis that is generalized (i.e., involves more than 30% of the body surface) is difficult to treat with topical medications. Treatments for generalized psoriasis include ultraviolet light phototherapy and photochemotherapy.

PHOTOTHERAPY Ultraviolet-B (UVB) light or narrowband UVB are treatments for generalized psoriasis. UVB light decreases the growth rate of epidermal cells, thereby decreasing hyperkeratosis. Mercury vapor lights or fluorescent UV tubes provide the UVB light; the latter are often arranged in a cabinet so the patient can stand and expose psoriatic lesions more easily. These units may be purchased or constructed, to be used in the patient's home. PUVA combines the oral or topical administration of psoralen (to make the skin more sensitive to light) with ultraviolet-A (UVA) light, which penetrates deeper into the skin than UVB. PUVA requires fewer treatments for remission of lesions, but has more side effects and long-term use increases the risk of skin cancers.

Light therapy is administered in gradually increasing exposure times, until the patient experiences a mild erythema, like mild sunburn. Treatments are given three times a week as an outpatient and are measured in seconds of exposure. The eyes are shielded during the treatment. The erythema response occurs in about 8 hours. Careful assessment is necessary to prevent more severe burning, which could exacerbate the psoriasis. In patients with extensive psoriasis, UVB treatments may be combined with tar preparations, which increase the photosensitivity of the skin.

PHOTOCHEMOTHERAPY In photochemotherapy, a light-activated form of the drug methoxsalen is used. This drug is an antimetabolite that inhibits DNA synthesis and thereby prevents cell mitosis, decreasing hyperkeratosis. Exposure to UVA rays activates methoxsalen; it is administered orally, and the patient is exposed to UVA 2 hours later. Treatments are administered two to three times a week, for 10 to 20 total treatments. Treatment causes tanning, and direct sunlight must be avoided for 8 to 12 hours thereafter. Photochemotherapy has had a high success rate in achieving remission of psoriasis, but it can accelerate aging of exposed skin, induce cataract development, alter immune function, and increase the risk of melanoma.

●○● NURSING CARE

Assessment

Refer to the Manifestations and Interprofessional Care sections above for assessment of the patient experiencing psoriasis.

Priorities of Care

Collaborating with the interprofessional team to ensure adequate treatment of the underlying process while providing care that supports the physical and psychologic responses to the disorder is a nursing priority. Teaching the patient and, as appropriate, caregivers strategies for self-care including the therapeutic regimen should also be considered a priority nursing action. The nurse also focuses on providing emotional support through nonjudgmental acceptance.

Diagnoses, Outcomes, and Interventions

The nursing interventions discussed in this section focus on the common nursing diagnoses of *Risk for Impaired Skin Integrity* and *Disturbed Body Image*.

Impaired Skin Integrity

Psoriatic lesions range from several scales to large, open areas. Typical psoriatic skin lesions increase the risk of infection, which can compromise healing. In addition, certain treatments (e.g., the use of UVA or retinoids) may cause erythema or peeling of the skin, further altering skin integrity.

Expected Outcome: Patient will experience lesion healing through primary intention as indicated by progressive reduction in lesion size and presence.

- Teach methods to reduce injury to the skin when taking therapeutic baths or treatments: Use warm, not hot, water; gently rub lesions with a soft washcloth, using a circular motion; dry the skin with a soft towel, using a blotting or patting motion; and keep the skin lubricated at all times. *Hot water and dry skin increase pruritus, further stimulating the itch–scratch–itch cycle. Dry skin also worsens psoriasis. Washing or drying the skin with rough linens or pressure may excoriate the skin over the psoriatic lesions.*
- Teach how to apply topical medications (see Box 16–2). *Applying a thin layer of medication more frequently is often more effective than*

BOX 16–2 General Guidelines for Applying Topical Medications

- Each time a medication is applied, the skin surface must be clean and dry. Remove the medication from the previous application. Remove creams by washing the skin with tap water; remove ointments by washing the skin first with mineral oil and then with a mild soap and water.
- To apply gels, creams, and pastes: Squeeze about 1/2 to 1 inch of the gel or cream into the palm of the hand. Rub the hands together until they are covered. Apply gels and creams to the affected areas with long strokes until the skin is thinly covered. Exceptions to these general guidelines follow:
  a. Corticosteroids are usually applied two to three times a day in small amounts and rubbed directly onto the lesions. Apply the medication after a bath and cover with an occlusive dressing.
  b. Apply medications containing tar in the direction of hair growth. Do not apply these medications to the face, to the genitals, or in skinfolds. If the tar is water based or oil based, it will stain clothing.
  c. Wear gloves when applying anthralin stains.
- To apply lotions: Shake the bottle of lotion well. Pour a small amount into the palm of the hand, and pat the medication onto the skin. If the lotion is thin, apply it with a gauze pad.
- To apply sprays: Hold the container about 6 inches from the skin and apply the medication in a short spray.
- To apply medicated shampoo: Rinse out medication from the previous application. Apply the shampoo, massage into the hair and over the scalp carefully, and allow it to remain for the prescribed time. Rinse.
- To apply pastes: Use enough paste on an applicator (such as a wooden tongue depressor) to cover the lesion thinly.

applying a single thick layer of medication. The medications used to treat psoriasis may irritate the eyes and mucous membranes; when applied in skinfolds, they may also cause maceration (skin breakdown due to prolonged exposure to moisture).

- Teach manifestations of infection and how to contact the healthcare provider if these occur: elevated temperature, increased swelling, redness, pain, increase in drainage, and any change in the color of the drainage. *The patient with skin lesions is at high risk for infection, as the skin is the body's first line of defense.*
- Teach manifestations of the complications of treatment: excoriation, increased erythema, increased peeling, and blister formation. *The topical medications or treatments may damage cells through chemical burns or excessive exposure to ultraviolet light. Times and methods of treatment need to be adjusted if these manifestations occur.*

Disturbed Body Image

The chronic skin lesions of psoriasis may cause patients to isolate themselves from social contacts, withdraw from normal roles and responsibilities, and feel helpless or powerless.

Expected Outcome: Patient will accept body appearance as evidenced by adjustment to changes in physical appearance.

- Establish a trusting relationship by expressing acceptance of the patient, both verbally and nonverbally. For example, touch the patient during social communications, demonstrating that the lesions are not contagious or offensive. *One's body image is affected not only by self-perception but also by the responses of others. Nonjudgmental acceptance helps the patient adapt to the change in body image. By touching the patient during interactions, the nurse demonstrates acceptance.*
- Encourage expression of self-perception and the asking of questions about the disease and treatment in view of the chronic nature of psoriasis. *The patient adapts to a changed body image through a process of recognition, acceptance, and resolution. Each person responds individually to disfigurement and loss.*
- Promote social interaction through family involvement in care and referral to support groups of people with psoriasis or other chronic skin conditions. *Acceptance by others is critical to acceptance of self. Psoriasis treatment is lifelong, time consuming, and often unappealing. By becoming involved in care, the family communicates acceptance. Sharing experiences with others who have the same health problem is a source of strength when adjusting to a visible, chronic illness.*

Delegating Nursing Care Activities

As appropriate and allowed by the designated duties and responsibilities of unlicensed assistive personnel, the nurse may delegate nursing care activities such as measuring fluid intake and output, collecting vital signs (including orthostatic vital signs), encouraging oral or enteral fluid intake, and nonpharmacologic skin care.

Continuity of Care

Patient and family teaching focuses on treatments and skin care needs. The following topics should be addressed:

- The chronic nature of the disease, factors that may precipitate an exacerbation, and methods to reduce stress.
- Interventions for pruritus and dry skin, and specific care for psoriasis:
  - Expose the skin to sunlight, but avoid sunburn.
  - Avoid trauma to the skin (e.g., do not scrub off scales, and use only an electric razor).
  - Avoid exposure to contagious illnesses such as influenza and colds.
  - Discuss current medications with the healthcare provider. Certain drugs (such as indomethacin [Indocin], lithium, and beta-adrenergic blocking agents) are known to precipitate exacerbations of psoriasis.
- Suggest the National Psoriasis Foundation, the National Institutes of Health, or the American Academy of Dermatology as resources.

Infections and Infestations of the Skin

The skin's resistance to infections and infestations is provided by protective mechanisms, including skin flora, sebum, and the immune response. Although the skin is normally resistant to infections and infestations, these disorders may occur as a result of a break in the skin surface, a virulent agent, and/or decreased resistance due to a compromised immune system. This section discusses skin disorders resulting from bacterial infections, fungal infections, parasitic infestations, and viral infections.

THE PATIENT WITH A BACTERIAL INFECTION OF THE SKIN

A number of bacteria normally inhabit the skin and do not cause an infection. However, when a break in the skin allows invasion by pathogenic bacteria, an infection, called a *pyoderma*, may occur. The most common bacterial infections are caused by gram-positive *Staphylococcus aureus* and beta-hemolytic streptococci. Bacterial infections of the skin may be primary or secondary. Primary infections are caused by a single pathogen and arise from normal skin; secondary infections develop in traumatized or diseased skin.

Most bacterial infections are treated by a primary care provider, and the patient remains at home for care. If the infection becomes more serious, inpatient care may be required. In addition, nosocomial infections of wounds or open lesions in hospitalized patients are often the result of bacterial infections, especially by methicillin-resistant *Staphylococcus aureus* (MRSA).

Pathophysiology

Bacterial infections of the skin arise from the hair follicle, where bacteria can accumulate and grow and cause a localized infection. However, the bacteria also can enter the body through open wounds, invade deeper tissues, and cause a systemic infection, a potentially life-threatening disorder. Various types of bacterial infections involve the skin, including folliculitis, furuncles and carbuncles, cellulitis, and MRSA.

FOLLICULITIS

Folliculitis is a bacterial infection of the hair follicle, most commonly caused by *S. aureus*. The infection begins at the follicle opening and

Figure 16–4 ■ The lesions of folliculitis are pustules surrounded by areas of erythema.

extends down into the follicle. The bacteria release enzymes and chemical agents that cause an inflammation. The lesions appear as pustules surrounded by an area of erythema on the surface of the skin (Figure 16–4 ■). The lesions are accompanied by discomfort ranging from slight burning to intense itching. A major complication is abscess formation. Folliculitis is found most often on the scalp and extremities. It is also often seen on the face of bearded men (*sycosis barbae*), on the legs of women who shave, and on the eyelids (a *stye*). Although folliculitis may appear without any apparent cause, contributing factors include poor hygiene, poor nutrition, prolonged skin moisture, tight heavy fabrics on the upper legs, and trauma to the skin.

PRACTICE ALERT!

A specific type of folliculitis, called "hot tub folliculitis," is caused by *Pseudomonas aeruginosa*, and is characterized by follicular or pustular lesions that occur 1 to 4 days after being in a hot tub, whirlpool, or public swimming pool.

FURUNCLES AND CARBUNCLES

Furuncles, often called boils, are inflammations of the hair follicle. They often begin as folliculitis, but the infection spreads down the hair shaft, through the wall of the follicle, and into the dermis. The causative organism is commonly *S. aureus*. A furuncle is initially a deep, firm, red, painful nodule from 1 to 5 cm in diameter (Figure 16–5 ■). After a few days, the nodule changes into a large, painful cystic nodule. The cysts may drain substantial amounts of purulent drainage. One

Figure 16–5 ■ A furuncle (boil) is a deep, firm, red, painful nodule.

or more furuncles may occur on any part of the body that has hair. Contributing factors include poor hygiene, trauma to the skin, areas of excessive moisture (including perspiration), and systemic diseases such as diabetes mellitus and hematologic malignancies.

A **carbuncle** is a group of infected hair follicles. The lesion begins as a firm mass located in the subcutaneous tissue and the lower dermis. This mass becomes swollen and painful and has multiple openings to the skin surface. Carbuncles are most frequently found on the back of the neck, the upper back, and the lateral thighs. In addition to the local manifestations, the patient may experience chills, fever, and malaise. The contributing factors for carbuncles are the same as for furuncles. Both infections are more common in hot, humid climates.

CELLULITIS

Cellulitis is a localized infection of the dermis and subcutaneous tissue. Cellulitis can occur following a wound or skin ulcer or as an extension of furuncles or carbuncles. The infection spreads as a result of a substance produced by the causative organism, called *spreading factor* (hyaluronidase). This factor breaks down the fibrin network and other barriers that normally localize the infection. The area of cellulitis is red, swollen, and painful (Figure 16–6 ■). In some cases, vesicles may form over the area of cellulitis. The patient may experience fever, chills, malaise, headache, and swollen lymph glands.

Figure 16–6 ■ Cellulitis is a bacterial infection localized in the dermis and subcutaneous tissue. The involved area is red, swollen, and painful.

METHICILLIN-RESISTANT *STAPHYLOCOCCUS AUREUS* INFECTION

Methicillin-resistant *Staphylococcus aureus* (MRSA) infection is caused by the *S. aureus* bacteria, an organism resistant to the broad-spectrum antibiotics (such as methicillin, oxacillin, amoxicillin, and penicillin) usually used to treat it. This potentially fatal disease is divided into two types: healthcare-associated infections (acquired in hospitals and other healthcare settings) (HA-MRSA) and community-associated infections (acquired in the community in otherwise healthy people) (CA-MRSA). MRSA in hospitalized patients may lead to infections of wounds, skin around invasive tubes or catheters, the blood, the lungs, or the urinary system. MRSA in patients in the community is often manifested as skin infections and a potentially life-threatening pneumonia.

S. aureus are normally found on the skin and in the nose of about one-third of the population. If present, but not causing illness, the person is said to be colonized and capable of spreading the bacteria to other people. The bacteria are spread by direct contact with the bacteria or with contaminated equipment. The incidence of CA-MRSA is about 5 per 100,000 people, but those numbers are increasing. The rates of both types are highest in healthcare workers, in males, in those over age 65, in Blacks, and in those with HIV and AIDS. The risk for CA-MRSA is increased in those who participate in contact sports, and in people sharing personal items and/or living in crowded or unsanitary conditions.

PRACTICE ALERT!

CA-MRSA is an increasing healthcare problem resulting from the overuse or misuse of antibiotics.

The infection usually begins as a small, raised, red nodule on the skin that resembles a pimple or spider bite. The nodule rapidly increases in size, becomes dark red, is painful, contains pus, and may become a deep abscess. Cellulitis involving the area containing the initial infection (such as an extremity) is common. Actions to prevent MRSA are outlined in Box 16–3.

BOX 16–3 Preventing MRSA in the Hospital and in the Community

IN THE HOSPITAL

- Wash your hands frequently.
- Ask all hospital staff to wash their hands or use an alcohol-based hand sanitizer every time before touching you or objects in your environment.
- Ensure all invasive tubes or needles are inserted under sterile conditions.

IN THE COMMUNITY

- Wash your hands often and for as long as it takes to hum the "Happy Birthday" song. Use a hand sanitizer with at least 60% alcohol for times when you can't wash your hands.
- Do not share personal items such as razors, towels, or athletic equipment.
- For athletes: Shower after practice or games with soap and water. Sit out practice or games if you have an infection of the skin. Wash towels and athletic clothing with hot water and bleach after every use.
- Keep cuts and scrapes covered with a dry sterile dressing until they are healed.
- Go to the physician if you have a skin infection that is painful and getting worse. Ask about being tested for MRSA.
- Use antibiotics appropriately. Take the full prescribed dose. Do not share.

●○● INTERPROFESSIONAL CARE

The diagnosis of a bacterial infection of the skin is made by assessing the appearance of the lesion and by identifying the causative organism. Antibiotics effective against the organism are used in treatment.

DIAGNOSIS

Drainage from a lesion or a blood culture may be ordered to identify the causative organism so that the most effective antibiotic can be chosen for treatment. People who experience repeated bacterial skin infections, or who provide care for others who exhibit infections, may have a culture taken from the external nares to determine whether they are carriers of bacteria (e.g., MRSA) and are reinfecting themselves or others.

MEDICATIONS

The primary treatment for bacterial infections of the skin is an antibiotic specific to the organism. The antibiotic is usually taken orally, but may also be applied topically. Multiple furuncles and carbuncles may be treated with cloxacillin (a penicillinase-resistant penicillin); the cephalosporins also are often effective. MRSA infections may be treated with antimicrobial therapy, including trimethoprim-sulfamethoxazole (Bactrim), minocycline (Minocin), doxycycline (Vibramycin), or clindamycin (Cleocin). There are no recommended guidelines for treating colonization. For repeated infections in a household, treatment may include mupirocin ointment (Bactroban Nasal) and an antiseptic body wash (Domino, 2013).

●○● NURSING CARE

Nursing care focuses on preventing the spread of infection and restoring normal skin integrity. Many patients provide self-care at home, but need education about preventing CA-MRSA.

Assessment

Refer to the Manifestations and Interprofessional Care sections above for assessment of the patient experiencing a bacterial infection of the skin.

Priorities of Care

Collaborating with the interprofessional team to ensure adequate treatment of the infection while providing care that supports infection control (including appropriate precautions) is a priority of care. Teaching the patient and, as appropriate, caregivers strategies to prevent spread of infection and optimize safe home and work environments also should be considered a priority nursing action. The nurse also focuses on promoting comfort and prevention of infection recurrence.

Diagnoses, Outcomes, and Interventions

Risk for Infection

Expected Outcome: Patient's infection will be effectively managed as evidenced by skin integrity and body temperature within normal range.

- Practice good hand washing (hand hygiene) and teach its importance. *Careful hand hygiene is one of the most effective methods to reduce the spread of infection both in and out of the hospital setting. Healthcare providers must wash their hands with soap and water before and after patient care and between each patient contact. All patients, family members, and visitors (both in the home and hospital setting) should be taught the importance of hand hygiene, but it is even more important for the patient with a bacterial infection.*
- Assess for and teach how to identify an increase in infection, which may be manifested systemically by fever, tachycardia, chills, and malaise. Local manifestations of the spread of the infection include an increase in erythema, the size of the lesion, and drainage. *This assessment is especially important for patients who are older, debilitated, or immunosuppressed and for those who have large or dirty wounds.*

SAFETY ALERT

If a patient with a bacterial skin infection is hospitalized, place him or her on isolation precautions to limit the spread of the organism to other patients.

- Cover draining lesions with a sterile dressing, and handle soiled dressings or linens according to standard precautions. When changing dressings, always wear disposable rubber gloves and masks. *These actions are necessary to prevent the spread of infection to other areas of the patient's body, to other patients, to visitors, and to the nurse providing care.*

Delegating Nursing Care Activities

As appropriate and allowed by the designated duties and responsibilities of unlicensed assistive personnel, the nurse may delegate nursing care activities such as measuring fluid intake and output, collecting vital signs (including orthostatic vital signs), encouraging oral or enteral fluid intake, and skin care.

Continuity of Care

The increasing numbers of people with community-associated MRSA have resulted in state laws about reporting of or screening for MRSA. Many state public health departments have guidelines available about the manifestations, prevention, and treatment of CA-MRSA, and the Centers for Disease Control and Prevention (CDC) (2012b) has issued treatment guidelines. Teaching for any bacterial infection focuses on facilitating tissue healing and eliminating the infection. Address the following topics:

- The importance of maintaining good nutrition
- The importance of maintaining cleanliness through careful hand hygiene and proper handling and disposal of dressings
- Preventing the spread of infection by not sharing linens and towels and washing clothing and linens in hot water
- The importance of not squeezing or trying to open a pimple or boil
- The importance of taking the full course of prescribed antibiotics.

Evidence for Nursing Care

The Patient with Bacterial Infection of the Skin

Selected resources that nurses may find helpful when planning evidence-based nursing care follow.

- Gould, D. (2012). Skin flora: Implications for nursing. *Nursing Standard, 26*(33), 48–56.
- Nazarko, L. (2012). An evidence-based approach to diagnosis and management of cellulitis. *British Journal of Community Nursing, 17*(1), 6–12.
- Powers, J., Peed, J., Burns, L., & Ziemba-Davis, M. (2012). Chlorhexidine bathing and microbial contamination in patients' bath basins. *American Journal of Critical Care, 21*(5), 338–343.

THE PATIENT WITH A FUNGAL INFECTION

Fungi are free-living, plantlike organisms that live in the soil, on animals, and on humans. The fungi that cause superficial skin infections are called *dermatophytes*. In humans, the dermatophytes live on keratin in the stratum corneum, hair, and nails. Fungal disorders are also called *mycoses*.

Pathophysiology

Fungal infections include dermatophytoses (tinea or ringworm) and candidiasis (yeast) infections. The candidiasis infections may affect various parts of the body, but are more commonly seen in women as vaginal infections, discussed and illustrated in Chapter 50.

DERMATOPHYTOSES (TINEA)

Superficial fungal infections of the skin are called **dermatophytoses** or, more commonly, ringworm. Fungal infections occur when a susceptible host comes in contact with the organism. The organism may be transmitted by direct contact with animals or other infected individuals or by inanimate objects such as combs, pillowcases, towels, and hats. The most important factor in the development of the infection is moisture; the onset and spread of a fungal infection is greatest in areas where moisture content is high, such as within skinfolds, between the toes, and in the mouth. Other factors that increase the risk of a fungal infection include the use of broad-spectrum antibiotics that kill off normal flora and allow the fungi to grow, diabetes mellitus, immunodeficiencies, nutritional deficiencies, pregnancy, increasing age, and iron deficiency. The dermatophyte infections are named by the body part affected, for example:

- *Tinea pedis* is a fungal infection of the soles of the feet, the space between the toes, and/or the toenail (Figure 16–7 ■). More often called athlete's foot, this is the most common tinea infection. The lesions vary from mild scaliness to painful fissures with drainage, and they are usually accompanied by pruritus and a foul odor. The infection is often chronic, absent in winter but reappearing in hot weather when perspiring feet are encased in shoes.
- *Tinea corporis* is a fungal infection of the body. It can be caused by several different fungi, and the lesions vary according to the causative organism. The most common lesions are large circular patches with raised red borders of vesicles, papules, or pustules. Pruritus and erythema are also present.
- *Tinea cruris* is a fungal infection of the groin that may extend to the inner thighs and buttocks. Often called "jock itch," it is often associated with tinea pedis and is more common in people who are physically active, are obese, and/or wear tight underclothing.

Figure 16–7 ■ Tinea pedis (athlete's foot) is a fungal infection that often occurs between the toes.

●○● INTERPROFESSIONAL CARE

Fungal infections are primarily diagnosed in outpatient settings and treated at home, but may also occur in hospitalized patients. The treatment is the same, regardless of the setting.

DIAGNOSIS

Diagnostic tests are conducted to determine the causative fungi and may include cultures, microscopic examination using KOH, and examination of the skin with ultraviolet light (Wood's lamp), described in Chapter 15.

MEDICATIONS

Fungal infections of the skin are treated by topical or systemic antifungal medications. The over-the-counter (OTC) medications (such as miconazole, clotrimazole, butenafine, and terbinafine) are often less expensive than prescription medications and are effective. Nursing implications for the antifungal medications are described in the Medication Administration box.

●○● NURSING CARE

Many people treat themselves with OTC antifungal medications. It is recommended, however, that the person be professionally diagnosed the first time the infection occurs. If symptoms reappear, self-treatment is usually satisfactory. The interventions discussed for nursing care of the patient with a bacterial infection are also appropriate for the patient with a fungal infection. Teaching topics specific to fungal infections are as follows:

- Fungal diseases are contagious. Do not share linens or personal items with others.
- Use a clean towel and washcloth each day.
- Carefully dry all skinfolds, including those under the breasts, under the arms, and between the toes.
- Wear clean cotton underclothing each day.
- Fungi grow in moist environments, such as on sweaty feet. To prevent further infections, do not wear the same pair of shoes every day, wear socks that permit moisture to wick away from the skin surface, do not wear rubber- or plastic-soled shoes, and use talcum powder or an OTC antifungal powder twice a day.

MEDICATION ADMINISTRATION

Antifungal Agents

EXAMPLES

butenafine (Mentax)
clotrimazole (Mycelex)
nystatin (Mycostatin, Nilstat)
econazole (generic only)
oxiconazole (Oxistat)
miconazole (Monistat)
undecylenic acid (Desenex)
ketoconazole (Nizoral)
fluconazole (Diflucan)
amphotericin B (generic only)
griseofulvin (generic only)

Antifungal medications are prepared in a variety of forms, depending on the specific drug: powders, creams, shampoos, suspensions, troches, vaginal suppositories, and oral tablets. Some drugs interfere with the permeability of the fungal cell membrane, others interfere with DNA synthesis. Most of these medications are fungistatic (inhibit fungal growth), but in large doses they may be fungicidal.

Nursing Responsibilities

- When taking the health history, ask about known hypersensitivity reactions to these agents; document carefully.
- Assess for side effects: skin rash, local irritation, gastrointestinal symptoms (if given PO), and mental status.
- Administer ketoconazole with food to minimize gastrointestinal irritation.
- Shake suspensions well before administration, and ask the patient to swish them around the mouth before swallowing.
- Tell the patient to allow oral tablets to dissolve in the mouth.

Health Education for the Patient and Family

- Therapy usually continues over a long period of time, but regular use of medications for the recommended period is necessary. Do not miss doses, and complete the full treatment.
- For griseofulvin: Take with meals or foods high in fat (such as ice cream) to avoid stomach upset and help with absorption. Avoid alcohol (which may cause rapid pulse and flushing) and exposure to sunlight (this drug causes increased sensitivity).
- For nystatin: Dissolve lozenges completely in the mouth. Hold suspensions in the mouth and swish throughout the mouth as long as possible before swallowing. Insert intravaginal medication high in the vagina. Continue with intravaginal applications throughout the menses.
- For antifungal shampoo: Use two times a week for 4 weeks, allowing at least 3 days between each shampoo. Wet hair, apply shampoo to produce lather, leave in place for 1 minute, and then rinse. Apply shampoo a second time, lather, leave in place for 3 minutes, and then rinse thoroughly.
- For topical application: Rub well into the affected areas, but do not get the medication in your eyes.
- For vaginal candidiasis infections: During therapy, refrain from sexual intercourse or advise partner to use a condom.
- Your sexual partner will need to be treated at the same time so that you do not pass the infection back and forth to each other.

THE PATIENT WITH A PARASITIC INFESTATION

Infestations of the skin by parasites are more common in developing countries but may occur in any geographic area of the world. They affect people of all social classes but are associated with crowded or unsanitary living conditions.

Pathophysiology

Two of the more common parasitic infestations of the skin are caused by lice and mites. These parasites do not normally live on the skin, but infest the skin through contact with an infested person or contact with clothing, linens, or objects infested with the parasites.

PEDICULOSIS

Pediculosis is an infestation with lice, parasites that live on the blood of an animal or human host. The louse is a 2- to 4-mm oval organism with a stylet that pierces the skin; an anticoagulant in its saliva prevents host blood from clotting while it eats. The female louse lays its eggs (small pearl-gray or brown eggs, called nits) on hair shafts. The louse within the egg hatches, reaches the adult reproductive stage, and dies in 30 to 50 days (Huether & McCance, 2011).

Two common types of human pediculosis are as follows:

- *Pediculosis corporis* is an infestation with body lice. This infestation is more common in people who do not have access to facilities for bathing or washing clothes, such as the homeless. The lice live in clothing fibers and are transmitted primarily by contact with infested clothing and bed linens. The skin lesions occur at the site of a louse bite; macules appear initially, followed by wheals and papules. Pruritus is common, and scratching often results in linear excoriations. The lesions are most often seen on the shoulders, trunk, and buttocks.
- *Pediculosis pubis* is an infestation with pubic lice (often called "crabs"). This infestation is spread through sexual activity with someone already infested or by contact with infested clothing or linens. The lice are found in the pubic region and occasionally spread to the axillae or men's beards. The lice cause skin irritation and intense itching.

SCABIES

Scabies is a parasitic infestation caused by a mite (*Sarcoptes scabiei*). The pregnant female mite burrows into the skin and lays two to three eggs each day for about a month. The eggs hatch in 3 to 5 days, and the larvae migrate to the surface of the skin but burrow into the skin for food or protection. The larvae develop, and the cycle repeats. Scabies infestation affects people of all socioeconomic classes. The infestation is found in webs between the fingers, the inner surfaces of the wrist and elbow, the axillae, the female nipple, the penis, the belt line, and the gluteal crease. The lesions are a small red-brown burrow, about 2 mm in length, sometimes covered with vesicles, which appears as a rash. Pruritus in response to the mite or its feces is common, especially at night, and excoriations may develop. The excoriations predispose the person to secondary bacterial infections. The incidence of scabies in residents of nursing homes and extended care facilities has increased.

●○● INTERPROFESSIONAL CARE

Parasitic infestations are diagnosed by identifying the organism and are treated with medications that kill the lice or mites.

DIAGNOSIS

When a patient has manifestations of pediculosis, the hair shaft and the clothing are examined to identify the lice or the nits. Microscopic examination of the parasite provides a positive diagnosis. Scabies is diagnosed by skin scrapings and microscopic examination for the mites or their feces.

MEDICATIONS

Lice are eradicated with agents that kill the parasite. Infestations of the body and pubic area are treated with topical medications that contain gamma benzene hexachloride, malathion (Prioderm lotion), or permethrin (NIX).

Infestations of the hair are treated with shampoos containing lindane, such as Kwell. A fine-toothed comb can be used to comb the dead nits off the hair shaft. Scabies may be eradicated by a single treatment of lindane lotion or Kwell applied to the entire skin surface for 12 hours. The associated itching is treated with systemic or topical medications, including corticosteroids. Secondary bacterial infections are treated with the appropriate antibiotic.

●○● NURSING CARE

Nursing care for patients with a parasite infestation most often focuses on teaching to prevent infestation or to eradicate an existing infestation. For a hospitalized patient with pediculosis, isolation procedures are instituted until the patient no longer has the infestation.

Patient and family teaching is necessary to facilitate treatment at home, to prevent the spread of the infestation, and to dispel the myth that lice infest only people in dirty living conditions or with poor hygiene. Specific information includes the following:

- Wash clothing and linens in soap and hot water, or have them dry cleaned.
- Ironing of clothes kills any lice eggs.
- All family members and sexual partners must also be treated.
- Lice and mites may infest anyone.

THE PATIENT WITH A VIRAL INFECTION

Viruses are pathogens that consist of an RNA or DNA core surrounded by a protein coat. They depend on live cells for reproduction and so are classified as intracellular pathogens. The viruses that cause skin lesions invade the keratinocyte, reproduce, and either increase cellular growth or cause cellular death.

An increase in the incidence of viral skin disorders has been attributed to a variety of causes. Some commonly used drugs, such as birth control medications and corticosteroids, are known to have immunosuppressive properties that allow viruses to multiply. Other drugs, such as antibiotics, kill off normal skin bacteria that would otherwise serve as a defense against viral infections.

Pathophysiology

Viral infections cause many different kinds of skin disorders, including warts, herpes simplex infections, and herpes zoster infections.

WARTS

Warts, or verrucae, are lesions of the skin caused by the human papillomavirus (HPV). Warts may be nongenital or genital. Nongenital

Figure 16–8 ■ The common wart, caused by a virus, appears as a raised, dome-shaped lesion.

Figure 16–9 ■ Herpes simplex is a viral infection of the skin and mucous membranes.

warts are benign lesions; genital warts may be precancerous. Warts are transmitted through skin contact. Wart lesions may be flat, fusiform (tapered at both ends), or round, but most are round and raised and have a rough, gray surface. There are many different types of warts; location and appearance of the warts depend on the causative virus. (Genital warts are discussed in Chapter 50.) Commonly occurring warts are as follows:

- A *common wart* (verruca vulgaris) may appear anywhere on the skin and mucous membranes of the body; they most commonly appear on the fingers. Common warts grow above the skin surface and may be dome shaped with ragged borders (Figure 16–8 ■).
- *Plantar warts* occur at pressure points on the soles of the feet. The pressure of shoes and walking prevents these warts from growing outward, so they tend to extend deeper beneath the skin surface than do common warts. Plantar warts are often painful.
- A *flat wart* (verruca plana) is a small, flat lesion, usually seen on the forehead or dorsum of the hand.

Depending on their size, location, and any associated discomfort, warts may be treated with medications, cryotherapy, or electrodesiccation and curettage. A common method of wart removal is acid therapy, using a colloidal solution of 16% salicylic acid and 16% lactic acid. The solution is applied to the wart every 12 to 24 hours; the wart disappears in 2 to 3 weeks. Other methods of eradicating warts are cryosurgery, freezing with liquid nitrogen, and electrodesiccation of the wart with an electric current followed by excision of the dead tissue. Warts may also resolve spontaneously when immunity to the virus develops. This response may take up to 5 years.

HERPES SIMPLEX

Herpes simplex (fever blister or cold sore) virus infections of the skin and mucous membranes are caused by two types of herpesvirus: HSV-1 and HSV-2. Most infections above the waist are caused by HSV-1, with herpes simplex lesions most often found on the lips, face, and mouth. (Genital herpes infections, caused by HSV-2, are discussed in Chapter 50.) The virus may be transmitted by physical contact, oral sex, or kissing.

The infection begins with a burning or tingling sensation, followed by the development of erythema, vesicle formation, and pain (Figure 16–9 ■). The vesicles progress through pustules, ulcers, and crusting until healing occurs in 10 to 14 days.

The initial infection is often severe and accompanied by systemic manifestations, such as fever and sore throat; recurrences are more localized and less severe. The virus lives in nerve ganglia and may cause recurrent lesions in response to sunlight, menstruation, injury, or stress. Oral acyclovir may be used prophylactically to prevent reoccurrences and to treat recurrent outbreaks.

HERPES ZOSTER

Herpes zoster, also called *shingles*, is a viral infection of a dermatome section of the skin caused by varicella zoster (the herpes virus that causes chickenpox). The infection is believed to result from reactivation of a varicella virus remaining in the sensory dorsal ganglia after a childhood infection of chickenpox. When reactivated, the virus travels from the ganglia to the corresponding skin dermatome area.

Herpes zoster affects more than 1 million people in the United States each year, with more than half of the cases being in adults over the age of 60 (Huether & McCance, 2011). Patients with Hodgkin's disease, certain types of leukemia, and lymphomas are more susceptible to an outbreak of the disease. Herpes zoster occurs more often in immunocompromised people, such as those with HIV infections, those receiving radiation therapy or chemotherapy, and those who have had major organ transplants. The appearance of the lesions in people with HIV infections may be one of the first manifestations of immune compromise. The herpes eruption lasts for about 2 to 3 weeks and usually does not recur.

Herpes zoster lesions are vesicles with an erythematous base. The vesicles appear on the skin area supplied by the neurons of a single or associated group of dorsal root ganglia (although they may occur beyond this area in immunosuppressed people). The lesions usually appear unilaterally on the face, trunk, and thorax (Figure 16–10 ■). New lesions continue to erupt for 3 to 5 days, then crust and dry. Recovery occurs in 2 to 3 weeks. The patient often experiences severe pain for up to 48 hours before and during eruption of the lesions. The pain may continue for weeks to months after the lesions have disappeared. The older adult is especially sensitive to the pain and often experiences more severe outbreaks of herpes zoster lesions.

Eruption of vesicles over a single dermatome usually occurs only one time. Generalized herpes zoster may indicate an associated immunocompromised disease, such as Hodgkin's disease or HIV infection. Patients infected with HIV are 20 times more likely to develop herpes zoster.

Figure 16–10 ■ Herpes zoster is a viral infection of a dermatome section of the skin. The typical lesions are painful vesicles lying along the path of the nerve.

Complications of herpes zoster include postherpetic neuralgia (a sharp, spasmodic pain along the course of one or more nerves) and visual loss. The neuralgia, described as burning or stabbing, results from inflammation of the root ganglia. Permanent loss of vision may follow occurrence of lesions that arise from the ophthalmic division of the trigeminal nerve. The disease may disseminate in immunocompromised patients, causing lesions beyond the dermatome, visceral lesions, and encephalitis. This serious complication may cause death.

●○● INTERPROFESSIONAL CARE

The treatment for viral skin infections focuses on stopping viral replication and treating patient responses, such as itching and pain.

DIAGNOSIS

Although diagnosis is usually based on manifestations and appearance of the lesions, laboratory tests may be necessary to differentiate herpes zoster from contact dermatitis and herpes simplex. The laboratory tests include a Tzanck smear, which identifies the herpes virus but does not distinguish herpes zoster from herpes simplex. Cultures of fluid from the vesicles and antibody tests are used to make the differential diagnosis of herpes virus types. HIV testing should be considered if patients are under age 55 with a history of HIV risk factors. See Chapter 15 for more information about these tests.

MEDICATIONS

Antiviral drugs are used to treat herpes zoster infections. Acyclovir (Zovirax) interferes with viral synthesis and replication. Although it does not cure herpes infections, it does decrease the severity of the illness and also decreases pain. It may be administered topically, orally, or parenterally. It is more effective if administration begins within the first 1 to 2 days after the first vesicles appear. Other antiviral medications include famciclovir (Famvir) and valacyclovir (Valtrex). Nerve blocks may be needed to treat initial pain. Narcotic and nonnarcotic analgesics are prescribed for pain management, and antihistamines may be administered for relief of pruritus. Patients with eye involvement are treated with topical steroid ophthalmic ointments and mydriatics.

Zostavax (a weakened form of varicella-zoster live virus) is a vaccine used for adults age 60 years or older to prevent herpes zoster. It works by increasing the immune system response; if the patient experiences an outbreak of blisters despite being vaccinated, the nerve pain that follows may be prevented. The vaccine should not be taken by people who are allergic to any of the ingredients, gelatin, or neomycin; those who have a weaker immune system (such as people with AIDS or leukemia); nor those taking steroids. Side effects include injection site manifestations (such as redness, itching, pain, bruising), headache, fever, hives at the injection site, joint or muscle pain, a rash, and swollen glands.

●○● NURSING CARE

Patients with herpes zoster require nursing care for infection, pruritus, and pain. They also require teaching about preventing the spread of the virus to others. See the Case Study & Nursing Care Plan for the patient with herpes zoster on page 404.

Assessment

Refer to the earlier Interprofessional Care section for assessment of the patient with a viral skin infection.

Priorities of Care

Collaborating with the interprofessional team to ensure adequate treatment of a viral skin infection while providing care that promotes recovery and comfort is a nursing priority. Teaching the patient and, as appropriate, caregivers strategies to prevent infection, optimize comfort, and promote safe home and work environments also should be considered a priority nursing action. The nurse also focuses on promoting comfort and maintaining asepsis for all interruptions of the integument.

Diagnoses, Outcomes, and Interventions

This section focuses on the nursing diagnoses of *Acute Pain* and *Risk for Infection*.

Acute Pain

The patient with herpes zoster often experiences severe pain over the entire dermatome supplied by the affected nerve root. The pain is described as burning, tearing, or stabbing. The patient may avoid movement and does not want clothing or bed linens to touch the affected area.

Expected Outcome: Patient will experience adequate pain control as evidenced by patient report of response to analgesics.

- Monitor the location, duration, and intensity of the pain. *Each person experiences and expresses pain in his or her own manner. Pain tolerance is also individual. Accurate assessment of the patient's perception and tolerance of pain is essential in facilitating pain management.*
- Explain the rationale for taking prescribed medications on a regular schedule. *Delaying or withholding medications may allow the pain to reach an intensity at which the medication is less effective in promoting relief.*
- Teach measures to relieve pruritus: Take prescribed antipruritic medications, apply calamine lotion or wet compresses if prescribed, keep the room temperature cool, and use a bed cradle to keep sheets off affected areas of the body. *Pruritus is a common problem for patients with herpes zoster; scratching may excoriate the*

CASE STUDY & NURSING CARE PLAN A Patient with Herpes Zoster

Jesus Rivera is a 34-year-old migrant farm worker who currently lives in temporary housing in a rural area of the southwestern United States. His family includes his wife, Marta, who is 3 months pregnant, and two children, ages 3 and 5. He takes his wife to a medical clinic staffed by volunteer nurses, physicians, and students from a nearby university for a prenatal checkup. The clinic is open only on Saturday and provides care on a sliding fee scale or for free if the family is unable to pay. While Mrs. Rivera is being examined, Mr. Rivera asks the nurse to have someone look at some very painful blisters on his chest that developed about a week ago. He is afraid that exposure to pesticides has caused the sores.

ASSESSMENT

Mr. Rivera speaks Spanish and is able to communicate only slightly in English. Anita Mendez, a student nurse fluent in Spanish, performs the initial assessment of Mr. Rivera. Mr. Rivera's history reveals problems with lower back pain but no significant past medical illnesses. He is not aware of any allergies and cannot remember having had chickenpox as a child. Two years ago, both children were sick and had blisters on their bodies, and a friend told them it was chickenpox. Mrs. Rivera thinks she had chickenpox as a child.

Because Mr. Rivera has not had any medical care for several years, baseline laboratory tests are ordered to screen for any other illnesses. The complete blood count (CBC), blood chemistry, and urinalysis are all within normal limits.

Mr. Rivera says that he did not feel well for several days before the blisters appeared, having experienced chills and general achiness. He had not taken his temperature because the family does not own a thermometer. Current vital signs are as follows: T 37.2°C (99°F), P 74 bpm, R 22/min, and BP 148/88 mmHg.

Physical examination of the trunk reveals a bandlike pattern of lesions across the left thorax. Some of the lesions are vesicles filled with serous fluid; others are darker in color and are oozing a light yellow drainage. The skin around the lesions is red and inflamed. Mr. Rivera complains of a severe, burning pain with itching across his chest. He is diagnosed with herpes zoster.

DIAGNOSES

- *Risk for Infection* related to open oozing areas on the left thorax
- *Acute Pain* related to the presence of lesions and pruritus
- *Deficient Knowledge* of the cause of the skin disorder and recommended treatment
- *Anxiety* related to need to work in areas of pesticide application
- *Ineffective Health Maintenance* related to limited access to healthcare due to transitory work conditions and cultural and language barriers

EXPECTED OUTCOMES

- Patient's skin lesions will heal without evidence of a secondary infection.
- Patient will limit his exposure (as much as possible) to his wife and children and to individuals with debilitating illnesses to prevent the spread of the virus.
- Patient will obtain relief from pain and pruritus with the proper use of medications.
- Patient will verbalize an understanding of the disease process and participate in the treatment plan.
- Patient will obtain follow-up care.
- Patient will make an appointment for a referral for information about occupational hazards.

PLANNING AND IMPLEMENTATION

- Provide verbal and written instructions (in Spanish) for self-care:
  - Wear a clean cotton undershirt each day.
  - Trim the fingernails short, and keep the hands clean.
  - Wash the hands each time the infected area is touched.
  - Wash any soiled clothes or linens in hot water and soap.
  - Do not allow other family members to use your towels.
  - Take medications as prescribed for itching and pain.
  - Take the medicine for your sores every 4 hours, even during nighttime hours, for 7 days.
  - As much as possible, do not touch your wife and children until the sores are covered with scabs. Do not have sex with your wife while you have these sores.
- Teach how to take care of skin lesions:
  - Wear disposable gloves every time you do this treatment.
  - Wash the sores and the skin around them very gently with a soft washcloth and a mild soap.
  - Using your fingers, carefully rub the cream on the sores. Do this once every morning after breakfast and once every evening after supper.
  - Wash your hands carefully before and after each treatment.
- Make a follow-up appointment for the next week.
- Provide Mr. Rivera with the name and phone number of the Occupational Safety and Health Administration (OSHA) and recommend he call for an appointment to discuss his concerns about pesticides.

EVALUATION

Mrs. Rivera explains how she has taken care of her husband, and Mr. Rivera is careful to describe how he has followed the nurse's instructions. The skin lesions are dry and crusty, with no new blister formation. Mr. Rivera says he has not called OSHA and is not sure that he will, but he thanks Miss Mendez for the phone number. The nurses make an appointment in 1 month for a prenatal checkup for Mrs. Rivera and for follow-up of Mr. Rivera's herpes zoster. Mr. Rivera promises to return if they are still living close enough to keep the appointment.

Clinical Reasoning in Patient Care

1. Identify barriers to care present in this case study. How may nursing interventions promote healthcare delivery to disadvantaged populations?
2. Although most cases of herpes zoster are self-limiting, what further assessments and interventions might have been indicated had the lesions shown little improvement over time and/or the pain remained severe?
3. If Mr. Rivera is advised not to work until his lesions heal, the family may face economic and sociocultural hardships. Develop a plan of care for Mr. Rivera for the nursing diagnosis *Ineffective Role Performance*.

See Evaluating Your Response in Appendix B.

skin and increase the risk for secondary infections. Pruritus may intensify the experience of pain.

- Encourage the use of distraction (such as music) or a specific relaxation technique (such as progressive muscle relaxation or deep breathing). *Noninvasive methods to relieve pain not only help the patient manage the pain experience but also increase the effectiveness of pain medications.*

Risk for Infection

Patients with herpes zoster have impaired skin integrity and pruritus with scratching and possible excoriation. These factors contribute to a high risk for secondary bacterial infection. In addition, the patient is contagious to others who did not have chickenpox as children.

Expected Outcome: Patient's infection will be effectively managed as evidenced by skin integrity and body temperature within normal range.

- If hospitalized, monitor white blood cell count and assess for lymph gland enlargement. *Secondary bacterial infections may occur in any patient with impaired skin integrity; if the patient is immunocompromised, the risk is even greater. Fever, changes in lesions or drainage, an increased white blood cell count, and lymph gland enlargement are manifestations of an infection.*
- Teach interventions to decrease the itch–scratch–itch cycle, thereby decreasing the possibility of excoriation (refer to the discussion about nursing care of patients with pruritus and psoriasis earlier in this chapter). *Excoriation from scratching provides an avenue for bacterial invasion.*
- Institute infection control procedures for patients who are hospitalized:
  - Maintain strict isolation for immunocompromised patients.
  - Wear gloves and gown if contact with lesions is likely.
  - Instruct pregnant women to avoid exposure until lesions have crusted over.

Isolation procedures are instituted for the immunocompromised patient to prevent patient infection. Wear gloves and gown to prevent spreading the infection to self or others. Pregnant women must avoid exposure to people with herpes zoster because the herpes virus can cross the placental barrier.

Delegating Nursing Care Activities

As appropriate and allowed by designated duties and responsibilities of unlicensed assistive personnel, the nurse may delegate nursing care activities such as measuring fluid intake and output, collecting vital signs (including orthostatic vital signs), encouraging oral or enteral fluid intake, and nonpharmacologic skin care.

Continuity of Care

Because most patients with viral infections provide self-care at home, the nurse focuses on teaching the patient and family how to provide the necessary care. With herpes zoster increasing in incidence in patients who are older or have a serious chronic illness, it may also be necessary to make a referral to a community health provider for continued support. Provide the following information and instructions:

- A vaccine is available to help prevent herpes zoster.
- The disease is usually self-limiting and heals completely. Second occurrences of herpes zoster are rare.
- Do not have social contact with children or pregnant women until crusts have formed over the blistered areas with herpes zoster, because the disease is contagious to people who have not had chickenpox.
- Use pain medications regularly.
- Follow suggestions to help reduce itching, scratching, and pain: Use medications as prescribed, wear lightweight cotton clothing, keep room temperatures cool, wear cotton gloves at night if scratching is a problem, and practice relaxation and distraction activities.
- Report any increase in pain, fever, chills, drainage that smells bad and has pus, or a spread in the blisters to your healthcare provider.

Inflammatory Disorders of the Skin

The inflammatory skin disorders discussed in this section include dermatitis, acne, pemphigus, and lichen planus.

THE PATIENT WITH DERMATITIS

Dermatitis is an inflammation of the skin characterized by erythema and pain or pruritus. Dermatitis may be acute or chronic.

Pathophysiology

Various exogenous and endogenous agents can cause an inflammatory response of the skin. Different types of skin eruptions occur, often specific to the causative allergen, infection, or disease. The initial skin responses to these agents or illnesses include erythema, formation of vesicles and scales, and pruritus (Figure 16–11 ■). Subsequently, irritation from scratching promotes edema, a serous discharge, and crusting. Long-term irritation in chronic dermatitis causes the skin to become thickened and leathery and darker in color.

CONTACT DERMATITIS

Contact dermatitis is a type of dermatitis caused by a hypersensitivity response or chemical irritation. The major sources known to cause contact dermatitis are dyes, perfumes, poison plants (ivy, oak, sumac), chemicals, and metals (Box 16–4). A contact dermatitis common in the healthcare field is latex dermatitis.

FAST FACTS

Latex Allergy

- It is estimated that 5% to 10% of healthcare providers are allergic to latex.
- The most common type of allergic response to latex gloves is type IV, T-cell–mediated contact dermatitis.
- Type I IgE-mediated hypersensitivity, manifested by urticaria, rhinoconjunctivitis, asthma, or anaphylaxis, is far more serious than the T-cell–mediated type.

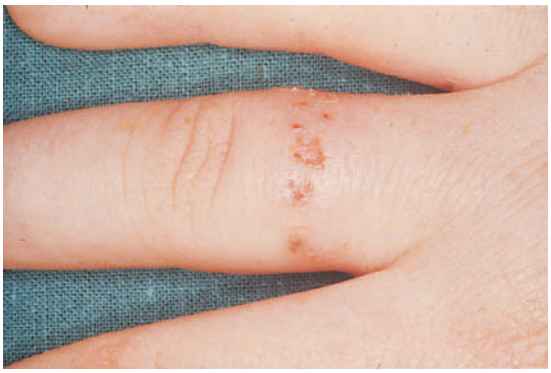

Figure 16–11 ■ Dermatitis may be a response to allergens, infections, or chemicals. This patient has contact dermatitis resulting from the metal salts in a ring.
Source: Biophoto Associates/Photo Researchers, Inc.

BOX 16–4 Common Causes of Contact Dermatitis

- Alkalis: soaps, detergents, household ammonia, lye, cleaners
- Cosmetics: perfumes, dyes, oils
- Hydrocarbons: crude petroleum, lubricating oil, mineral oil, paraffin, asphalt, tar
- Fabrics: wool, polyester, dyes, sizing
- Metal salts: calcium chloride, zinc chloride, copper, mercury, nickel, silver
- Plants: ragweed, poison oak, poison sumac, poison ivy, pine

Allergic contact dermatitis is a cell-mediated or delayed hypersensitivity to a wide variety of allergens. Sensitizing antigens include microorganisms, plants, chemicals, drugs, metals, or foreign proteins. On initial contact with the skin, the allergen binds to a carrier protein, forming a sensitizing antigen. The antigen is processed and carried to the T cells, which in turn become sensitized to the antigen. The first exposure is the sensitizing contact and the person does not experience manifestations, which occur with subsequent exposures. The manifestations include erythema, swelling, and pruritic vesicles in the area of allergen contact. For example, a person hypersensitive to metal may have lesions under a ring or watch.

Irritant contact dermatitis is an inflammation of the skin from irritants; it is not a hypersensitivity response. Common sources of irritant contact dermatitis include chemicals (such as acids), soaps, and detergents. The skin lesions are similar to those seen in allergic contact dermatitis.

ATOPIC DERMATITIS

Atopic dermatitis is an inflammatory skin disorder that is also called eczema. The exact cause is unknown, but related factors include depressed cell-mediated immunity, elevated IgE levels, and increased histamine sensitivity. Patients with atopic dermatitis have a family history of hypersensitivity reactions, such as dry skin, eczema, asthma, and allergic rhinitis. Although up to one-third of patients with atopic dermatitis also have food allergies, a positive correlation has not been found.

The dermatitis results from a type I hypersensitivity reaction (refer to Chapter 13). The immune response interacts with the allergen to create a chronic inflammatory condition. In the adult form of atopic dermatitis, characteristic lesions include chronic lichenification, erythema, and scaling, the result of pruritus and scratching. The lesions are usually found on the hands, feet, or flexor surfaces of the arms and legs. Scratching and excoriation increase the risk of secondary infections, as well as invasion of the skin by viruses such as herpes simplex. Serum studies may find elevated eosinophil and IgE levels.

SEBORRHEIC DERMATITIS

Seborrheic dermatitis is a chronic inflammatory disorder of the skin that involves the scalp, eyebrows, eyelids, ear canals, nasolabial folds, axillae, and trunk. The cause is unknown. Patients taking methyldopa (generic only) for hypertension occasionally develop this disorder, which is also a component of Parkinson's disease. Seborrheic dermatitis is frequently seen in patients with AIDS.

The lesions are yellow or white plaques with scales and crusts. The scales are often yellow or orange and have a greasy appearance. Mild pruritus is also present. Diffuse dandruff with erythema of the scalp often accompanies the skin lesions.

EXFOLIATIVE DERMATITIS

Exfoliative dermatitis is an inflammatory skin disorder characterized by excessive peeling or shedding of skin. The cause is unknown in about half of all cases, but a preexisting skin disorder (such as psoriasis, atopic dermatitis, contact dermatitis, or seborrheic dermatitis) is found in up to 63% of the cases. Reactions to medications, such as sulfonamides, account for 20% to 40% of cases. Certain cancers (such as lymphoma) may also cause exfoliative dermatitis.

Both systemic and localized manifestations may appear. Systemic manifestations include weakness, malaise, fever, chills, and weight loss. Scaling, erythema, and pruritus may be localized or involve the entire body. In addition to peeling of skin, the patient may lose his or her hair and nails. Generalized exfoliative dermatitis may cause debility and dehydration. The impairment of skin integrity increases the risk for local and systemic infections.

●○● INTERPROFESSIONAL CARE

The patient with dermatitis is treated primarily with topical medications and therapeutic baths. If the dermatitis is due to hypersensitivity to an allergen, the patient avoids exposure to environmental irritants and suspected foods. The patient discontinues as many medications as possible to determine whether the dermatitis is the result of a drug allergy.

DIAGNOSIS

The diagnosis is often based on the manifestations of the disorder and on a history of exposure to a known allergen. Scratch tests and intradermal tests are used to identify a specific allergen.

MEDICATIONS

The medications used depend on the cause of the dermatitis and the severity of the manifestations. Minor cases are treated with antipruritic medications, whereas more severe cases are treated with oral antihistamines, oral and/or topical corticosteroids, and wet dressings for weeping lesions. Topical immunosuppressive modulators (tacrolimus and pimecrolimus) are effective, but the FDA has published an alert about a possible link with skin cancer and lymphoma. Topical anti-infectives may be prescribed if necessary.

●○● NURSING CARE

Nursing care of the patient with dermatitis focuses primarily on providing information for self-care at home. The patient is responsible for managing skin problems and requires education and support. Address the following topics:

- Medications and treatments do not cure the disease; they only relieve the symptoms.
- Dry skin increases pruritus, which stimulates scratching. Scratching may in turn cause excoriation, and excoriation increases the risk of infection.
- It may be necessary to change the diet or environment to avoid contact with allergens.
- When using steroid preparations, apply only a thin layer to slightly damp skin (e.g., after taking a bath).
- If occlusive dressings are necessary, a plastic suit may be used.
- When using oral corticosteroids, never abruptly stop taking the medication. Follow instructions to taper the dosage gradually.

- Advise to discuss use of topical steroids on the face for more than 2 weeks with healthcare provider to avoid adverse reactions, including steroid rosacea and steroid addiction syndrome.
- Antihistamines cause drowsiness. When using these medications, avoid alcohol and use caution when driving or working around machinery.

THE PATIENT WITH ACNE

Acne is a disorder of the pilosebaceous (hair and sebaceous gland) structure, which opens to the skin surface through a pore. Sebaceous glands are present over the entire skin surface except the soles of the feet and the palms of the hands, but the largest glands are on the face, scalp, and scrotum. The sebaceous glands, which empty directly into the hair follicle, produce sebum, a lipid substance. Sebum production is a response to direct hormonal stimulation by testicular androgens in men and adrenal and ovarian androgens in women.

Pathophysiology

Acne may be noninflammatory or inflammatory. Noninflammatory acne lesions are primarily **comedones**, more commonly called pimples, whiteheads, and blackheads. Whiteheads are pale, slightly elevated papules categorized as closed comedones. Blackheads are plugs of material that accumulate in the sebaceous glands. They are categorized as open comedones. The color is the result of the movement of melanin into the plug from surrounding epidermal cells. Inflammatory acne lesions include comedones, erythematous pustules, and cysts (Figure 16–12 ■). Inflammation close to the skin surface results in pustules; deeper inflammation results in cysts. The inflammation is believed to result from irritation by fatty acid constituents of the sebum and by substances produced by *Propionibacterium acnes* bacteria, both of which escape into the dermis when the follicular wall of closed comedones ruptures.

Several forms of acne occur at different periods of the life span. The most common are acne vulgaris, acne rosacea, and acne conglobata.

ACNE VULGARIS

Acne vulgaris is the form of acne common in adolescents and young to middle adults. The actual cause of acne vulgaris is unknown. Possible causes include androgenic influence on the sebaceous glands, increased sebum production, and proliferation of the organism *Propionibacterium acnes*. Many factors once thought to cause acne vulgaris, including high-fat diets, chocolate, infections, and cosmetics, have been disproved.

Figure 16–12 ■ Acne vulgaris lesions include comedones, erythematous pustules, and cysts.
Source: Medical-On-Line/Alamy.

FAST FACTS

Acne Vulgaris

- Acne vulgaris is the most common of all skin conditions.
- Twelve percent of women and 3% of men over the age of 25 have acne vulgaris, and the rate does not begin to decrease until after age 44.
- Scarring may be a sequelae of the disease, or may result from the patient picking and manipulating the comedones.

Mild cases may involve only a few scattered comedones, but severe cases are manifested by multiple lesions of all types. Most acne vulgaris lesions form on the face and neck, but they also occur on the back, chest, and shoulders. Women in their 30s and 40s, often with no prior acne, may develop papular lesions on the chin and around the mouth. The lesions are usually mildly painful and may itch. The complications of acne vulgaris, especially in severe cases, are formation of cysts, pigment changes in people with dark skin, severe scarring, and lowered self-concept from the skin eruptions.

ACNE ROSACEA

Acne rosacea is a chronic type of facial acne that occurs more often in middle and older adults. The cause is unknown. The lesions of acne rosacea begin with erythema over the cheeks and nose. Other skin lesions may or may not appear. Over the years, the skin color changes to dark red, and the pores over the area become enlarged. The soft tissue of the nose may exhibit rhinophyma, an irregular bullous thickening.

ACNE CONGLOBATA

Acne conglobata is another chronic type of acne of unknown cause that begins in middle adulthood. This type causes serious skin lesions: Comedones, papules, pustules, nodules, cysts, and scars occur primarily on the back, buttocks, and chest but may occur on other body surfaces. The comedones have multiple openings and a discharge that ranges from serous to purulent with a foul odor.

●○● INTERPROFESSIONAL CARE

The management of acne is similar, regardless of type. Because acne vulgaris is most common, the discussions of interprofessional and nursing care focus on that type. Treatment is based on the type and severity of the lesions.

DIAGNOSIS

The disease is diagnosed by the typical location and appearance of lesions. If the patient has pustules, a culture of the drainage is performed to differentiate viral or bacterial dermatitis from acne.

MEDICATIONS

The treatment of acne is tailored to the individual and is based on the severity of the lesions. For acne with comedones, tretinoin (retinoic acid, Retin-A) or benzoyl peroxide preparations are prescribed. Azelaic acid (Azelex) may also be used. The administration of these vitamin A analogues is discussed in the accompanying Medication Administration feature. Benzoyl peroxide preparations are found

MEDICATION ADMINISTRATION

Acne Medications

TRETINOIN (AVITA, RENOVA, RETIN-A)

- Use the cream in a test area twice at night to test for sensitivity; if no reaction occurs, increase applications gradually to the prescribed frequency.
- A pea-sized amount of the cream is enough to cover the entire face.
- Apply the cream to clean, dry skin.
- Do not apply the cream to the eyes, mouth, angles of the nose, or mucous membranes.
- Wash your face no more than two to three times a day, using a mild soap. Do not use skin preparations (such as aftershave lotion or perfumes) that contain alcohol, menthol, spice, or lime; they may irritate your skin.
- The medication may cause a temporary stinging or warm sensation but should not cause pain.
- The skin where you apply the cream will be mildly red and may peel; if you experience a more severe reaction, consult your healthcare provider.
- The medication may cause increased sensitivity to sunlight; use sunscreens and wear protective clothing when outdoors.
- Your acne may become worse during the first 2 weeks of treatment; this is an expected response.

in OTC medications such as Fostex, Acne-Dome, Desquam-X, Benzagel, Clear By Design, and Xerac BP. These products are keratolytic and loosen the comedones. Epiduo (a prescription gel) combines adapalene and benzoyl peroxide to treat acne vulgaris.

Mild forms of papular inflammatory acne are treated with topical clindamycin (Cleocin T), a bacteriostatic agent that decreases the amount of fatty acids on the skin surface. This medication may be combined with tretinoin therapy.

Moderate forms of papular inflammatory acne are treated with oral or topical antibiotics, such as tetracycline, erythromycin, and minocycline. These antibiotics are administered for 3 to 4 months; if the patient's skin is clear, the dose is lowered gradually to a maintenance dose that will maintain clear skin.

TREATMENTS

Acne scars may alter the individual's self-concept. The scars may be removed by dermabrasion and laser treatment. (Dermabrasion is discussed in greater detail later in this chapter.)

●○● NURSING CARE

Nursing care is individualized and is conducted primarily through teaching in clinics or healthcare provider offices. Regardless of the patient's age or gender, the nurse should remember that almost all patients with acne are embarrassed by and self-conscious of their appearance. Prior to teaching, establish rapport with the patient and clarify beliefs; for example, the patient may believe the lesions result from poor hygiene, masturbation, use of cosmetics, eating the wrong types of foods, or lack of sexual activity. It is critical to teach the patient about the causes of and factors involved in acne prior to teaching self-care.

The teaching plan for the patient with acne includes general guidelines for skin care and health as well as specific guidelines for care of the acne lesions. The following topics should be addressed:

- Wash the skin with a mild soap and water at least twice a day to remove accumulated oils.
- Shampoo the hair often enough to prevent oiliness.
- Eat a regular, well-balanced diet. Foods do not cause or increase acne.
- Expose the skin to sunlight, but avoid sunburn.
- Get regular exercise and sleep.
- Try to avoid putting your hands on your face.
- Do not squeeze a pimple. Squeezing forces the material of the pimple deeper into the skin and may cause the pimple to become larger and infected.
- The treatment for acne lasts months, in some cases for the rest of one's life. It is very important to take the medications each day for the prescribed length of time.

THE PATIENT WITH PEMPHIGUS VULGARIS

Pemphigus vulgaris is a chronic disorder of the skin and oral mucous membranes characterized by blister formation. The disease is caused by autoantibodies that cause acantholysis (the separation of epidermal cells from one another). The disorder is associated with IgG antibodies and HLA-A10 antigen. Septicemia from an infection of *Staphylococcus aureus* is the most common cause of death. The disease occurs in middle and older adults of all races and ethnic backgrounds. The disorder has been associated with other autoimmune disorders and with the administration of certain drugs, such as penicillamine and captopril.

The blisters that form in pemphigus vulgaris usually appear first in the mouth and on the scalp and then spread in crops or waves to involve large areas of the body, including the face, back, chest, umbilicus, and groin. The blisters form in the epidermis and cause the epidermal cells to separate above the basal layer. These blisters rupture, leaving denuded skin, crusting, and oozing of fluid with a musty odor. The lesions are painful. Pressure on a blister causes it to spread to adjacent skin (Nikolsky's sign). The loss of fluid from the blisters may result in fluid and electrolyte imbalances. Secondary bacterial infections are a serious risk.

●○● INTERPROFESSIONAL CARE

The goals of treatment are to control the severity of the disease, to prevent infection and loss of fluids, and to promote healing. Patients who experience severe attacks or secondary infections are usually hospitalized. Although the disease cannot be cured, the manifestations can be controlled.

DIAGNOSIS

Pemphigus vulgaris is diagnosed by manifestations and diagnostic tests, including immunofluorescence microscopy, which is done to identify the presence of IgG antibodies in the epidermis and serum,

and skin biopsy (refer to Chapter 15) to determine the presence of acantholysis.

MEDICATIONS

Early lesions are treated with highly potent topical corticosteroids. As the disease becomes more severe, systemic corticosteroids or immunosuppressive agents (such as azathioprine or methotrexate) are prescribed. Secondary infections are treated with topical and/or systemic antibiotics.

TREATMENTS

Plasmapheresis is occasionally used to treat pemphigus. In this procedure, the plasma is selectively removed from whole blood and donor plasma is reinfused into the patient. This decreases the serum level of antibodies for a period of time. Plasmapheresis with related nursing care is discussed in Chapter 44.

●○● NURSING CARE

The hospitalized patient with pemphigus requires careful assessment of skin lesions and monitoring for manifestations of infection. Provide skin care through bathing and applying dressings to denuded areas, using aseptic technique to prevent infection. The patient may be placed on reverse isolation as a protective measure. Monitor the patient's hydration status to prevent a fluid volume deficit and incorporate pain medications and noninvasive pain management techniques in the plan of care. Oral lesions often make eating difficult; the patient requires meticulous oral hygiene and nonirritating foods. The patient often is depressed and fearful; establishing a therapeutic relationship is essential, and referrals for counseling may be necessary.

Teaching the patient and family how to provide care at home involves skin care, oral care, diet, pain management, prevention of infection, and how to take prescribed medications. A referral to a home health agency or local health department may be necessary.

THE PATIENT WITH LICHEN PLANUS

Lichen planus is an inflammatory disorder of the mucous membranes and skin. It has no known cause but has been associated with exposure to drugs or to film processing chemicals. The disease affects adults of all ages.

The lesions first appear as violet papules, 2 to 10 mm in size, commonly occurring on the wrists, ankles, lower legs, and genitals. The lesions itch intensely. Over time, persistent lesions thicken and become dark red, forming hypertrophic lichen planus. Lesions on the oral mucous membranes appear as white, lacey rings; lesions may also appear on the mucous membranes of the vaginal area and the penis. The nails become thin and may shed.

Lichen planus lesions are self-limiting but last for an average of 12 to 18 months. The disorder is diagnosed by manifestations. Corticosteroids are used to control the inflammation, and antihistamines are used to control the pruritus.

Malignant Skin Disorders

The skin, despite its ability to protect the internal body from external damage, is a fragile organ and is subject to damage from ultraviolet radiation and chemicals. Over time, this damage results in alterations in cellular structure and function, and malignancies of the skin occur. Many of these lesions are found on skin surfaces that have undergone long-term exposure to the sun or the environment. Malignant skin tumors are the most common of all cancers.

FAST FACTS

Skin Cancer

- One in five Americans will develop skin cancer in the course of a lifetime.
- Tanning beds are considered a proven cancer-causing agent.
- Up to 90% of skin changes visible with aging are caused by the sun.

Source: (American Cancer Society [ACS], 2013; Skin Cancer Foundation, 2014).

THE PATIENT WITH ACTINIC KERATOSIS

Actinic keratosis, also called senile or solar keratosis, is an epidermal skin lesion directly related to chronic sun exposure and photodamage. The prevalence is highest in people with light-colored skin; these lesions are rare in people with dark skin. About 20% of actinic keratoses convert to squamous cell carcinoma (Huether & McCance, 2011). However, there is some thought that the lesions are all premalignant.

The lesions are erythematous rough macules a few millimeters in diameter. They are often shiny but may be scaly; if the scales are removed, the underlying skin bleeds. They occur in multiple patches, primarily on the face, dorsa of the hands, the forearms, and sometimes on the upper trunk (Figure 16–13 ■). Enlargement or ulceration of the lesions suggests transformation to malignancy. The lesions are usually treated by cryosurgery (freezing) or with 5-fluorouracil (5-FU) cream, which erodes the lesions.

THE PATIENT WITH NONMELANOMA SKIN CANCER

The nonmelanoma skin cancers are basal cell cancer and squamous cell cancer. Other types of nonmelanoma skin cancers, accounting for less than 1% of cases (ACS, 2013), are Merkel cell carcinoma; Kaposi's sarcoma; and lymphomas, sarcomas, and adnexal tumors of the skin. These uncommon tumors are not included in this discussion, but information can be found on the American Cancer Society website or the National Cancer Institute website.

Incidence

Nonmelanoma skin cancer is the most common malignant neoplasm found in fair-skinned Americans. The ACS (2012b) estimates that more than 2 million new cases of nonmelanoma skin cancer are diagnosed in the United States each year. Of that number, about 80% are basal cell cancers and 20% are squamous cell cancers. Deaths from nonmelanoma skin cancer have dropped by 30% in the past 30 years. Men develop nonmelanoma skin cancer more often than do women, probably because of occupational exposures. Although nonmelanoma skin cancer may occur at any age, the incidence increases with

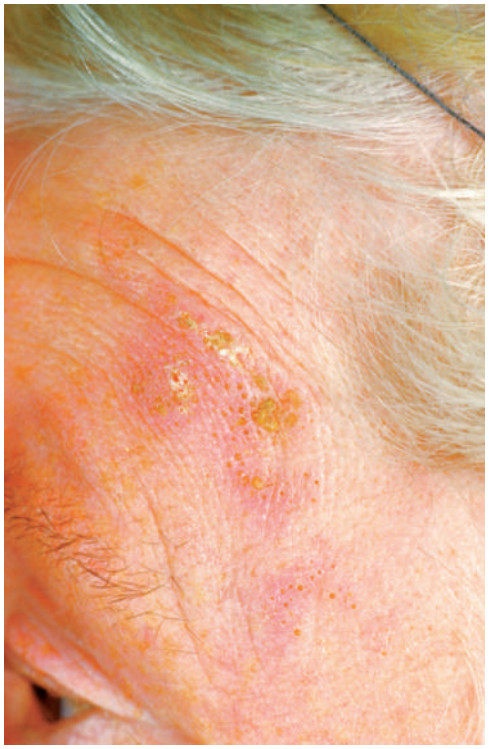

Figure 16–13 ■ The effects of long-term sun exposure are illustrated in this epidermal skin lesion, called actinic keratosis.
Source: Medical-On-Line/Alamy.

each decade of life. Adults between the ages of 30 and 60 have the majority of these cancers.

Risk Factors

Multiple etiologic factors are involved in the development of nonmelanoma skin cancer, including environmental factors and host factors.

FAST FACTS

Risk Factors for Nonmelanoma Skin Cancer

- Fair skin, freckles, blue or green eyes, and blond or red hair
- Family history of skin cancer
- Unprotected and/or excessive exposure to UV radiation (natural or artificial)
- Occupational exposures to coal tar, pitch, creosote, arsenic compounds, or radium
- Severe sunburns as a child

ENVIRONMENTAL FACTORS

Ultraviolet radiation (UVR) from the sun is believed to be the cause of most nonmelanoma skin cancers. Sunlight contains both short-length rays (UVB) and long-length rays (UVA). UVB rays are absorbed by the top layer of skin and cause sunburn. UVA rays penetrate deeper into the skin layers, causing tissue damage. Both types of rays cause DNA alterations and suppress T-cell and B-cell immunity, allowing cancer cells to grow. Researchers have also discovered that many skin cancers contain changes in tumor suppressor genes (these genes normally help keep cells from growing out of control). The damaged gene found in basal cell cancer is *p53*, a gene that normally causes damaged cells to die. The damaged gene found in squamous cell cancer is the "patched" (*PTCH*) gene, which normally helps keep cell growth in check (ACS, 2014).

The amount of UVR reaching the earth is increasing, most likely from depletion of the ozone layer surrounding the planet. The U.S. Environmental Protection Agency predicts that for every 1% decrease in the ozone layer, a corresponding 1% to 3% increase per year in nonmelanoma skin cancer will occur.

Geographic, environmental, and lifestyle factors affect the amount of exposure to the sun and the risk for nonmelanoma skin cancer. People who live in latitudes close to the equator and those who live at higher altitudes receive greater UVR exposure. The amount of clothing worn, the time of day, and amount of time in the sun also determine the amount of exposure. Exposure to UVR in tanning booths is also implicated in the development of nonmelanoma skin cancer.

Certain chemicals have long been associated with nonmelanoma skin cancer. Polycyclic aromatic hydrocarbons, found in mixtures of coal, tar, asphalt, soot, and mineral oils, have been linked with skin cancers. Psoralens, used in conjunction with UVA for treatment of psoriasis and cutaneous T-cell lymphoma, increase the risk of squamous cell cancer. Other factors associated with nonmelanoma skin cancer are the use of ionizing radiation, viruses, and physical trauma. X-ray therapy for tinea capitis and the use of radium to treat other malignancies are risk factors. Human papillomavirus is implicated in the development of squamous cell cancer, as is damage to the skin from burns. Organ transplant recipients who undergo immunosuppression to prevent rejection are also at risk for the development of squamous cell cancer.

HOST FACTORS

Skin pigmentation is an important factor in the development of nonmelanoma skin cancer. The amount of melanin pigment produced by the melanocytes determines a person's skin color. The more melanin, the more the skin is protected from the damage produced by ultraviolet rays. Thus, Asians and people of African and Mediterranean descent have a much lower incidence of nonmelanoma skin cancer than do people who have fair complexions and tend to freckle or sunburn easily, such as people of Irish, Scandinavian, or English ancestry.

Although most people have numerous pigmented lesions on their body, almost all of these are normal. However, a major risk factor in the development of nonmelanoma skin cancer is a change in an existing lesion or the presence of a premalignant lesion, such as actinic keratosis.

Pathophysiology

Basal cell cancer and squamous cell cancer arise from epithelial tissue but have different pathophysiology, classifications, and manifestations. These cancers are classified as keratinocyte cancers; when viewed under a microscope they share some features with keratinocytes, the most abundant skin cell type.

BASAL CELL CANCER

Basal cell cancer is an epithelial tumor believed to originate either from the basal layer of the epidermis or from cells in the surrounding dermal structures. These tumors are characterized by an impaired ability of the basal cells of the epidermis to mature into keratinocytes, with mitotic division beyond the basal layer. This results in a bulky tumor that grows by direct extension and, if untreated, destroys surrounding tissue, including healthy skin, nerves, blood vessels, lymphatic tissue, cartilage, and bone. Basal cell cancer is the most

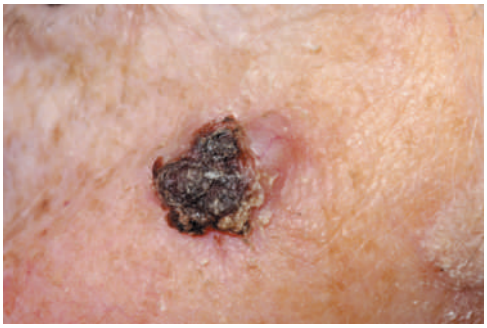

Figure 16–14 ■ A superficial basal cell cancer is characterized by erythema, ulcerations, and well-defined borders.

common but least aggressive type of skin cancer, rarely metastasizing. Although once seen only in middle to older adults, it is now being seen in younger people, probably due to increased sun exposure.

Basal cell cancers tend to recur. Tumors greater than 2 cm in diameter have a high recurrence rate. Predisposing factors for metastasis are the size of the tumor and the patient's resistance to treatment with surgery or chemotherapy. Even though they rarely metastasize, untreated basal cell cancers invade surrounding tissue and may destroy body parts, such as the nose or eyelid. Basal cell cancer is classified as nodular, superficial, pigmented, morpheaform, or keratotic.

Nodular basal cell cancer, the most common type of basal cell cancer, most often appears on the face, neck, and head. The tumor is made up of masses of cells that resemble epidermal basal cells and grow in a bulky, nodular form from lack of keratinization. In early stages, the tumor is a papule that looks like a smooth pimple. It is often pruritic and continues to grow at a steady rate, doubling in size every 6 to 12 months. As the tumor grows, the epidermis thins, but it remains intact. The skin over the tumor is shiny, pearly white, pink, or flesh colored. Telangiectasis may be visible over the area of the tumor. As the tumor continues to increase in size, the center or periphery may ulcerate, and the tumor develops well-circumscribed borders. It bleeds easily from mild injury.

Superficial basal cell cancer, found most often on the trunk and extremities, is the second most common type of basal cell cancer. This tumor is a proliferating tissue that attaches to the undersurface of the epithelium. The tumor is a flat papule or plaque, often erythematous, with well-defined borders. The tumor may ulcerate and be covered with crusts or shallow erosions (Figure 16–14 ■).

Pigmented basal cell cancer, found on the head, neck, and face, is less common. This tumor concentrates melanin pigment in the center of the basal cancer cells, giving it a dark brown, blue, or black appearance. The border of the tumor is shiny and well defined.

Morpheaform basal cell cancer, the rarest form of basal cell cancer, usually develops on the head and neck. The tumor forms finger-like projections that extend in any direction along dermal tissue planes. The tumor resembles a flat ivory or flesh-colored scar. This form is more likely to extend into and destroy adjacent tissue, especially muscle, nerve, and bone. It is often more difficult to diagnose than other types of basal cell cancer because of its appearance.

Keratotic basal cell cancer (basosquamous) is found on the preauricular and postauricular groove. It contains both basal cells and squamoid-appearing cells that keratinize. Its appearance is much like that of nodular basal cell cancer. This type of basal cell cancer tends to recur locally and also is the type most likely to metastasize.

Figure 16–15 ■ As a squamous cell cancer grows, it tends to invade surrounding tissue. It also ulcerates, may bleed, and is painful.

SQUAMOUS CELL CANCER

Squamous cell cancer is a malignant tumor of the squamous epithelium of the skin or mucous membranes. It occurs most often on areas of skin exposed to ultraviolet rays and weather, such as the forehead, helix of the ear, top of the nose, lower lip, and back of the hands. Squamous cell cancer may also arise on skin that has been burned or has chronic inflammation. This is a much more aggressive cancer than basal cell cancer, with a faster growth rate and a much greater potential for metastasis if untreated. The tumors arise when the keratinizing cells of the squamous epithelium proliferate, producing a growth that eventually fills the epidermis and invades the dermal tissue planes. Keratinization of some cells is present, and the formation of keratin "pearls" is common. The keratin formation diminishes as the tumor grows. As the tumor grows, the tumor cells increase in number and rate of mitosis, forming odd shapes. An early form of squamous cell cancer is called Bowen's disease or cancer in situ.

Squamous cell cancer begins as a small, firm red nodule. The tumor may be crusted with keratin products. As it grows, it may ulcerate, bleed, and become painful. As the tumor extends into the surrounding tissue and becomes a nodule, the area around the nodule becomes indurated (hardened) (Figure 16–15 ■).

Recurrent squamous cell cancer can be invasive, increasing the risk of metastasis. Invasive squamous cell cancer may arise from preexisting skin lesions, such as scars and actinic keratosis, and extend into the dermis (called intraepidermal squamous cell cancer). This form appears as a slightly raised erythematous plaque with well-defined borders. Metastasis occurs most often via the lymphatics. The degree of risk for metastasis depends on the size and depth of penetration of the tumor.

●○● INTERPROFESSIONAL CARE

Treatment of nonmelanoma skin cancer focuses on removal of all malignant tissue using such methods as surgery, curettage and electrodesiccation, cryotherapy, or radiotherapy. These modalities offer a greater than 90% cure rate. After the malignant tissue is removed, the patient should have regular examinations for recurrence.

DIAGNOSIS

Nonmelanoma cancer is diagnosed by microscopic examination of tissue biopsied from the tumor. The biopsy is usually done as an office procedure under local anesthesia. The types of biopsy used are shave, punch, incisional, and excisional. Information about skin biopsy is provided in Chapter 15.

TREATMENTS

Depending on the stage, type, size, and location of a nonmelanoma cancer, it may be treated with surgical excision, Mohs' surgery, curettage and electrodessication, radiation, or other forms of local therapy.

SURGICAL EXCISION Both basal cell and squamous cell cancers are excised surgically. The surgery may be minor or major, depending on the size and location of the tumor. Surgery for small tumors is most often performed in the outpatient surgery department or in the surgeon's office. Surgical excision allows rapid healing and yields good cosmetic results.

The goal of surgical excision is to remove the tumor completely, so some surrounding tissue is excised along with the tumor. If the tumor is on the face, the incision is made along normal wrinkle or anatomic lines so that the scars will be less obvious. The incision is closed in layers to leave the smallest possible scar. A pressure dressing is usually applied over the incision to provide support. If a large tumor is removed, a skin graft or skin flap may be performed to cover the excised area. If grafting is necessary, the patient is hospitalized.

MOHS' SURGERY In Mohs' surgery, thin layers of the tumor are horizontally shaved off. A frozen section of the tissue is stained at each level to determine tumor margins. This method is the most accurate in assessing the extent of nonmelanoma skin cancer and the method that conserves the most normal tissue. It is often used in areas such as the nose, the nasolabial fold, the medial canthus, and the ear.

CURETTAGE AND ELECTRODESICCATION Curettage and electrodesiccation are used to treat basal cell cancers that are less than 2 cm in diameter, are superficial, or recur because of poor margin control. This treatment may also be used for primary squamous cell cancers that are less than 1 cm in diameter and have distinct borders. This type of treatment is most successful for tumors on anatomic sites over a fixed underlying surface, such as the ear, chest, and temple.

Abnormal tissue is scraped away (curettaged) within 1 to 2 mm of the margin and then a low-voltage electrode is used to abrade the tumor base (electrodesiccation). Curettage and electrodesiccation is not used for lesions where the dermis is thin (such as the eyelid) or where the tumor extends into the subcutaneous tissue. This treatment provides good cosmetic results and preserves normal tissue. However, healing time is longer, and it is difficult to ensure that all tumor margins have been removed.

Instead of a low-voltage electrode, some physicians use a carbon dioxide laser to vaporize the tumor. When used in conjunction with curettage, this treatment is effective on superficial basal cell cancers. Carbon dioxide vaporization results in minimal thermal injury to adjacent cells, less pain, and quicker healing.

RADIATION THERAPY Radiation is most often used for lesions that are inoperable because of their location (such as tumors on the corner of the nose, the eyelid, the canthus, and the lip) or size (between 1 and 8 cm). It is also used for patients who are older and of poor surgical risk. Radiation is painless and can be used to treat areas surrounding the tumor if necessary. However, the treatment is given over 3 to 4 weeks in a clinical facility, does not allow control of tumor margins, and may itself cause skin cancer.

OTHER FORMS OF LOCAL THERAPY Other forms of local therapy include the following:

- *Cryosurgery* involves applying liquid nitrogen to the tumor to freeze and kill abnormal cells.
- *Photodynamic therapy* (PDT) involves administering a topical or injectable chemical that collects in the tumor cells and makes them more sensitive to light. A light source is then focused on the tumor and the cells die.
- *Topical chemotherapy* means that an anticancer drug (usually 5-FU) is applied as a cream directly on the skin to kill the tumor cells.
- Immune response modifiers cause an immune response to the cancer, causing it to decrease in size and die. The drugs used are imiquimod (Aldara) (a topical cream) and interferon (injected directly into the tumor).
- Laser surgery uses laser light to vaporize cancer cells.

●○● NURSING CARE

The increasing number of people with skin cancer means that nurses must be involved in prevention and early detection. Nurses have the opportunity to teach preventive behaviors in all settings, including the hospital, home, community, school, and clinic.

Nursing care for the patient with nonmelanoma skin cancer depends on the treatment used. Surgical excision is the most common form of treatment; nursing care depends on the extent of the procedure. However, regardless of the type of treatment, the patient will have impaired skin integrity, an increased risk for infection, and anxiety about the future following a diagnosis of cancer. Interventions with rationales for the patient with any type of skin cancer are discussed in the later section on melanoma.

Health Promotion

It is well known that cumulative sun exposure positively correlates with nonmelanoma skin cancers. Many skin cancers can be prevented by limiting exposure to risk factors. Primary prevention behaviors recommended by the ACS and the Skin Cancer Foundation are outlined in Box 16–5. In addition to these preventive behaviors, the ACS recommends the "Slip! Slop! Slap! Wrap!" method: **slip** on a shirt, **slop** on 15 SPF (or higher) sunscreen, **slap** on a hat, and **wrap** on sunglasses before exposure to the sun. Information about sunscreens is given in Box 16–6.

Nurses also provide patient and family education for early detection of nonmelanoma skin cancer. Numerous brochures describing the types of skin cancers, photographs of lesions, and prevention behaviors are available from the ACS, health education and support agencies, and pharmaceutical companies that manufacture sunscreen. Most of this literature is free.

The patient or family at risk for or diagnosed with a skin cancer must be taught how to conduct a self-examination of the skin, described in Box 16–7, as well as the importance of conducting

BOX 16–5 Health Promotion: Preventing Skin Cancer

- Minimize sun exposure between the hours of 10 A.M. and 3 P.M., when ultraviolet rays are the strongest.
- Cover up with a wide-brimmed hat, sunglasses, long-sleeved shirt, and long pants made of tightly woven materials when in the sun.
- Apply a waterproof or water-resistant sunscreen with an SPF of 15 or more at least 30 minutes before every exposure to the sun. If swimming or sweating heavily, reapply every hour. Apply sunscreen not only on sunny days but also on cloudy days (when ultraviolet rays can penetrate 70% to 80% of the cloud cover).
- Adequate sunscreen to achieve SPF is 2 mg per square centimeter of skin. This is about 2 tablespoons to exposed face and body, or about a nickel-sized amount for the face alone (Skin Cancer Foundation, 2014).
- Use sunscreen and protective clothing when you are on or near sand, snow, concrete, or water (which can reflect more than 50% of the ultraviolet rays onto your skin).
- Avoid tanning booths; UVR emitted by tanning booths damages the deep skin layers.

BOX 16–6 Sunscreen Information

TYPES OF SUNSCREEN

Chemical

Chemical sunscreens absorb ultraviolet light and act as a radiation filter. Examples follow:

- *p*-Aminobenzoic acid (PABA)
- Benzophenones
- Anthranilates
- Salicylates.

Physical

Physical sunscreens reflect and scatter ultraviolet light. Examples follow:

- Zinc oxide
- Titanium dioxide
- Magnesium silicate
- Ferric chloride
- Kaolin
- Ichthyol.

Adverse Reactions Associated with Sunscreens

Adverse reactions associated with sunscreens include contact and photocontact dermatitis. People with previous hypersensitivity reactions to benzocaine, procaine, sulfonamides, or paraphenylenediamine may develop hypersensitivity responses to PABA. People who are also taking systemic thiazide diuretics or sulfonamides may develop eczematous dermatitis.

Sunscreen Ratings

In the United States, the FDA rates commercial sunscreens according to their sun protection factor, or SPF. The SPF value is the ratio of the time required to produce minimal skin redness through a sunscreen product to the time required to produce the same degree of redness without the sunscreen. A person who can tolerate 1/2 hour of sun without a sunscreen should be able to tolerate 3 hours of sun when a sunscreen of SPF 6 is applied to the skin. SPF values of sunscreens range from 2 to 100. An SPF of 15 or greater is recommended.

the examination on the same day of each month. Family members can help with areas that are hard to examine, such as the ears, scalp, and back.

BOX 16–7 Health Promotion: Skin Self-Examination

1. Choose the same day each month (such as the first day) to do the examination.
2. The best time to do the examination is after you take a bath or shower. Examine yourself in a well-lighted room in front of a full-length mirror. Have a hand mirror, a chair, and a hair dryer available. If you have difficulty seeing your back and scalp (or any other parts of your body), ask someone to help you.
3. Follow the same pattern with each examination:

Examine head and face, using one or both mirrors. Use blow dryer to inspect scalp.

Check hands, including nails. In full-length mirror, examine elbows, arms, underarms.

Focus on neck, chest, torso. Women: Check under breasts.

With back to the mirror, use hand mirror to inspect back of neck and back including buttocks.

Sitting down, check legs and feet, including soles, heels, and nails. Use hand mirror to examine genitals.

Continuity of Care

Teach the patient and family specific measures for self-care following surgery, including the following information:

- How and when to change dressings
- The use of aseptic technique and careful hand hygiene when caring for the wound
- Symptoms to report (such as bleeding, fever, or signs of wound infection), and how to protect the operative site against trauma and irritations.

THE PATIENT WITH MELANOMA

Melanoma (**malignant melanoma**) arises from melanocytes. This serious skin cancer is increasing in incidence each year. Melanoma accounts for less than 5% of skin cancers, but it causes a large majority of skin cancer deaths (ACS, 2012b).

Incidence

This disease is over 10 times more common in fair-skinned people than in dark-skinned people. It is slightly more common in men than in women. Melanoma occurs more often in people who live in sunny climates, burn easily, and patronize tanning parlors. However, it may arise from already present lesions or from skin normally covered with clothing. Melanoma occurs in a wide age range, from adolescents to older adults, with the greatest rates in those over the age of 80.

Risk Factors

Although the exact cause of melanoma is unknown, it is known that certain risk factors are associated with the disease. The risk factors for melanoma are listed in Box 16–8.

Pathophysiology

Melanomas arise from melanocytes, cells located at or near the basal layer (the deepest epidermal layer). These cells produce melanin, the dark skin pigment. Melanin is made in granules and transferred to keratinocytes, where it accumulates on the superficial side of each keratinocyte and forms a shield of pigment over the nucleus as protection against ultraviolet rays. Melanomas can develop wherever there is pigment, but about one-third of them originate in existing nevi (moles).

Almost all melanomas are more than 6 mm in diameter, are asymmetric, and initially develop within the epidermis over a long period. While they are still confined to the epidermis, the lesions (called melanoma in situ) are flat and relatively benign. However, when they penetrate the dermis, they mingle with blood and lymph vessels and are capable of metastasizing. At this latter stage, the tumors develop a raised or nodular appearance and often have smaller nodules, called satellite lesions, around the periphery.

The prognosis for survival for people diagnosed with melanoma is determined by several variables, including location of tumor, tumor thickness, ulceration, metastasis, site, age, and gender. Younger patients and women have a somewhat better chance of survival. Patients with tumors on the scalp and neck have a lower survival rate.

BOX 16–8 Risk Factors for Melanoma Skin Cancer

- A high number of moles, or large moles
- Fair skin, freckling, blond hair, or blue eyes
- Close relative with the disease
- Men with gene changes from a family history of breast or ovarian cancer
- Treatment with medications that suppress the immune system
- Too much exposure to UV radiation from sunlight, tanning lamps, or tanning booths
- Over age 50
- Xeroderma pigmentosus, a rare inherited disease in which people are less able to repair damage caused by sunlight
- Past history of melanoma

PRECURSOR LESIONS

The three specific precursor lesions for the development of melanoma are congenital nevi, dysplastic nevi, and lentigo maligna. A precursor lesion is also called a premalignant lesion, a name that indicates that the lesion's risk of becoming malignant is greater than normal.

CONGENITAL NEVI Congenital nevi are present at birth. Some lesions are small; others are large enough to cover an entire body area. Their color can range from brown to black. They are often slightly raised, with an irregular surface and a fairly regular border.

DYSPLASTIC NEVI Dysplastic nevi are also called atypical moles. Although dysplastic nevi are not present at birth, they appear as normal nevi during childhood and become dysplastic (having abnormal development) after puberty. A patient with classic dysplastic nevi has more than 100 nevi, at least one of which is larger than 8 mm in diameter, and at least one of which has the characteristics of melanoma (asymmetry, irregular border, color variegation, and a diameter greater than 6 mm). A familial tendency to dysplastic nevi increases the risk for the development of melanoma. Having many moles, whether normal or atypical, is a risk factor for melanoma.

Dysplastic nevi most often appear on the face, trunk, and arms but also are seen on the scalp, female breast, groin, and buttocks. The pigmentation of the nevi is irregular, with mixtures of tan, brown, black, red, and pink, where an area of lighter pigmentation is surrounded by a papular area of deeper pigmentation (described as a "fried egg appearance"). The borders of the nevi are irregular.

LENTIGO MALIGNA Lentigo maligna, also called Hutchinson's freckle, is a tan or black patch on the skin that looks like a freckle. It grows slowly, becoming mottled, dark, thick, and nodular. It is usually seen on one side of the face of an older adult who has had a large amount of sun exposure.

CLASSIFICATION

Melanomas are classified into different types. The major types are superficial spreading melanoma, lentigo maligna melanoma, nodular melanoma, and acral lentiginous melanoma. Each of these tumors is characterized by a radial and/or vertical growth phase. During the initial radial phase, which may last from 1 to 25 years (depending on the type), the melanoma grows parallel to the skin surface. During this phase, the tumor rarely metastasizes and is often curable by surgical excision. However, during the vertical growth phase, atypical melanocytes rapidly penetrate into the dermis and subcutaneous tissue, greatly increasing the risk for metastasis and death.

SUPERFICIAL SPREADING MELANOMA Superficial spreading melanoma is the most common type, comprising 70% to 80% of all melanomas (Huether & McCance, 2011). The lesions are usually flat and scaly or crusty and are about 2 cm in diameter. They often arise from a preexisting nevus. This type of melanoma is found on the trunk and back of men and on the legs of women. Superficial spreading melanomas occur more often in women than in men. The median age of occurrence is the 50s.

The radial growth phase lasts from 1 to 5 or more years. When the lesion enters the vertical growth phase, it grows rapidly, and its color changes from a mixture of tan, brown, and black to a characteristic

Figure 16–16 ■ Malignant melanoma is a serious skin cancer that arises from melanocytes.

red, white, and blue. The lesion also develops irregular borders and often has raised nodules and ulcerations (Figure 16–16 ■).

LENTIGO MALIGNA MELANOMA Lentigo maligna melanoma often arises from the precursor lesion, lentigo maligna. The lesions are large and tan with different shades of brown. This type of melanoma makes up 5% to 10% of malignant melanomas and is the least serious form (Huether & McCance, 2011). It occurs on skin that has had long-term sun exposure, such as the face, neck, and sometimes the dorsal surface of the hands and lower extremities. Lentigo maligna melanoma affects women more than men. It is typically diagnosed in people in their 60s and 70s.

Lentigo maligna melanoma is characterized by a proliferation of atypical melanocytes parallel to the basal layer of the epidermis. The radial growth phase may last from 10 to 25 years, with the lesion growing to as large as 10 cm. The lesion becomes malignant as soon as the melanocytes invade the dermis. In the vertical growth phase, raised nodules may appear on the surface of the lesion. The lesion tends to acquire a freckled or mottled appearance.

NODULAR MELANOMA Nodular melanoma lesions are raised, dome-shaped, blue-black or red nodules on areas of the head, neck, and trunk that may or may not have been exposed to the sun. The lesions may look like a blood blister, or they may ulcerate and bleed. The lesions arise from unaffected skin rather than from a preexisting lesion. This type makes up 10% to 15% of malignant melanomas and is often diagnosed in people in their 50s (Huether & McCance, 2011).

Nodular melanoma has only a vertical growth phase, but it grows aggressively during that phase. However, the absence of a radial growth phase makes this type more difficult to diagnose before it metastasizes.

ACRAL LENTIGINOUS MELANOMA Acral lentiginous melanoma, also called mucocutaneous melanoma, is less common in people with fair skin and more common in people with dark skin. The lesions progress from tan, brown, or black flat lesions to elevated nodules and are about 3 cm in diameter. The radial phase lasts from 2 to 5 years, and the lesions are found on the palms of the hands, soles of the feet, the mucous membranes, and the nail beds. Acral lentiginous melanoma affects both men and women equally and is most often diagnosed in people in their 50s and 60s.

●○● INTERPROFESSIONAL CARE

The management of the patient with melanoma begins with identification, diagnosis, and tumor staging. If treatable, the tumor is removed through surgical excision. Melanoma is also treated with chemotherapy, immunotherapy, and radiation therapy. Other therapies used with success include biologic therapies with interleukin-2 and interferon and therapeutic vaccines containing melanoma antigens.

IDENTIFICATION

Melanoma is most often found on the trunk of men and on the lower extremities of women. Nevertheless, it is important for the patient to have a complete physical examination and total skin assessment. In addition to a visual examination of all skin surfaces, palpation of regional lymph nodes, the liver, and the spleen is essential to assess for metastasis when a melanoma is suspected or found.

A change in the color or size of a nevus is reported in 70% of people diagnosed with a melanoma. The ABCDE rule is used to assess suspicious lesions.

FAST FACTS

The ABCDE Rule + The Ugly Duckling Sign

Using the ABCDE rule to assess for melanoma:

A = asymmetry (one half of the nevus does not match the other half)
B = border irregularity (edges are ragged, blurred, or notched)
C = color variation or dark black color
D = diameter greater than 6 mm (size of a pencil eraser)
E = evolving or changing

The Ugly Duckling Sign = a mole that looks or feels different than other moles, or changes differently over time than other moles

DIAGNOSIS

In addition to biopsy of any suspicious lesion, diagnostic tests are conducted to determine whether the tumor has metastasized. Because malignant melanoma may metastasize to any organ or tissue of the body, a variety of tests may be conducted, including microscopic examination, biopsy, and tests for metastasis (liver function tests and CT scan of the liver, a complete blood count, serum blood chemistry profile, chest x-ray, bone scan, and CT scan or MRI of the brain).

MICROSTAGING

The term *microstaging* describes the assessment of the level of invasion of a malignant melanoma and the maximum tumor thickness. In one method, the Clark system of microstaging, the vertical growth of the lesion is measured from the epidermis to the subcutaneous tissue to determine the level of invasion (Figure 16–17 ■).

TREATMENTS

Surgical excision is the preferred treatment for malignant melanoma. Other methods of treatment include chemotherapy (see Chapter 14), immunotherapy, radiation therapy, and biologic therapy.

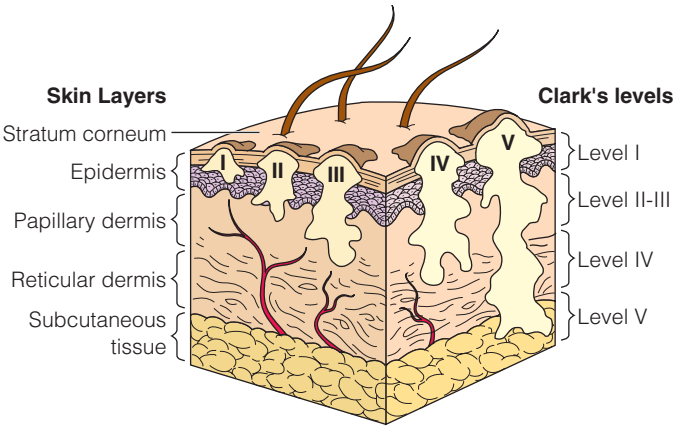

Figure 16–17 ■ Clark's levels for staging measure the invasion of a melanoma from the epidermis to the subcutaneous tissue.

SURGERY If a biopsy identifies the lesion as a melanoma, a wide excision is performed that includes the full thickness of the skin and subcutaneous tissue. Regional lymph nodes are the most common sites for metastasis of melanoma. Standard surgical treatment for clinically suspicious lymph node involvement includes excision of the primary lesions as well as surgical dissection of the involved lymph nodes. Surgery also is indicated for palliative management of isolated metastasis. Removal of metastatic tumors in the brain, liver, lung, gastrointestinal tract, or subcutaneous tissue may relieve symptoms and prolong life. (See the Case Study & Nursing Care Plan on page 418.)

IMMUNOTHERAPY Immunotherapy is a relatively new treatment modality for melanoma. The role of the immunologic response initially was recognized because of the numerous spontaneous remissions seen in patients with melanoma—a higher occurrence than with any other adult tumor. In addition, researchers have recently identified tumor-specific antigen–antibodies in patients with melanoma.

Agents such as interferons, interleukins, monoclonal antibodies, bacille Calmette-Guérin (BCG), levamisole, transfer factors, and tumor vaccines have shown activity in melanoma, with varying response rates. The effectiveness of these agents, used either alone, in combination with chemotherapy, or in combination with each other, is under investigation. The use of immunotherapy in the treatment of melanoma is still new and requires further investigation.

RADIATION THERAPY Melanoma responds to higher dose radiation, especially if the tumor is small. Response rates to radiation therapy depend on the site of the tumor, the thickness of the tumor, the type of melanoma, and the patient's general health, but may range from 0% to 71%. Radiation frequently is used for palliation of symptoms resulting from metastasis to the brain, bone, lymph nodes, gastrointestinal tract, skin, or subcutaneous tissue. Liver and lung metastases are not treated with radiation therapy because a loss of organ function may result.

BIOLOGIC THERAPY Biologic therapy is used to boost or restore the ability of the immune system to fight the cancer. Agents used include the monoclonal antibodies, growth factors, and vaccines. These agents may also have a direct antitumor effect.

NEW METHODS OF TREATMENT Melanoma skin cancer research is ongoing and directed toward more specific methods of diagnosis and treatment. Examples are as follows:

- ***Gene therapy:*** Clinical trials are in progress to test the effectiveness of adding certain genes to the malignant cells.
- ***Melanoma DNA research:*** Genes such as *CDKN2A* (also known as *p16*) have been found to be mutated in some families with a high rate of melanoma.
- ***Staging:*** Very sensitive new tests can better detect the spread of melanoma to lymph nodes and can possibly better identify people who could be helped by a treatment such as immunotherapy after surgery.

●○● NURSING CARE

Nurses have the opportunity to assess the skin of patients requiring care for many different health problems and may be the first healthcare provider to identify suspicious lesions. Wide excision and the high risk of metastasis from melanoma usually requires inpatient surgical treatment, with the nurse providing care and teaching. See the Evidence for Nursing Care box for selected resources related to the patient with malignant melanoma.

Health Promotion and Assessment

The most important aspect of preventing melanoma is a health history and skin assessment. The ACS recommends that people between the ages of 20 and 40 see a skin specialist every 3 years and those over 40 have annual skin checkups. People with actinic keratoses should also have their skin checked regularly for any signs of change. Patients at risk (those with precancerous lesions and with personal risk factors), as well as those over the age of 40, should conduct a monthly skin self-examination (refer to Box 16–7). When self-assessing for melanoma, the patient looks for a change in the following:

- Color, especially any lesion that becomes darker or variegated in shades of tan, brown, black, red, white, or blue
- Size, especially any lesion that becomes larger or spreads out
- Shape, especially any lesion that protrudes more from the skin or begins to have an irregular outline
- Appearance of a lesion, especially bleeding, drainage, oozing, ulceration, crusting, scaliness, or development of a mushrooming outward growth

Evidence for Nursing Care

The Patient with Malignant Melanoma

Selected resources that nurses may find helpful when planning evidence-based nursing care follow.

- Garbe, C., Eigentler, T. K., Keilholz, U., Hauschild, A., & Kirkwood, J. M. (2011). Systematic review of medical treatment in melanoma: Current status and future prospects. *Oncologist, 16*(1), 5–24.
- Lansbury, L., & Bath-Hextall, F. (2012). What's new in skin cancer? An evidence-based update. *Dermatological Nursing, 11*(1), 36–39.
- Larkin, J. M. G., Fisher, R. A., & Gore, M. E. (2012). Adjuvant interferon therapy for patients at high risk for recurrent melanoma: An updated systematic review. *Clinical Oncology, 24*(6), 410–412.

BOX 16–9 Nursing Assessment for Skin Cancer

INTERVIEW QUESTIONS

- Have any members of your family ever been treated for skin cancer?
- Have you had a skin cancer removed from any part of your body?
- Have you noticed any change in the size, shape, or color of a mole, wart, birthmark, or scar?
- Do you have any moles, warts, birthmarks, or scars that itch, are painful, have crusting, or bleed?
- In what parts of the country or world have you lived?
- Have you ever been badly sunburned?
- Do you visit tanning salons?
- Are you exposed to any hazardous chemicals in your job?
- Have you been taught how to examine your skin? If so, how do you do this examination? How often?

PHYSICAL ASSESSMENT

1. Ask the patient to remove all clothing and put on an examination gown. Ensure good light; natural, bright light is best for inspection of lesions. The patient may sit, stand, or lie down.
2. Inspect and palpate the skin. Stretching the skin tightly during assessment facilitates assessment of nodular and scaly lesions and lesions in the dermis. Assess for the following:
   a. Obvious lesions
   b. Visible swellings
   c. Alterations in normal contour and borders of nevi
   d. Enlarged lymph glands
   e. Skin or mucosal discolorations
   f. Areas of ulceration, scaling, crusting, or erosion.
3. The order of assessment follows:
   a. Head and neck: entire scalp, eyelids, external ear, auditory canals, external surface of the nose, internal surface of the nose, the oral cavity, facial skin, the facial glands (parotid, submaxillary, sublingual)
   b. Thyroid and neck, including lymph glands
   c. Chest and abdomen, with special attention under pendulous breasts, in skinfolds, and in areas covered with hair
   d. Back and buttocks, with special attention to the area between the buttocks
   e. Extremities, with special attention to the axillae, nail beds, webs between the fingers and toes, and soles of the feet
   f. External genitals, with special attention to skinfolds, mucous membranes, and areas covered with hair
4. Measure and record a description of all skin lesions on an anatomic chart. Take photographs (if possible) of any suspicious lesion, and include them in the patient's record for future reference.

- Consistency, especially any lesion that becomes softer or is more easily irritated
- Skin around a lesion, such as redness, swelling, or leaking of color from a lesion into the surrounding skin
- Sensation, such as itching or pain.

Assessment

A complete skin assessment is discussed in Chapter 15. Specific health history questions and assessments for skin cancer are outlined in Box 16–9.

Priorities of Care

Collaborating with the interprofessional team to ensure adequate treatment of the melanoma skin cancer while providing care that promotes recovery and comfort is a nursing priority. Teaching the patient and, as appropriate, caregivers strategies to prevent infection, optimize comfort, and promote safe behaviors to prevent ongoing sun exposure also should be considered a priority nursing action. The nurse also focuses on promoting comfort and maintaining asepsis for all interruptions of the integument.

Diagnoses, Outcomes, and Interventions

Although many different nursing diagnoses may be appropriate for the patient with a melanoma, common responses are *Impaired Skin Integrity*, *Hopelessness*, and *Anxiety*. These diagnoses are also appropriate for use with patients with nonmelanoma skin cancer.

Impaired Skin Integrity

Melanomas not only destroy skin layers but also invade body structures. Certain types of melanomas may ulcerate prior to diagnosis, and treatment typically involves some type of surgical biopsy and excision. Any open lesion or incision increases the risk for secondary infection.

Expected Outcome: Patient will experience effective wound healing through primary intention as indicated by progressive approximation of wound borders.

- Monitor for manifestations of infection: fever, tachycardia, malaise, incisional erythema, swelling, pain, or drainage that increases or becomes purulent. *Intact skin is the first line of defense against infection; impaired skin integrity increases the risk for infection. If infection is present, the patient may have both systemic and local manifestations.*
- Keep the incision line clean and dry by changing dressings as necessary. *Moisture increases the risk of infection.*
- Follow principles of medical and surgical asepsis when caring for patient's incision. Teach family members and visitors the importance of careful hand hygiene. Maintain standard precautions if drainage is present. *Careful hand hygiene is essential in preventing the spread of infection. Aseptic techniques are necessary when caring for any surgical incision to prevent infection.*
- Encourage and maintain adequate caloric and protein intake in the diet. Suggest a consultation with a dietitian if the patient does not want to eat. *Adequate calories and protein are necessary for proper healing. The patient with cancer has increased metabolic needs; if these needs are not met, nutritional problems that impair healing may result.*

Hopelessness

Hopelessness is an emotional state in which a person feels that there is no possibility that life will improve. Patients who experience hopelessness are often withdrawn, passive, and apathetic.

The diagnosis of melanoma threatens the quality and quantity of life as the patient faces the possibility or reality of metastasis; the possibility that the cancer may recur and cause death; and alterations in self-concept, roles, and relationships. Inspiring hope in patients during this health crisis is a legitimate nursing action.

CASE STUDY & NURSING CARE PLAN A Patient with Malignant Melanoma

Geoff Sanders, age 69, is retired from the postal service. He has always been an avid participant in outdoor sports: When he was younger he played baseball and tennis, and for the past 10 years he has played golf at least twice a week. He now lives in Connecticut, but as a younger man he lived in Florida for almost 15 years. Mr. Sanders has a variety of warts and moles and rarely pays attention to them. However, after taking a shower one day he noticed that a mole on his left lower leg looked bigger and darker. Mr. Sanders had just seen a public service announcement on television about the dangers of changes in moles, and he immediately called his primary care physician for an appointment at the dermatology clinic.

ASSESSMENT

On arriving at the clinic, Mr. Sanders is interviewed and examined by Tom Hall, a clinical nurse specialist. Following the assessment, Mr. Hall documents the following information.

Mr. Sanders has a family history of skin cancer; his father had several squamous cell cancers removed from his face. He has numerous nevi on his body; the one causing concern is located on the medial anterior left leg, 2 inches below the patella. Mr. Sanders states that the mole has been present for years but that he noticed just yesterday that it has become larger and darker. On further questioning, he states that the mole itches sometimes but has never hurt or bled. Mr. Sanders lived in Florida for 15 years and now experiences a sunburn early each summer before he tans. The sunburn involves the lower legs because Mr. Sanders wears shorts during his twice-weekly golf game.

A complete skin assessment reveals various freckles, warts, and nevi. With the exception of the nevus that prompted Mr. Sanders to come to the clinic, all lesions appear normal. The nevus in question is raised, 3 cm in diameter, with irregular borders and a nodular surface. It is variegated in color, with various shades of brown. The skin surrounding the nevus is slightly erythematous. Inguinal lymph nodes are not enlarged or painful. Mr. Hall takes a photograph of the lesion with Mr. Sanders's permission.

Following the assessment, Mr. Sanders discusses the lesion with a surgeon, who recommends excision. They discuss the possibility of skin cancer and the importance of early detection and treatment. Mr. Sanders is scheduled for a biopsy of the nevus under a local anesthetic the following morning. Following the biopsy, histologic examination reveals lentigo maligna melanoma. Staging of the tumor reveals that it is a melanoma in situ, with no metastasis to regional lymph nodes. Mr. Sanders undergoes a wide excision of the lesion the following afternoon.

DIAGNOSES

- *Impaired Skin Integrity* related to excision of melanoma from the left lower leg
- *Risk for Infection* related to surgical wound on left lower leg
- *Acute Pain* related to wide excision of melanoma on left lower leg
- *Anxiety* related to diagnosis of skin cancer

EXPECTED OUTCOMES

- Patient will demonstrate complete healing of the incision without manifestations of infection.
- Patient will verbalize relief of pain by the time the incision is healed.
- Patient will verbalize fears and concerns about the diagnosis.

PLANNING AND IMPLEMENTATION

- Make the first dressing change, but ensure that Mr. Sanders can safely change the dressing himself prior to discharge the day after surgery.
- On discharge, provide adequate dressings and tape for the first home dressing change; include in discharge instructions necessary information about where to buy supplies and how many dressing supplies will be needed.
- Review and provide written instruction for prescribed systemic antibiotic and pain medication.
- Provide written instructions for dressing change, manifestations of infection, and phone number of clinic; stress importance of calling if any abnormal symptoms occur.
- Teach how to protect the incision from bumps and to protect the site from irritants.
- Discuss diagnosis, positive outlook for treatment of melanoma in situ, and the patient's concerns.
- Stress importance of lifelong regular healthcare evaluations to identify any recurrence or metastasis.

EVALUATION

Mr. Sanders returned to the dermatology clinic 1 week after his surgical incision. His incision is well approximated and shows no signs of infection. He is taking his antibiotic four times a day as prescribed and reports that his need for pain medications is decreasing. During his clinic visit the following week, Mr. Hall removes the sutures and assesses the wound as healed. Mr. Sanders completed his antibiotics and no longer requires pain medications. He says he is still "scared to death" about having cancer, but he has decided to join a local cancer support group. He also says he had gotten a list of skin safety rules from the American Cancer Society and will be sure to cover up and use sunscreens when he plays golf. Mr. Sandezrs makes an appointment for follow-up care in 3 months.

Clinical Reasoning in Patient Care

1. Consider reasons why people who notice a change in a skin lesion put off seeking healthcare. What can nurses do to effect change?
2. Design a teaching plan for young adults for preventing skin cancers.
3. What would you say to Mr. Sanders if he called the clinic and said that the antibiotics were making him sick and he didn't think he needed them anyway?
4. Design a nursing care plan for Mr. Sanders for the diagnosis of *Powerlessness*.

See Evaluating Your Response in Appendix B.

Expected Outcome: Patient will express hope as evidenced by expectation of positive outcome.

- Provide an environment that encourages the patient to identify and express feelings, concerns, and goals:
  - Use active listening, ask open-ended questions, and reflect on the patient's statements.
  - Acknowledge and respect feelings of apathy and/or anger as expressions of distress.
  - Convey an empathetic understanding of the fears and concerns.
  - Provide opportunities to express positive emotions: hope, faith, a sense of purpose, and the will to live.
  - Explore the patient's perceptions, and modify or clarify them if necessary by providing information and correcting misconceptions.
  - Encourage the patient to identify support systems and sources of strength and coping in the past.

  Verbalizing feelings, concerns, and goals allows others to validate or correct them, promotes a therapeutic nurse–patient relationship, and fosters feelings of self-worth. Expressing positive emotions and calling on support systems and sources of strength that were effective in coping with past crises help the person resolve the crisis and develop hope.
- Encourage active participation in self-care as well as in mutual decision making and goal setting. *Meeting self-care needs and making*

decisions about care increase personal confidence in one's capacity for coping.

- Encourage a focus not only on the present but also on the future: Review past occasions for hope, discuss the patient's personal meaning of hope, establish and evaluate short-term goals with the patient and family, and encourage them to express hope for the future. *The nurse mobilizes the patient's resources to strengthen motivation, hope, and the will to live.*

Anxiety

The intensity of anxiety, aroused by a perceived threat, depends on the severity of the present situation and the patient's ability to handle the threat. Anxiety is one of the most common psychosocial responses in patients with cancer. Anxiety increases at the time of diagnosis and remains a constant emotion throughout the course of treatment, regardless of treatment type or setting. Interventions center on helping the patient recognize the manifestations of anxiety, determining whether the patient wishes to do anything about the anxiety, and facilitating coping strategies.

Expected Outcome: Patient will exhibit self-control of anxiety through use of coping strategies.

- Provide reassurance and comfort:
  - Set aside time to sit quietly with the patient.
  - Speak slowly and calmly.
  - Convey empathetic understanding by touch and supporting present coping mechanisms, such as crying and talking.
  - Do not make demands or expect the patient to make decisions.

Coping behaviors differ from situation to situation and from person to person. Anxiety at moderate to severe levels narrows perceptions and the ability to function.

- Decrease sensory stimuli by using short, simple sentences; focusing on the here and now; and providing concise information. *Higher levels of anxiety result in a focus on the present, inability to concentrate, and difficulty in understanding verbal communications.*
- Provide interventions that decrease anxiety levels and increase coping:
  - Provide accurate information about the illness, treatment, and expected length of recovery.
  - Encourage discussion of expected physical changes and ways to minimize disfigurement through cosmetics and clothing.
  - Include family members in teaching sessions.
  - Encourage participation in care.

Although the prognosis and treatment of melanoma depend on various factors, the prognosis of complete cure is decreased with metastasis. Surgical incisions include excision with wide margins, which may cause disfigurement. Active participation in care gives the patient some control over the future and is often an effective means of coping with anxiety.

Delegating Nursing Care Activities

As appropriate and allowed by the designated duties and responsibilities of unlicensed assistive personnel, the nurse may delegate nursing care activities such as measuring fluid intake and output, collecting vital signs (including orthostatic vital signs), encouraging oral or enteral fluid intake, and skin care.

Continuity of Care

Teaching for the patient and family experiencing the diagnosis and treatment of melanoma focuses on self-care and ongoing self-monitoring. Education for the patient and family is specific to the type of treatment. In addition to wound care, patients who have had a lymph node dissection need instructions in how to protect the extremity from bleeding, trauma, and infection. Address the following topics:

- Schedule regular medical checkups every 3 months for the first 2 years, every 6 months for the next 5 years, and yearly thereafter.
- Proper self-care combined with regular medical care can help the patient lead a fairly normal life.
- If assistance for home care is necessary, provide referrals to a community health agency or a home care agency. In addition, refer the patient to a local cancer support group if desired. Other resources are the ACS, the Skin Cancer Foundation, and the National Cancer Institute.

Skin Trauma

Trauma to the skin can be unintentional or intentional (as in the case of surgery). Chemicals, radiation, pressure, or thermal changes cause skin trauma. This section discusses pressure ulcers and frostbite, as well as intentional trauma from cutaneous and plastic surgery or treatment. Thermal injury, or burns, is discussed in Chapter 17.

THE PATIENT WITH A PRESSURE ULCER

Pressure ulcers are ischemic lesions of the skin and underlying tissues caused by unrelieved pressure that impairs the flow of blood and lymph. The ischemia causes tissue necrosis and eventual ulceration. These ulcers, also called bed sores or decubitus ulcers, tend to develop over a bony prominence (such as the heels, greater trochanter, sacrum, and ischia), but they may appear on the skin of any part of the body subjected to external pressure, friction, or shearing forces.

Incidence

The increasing incidence of pressure ulcers in all healthcare settings, but especially in hospitals and long-term care facilities, has resulted in infection, loss of function, and pain for patients. These complications, in turn, have caused increased length of stay and costs. As a result, the Centers for Medicare and Medicaid Services will no longer make additional reimbursement payments to hospitals to cover the cost of pressure ulcers developed during a hospital stay.

FAST FACTS

Pressure Ulcers

- The incidence of pressure ulcers in hospitals is approximately 8%; the incidence in long-term care ranges from 2.4% to 23%.
- An estimated 60,000 patients die each year from pressure ulcer complications.
- The cost of treating these chronic wounds is about $11 billion a year.

Source: (Agency for Healthcare Research and Quality, 2012).

The prevention and treatment of pressure ulcers is a public health issue. The national health policy statement *Healthy People 2010* set a target of a 50% decrease in the prevalence of pressure ulcers in long-term care residents. The national Institute for Healthcare Improvement (IHI) has made preventing pressure ulcers 1 of 12 interventions to save lives. The IHI recommendations are described in the Nursing Care section that follows. Pressure ulcers are preventable, with nursing care being a major part of prevention.

Pathophysiology

Pressure ulcers develop from external pressure that compresses blood vessels or from friction and shearing forces that tear and injure vessels. Both types of pressure cause traumatic injury and initiate the process of pressure ulcer development.

External pressure that is greater than capillary pressure and arteriolar pressure interrupts blood flow in capillary beds. When pressure is applied to skin over a bony prominence for 2 hours, tissue ischemia and hypoxia from external pressure cause irreversible tissue damage. For example, when the body is in the supine position, the body's weight applies pressure to the sacrum. The same amount of pressure causes more damage when it is applied to a small area than when it is distributed over a large surface.

Shearing forces result when one tissue layer slides over another. The stretching and bending of blood vessels cause injury and thrombosis. Patients in hospital beds are subject to shearing forces when the head of the bed is elevated and the torso slides down toward the foot of the bed. Pulling the patient up in bed also subjects the patient to shearing forces. (For this reason, always lift patients up in bed using a lift sheet.) In both cases, friction and moisture cause the skin and superficial fascia to remain fixed to the bed sheet, while the deep fascia and bony skeleton slides in the direction of body movement.

When a person lies or sits in one position for an extended length of time without moving, pressure on the tissue between a bony prominence and the external surface of the body distorts capillaries and interferes with normal blood flow. If the pressure is relieved, blood flow to the area increases, and a brief period of reactive hyperemia occurs without permanent damage. However, if the pressure continues, platelets aggregate in the endothelial cells surrounding the capillaries and form microthrombi. These microthrombi impede blood flow, resulting in ischemia and hypoxia of tissues. Eventually, the cells and tissues of the immediate area of pressure and of the surrounding area die and become necrotic.

Alterations in the involved tissue depend on the depth of the injury. Injury to superficial layers of skin results in blister formation, whereas injury to deeper structures causes the pressure ulcer area to appear dark reddish-blue. As the tissues die, the ulcer becomes an open wound that may be deep enough to expose the muscles and bone. The necrotic tissue elicits an inflammatory response, and the patient experiences increases in temperature, pain, and white blood cell count. Secondary bacterial invasion is common. Enzymes from bacteria and macrophages dissolve necrotic tissue, resulting in a foul-smelling drainage.

Pressure ulcers are staged to classify the degree of tissue damage. The updated stages from the National Pressure Ulcer Advisory Panel (2012) are listed in Box 16–10.

Risk Factors

Although a pressure ulcer may develop in an adult of any age who has an impairment in mobility, those most at risk are older adults with limited mobility and fractured hips, people with quadriplegia, and patients in the critical care setting (Huether & McCance, 2011). Other patients prone to develop pressure ulcers are those with fractures of large bones (e.g., hip or femur) or those who have undergone orthopedic surgery or sustained spinal cord injury. In addition to deficits in mobility and activity, incontinence and nutritional deficit also increase the risk of pressure ulcer development. Patients with chronic illnesses, such as renal failure and anemia, and those with edema or infection are also at increased risk. See the accompanying Nursing Care of the Older Adult box for information about preventing pressure ulcer development in older adults.

NURSING CARE OF THE OLDER ADULT

Pressure Ulcer Prevention

Older adults are at a greater risk than younger people for developing pressure ulcers because of age-related changes in the integumentary system. Cell renewal slows, resulting in skin that has decreased elasticity. The margin between the epidermis and the dermis separates more easily, making the skin more prone to tearing. In addition, thinning subcutaneous tissue provides less cushioning over bony prominences. Water content decreases, and the skin becomes drier. These changes increase the older adult's susceptibility to skin trauma and prolong wound healing.

Chronic conditions associated with immobility and self-care deficit place older adults at risk of developing pressure ulcers. For example, bowel or bladder incontinence can produce regions of wet skin that are prone to infections and breakdown. Furthermore, sensory-perceptual alterations and impaired cognitive functioning may reduce the frequency with which the older adult shifts position when sitting or lying in bed. Finally, undernutrition, which is often seen in older adults, heightens the risk for developing pressure ulcers.

To prevent pressure ulcers, the skin of older adults should be kept clean, dry, and well hydrated. Moisturizers are recommended to keep the skin free of excessive dryness. Older adults should be taught to avoid bumping into furniture and to wear long skirts or pants to help protect the lower extremities from trauma.

When hospitalized, older adults should have a validated risk assessment for pressure ulcers completed on admission and as often as the tool suggests. A daily systematic skin inspection with particular attention to bony prominences should be completed.

Once pressure ulcers develop in older adults, the treatment is the same as for younger patients. However, additional steps may need to be taken. Because local perfusion to tissues is compromised, steps should be taken to prevent under- or overhydration. It is essential for optimal nutritional status to be maintained. Also, keep in mind that it may take a longer time for the pressure ulcer to heal.

●○● INTERPROFESSIONAL CARE

For the patient at risk for pressure ulcers, the goal is prevention. Existing ulcers require interprofessional treatment to promote healing and restore skin integrity.

DIAGNOSIS

Diagnostic tests are conducted to determine the presence of a secondary infection and to differentiate the cause of the ulcer. If the ulcer is deep or appears infected, drainage or biopsied tissue is cultured to determine the causative organism.

BOX 16–10 NPUAP's Updated Pressure Ulcer Staging

Stage I

A sign of risk. Intact skin with nonblanchable redness of a localized area, usually over a bony prominence. The area may be painful, firm, soft, warmer, or cooler than adjacent tissue. May be difficult to detect in people with dark skin.

Stage II

Partial-thickness loss of dermis presenting as a shallow open ulcer with a red or pink wound bed. May also present as an intact or open blister. The ulcer may be shiny or dry, without bruising or slough (loss of tissue).

Stage III

Full-thickness tissue loss. Subcutaneous fat may be visible but bone, tendon, or muscle is *not* exposed. Slough may be present but does not obscure the depth of tissue loss. *May* include undermining and tunneling.

Stage IV

Full-thickness skin loss with exposed bone, tendon, or muscle. Slough or eschar (dead tissue such as a scab) may be present on some parts of the wound bed. Often includes undermining and tunneling.

MEDICATIONS

Topical and systemic antibiotics specific to the infectious organism eradicate any infection present. Additionally, a variety of products promote healing. Examples are listed in Table 16–2.

SURGICAL TREATMENT

Surgical debridement may be necessary if the pressure ulcer is deep, if subcutaneous tissues are involved, or if an eschar has formed over the ulcer, preventing healing by granulation. Large wounds may require skin grafting for complete closure.

●○● NURSING CARE

The patient with one or more pressure ulcers not only has impaired skin integrity but also is at increased risk for infection, pain, and decreased mobility. Pressure ulcers prolong treatment for other

TABLE 16–2 Products Used to Treat Pressure Ulcers

Product	Purpose
Hydrocolloid dressing (such as DuoDERM)	May be used for stages I, II, III, and IV with minimal exudate. Forms a gel when it comes in contact with wound exudate. Forms an occlusive barrier over the ulcer while maintaining a moist environment and preventing infection. Helps prevent friction and shear.
Alginate dressing (such as SilvaSorb and Sorbsan)	May be used for stages II, III, and IV with moderate to heavy drainage, and in infected and noninfected wounds. Forms a gel when coming into contact with wound exudate. Should not be applied to dry or minimally draining wounds, because dehydration and delay in healing may result.
Hydrofiber (such as Aquacel)	May be used for stages II, III, and IV with moderate to heavy exudate. Can be used with actual or risk for infection. Combines the absorption of the hydrofiber with 1.2% silver as an antimicrobial agent.
Hydrogel dressing (such as IntraSite gel)	May be used for stages II, III, and IV. Rehydrates the wound bed and decreases pain. Promotes autolytic debridement.
Transparent adhesive dressing (such as OpSite and Tegaderm)	May be used in shallow stage I, II, and III ulcers. Provides a moist wound setting, prevents infection, and promotes reepithelialization. Minimizes friction and shear.
Wet-to-dry dressings	Provides mechanical debridement.
Vacuum-assisted closure (VAC) sponge	Stimulates wound contracture while removing the exudate and wound edema.

health problems, increase healthcare costs, and diminish the patient's quality of life. See the Moving Evidence into Action research box below for information on evidence-based interventions.

Assessment

See the Risk Factors and Interprofessional Care sections for assessment of the patient with a pressure ulcer.

Priorities of Care

Collaborating with the interprofessional team to ensure adequate prevention for high-risk patients or treatment of the pressure ulcer while providing care that promotes healing and infection prevention is a priority. Teaching the patient and, as appropriate, caregivers strategies to prevent development or progression of pressure ulcer injuries also should be considered a priority nursing action. The nurse

Moving Evidence into Action

Preventing Pressure Ulcers in Acute Care and Home Care Settings

Despite advances in healthcare to extend life and improve functional status, older adults with chronic illnesses are at increased risk of developing pressure ulcers. The older adult, with age-related compromised cellular activity, is especially vulnerable to impaired healing of injured tissue such as pressure ulcers. An evidence-based toolkit by the Agency for Health Care Research and Quality (AHRQ, 2012) provides detailed information of the best practices for prevention of pressure ulcers. The toolkit also contains information for systematic practice change and specific tools and instruments to be used for pressure ulcer assessment, prevention, and management. The best practices discussed include a focus on a multidisciplinary approach and the care individualized to each patient. Additionally the plan needs to focus on the multiple dimensions related to pressure ulcers (skin management, nutrition, environment) yet allow for the development of a professional habit for consistent assessment and management of pressure ulcers.

A pressure ulcer "bundle" of care interventions includes:

- Assess all individuals admitted to a healthcare facility with a pressure ulcer for the risk of developing additional pressure ulcers by using a standardized risk assessment scale.
- Perform a complete history and physical examination, combined with a detailed assessment of the ulcer characteristics (location, stage, type of tissue, presence of tunneling or tracts, exudate, odor, and condition of skin around the ulcer).
- Remove necrotic tissue and debris from the ulcer to decrease the growth of bacteria and remove foreign materials, such as exudates and metabolic wastes.
- Provide a moist wound environment to promote reepithelialization and healing.
- Control bacterial levels in the wound by using cleansing and debridement, as well as systemic and topical antibiotics.
- Supply essential substrates for tissue repair, including protein, calories, vitamins, and minerals. Maintain a positive nitrogen balance.
- Manage tissue loads by positioning to avoid external force on the ulcer.

Implications for Nursing

The design and implementation of a pressure ulcer prevention and treatment plan are essential for any person at risk, including older adults, those with debilitating or multiple illnesses, and those with health problems limiting mobility. To effectively implement a plan, it is important to instruct providers on the use of a standard protocol through educational programs, and to monitor indicators of improvement or deterioration in the ulcer and presence or absence of new ulcers. These outcomes should be assessed and recorded on a weekly basis.

Moving Knowledge into Action

1. Describe the differences and similarities in the pressure ulcer prevention plans of care you would develop for two patients: a 76-year-old man in a nursing home who has had a stroke that paralyzed his left side, and a 36-year-old man with a spinal cord injury from a motorcycle accident who cannot walk and lives at home.
2. Consider the activities to treat pressure ulcers, and answer the following:
   a. What level of healthcare provider would you delegate to care for these patients described in question 1?
   b. How much time in an 8-hour period would be needed for nursing care?
3. What would you teach family caregivers about providing care at home?

also focuses on promoting comfort and maintaining asepsis for all interruptions of the integument.

Diagnoses, Outcomes, and Interventions

The following interventions and rationales are adapted from the clinical guidelines developed by the Agency for Health Care Research and Quality (2012) for identifying adults at risk and treating those with stage I pressure ulcers.

Risk for Impaired Skin Integrity

Expected Outcome: Patient will experience wound healing through primary intention as indicated by progressive approximation of wound borders.

- Identify at-risk individuals needing prevention and the specific factors placing them at risk.
- Assess bed- and chair-bound patients, as well as those who are unable to reposition themselves, for additional risk factors: immobility, incontinence, nutritional factors (such as inadequate dietary intake and impaired nutritional status), and altered level of consciousness.
- Assess patients on admission to acute care and rehabilitation hospitals, nursing homes, home care programs, and other healthcare facilities.
- Conduct a systematic risk assessment by using a validated risk assessment tool (such as the Braden scale). See the information about predicting risk and using the Braden scale at the Nursing Center website.
- Document all assessments of risk. *Individuals at risk for pressure ulcers must be identified so that risk factors can be reduced through intervention. The primary risk factors for pressure ulcers are immobility and limited activity; therefore, assess patients who cannot reposition themselves or whose activity is limited to a bed or chair. Validated tools ensure systematic evaluation of individual risk factors. The patient requires periodic reassessment for pressure ulcers. Accurate and complete documentation of all risk assessments ensures continuity of care and may be used as a foundation for the skin care plan.*
- Conduct a systematic skin inspection at least once a day, paying particular attention to the bony prominences. Systematic, comprehensive, and routine skin care may decrease pressure ulcer incidence. Inspect the following to assess a pressure ulcer:
  - Location of any lesion or ulcer
  - Estimation of the stage
  - Dimensions of the ulcer: length, width, depth
  - Presence of any abnormal pathways in the wound
  - Sinus tract: a cavity or channel underneath the wound
  - Tunneling: a passageway or opening that may be visible at skin level, but with most of the tunnel under the surface of the skin
  - Undermining: areas of tissue destruction underneath intact skin along wound margins
  - Visible necrotic tissue (Slough is necrotic tissue that is in the process of separating from viable tissue.)
  - Presence of an exudate
  - Presence or absence of granulation tissue

  Skin inspection provides data the nurse uses in designing interventions to reduce risk and in evaluating outcomes of those interventions.
- Clean the skin at the time of soiling and at routine intervals, as frequently as the patient's need or preference dictates. Avoid hot water, use a mild cleansing agent, and clean the skin gently, applying as little force and friction as possible. *Metabolic wastes and environmental contaminants accumulate on the skin; these potentially irritating substances should be removed frequently. Feces and urine cause chemical irritation and should be removed as soon as possible. Hot water may cause skin injury. Mild cleansing agents are less likely to remove the skin's natural barrier.*
- Minimize environmental factors leading to skin drying, such as low humidity and exposure to cold. Treat dry skin with moisturizers. *Well-hydrated skin resists mechanical trauma. Hydration decreases as the ambient air temperature decreases, especially when the air humidity is low. Poorly hydrated skin is less pliable, and severe dryness is associated with fissuring and cracking of the stratum corneum. Moisturizers reduce dry skin.*
- Avoid massage over bony prominences. *Although massage has been practiced for years, evidence now suggests that massage over bony prominences may lead to deep tissue trauma in patients at risk for or with beginning skin manifestations of a pressure ulcer.*
- Minimize skin exposure to moisture due to incontinence, perspiration, or wound drainage. When these sources of moisture cannot be controlled, use breathable underpads or briefs made of materials that absorb moisture and present a quick-drying surface to the skin. Change underpads and briefs frequently. Do not place plastic directly against the skin. *Moisture from incontinence, perspiration, or wound drainage may contain factors that irritate the skin; moisture alone can increase the susceptibility of the skin to injury.*
- To minimize skin injury due to friction and shearing forces, use proper positioning, transferring, and turning techniques. Lubricants (such as cornstarch or creams), protective films (such as transparent dressings and skin sealants), protective dressings (such as hydrocolloids), and protective padding may also reduce friction injuries. *Shear injury occurs when skin remains stationary and the underlying tissue shifts. This shift diminishes the blood supply to the skin and results in ischemia and tissue damage. Proper positioning, however, can eliminate most shear injuries. Friction injuries to the skin occur when it moves across a coarse surface, such as bed linens. Most friction injuries can be avoided by using appropriate techniques to move patients so that their skin never drags across the linens. Any agent that eliminates contact or decreases the friction between the skin and the linens reduces the potential for injury.*
- Assess factors involved in inadequate dietary intake of protein or kilocalories. Offer nutritional supplements, and support the patient during mealtimes. If dietary intake remains inadequate, consult with a dietitian about other dietary interventions. *The role nutrition plays in the development of (and to a lesser degree, the healing of) pressure ulcers is not understood, but poor dietary intake of kilocalories, protein, and iron has been associated with the development of pressure ulcers.*
- Maintain the patient's current level of activity, mobility, and range of motion. *Frequent turning, repositioning, and movement are essential in reducing the risk of pressure ulcers.*
- For the patient on bed rest or who is immobile, provide interventions against the adverse effects of the external mechanical forces of pressure, friction, and shear:
  - Reposition all at-risk patients at least every 2 hours, using a written schedule for systematic turning and repositioning.
  - For patients on bed rest, use positioning devices, such as pillows or foam wedges, to protect bony prominences.

- For completely immobile patients, use devices to totally relieve pressure on the heels (the most common method is to raise the heels off the bed). Do not use donut-type devices.
- Avoid placing patients in the side-lying position directly on the trochanter.
- Maintain the head of the bed at the lowest degree of elevation consistent with the patient's medical condition and other restrictions. Limit the amount of time the head of the bed is elevated.
- Use assistive devices, such as a trapeze or bed linen, to move patients in bed who cannot assist during transfers and position changes.
- Place any at-risk patient on a pressure-reducing device, such as a foam, static air, alternating air, gel, or water mattress.
  Data indicate that the more spontaneous movements that bedridden, older adult patients make, the lower the incidence of pressure ulcers and that fewer pressure ulcers develop in at-risk patients who are turned every 2 to 3 hours. Proper positioning can reduce pressure on bony prominences. It is difficult to redistribute pressure under heels; suspending the heels is the best method. Donut cushions are more likely to cause than to prevent pressure ulcers. Shearing forces are exerted on the body when the head of the bed is elevated. Lifting (rather than dragging) is less likely to cause injury from friction. Pressure-reducing devices and beds can decrease the incidence of pressure ulcers.
- For chair-bound patients, use pressure-reducing devices. Consider postural alignment, distribution of weight, balance and stability, and pressure relief when positioning these patients. Avoid uninterrupted sitting in a chair or wheelchair. Reposition the patient every hour. Teach patients who can do so to shift their weight every 15 minutes. Use a written plan for positioning, movement, and the use of positioning devices. Do not use donut devices. *Prolonged, uninterrupted mechanical pressure results in tissue breakdown. The patient's weight should be shifted at least every hour.*

Delegating Nursing Care Activities

As appropriate and allowed by the designated duties and responsibilities of unlicensed assistive personnel, the nurse may delegate nursing care activities such as assisting the patient with position changes, fluid intake and output, collecting vital signs (including orthostatic vital signs), encouraging oral or enteral fluid intake, and nonpharmacologic skin care.

Continuity of Care

Patient and family teaching for care of a pressure ulcer focuses on prevention and includes much of the same information presented in the preceding section. Because many patients with pressure ulcers are older or have other serious illnesses, a caregiver may require teaching on such topics as the following:

- Definition and description of pressure ulcers
- Common locations of pressure ulcers
- Risk factors for the development of pressure ulcers
- Skin care
- Ways to avoid injury
- Diet

Depending on the stage of the pressure ulcer, the nurse teaches the patient or caregiver how to care for ulcers that are already present: how to change wet-to-dry dressings, apply skin barriers, and avoid injury and infection. Referrals to a home health agency or community health department can help the family through the lengthy healing process.

THE PATIENT WITH FROSTBITE

Frostbite is an injury of the skin from freezing. If the exposure to freezing temperatures is limited, only the skin and subcutaneous tissues become involved. However, as exposure increases, deeper structures freeze. The skin freezes when the temperature drops to 21° to 24°C (14° to 24.8°F). Frostbite is most common on exposed or peripheral areas of the body, such as the nose, ears, feet, and hands.

As human tissues freeze, ice crystals form and increase intracellular sodium content. Small blood vessels initially vasoconstrict but then vasodilate and become more permeable, causing cellular and tissue swelling. With continued exposure, vasoconstriction and increased viscosity of the blood cause infarction and necrosis of the affected tissue.

Superficial frostbite causes numbness, itching, and prickling. The skin appears cyanotic, reddened, or white. Deeper frostbite causes stiffness and paresthesias. As the skin and tissues thaw, the skin becomes white or yellow and loses its elasticity. The patient experiences burning pain. Edema, blisters, necrosis, and gangrene may appear.

Rapid thawing may significantly decrease tissue necrosis. General guidelines for rewarming areas of frostbite follow:

- If you are outdoors, treat superficial frostbite by applying firm pressure with a warm hand or by placing frostbitten hands in the axillae. If the feet are frostbitten, remove wet footwear, dry the feet, and put on dry footwear. Do not rub the areas with snow.
- In the hospital, rapidly rewarm affected areas in circulating warm water, 40° to 40.5°C (104° to 105°F), for 20 to 30 minutes. Do not rub or massage the areas.

Following rewarming, the patient is kept on bed rest with the affected parts elevated. Pain medications and anti-inflammatory agents are administered. Blisters are debrided. Whirlpool therapy may be used to clean the skin and debride necrotic tissue. Recovery from frostbite is usually complete if the involved area has not become necrotic. Necrotic tissue may require amputation.

THE PATIENT UNDERGOING CUTANEOUS AND PLASTIC SURGERY

Although many skin disorders are so small and benign that no treatment is necessary, others require some type of surgery of the skin to remove the lesion. Other surgeries and treatments for skin lesions and deformities are used to restore function and change appearance. This section discusses both cutaneous and plastic surgery, as well as other types of treatment modalities used in the care of the patient with a skin disorder.

Cutaneous Surgery and Procedures

The basic types of cutaneous surgery described here are excision, electrosurgery, cryosurgery, curettage, and laser surgery. Two nonsurgical procedures, chemical destruction and sclerotherapy, are also discussed. Most of these procedures are performed in the office or outpatient clinic.

FUSIFORM EXCISION

Fusiform excision is the removal of a full thickness of the epidermis and dermis, usually with a thin layer of subcutaneous tissue. It is used to remove tissue for biopsies and for complete removal of benign and malignant lesions of the skin. Excision of small, superficial lesions is performed under a local anesthetic, and care is taken to place the incision in a way that will provide good cosmetic results.

ELECTROSURGERY

Electrosurgery involves the destruction or removal of tissue with high-frequency alternating current. A variety of surgical procedures may be performed, including *electrodesiccation* (which produces superficial skin destruction), *electrocoagulation* (which produces deeper tissue destruction), and *electrosection* (which can cut through skin and tissue). Electrodesiccation is used to remove benign surface lesions, such as skin tags, keratoses, warts, and angiomas. It is also used to produce hemostasis for capillary bleeding. Electrocoagulation is used to remove telangiectases, warts, and superficial nonmelanoma skin cancers. Electrosection is used to make incisions, excise tissue, and perform biopsies.

CRYOSURGERY

Cryosurgery is the destruction of tissue by cold or freezing with agents such as fluorocarbon sprays, carbon dioxide snow, nitrous oxide, and liquid nitrogen. Cryosurgery is used to treat many skin lesions. The freezing agents are applied topically to the lesion. The effects depend on the degree of freeze. Light freezing causes damage to the epidermis with blistering or crusting that heals without scarring. Deeper freezes, used to treat malignant cells, cause edema, necrosis, and tissue slough. The effects of cryosurgery may not be obvious until 24 hours following the treatment. Postoperatively, infection is prevented by applying a topical antibiotic and keeping the treated areas clean. Healing occurs in 2 to 3 weeks.

CURETTAGE

Curettage is the removal of lesions with a curette (a semisharp cutting instrument). It is used to remove benign and malignant superficial epidermal lesions. Benign lesions removed include keratoses, nevi, and angiomas. Nonmelanoma skin lesions are removed by curettage if they are small, well-defined, primary tumors. Curettage is also used to remove specimens of tissue for biopsy.

Following curettage, the wound may be treated with electrodesiccation to destroy any remaining malignant cells and to provide hemostasis. These wounds are not closed; rather, they are left open to heal by second intention. Topical antibiotic ointments and dressings may be used in the postoperative period.

LASER SURGERY

Laser surgery is used to treat a variety of skin disorders. A laser is an intense light that produces a thermal injury on contact with tissue. The injury causes coagulation, vaporization, excision, and ablation (removal of a growth). Argon, pulsed dye, carbon dioxide, and Nd:YAG lasers are used in cutaneous and plastic surgery. A local anesthetic may be used, although a pulsed dye laser causes minimal pain and anesthesia is rarely required.

CHEMICAL DESTRUCTION

Chemical destruction is the application of a specific chemical to produce destruction of skin lesions. Chemical destruction is used to treat both benign and premalignant lesions. The chemical is applied to the lesion or is used to cause peeling. After application, the treated area forms a thin crust that sloughs off in about a week.

SCLEROTHERAPY

Sclerotherapy is the removal of benign skin lesions with a sclerosing agent that causes inflammation with fibrosis of tissue. Agents that cause therapeutic sclerosis include aethoxysklerol (Sclerodex) and hypertonic sodium chloride. This type of treatment is used for telangiectases and superficial spider veins of the lower extremities. The solution is injected into the affected veins, causing a reaction that closes the lumen of the vein.

Plastic Surgery

Plastic surgery is the alteration, replacement, or restoration of visible portions of the body, performed to correct a structural or cosmetic defect. The word *plastic* comes from the Greek word *plastikos*, which means "able to be molded."

Many skin disorders discussed in this chapter cause changes in appearance. For example, acne may leave deep pitting scars, nevi and keloids are often disfiguring, and skin cancers may require wide excision and skin grafting. These scars, lesions, and wounds often cause embarrassment and alterations in body image. In addition, the removal of lesions may leave unsightly scars or areas of obviously missing tissue.

Cosmetic surgery involves procedures to enhance the attractiveness of normal features. There were 4.6 million surgical (minimally invasive and surgical) cosmetic procedures performed in 2012, an increase of 5% since 2011. About 8.5 million nonsurgical procedures were performed in 2012 (American Society for Aesthetic Plastic Surgery, 2012). The most frequently performed procedures were Botox injections, liposuction, breast augmentation, and laser hair removal. Reconstructive surgery uses similar techniques; however, its purpose is to improve the function or appearance of parts of the body damaged by trauma, disease, or birth defects.

Many of the plastic surgeries permanently alter body image. To provide the patient with a preview of what surgery will accomplish, some surgeons integrate computer imaging into preoperative teaching. The computer projects a photograph of the targeted area onto a monitor and uses graphics to demonstrate how the size and/or shape of the body part or area will change as a result of the surgery.

SKIN GRAFTS AND FLAPS

Skin grafts and flaps are used to restore function and an acceptable appearance. Both of these procedures involve the movement of skin from one part of the body to another part.

A **skin graft** is a surgical method of detaching skin from a donor site and placing it in a recipient site, where it develops a new blood supply from the base of the wound. Skin grafting is an effective way to cover wounds that have a good blood supply, that are not infected, and in which bleeding can be controlled.

Skin grafts may be either split thickness or full thickness. A split-thickness graft contains epidermis and only a portion of dermis of the donor site. A common donor site for a skin graft is the anterior thigh. Skin is removed in sheets from the donor site with a dermatome. A full-thickness graft contains both epidermis and dermis. These layers contain the greatest number of skin elements (sweat glands, sebaceous glands, or hair follicles) and are best able to withstand trauma.

Areas of thin skin are the best donor sites for full-thickness skin grafts. The donor site must be surgically closed and will scar.

A skin flap is a piece of tissue whose free end is moved from a donor site to a recipient site while maintaining a continuous blood supply through its connection at the base or pedicle. Flaps carry their own blood supply and are therefore used to cover recipient sites that have a poor blood supply or have sustained a major tissue loss. They are often used for reconstruction or closure of large wounds. Microsurgical techniques, with anastomosis of small blood vessels and nerves, allow reconstruction with free flaps (in which the flap is completely removed from its donor site and moved to the recipient site).

CHEMICAL PEELING

Chemical peeling is the application of a chemical to produce a controlled and predictable injury that alters the anatomy of the epidermis and superficial dermis. The result is skin that appears firmer, smoother, and less wrinkled. This form of cosmetic surgery is more useful in people who have fair, thin skin with fine wrinkling. Chemical agents used for peeling include phenol, trichloroacetic acid (TCA), and alpha-hydroxy acids (AHA).

LIPOSUCTION

Liposuction is a method of changing the contours of the body by aspirating fat from the subcutaneous layer of tissue. This treatment is used to remove excess fat from the buttocks, flanks, abdomen, thighs, upper arms, knees, ankles, and chin. It is not a cure for obesity and should not be used as a substitute for weight loss. The procedure is usually done for younger patients because their skin is more elastic. Liposuction may be performed on either an outpatient or inpatient basis.

To aspirate the fat, a small incision is made close to the area, and a suction cannula or curette is inserted and attached to a suction apparatus. The high vacuum pressure caused by the suction machine causes fat cells to emulsify, and they are aspirated out of the body. Following removal of the fat, a pressure dressing is applied to help the skin conform to the new tissue size.

DERMABRASION

Dermabrasion is a method of removing facial scars, severe acne, and pigment from unwanted tattoos. The area is sprayed with a chemical to cause light freezing and is then abraded with sandpaper or a revolving wire brush to remove the epidermis and a portion of the dermis.

FACIAL COSMETIC SURGERY

Many different reconstructive surgeries may be performed to correct deformities or improve cosmetic appearance. Those discussed here are rhinoplasty, blepharoplasty, and rhytidectomy (face-lift):

- A *rhinoplasty* is conducted to improve the appearance of the external nose. The nasal skeleton is reshaped, and the overlying skin and subcutaneous tissue are allowed to redrape over the new framework. A submucous resection of the nasal septum is often done at the same time; this surgery resects a segment of the septal cartilage to improve the nasal airway and also to alter the appearance of the nose. This surgery is done through incisions within the nose, so no visible scars remain after healing.
- A *blepharoplasty* is a cosmetic surgery in which loose skin and protruding periorbital fat are removed from the upper and lower eyelids. With aging, the eyelid skin sags, allowing the periorbital fat to bulge; the skin of the upper eyelid can be so lax that it partially obstructs vision. The procedure is performed under local anesthesia, and excess skin and fat are excised. The incision is made in the normal eyelid lines so that scars are not visible after healing.
- A *rhytidectomy*, or face-lift, is a cosmetic surgery done to improve appearance by removing excess skin (and sometimes fat) from the face and neck. As one ages, the skin of the face and neck tends to become loose and wrinkled. The procedure is usually performed with local anesthesia. To perform the surgery, bilateral incisions are made from the scalp at the temple, in front of the ear in the natural skin line, around the earlobe, and to the occipital scalp. The skin is then elevated, fat is removed or suctioned, and excess skin is excised. The incision lines are sutured, and a pressure dressing is applied.

●○● NURSING CARE

Nursing care for the patient having cutaneous or plastic surgery is highly individualized. It depends on the type of surgery or procedure performed, the type of deficit treated, the reason for the surgery or procedure, the expected results of the treatment, and the response of the patient to the lesion or surgery. Although some surgeries, such as skin grafts and flaps, require in-hospital care, many of the surgeries are carried out in a primary care setting, and the patient provides self-care at home following or between treatments.

Assessment

Assessment is based on the extent of surgery and procedure performed.

Priorities of Care

Collaborating with the interprofessional team to ensure adequate treatment of the viral skin infection while providing care that promotes recovery and comfort is a nursing priority. Teaching the patient and, as appropriate, caregivers strategies to prevent infection, optimize comfort, and promote safe home and work environments also should be considered a priority nursing action. The nurse also focuses on promoting comfort and maintaining asepsis for all interruptions of the integument.

Diagnoses, Outcomes, and Interventions

A variety of nursing diagnoses may be appropriate for the patient having cutaneous or plastic surgery or procedures; the most common are *Impaired Skin Integrity*, *Acute Pain*, and *Disturbed Body Image*.

Impaired Skin Integrity

The patient having surgery of the skin has impaired skin integrity. Skin grafts and flaps are performed to repair large wounds, and it is necessary to inflict further wounds to collect the graft or flap from a donor site. Excisions and various cosmetic surgeries cause wounds. Skin is traumatized by freezing, chemicals, abrasion, sclerosing agents, electrical currents, and lasers. Although all of these treatment modalities are conducted to remove lesions, improve function, or improve appearance, they first impair the integrity of the skin. These impairments increase the risk for infection, which would further impair the skin integrity and may negate the benefits of surgery.

Expected Outcome: Patient will experience skin graft and flap healing as indicated by progressive approximation of wound borders.

Nurses provide preoperative care and teaching, intraoperative assistance, and postoperative care and teaching; in each case, care and teaching are specific to the type of surgical treatment and

the individual patient. In all cases, the nurse provides appropriate preoperative interventions to prepare the patient physically and emotionally for surgery and the postoperative period. The following interventions are appropriate for the patient having inpatient skin grafts or flaps:

- Monitor incisions and graft, and flap donor and recipient sites, for manifestations of infection and necrosis:
  - Take and record vital signs every 4 hours.
  - Monitor all wounds for changes in color, consistency, amount, and odor of drainage every 4 to 8 hours.
  - Monitor wounds for increased swelling, redness, and pain every 4 to 8 hours.
  - Monitor and document assessment of graft every 4 hours.
  - Monitor and document temperature, turgor, color, dermal bleeding, and capillary refill of flaps every 4 hours.

  When bacterial infection is present, the inflammatory phase of wound healing is prolonged, retarding healing. Increased body temperature and tachycardia are manifestations of infection. The drainage in wounds that become infected is often increased in amount, purulent, thicker, and has a musty or foul odor. Tissue response to infection includes edema, increased erythema, and pain. Grafts and flaps that do not have adequate blood supply will appear black instead of the normal pink-red color.
- Provide care for the donor site:
  - Position the patient to minimize pressure on the donor site.
  - Use a bed cradle to keep linens off the area.
  - If the donor site is left open and a heat lamp is to be applied to the area, place the lamp no closer than 2 feet from the wound.
  - Avoid moving the body part containing the donor site, if possible.
  - If the donor site is on the posterior portion of the body, place the patient on a special bed (such as a low-pressure or fluidized bed) to decrease pressure and allow air circulation around the donor site.

  Minimizing trauma from pressure and movement facilitates healing of the donor site. Leaving the site open to the air and providing heat increase healing. Special beds minimize ischemia and allow donor sites on the posterior side of the body to dry.
- Encourage a diet high in protein, ascorbic acid, vitamins, and minerals. *An adequate protein intake is necessary to supply amino acids for tissue repair. Vitamin C is necessary for collagen formation and wound strength. Vitamins and minerals contribute to the healing process.*
- Change dressings as prescribed, or if the frequency is not indicated, as necessary. Determine which dressings are not to be removed during the healing process and which are to be changed, and whether the wound is to be kept dry or moist. Use aseptic technique and follow standard precautions when changing dressings. Remove old dressings carefully and gently.

  Donor sites may be covered with an adherent gauze dressing that is allowed to dry and remains adherent through the healing process. Aseptic techniques prevent secondary bacterial infections. Standard precautions protect the nurse from HIV infection. Unless care is taken, the removal of adherent old dressings may damage the wound by traumatizing granulation tissue or wound edges. The use of semipermeable transparent dressings provides an environment that optimizes wound healing by promoting collagen synthesis and the formation of granulation tissue; it also increases cell migration and epithelial resurfacing and prevents the formation of scabs, crusts, and eschar.

Acute Pain

The patient having a graft or flap has two wounds; in fact, the donor site may be more painful than the recipient site. Cutaneous surgeries, dermabrasions, and chemical treatments result in blistering, swelling, and loss of epidermal tissue. The patient having facial reconstructive surgery has edema, with resultant pain.

Expected Outcome: Patient will experience adequate pain relief and management as indicated by subjective report.

- Administer pain medications on a regular basis, following guidelines for controlling pain in patients having operative procedures (refer to Chapter 9). *Established, severe pain is difficult to control and has negative physical and psychologic consequences.*
- Use alternative pain relief measures as appropriate and prescribed, such as ice bags or cold compresses. *Cold reduces swelling, acts as a local anesthetic, and decreases pain.*
- Teach noninvasive methods of pain relief, such as deep breathing, relaxation, and guided imagery. *Noninvasive methods of pain relief increase the effectiveness of pain medications and also allow the patient some control and self-management of pain.*

Disturbed Body Image

Cosmetic surgery is performed for a variety of reasons in adult patients of all ages. Changes in appearance, especially in a society that values youth and beauty, affect one's self-perception. Lesions or scars, especially of the face, may decrease self-esteem and cause a person to avoid social interactions and relationships. With aging, the skin becomes looser and wrinkles appear; this can be a source of anxiety and despair, especially to the woman who has always prided herself on her youthful appearance. Most patients cite one reason for having plastic surgery: to "feel better about myself."

Expected Outcome: Patient's acceptance of body appearance as evidenced by adjustment to changes in physical appearance.

- Provide preoperative teaching: Explain that bruising and swelling will be present and that it will be several weeks before these responses to surgery disappear. Explain that it may take a year for healing to be completed and the final results to appear.

  Expectations differ; many people expect immediate results. Knowledge of postoperative responses is necessary for the patient to adapt to change. The patient may need to make arrangements to take time off from work during the initial healing stage.
- Provide time for the patient to verbalize feelings and concerns. Be empathetic, and listen nonjudgmentally. *Such nurse–patient interaction facilitates acceptance of changes in body image.*
- Refer to a consultant who can provide information on the use of cosmetics and apparel to enhance personal appearance. *Knowledgeable use of cosmetics and clothing can make scars much less noticeable. If the patient feels better about appearance, body image is improved.*

Delegating Nursing Care Activities

Collaborating with the interprofessional team including unlicensed assistive personnel to promote postoperative progression while providing care that promotes recovery and comfort is a nursing priority.

Teaching the patient and, as appropriate, caregivers strategies to prevent infection, optimize comfort, and promote safe behaviors to prevent postoperative infections or other complications also should be considered a priority nursing action. The nurse focuses on promoting comfort and maintaining asepsis for all interruptions of the integument.

Continuity of Care

The nurse teaches the patient and family to provide self-care at home after cutaneous and plastic surgery and procedures. The nurse asks about the patient's expectations and stresses that final results will not be seen for several months, providing written instructions about wound care and manifestations of infection.

Hair and Nail Disorders

Disorders of the hair and nails are not serious threats to health, but they may cause embarrassment and a negative body image. Changes in hair growth and pattern as well as in nail growth and character occur as secondary responses to other illnesses or treatments and are also a part of the aging process.

THE PATIENT WITH A DISORDER OF THE HAIR

Racial characteristics and gender influence the amount and type of hair one has. Caucasians typically have more facial and body hair than do Asians. People of Mongolian or Native American descent usually have straight hair, those of African descent have wavy to curly hair, and Whites have straight to curly hair. In addition, male hair growth characteristics (such as facial hair and hair on the lower extremities) are normal in certain women of some races and families.

Pathophysiology

Hair color, growth, and pattern vary from person to person, and they are determined largely by genetic inheritance. Changes such as hair loss in men or excess facial hair in women may seem minor, but they may create psychosocial problems for the person experiencing the changes.

HIRSUTISM

Hirsutism (hypertrichosis) is the appearance of excessive hair in women. Hirsutism most often occurs in a male distribution (that is, on the upper lip, chin, abdomen, and chest) in women. The excess hair is primarily the result of an increase in androgen levels (especially testosterone) that may be due to familial predisposition (considered normal); polycystic ovary syndrome; ovarian, adrenal, or pituitary tumors; Cushing's syndrome (an adrenal disorder); some central nervous system disorders; and medications, such as minoxidil, cyclosporine, phenytoin, certain progestins, and anabolic steroids.

The manifestations of hirsutism include increased male pattern hair growth, acne, and menstrual irregularities. If the androgen excess is great, defeminization (a decrease in breast size and loss of normal adipose tissue) and virilization (frontal balding, increased muscle mass, deepening of the voice, and enlargement of the clitoris) may occur.

ALOPECIA

Alopecia is loss of hair, or baldness. Alopecia may result from scarring, various systemic diseases, or genetic predisposition. Scarring from trauma, radiation, and severe bacterial, fungal, or viral infections causes permanent and irreversible hair loss over the scarred area. Systemic diseases that may cause alopecia include systemic lupus erythematosus, thyroid disorders, and pituitary insufficiency. The hair loss from these disorders may be reversible. Hair loss from androgenic causes may also occur in the postmenopausal woman. Alopecia may be drug induced and is a side effect of a variety of medications (Box 16–11).

Examples of types of alopecia follow:

- Male pattern baldness is the most common cause of alopecia in men and is genetically predetermined. The hair loss begins at the temples, with recession of the hairline and baldness of the crown.
- Female pattern alopecia begins in women in their 20s and 30s, with progressive thinning and loss of hair over the central part of the scalp. Unlike men, women do not lose hair from the frontal hairline. Many of these women have elevated adrenal androgens.
- Alopecia areata is characterized by round or oval bald patches on the scalp as well as on other hairy parts of the body. The cause is unknown. This type of alopecia is usually self-limiting and reverses without treatment, although it often recurs.

●○● INTERPROFESSIONAL CARE

The patient with hirsutism is examined for hormone levels and indications of other systemic illnesses. Hirsutism is treated by addressing the underlying systemic disorder and stopping medications that may be causing the problem. Hirsutism is also treated using laser therapy, which reduces unwanted hair. Alopecia is diagnosed by assessing the appearance of the hair and hair loss and by assessing the patient for other systemic diseases and the use of medications that may cause hair loss. Various treatments are used to restore hair.

DIAGNOSIS

Diagnostic tests that may be ordered for the woman with hirsutism include serum testosterone levels and an adrenal CT scan. Testosterone

BOX 16–11 Medications Causing Alopecia

- Thallium
- Retinoids
- Anticoagulants
- Antimitotic agents
- Antithyroid drugs
- Oral contraceptives
- Trimethadione
- Excessive doses of vitamin A
- Allopurinol
- Propranolol
- Indomethacin
- Amphetamines
- Salicylates
- Levodopa
- Gentamicin
- Chemotherapy

levels are measured and levels greater than 200 ng/dL indicate the need for further tests, such as a pelvic examination and tests of ovarian function. Adrenal tumors, a possible cause of hirsutism, are identified with an adrenal CT scan.

MEDICATIONS

Hirsutism is treated with medications specific to the underlying cause. Oral contraceptives containing estrogen decrease ovarian androgen production and decrease free testosterone levels. Dexamethasone (Decadron) may be prescribed for people with high cortisol levels. Ketoconazole (Nizoral) inhibits androgen production. Antiandrogenic medications cause congenital abnormalities in male infants and are therefore given only to nonpregnant women, who are cautioned to avoid pregnancy while taking the medications.

Male pattern baldness has been successfully treated with topical minoxidil (Loniten) or Rogaine Extra Strength, a commercial product that contains minoxidil. These drugs, which are vasodilators, stimulate vertex hair growth, probably by stimulating the epithelium of the hair follicle. About 40% of patients treated two times a day for a year will have moderate to dense regrowth of hair at the temples.

SURGERY

Hair transplant techniques are used to restore hair or reduce the size of areas of alopecia. Transplanting hairs as small hair plugs or single hairs taken from the back or sides of the scalp is an effective means of replacing hair to areas of alopecia. This procedure is done in an outpatient office or clinic. Other types of surgical procedures include scalp reduction and flaps.

●○● NURSING CARE

The patient with either hirsutism or alopecia is often self-conscious about appearance and tries a variety of OTC treatments before seeking medical care. Nursing care for the patient with hair disorders focuses on teaching the patient self-care and providing support during long-term care. Women with hirsutism are taught to use various means of removing unwanted hair, such as shaving, applying depilatories, waxing, or undergoing electrolysis. Women with mild hirsutism may bleach facial hair to make it less obvious. Patients with alopecia may wear hairpieces or wigs.

THE PATIENT WITH A DISORDER OF THE NAILS

Nail disorders may be congenital or genetic, or they may be due to systemic diseases, trauma, allergies, or irritants. Nails may be discolored, multicolored, malformed, infected, or separated from underlying tissue.

Pathophysiology

The nail disorders discussed here are separation of the nail, infection, and ingrown toenails:

- *Onycholysis* is the separation of the distal nail plate from the nail bed. It occurs most often in the fingernails. This disorder may result from many different factors, including excessive or prolonged exposure to water, soaps, detergent, alkalies, and industrial keratolytic agents; *Candida* infections; nail hardeners; and thyroid disorders. Prolonged application of false fingernails may also cause this disorder.
- A **paronychia** is an infection of the cuticle of the fingernails or toenails. The disorder often follows a minor trauma and secondary infection with staphylococci, streptococci, or *Candida*. The acute form begins with a painful inflammation that may progress to an abscess. The chronic form is seen most often in people who have frequent exposure to water. In the chronic form, the skin around the nail is painful, edematous, and infected. The nail plate may become ridged and discolored.
- An *onychomycosis* is a fungal or dermatophyte infection of the nail plate. The nail plate elevates and becomes yellow or white. Psoriasis infections of the nail plate cause the nails to pit.
- An *ingrown toenail* (unguis incarnatus) results when the edge of the nail plate grows into the soft tissue of the toe. Pain and infection may occur. The infection, if untreated, may spread to the bone. This disorder is especially dangerous for the person with diabetes mellitus or peripheral vascular disease.

●○● INTERPROFESSIONAL CARE

The treatment of disorders of the nail varies from pharmacologic treatment to surgical removal. Infections of the nails are treated with antifungal or antibiotic medications. If the causative agent is a fungus or chronic dermatologic disorder, treatment is difficult and may not be effective. Persistently painful and/or infected nails are in some cases surgically removed.

●○● NURSING CARE

Nursing care of the patient with a disorder of the nail focuses on teaching self-care. Patients with nail disorders that are caused by frequent exposure to water are taught to protect the hands or feet by wearing rubber gloves or boots and to keep the nails as clean and dry as possible. Patients with ingrown toenails are cautioned not to cut into the lateral nail bed, but rather to soak the nail twice a day and insert a piece of cotton or gauze under the softened nail until the nail has grown out enough to trim.

CHAPTER HIGHLIGHTS

- **The skin provides the first barrier between the internal and external environments.**
- **Skin disorders, lesions, and infections can range from mild to life threatening.**
- **Nursing plays a central role in the treatment and management of skin disorders.**
- Pruritus (itching) accompanies dry skin (xerosis) and many skin disorders and may result in excoriation and infection as a result of scratching.
- Cysts, keloids, nevi, angiomas, skin tags, and keratoses are benign skin lesions. However, nevi should be monitored for changes indicating transformation into malignant lesions.
- Psoriasis is a chronic immune skin disorder arising from keratinocytes. A variety of medications and treatments are used, with ultraviolet light therapy being most effective for generalized lesions.
- Skin disorders may be caused by a variety of bacteria, fungi, parasites, and viruses. The disorders are treated with organism-specific antibiotics, fungicides, antiviral agents, or agents that kill the parasites. Herpes zoster, believed to follow a childhood infection with chickenpox, causes acute pain.
- Inflammatory disorders of the skin range from mild to potentially lethal. Acne, a disorder of the hair and sebaceous glands opening to the skin surface, is characterized by comedones, pustules, and cysts.
- Malignant skin disorders include actinic keratosis, nonmelanoma skin cancer (basal cell cancer and squamous cell cancer), and malignant melanoma skin cancer. Skin cancer is the most common malignancy found in fair-skinned Americans. Avoiding sunburn, using sunscreen, and maintaining monthly skin self-examination are critical in preventing loss of tissue or metastasis and death.
- Skin trauma may be intentional (as in the case of cutaneous and plastic surgery) or unintentional (as from trauma, frostbite, and pressure ulcers). Older adults with limited mobility, as well as patients who are unable to move or who are in critical care units, are at greater risk for pressure ulcers. Prevention of pressure ulcers is the goal of both interprofessional and nursing care.
- Disorders of the hair include hirsutism (excess hair in women) and alopecia (loss of hair). Nails may be discolored, multicolored, malformed, infected, or separated from underlying tissue.

TEST YOURSELF NCLEX-RN® REVIEW

1. An older patient has severe xerosis. What topic should the nurse include in a teaching plan for this patient?
   1. Take a hot bath every day.
   2. Maintain a warm environment.
   3. Apply skin lotions after a bath.
   4. Use fabric softeners when laundering clothing.

2. The nurse is concerned that a patient's skin lesion can become malignant. Which lesion did the nurse assess in the patient?
   1. nevi
   2. keloid
   3. skin tag
   4. angioma

3. The nurse is teaching a patient with generalized psoriasis about ultraviolet light therapy (UVB). What should be included in this teaching?
   1. "When combined with hot baths, UVB is very effective."
   2. "Treatments with UVB have to be given in the hospital to be safe."
   3. "UVB slows the growth of epidermal cells and decreases keratosis."
   4. "The exact effect of UVB is unknown, but it decreases severe itching."

4. The nurse is preparing a teaching session for a group of community members on the dangers of skin cancer. Which skin lesion should the nurse emphasize as increasing the risk of developing skin cancer?
   1. folliculitis
   2. pressure ulcer
   3. lice infestation
   4. actinic keratosis

5. A patient is experiencing a rash of painful vesicles over the left thorax. What question should the nurse include when completing this patient's health history?
   1. "Have you ever been diagnosed with acne?"
   2. "Are you a regular patron of tanning booths?"
   3. "Do you remember being sunburned as a child?"
   4. "Did you have chickenpox when you were young?"

6. A patient is devastated after being diagnosed with body lice. What should the nurse explain to the patient about lice infestation?
   1. "Lice are a form of fungus."
   2. "Only dirty people have lice."
   3. "Lice do not like to live on humans."
   4. "Lice are associated with crowded living conditions."

7. At the completion of an assessment the nurse determines that a patient is at risk for developing nonmelanoma skin cancer. What did the nurse assess in this patient?
   1. alopecia, thin hair, itching
   2. blond hair, freckles, fair skin
   3. dark hair, dark skin, dry skin
   4. tanned skin, dark hair, edema

8. A patient is being assessed for a melanoma skin lesion. Which assessment finding suggests that further investigation for a melanoma is necessary?
   1. change in the color or size of a nevus
   2. dry, fissured, and hyperkeratotic skin
   3. red circumscribed plaques covered by silvery white scales
   4. firm mass located in the subcutaneous tissue and the lower dermis

9. When caring for a patient recovering from a stroke, the nurse coordinates a group of caregivers to help lift the patient up in bed. Why should the patient be lifted instead of pulled into position?
1. Pulling a patient up in bed promotes capillary blood flow.
2. Lifting a patient prevents tissue injury from shearing forces.
3. Pulling a patient up -in bed decreases tissue ischemia and hypoxia.
4. Lifting a patient allows a brief period of increased capillary circulation.

10. A young adult with acne scars asks the nurse what can be done to reduce the scarring. Which procedure should the nurse discuss with this patient?
1. skin flap
2. liposuction
3. dermabrasion
4. blepharoplasty

17 Nursing Care of Patients with Burns

LEARNING OUTCOMES

1. Discuss the types and causative agents of burns.
2. Explain burn classification by depth and extent of injury.
3. Compare and contrast the pathophysiology and interprofessional care of a minor burn and a major burn.
4. Discuss the systemic pathophysiologic effects of a major burn and the stages of burn wound healing.
5. Explain the interprofessional care and nursing implications necessary during the emergent/resuscitative stage, the acute stage, and the rehabilitative stage of a major burn.

CLINICAL COMPETENCIES

1. Assess functional health status of patients with burns, and monitor, document, and report abnormal manifestations.
2. Use evidence-based practice to plan and implement nursing care for patients with burns.
3. Determine priority nursing diagnoses, based on assessed data, to select and implement individualized nursing interventions for patient with burns.
4. Administer medications knowledgeably and safely to patients with burns.
5. Integrate interprofessional care into the care of patients with burns.
6. Provide teaching appropriate for prevention of burns.
7. Revise plan of care as needed to provide effective interventions to promote, maintain, or restore functional health status to patients with burns.

MAJOR CHAPTER CONCEPTS

- A burn injury results from exposure to heat, chemicals, radiation, or electric current resulting in tissue injury.
- The burn wound healing process involves three phases: inflammation, proliferation, and remodeling. These occur more slowly over a longer period of time compared to other wound healing experiences.
- Major burns involve all body processes. Extensive loss of skin (the body's protective barrier) can result in massive infection, fluid and electrolyte imbalances, and hypothermia.

A **burn** is an injury resulting from exposure to heat, chemicals, radiation, or electric current. A transfer of energy from a source of heat to the human body initiates a sequence of physiologic events that in the most severe cases leads to irreversible tissue destruction. Burns range in severity from a minor loss of small segments of the outermost layer of the skin to a complex injury involving all body systems. Treatments vary from simple application of a topical antiseptic agent in an outpatient clinic to an invasive, multisystem, interprofessional team approach in the aseptic environment of a burn center.

It is estimated that 450,000 burn injuries that require medical intervention occur each year in the United States, and of those, about 45,000 require hospitalization, with approximately 35,000 of the burn injuries resulting in death (American Burn Association [ABA], 2012). The home is the most common site for fire-related burns (68%). Home fires cause 85.7% of all fire-related deaths. Most residential fires are caused by unattended cooking and result from combustible grease, cabinets, wall coverings, curtains, and paper or plastic bags. Smoking materials, including cigarettes, cigars, and pipes, are the leading cause of home fire deaths. Trash, mattresses, and upholstered furniture are frequently ignited materials in the home.

FAST FACTS

Causes of Home Fires

- Cooking fires
- Smoking
- Heating equipment

Factors associated with deaths from burns are age (especially children under age 5 and adults ages 65 and older), careless smoking, alcohol or drug intoxication, and physical and mental disabilities. A common source of burns in young children and older adults is from tap water scalds, while older children receive most burns from flame injuries. Older adults are more susceptible to deep burns from scalds because of their thinner skin. Fire injuries and deaths occurring among college-age students usually are due to alcohol use that impairs judgment and hampers escape (National Fire Protection Association, 2012). Occupations involving work with chemicals, gasoline, or electricity pose another risk factor. Abuse is suspected when scald burns show a clear line of demarcation, indicating deliberate immersion. The presence of small, circular burns may be from cigarette burns inflicted by an abuser.

Older adults are more vulnerable to fire and burn injury because of decreased visual acuity, depth perception, sense of smell, and hearing, in addition to impaired mobility. All of these factors increase the risk for accidentally starting a fire and diminish the ability to survive it.

FAST FACTS

Fire Deaths in Older Adults

- More than 1200 deaths in adults ages 65 and older occur each year.
- Leading causes of fire-related deaths are smoking, heating, and cooking.
- One-fifth of the deaths occur in older adults who are bedridden or physically challenged.

Infants and older adults have a greater risk of mortality. Morbidity increases in patients with preexisting cardiac, pulmonary, or renal disorders, and diabetes mellitus. Patients with alcoholism have lower survival rates after a major burn injury due to the development of more complications. Men account for 69% of burn patients versus 31% for women (ABA, 2012).

TYPES OF BURN INJURY

The four types of burn injury are thermal, chemical, electrical, and radiation. Although all four types can lead to generalized tissue damage and multisystem involvement, the causative agents and priority treatment measures are unique to each (Table 17–1).

Thermal Burns

Thermal burns result from exposure to dry heat (flames) or moist heat (steam and hot liquids). They are the most common burn injuries and occur most often in children and older adults. Direct exposure to the source of heat causes cellular destruction that can result in charring of vascular, bony, muscle, and nervous tissue.

Chemical Burns

Chemical burns are caused by direct skin contact with acids, alkaline agents, or organic compounds. These chemicals destroy tissue protein, leading to necrosis. More than 25,000 products found in the home or workplace can cause chemical burns. Burns caused by alkalis (such as lye) are more difficult to neutralize than are burns caused by acids. They also tend to have deeper penetration with a correspondingly more severe burn than from acid. Organic compound burns, such as those caused by petroleum distillates, result in cutaneous damage through fat solvent action and may also cause renal and liver failure if absorbed.

Chemical agents are further classified according to the manner by which they structurally alter proteins. Oxidizing agents, such as household bleach, alter protein configuration through the chemical process of reduction. Corrosives, such as lye, cause extensive protein denaturation. Protoplasmic poisons, such as organic compounds, form salts with proteins, inhibiting calcium and other ions needed for cell viability. The severity of the chemical burn is related to the type of agent, the concentration of the agent, the mechanism of action, the duration of contact, and the amount of body surface area exposed. Box 17–1 lists household cleaning agents that may cause burns.

TABLE 17–1 Types of Burns, Their Causative Agents, and Priority Treatment Measures

Type	Causative Agent	Priority Treatment
Thermal	Open flame Steam Hot liquids (water, grease, tar, metal)	Extinguish flame (stop, drop, and roll). Flush with cool water. Consult fire department.
Chemical	Acids Strong alkalis Organic compounds	Neutralize or dilute chemical. Remove clothing. Consult poison control center.
Electrical	Direct current Alternating current Lightning	Disconnect source of current. Initiate CPR if necessary. Move to area of safety. Consult electrical experts.
Radiation	Solar (ultraviolet) X-rays Radioactive agents	Shield the skin appropriately. Limit time of exposure. Move the patient away from the radiation source. Consult a radiation expert.

Electrical Burns

The severity of electrical burns depends on the type and duration of current and the amount of voltage. It is particularly difficult to assess the extent of an electrical burn injury, because the destructive processes initiated by the electrical insult are concealed and may persist for weeks beyond the time of the incident. It is challenging to assess the depth and extent of the burn, because electricity follows the path of least resistance, which in the human body tends to lie along muscles, bone, blood vessels, and nerves. Entry and exit wounds tend to

BOX 17–1 Household Cleaning Agents That May Cause Burns

- Drain cleaners
- Lye
- Industrial-strength ammonia
- Household ammonia
- Oven cleaners
- Toilet bowl cleaners
- Dishwasher detergents
- Bleach

be small, masking widespread tissue damage underneath the wound. Tissue necrosis results from impaired blood flow, secondary to blood coagulation at the site of the electrical injury. Because electrical burn wounds of the extremities often cause severe tissue necrosis, they frequently develop gangrene that necessitates amputation.

Alternating current (AC), as is found in conventional households, produces repeated electrical surges that lead to tetanic muscle contractions. Such sustained muscle contractions inhibit respiratory efforts for the duration of contact and result in respiratory arrest. The contractions also cause the person to clamp down on the power source (such as an electrical cord) and thus may increase the duration of contact with the source. Direct current (DC), as in injury from a lightning bolt, exposes the body to very high voltage for an instantaneous period of time. A high-voltage (lightning) injury usually results in entry and exit wounds. The flashover effect, a phenomenon unique to lightning injury, actually saves the patient from death. It is seen in those instances in which the current travels over the moist surface of the skin rather than through deeper structures. Cardiopulmonary arrest is the most common cause of death from lightning.

Radiation Burns

Radiation burns are usually associated with sunburn or radiation treatment for cancer. These kinds of burns tend to be superficial, involving only the outermost layers of the epidermis. All functions of the skin remain intact. Symptoms are limited to mild systemic reactions: headache, chills, local discomfort, nausea, and vomiting. More extensive exposure to radiation or radioactive substances, as in nuclear power accidents, leads to the same degree of tissue damage and multisystem involvement associated with other types of burns.

FACTORS AFFECTING BURN CLASSIFICATION

Tissue damage following a burn is determined primarily by two factors: depth of the burn (the layers of underlying tissue affected) and extent of the burn (the percentage of body surface area involved).

Depth of the Burn

The depth of a burn injury is determined by the elements of the skin that have been damaged or destroyed. Burn depth results from a combination of the temperature of the burning agent and the length of contact. Burns are classified as either superficial, partial thickness, or full thickness. Characteristics of burns are described next, summarized in Table 17–2, and illustrated in Figure 17–1 ■.

SUPERFICIAL BURNS

A **superficial burn** involves only the epidermal layer of the skin. This type of burn most often results from a sunburn, ultraviolet light, a minor flash injury (from a sudden ignition or explosion), or a mild radiation burn associated with cancer treatment. Because the skin remains intact, this degree of burn is not part of a calculated burn injury estimate. The skin color ranges from pink to bright red, and there may be slight edema over the burned area. Superficial burns involving large body surface areas may be manifested by chills, headache, nausea, and vomiting. The injury usually heals in 3 to 6 days, with dryness and peeling of the outer layer of skin. There is no scar formation. Superficial burns are treated with mild analgesics and the application of water-soluble lotions. Extensive superficial burns, especially in older adults, may require intravenous fluid treatment.

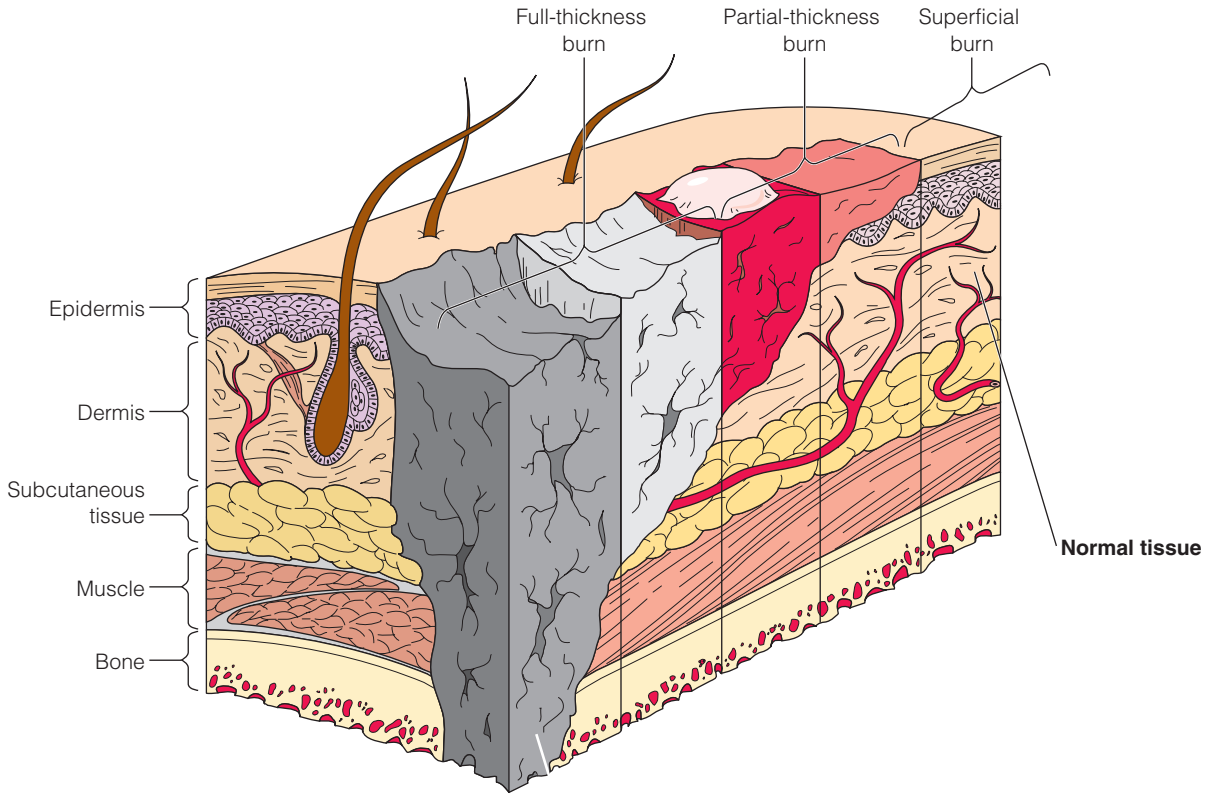

Figure 17–1 ■ Burn injury classification according to the depth of the burn.

TABLE 17–2 Characteristics of Burns by Depth

Characteristic	Superficial	Partial Thickness	Full Thickness
Skin layers lost	Epidermis	Epidermis and dermis	Epidermis, dermis, and underlying tissues
Skin appearance over burn	Pink to red and dry; may have local edema	Fluid-filled blisters; bright pink or red with superficial partial-thickness burns Pale, mottled, waxy white with deep partial-thickness burns	Waxy white; dry, leathery, charred
Skin function	Present	Absent	Absent
Pain sensation	Present	Present	Absent
Manifestations at the burn site	Pain; local edema	Severe pain; edema; weeping of fluid	Little pain; edema
Treatment	Regular cleaning Topical agent of choice	Regular cleaning Topical agent of choice May require skin grafting with deep partial-thickness burns	Regular cleaning Topical agent of choice Skin substitutes Excision of eschar Skin grafting
Scarring	None	May occur in deep burns	Of grafted area
Time to heal	3–6 days	14–21+ days	Requires skin grafting to heal

PARTIAL-THICKNESS BURNS

Partial-thickness burns may be subdivided into superficial partial-thickness and deep dermal partial-thickness burns. The classification depends on the depth of the burn.

A *superficial partial-thickness burn* involves the epidermis and the papillae of the dermis. Causes may include such injuries as a brief exposure to flash flame or dilute chemical agents, or contact with a hot surface. This burn is often bright red, but has a moist, glistening appearance with blister formation (Figure 17–2 ■). The burned area will blanch on pressure, and touch and pain sensation remain intact. Pain in response to temperature and air is usually severe due to exposure of intact nerves. These injuries heal within 21 days with minimal or no scarring, but pigment changes are common. Analgesics are administered, and if large blistered areas are disrupted, skin substitutes may be used.

A *deep partial-thickness burn* also involves the entire epidermis, but extends further into the dermis than a superficial partial-thickness burn. Hair follicles, sebaceous glands, and epidermal sweat glands remain intact (Huether & McCance, 2013). Hot liquids or solids, flash flame, direct flame, intense radiant energy, or chemical agents may cause this level of burn wound. The surface of the burn wound appears pale and waxy and may be moist or dry. Large, easily ruptured blisters may be present, or the blisters may look like flat, dry tissue paper. Capillary refill is decreased, and sensation to deep pressure is present. The burn wound is less painful than a superficial partial-thickness burn due to more nerve destruction, reducing sensation, but areas of pain and areas of decreased sensation may be present. Deep partial-thickness burn wounds often require more than 21 days for healing and may convert to a full-thickness injury as necrosis extends the depth of the wound. Contractures are possible, as are hypertrophic scarring and functional impairment (Figure 17–3 ■). Excision and grafting may be necessary to decrease scarring and loss of function.

FULL-THICKNESS BURNS

A **full-thickness burn** involves all layers of the skin, including the epidermis, the dermis, and the epidermal appendages (Figure 17–4 ■). The burn wound may extend into the subcutaneous fat, connective tissue, muscle, and bone. Full-thickness burns are caused by prolonged contact with flames, steam, chemicals, or high-voltage electric current.

Figure 17–2 ■ Partial-thickness burn injury.

Figure 17–3 ■ Burn contracture.

Figure 17–4 ■ Full-thickness burn injury.
Source: Photo Researchers, Inc.

Depending on the cause of injury, the burn wound may appear pale, waxy, yellow, brown, mottled, charred, or nonblanching red. The wound surface is dry, leathery, and firm to the touch. Thrombosed blood vessels may be visible under the surface of the wound. There is no sensation of pain or light touch, because pain and touch receptors have been destroyed. Full-thickness burns require skin grafting to heal.

Extent of the Burn

The extent of the burn injury is expressed as a percentage of the total body surface area (TBSA). Several methods are used to determine the extent of injury. The "rule of nines" is a rapid method of estimation used during the prehospital and emergency care phases. In this method, the body is divided into five surface areas—head and neck, trunk, arms, legs, and perineum—and percentages that equal or total a sum of nines are assigned to each body area (Figure 17–5 ■). For example, a patient with burns of the face, anterior right arm, and anterior trunk has burn injury involving 27% of the TBSA (in this example, face = 4.5%, arm = 4.5%, and trunk = 18% to total 27%). Only partial- and full-thickness burns are included in the estimation.

On the patient's admission to the hospital, critical care area, or burn center, more accurate methods for estimating the extent of injury are employed. For example, the Lund and Browder method (Figure 17–6 ■) determines surface area measurements for each

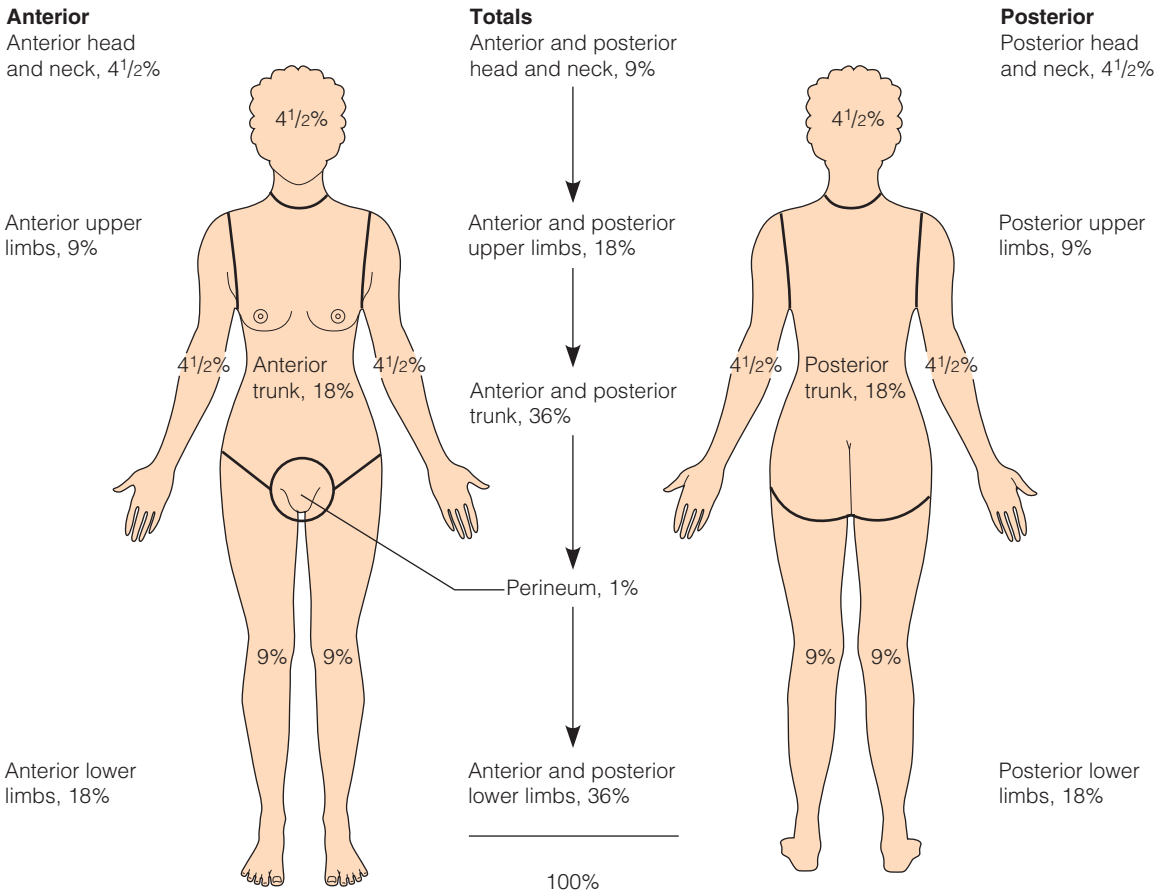

Figure 17–5 ■ The "rule of nines" is a method for quickly estimating the percentage of TBSA affected by a burn injury. Although useful in emergency care situations, the rule of nines is not accurate for estimating TBSA for adults who are short, obese, or very thin.

Area	Age (years)					% 1°	% 2°	% 3°	% Total
	0–1	1–4	5–9	10–15	Adult				
Head	19	17	13	10	7				
Neck	2	2	2	2	2				
Ant. trunk	13	13	13	13	13				
Post. trunk	13	13	13	13	13				
R. buttock	$2\frac{1}{2}$	$2\frac{1}{2}$	$2\frac{1}{2}$	$2\frac{1}{2}$	$2\frac{1}{2}$

					Total				

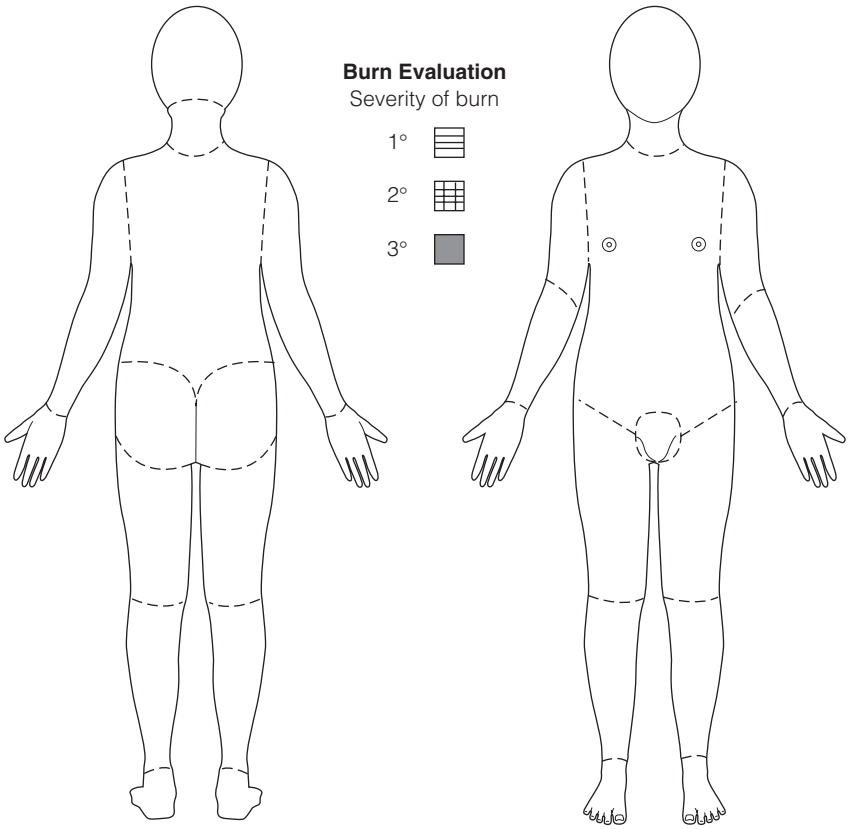

Figure 17–6 ■ The Lund and Browder burn assessment chart. This method of estimating TBSA affected by a burn injury is more accurate than the "rule of nines" because it accounts for changes in body surface area across the life span.

TABLE 17–3 American Burn Association Classification of Burn Injury

Minor Burn Injury	Moderate Burn Injury	Major Burn Injury
Excludes electrical injury, inhalation injury, complicated injuries (such as multiple trauma), and all patients who are considered to be at high risk (such as older adults and those with chronic illnesses).	Excludes electrical injury, inhalation injury, complicated injuries (such as multiple trauma), and all patients who are considered to be at high risk (such as older adults and those with chronic illnesses).	Includes all burns of the hands, face, eyes, ears, feet, and perineum; all electrical injuries, inhalation injuries, multiple-trauma injuries, and all patients who are considered to be at high risk.
Partial-thickness burns of less than 15% of the total body surface area in adults	**Partial-thickness burns** of 15% to 25% of the total body surface area in adults	**Partial-thickness burns** of greater than 25% of the total body surface area in adults
Full-thickness burns of less than 2% of the total body surface area not involving special care areas (eyes, ears, face, hands, feet, perineum)	**Full-thickness burns** of less than 10% of the total body surface area not involving special care areas (eyes, ears, face, hands, feet, perineum)	All **full-thickness burns** of 10% or greater of the total body surface area

Note: Burn injuries described in this table (except minor burns) should be treated in a specialized burn center. These criteria have been established by the American Burn Association.

body part according to the age of the patient and is considered the most accurate estimation of burn injury extent.

A recognized system for describing a burn injury, developed by the ABA, uses both the extent and depth of burn to classify burns as minor, moderate, or major (Table 17–3).

BURN WOUND HEALING

Burns heal using the same processes as do other wounds, but the wound healing phases occur more slowly and last longer. The healing process involves three phases: inflammation, proliferation, and remodeling. The following physiologic events occur (Huether & McCance, 2013):

- ***Inflammation.*** Immediately following the injury, platelets coming in contact with the damaged tissue aggregate. Fibrin is deposited, trapping further platelets, and a thrombus is formed. The thrombus, combined with local vasoconstriction, leads to hemostasis, which walls off the wound from the systemic circulation.

  Local vasodilation and an increase in capillary permeability follow hemostasis. Neutrophils infiltrate the wound and peak in about 24 hours, and then monocytes dominate. The monocytes are converted into macrophages, which consume pathogens and dead tissue and also secrete various growth factors. These growth factors stimulate the proliferation of fibroblasts and the deposit of a provisional wound matrix.
- ***Proliferation.*** Within 2 to 3 days postburn, fibroblasts are the major cell within the wound. Their number peaks at about 14 days after the injury. Granulation tissue begins to form, with complete reepithelialization occurring during this stage. Epithelial cells cover the wound as each cell stretches across the wound surface to join with other epithelial cell sheets or the other side of the wound. The proliferation phase lasts until complete reepithelialization occurs, by epithelial cell migration, surgical intervention, or a combination of the two.
- ***Remodeling.*** This phase may last for years. Collagen fibers, laid down during the proliferative phase, are reorganized into more compact areas. Scars contract and fade in color. In normal healing following a minor burn injury, the newly formed skin closely resembles its neighboring tissue. However, when a burn injury extends into the dermal layer of skin, two types of excessive scar may develop. A **hypertrophic scar** is an overgrowth of dermal tissue that remains within the boundaries of the wound. A **keloid** is a scar that extends beyond the boundaries of the original wound. People with dark skin are at greater risk for hypertrophic scars and keloids.

THE PATIENT WITH A MINOR BURN

Minor burn injuries consist of superficial burns that are not extensive, superficial partial-thickness burns that involve less than 15% of TBSA, and full-thickness burns that involve less than 2% of TBSA, excluding the special care areas (eyes, ears, face, hands, feet, perineum, and joints). Minor burn injuries are not associated with immunosuppression, hypermetabolism, or increased susceptibility to infection.

A minor burn injury is usually treated in an outpatient facility. The goal of therapy is to promote wound healing, eliminate discomfort, maintain mobility, and prevent infection.

Pathophysiology

SUNBURN

Sunburns result from exposure to ultraviolet light. Such injuries, which tend to be superficial, are more commonly seen in patients with lighter skin. Because the skin remains intact, the manifestations in most cases are mild and are limited to pain, nausea, vomiting, skin redness, chills, and headache. Treatment is performed on an outpatient basis and generally consists of applying mild lotions, increasing liquid intake, administering mild analgesics, and maintaining warmth. Older adults should be monitored for evidence of dehydration. Proper use of sunscreen and limiting sun exposure to the less hazardous hours of the day (before 10 a.m. and after 3 p.m.) can prevent sunburn.

SCALD BURN

Minor scald burns result from exposure to moist heat and involve superficial and superficial partial-thickness burns of less than 15% of TBSA. The goals of therapy are to prevent wound contamination and to promote healing. The nurse teaches the patient to apply antibiotic solutions and light dressings and to maintain adequate nutritional intake. Mild analgesics may be ordered to help the patient carry out activities of daily living.

●○● INTERPROFESSIONAL CARE

In the outpatient facility, the wound may be washed with mild soap and water. Tetanus toxoid booster is recommended for all patients whose immunization histories are in doubt. Minor burns with blisters may be left intact, or debrided. Follow-up care for a minor burn injury includes twice-daily wound cleansing with application of a topical ointment, range-of-motion (ROM) exercises to affected joints, and weekly clinic appointments until the wound heals completely.

●○● NURSING CARE

Although the nurse seldom treats minor burns in the acute care environment, the burn treatment methods used in the outpatient setting follow the same standard approaches to care. General nursing measures include taking the history, estimating the extent and depth of the injury, cleansing the wound, applying topical agents, dressing the wound, controlling pain, and establishing follow-up care.

Assessment

Assessment of minor burns includes health history and determining the extent and depth of the burn injury.

Priorities of Care

Collaborating with the interprofessional team to delivery adequate treatment of the underlying burn injury while providing care that supports the physical and psychologic responses to the injury is a nursing priority. Teaching the patient and, as appropriate, caregivers, strategies for pain management, infection control, and self-care included in the therapeutic regimen also should be considered priority nursing actions. The nurse also focuses on providing emotional support throughout the patient's experience.

Continuity of Care

The nurse should address the following topics to facilitate self-care of minor burns at home:

- How to identify and report manifestations of impaired wound healing:
  - Change in healthy appearance of the wound (altered skin integrity, swelling, blister formation, erythema)
  - Signs of infection (fever, purulent drainage, foul odor).
- Wound care:
  - Daily cleansing with mild soap and water
  - Using sterile technique to change dressings
  - Correct application of ordered topical agents.
- Pain management:
  - Use mild analgesics as ordered
  - Use alternative pain management therapies.

THE PATIENT WITH A MAJOR BURN

A major burn involves serious injury to the underlying layers of skin and covers a large body surface area. The ABA defines a major burn as one that involves:

- More than 25% TBSA in adults less than 40 years of age
- More than 20% TBSA in adults more than 40 years of age
- More than 10% TBSA full-thickness burn
- Injuries to the face, eyes, ears, hands, feet, or perineum
- High-voltage electrical injuries
- All burn injuries with inhalation injury or major trauma.

Pathophysiology

The pathophysiologic changes that result from major burn injuries involve all body systems. Extensive loss of skin (the body's protective barrier) can result in massive infection, fluid and electrolyte imbalances, and hypothermia. Often the person inhales the products of combustion, thus compromising respiratory function. Cardiac dysrhythmias and circulatory failure are common manifestations of serious burn injuries. A profound catabolic state dramatically increases caloric expenditure and nutritional deficiencies. An alteration in gastrointestinal motility predisposes the patient to developing paralytic ileus, and hyperacidity leads to gastric and duodenal ulcerations. Dehydration slows glomerular filtration rates and renal clearance of toxic wastes and may lead to acute tubular necrosis and renal failure. Overall body metabolism may be profoundly altered. Systemic responses to burns are shown in Figure 17–7 ■ and discussed in the following sections.

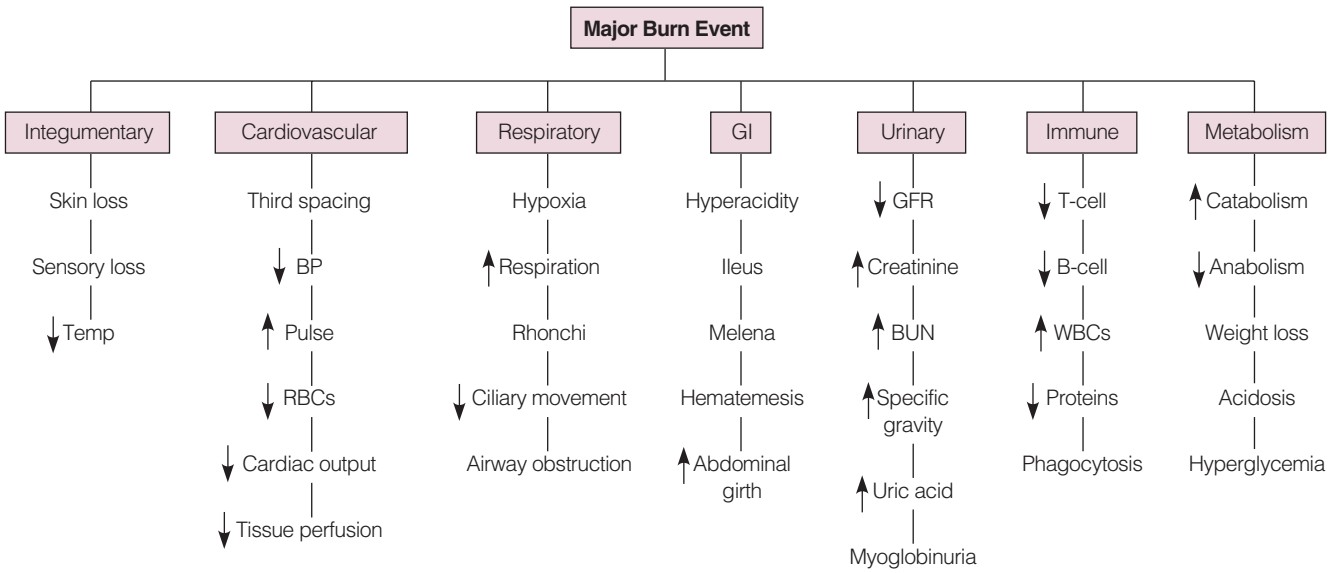

Figure 17–7 ■ Effects of a severe burn on major body systems and metabolism.

INTEGUMENTARY SYSTEM

The loss of skin in burn injuries interrupts normal skin functions and the skin's protective mechanisms (refer to Chapter 15). Key mechanisms lost in burn injuries include the prevention of evaporative water loss and bacteria entry, as well as the maintenance of body warmth.

Heat transfer to skin is a complex phenomenon. If the microcirculation of the skin remains intact during burning, it cools and protects the deeper portions of the skin and cools the outer surface once the heat source is removed. With extensive burn injury, the integrity of the microcirculation is lost, and the burning process continues even after the heat source is removed.

Burns have a characteristic skin surface appearance that resembles a bull's-eye, with the most severe burn located centrally and the lesser burns located along the peripheral wound edges. Depending on their intensity, burns consist of one, two, or three concentric three-dimensional zones closely corresponding on the skin surface to the depth of the burn (Figure 17–8 ■):

- The outer zone of hyperemia is unburned tissue, blanches on pressure, and heals in 2 to 7 days postburn.
- The medial zone of stasis is initially moist, red, and blistered and blanches on pressure. It may recover or become pale and necrotic on days 3 to 7 postburn due to decreased perfusion or infection.
- The inner zone of coagulation immediately appears leathery and coagulated. It may merge with the zone of stasis in 3 to 7 days postburn.

The overall thickness of the dermis and epidermis varies considerably from one area of the body to another. Similar temperatures produce different depths of injury to different body parts. For example, in the adult, the skin covering the medial aspect of the forearm is thinner and more easily damaged than the skin covering the back of the same person. Skin dissipates heat maximally in areas of greatest vascularization. When heat absorption exceeds the rate of dissipation, cellular temperatures rise, and skin tissue is destroyed.

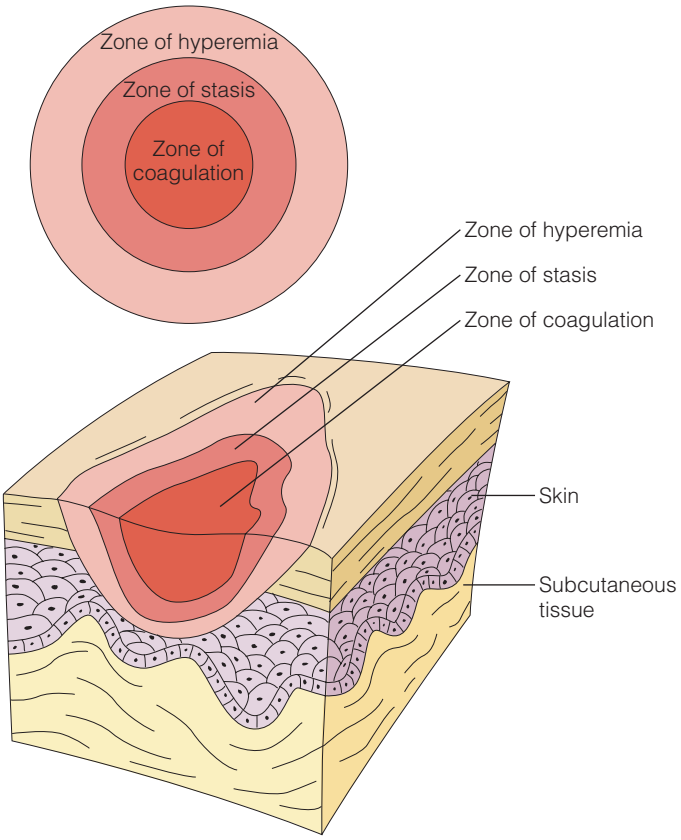

Figure 17–8 ■ The zones of injury.

A burn injury results in the formation of necrotic skin and subcutaneous tissue. During the acute stage of the injury, a hard crust (**eschar**) forms, which covers the wound and harbors necrotic tissue. The eschar is characteristically leathery and rigid. Removal of the eschar facilitates healing.

CARDIOVASCULAR SYSTEM

The effects of a major burn are manifested in all components of the vascular system, and include hypovolemic shock (burn shock), cardiac dysrhythmias (such as ventricular fibrillation), cardiac arrest, and vascular compromise.

HYPOVOLEMIC SHOCK (BURN SHOCK) Within minutes of a burn injury, a cascade of cellular events is initiated, and a massive amount of fluid shifts from the intracellular and intravascular compartments into the interstitium (third spacing). This shift is a type of hypovolemic shock called **burn shock**, and it continues until capillary integrity is restored, usually within 24 to 36 hours of the injury. Although the pathophysiologic mechanisms of postburn vascular changes and fluid volume shifts are not clearly understood, three processes occur early in the postburn phase in patients with injury to >40% TBSA:

- Increase in microvascular permeability at the burn wound site
- Generalized impairment of cell wall function, resulting in intracellular edema
- Increase in osmotic pressure of the burned tissue, leading to extensive fluid accumulation.

During burn shock, the shifting of fluid is the direct result of a loss of cell wall integrity at the site of injury and in the capillary bed. Fluid leaks from the capillaries into interstitial compartments located at the burn wound site and throughout the body, resulting in a decrease in fluid volume within the intravascular space. Plasma proteins and sodium escape into the interstitium, enhancing edema formation. Blood pressure falls as cardiac output diminishes.

Vasoconstriction results as the vascular system attempts to compensate for fluid loss. Abnormal platelet aggregation and white blood cell (WBC) accumulation result in ischemia in the deeper tissue below the burn, leading to eventual thrombosis. Red blood cells (RBCs) and WBCs remain in the circulation, producing an elevation in erythrocyte and leukocyte counts secondary to hemoconcentration.

The leakage of fluid into the interstitium compromises the lymphatic system, resulting in intravascular hypovolemia and edema at the burn wound site. Edematous body surfaces impair peripheral circulation and result in necrosis of the underlying tissue. During burn shock, potassium ions leave the intracellular compartment, predisposing the patient to developing cardiac dysrhythmias. The process of burn shock continues until capillary integrity is restored, usually within 24 hours of the injury.

Burn shock reverses when fluid is reabsorbed from the interstitium into the intravascular compartment. The blood pressure rises as cardiac output increases, and urinary output improves. Diuresis continues from several days to 2 weeks postburn. During this phase,

the extra cardiac workload may predispose the older patient, or the patient with cardiovascular disease, to fluid volume overload.

CARDIAC RHYTHM ALTERATIONS Burns of more than 40% TBSA cause significant myocardial dysfunction, with a decrease in myocardial contractibility and cardiac output. These changes, which occur prior to a decrease in plasma volume, are believed to be due to the release of substances and oxygen-free radicals from the burn wound and from ischemic myocardial cells. Electrical burns often result in cardiac dysrhythmias or cardiopulmonary arrest caused by heat damage to the myocardium or electrical interference with cardiac electrical activity.

PERIPHERAL VASCULAR COMPROMISE Direct heat damage to extremities, especially if circumferential burns are present, results in damage to blood vessels. Circulation to extremities may be further impaired by edema and by peripheral vasoconstriction that occurs during burn shock. In addition, **compartment syndrome** (in which the tissue pressure within a muscle compartment exceeds microvascular pressure, interrupting cellular perfusion) may result from circumferential burns and edema.

RESPIRATORY SYSTEM

Pulmonary damage may result from either direct inhalation injury or as part of the systemic response to the injury. Inhalation injury is a frequent and often lethal complication of burns. The injury may range from mild respiratory inflammation to massive pulmonary failure such as acute respiratory distress syndrome. Exposure to heat, asphyxiants, and smoke initiates the pathophysiologic process associated with inhalation injury.

Inflammation occurs at localized sites within the airway and is manifested as hyperemia. As a result, cells are destroyed and the bronchial cilia are rendered inactive. Because the mucociliary transport mechanism no longer functions, the patient may develop bronchial congestion and infection.

Interstitial pulmonary edema develops secondary to the escape of fluid from the pulmonary vasculature into the interstitial compartment of the lung tissue. Surfactant is inactivated, resulting in atelectasis and alveolar collapse. Sloughing of the damaged and dead lung tissue occasionally produces debris that may lead to complete airway obstruction.

Upper airway (above the level of the glottis) thermal injury results from the inhalation of heated air or chemicals dissolved in water. Inhalation injury is suspected when the patient has singed facial, scalp, or nasal hair. Physical findings include the presence of soot, charring, edema, blisters, and ulcerations along the mucosal lining of the oropharynx and larynx. The resulting edema in the airway peaks within the first 24 to 48 hours of injury. Ominous signs of hoarseness, labored breathing, or stridor indicate possible airway obstruction due to edema. Lower airway thermal injury is a rare occurrence. Thermal injury below the vocal cords is seldom seen because the lower airway is protected by laryngeal reflexes. However, when it does occur, it is typically associated with the inhalation of steam or explosive gases or the aspiration of hot liquids. A classic finding is sputum containing soot or carbon particles.

Smoke poisoning results when toxic gases and particulate matter, the products of incomplete combustion, deposit directly onto the pulmonary mucosa. The composition of the products of combustion depends on the combustible material, the rate at which the temperature increases, and the amount of ambient oxygen present. Irritant gases and particulate matter have a direct cytotoxic effect. The degree of injury is determined by their solubility in water, duration of exposure, and the size of the particulate or aerosol droplet.

Carbon monoxide, a common asphyxiant, is a colorless, tasteless, odorless gas that has a 200 times greater affinity for hemoglobin than does oxygen. It displaces oxygen to bind with hemoglobin, forming carboxyhemoglobin. As a result, the decrease in arterial oxyhemoglobin produces tissue hypoxia. Carbon monoxide impairs both oxygen delivery and cellular oxygen use. The clinical manifestations of carbon monoxide poisoning range from mild visual impairment to coma and death (see the following Manifestations box).

Cyanide gas is released when plastics, polyurethane, nylon, or silk is burned. The released cyanide gas affects cellular respiration. The brain and heart are most vulnerable to cyanide poisoning. Treatment addresses the inability of the body to use oxygen. Hyperbaric oxygen (oxygen delivery in a high-pressure chamber) may be used with inhalation of smoke. Hydroxocobalamin (Cyanokit) is a form of vitamin B_{12} that converts cyanide to a form that can be excreted from the body.

FAST FACTS

Cyanide Poisoning Signs and Symptoms

- Headache
- Dizziness
- Seizures
- Tachycardia
- Lethal dysrhythmias

GASTROINTESTINAL SYSTEM

Dysfunction of the gastrointestinal system is directly related to the size of the burn wound. Patients with burns to ≥20% TBSA experience decreased peristalsis with resultant gastric distention and increased risk of aspiration. A decrease in or absence of bowel sounds is a manifestation of paralytic ileus (adynamic bowel) secondary to burn trauma. The resulting cessation of intestinal motility leads to gastric distention, nausea, vomiting, and hematemesis.

Stress ulcers (**Curling's ulcers**) are acute ulcerations of the stomach or duodenum that form following a burn injury. Abdominal pain, acidic gastric pH levels, hematemesis, and melena in the stool may indicate a gastric ulcer.

In addition, ischemia of the intestine from splanchnic vasoconstriction increases the intestinal mucosal permeability. As a result, normal intestinal bacteria move from the lumen of the bowel to

MANIFESTATIONS OF CARBON MONOXIDE POISONING

Level of Carbon Monoxide	Manifestations
10%–20%	Headache, dizziness, nausea, abdominal pain
21%–40%	Headache, nausea, drowsiness, dizziness, irritability, confusion, stupor, hypotension, bradycardia, skin color ranging from pale to dark red
41%–60%	Convulsion, coma, hypotension, tachycardia
>60%	Death

extraluminal sites, a process called *bacterial translocation*. This process is believed to be one of the mechanisms causing systemic sepsis and multiple organ dysfunction syndrome.

URINARY SYSTEM

During the early stages of a burn injury, renal blood flow and glomerular filtration rates are greatly reduced from the decreased intravascular blood volume and the release of antidiuretic hormone (ADH) by the posterior pituitary. Urine output decreases, and serum creatinine and blood urea nitrogen levels increase.

Dark brown concentrated urine may indicate myoglobinuria or hemoglobinuria, the result of underlying muscle damage or the release of large amounts of dead or damaged erythrocytes after a major burn injury. When large amounts of these pigments are released, the liver cannot keep pace with conjugation and the pigments pass through the glomeruli. The pigments can occlude the renal tubules and cause renal failure, especially when dehydration, acidosis, or shock is also present.

IMMUNE SYSTEM

The function of the immune system is to protect the human body from invasion by foreign microorganisms. The capillary leak that occurs in the early stages of a burn injury continues throughout the burn shock phase and impairs the active components of both the cell-mediated and humoral immune systems.

The humoral immune system relies on B cells to produce antibodies or immunoglobulins (refer to Chapter 13). In the burn patient, the serum levels of all immunoglobulins are significantly diminished. Serum protein levels remain persistently low throughout the clinical course until wound closure is completed. A marked decrease in T-cell counts results in a reduction of cytotoxic activity and suppression of the cell-mediated immune system.

The compromise in the humoral and cell-mediated immune systems constitutes a state of acquired immunodeficiency, which places the burn patient at risk for infection. The period of vulnerability is transient and may last from 1 to 4 weeks following the onset of a burn injury. During this time frame, opportunistic infections can be fatal despite aggressive antimicrobial therapy.

METABOLISM

Two distinct phases characterize the body's metabolic response to a burn injury. The ebb phase, occurring during the first 3 days of the injury, is manifested by decreased oxygen consumption, fluid imbalance, shock, and inadequate circulating volume. These responses protect the body from the initial impact of the injury.

A second phase, the flow phase, occurs when adequate burn resuscitation has been accomplished. This phase is characterized by increases in cellular activity and protein catabolism, lipolysis, and gluconeogenesis. The basal metabolic rate (BMR) significantly increases, reaching twice the normal rate. Body weight and heat drop dramatically. Total energy expenditure may exceed 100% of normal BMR. Hypermetabolism persists until after wound closure has been accomplished and may reappear if complications occur.

●○● INTERPROFESSIONAL CARE

The burn team is composed of an interprofessional group of healthcare professionals who together plan the care and treatment of the burn-injured patient during the acute and rehabilitative stages. The burn team consists of the nurse, physician, physical therapist, occupational therapist, nutritionist, psychiatrist/psychologist, and social worker. Team members meet regularly to discuss patient progress and to determine collaboratively the most effective regimen of care and psychosocial support.

STAGES OF INTERPROFESSIONAL CARE

The clinical course of treatment for the burn patient is divided into three stages: the emergent/resuscitative stage, the acute stage, and the rehabilitative stage. Although these stages are useful predictors of the clinical needs of burn patients, it is important to recognize that the process of burn injury is dynamic and that, in many cases, the clinical stage may not be clearly delineated. Assessment and management of burn-injured patients are ongoing processes determined by the clinical picture; they last throughout the course of treatment. Figure 17–9 ■ shows the burn patient's progression through the healthcare system during each clinical stage of burn care. During each stage, different groups of nurses, physicians, and other healthcare specialists collaborate to manage the patient's recovery.

THE EMERGENT/RESUSCITATIVE STAGE The emergent/resuscitative stage lasts from the onset of injury through successful fluid resuscitation. During this stage, healthcare workers estimate the extent of burn injury, institute first-aid measures, and implement fluid resuscitation therapies. The patient is assessed for shock and evidence of respiratory distress. If indicated, intravenous lines are inserted, and the patient may be prophylactically intubated. During this stage, healthcare workers determine whether the patient needs to be transported to a burn center to take advantage of the complex intervention strategies offered by a specialized interprofessional burn team.

Although many burn injuries are treated in local tertiary care facilities, the ABA has developed guidelines for determining whether a patient should be transported to a burn center for interprofessional approaches to treatment and rehabilitation. Adult patients who should be treated at burn centers include those with the following:

- Second- or third-degree burns > 10% TBSA in adults older than age 50
- Second- or third-degree burns > 20% TBSA in adults younger than age 50
- Third-degree burns > 5% TBSA in adults of any age
- Burns involving the hands, feet, face, eyes, ears, or perineum
- Electrical (including lightning), chemical, and inhalation injuries
- Circumferential burns of the extremities and/or chest
- Any burn associated with extenuating problems, preexisting illness, fractures, or other trauma.

ACUTE STAGE The acute stage begins with the start of diuresis and ends with closure of the burn wound (either by natural healing or by using skin grafts). During this stage, wound care management, nutritional therapies, and measures to control infectious processes are initiated. Hydrotherapy and excision and grafting of full-thickness wounds are performed as soon as possible after injury. Enteral and parenteral nutritional interventions are started early in the treatment plan to address caloric needs resulting from extensive energy expenditure. Measures to combat infection are implemented during this stage, including the administration of topical and systemic antimicrobial agents. Tetanus toxoid booster is recommended for all patients whose immunization histories are in doubt. Pain management

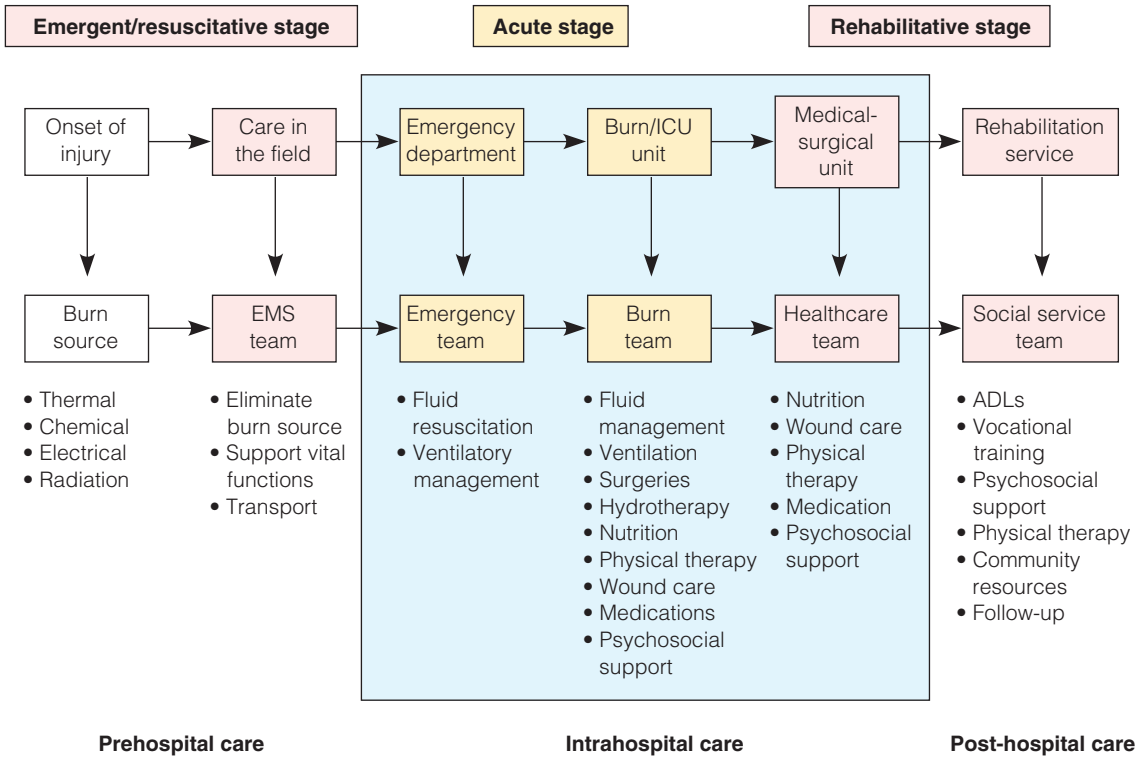

Figure 17–9 ■ The patient's progression through the healthcare system during the emergent, acute, and rehabilitative stages of burn injury.

constitutes a significant segment of the nursing care plan throughout the clinical course of patients with burn injuries. The administration of narcotic pharmaceutical agents must precede all invasive procedures to maximize patient comfort and to reduce the anxieties associated with wound debridement and intensive physical therapy.

REHABILITATIVE STAGE The rehabilitative stage begins with wound closure and ends when the patient returns to the highest level of health restoration, which may take years. During this stage, the primary focus is the biopsychosocial adjustment of the patient, specifically the prevention of contractures and scars and the patient's successful resumption of work, family, and social roles through physical, vocational, occupational, and psychosocial rehabilitation. The patient is taught to perform ROM exercises to enhance mobility and to support injured joints.

PREHOSPITAL PATIENT MANAGEMENT

Treatment at the injury scene includes measures to limit the severity of the burn and support vital functions. Before attempting to remove the patient from the source of burn injury, rescuers must ensure their own safety. Depending on the causative agent, rescuers may need to consult with experts to determine the best way to eliminate the source of the injury. Once the safety of the rescuers has been established, all prehospital interventions are aimed at eliminating the heat source, stabilizing the patient's condition, identifying the type of burn, preventing heat loss, reducing wound contamination, and preparing for emergency transport. Restrictive jewelry and clothing are removed at the scene to prevent circumferential constriction of the torso and extremities.

STOP THE BURNING PROCESS Emergency measures, by type of injury, are discussed next.

THERMAL BURNS If the thermal injury has been caused by dry heat, smother inflamed clothing or lavage with water. Help the person "stop, drop, and roll" to extinguish the flame and limit the extent of burn. Once the flame has been extinguished, cover the body to prevent hypothermia. If the thermal injury has been caused by moist heat, lavage the area with cool water. Ice is not used for cooling because it causes vasoconstriction and may result in further injury. Tar and asphalt can be removed with Medisol, a citrus and petroleum distillate with a hydrocarbon structure.

CHEMICAL BURNS For chemical burns, immediately remove the clothing and use a hose or shower to lavage the involved area thoroughly for a minimum of 20 minutes. Many chemicals are in powder form and as much dry chemical needs to be removed as possible before flushing the surface with water. Unusual chemicals may require consultation with the poison control center about appropriate treatment. Protective clothing should be worn during this process to protect the rescuer from chemical exposure. Chemical splashes in or near the eye require immediate eye irrigation with clean, cool water or saline.

ELECTRICAL BURNS Electrical injuries pose serious potential harm to both rescuer and burn victim. Ensure that the source of electrical current has been disconnected, or move the person to safety and away from the energy source using a nonconductive device such as an unpainted broomstick. If the person is unresponsive, assess for the presence of cardiac and respiratory function. If indicated, begin cardiopulmonary resuscitation (CPR). A spinal cord injury may be present secondary to the forceful contraction of the muscles of the neck and back during exposure to the current. If possible, place the person in a cervical collar and transport on a spinal board.

RADIATION BURNS Radiation injuries are usually minor and involve only the epidermal layer of skin. Treatment focuses on helping normal body mechanisms promote wound healing. For severe radiation burns, such as those that result from industrial radiation accidents, trained personnel may need to render the area safe for entry prior to rescue. All interventions are aimed at shielding, establishing distance, and limiting the time of exposure to the radioactive source.

SUPPORT VITAL FUNCTION The initial assessment of the patient's respiratory and hemodynamic status begins with an evaluation of the patient's airway, breathing, and circulation (the ABCs of care).

- If the patient has no pulse and is not breathing, begin CPR. Establish an airway, and start chest compressions. Continue CPR until spontaneous cardiopulmonary function returns or until the emergency management team takes over.
- Position the patient with the head elevated at greater than 30 degrees, and administer 100% humidified oxygen by face mask. Use nasotracheal suction as necessary to maintain a patent airway. Endotracheal intubation may be necessary if the patient has facial edema and inhalation injury. Auscultate the lungs often onsite to monitor respiratory status. Continuous pulse oximetry provides ongoing assessment of the patient's oxygen saturation levels.
- Monitor for cardiac dysrhythmias or arrest. When available, connect the patient to a cardiac monitor and observe for dysrhythmias. Elevate burned extremities above the level of the heart to facilitate circulation.
- Initiate fluid replacement therapy for burn wounds that involve more than 20% TBSA. Continuously assess heart and lung sounds and observe level of consciousness, cardiac rate and rhythm, blood pressure, and urine output.
- Cover the patient to maintain body temperature and to prevent further wound contamination and tissue damage.

EMERGENCY AND ACUTE CARE

Prehospital personnel report to the emergency department staff all findings and medical interventions that occurred at the scene of the injury. The nurse obtains a history of the injury, estimates the depth and extent of the burn, begins fluid resuscitation, and maintains ventilation according to protocol.

FLUID RESUSCITATION **Fluid resuscitation** is the administration of intravenous fluids to restore the circulating blood volume during the acute period of increasing capillary permeability. To counteract the effects of burn shock, fluid resuscitation guidelines are used to replace the extensive fluid and electrolyte losses associated with major burn injuries. Fluid replacement is necessary in all burn wounds that involve ≥20% TBSA.

Crystalloid fluids are administered through two large-bore (14- to 16-gauge) catheters, preferably inserted through unburned skin. Warmed Ringer's lactate solution is the intravenous fluid most widely used during the first 24 hours after burn injury, because it most closely approximates the body's extracellular fluid composition. Several formulas may be used to replace fluid loss. The Consensus formula is the most commonly used:

- Lactated Ringer's or other balanced saline solution is administered: 2 to 4 mL × kg × % TBSA burn.
- Half of the amount is infused during the first 8 hours. The remainder of the amount is infused during the next 16 hours.

Hourly urine output is often used as an indicator of effective fluid resuscitation, with about 0.5 mL/kg/hr for an adult considered adequate. Another indicator is heart rate; if fluid resuscitation is adequate, the rate should be fewer than 120 bpm or in the upper limits of normal for age. However, the fear, anxiety, and pain that accompany burn injuries often increase the heart rate. Blood pressure changes are less reliable because significant hypotension does not develop until volume losses exceed 30% due to the body's compensatory mechanisms. Assessment for narrowed pulse pressure, which indicates shock earlier, should be considered along with urine output to monitor adequate fluid resuscitation.

During the fluid resuscitation stage, the patient may require invasive hemodynamic monitoring (see Chapter 29). An arterial catheter cardiac output monitoring device can be used to monitor cardiac output, and cardiac index. All measurements must be maintained within normal limits to effect adequate fluid resuscitation.

RESPIRATORY MANAGEMENT Upon the patient's admission to the emergency department, several baseline assessments of respiratory status must be obtained: chest x-ray study, arterial blood gases (ABGs), vital signs, and carboxyhemoglobin levels. Intubation is indicated for all patients with burns of the chest, face, or neck. The primary treatment plan is oriented toward preventing atelectasis and maintaining alveolar oxygen exchange. The following interventions should be initiated:

- Maintain the head of the bed at 30 degrees or greater to maximize the patient's ventilatory efforts. Turn the patient side to side every 2 hours to prevent hypostatic pneumonia.
- To keep airway passages clear, suction the patient frequently, encourage the patient to use incentive spirometry hourly, and help the patient perform coughing and deep-breathing exercises every 2 hours.
- In the face of impending airway obstruction, the patient will require immediate intubation. Orotracheal tube placement is the preferred route to reduce sinus infections seen with nasotracheal tubes. If the patient has suffered nasolabial burns, however, the orotracheal route is preferred. Nasotracheal and orotracheal intubation is reserved for short-term ventilatory management. For long-term ventilatory management (i.e., greater than 3 weeks), a tracheostomy is performed.
- Humidification of either room air or oxygen helps prevent the drying of tracheal secretions. Ambient air or oxygen flow is based on ABG results. The patient may be placed on a face mask, steam collar, T-piece, mechanical ventilation with positive end-expiratory pressure (PEEP), pressure support ventilation, or high-frequency jet ventilation. The goal of all therapies is to maintain adequate tissue oxygenation with the least amount of inspired oxygen flow necessary.
- Medications to dilate constricted bronchial passages are administered intravenously and as inhalants to control bronchospasms and wheezing. Mucolytic agents liquefy tenacious sputum and aid in expectoration.
- An arterial line is placed in the patient with major burn injury for continuous assessment of ABGs and blood pressure. Pulmonary artery pressure catheters may be inserted to measure pulmonary vascular resistance (PVR), pulmonary artery pressure (PAP), pulmonary artery wedge pressure (PAWP), and mixed venous oxygen saturation (SvO_2). The PVR and PAP rise in the presence

of hypoxia. The SvO_2 is the average percentage of hemoglobin bound with oxygen in the venous blood and reflects overall tissue utilization of oxygen. Pulse oximetry monitors arterial oxygen saturation levels.

- In the presence of carbon monoxide (CO) poisoning, monitor carboxyhemoglobin (COHgb) levels. Pulse oximetry cannot distinguish between oxyhemoglobin and COHgb; thus, a false normal or high pulse oximetry reading is seen. High-flow 100% oxygen is given immediately by nonrebreather mask. Patients with COHgb greater than 15% may require hyperbaric oxygen therapy to replace the CO.
- Pain medications are administered if the patient is not in shock.

After stabilization in the emergency department, the patient is transferred to the critical care unit or a specialized burn center (a facility that has a burn physician as director of a specialized nursing unit with dedicated burn beds). In both settings, continuous monitoring of diagnostic tests, administration of medications, pain control, wound management, and nutrition support therapies constitute the initial plan of care.

DIAGNOSIS

The following diagnostic tests are used to evaluate the patient's progress and to modify intervention strategies:

- *Urinalysis* indicates the adequacy of renal perfusion and the patient's nutritional status. In catabolic states, nitrogen is excreted in large amounts into the urine. Nitrogen loss is measured through 24-hour urine collections for total nitrogen, urea nitrogen, and amino acid nitrogen. *Myoglobinuria*, which manifests as a dark brown, wine-colored urine, signals the development of acute tubular necrosis. Loss of plasma protein and dehydration lead to proteinuria and elevated urine specific gravity. A fixed urine specific gravity of 1.010 can indicate renal failure even with normal volume. Glycosuria is a transient development following major burn injury; it indicates a need to adjust the nutritional program.
- The *complete blood count* is monitored regularly. Hematocrit is elevated secondary to hemoconcentration and fluid shifts from the intravascular compartment. Hemoglobin is decreased secondary to hemolysis. White blood cells are elevated if infection is present.
- *Serum electrolytes* are monitored regularly. Sodium levels are decreased secondary to massive fluid shifts into the interstitium. Potassium levels initially are elevated during burn shock, as a result of cell lysis and fluid shifts into the extracellular space. Potassium levels decrease after burn shock resolves, as fluid shifts back to intracellular and intravascular compartments.
- *Renal function* test results are closely monitored. Blood urea nitrogen (BUN) is elevated secondary to dehydration. Creatinine is elevated in the presence of renal insufficiency.
- *Total protein, albumin, transferrin, prealbumin, retinol binding protein, alpha$_1$-acid glycoprotein, and C-reactive protein* levels indicate protein synthesis and nutritional status. Because of the fluid shifts that occur during the early stages of a burn injury, they are more useful as markers during the rehabilitative phase of care.
- *Creatine phosphokinase (CPK)* is elevated following an electrical burn, secondary to extensive muscle damage.
- Blood glucose is transiently elevated after major burn injury.
- *Serial ABGs* indicate the presence of hypoxia and acid–base disturbances and indicate patient responses to changes in oxygen therapies.
- *Pulse oximetry* allows continuous assessment of oxygen saturation levels. The burn-injured patient may have saturation levels below 95%.
- *Serial chest x-ray studies* document changes within the first 24 to 48 hours that may reflect the presence of atelectasis, pulmonary edema, or acute respiratory distress syndrome (ARDS).
- *Serial 12-lead electrocardiograms (ECGs)* are necessary to monitor the development of dysrhythmias, especially those associated with hypokalemic and hyperkalemic states.

MEDICATIONS

PAIN CONTROL Burns often cause excruciating pain. In the emergent stages of care, intravenously administered narcotics such as morphine, hydromorphone, or fentanyl are the best means of managing pain. Morphine is the drug of choice in a typical dosage of 3 to 5 mg intravenously every 5 to 10 minutes for an adult. Meperidine is avoided because of potential normeperidine accumulation, which can produce tremors and anxiety. Once the patient has been stabilized, it is appropriate to administer narcotics, especially intravenous fentanyl, prior to initiating hydrotherapy or intensive exercise routines. Burn treatments can also produce high levels of anxiety, necessitating the use of anxiolytic agents such as midazolam and lorazepam. Anxiolytics are especially useful when administered 1 hour before wound care. During the acute stage, opioids are administered around-the-clock to decrease pain that occurs at rest. Patient-controlled analgesia (PCA) enhances the patient's ability to cope with pain. The oral, subcutaneous, or intramuscular route of administration should be avoided until hemodynamic stability and unimpaired tissue perfusion returns.

As the patient enters the rehabilitative stage of care, alternative therapies for pain control may be added to the plan of care. Distraction, self-hypnosis, guided imagery, and relaxation techniques are helpful adjuncts in managing pain and coping with loss. Refer to Chapter 9 for a discussion of strategies for managing pain.

ANTIMICROBIAL AGENTS Systemic infection is a leading cause of death in major burn patients. Gram-positive organisms such as *Staphylococcus* and *Streptococcus* colonize the burn surface during the first week postburn; gram-negative enteric organisms become more common with longer periods of hospitalization. Diagnosing infection is best done through a burn wound biopsy. To eliminate infection on the surface of the burn wound, topical antimicrobial therapy is used, depending on protocol. Generally, topical antimicrobials are not applied until the patient is admitted to a burn unit. Of the many antimicrobial agents available, the three most widely used are mafenide acetate (Sulfamylon) cream, silver sulfadiazine (Silvadene) cream, and silver nitrate 0.5% soaks. All three are broad-spectrum antibiotics. The choice of topical antibiotic is based on the extent of the burn wound, the presence of identified bacterial organisms, whether an open (exposing the wound to the air) or closed (using bulky dressings) method of treatment is used, and patient response. Despite antimicrobial therapy, patients with major burn assault have a greater risk for sepsis and septic shock.

FAST FACTS

Local Signs of Burn Wound Infection

- Increased sloughing of burn tissue
- Increased edema around wound edges
- Partial-thickness wound converting to full-thickness wound
- Black or brown areas of discoloration

Patients with major burns are usually given prophylactic antibiotics. Systemic antimicrobial therapy is indicated in the immediate preoperative and postoperative period associated with excision and autografting. Postoperatively, the therapy is discontinued as soon as the patient's hemodynamic status returns to normal, usually within the first 24 hours. In the long-term treatment of identified infectious processes, drug administration is limited to the least amount of time required to eradicate the infection. See the following Medication Administration box for nursing implications when topical antimicrobial therapy is used with a burn patient.

TETANUS PROPHYLAXIS If the patient's immunization status is in doubt, tetanus toxoid is administered intramuscularly early in the acute phase of care to prevent *Clostridium tetani* infection.

PREVENTING GASTRIC HYPERACIDITY Hyperacidity must be controlled to prevent Curling's ulcer. A nasogastric tube is placed during the emergent phase of care, and gastric aspirant is obtained hourly. The gastric pH should be assessed and maintained at levels above 5. To control gastric acid secretion during the acute phase of care, histamine H_2 blockers (e.g., famotidine [Pepcid]) or proton pump inhibitors (e.g., pantoprazole [Protonix]) can be administered intravenously, either intermittently or as continuous infusions. As soon as bowel sounds become audible, the patient is placed on an antacid regimen.

TREATMENTS

SURGERY Three surgical interventions are commonly employed to manage the burn wound: escharotomy, surgical debridement, and autografting.

ESCHAROTOMY When the burn eschar forms circumferentially around the torso or extremities, it acts as a tourniquet, impairing circulation. Left unchecked, the affected body part becomes gangrenous.

To prevent circumferential constriction of the torso or extremity, an **escharotomy** is performed by the physician with a scalpel or by electrocautery (Figure 17–10 ■). A sterile surgical incision is made longitudinally along the extremity or the trunk to release taut skin and allow for expansion caused by edema formation. In the first 24 hours following the procedure, the incision should be gently packed with fine mesh gauze. After 24 hours, the site may be treated with a direct application of a topical antimicrobial agent. See Box 17–2 for nursing implications for care of the patient undergoing escharotomy.

SURGICAL DEBRIDEMENT **Surgical debridement** refers to the process of excising the wound to the level of fascia (fascial excision) or sequentially removing thin slices of the burn wound to the level of viable tissue (tangential excision). Because **fascial excision**, or **fasciectomy**, sacrifices potentially viable fat and lymphatic tissue, its use is reserved for patients with extensive or full-thickness burns. The most common technique is electrocautery with cutting and coagulating current capabilities. Tangential excision is performed with the use of a dermatome. Shallow burns and some of moderate depth bleed briskly after one slice. If bleeding does not occur, the procedure is repeated until a viable bed of dermis or subcutaneous fat is reached. Following surgical debridement, the patient is returned to the burn unit.

Figure 17–10 ■ Escharotomy. The surgical procedure consists of removing the eschar that forms on the skin and underlying tissue following severe burns. The procedure is particularly helpful in restoring circulation to the extremities of patients when scar tissue forms a tight, constrictive band around the circumference of a limb.

AUTOGRAFTING A procedure performed in the surgical suite, **autografting** is used to effect permanent skin coverage. Early burn wound excision and skin grafting decrease the hospital stay and enhance rehabilitation. Skin is removed from healthy tissue (donor site) of the burn-injured patient and applied to the burn wound (Figures 17–11 ■ and 17–12 ■). (Skin grafts and flaps are discussed

Figure 17–11 ■ Skin graft for burn injury (autograft).

MEDICATION ADMINISTRATION

Topical Burn Medications

TOPICAL ANTIMICROBIAL AGENTS

mafenide acetate (Sulfamylon)

silver nitrate

silver sulfadiazine (Silvadene)

Research shows that the most effective topical agents are those that (1) act against the major pathogens responsible for causing burn wound infection, (2) achieve levels of concentration sufficient to decrease microbial colonization, (3) are rapidly excreted or metabolized, (4) are nontoxic, and (5) are easy to use and inexpensive.

MAFENIDE ACETATE

Mafenide acetate is a synthetic antibiotic closely related chemically, but not pharmacologically, to the sulfonamides. Although the mechanism of action is unclear, the drug appears to interfere with the metabolism of bacterial cells. Mafenide acetate is a bacteriostatic agent effective against many gram-positive and gram-negative organisms.

For topical administration, mafenide acetate is used in an 8.5% cream in a water-miscible base. Following application, the drug is rapidly diffused through the burn eschar and absorbed systemically.

In the general circulation, mafenide acetate metabolizes to a weak carbonic anhydrase inhibitor known as *p*-carboxybenzenesulfonamide, a substance that impairs the renal mechanisms involved in the buffering of blood. Bicarbonate excretion in the urine increases, and ammonia and chloride excretion decreases. To maintain normal acid–base balance, the pulmonary system effects a compensatory hyperventilatory state. If the compensatory hyperventilation is insufficient, the patient develops metabolic acidosis.

Nursing Responsibilities

- Use mafenide acetate with caution in patients with renal or pulmonary disease.
- Approximately 3% to 5% of patients develop a hypersensitivity to mafenide acetate, resulting in a maculopapular rash on the unburned areas. Assess the patient for the following:

Pruritus	Urticaria
Facial edema	Blisters
Swelling	Eosinophilia

  If hypersensitivity reactions occur, discontinue the drug and administer antihistamines.
- Monitor the patient for superinfection within the burn eschar, in the subeschar tissue, or in viable tissue adjacent to the wound.

Health Education for the Patient and Family

- Expect intense pain, stinging, or a burning sensation following drug application. Take appropriate measures to control pain before applying the drug.
- Apply the drug to clean, debrided burn wounds once or twice daily. Continue applications until healing is apparent.
- If any signs of allergy develop, discontinue the drug and notify the physician.
- Report any sudden and prolonged increases in respiratory rate.

SILVER NITRATE

Silver nitrate is a bacteriostatic agent that inhibits a wide variety of gram-positive and gram-negative organisms. Its antimicrobial effect is due to the actions of silver ions, which markedly alter the microbial cell wall and membrane. Additionally, the drug denatures bacterial protein, thereby inactivating and precipitating the microbes.

Nursing Responsibilities

- Silver nitrate is used as a 0.5% solution in distilled water. Apply the solution to bulky gauze dressings every 2 hours, and provide complete dressing changes twice daily.
- Silver nitrate has limited penetrating ability and is ineffective if used more than 72 hours following a burn injury.
- At the local tissue level, silver nitrate immediately interacts with chloride ions to form a black silver chloride precipitate that discolors both the burn wound and the adjacent tissues. The discoloration significantly hampers visual inspection of the wound.
- High concentrations of the drug result in cellular toxicity of surrounding healthy tissue.
- Because large amounts of water are systemically absorbed from the dressing site, the patient may demonstrate a hypotonic state. Hyponatremia and hypochloremic alkalosis are common manifestations in burn-injured patients treated with silver nitrate.

Health Education for the Patient and Family

- Watch for and report any signs and symptoms of hypotonicity: swelling, weight gain, difficulty in breathing.
- This drug causes a black discoloration on all skin surfaces and dressings with which it comes into contact.
- Because discoloration can conceal evidence of infection, watch for systemic manifestations of infection: fever, malaise, rapid pulse rate, and listlessness.
- Saturate the wound dressings every 2 hours with a 0.5% aqueous solution of the drug. Change the dressings completely twice daily.

SILVER SULFADIAZINE

Silver sulfadiazine, a sulfonamide, is the most commonly used topical agent. The drug acts on the cell membrane and cell wall of susceptible bacteria and binds to cellular DNA. The drug is bactericidal and effective against a wide variety of gram-negative and gram-positive organisms.

Nursing Responsibilities

- Many patients develop a marked leukopenia in response to this drug, which tends to improve spontaneously over the course of therapy. This finding does not contraindicate use of the drug.
- Hypersensitivity to silver sulfadiazine has been reported in a small number of cases. If the patient develops hypersensitivity, administer antihistamine and change the topical agent.
- If sulfa crystals form in the urine, keep the patient well hydrated.
- Treatment with this drug can cause systemic uptake of propylene glycol, which results in an elevated serum osmolality and high urine specific gravity in the patient who is not dehydrated. These findings tend to create confusion during the fluid resuscitative stage of care. Whenever the serum osmolality and urine specific gravity fail to correlate with a clinical picture that reflects fluid volume overload (elevated CVP/PCWP, rhonchi/wheezing, edema), suspect systemic propylene glycol uptake.

Health Education for the Patient and Family

- Apply the drug to clean, debrided wounds once or twice daily, completely covering the burn wound at all times.
- Continue applying the drug until healing is apparent.
- If any signs of allergy develop, discontinue the drug and notify the physician.
- Watch for evidence of concentrated urine, and notify the physician.
- If not contraindicated, drink large amounts of fluids to prevent sulfa crystals from forming in the urine.

BOX 17–2 Nursing Implications for Circumferential Wound Management

ESCHAROTOMY

A circumferential burn wound increases the risk for impaired tissue perfusion of the involved area. To prevent arterial occlusion, an escharotomy is performed to release tension and permit unobstructed arterial blood flow. The nurse continuously assesses the involved area and notifies the physician of the need to perform this emergent procedure, which is done at the bedside. Because only the dead burn wound tissue is excised, the patient experiences very little pain.

NURSING RESPONSIBILITIES

- For circumferential burn wounds of the extremity, assess the extremity for absence of blood flow:
  a. Using a Doppler ultrasound stethoscope, check hourly for the presence of a pulse.
  b. Assess the extremity hourly for warmth, color, sensation, and capillary refill.
  c. Observe for evidence of numbness or tingling.
- For circumferential burn wounds of the torso, assess for evidence of respiratory distress:
  a. Obtain ABGs as needed.
  b. Auscultate lung sounds hourly.
  c. Observe for evidence of cyanosis, tachypnea, anxiety, or restlessness.
- For circumferential burn wounds of the neck, assess for evidence of respiratory distress. Prepare the patient for prophylactic intubation.
- Monitor for excessive blood loss, and transfuse the patient if indicated.
- Dress the open wound (escharotomy) with topical antimicrobial agents as ordered.

PATIENT TEACHING

- Teach the patient the importance of reporting any evidence of impaired circulation: numbness, tingling, blue color to the extremity, absence of sensation.
- Assure the patient that the procedure will not be painful and will provide immediate relief.
- Teach the patient the importance of protecting the open wound (escharotomy) from infection.
- Explain the rationale supporting prophylactic intubation for burn wounds involving the head and neck.
- Provide assurance that all blood loss will be replaced and that bleeding at the site will be controlled.

Figure 17–12 ■ Cultured epithelial autografting of a skin culture.

in Chapter 16.) After the autograft is applied, the grafted area is immobilized. The site is assessed daily for evidence of adherence. The patient resumes ROM exercises 5 days postgraft. As the wound heals, the patient may complain of itching, which can be treated with mild lotions.

Cultured epithelial autografting is a technique in which skin cells are removed from unburned sites on the patient's body, then minced and placed in a culture medium for growth. Over a 5- to 7-day period, the cells expand to 50 to 70 times the size of the initial biopsies. The cells are again separated out and placed in a new culture medium for continued growth. With this technique, enough skin can be grown over a period of 3 to 4 weeks to cover an entire human body. The cells are prepared in sheets and attached to petroleum jelly gauze backing, which is applied to the burn wound site. Problems with infection and lack of attachment have occurred.

BIOLOGIC AND BIOSYNTHETIC DRESSINGS The terms *biologic dressing* and *biosynthetic dressing* refer to any temporary material that rapidly adheres to the wound bed, promotes healing, and/or prepares the burn wound for permanent autograft coverage. Ideally, these kinds of dressings should be easy to apply and remove, inexpensive, nonantigenic, elastic, able to reduce pain, able to serve as a bacterial barrier, and able to enhance the natural healing process. The dressings are applied to the burn wound as soon as possible. Covering the wound eliminates the loss of water through evaporation, reduces infection, and promotes wound healing. Biologic and biosynthetic dressings that are currently in use include homograft (allograft), heterograft (xenograft), and synthetic materials.

Homograft, or **allograft**, is human skin that has been harvested from cadavers. It is stored in skin banks located throughout the nation. The development of methods to achieve prolonged storage of frozen, viable skin has increased the use of this dressing; however, its short supply and expense still pose problems. It is manufactured as strips cut to the pattern of the burn and applied using sterile technique. Under normal circumstances, a homograft provides effective temporary closure for 14 to 21 days following application.

Heterograft, or **xenograft**, is skin obtained from an animal, usually a pig. Although fresh porcine heterograft is available to some centers, frozen heterograft is much more commonly used. Once applied, heterograft appears to undergo early softening and lysis from enzymatic action from the wound. As a result, frequent changes of the heterograft dressing are necessary. Because of the high infection rates associated with this dressing, silver-nitrate–treated porcine heterograft has been developed to retard microbial growth.

The multiple problems associated with the use of biologic dressings have driven the development of synthetic materials. One such material is Biobrane (UDL Laboratories Inc.), a composite material consisting of nylon mesh bonded to silicone that has proved successful in the temporary coverage of second- and third-degree burns. Whereas Biobrane adheres well to moderately clean wounds, it cannot adhere to or lower bacterial counts in grossly contaminated wounds. Biobrane dressing is supplied in various sizes, cut to fit the wound site, and secured with tape or Steri-Strips. It spontaneously separates from the wound when the underlying tissue heals. Other biosynthetic wound dressings include Integra (Integra Life Sciences Corp.) and Alloderm (LifeCell Corp.). If dermal thickness is lost in deep partial-thickness or full-thickness burns, several products can serve as a dermal replacement. Integra is a synthetic dermal substitute, and Alloderm is human cadaver allograft dermis that is nonimmunogenic. These products are placed in the wound, and split-thickness autografts are then placed over the dermal replacement. These products are used to provide temporary wound coverage, reduce pain, and facilitate healing.

Two recent temporary skin substitutes are TransCyte and Apligraf. TransCyte is a bioengineered substance, derived from human fibroblast cells grown within mesh. As the cells grow, they secrete human dermal collagen, matrix proteins, and growth factors. The product is produced, extensively tested for any infectious agents, and then frozen. It is used as a temporary covering for surgically debrided full-thickness and deep partial-thickness burn wounds, and is an alternative to silver sulfadiazine and cadaver skin. TransCyte forms a transparent, protective barrier over the wound surface and is typically applied only once. The best results have been obtained when it was applied within 24 hours of injury. Apligraf is bilayered skin substitute cultured from neonatal foreskin.

Hydrocolloid dressings such as DuoDERM (ConvaTec) are a type of synthetic material. They are occlusive wafers of gumlike materials that provide a water-resistant outer layer for coverage of the donor site. They protect healing tissue from excessive drying, liquefy necrotic tissue, and absorb wound drainage. Other synthetics are Aquacel (ConvaTec), a temporary dressing (up to 14 days) that is impregnated with silver; Acticoat (Smith & Nephew Inc.), an antimicrobial barrier dressing; and Calcium alginate [Kaltostat] (ConvaTec), a calcium alginate absorptive dressing.

The newest treatment method uses the vacuum-assisted closure (VAC) device. VAC consists of a sponge placed over the wound and tubing that connects the sponge to a pump. An occlusive, adhesive dressing covers the wound and tubing, sealing the wound to create negative pressure. VAC has shown positive results in reducing wound edema, removing exudate, and improving wound healing in partial-thickness burns and deep hand burns.

WOUND MANAGEMENT The outcomes of care for the patient with a major burn depend on the prevention and treatment of infection through daily topical wound care, wound monitoring, and wound excision and closure. The goals of wound management are as follows:

- Control microbial colonization and prevent wound infection.
- Prevent wound progression.
- Achieve wound coverage as early as possible.
- Promote function of healing skin.

DEBRIDING THE WOUND Burned tissue releases chemical mediators that stimulate phagocytosis in an attempt to digest debris left by decaying necrotic tissue. Necrotic tissue that remains despite phagocytic action retards healing and prolongs inflammation. **Debridement** is the process of removing all loose tissue, wound debris, and eschar (dead tissue) from the wound. Three methods of debridement are employed: mechanical, enzymatic, and surgical (surgical debridement was previously discussed).

A nurse may perform mechanical debridement by applying and removing gauze dressings (wet-to-dry or wet-to-moist), hydrotherapy, irrigation, or scissors and tweezers. However, removal of gauze dressings can cause pain and possibly damage granulation tissue (Honari, 2004). During hydrotherapy (in an immersion tank, a shower, or on a spray table) the burn injury may be gently washed with a mild, nonperfumed, antimicrobial soap or wound cleaner solution to remove dead skin and separate eschar. The solution is then rinsed off with warm saline or tap water. Body hair (except for eyebrows) should be shaved within the burn and to within 2.5 cm of the wound edges. Blistered skin is grasped with a dry gauze and gently removed. The edges of blisters or eschar are trimmed with blunt scissors. The wound is then covered with a topical antimicrobial agent.

Enzymatic debridement involves the use of a topical agent to dissolve and remove necrotic tissue, as well as lift eschar. An enzyme (such as Accuzyme, collagenase [Santyl], or fibrinolysis-deoxyribonuclease [Elase]) is applied in a thin layer only within the wound area and covered with one layer of fine mesh gauze. A topical antimicrobial agent is then applied and covered with a bulky wet dressing; the wound is immobilized with expandable mesh gauze. Enzymatic agents are discontinued once the eschar is removed and granulation tissue appears (Honari, 2004).

DRESSING THE WOUND Once the wound has been cleaned and debrided, it may be dressed using one of two methods. In the open method, the burn wound remains open to air, covered only by a topical antimicrobial agent. This method allows the wound to be easily assessed. Topical agents must be frequently reapplied because they tend to rub off onto the bedding. The open method also increases the risk for hypothermia.

In the closed method, a topical antimicrobial agent is applied to the wound site, which is covered with gauze or a nonadherent dressing and then gently wrapped with a gauze roll bandage (Figure 17–13 ■). With the closed method, burn wounds are usually dressed twice daily and as needed. Dressings are applied circumferentially in a distal-to-proximal manner. All fingers and toes are wrapped separately. Dressings are held in place with stockinettes rather than tape to prevent further skin injury. The closed method decreases heat loss but may impair range of motion.

POSITIONING, SPLINTS, AND EXERCISE **Contractures** are a common problem for patients with burn injuries. During therapy, the patient must be maintained in positions that prevent contractures from forming. Because flexion is the natural resting position of joints and extremities, early physical therapy includes maintaining antideformity positions. Splints immobilize body parts and prevent contractures of the joints. They are applied as soon as possible after the injury and removed according to schedules established by a physical therapist or occupational therapist.

Figure 17–13 ■ Closed method of dressing a burn.

Early in the acute phase of care, a physical therapist or occupational therapist prescribes active and passive ROM exercises, which are performed every 2 hours at the bedside, most often by physical therapy. Ideally an exercise program is initiated on admission and continued until wounds are healed. Early ambulation is also part of the plan of care once the patient's condition becomes stable.

SUPPORT GARMENTS Applying uniform pressure can prevent or reduce hypertrophic scarring. Tubular support bandages are applied 5 to 7 days postgraft to maintain a tension ranging from 10 to 20 mmHg to control scarring. The patient wears custom-made elastic pressure garments such as a Jobst garment for 6 months to a year postgraft. The garments are to be worn 7 days/week, 23 to 24 hours per day.

NUTRITIONAL SUPPORT The patient with a major burn is in a hypermetabolic and catabolic state. The resting energy expenditure after severe burn injury can increase by as much as 100% above normal levels, depending on the extent of catabolism and the patient's physical activity, size, age, and gender. This increase is believed to be due to heat loss from the burn wound, an increase in beta-adrenergic activity, pain, and infection. As a result, total caloric needs may be as great as 4000 to 6000 kcal per day.

Traditional dietary management based on oral intake seldom meets the kcal requirements necessary to reverse negative nitrogen balance and begin the healing process. Enteral feedings with a nasointestinal feeding tube are therefore instituted within 24 to 48 hours of the burn injury to offset hypermetabolism, improve nitrogen balance, decrease sepsis, and decrease length of hospital stay. A nasointestinal feeding tube is placed under fluoroscopy, with the tip extending past the pylorus to prevent reflux and aspiration.

Although enteral feeding is the preferred nutritional therapy, it is contraindicated in Curling's ulcer, bowel obstruction, feeding intolerance, pancreatitis, or septic ileus. When the enteral route cannot be used, a central venous catheter is inserted via the subclavian or jugular vein for the administration of total parenteral nutrition (TPN).

●○● NURSING CARE

The patient with a major burn has complex, multisystem needs. Table 17–4 lists overall nursing interventions for the emergent, acute, and rehabilitative stages of burn injury. Also see the Case Study & Nursing Care Plan on page 455.

TABLE 17–4 Interventions in Various Stages of Burn Injury

Stage of Burn Injury	Onset	End Point	Interventions
Emergent/resuscitative	Occurrence of burn injury	Successful fluid resuscitation	Remove patient from heat source. Initiate first-aid. Assess extent of burn injury. Prevent hypothermia. Assess for shock. Determine need for intubation. Determine need for intravenous therapy. Follow protocol for fluid resuscitation. Obtain history. Transport to tertiary care facility.
Acute	Diuresis	Wound closure	Begin hydrotherapy. Determine need for excision of burn wound. Control spread of infection. Institute wound care. Start nutrition support. Graft burn wound. Initiate physical therapy. Manage pain.
Rehabilitative	Wound closure	Return to highest level of health restoration	Prevent scar formation. Continue physical therapy. Address psychosocial, cultural, and spiritual needs. Consider occupational therapy. Consider vocational training. Assess home maintenance management.

Health Promotion

Although treatments have improved significantly during the past several decades, there is no cure for burns. Prevention remains the primary goal. With the public's increasing attention to health promotion and disease prevention, the nursing profession currently is well positioned to collaborate with other disciplines to develop initiatives to reduce the number of burn injuries. For example, as patient advocates, nurses can alert political leaders to the need to pass legislation aimed at reducing the incidence of burns. Appropriate legislative themes might center on safety in the workplace (e.g., requirements for smoke alarms and sprinkler systems), on the highways (e.g., regulations regarding the transportation of flammable liquids), and in the home (e.g., requirements for safety devices for water heaters and wood-burning stoves, and for self-extinguishing cigarettes). As educators, nurses can develop teaching plans for families and communities to heighten awareness of the problem. As researchers, nurses can investigate conditions leading to burn injury and suggest methods to reduce its prevalence. Working together with healthcare policy makers and community leaders, nurses can join the effort to lower the number of annual burn cases.

Nursing Assessment

Nursing assessment is continuous from the time of initial contact with a patient with a burn injury. This section describes the survey conducted when the patient arrives at the emergency department (ED).

Priorities of Care

Collaborating with the interprofessional team to delivery adequate treatment of the underlying burn injury while providing care that supports the physical and psychologic responses to the injury is a nursing priority. Once the patient arrives in the ED, the interprofessional team must act quickly to obtain the patient's history of the burn injury, including the time of injury, causative agents, early treatment, medical history, and patient's age and body weight. In most cases, the patient is awake and oriented and able to relate the information during the emergent phase of care. Because changes in sensorium will become evident within the first few hours following a major burn injury, the nurse obtains as much information as is possible immediately on the patient's arrival.

- ***Time of injury.*** In many cases, the patient is admitted to the ED an hour or more after the injury occurred. The time of the burn injury must be documented as precisely as possible at the scene, because all fluid resuscitation calculations are based on the time of the burn injury, not on the patient's time of arrival at the ED.
- ***Cause of the injury.*** Because the type of burn injury determines which nursing measures take priority, identify the specific causative agent to establish the appropriate plan of care.
- ***First-aid treatment.*** Prior to the arrival of medical personnel, the patient or family may have applied home remedies to treat the burn wound. It is important for the nurse to ascertain and document the nature of all home treatment interventions, including the application of neutralizing agents, liquids, and immobilizing devices used to splint associated injuries.
- ***Past medical history.*** Patients with histories of respiratory, cardiac, renal, metabolic, neurologic, gastrointestinal, or skin diseases; alcohol abuse; or altered immune states require more intense observation. Known allergies are obtained.
- ***Age.*** Older adults tend to require more supportive care (see the accompanying box).
- ***Medications.*** Drugs, either prescribed or recreational, taken by the patient prior to the burn injury may further complicate the treatment regimen. Drugs that affect any of the major body systems or cause mood alterations will need to be factored into the treatment plan. As part of the early assessment, obtain and document blood levels of therapeutic pharmaceutical agents and mood-altering substances.
- ***Body weight.*** During the acute and rehabilitative phases of the burn injury, the patient will lose as much as 20% of preburn weight. This fact will have significant implications for all patients, especially for those who are underweight or cachectic at the time of the injury.

Evidence for Nursing Care

The Patient with Compartment Syndrome

Selected resources that nurses may find helpful when planning evidence-based nursing care follow.

- Burd, A., Chiu, T., Wong, P. S., Ng, F. Y., & Wong, D. S. (2011). The process of decompression in acute burns. *Burns, 37*(4), 721–722.
- Purdue, G. F., Arnoldo, B. D., & Hunt, J. L. (2011). Acute assessment and management of burn injuries. *Physical Medicine and Rehabilitation Clinics of North America, 22*(2), 201–212.

Meeting Individualized Needs

Burns in the Older Adult

Older adults are at greater risk than younger people for burns of all degrees of severity, with burns and fires being a major cause of death. Most burns are accidental, the result of slower reaction times, decreased mobility, visual deficits, a decreased sense of smell, forgetfulness, and impaired sensation. Many older adults are burned by stoves, hot water, hot food, irons, cookware, and heating pads. Older adults with cognitive impairments or dementias may start fires by leaving foods cooking unattended. The most common burns in this age group are the result of catching clothing on fire and scalding from tap water that is too hot.

The care of the older adult with burns presents unique challenges. They may delay seeking treatment, thus increasing the risk of infection. Their care is often complicated by the presence of other chronic illnesses. They may live alone, and have no one to care for them during rehabilitation. Even small burns have the potential to become lethal in older adults.

Burn prevention topics for older adults are as follows:

- Have a relative or neighbor routinely check for the odor of gas.
- Check the smoke detector battery once a month.
- Wear close-fitting clothing when cooking.
- Use a cooking timer with a loud alarm.
- Never lay anything over a heating device.
- Set the temperature of the hot water heater no higher than 120°F.
- Install antiscald devices in bathroom plumbing.
- Encourage no smoking in the house.

Diagnoses, Outcomes, and Interventions

A major burn affects virtually every body system, as well as social, cultural, economic, psychologic, and spiritual well-being. Immediate treatment in an intensive care setting is followed by years of rehabilitation and a lifetime of change in what was possible for an individual before the injury. Many nursing diagnoses are appropriate for the patient with a major burn injury; those described here are *Impaired Skin Integrity*, *Deficient Fluid Volume*, *Acute Pain*, *Risk for Infection*, *Impaired Physical Mobility*, *Imbalanced Nutrition: Less than Body Requirements*, and *Powerlessness*.

Impaired Skin Integrity

The burn injury significantly impairs skin integrity. The severity of wounds varies according to the depth and extent of the burn. General treatment measures are designed to restore normal skin function as quickly as possible. Nursing care focuses on assessing and cleansing the wound and controlling infection.

Expected Outcome: Patient will experience effective wound healing and infection management as evidenced by skin integrity and body temperature within normal range.

- Estimate the extent and depth of the burn wound and recalculate extent of unhealed burns weekly. *The severity of the burn injury is the basis for determining which types of interventions are appropriate. Reassessment on a regular basis is necessary to monitor the healing process.*
- Provide daily wound care (including debridement method, dressing method, and medication administration) as prescribed *to remove dead tissue, control infection, and promote reepithelialization as soon as possible.*

SAFETY ALERT

When cleansing wounds, avoid cross-contamination of the patient's wounds.

- Elevate burned or newly skin grafted extremities at or above heart level *to increase venous return and to prevent edema formation.*
- Immobilize skin graft sites for 3 to 5 days or as ordered *to promote graft adherence and to prevent loss of newly grafted skin.*

SAFETY ALERT

Move patients slowly and carefully across bed sheets to prevent shearing or dislodgement of the new skin grafts.

- Provide special skin care to sensitive body areas:
  - Clean burns involving the eyes with normal saline or sterile water *to prevent corneal and conjunctival drying and adherence.*

Evidence for Nursing Care

The Patient with Curling's Ulcers

A selected resource that nurses may find helpful when planning evidence-based nursing care follows.

- Koczka, C. P., Geraldino-Pardilla, L. B., & Goodman, A. J. (2012). Physician's opinions of stress ulcer prophylaxis: Survey results from a large urban medical center. *Digestive Diseases and Sciences, 58*(3), 777–781. doi:10.1007/s10620-012-2423-x

  If contracture of the eyelid develops, apply drops or ointment to the eye *to prevent corneal abrasion.*
- Gently wipe burns of the lips with saline-soaked pads. Apply an antibiotic ointment as prescribed. Assess the mouth frequently, and perform mouth care routinely. If an oral endotracheal tube is in place, reposition it often *to prevent pressure ulcer formation.*
- Gently debride burns of the nose, and apply mafenide acetate (Sulfamylon) cream. Position nasogastric and nasotracheal tubes *to prevent excessive pressure.*
- Apply mafenide acetate (Sulfamylon) cream to burns of the ear. Gently debride and thoroughly clean the wound with a water spray. Do not cover ears with dressings. Do not use pillows; to reduce pressure to the area, use a foam doughnut instead. *Burns of the ears are prone to infection; special positioning devices are necessary to decrease pressure ulcer formation.*

Deficient Fluid Volume

Fluid resuscitation rates are adjusted periodically throughout the emergent stage of care. The nurse should be particularly aware of several situations that may warrant the administration of fluids at rates in excess of the calculations needed to maintain adequate urine output: initial underestimation of the burn size, sequestration of fluid into the lung tissue in inhalation injury, electrical injury (which tends to cause more extensive damage than is immediately visible), full-thickness burns, and inordinately delayed starts of fluid resuscitation.

Expected Outcome: Patient will achieve fluid balance as evidenced by blood pressure, pulse, and temperature readings within normal limits, and adequate urine output.

- Assess blood pressure and heart rate frequently. *Vital signs rapidly deteriorate when fluid resuscitation is inadequate.*

PRACTICE ALERT!

Tachycardia in the burn patient is not considered until the heart rate is greater than 120 bpm.

- Monitor hemodynamic status, including CVP and PCWP. *Inadequate fluid resuscitation is manifested by a drop in the central venous pressure and pulmonary capillary wedge pressure.*
- Follow prescribed protocols for intravenous fluid resuscitation. *Therapy for burn shock is aimed at supporting the patient through the period of hypovolemic instability.*
- Monitor intake and output hourly. *Report urine outputs of less than 50 mL/h. Intake and output measurements indicate the adequacy of fluid resuscitation, and should range from 30 to 50 mL/h in an adult.*
- Weigh daily. *Body weight is used to calculate fluid requirements.*
- Test all stools and emesis for the presence of blood. *Occult blood in emesis or stool indicates gastrointestinal bleeding.*
- Maintain a warm environment. *Hypothermia leads to shivering and further loss of body fluid through increased energy expenditure and catabolism.*
- Monitor for fluid volume overload. *Older patients and those with underlying cardiac disease may demonstrate symptoms of heart failure during the fluid resuscitation stage.*

SAFETY ALERT

Major burn patients receive 10 or more liters of fluid and will gain weight with the fluid shifts. When capillary membrane integrity resumes, patients have a high CVP and urine output that necessitates monitoring urine electrolytes.

Acute Pain

The patient experiences excruciating pain with extensive superficial and all partial-thickness burns. Intense pain is also experienced during wound care and physical therapy. In addition, increased levels of anxiety about treatments and outcomes may further increase the perception of pain.

Expected Outcome: Patient will achieve adequate pain control as evidenced by reduced pain-related behaviors and by effective patient rest and sleep behaviors.

- Measure the patient's level of pain, using a consistent measurement tool. *Pain tolerance is the duration and intensity of pain that the patient is able to endure. Pain tolerance differs from one patient to the next and may vary in the same patient in different situations.*
- Medicate before painful procedures and determine when PCA is appropriate. *The inability to manage pain results in feelings of despair and frustration.*
- Administer intravenous narcotic analgesics as prescribed. *Nurses' fear of precipitating addiction often makes them reluctant to administer narcotics. During the acute stage of burn injury, however, invasive procedures and exposed neurosensory nerve endings dictate the need for narcotic pharmaceutical agents.*
- Explain all procedures and expected levels of discomfort. *Patients who are prepared for painful procedures and know beforehand the actual sensations they will feel experience less stress.*
- Use methods of nonnarcotic pain control in combination with medications for pain. *Noninvasive pain relief measures (e.g., relaxation, massage, distraction) can enhance the therapeutic effects of pain relief medications.*
- Allow the patient to verbalize the pain experience. *Each person experiences and expresses pain in his or her own manner, using various sociocultural adaptation techniques.*

SAFETY ALERT

Narcotics are always administered intravenously rather than orally, subcutaneously, or intramuscularly in the emergent or acute stage of a burn due to decreased circulation and absorption of medications.

Risk for Infection

From the onset of the burn injury, loss of the body's natural barrier to the external environment increases the risk of infection. Nursing interventions focus on controlling infectious processes. Monitor the results of diagnostic tests, maintain nutritional therapies, and apply antimicrobial agents to monitor and prevent the spread of infection, a major complication of the burn injury.

Expected Outcome: Patient will experience effective infection management and control as evidenced by freedom from symptoms of infection, maintenance of white blood cell count and differential, and vital signs within normal limits.

- Monitor daily for manifestations of wound infection. Remove topical medications and wound exudate and examine the entire wound. *Early manifestations of wound infection include swelling and inflammation in intact skin surrounding the wound; a change in the color, odor, or amount of exudate; increased pain; and loss of previously healed skin grafts.*
- Monitor for positive blood cultures, *which indicate bacteremia.*
- Monitor for hyperemia, cough, chest pain, wheezing, rhonchi, decreased oxygen saturation, and purulent sputum, *which are manifestations of pneumonia.*
- Monitor for the presence of bacteria in the urine, fever, urgency, frequency, dysuria, and superpubic pain, *which are manifestations of urinary tract infections.*
- Obtain daily WBC counts. *Leukocyte counts are indicators of immune system function; they increase in the presence of infection.*
- Determine tetanus immunization status. *Burn patients are at risk for anaerobic infection caused by* Clostridium tetani.
- Maintain high kilocalorie intake. *Nutritional support provides the nutrients needed to maintain the body's defense mechanisms.*
- Maintain an aseptic environment, using standard precautions (including gloving, gowning, and sterile procedures). *Strict isolation technique deters the development of a nosocomial infection.*
- Culture all wounds and body secretions per protocol. *Culture and sensitivity reports identify the presence of infectious microbes and indicate appropriate antimicrobial therapies.*
- Administer prescribed antimicrobial medications *to decrease invasive wound infections.*
- If the patient has an indwelling catheter, assess the urine for cloudiness and a foul odor, and obtain a urine culture and sensitivity at least weekly. *Urine culture and sensitivity report identify presence of infectious microbes and indicate appropriate antimicrobial therapies.*

Impaired Physical Mobility

As the burn wound heals and new skin tissue forms, the involved area tends to shrink. Contractures form at the site and significantly limit mobility, especially when a joint is involved. Physical therapy is important, beginning in the early stages of treatment. The nurse institutes ambulation and planned exercise regimens as soon as the patient's condition stabilizes.

Expected Outcome: Maintenance of joint range of motion with progression to transfers and ambulation.

- Perform active or passive ROM exercises to all joints every 2 hours. Ambulate when stable. *Regular exercise prevents further loss of motion, restores movement, and improves functional status.*
- Apply splints as prescribed. Maintain antideformity positions, and reposition the patient hourly. *Splinting and positioning retard the formation of contractures.*
- Maintain limbs in functional alignment *to preserve joint mobility.*
- Anticipate the need for analgesia. *Administering analgesics promotes the patient's comfort during exercising sessions.*
- Assess all patients, but especially the older adult, for indications of pressure ulcer formation under a splint. *Careful integumentary assessment can prevent pressure ulcer formation by early detection of early skin changes.*

Moving Evidence into Action

The Patient with a Major Burn

Patients with major burn injuries experience significant pain related to the injury and treatment. While pain medications significantly reduce pain, other interventions should be considered for use.

DeJong and colleagues (2007) conducted a systematic review of nonpharmacologic and nursing interventions for pain relief during burn procedures. Twenty-six articles were included. The interventions fell under two domains of the Nursing Intervention Classification system: behavioral (17 studies) and physical interventions (9 studies). Interventions most commonly used were hypnosis and rapid induction analgesia. Other interventions included combinations of relaxation, guided imagery, attention, information, distraction, and/or music. Of the 26 studies, 17 found that the interventions had a positive effect on perceived pain. The authors also report that one underlying concept that explains the intervention effectiveness is the sense of control provided to the patient during painful procedures.

Implications for Nursing

The use of nonpharmacologic interventions gains attention and acceptance as adjuncts to pain medication. Nurses are in a unique position to use such interventions within their scope of practice. Nonpharmacologic interventions are *feasible* (ease of use, minimal time and effort expenditure both while learning and using the intervention) and *acceptable* (related to patient preference). Use of such interventions must be individualized to the patient. Reevaluation of these interventions should continue over time with continued burn procedures so they can be modified to meet the patient's current needs. The interventions discussed in the review are low risk for adverse events and can be used with appropriate training of the nurses delivering them.

Moving Knowledge into Action

1. When planning pain relief interventions for the burn patient, what salient points should be considered?
2. How should the nurse determine with the patient what nonpharmacologic interventions may be effective?
3. Develop a teaching plan for instructing nurses on two commonly used nonpharmacologic interventions that can be used in conjunction with pain medications during burn care procedures.

Imbalanced Nutrition: Less Than Body Requirements

The burn injury initiates a complex series of events that have a profound effect on the body's use of nutrients and expenditure of energy. Daily kilocalorie requirements are determined by the nutritionist, and enteral feedings are initiated as soon as possible. Nasointestinal tubes are placed to enhance intestinal absorption and retard gastric reflux. Parenteral nutrition is reserved for instances in which enteral feedings are contraindicated. Nursing measures focus on assessing feeding tolerance and use of nutrients.

Expected Outcome: Patient's nutritional intake will be adequate for meeting physiologic processes as evidenced by oral or enteral intake of high-protein, high-nutrient diet.

- Maintain nasogastric/nasointestinal tube placement. *Correct tube placement ensures appropriate absorption of nutrients and prevents aspiration.*
- Maintain enteral/parenteral nutritional support as prescribed. Observe and report any evidence of feeding intolerance: diarrhea, vomiting, excessive gastric residual, abdominal distention, absent bowel sounds, and constipation. *The nutritionist, in collaboration with the physician, selects and individualizes the feeding formula according to the patient's daily energy expenditure requirements and feeding tolerance. Failure to maintain rates of infusion predisposes the patient to continued catabolism and negative nitrogen balance.*
- Weigh the patient daily. *Weight indicates the adequacy of nutritional support therapies.*
- Obtain daily laboratory values for protein, iron, CBC, glucose, and albumin. *Decreased serum values indicate inadequate nutritional intake.*

Powerlessness

Usually, the patient with a major burn injury endures a lengthy hospital stay involving many treatments and care protocols that are beyond his or her control. During the early stages, much of the care regimen involves excruciating pain. Further, the foreign environment of the burn unit makes it difficult for the patient to relate to the immediate surroundings. For example, the need to control infection in the burn unit requires hospital personnel and family members to don sterile clothing prior to coming to the patient's bedside. Family members and nursing personnel appear radically different when they are masked and gowned, and their odd appearance can add to the burn-injured patient's sense of alienation. The patient's body image is often altered, depending on the extent and location of the burn injury.

Expected Outcome: Patient will resolve feelings of powerlessness and other related feelings as evidenced by participation in planning and implementation of care.

- Allow the patient as much control over the surroundings and daily routine as possible. For example, allow the patient to choose times of dressing changes. *Powerlessness derives from the belief that one is unable to influence the outcome of a situation.*
- Keep needed items within reach, such as call bell, urinal, water pitcher, and tissues, *to reinforce the patient's feelings of control.*
- Encourage the patient to express feelings. *The nurse can help the patient cope by therapeutically listening, displaying a caring presence, clarifying misconceptions, and providing positive feedback.*
- Set short-term, realistic goals (e.g., set a goal for the patient to ambulate from bedside to chair twice daily). *Small incremental gains are easier to achieve than large ones and allow for frequent positive reinforcement.*

Continuity of Care

Patient and family teaching is an important component of all phases of burn care. As treatment progresses, the nurse encourages family members to assume more responsibility in providing care. From admission to discharge, the nurse teaches the patient and family to assess all findings, implement therapies, and evaluate progress. The following topics should be addressed in preparing the patient and family for home care:

- The long-term goals of rehabilitation care: to prevent soft tissue deformity, protect skin grafts, maintain physiologic function, manage scars, and return the patient to an optimal level of independence

- Avoiding exposure to people with colds or infections and following aseptic technique meticulously when caring for the wound
- The need for progressive physical activity
- How to apply splints, pressure support garments, and other assistive devices
- Dietary requirements with required kilocalories
- Alternative pain control therapies, such as guided imagery, relaxation techniques, and diversional activities
- Care of the graft and donor sites
- Referral for occupational therapy, social service, clergy, and/or psychiatric services as appropriate
- Helpful resources:
  - American Burn Association
  - International Society for Burn Injuries
  - American Academy of Facial Plastic and Reconstructive Surgery.

CASE STUDY & NURSING CARE PLAN A Patient with a Major Burn

Craig Howard, a 39-year-old truck driver, is admitted to the hospital following an accident in which the cab of his truck caught on fire. He was freed from the truck by a passing motorist, who stayed with him until the rescue team arrived and transported him to a local emergency department (ED). Mr. Howard's wife, Mary, and twin daughters, Jessica and Jane, age 10, have been notified.

ASSESSMENT

On his admission to the ED, Mr. Howard is diagnosed with deep partial-thickness and full-thickness burns of the anterior chest, arms, and hands. A quick assessment based on the rule of nines estimates the extent of his burn injury at 36% TBSA. His vital signs are as follows: T 35.6°C (96.2°F), P 140 bpm, R 40/min, and BP 98/60 mmHg. In the field, the paramedics had inserted a large-bore central line into Mr. Howard's right subclavian vein and started the rapid infusion of lactated Ringer's solution. Mr. Howard is receiving 40% humidified oxygen via face mask. Initial ABGs are pH 7.49, PO_2 60 mmHg, PCO_2 32 mmHg, and bicarbonate 22 mEq/L. Lung sounds indicate inspiratory and expiratory wheezing, and a persistent cough reveals sooty sputum production. A Foley catheter is inserted and initially drains a moderate amount of dark, concentrated urine. A nasogastric tube is connected to low-intermittent suction. Mr. Howard is alert and oriented and complains of severe pain associated with the burn injuries. The burn unit is notified, and Mr. Howard is transferred there.

DIAGNOSIS

- *Risk for Ineffective Airway Clearance*, related to increasing lung congestion secondary to smoke inhalation
- *Deficient Fluid Volume*, related to abnormal fluid loss secondary to burn injury
- *Risk for Ineffective Tissue Perfusion (Peripheral)*, related to peripheral constriction secondary to circumferential burn wounds of the arms

EXPECTED OUTCOMES

- Patient will demonstrate a patent airway, as evidenced by clear breath sounds; absence of cyanosis; and vital signs, chest x-ray findings, and ABGs within normal limits.
- Patient will demonstrate adequate fluid volume and electrolyte balance, as evidenced by urine output, vital signs, mental status, and laboratory findings within normal limits.
- Patient will demonstrate adequate tissue perfusion, as evidenced by palpable pulses, warm extremities, normal capillary refill, and absence of paresthesia.

PLANNING AND IMPLEMENTATION

- Prepare for prophylactic nasotracheal intubation to maintain airway patency.
- Initiate fluid resuscitation therapy using the Consensus formula to calculate intravenous fluid rate for the first 24 hours postburn.
- Assist the physician to perform escharotomies of both upper extremities.

EVALUATION

The nurse anesthetist inserted a nasotracheal tube and connected Mr. Howard to a T-piece delivering 40% oxygen. Vigorous respiratory toileting has significantly improved his ABGs. Bronchodilators have been parenterally administered and mucolytic agents added to his respiratory treatments. His tracheal secretions have begun to show evidence of clearing. Hourly urine outputs indicate adequate fluid resuscitation. Urine output has been maintained at 50 mL/h, and color and concentration have improved. CVP readings have been maintained at 6 cm H_2O, and blood pressure has increased to 100/64 mmHg. The pulse rate has decreased to 100 bpm.

To improve tissue perfusion of both arms, the physician has performed bilateral escharotomies and the wounds are dressed, using sterile procedure. The extremities have demonstrated improved circulation.

Clinical Reasoning in Patient Care

1. Explain the rationale for the immediate insertion of a Foley catheter and nasogastric tube.
2. An escharotomy was performed on both arms. Why was this procedure necessary in Mr. Howard's case?
3. What is the rationale supporting the intravenous administration of narcotics to control Mr. Howard's pain?
4. Explain the sequence of events that led to a fluid and electrolyte shift during the first 24 to 48 hours after Mr. Howard sustained his injury.

See Evaluating Your Response in Appendix B.

CHAPTER HIGHLIGHTS

- **Four types of burn injuries are thermal, chemical, electrical, and radiation. The depth of the burn injury determines whether it is classified as a superficial, partial-thickness, or full-thickness burn.**
- The "rule of nines" is a simple method to estimate the extent of a burn injury, but the Lund & Browder Chart is considered most accurate method as it compensates for changes in body shape with age.
- **Major burns involve multiorgan pathophysiologic alterations. Most critical is the fluid shift from the intracellular and intravascular compartments into the interstitium, resulting in a type of hypovolemic shock called burn shock. Other pathologic processes include an impaired immune system, disturbed functions of the skin, inhalation injury, gastrointestinal ulcerations and ileus, renal failure, and hypermetabolism.**
- Interprofessional care focuses on managing the patient during the emergent/resuscitative, acute, and rehabilitative stages. To counter the effects of burn shock, fluid resuscitation using guidelines such as the Consensus formula are initiated to replace fluid and electrolyte losses.
- Additional management for the patient with major burns includes preventing atelectasis, maintaining respiratory function, controlling pain, preventing infection and Curling's ulcer, promoting nutrition, and providing wound care.
- Extensive eschar of an extremity or the torso, called circumferential wounds, can potentially occlude arterial flow or decrease respiratory function. An escharotomy is used to release tension, preventing additional complications.
- Surgical management of burn wounds include debridement and skin grafting. Biologic and biosynthetic dressings provide temporary covering and prepare the wound for permanent autografts.
- Continual psychologic support of the patient and family is essential throughout convalescence and rehabilitation.

TEST YOURSELF NCLEX-RN® REVIEW

1. The nurse is reviewing laboratory values for a patient receiving treatment during the emergent phase of burn management. Which laboratory result should the nurse expect for the patient at this time?
   1. increased hematocrit
   2. increased serum albumin
   3. decreased serum potassium
   4. decreased blood urea nitrogen

2. The skin of a patient with severe burns to the face and chest is dry and leathery, with no pain sensations present. How should the nurse classify this burn?
   1. superficial
   2. full thickness
   3. deep partial thickness
   4. superficial partial thickness

3. The nurse is triaging recent patients brought into the burn center. Which patient is most at risk for developing burn shock?
   1. 30-year-old with 10% TBSA from a gasoline explosion
   2. 21-year-old with 90% superficial burn from a tanning bed
   3. 39-year-old with radiation burns following treatment for cancer
   4. 48-year-old with >50% TBSA from a high-voltage electrical accident

4. A patient with a major burn is receiving silver sulfadiazine (Silvadene) treatment. What nursing action should be implemented when using this medication?
   1. Monitor WBC count daily.
   2. Observe for signs of dehydration.
   3. Monitor serum electrolyte levels daily.
   4. Premedicate for pain prior to application.

5. A patient weighing 70 kg is being treated for full-thickness burns over 50% of the body. Using the Consensus formula, calculate the amount of fluid replacement that the nurse should deliver in the first 8 hours.
   1. 3500 mL
   2. 7000 mL
   3. 10,500 mL
   4. 14,000 mL

6. The nurse is evaluating the effectiveness of fluid resuscitation provided to a patient with a major burn. Which evaluation criterion indicates that fluid resuscitation has been effective during the first 24 hours of care?
   1. blood pressure 96/70 mmHg
   2. heart rate of 130 bpm
   3. central venous pressure of 18
   4. urine output of 30 to 50 mL/h

7. The nurse is caring for a patient with deep partial-thickness burns to the entire left arm and left side of the back. After a routine assessment, what finding should be immediately reported to the physician?
   1. pain in the left arm
   2. decreased left radial pulse
   3. fluid-filled vesicles on the left arm
   4. blanching when pressure applied to the left hand

8. The nurse is calculating the percentage of total body surface area that has been burned for a patient with deep partial-thickness burns to the anterior trunk, perineum, and anterior and posterior left arm. Using the "rule of nines," what is the percent of TBSA that was burned?
   1. 18%
   2. 28%
   3. 36%
   4. 40%

9. The nurse is planning an educational program on burn prevention for residents of a senior citizen center. Which topics should the nurse include in this presentation? (Select all that apply.)
1. Use a solar-powered nightlight.
2. Check smoke detectors annually.
3. Set the water heater no higher than 120°F.
4. Wear close-fitting clothing when cooking.
5. Install antiscald devices in bathroom plumbing.
6. Have a neighbor routinely check for the odor of gas.

10. The nurse is caring for a patient with possible carbon monoxide poisoning secondary to smoke inhalation. Which assessment finding is consistent with a 15% carbon monoxide level?
1. dizziness
2. drowsiness
3. hypotension
4. dark red skin color

See Test Yourself answers in Appendix B.

UNIT

4 Building Clinical Competence

Responses to Altered Integumentary Structure and Function

CLINICAL SCENARIO

Directions: *Read the following clinical scenarios and answer the questions that follow. To complete this exercise successfully, you will utilize not only knowledge of the content in this unit, but also principles related to priority setting and maintaining patient safety.*

You have been assigned to work with the following four patients for the 0700 shift on a medical-surgical unit. Significant data obtained during report is as follows:

- Mr. Johnson is a 46-year-old who is hospitalized for surgery to release contractures at his elbows that resulted from a flash burn from a grill fire 3 years ago. He is scheduled for surgery at 0800 and needs vital signs, preoperative medication, and the preoperative checklist completed.
- Mrs. Carter is a 35-year-old who was hospitalized 2 days ago with cellulitis of the right calf due to community-associated methicillin resistant *Staphylococcus aureus* (CA-MRSA). Vital signs are temperature 38°C (100.4°F), pulse 80 bpm, respirations 20/min, and blood pressure 116/76 mmHg. She is complaining of a headache and pain in the right calf. She was last medicated for pain at 0300.
- Mr. Jenkins is an 86-year-old with herpes zoster. He was admitted 4 days ago with lesions on his left neck and trunk areas. Vital signs are temperature 37.2°C (99°F), pulse 88 bpm, respirations 26/min, and blood pressure 158/90 mmHg. He is complaining of burning pain across his back and is concerned more lesions are forming.
- Rami Ugandi is a 34-year-old African male who has a history of AIDS. He was transferred from the burn ICU to the medical-surgical unit at 0600 after being treated for partial-thickness burns of his lower extremities for the past month. He will be discharged to his home with limited activity.

CLINICAL REASONING

1. Postoperatively Mr. Johnson is given morphine sulfate for incisional pain described as "9 out of 10" on a numeric scale of "1 (least) to 10 (most)." Which of the following findings requires immediate nursing intervention?
   A. vomiting once after medication administered
   B. respiratory rate below 8 breaths per minute
   C. peripheral pulse of 68 bpm after a baseline pulse of 78 bpm
   D. blood pressure of 110/70 mmHg after a baseline blood pressure of 120/80 mmHg

Priority Setting

2. In what order would you visit these patients after report? What is the rationale for your choice?
   A. _____
   B. _____
   C. _____
   D. _____

Health Promotion

3. Which foods should you encourage Mr. Ugandi to eat to help prevent pressure ulcers?
   A. eggs and chicken
   B. broccoli and oranges
   C. oatmeal and bananas
   D. whole-grain bread and kidney beans

Nursing Process

4. Mr. Johnson received partial-thickness and full-thickness flash burns on both anterior and posterior arms and his anterior trunk from a grill fire. Using the "rule of nines," what is the percentage of total body surface (TBSA) burned? _____%

5. Mrs. Carter was admitted with cellulitis in the right calf due to CA-MRSA. Which of the following clinical manifestations does the nurse determine are consistent with this diagnosis?
   A. redness, edema, and pain in the right calf
   B. purulent drainage, pale skin, and pain in right calf
   C. rash, redness, and swelling in right calf
   D. itching, rash, and pain in right calf

Communication

6. Mr. Jenkins states, "I am tired of having these sores all over. Once they heal they won't ever come back, will they? I think I would rather die than go through this again." How will you answer this question?

Delegation

7. Which care activities can be delegated to the unlicensed assistive personnel (UAP) for each patient?

Interprofessional Care

8. The nurse collaborates with the healthcare provider regarding discontinuation of mafenide acetate (Sulfamylon) for treatment of Mr. Ugandi's open skin wounds caused by toxic epidermal necrolysis after which of the following hypersensitivity responses is noted?

A. tachycardia and tachypnea
B. nausea and vomiting
C. facial edema and pruritus
D. diarrhea and candidiasis

Continuity of Care

9. Which of the following should the nurse include in the discharge teaching for Mr. Jenkins?

A. "Continue taking the antiviral medication to cure the herpes zoster."
B. "You can attend church functions because herpes zoster is not contagious."
C. "Use narcotic pain medications only for severe pain so you do not become addicted to the medication."
D. "Wear cotton clothing and keep room temperatures cool to decrease the pain and itching from the herpes zoster lesions."

Safety

10. Which of the following should the nurse do to support a culture of safety?

A. Change gloves between cleansing of different burn wounds.
B. Teach senior citizens to set hot water temperatures to no higher than 130°F.
C. Maintain airborne precautions for the client with cellulitis due to CA-MRSA.
D. Silence alarms on electronic infusion devices at night to avoid disrupting the sleep of a patient with a burn injury.

Quality Improvement

11. The nurse manager of the medical-surgical unit has noted an increase in the number of patients with pressure ulcers on the unit. What processes can be instituted to assist with reducing the incidence of pressure ulcers?

Informatics

12. Mr. Ugandi was transferred from the burn ICU with toxic epidermal necrolysis. Where in the medical record would you expect to find the following?

_____ Electronic order entry sheet
_____ Flow sheet
_____ Nursing care plan
_____ Interprofessional communication notes

A. documentation of patient response to occupational therapy session upon return to the unit
B. documentation of physician-ordered treatments
C. documentation of diagnoses, outcomes, and interventions
D. documentation of vital signs

Responses to Altered Endocrine Function

18 Assessing the Endocrine System 461

19 Nursing Care of Patients with Endocrine Disorders 475

20 Nursing Care of Patients with Diabetes Mellitus 501

Nutritional–Metabolic Pattern

The endocrine system regulates metabolism, biochemical processes necessary for life.

18 Assessing the Endocrine System

LEARNING OUTCOMES

1. Describe the anatomy and physiology of the endocrine glands.
2. Summarize the functions of the hormones secreted by the endocrine glands.
3. Describe specific topics to consider during a health history interview of the patient with health problems involving endocrine function.
4. Explain techniques for assessing the thyroid gland and the effects of altered function of thyroid hormones.
5. Describe normal variations in endocrine assessment findings for the older adult.
6. Give examples of genetic disorders of the endocrine glands.
7. Identify abnormal findings that may indicate malfunction of the glands of the endocrine system.

CLINICAL COMPETENCIES

1. Conduct and document a health history for patients who have or are at risk for alterations in the structure or function of the endocrine glands.
2. Monitor the results of diagnostic tests and report abnormal findings.
3. Conduct and document a physical assessment of the structure of the thyroid gland.
4. Assess and document the effects of altered endocrine function on other body structures and functions.

MAJOR CHAPTER CONCEPTS

- The endocrine system is comprised of the pituitary gland, thyroid gland, parathyroid glands, adrenal glands, pancreas, and gonads (reproductive glands).
- The endocrine system is essential to the regulation of the body's internal environment; homeostasis is dependent on a balanced level of each type of hormone.
- Hormones regulate growth, development, and metabolism. Endocrine glands release most hormones, including thyroid hormone and insulin, into the bloodstream. Hormone receptors are located on or inside target cells. They recognize a specific hormone and translate the message into a cellular response.
- A targeted health history and physical assessment as well as various diagnostic tests help to diagnose endocrine disorders.

KEY TERMS

acromegaly, *472*
carpal spasm, *473*
Chvostek's sign, *473*
dwarfism, *473*
exophthalmos, *472*
goiter, *472*
tetany, *473*
Trousseau's sign, *473*

EQUIPMENT NEEDED

- Reflex hammer
- Safety pin, cotton ball, containers with hot and cold water, tuning fork
- Blood pressure cuff
- Stethoscope

The endocrine system is essential to the regulation of the body's internal environment. Through hormones secreted by its glands, the endocrine system regulates such varied functions as growth, reproduction, metabolism, fluid and electrolyte balance, and gender differentiation. It also has a role in adapting to constant alterations in the internal and external environment. Disorders of the endocrine system primarily result from either too much or too little hormone production. These alterations in hormone levels affect a wide variety of human functions, including activity and exercise, nutrition and metabolism, elimination, self-perception and self-concept, sexuality and reproduction, coping with stress, and role-relationships.

Anatomy, Physiology, and Functions of the Endocrine System

The endocrine system is comprised of the pituitary gland, thyroid gland, parathyroid glands, adrenal glands, pancreas, and gonads (reproductive glands). The locations of these glands are illustrated in Figure 18–1 ■. Table 18–1 summarizes the functions of the endocrine glands and their hormones. Specific information about the ovaries and testes is found in Chapters 47 through 49.

Pituitary Gland

The pituitary gland (hypophysis) is located in the skull beneath the hypothalamus of the brain (Figure 18–2 ■). It often is called the master gland because its hormones regulate many body functions. The pituitary gland has two parts: the anterior pituitary (or adenohypophysis) and the posterior pituitary (or neurohypophysis). The anterior pituitary is glandular tissue; the posterior pituitary is an extension of the hypothalamus.

ANTERIOR PITUITARY

The anterior pituitary has several types of endocrine cells and secretes at least six major hormones (Figure 18–3 ■).

- Somatotropic cells secrete growth hormone (GH) (also called somatotropin). GH stimulates growth of the body by signaling cells to increase protein production and by stimulating the epiphyseal plates of the long bones.
- Lactotrophic cells secrete prolactin (PRL). Prolactin stimulates the production of breast milk.

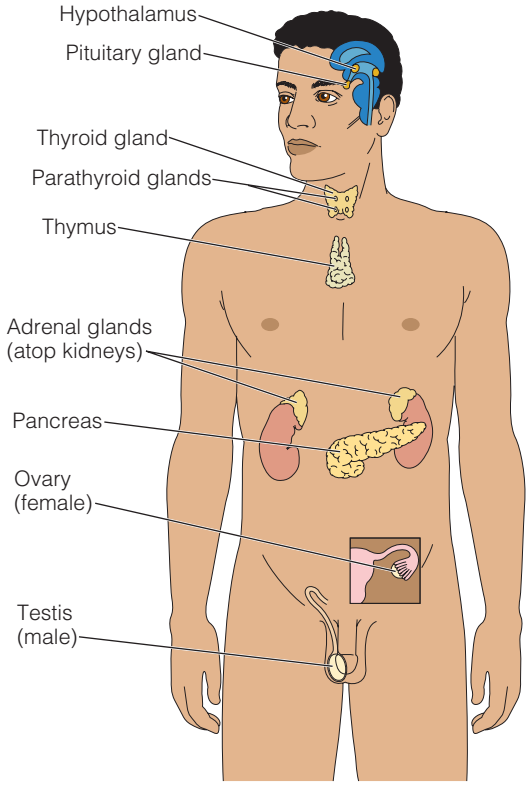

Figure 18–1 ■ Locations of the major endocrine glands.

TABLE 18–1 Organs, Hormones, Functions, and Feedback Mechanisms of the Endocrine System

Endocrine Gland	Hormone Secreted	Target Organ and Feedback Mechanism
Thyroid gland	Thyroid hormone (TH): thyroxine (T_4) is the major hormone secreted by the thyroid gland. It is converted to triiodothyronine (T_3) at the target tissues.	Maintains metabolic rate and growth and development of all tissues. T_3 and T_4 are secreted in response to TSH.
	Calcitonin	Maintains serum calcium levels by decreasing bone resorption and decreasing resorption of calcium in the kidneys in response to elevated levels of plasma calcium.
Parathyroid gland	Parathyroid hormone (PTH)	Maintains serum calcium levels by stimulating bone resorption and by stimulating kidney resorption of calcium in response to falling levels of plasma calcium.
Adrenal cortex	Mineralocorticoids (e.g., aldosterone)	Promote reabsorption of sodium and water in kidney tubule and excretion of potassium in response to elevated levels of potassium and low levels of sodium, thereby increasing blood pressure and blood volume.
	Glucocorticoids (e.g., cortisol)	Help regulate metabolism of carbohydrates, fats, and proteins. Activate anti-inflammatory responses to stressors. Low cortisol levels stimulate hypothalamic secretion of corticotropin-releasing hormone (CRH), which stimulates the anterior pituitary gland to release ACTH, which in turn stimulates the adrenal cortex to secrete cortisol.
	Gonadocorticoids (androgens and small amounts of estrogen and progesterone)	The quantity of sex hormones produced here is small, and the mechanism is not well understood.
Adrenal medulla	Catecholamines (epinephrine and norepinephrine)	Stimulate the heart, constrict blood vessels, inhibit visceral muscles, dilate bronchioles, increase respiration and metabolism, increase blood glucose. Secreted in response to physical or psychologic stress.
Anterior pituitary (adenohypophysis)	Growth hormone (GH)	Promotes growth of body tissues by enhancing protein synthesis and promoting use of fat for energy and thus conserving glucose. Release is stimulated by growth hormone–releasing hormone (GHRH) in response to low GH levels, hypoglycemia, increased amino acids, low fatty acids, and stress.

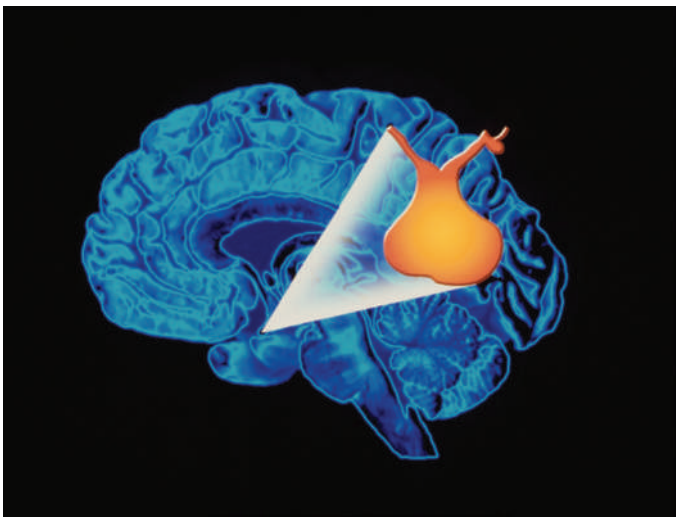

Figure 18–2 ■ Location of the pituitary gland.
Source: ISM/Phototake NYC.

- Gonadotropic cells secrete the gonadotropin hormones, follicle-stimulating hormone (FSH), and luteinizing hormone (LH). These hormones stimulate the ovaries and testes (the gonads).
- Thyrotropic cells secrete thyroid-stimulating hormone (TSH). TSH stimulates the synthesis and release of thyroid hormones from the thyroid gland.
- Corticotropic cells secrete adrenocorticotropic hormone (ACTH). ACTH stimulates release of hormones, especially glucocorticoids, from the adrenal cortex.

POSTERIOR PITUITARY

The posterior pituitary is made of nerve tissue. Its primary function is to store and release antidiuretic hormone (ADH) and oxytocin, produced in the hypothalamus:

- ADH, also called vasopressin, decreases urine production by causing the renal tubules to reabsorb water from the urine and return it to the circulating blood.
- Oxytocin induces contraction of the smooth muscles in the reproductive organs. In women, oxytocin stimulates the myometrium of the uterus to contract during labor. It also induces milk ejection from the breasts.

Thyroid Gland

The thyroid gland (Figure 18–4 ■) is anterior to the upper part of the trachea and just inferior to the larynx. This butterfly-shaped gland has two lobes connected by a structure called the isthmus.

The glandular tissue consists of follicles filled with a jelly-like colloid substance named thyroglobulin, a glycoprotein-iodine complex. Cells within the follicles secrete thyroid hormone (TH), a general name for two similar hormones: thyroxine (T_4) and triiodothyronine (T_3). The primary role of thyroid hormones in adults is to increase metabolism. TH secretion is initiated by the release of TSH by the pituitary gland and is dependent on an adequate supply of iodine.

The thyroid gland also secretes calcitonin, a hormone that decreases excessive levels of calcium in the blood by slowing the calcium-releasing activity of bone cells, serves as a marker for sepsis, and is believed to be a mediator of inflammatory responses.

Parathyroid Glands

The parathyroid glands (usually four to six in number) are embedded on the posterior surface of the lobes of the thyroid gland. They secrete parathyroid hormone (PTH), or parathormone. When calcium levels in the plasma fall, PTH secretion increases. PTH also controls phosphate metabolism. It acts by increasing renal excretion of phosphate in the urine, by decreasing the excretion of calcium, and by increasing bone reabsorption to cause the release of calcium from bones. Normal levels of vitamin D are necessary for PTH to exert these effects on bone and kidneys.

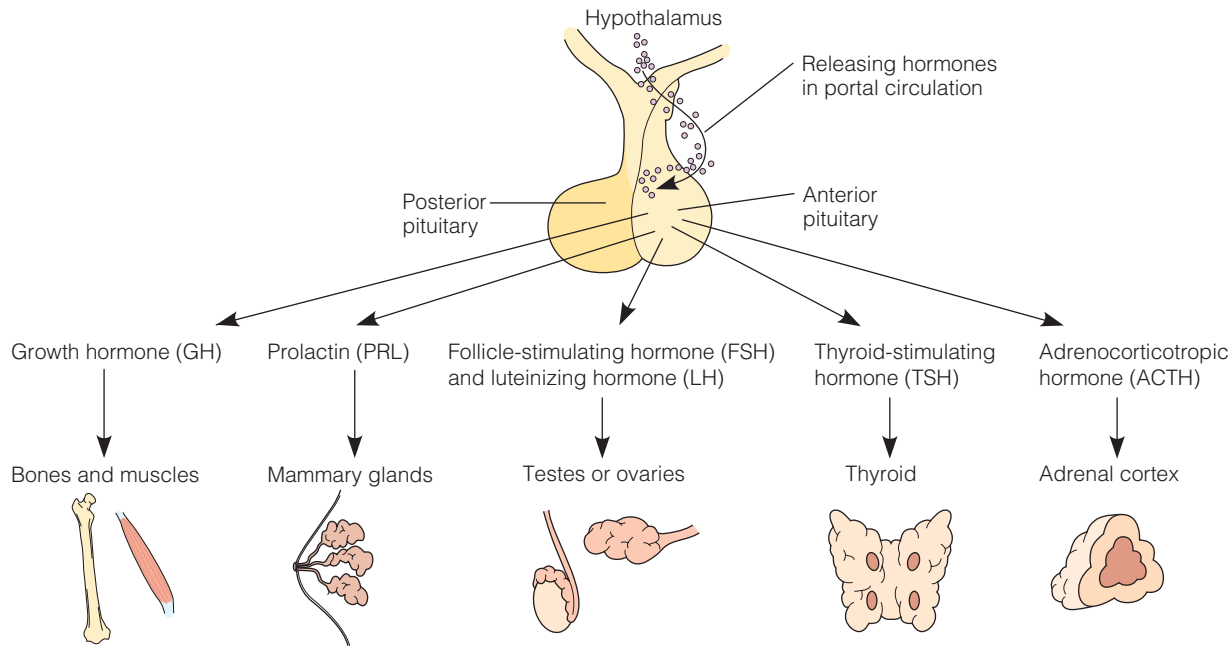

Figure 18–3 ■ Actions of the major hormones of the anterior pituitary.

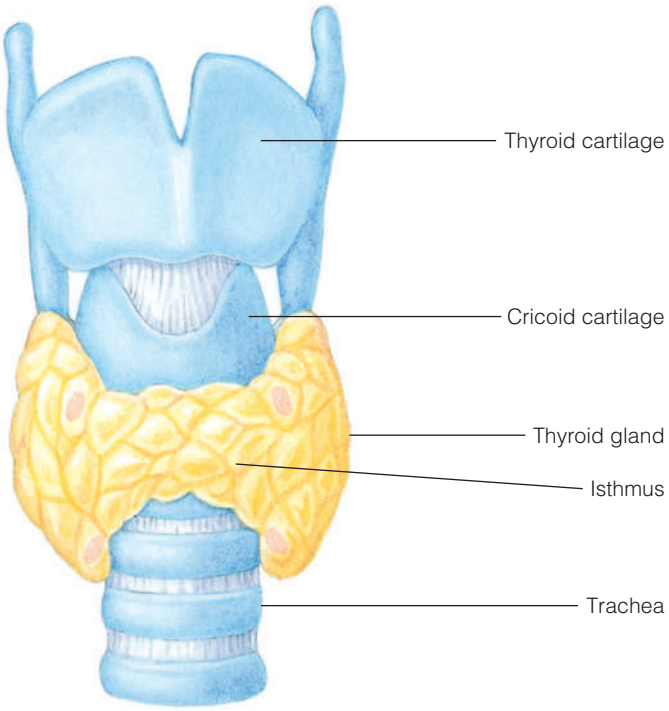

Figure 18–4 ■ The thyroid gland.
Source: Dorling Kindersley Media Library.

Adrenal Glands

The two adrenal glands are pyramid-shaped organs that sit on top of the kidneys (Figure 18–5 ■). Each gland consists of two parts, an inner medulla and an outer cortex.

The adrenal medulla produces two hormones (also called *catecholamines*): epinephrine (adrenalin) and norepinephrine (noradrenalin). These hormones are similar to substances also released by the sympathetic nervous system and thus are not essential to life. Epinephrine increases blood glucose levels and stimulates the release of ACTH from the pituitary; ACTH in turn stimulates the adrenal cortex to release glucocorticoids. Epinephrine also increases the rate and force of cardiac contractions; constricts blood vessels in the skin, mucous membranes, and kidneys; and dilates blood vessels in the skeletal muscles, coronary arteries, and pulmonary arteries.

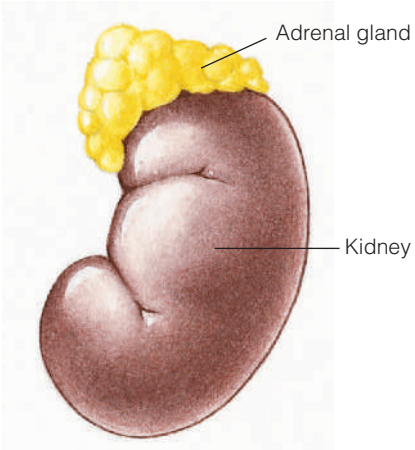

Figure 18–5 ■ Location of the adrenal glands.
Source: Dorling Kindersley Media Library.

Norepinephrine increases heart rate, increases the force of cardiac contractions, and vasoconstricts blood vessels throughout the body.

The adrenal cortex secretes several hormones, all corticosteroids. They are classified into two groups: mineralocorticoids and glucocorticoids. These hormones are essential to life.

The release of the mineralocorticoids is controlled primarily by renin (an enzyme). When a decrease in blood pressure or sodium is detected, specialized kidney cells release renin to act on angiotensinogen, manufactured by the liver. Angiotensinogen is modified by renin and other enzymes to become angiotensin, which stimulates the release of aldosterone from the adrenal cortex. Aldosterone prompts the distal tubules of the kidneys to release increased amounts of water and sodium back into the circulating blood to increase circulating blood volume and pressure. This system (the renin–angiotensin–aldosterone system) is illustrated in Chapter 10 with the discussion of body fluid regulation.

The glucocorticoids include cortisol and cortisone. These hormones affect carbohydrate metabolism by regulating glucose use in body tissues, mobilizing fatty acids from fatty tissue, and shifting the source of energy for muscle cells from glucose to fatty acids. Glucocorticoids are released in times of stress. An excess of glucocorticoids in the body depresses the inflammatory response and inhibits the effectiveness of the immune system.

Pancreas

The pancreas, located behind the stomach between the spleen and the duodenum, is both an endocrine gland (producing hormones) and an exocrine gland (producing digestive enzymes). The digestive enzymes produced by the pancreas are discussed in Chapter 21. The content in this chapter discusses the endocrine pancreatic hormones.

The endocrine cells of the pancreas produce hormones that regulate carbohydrate metabolism. They are clustered in structures called pancreatic islets (or islets of Langerhans) scattered throughout the pancreas. Pancreatic islets have at least four different cell types:

- Alpha cells produce glucagon, which decreases glucose oxidation and promotes an increase in the blood glucose level by signaling the liver to release glucose from glycogen stores.
- Beta cells produce insulin, which facilitates the uptake and use of glucose by muscle, liver, and fat cells and prevents an excessive breakdown of glycogen in the liver and muscle. In this way, insulin decreases blood glucose levels. Insulin also facilitates lipid formation, inhibits the breakdown and mobilization of stored fat, and helps amino acids move into cells to promote protein synthesis. In general, the actions of glucagon and insulin oppose one another, helping to maintain a stable blood glucose level.
- Delta cells secrete somatostatin, which inhibits the secretion of glucagon and insulin by the alpha and beta cells.
- F cells secrete pancreatic polypeptide, which is believed to inhibit the exocrine activity of the pancreas.

Gonads

The gonads are the testes in men and the ovaries in women. These organs are the primary source of steroid sex hormones in the body. The hormones of the gonads are important in regulating body growth and promoting the onset of puberty. The structure and functions of the gonads are discussed in Chapter 47.

AN OVERVIEW OF HORMONES

Hormones are chemical messengers secreted by the endocrine organs and transported throughout the body, where they exert their action on specific cells called target cells. Hormones do not cause reactions directly but rather regulate tissue responses. They may produce either generalized effects or local effects.

Hormones are transported from endocrine gland cells to target cells in the body in one of four ways:

- Endocrine glands release most hormones, including TH and insulin, into the bloodstream. Some hormones require a protein carrier.
- Neurons release some hormones, such as epinephrine, into the bloodstream. This is called the neuroendocrine route.
- The hypothalamus releases its hormones directly to target cells in the posterior pituitary by nerve cell extension.
- With the paracrine method, released messengers diffuse through the interstitial fluid. This method of transport involves a number of hormonal peptides that are released throughout various organs and cells and act locally. An example is endorphins, which act to relieve pain.

Hormone levels are controlled by the pituitary gland and by feedback mechanisms. Feedback is controlled much as the thermostat in a house regulates temperature. Sensors in the endocrine system detect changes in hormone levels and adjust hormone secretion to maintain normal levels. When the sensors detect a decrease in hormone levels, they start actions that cause an increase in hormone levels; when hormone levels rise above normal, the sensors cause a decrease in hormone production and release. For example, when thyroid hormone rises, the production of thyroid-stimulating hormone is inhibited, which results in a decrease in the output of TH by the thyroid gland. See Figure 18–6 ■.

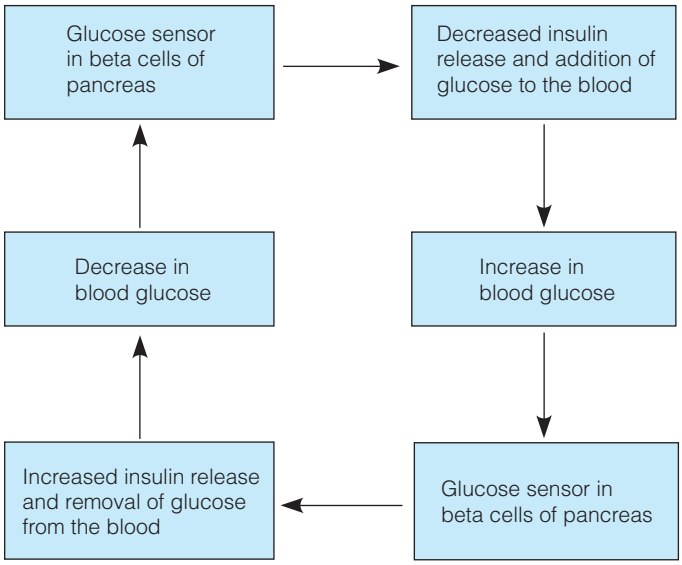

Figure 18–6 ■ Negative feedback.

In positive feedback mechanisms, increasing levels of one hormone cause another gland to release a hormone. For example, the increased production of estradiol (a female ovarian hormone) during the follicular stage of the menstrual cycle in turn stimulates increased FSH production by the anterior pituitary gland. Estradiol levels continue to increase until the ovarian follicle disappears, eliminating the source of the stimulation for FSH, which then decreases.

Stimuli for hormone release may also be classified as hormonal, humoral, or neural (Figure 18–7 ■). In hormonal release, hypothalamic hormones stimulate the anterior pituitary to release hormones. Fluctuations in the serum level of these hormones in turn prompt

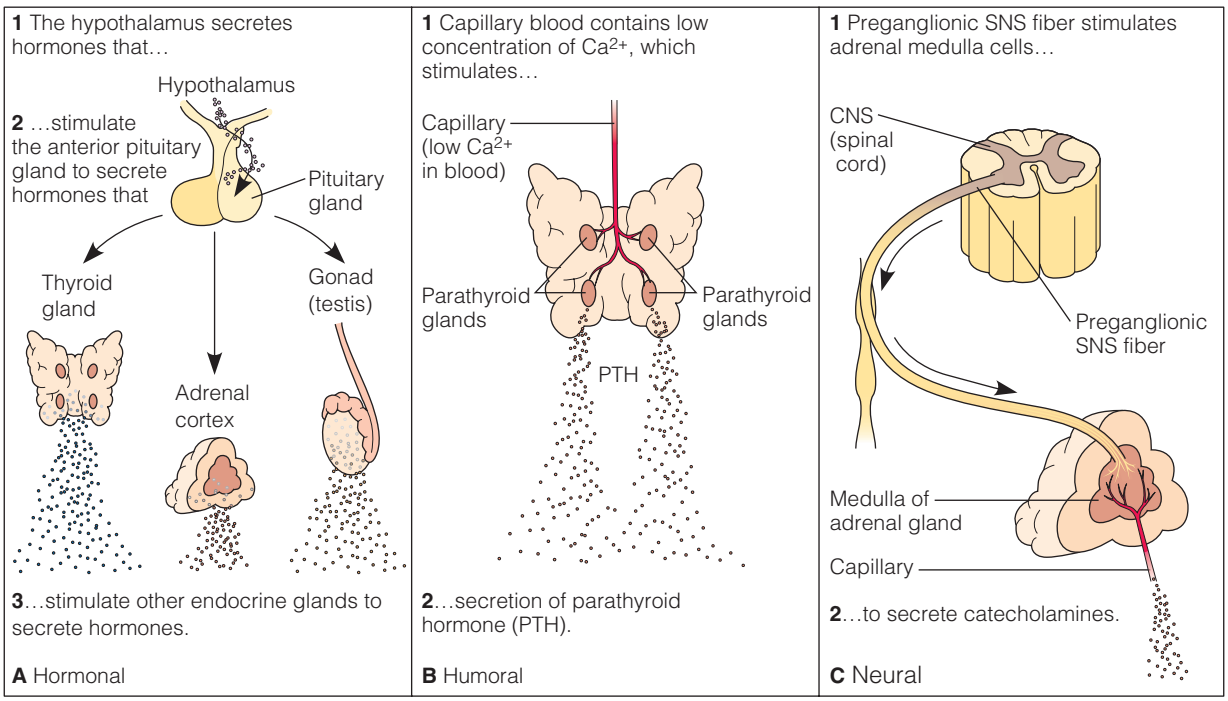

Figure 18–7 ■ Examples of three mechanisms of hormone release: A, hormonal; B, humoral; or C, neural.

other endocrine glands to release hormones. In humoral release, fluctuations in the serum levels of certain ions and nutrients stimulate specific endocrine glands to release hormones to bring these levels back to normal. In neural release, nerve fibers stimulate the release of hormones.

ASSESSING ENDOCRINE FUNCTION

The function of the endocrine glands is assessed by findings from diagnostic tests, a health assessment interview to collect subjective data, and a physical assessment to collect objective data. Hormones affect all body tissues and organs, and manifestations of dysfunction are often nonspecific, making assessment of endocrine function sometimes more difficult than assessment of other body systems.

Diagnostic Tests

The results of diagnostic tests of the endocrine system are used to support the diagnosis of a specific disease, to provide information to identify or modify the appropriate medication or therapy used to treat the disease, and to help monitor the patient's responses to treatment and nursing care interventions. Diagnostic tests to assess the structure and function of the glands of the endocrine system are described in the following table. More information is included in the discussion of specific disorders in Chapters 19 and 20.

Regardless of the type of diagnostic test, the nurse is responsible for explaining the procedure and any special preparation needed, for assessing for medication use that may affect the outcome of the tests, for ensuring the consent form is signed (if necessary), for supporting the patient during the examination as necessary, for documenting the procedures as appropriate, and for monitoring the results of the tests. The nurse is also responsible for postprocedure care and patient teaching for self-care at home.

Genetic Influences

When conducting a health assessment interview and physical assessment, it is important for the nurse to consider genetic influences on the health of the adult. During the health assessment interview, ask about endocrine disorders in immediate family members, including

DIAGNOSTIC TESTS of the Endocrine System

PITUITARY TESTS

Name of Test	Purpose and Description	Related Nursing Interventions
Growth hormone (GH), human growth hormone (hGH)	In this blood test, GH levels (affected by food, stress, and activity) are measured to identify GH deficiency (dwarfism) or GH excess (gigantism, acromegaly). Normal value: Men: <5 ng/mL Women: <10 ng/mL	Tell patient not to eat or drink 8–10 h prior to having blood drawn. Have patient rest for 30–60 min before blood is drawn.
Magnetic resonance imaging (MRI)	This imaging study is done to identify tumors of the hypothalamus or pituitary gland.	Tell patient of need to lie still during the examination. Assess for any metallic implants (such as pacemakers, clips on brain aneurysms, body piercings, tattoos, shrapnel). If present, notify imaging physician. Remove transdermal medication patches unless otherwise ordered. Replace the patch following the procedure. Ask the patient to tell the staff about the patch when making the appointment and when completing the admission information. Ask if patient is pregnant; if so, the test is not performed. Ask about claustrophobia; if a problem, instruct patient to ask for a relaxing medication to take prior to the MRI (Beddoe & Pravikoff, 2011).
Somatomedin C (Insulin-like growth factor or IGF-1)	The results of this blood test are used to evaluate secretion of growth factor and to identify GH deficiency or excess (as discussed earlier). Normal value: 125–250 ng/mL	None; overnight fasting is preferred but not necessary.
Water deprivation test	This combination of blood and urine tests is used to identify causes of polyuria (increased urine output), including central diabetes insipidus, neurogenic diabetes insipidus, and psychogenic polydipsia (drinking excessive amounts of fluids). In patients without pathology, there is no change in urine and plasma osmolality. Urine osmolality increases in central diabetes insipidus and decreases in nephrogenic diabetes insipidus (Graczyk et al., 2011).	Tell patient not to smoke, eat, or drink as directed, and that the test will take up to 8 h. Assess weight, take postural BP (lying and standing measures separated by 2 min), assess urine volume and specific gravity, and send samples of urine to the lab for osmolality hourly during the test. Blood samples for osmolality are taken when urine samples are collected and when patient demonstrates orthostatic hypotension. Coordinate specimen collection with the laboratory (Graczyk et al., 2011).

DIAGNOSTIC TESTS of the Endocrine System (*continued*)

THYROID TESTS

Name of Test	Purpose and Description	Related Nursing Interventions
Magnetic resonance imaging (MRI)—thyroid	This imaging study is done to identify tumors of the thyroid gland.	See information for MRI of the pituitary.
Radioactive iodine uptake (RIA)	This test provides a direct measure of thyroid activity and is useful in evaluating the activity of solitary thyroid nodules. Based on the rationale that the thyroid gland takes up iodine in any form, radioactive iodine is given orally or IV, and the thyroid gland uptake is measured with a scanner at several hourly intervals and at 24 h. Normal value for uptake: 2–4 h: 3%–19% 24 h: 11%–30%	The patient should not eat or drink for 6–8 h before the test, but can have food 1 h after the oral dose is given. Tell patients not to take supplemental iodine several weeks before the test and thyroid medications should be discontinued.
Thyroid antibodies (TA)	A blood test used to identify thyroid immune disease (Graves' disease, chronic thyroiditis, Hashimoto's thyroiditis). Normal values: Antithyroglobulin: negative to titer $<$1:20 Antimicrosomal: negative to titer $<$1:100	Assess for family history of thyroid disease and ask about recent viral infection (which could trigger autoimmune disease).
Thyroid scan	This nuclear scan evaluates thyroid nodules. Radioactive isotopes are given orally and a scanner is passed over the thyroid to make a graphic record of the radiation emitted. A normal thyroid scan has a homogeneous pattern of radiation with symmetric lobes. Benign lesions appear as warm spots (take up more radiation); malignant tumors appear as cold spots (less radiation taken up).	No special preparation is needed.
Thyroid-stimulating hormone (TSH)	In this blood test, levels of circulating TSH are measured, with levels above or below normal indicating thyroid disease. TSH levels also are compared with T_4 levels to differentiate between pituitary and thyroid dysfunction. A decreased T_4 level and a normal or increased TSH level can indicate a thyroid disorder. A decreased T_4 level and a decreased TSH level can indicate a pituitary disorder. Normal value: $<$3 ng/mL	Tell patients to avoid shellfish for several days prior to the test. Assess medications: TSH value may be increased by aspirin, steroids, dopamine, and heparin; and decreased by lithium and potassium iodide.
Thyroid suppression test	Triiodothyronine (T_3) is taken for 7–10 days, and a reduction of its uptake to less than half of the initial uptake after that time is considered normal. The test is used to diagnose hyperthyroidism and hypothyroidism.	Explain the importance of taking the triiodothyronine for the length of time prescribed.
Thyrotropin-releasing hormone (TRH) stimulation test	A baseline TSH is measured; followed by an injection of TRH to stimulate the pituitary to release TSH. A second blood sample is drawn 20–30 min later and the TSH level is again measured. Levels higher or lower than normal are indicative of thyroid disease.	No special preparation is needed.
Thyroxine (T_4)	The results of this blood test are used to determine thyroid function and aid in the diagnosis of hyperthyroidism and hypothyroidism. Normal value: Free T_4: 1.0–2.3 ng/dL	Assess medications: Value may be decreased by cortisone, chlorpromazine (Thorazine), phenytoin (Dilantin), heparin, lithium, sulfonamides, reserpine (Serpasil), testosterone, propranolol (Inderal), tolbutamide (Orinase), and salicylates in high doses. Values may be increased by oral contraceptives, estrogen, clofibrate, and perphenazine (Trilafon).
Triiodothyronine (T_3)	The results of this blood test are used to diagnose hyperthyroidism and to compare T_3 with T_4 for diagnosis of thyroid disorder. Normal value: 80–200 ng/dL	Assess medications: Value can be decreased by propylthiouracil, methimazole (Tapazole), lithium, phenytoin (Dilantin), propranolol (Inderal), reserpine (Serpasil), large doses of aspirin, steroids, and sulfonamides. Value can be increased by estrogen, progestins, oral contraceptives, T_3, and methadone.

(*continued*)

DIAGNOSTIC TESTS of the Endocrine System (*continued*)

Name of Test	Purpose and Description	Related Nursing Interventions
Triiodothyronine resin uptake (T_3RU)	This test is an indirect measure of free thyroxine (T_4). The patient's blood is mixed with radioactive T_3 and synthetic resin. The radioactive T_3 will bind with available thyroid-binding globulin sites. The unbound radioactive T_3 is added to resin for T_3 uptake. In hyperthyroidism there are few binding sites left, more T_3 is taken up by the resin, and a high T_3 resin uptake results. The opposite occurs in hypothyroidism. Normal value: 25%–35% uptake	No special preparation is needed.

PARATHYROID TESTS

Name of Test	Purpose and Description	Related Nursing Interventions
Calcium (Ca)	This blood test is used to check for serum calcium excess or deficit in parathyroid and bone disorders, and to monitor calcium levels. Normal value: 9.0–11.0 mg/dL, 4.5–5.5 mEq/L, or 2.3–2.8 mmol/L (SI units)	Assess for manifestations of tetany, including positive Chvostek's and Trousseau's signs, if hypocalcemia is present (see Chapter 10).
Magnetic resonance imaging (MRI)—parathyroid glands	This imaging study is done to identify tumors of the parathyroid glands.	See information for MRI of the pituitary for related nursing interventions.
Parathyroid hormone (PTH)	This blood test is used to identify hypoparathyroidism or hyperparathyroidism, and is also used to monitor response to PTH therapy. Normal value: Intact PTH: 11–54 pg/mL C-terminal PTH: 50–330 pg/mL N-terminal PTH: 8–24 pg/mL	Tell patients not to eat or drink for 8 h before the test.

ADRENAL TESTS

Name of Test	Purpose and Description	Related Nursing Interventions
Adrenocorticotropic hormone (ACTH)	This blood test is used to determine if a decreased plasma level of cortisol is due to adrenal cortex hypofunction or pituitary hypofunction. Normal value: 7–10 a.m.: 8–80 pg/mL 4 p.m.: 5–30 pg/mL 10–12 p.m.: <10 pg/mL	Tell the patient that food and fluids may be restricted, and that stress and exercise may affect results. Assess medications: ACTH values may be increased by alcohol, amphetamines, estrogen, aldosterone, vasopressin, and insulin, and decreased by steroids, estrogen, and alcohol.
ACTH stimulation	This test is conducted to differentiate adrenal insufficiency from pituitary hypofunction. ACTH (cosyntropin) is administered; if the plasma cortisol level is unchanged in 1 h, adrenal insufficiency is the cause. To identify pituitary hypofunction, the drug metyrapone (Metopirone) is given to block the production of cortisol, thus causing increased ACTH secretion. If the ACTH level does not increase, the problem is pituitary insufficiency.	Assess medications and provide teaching as for ACTH test.
ACTH suppression	For the ACTH suppression test, the drug dexamethasone (Decadron) is given to suppress ACTH production. If an extremely high dose is needed, the cause is of pituitary origin; if the plasma cortisol remains high, the cause could be adrenal cortex hyperfunction (Cushing's syndrome).	Provide teaching and assess medications as for ACTH test. If dexamethasone (Decadron) causes gastric irritation, milk or antacids may be required.
Aldosterone	This blood test is done to identify a deficit or an excess of aldosterone, and to help determine the cause of overhydration.	Instruct patient to maintain usual diet prior to the test, avoiding excess salt or licorice, and to rest in the supine position for 1 h before blood is drawn as position changes affect the results.

DIAGNOSTIC TESTS of the Endocrine System (*continued*)

Name of Test	Purpose and Description	Related Nursing Interventions
Aldosterone (*cont.*)	Normal value: <16 mcg/dL (fasting) A 24-h urine test is considered a more reliable measure of aldosterone than a random aldosterone test. Normal value: 6–25 mcg/24 h	If a urine test is ordered, instruct patient to void, discarding urine and noting the time to start the test, then collect all urine in the designated container for 24 hours, including a final voiding when the test is to be concluded. Avoid feces or toilet paper in the urine. Results of serum or urine aldosterone tests may be altered by excess or low dietary sodium, and antihypertensive drug therapy.
Computerized tomography (CT) of the abdomen	This radiologic study is used to assess the adrenal gland for tumors (including size and metastasis).	Determine if contrast medium will be used; if so, assess patient for allergy to iodine (shellfish) or radiologic contrast media.
Cortisol	This blood test is used to measure the total cortisol level in the serum and to evaluate adrenal cortex function. Values are decreased in Addison's disease and hypothyroidism, and increased in Cushing's syndrome and hyperthyroidism. Normal value: 8–10 a.m.: 138–635 nmol 4–6 p.m.: 83–359 nmol A 24-h urine test may be conducted to measure free (unbound) cortisol Normal value: <100 mcg/24 h	Tell patient not to eat or drink and to rest for 2 h before the test. Evaluate medications: Cortisol is decreased by androgens and phenytoin (Dilantin), and increased by oral contraceptives, estrogen, and spironolactone (Aldactone). For a urine cortisol test, instruct patient to save urine for 24-h period (see urine aldosterone above), and to avoid stressful situations and physical activity for at least 24 h prior to the test.
Dexamethasone suppression test	This test is used to differentiate the cause of adrenal disorders. Baseline plasma cortisol and urine hydroxycorticosteroids (17-OHCS) are obtained. Dexamethasone 1 mg is administered orally at 11 p.m. A serum cortisol is collected at 8 a.m. the next morning. The dexamethasone suppresses ACTH. If an extremely high dose of dexamethasone is required to suppress ACTH, the primary disorder is adrenal cortex hyperplasia (Cushing's disease). If ACTH is not suppressed with the synthetic cortisol, an adrenal tumor is suspected.	
17-Ketosteroids	This 24-hour urine test is done to measure metabolites in urine and evaluate adrenal cortex function. Normal value: Men: 5–25 mg in 24 h Women: 5–15 mg in 24 h	Instruct patient how to save urine (urine must contain a preservative and be refrigerated). Assess medications: Levels are affected by a variety of drugs; if possible, these should be discontinued for 48 h before the test (check with healthcare provider and agency protocol). Postpone the test for women who are menstruating because blood can cause a false-positive finding.
Magnetic resonance imaging (MRI)—adrenal glands	This imaging study is done to identify tumors of the adrenal glands.	See information for MRI of the pituitary.
MIBG scan	This nuclear medicine scan is used to detect the presence and location of adrenal pheochromocytomas. A special radioactive dye is given and concentrates on the tumor in the adrenal gland; the tumor can then be seen on x-ray.	Explain that the test takes about an hour a day for 3 or 4 days.

PANCREATIC ENDOCRINE TESTS

Name of Test	Purpose and Description	Related Nursing Interventions
C-peptide	C-peptide has an essential function related to the synthesis of insulin in the beta cells. C-peptide is often used as a diagnostic test to prove that an individual with type 1 diabetes is not producing insulin, and helps to differentiate between type 1 and type 2 diabetes.	Monitor results: A C-peptide level of zero means that the individual with diabetes produces no insulin and has type 1 diabetes. Individuals with type 2 diabetes produce insulin and will generally have positive C-peptide levels.

(*continued*)

DIAGNOSTIC TESTS of the Endocrine System (*continued*)

Name of Test	Purpose and Description	Related Nursing Interventions
Computed tomography (CT) of the abdomen	This radiographic test is done to identify pancreatic tumors or cysts.	If contrast medium is used, assess for allergy to iodine (shellfish) or radiologic media.
Fasting blood sugar (FBS)	This blood test is used to identify or confirm a diagnosis of diabetes mellitus. It is also used to monitor treatment of diabetes mellitus. A finding of greater than 110 mg/dL, if confirmed with OGTT, and Hgb A_1C is indicative of diabetes. Normal value: Serum/plasma: 70–110 mg/dL (value varies in individual laboratories)	Tell the patient not to eat or drink anything other than water for 6–8 h before the test. Do not administer insulin until blood specimen is taken. Assess medications: FBS may be increased by cortisone, diuretics, ACTH, levodopa, epinephrine, anesthetics, and phenytoin (Dilantin).
Oral glucose tolerance test (OGTT)	This blood and urine test is used to diagnose diabetes mellitus if prior fasting blood sugar (FBS) findings are increased or inconsistent. A solution of 75–100 g of glucose is administered and samples of blood and urine are taken immediately and at 30, 60, and 120 min (it may extend from 2 to 6 h). Values for 2-h plasma at 139 or below are considered normal; values at 200 or greater, if confirmed with a second test on a different day, are diagnostic of diabetes mellitus.	The tests will not be done if patient's FBS is consistently high. Tell the patient not to eat or drink (except water) for 6–8 h before the test. Assess medications: Drugs that may increase OGTT levels are steroids, oral contraceptives, estrogens, thiazide diuretics, and salicylates. Explain to the patient that he or she may feel weak and may perspire during the test and that these symptoms should be reported to the nurse. Although they usually are transitory, they may be manifestations of prediabetes.
Glycosylated hemoglobin (Hgb A_1C)	This blood test is used as a diagnostic tool and to monitor diabetes mellitus management. The results represent an average blood glucose level during the life of the red blood cell (90–120 days); an elevated level indicates poorly controlled diabetes mellitus and increased risk for complications. Normal value: In most labs, the normal range is 2%–5%. A glycosylated hemoglobin of 6.5% or higher is diagnostic for diabetes, and a level between 5.7% and 6.5% is indicative of impaired glucose tolerance or prediabetes. In individuals with well-controlled diabetes, it is less than 6.5%–7.0%.	Monitor findings: Decreased levels can be caused by anemia, long-term blood loss, and chronic renal failure. Increased levels may result from hyperglycemia, alcohol ingestion, pregnancy, hemodialysis, prolonged cortisone intake, impaired glucose tolerance, or prediabetes.
Magnetic resonance imaging (MRI)—pancreas	This imaging study is done to identify tumors of the pancreas.	See information for MRI of the pituitary.

the family members' age of onset and gender. Ask the patient about a family history of such diseases as diabetes mellitus, diabetes insipidus, thyroid disorders, growth problems, hypertension, and obesity. Ask women about problems with pregnancy, menstruation, and/or menopause.

During the physical assessment, assess for any manifestations that might indicate a genetic disorder (see the Genetic Considerations box). If data are found to indicate genetic risk factors or alterations, ask about genetic testing and refer for appropriate genetic counseling and evaluation. Chapter 8 provides further information about genetics in medical-surgical nursing.

Health Assessment Interview

A health assessment interview to determine problems with the endocrine system may be part of a health screening or total health assessment, or it may focus on a chief complaint (such as increased urination or changes in energy levels). If the patient has a problem with endocrine function, the nurse analyzes its onset, characteristics

GENETIC CONSIDERATIONS

Examples of Endocrine System Disorders

- Type 1 and type 2 diabetes mellitus are classified as multifactorial inheritance disorders because both genetic and environmental factors are necessary for onset of these disorders.
- Pendred syndrome is an inherited disorder in which people have deafness and a thyroid goiter.
- Hashimoto's disease (chronic thyroiditis) is believed to have a genetic component.
- Multiple endocrine neoplasia is a group of rare diseases caused by genetic defects leading to hyperplasia and hyperfunction of two or more components of the endocrine system (especially the parathyroid, pancreas, and pituitary glands).
- Fragile X syndrome is a genetic condition that causes developmental problems including learning disabilities and mental retardation. Males are usually more severely affected than females.

and course, severity, precipitating and relieving factors, and any associated symptoms, noting the timing and circumstances. For example, the nurse may ask the patient the following:

- "Describe the swelling you noticed in the front of your neck. When did it begin? Have you noticed any changes in your energy level? If so, describe them."
- "When did you first notice that your hands and feet were getting larger?"
- "Have you noticed that your appetite has increased even though you have lost weight?"

The health history includes information about the patient's medical history, family history, and social and personal history. Ask the patient about any changes in normal growth and development as well as in height and weight. Changes in the size of extremities can often be detected by asking whether the patient has had to have rings enlarged or to buy increasingly larger gloves and shoes. Enlargement of the neck may be identified by asking whether the patient has difficulty finding shirts or blouses with a collar that fits. Also explore changes such as difficulty swallowing; increased or decreased thirst, appetite, and/or urination; visual changes; sleep disturbances; altered patterns of hair distribution (such as increased facial hair in women); changes in menstruation; changes in memory or ability to concentrate; and changes in hair and skin texture. Ask the patient about any injury or surgery of the head, as well as previous hospitalizations, chemotherapy, radiation (especially to the neck), and the use of medications (especially hormones or steroids).

The nurse also asks about the patient's occupational and social history. Include questions about the patient's satisfaction with occupation, personal relationships, and lifestyle. Other areas of assessment include the patient's usual means of coping; use of alcohol, smoking, or drugs; diet (including weight gain or loss); exercise patterns; and sleep patterns. Although the patient may not recognize changes in behavior, family members may be able to provide important information.

Physical Assessment

Physical assessment of the endocrine system may be performed as part of a total health assessment or it may be a focused assessment of patients with known or suspected problems with endocrine function. Sample documentation of an assessment of the thyroid gland is included in an accompanying box.

SAMPLE DOCUMENTATION

Assessment of the Thyroid Gland

A 37-year-old female presents at a community clinic for complaints of "always feeling so hot," "always hungry but losing weight," and "can't sleep at night—too jittery." Weight 110 lb (loss of 12 pounds in last 3 months). BP 90/78 mmHg (averages 84/72), P 96 bpm. Skin very warm and moist. Anterior neck has diffuse enlargement. Thyroid gland enlarged bilaterally on palpation. Referral made to endocrine clinic for further evaluation.

The only endocrine organ that can be palpated is the thyroid gland; however, other assessments that provide information about endocrine pathophysiology include inspection of the skin, hair, nails, facial appearance, reflexes, and musculoskeletal system. Measuring and monitoring trends in height and weight and vital signs also provide clues to altered endocrine system function.

The patient may sit during the examination. A reflex hammer is used to test deep tendon reflexes. Prior to the examination, the nurse collects the necessary equipment and explains the techniques to the patient to decrease anxiety. Additional techniques for assessing hypocalcemic tetany, a complication of endocrine disorders or surgery, are included here in the examination sequence. Normal age-related changes in assessment findings are described in the Nursing Care of the Older Adult box.

NURSING CARE OF THE OLDER ADULT

Age-Related Endocrine Changes

Age-Related Change	Significance
Pituitary: ↓ production of ACTH, TSH, FSH	• Decreased secretion of glucocorticoids, 17-ketosteroids, progesterone, androgen, and estrogen (and thus lower levels on diagnostic tests)
Thyroid: ↑ in fibrosis and nodularity, ↓ in gland activity	• Lower basal metabolic rate • Increased incidence of hypothyroidism • Palpable nodules on palpation
Adrenal medulla: ↑ secretion and level of norepinephrine, ↓ beta-adrenergic response to norepinephrine	• Decreased response to beta-adrenergic receptor blockers (medications) • May contribute to increased incidence of hypertension
Pancreas: calcification of blood vessels and distention and dilation of pancreatic ducts	• Decreased production of lipase with reduced fat absorption and digestion, leading to intolerance of fatty foods and indigestion • Decreased absorption of fat-soluble vitamins
Pancreas: delayed and decreased insulin release; believed accompanied by decreased sensitivity to circulating insulin	• Decreased ability to metabolize glucose and increased insulin resistance with higher and more prolonged blood glucose levels may contribute to increased incidence of type 2 diabetes mellitus with aging (however, higher than normal blood glucose levels are not unusual in nondiabetic older adults)

Endocrine Assessments

Technique/Normal Findings	Abnormal Findings
Skin Assessments	
Inspect skin color. *Skin color should be even and appropriate to age and race of the patient.*	• Hyperpigmentation may be seen in patients with Addison's disease or Cushing's syndrome. • Acanthosis nigricans is a darkening of skinfolds seen especially at the nape of the neck, elbow folds, and under the arms. This condition has many causes, one of which is the hyperinsulinemia seen in prediabetes and type 2 diabetes. • A yellowish cast to the skin might indicate hypothyroidism. • Purple striae over the abdomen and bruising may be present in the patient with Cushing's syndrome.
Palpate the skin, assessing texture, moisture, and the presence of lesions. *Skin color should be appropriate to the patient's race; smooth, warm, dry, and intact without lesions.*	• Rough, dry skin is often seen in patients with hypothyroidism, whereas smooth and flushed skin can be a sign of hyperthyroidism. • Lesions (such as ulcerations) on the lower extremities might indicate diabetes mellitus.
Nails and Hair Assessment	
Assess texture, distribution, and condition of nails and hair. *Hair should be of normal texture, appropriately distributed for gender; nail surfaces should have even color with smooth surfaces.*	• Increased pigmentation of the nails is often seen in patients with Addison's disease. • Dry, thick, brittle nails and hair may be apparent in hypothyroidism; thin, brittle nails and thin, soft hair may be apparent in hyperthyroidism. • Hirsutism (excessive facial, chest, or abdominal hair) may be seen in Cushing's syndrome.
Facial Assessments	
Inspect the symmetry and form of the face. *Face should be bilaterally symmetrical.*	• Variations of form and structure may indicate growth abnormalities such as **acromegaly** (continued growth of bone from growth hormone hypersecretion).
Inspect position of eyes. *Eyes should be equal in position on both sides of the face. Eyelids should close over eyes.*	• **Exophthalmos** (protruding eyes) may be seen in hyperthyroidism.
Thyroid Gland Assessment	
Palpate the thyroid gland for size and consistency.	• The thyroid may be enlarged in patients with Graves' disease or a **goiter** (enlarged thyroid gland).
Stand behind the patient and place your fingers on either side of the trachea below the thyroid cartilage (Figure 18–8 ■). Ask the patient to tilt his or her head to the right. Now ask the patient to swallow. As the patient swallows, displace the left lobe while palpating the right lobe. Repeat to palpate the left lobe. *Thyroid gland is not usually palpable. If it is, lobes should feel smooth, rubbery, and free of nodules.*	• Multiple nodules may be seen in metabolic disorders, whereas the presence of only one nodule may indicate a cyst or a benign or malignant tumor. • A single enlarged nodule suggests malignancy.
Motor Function Assessment	
Assess the deep tendon reflexes. Deep tendon reflexes are assessed with the reflex hammer, and include the biceps reflex, brachioradialis reflex, triceps reflex, patellar reflex, and Achilles reflex. *Normal values range from 1+ (present, but decreased) to 2+ (normal) to 3+ (increased). See Chapter 41 for guidelines and illustrations of deep tendon reflex assessment.*	• Increased reflexes may be seen in hyperthyroidism; decreased reflexes may be seen in hypothyroidism.

Figure 18–8 ■ Palpating the thyroid gland from behind the patient.

Endocrine Assessments (*continued*)

Technique/Normal Findings	Abnormal Findings
Sensory Function Assessment	
Test the patient's sensitivity to pain, temperature, vibration, light touch, and stereognosis (the ability to identify an object by touch). Compare symmetric areas on both sides of the body, and compare the distal to the proximal regions of the extremities. Ask the patient to close his or her eyes. *Sensory function should be bilaterally intact.* • To test pain, use the blunt and sharp ends of a new safety pin. Discard the pin after use. • To test temperature, use cups or other containers of cold and hot water. • To test vibration, use a tuning fork over one of the patient's finger or toe joints. • To test light touch, use a cotton wisp. • To test stereognosis, place in the patient's hand a simple, familiar object, such as a rubber band, cotton ball, or button. Ask the patient to identify the object.	• Peripheral neuropathy and paresthesias (altered sensations) may occur in diabetes, hypothyroidism, or acromegaly.
Musculoskeletal Assessment	
Inspect the size and proportions of the patient's body structure. *Size and proportion of body structures should be bilaterally equal.*	• Extremely short stature may indicate **dwarfism** (a condition characterized by short stature); insufficient pituitary growth hormone is one cause. • Extremely large bones may indicate acromegaly, caused by excessive growth hormone.
Assessing for Hypocalcemic Tetany	
Assess for **Trousseau's sign** (a test for hypocalcemia) with resulting **tetany** (tonic muscle spasms) by inflating a blood pressure cuff above the antecubital space to a point greater than systolic blood pressure for 2–5 min. Trousseau's sign is discussed in relation to hypocalcemia in Chapter 10. *A normal finding is no carpal spasm in response to compression of the arm by the blood pressure cuff.*	• Decreased calcium levels cause the patient's hand and fingers to contract (**carpal spasm**).
Assess for **Chvostek's sign** (a test for hypocalcemia) by tapping your finger in front of the patient's ear at the angle of the jaw. A positive Chvostek's sign causes facial grimacing due to repeated contractions of the facial muscle. Chvostek's sign is discussed and illustrated in relation to hypocalcemia in Chapter 10. *A normal finding is no facial grimacing in response to tapping the patient's face in front of the ear.*	• Decreased calcium levels cause the patient's lateral facial muscles to contract.

CHAPTER HIGHLIGHTS

- **The endocrine system is comprised of several glands: the pituitary gland, thyroid gland, parathyroid glands, adrenal glands, pancreas, and gonads (reproductive glands).**
- **The endocrine system is essential to the regulation of the body's internal environment and affects a wide variety of human functions.**
- Endocrine glands release most hormones, including thyroid hormone and insulin, into the bloodstream. Hormone receptors are located on or inside target cells. They recognize a specific hormone and translate the message into a cellular response.
- **A targeted health history and physical assessment as well as various diagnostic tests help to diagnose endocrine disorders.**

TEST YOURSELF NCLEX-RN® REVIEW

1. A patient is being treated for a condition where the pituitary gland is producing an increased amount of antidiuretic hormone (ADH). What finding would the nurse most likely assess in this patient?
   1. increased output of urine
   2. decreased output of urine
   3. decreased production of testosterone
   4. increased facial hair growth in women
2. During an assessment the nurse decides to assess a patient's calcium level. Which action will the nurse take to identify a low calcium level?
   1. Palpate turgor of skin.
   2. Observe color of skin.
   3. Conduct a Trousseau's sign test.
   4. Save urine to measure 17-ketosteroids.
3. A patient with adrenal cortex dysfunction is experiencing an increased amount of glucocorticoids being released into the general circulation. For which physiologic response should the nurse plan care for this patient?
   1. delayed onset of puberty
   2. decreased metabolic rate
   3. inhibited immune response
   4. increased response to glucagon
4. The nurse is conducting a health history with a patient that focuses on the endocrine system. Which question should the nurse include in this assessment?
   1. "How did you get this scar on your leg?"
   2. "Have you noticed a change in your thirst?"
   3. "Do your children have problems with urination?"
   4. "When did you first notice the pain in your abdomen?"
5. The nurse is preparing to assess a patient's thyroid gland. For which criteria is the nurse assessing this gland?
   1. pain and pulse rate
   2. size and consistency
   3. character and texture
   4. edema and movement
6. The nurse notes that a patient has a low calcium level and plans to assess for Chvostek's sign. How will the nurse conduct this assessment?
   1. Depress the skin over the shin.
   2. Pinch a fold of skin over the sternum.
   3. Tap a finger in front of the patient's ear.
   4. Inflate a blood pressure cuff above the antecubital space.
7. The nurse reviews the laboratory tests prescribed for a patient. Which test will be used to determine the patient's thyroid function?
   1. GH
   2. TSH
   3. FBS
   4. aldosterone
8. The nurse is assessing the endocrine system of an older female patient. Which finding is considered an expected age-related change in this system?
   1. normal heart tones
   2. decreased facial hair
   3. thyroid nodules present
   4. pituitary enlarged and firm
9. The nurse is caring for a patient with newly diagnosed hypothyroidism. What should the nurse expect when assessing this patient's skin?
   1. rough, dry skin
   2. smooth, flushed skin
   3. increased hair growth
   4. cold and clammy skin
10. The nurse is assessing a patient's deep tendon reflexes. For which endocrine disorder is this nurse assessing?
    1. tetany
    2. acromegaly
    3. hyperthyroidism
    4. Cushing's syndrome

19 Nursing Care of Patients with Endocrine Disorders

LEARNING OUTCOMES

1. Apply knowledge of normal anatomy, physiology, and assessments of the thyroid, parathyroid, adrenal, and pituitary glands when providing nursing care for patients with endocrine disorders.
2. Compare and contrast the manifestations of disorders that result from hyperfunction and hypofunction of the thyroid, parathyroid, adrenal, and pituitary glands.
3. Explain the nursing implications for medications prescribed to treat disorders of the thyroid and adrenal glands.
4. Provide appropriate nursing care for the patient before and after a subtotal thyroidectomy and an adrenalectomy.
5. Use the nursing process as a framework for providing individualized care to patients with disorders of the thyroid, parathyroid, adrenal, and pituitary glands.

CLINICAL COMPETENCIES

1. Assess health status of patients with endocrine disorders and monitor, document, and report unexpected or abnormal manifestations.
2. Use assessed data, patient values, clinical expertise, and evidence to determine priority nursing diagnoses and select and implement nursing interventions.
3. Effectively communicate with and function within the interprofessional team to plan and provide patient care.
4. Administer medications knowledgeably and safely.
5. Plan and provide patient and family teaching to promote, restore, and maintain health status.
6. Monitor for respiratory problems and tetany in patients having a thyroidectomy.
7. Adapt individual and cultural values and variations as well as expressed needs and preferences into each patient's plan of care.
8. Evaluate responses to care and use data to revise plan as needed.

MAJOR CHAPTER CONCEPTS

- Hormones regulate growth, development, and metabolism. Homeostasis is dependent on a balanced level of each type of hormone. Not only do hormones affect organ function, but they also interact, and when excesses or deficits occur, manifestations of other endocrine disorders may result.
- Patients with endocrine disorders often experience life-altering changes that require nursing assessment, care, and follow-up with the goal of providing holistic care to the patient.
- Thyroid disorders are identified by their effects on metabolism: hyperthyroidism causes an increased metabolic rate, and hypothyroidism causes a decreased metabolic rate. Both can cause be life-threatening if ineffectively managed.
- The parathyroid glands regulate serum calcium levels. Manifestations of parathyroid disorders are primarily those related to hypercalcemia or hypocalcemia.
- Cushing's syndrome and Addison's disease, disorders of the adrenal cortex, are polar opposites. Treatment of one can create the manifestations of the other. Patients with these diseases require education to fully grasp the significance of the condition and the importance of adhering to the treatment plan.
- Disorders of the anterior pituitary may be manifested by the effects of excess growth hormone, whereas posterior pituitary disorders affect the production of antidiuretic hormone and fluid and electrolyte balance.

thyrotoxicosis, *476*

The thyroid, parathyroid, adrenal, and pituitary glands are part of the endocrine system. Disorders of the structure and function of these glands alter normal hormone levels and the way body tissues use those hormones. When hormone production increases or decreases, people experience alterations in health.

Patients with disorders of the glands discussed in this chapter require nursing care for multiple functional problems. They often face exhausting diagnostic tests, changes in physical appearance and emotional responses, and permanent alterations in lifestyle. Nursing care is directed toward meeting physiologic needs, providing education, and ensuring psychologic support for the patient and family. A holistic approach to the complex needs of patients with these endocrine disorders is an essential component of nursing care.

Disorders of the Thyroid Gland

Altered thyroid hormone (TH) production or use affects all major organ systems. In the adult, TH changes primarily affect metabolism, cardiovascular function, gastrointestinal function, and neuromuscular function. Thyroid disorders—both hyperthyroidism and hypothyroidism—are among the most common endocrine disorders.

THE PATIENT WITH HYPERTHYROIDISM

Hyperthyroidism (**thyrotoxicosis**) is a disorder caused by excessive delivery of TH to the tissues. Because the primary effect of TH is to increase metabolism and protein synthesis, hyperthyroidism affects all major organ systems of the body. The increase in metabolic rate and the alterations in cardiac output, peripheral blood flow, oxygen consumption, and body temperature are similar to those found in increased sympathetic nervous system activity (Grossman & Porth, 2014).

Pathophysiology and Manifestations

The effects of hyperthyroidism are the result of increased circulating levels of TH. This hormonal excess increases the metabolic rate and heightens the sympathetic nervous system's physiologic response to stimulation. The sensitizing effect of abnormally elevated TH levels increases the cardiac rate and stroke volume. As a result, cardiac output and peripheral blood flow increase. Elevated TH levels increase carbohydrate, protein, and lipid metabolism. Lipids are depleted, and glucose tolerance decreases. Protein degradation increases, resulting in a negative nitrogen balance. Over time, the hypermetabolic effects of excess TH result in caloric and nutritional deficiencies.

Hyperthyroidism results from many different factors, including autoimmune stimulation (as in Graves' disease), excess secretion of thyroid-stimulating hormone (TSH) by the pituitary gland, thyroiditis, neoplasms (such as toxic multinodular goiter), side effect of certain drugs, and an excessive intake of thyroid medications. The most common etiologies of hyperthyroidism are Graves' disease and toxic multinodular goiter.

The patient with hyperthyroidism typically has an increased appetite and may gain weight, although weight loss is more typical, and may have hypermotile bowels and diarrhea. Additional manifestations related to hypermetabolism include emotional liability, heat intolerance, insomnia, palpitations, and increased sweating. The skin is smooth and warm, hair may become fine, and hair loss in the scalp, eyebrow, axilla, or pubic region is common. See the Multisystem Effects of Hyperthyroidism feature on page 478.

GRAVES' DISEASE

Graves' disease, the most common cause of hyperthyroidism, is an autoimmune disorder, sometimes associated with the presence of other autoimmune disorders such as myasthenia gravis, diabetes mellitus, celiac, and pernicious anemia (McPhee et al., 2012). The serum of patients with Graves' disease has an antibody that binds to TSH receptors in the thyroid follicles and causes the thyroid cells to hyperfunction. When this antibody binds to the TSH receptors, it stimulates hormone synthesis and secretion, enlarging the gland. The cause is unknown, but there is a hereditary link. Graves' disease is seen eight times more often in women than in men and occurs most frequently between the ages of 20 and 40 (McPhee et al., 2012).

Patients with Graves' disease have an enlarged thyroid gland (**goiter**) and manifestations of hyperthyroidism. The goiter can result from excess TSH stimulation (when the amount of circulating TH is deficient), abnormal growth-stimulating immunoglobulins, or substances that inhibit TH synthesis. A goiter may be present in hyperthyroidism or hypothyroidism.

The eye pathology of Graves' disease is manifested as proptosis and visual dysfunction. **Proptosis** (forward displacement) of the eye occurs in about one-third of cases (Grossman & Porth, 2014). The forward protrusion of the eyeballs (**exophthalmos**) results from an accumulation of inflammation by-products in the retro-orbital tissues. The sclera may be visible above the iris, the upper lids may be retracted, and the person has a characteristic unblinking stare (Figure 19–1 ■). Exophthalmos is usually bilateral, but it may involve only one eye. The patient may experience blurred vision, diplopia, eye pain, lacrimation, and photophobia. The inability to close the eyelids completely over the protruding eyeballs increases the risk of corneal dryness, irritation, infection, and ulceration. Infiltration of the muscles that move the eye and of the optic nerve leads

Figure 19–1 ■ Exophthalmos in a patient with Graves' disease. The disease causes edema of fat deposits behind the eyes and inflammation of the extraocular muscles. The accumulating pressure forces the eyes outward from their orbits.
Source: Medical-on-Line/Alamy.

to paralysis and vision loss. The treatment of Graves' disease may stabilize the manifestations but generally does not reverse these changes in the eyes.

Other manifestations include fatigue, difficulty sleeping, hand tremors, and changes in menstruation ranging from decreased flow to amenorrhea. Older patients may present with atrial fibrillation, angina, or congestive heart failure.

TOXIC MULTINODULAR GOITER

Toxic multinodular goiter (Figure 19–2 ■) is a thyroid tumor characterized by small, discrete, independently functioning nodules in the thyroid gland tissue that secrete excessive amounts of TH. It is not known how these nodules grow or become independent, but a genetic mutation of follicle cells is suspected. Elevated TH levels result in manifestations of hyperthyroidism; however, they are slower to develop and there is no pathology involving the eyes or skin (Davis & Griffing, 2011). The patient with this type of hyperthyroidism is usually a woman in her 60s or 70s who has had a goiter for a number of years.

THYROIDITIS

Thyroiditis (inflammation of the thyroid gland) is most often the result of a viral infection of the thyroid gland. The manifestations of thyroiditis are those of acute inflammation and the effects of increased TH. Thyroiditis is an acute disorder that may become chronic, resulting in a hypothyroid state as repeated infections destroy gland tissue. See the discussion of Hashimoto's thyroiditis later in this chapter.

Figure 19–2 ■ Toxic multinodular goiter. The formation and growth of numerous nodules in the thyroid gland cause the characteristic massive enlargement of the neck.

THYROID CRISIS

Thyroid crisis (thyroid storm) is an extreme state of hyperthyroidism that is rare today because of improved diagnosis and treatment methods (Grossman & Porth, 2014). When it does occur, those affected are usually people with untreated hyperthyroidism (most often Graves' disease) and people with hyperthyroidism who have experienced a stressor, such as an infection, trauma, untreated diabetic ketoacidosis, or manipulation of the thyroid gland during surgery. Thyroid crisis is a life-threatening condition.

The rapid increase in metabolic rate that results from the excessive TH causes the manifestations of thyroid crisis. The manifestations include hyperthermia, with body temperatures ranging from 39° to 41°C (102° to 106°F), tachycardia, systolic hypertension, dyspnea, and GI manifestations (abdominal pain, vomiting, diarrhea). Agitation, restlessness, and tremors are common, progressing to confusion, psychosis, delirium, and seizures. Unrecognized and untreated, the mortality rate is high. Rapid treatment of thyroid storm is essential to preserve life. Treatment includes cooling without aspirin (which increases free TH) and prevention of shivering (which may further increase the temperature); replacing fluids, glucose, and electrolytes; relieving respiratory distress by administering oxygen; stabilizing cardiovascular function; and reducing TH synthesis and secretion.

MEMORY CUE

Excessive hormone amplifies manifestations of normal levels of the hormone.

●○● INTERPROFESSIONAL CARE

Treatment of hyperthyroidism focuses on reducing the production of TH by the thyroid gland, thus establishing a **euthyroid** (normal thyroid) state, and preventing or treating complications. Depending on the patient's age and physical status, either medications, radioactive iodine therapy, or surgery may be used.

DIAGNOSIS

Hyperthyroidism is diagnosed according to the manifestations of the specific disorders causing excessive TH and by the diagnostic test results described in Chapter 18. Elevated levels of TH (both T_3 and T_4) and increased radioactive iodine (RAI) uptake are diagnostic criteria of hyperthyroidism. In addition, a TSH level may be measured and compared with thyroxine (T_4) to differentiate pituitary dysfunction from thyroid dysfunction. Other diagnostic tests include thyroid antibodies (TA), TSH, triiodothyronine (T_3), T_4, and triiodothyronine resin uptake (T_3RU). Laboratory findings in hyperthyroidism are outlined in Table 19–1. A thyroid scan may be used to evaluate thyroid nodules and an MRI of the thyroid is used to identify thyroid tumors.

MEDICATIONS

Hyperthyroidism is treated by administering antithyroid medications that reduce TH production. Because these drugs do not affect

MULTISYSTEM EFFECTS OF Hyperthyroidism

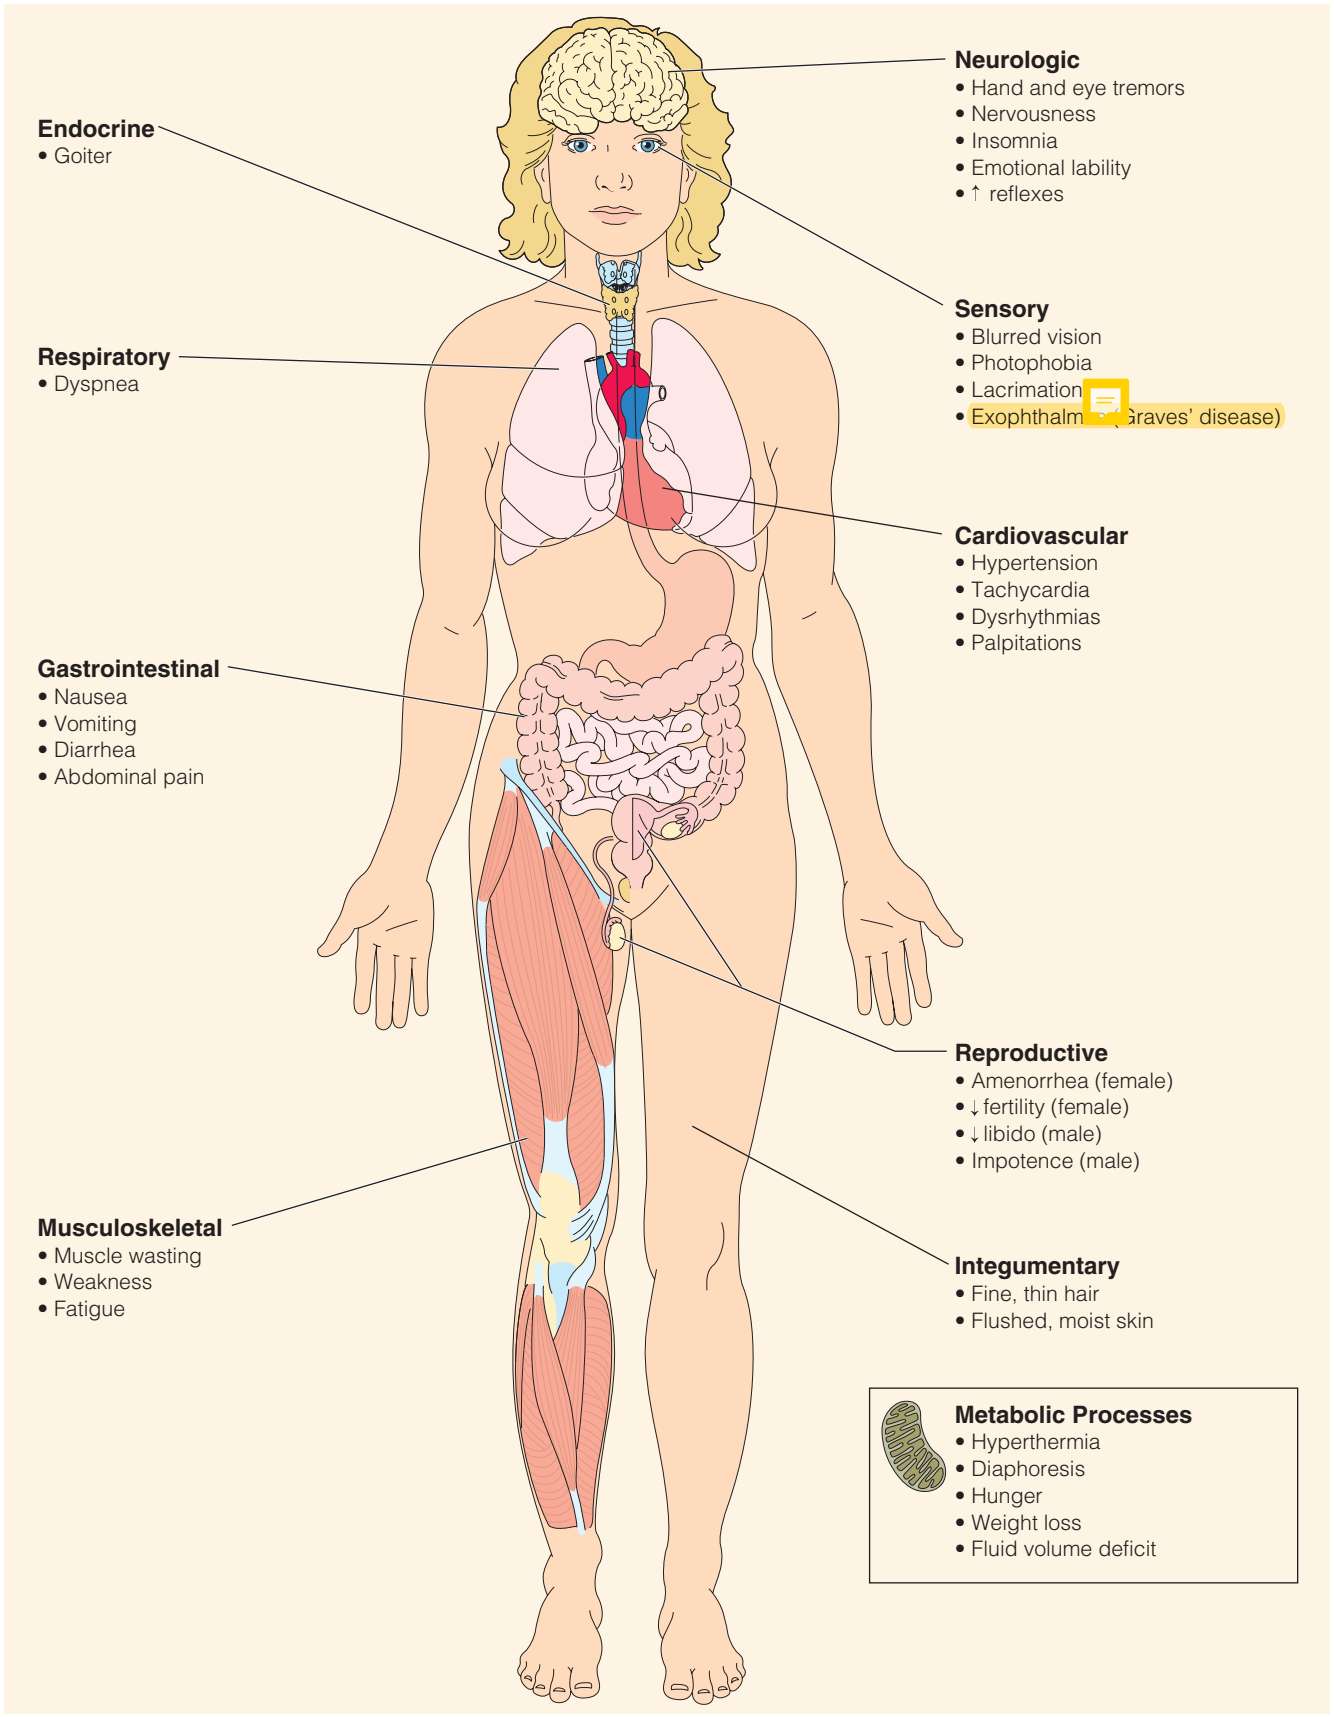

TABLE 19–1 Laboratory Findings in Thyroid Disorders

Test	Normal Values	Hyperthyroidism	Hypothyroidism
Serum TA	Negative to 1:20	Increased	Normal
Serum TSH	<3 ng/mL	Decreased in primary hyperthyroidism	Increased in primary hypothyroidism
Serum T_4	5–12 mcg/dL	Increased	Decreased
Serum T_3	80–200 ng/dL	Increased	Decreased
T_3 uptake (T_3RU)	25–35 relative percentage	Increased	Decreased
Thyroid suppression		Increased RAI uptake and T_4 levels	No change

the release or activity of hormone that is already formed, therapeutic effects may not be seen for several weeks. To rapidly decrease the cardiovascular manifestations associated with hyperthyroidism, propranolol (Inderal), a beta-blocker, or esmolol, a rapid-acting parenteral beta-blocker, is part of initial treatment. Some commonly prescribed drugs, their actions, and nursing implications are shown in the Medication Administration box below.

RADIOACTIVE IODINE THERAPY

Because the thyroid gland takes up iodine in any form, radioactive iodine (^{131}I) concentrates in the thyroid gland and damages or destroys thyroid cells so that they produce less TH. Radioactive iodine is given orally. Results are typically seen in 6 to 8 weeks. In most instances, the patient is not hospitalized during treatment and does not require radiation precautions. This type of therapy is contraindicated in pregnant women because radioactive iodine crosses the placenta and can have negative effects on the developing fetal thyroid gland. Because the amount of gland destroyed is not readily controllable, the patient may develop hypothyroidism and require lifelong TH replacement. Adverse reactions include thyroiditis and cardiac instability due to liberation of stored thyroid hormone in the gland (Davis & Griffing, 2011).

SURGERY

Some hyperthyroid patients have such enlarged thyroid glands that pressure on the esophagus or trachea causes breathing or swallowing problems. In these cases, removal of all or part of the gland (**thyroidectomy**) is indicated. A subtotal thyroidectomy is usually performed. This procedure leaves enough of the gland in place to produce an adequate amount of TH. A total thyroidectomy is performed to treat cancer of the thyroid; the patient then requires lifelong hormone replacement (McPhee et al., 2012).

Before surgery, the patient should be in as nearly a euthyroid state as possible. The patient may be given antithyroid drugs to reduce

MEDICATION ADMINISTRATION

Hyperthyroidism

IODINE SOURCES

strong iodine solution (Lugol's solution)

potassium iodide (SSKI, Thyro-Block, Pima)

Large doses of iodine for a short term inhibit TH synthesis and release. Iodine makes the hyperplastic thyroid less vascular prior to surgery and hastens the ability of other antithyroid drugs to reduce natural hormone output. It is also used in thyroid storm.

Nursing Responsibilities

- Assess for hypersensitivity to iodine before giving medication; for example, ask patient about allergies to shellfish.
- Dilute liquid iodine sources in water or orange juice to disguise bitter taste.
- Monitor for increased bleeding tendencies if the patient is also taking anticoagulants because iodine increases their effect.

Health Education for the Patient and Family

- The maximum effect of iodine in large doses usually occurs in 10 to 15 days.
- Long-term iodine therapy is not effective in controlling hyperthyroidism.

ANTITHYROID DRUGS

methimazole (Tapazole)

carbimazole (converted to methimazole when absorbed)

propylthiouracil (PTU, Propyl-Thyracil)

Antithyroid drugs inhibit TH production. They do not affect already formed hormones; thus, several weeks may elapse before the patient experiences therapeutic effects. Methimazole crosses the placenta and is not recommended during pregnancy (Wilson et al., 2013).

Nursing Responsibilities

- Monitor for side effects: agranulocytosis (reduction in neutrophils, eosinophils, or basophils), hypothyroidism, pruritus, rash, elevated temperature, anorexia, loss of taste, hair loss, changes in menstruation.
- Administer drugs at the same time each day with meals to maintain stable blood levels.
- Monitor for manifestations of hypothyroidism: fatigue, weight gain, periorbital edema,.

Health Education for the Patient and Family

- Watch for unusual bleeding, redness, swelling, nausea, loss of taste, or epigastric pain. Report any such manifestations to the physician.
- Propylthiouracil is associated with weight changes; check weight daily when starting this medication to determine effect. Report significant changes to physician.
- If you are also taking warfarin, report any signs of bleeding.
- If you are taking lithium, be aware of manifestations of hypothyroidism.
- It may take up to 12 weeks before you experience the full effects of the drugs. Take the medication regularly and exactly as prescribed. Do not discontinue abruptly.

hormone levels and iodine preparations to decrease the vascularity and size of the gland (which also reduces the risk of hemorrhage during and after surgery). Nursing care of the patient having a subtotal thyroidectomy is discussed in the box on page 481.

●○● NURSING CARE

Health Promotion

Although hyperthyroidism is not preventable, it is important to teach patients the importance of regular healthcare provider visits and medication intake.

Assessment

The following data are collected through the health history and physical examination. Further focused assessments are described with nursing interventions.

- *Health history:* other diseases, family history of thyroid disease, when manifestations began, severity of manifestations, intake of thyroid medications, menstrual history, changes in weight, bowel elimination.
- *Physical assessment:* muscle strength, tremors, vital signs, cardiovascular and peripheral vascular systems, integument, size of thyroid, presence of bruit over thyroid, eyes and vision.

Priorities of Care

In planning and implementing nursing care for the patient with hyperthyroidism, the nurse considers the patient's responses to the systemic effects of the disorder. Although each patient may have different needs, nursing diagnoses discussed in the next section focus on the most common health problems: cardiovascular problems, visual deficits, altered nutrition, and disturbed body image. See the accompanying Case Study & Nursing Care Plan on page 482.

Diagnoses, Outcomes, and Interventions

Risk for Decreased Cardiac Output

The patient with hyperthyroidism is at risk for alterations in cardiac output. Excess TH directly affects the heart, resulting in increased rate and stroke volume. Increases in the metabolic demands and oxygen requirements of peripheral tissues increase the demands on the heart, and systolic hypertension, angina, dysrhythmias, or heart failure may occur. The patient often has palpitations and shortness of breath and is easily fatigued. The risk of complications is greater in patients with preexisting cardiovascular disorders.

Expected Outcome: Normal heart rate, blood pressure and pulse quality, and normal respiratory rate will be restored with treatment. Patient will experience no episodes of palpitations, fatigue with activity, and angina.

- Monitor blood pressure, pulse rate and rhythm, respiratory rate, and breath sounds. Assess for peripheral edema, jugular vein distention, and increased activity intolerance. *Increased TH increases cardiac rate, stroke volume, and tissue demand for oxygen, causing stress on the heart. This may result in hypertension, arrhythmias, tachycardia, and congestive heart failure.*
- Suggest keeping the environment as cool and free of distraction as possible. Decrease stress by explaining interventions and teaching relaxation procedures. *A physically comfortable and psychologically calm environment can reduce stimuli and stressors. Stress increases circulating catecholamines, which further increase cardiac workload.*
- Encourage a balance of activity with rest periods. *Rest periods decrease energy expenditure and tissue requirements for oxygen, decreasing cardiac workload.*

Evidence for Nursing Care

The Patient with Thyroid Disorders (Hypo, Hyper, or Both)

A resource that nurses may find helpful when planning evidence-based nursing care follows.

- National Endocrine and Metabolic Disease Information Service. (2012). *Hyperthyroidism*. Retrieved from http://www.endocrine.niddk.nih.gov/pubs/hyperthyroidism/index.aspx

Impaired Vision

Visual changes that occur in patients with hyperthyroidism include difficulty focusing, diplopia (double vision), or visual loss. If the patient is unable to close the eyelids because of exophthalmos, the risk of corneal dryness with resultant infection or injury increases. Visual deficits may result from pressure on the optic nerve from retroorbital edema. Although treatment of hyperthyroidism may stop the progression of eye changes, not all manifestations are reversible.

Expected Outcome: Patient should experience no worsening of visual acuity and the eyes will be moist at all times.

- Monitor visual acuity, photophobia (excessive sensitivity to light), integrity of the cornea, and lid closure. *The cornea is at risk for dryness, injury, conjunctivitis, and corneal infections. Injury and infection of the cornea can result in further loss of visual acuity.*
- Teach measures for protecting the eye from injury and maintaining visual acuity:
  - Use tinted glasses or shields as protection.
  - Use artificial tears to moisten the eyes.
  - Use cool, moist compresses to relieve irritation.
  - Promptly report any pain or changes in vision.

  The measures outlined decrease the risk of injury, provide comfort, decrease periorbital edema that can further compromise vision, and ensure immediate care for problems, thereby minimizing the risk of further visual loss.

SAFETY ALERT

Teach the patient to cover the eyes at night if they do not close, and to sleep with the head of the bed elevated 45 degrees (to decrease periorbital fluid accumulation).

Imbalanced Nutrition: Less Than Body Requirements

The hypermetabolic state that occurs in hyperthyroidism causes gastrointestinal hypermotility, with nausea, vomiting, diarrhea, and abdominal pain. Although the patient may have an increased appetite and eat more than usual, weight loss continues.

Expected Outcome: Patient's weight is appropriate for height and stable. Patient is free of nausea, vomiting, diarrhea, and abdominal pain.

- Ask the patient to weigh daily (at the same time each day) and keep a record of results. *The inability to meet metabolic demands results in loss of body weight.*
- In collaboration with a dietitian, teach the patient the need for a diet high in carbohydrates and protein and including between-meal snacks. Six small meals a day may be more desirable than three large meals. Caloric intake may need to be increased to 4000 kcal/day if weight loss exceeds 10% to 17% for height and frame. *Increased nutrients as part of a well-balanced diet are necessary to meet metabolic demands. Patients are often better able to increase food intake by eating frequent, small meals. A 1-lb weight gain requires approximately 3500 extra kilocalories.*
- Monitor nutritional status through results of laboratory data. Serum albumin, transferrin, and total lymphocyte counts are commonly lower than normal in nutritional deficits. *A negative nitrogen balance signifies a catabolic state in which protein is lost and metabolic demands are not being met.*

Disturbed Body Image and Anxiety

Physical changes common in hyperthyroidism include exophthalmos, goiter, tremors, hair loss, increased perspiration, loss of strength, fatigue, weight loss, and changes in reproductive and sexual function (amenorrhea in women and impotence in men). In addition, the patient often has mood changes and insomnia and is constantly nervous and anxious. There may even be periods of psychosis. These changes are frightening not only for the patient but also for family members.

Expected Outcome: Patient's body image is improved with resolution of symptoms of hyperthyroidism, decreased mood alterations, and normal sleep patterns.

- Establish a trusting relationship; encourage the patient to verbalize feelings about self and to ask questions about the illness and treatment. Provide reliable information and clarify misconceptions. *Establishing trust facilitates open sharing of feelings and perceptions.*

Delegating Nursing Care Activities

The professional nurse may delegate nursing care activities such as repositioning and activity, providing hygiene, and assisting with feeding and dietary needs. The registered nurse assesses the patient on admission (or transfer of care), preoperatively, postoperatively, and upon discharge. The nurse provides teaching and develops the plan of care, coordinates the healthcare team, and evaluates the results of

NURSING CARE OF THE PATIENT

Having a Subtotal Thyroidectomy

PREOPERATIVE CARE

- Administer ordered antithyroid medications and iodine preparations, and monitor their effects. *Antithyroid drugs are given before surgery to promote a euthyroid state. Iodine preparations are given to the patient before surgery to decrease vascularity of the gland, thereby decreasing the risk of hemorrhage.*
- Teach the patient to support the neck by placing both hands behind the neck when sitting up in bed, while moving about, and while coughing. *Placing the hands behind the neck eases tension on the suture line in the front of the neck.*
- Answer questions, and allow time for the patient to verbalize concerns. *Because the incision is made at the base of the throat, patients (especially women) are often concerned about their appearance after surgery. Explain that the scar will eventually be only a thin line and that jewelry or scarves may be used to cover the scar.*
- Teach the patient to expect hoarseness due to generalized swelling at the suture line. *This is expected to diminish with healing and is not caused by laryngeal nerve damage.*

POSTOPERATIVE CARE

- Provide comfort measures: Administer analgesic pain medications as ordered, and monitor their effectiveness; place the patient in a semi-Fowler's position after recovery from anesthesia; support head and neck with pillows. *Analgesic medications reduce the perception of pain and reduce physical stress during the postoperative period. Positioning the patient in a semi-Fowler's position and supporting the head and neck decrease strain on the suture line.*
- Perform focused assessments to monitor for complications:
  a. *Hemorrhage:* Assess dressing (if present) and the area behind and under the patient's neck and shoulders for drainage. Monitor blood pressure and pulse for manifestations of hypovolemic shock. Assess tightness of dressing (if present). *The vascularity of the gland increases the risk of hemorrhage. The location of the incision and the position of the patient may cause the drainage to run back and under the patient. The danger of hemorrhage is greatest in the first 12 to 24 hours after surgery.*
  b. *Respiratory distress:* Assess respiratory rate, rhythm, depth, and effort. Maintain humidification as ordered. Assist the patient with coughing and deep breathing. Have suction equipment, oxygen, and a tracheostomy set available for immediate use. *Respiratory distress may result from hemorrhage and edema, which may compress the trachea; from tetany and laryngeal spasms resulting from decreased hormones due to removal or damage to the parathyroid glands; and from damage to the laryngeal nerve, causing spasms of the vocal cords. Stridor is heard in acute obstructions. This is a high-pitched, squeaky sound and is a sign of airway obstruction. Equipment must be immediately available if the patient experiences respiratory distress that requires interventions and treatment.*
  c. *Laryngeal nerve damage:* Assess for the ability to speak aloud, noting quality and tone of voice. *The location of the laryngeal nerve increases the risk of damage during thyroid surgery. Although hoarseness may be due to edema or use of an endotracheal tube during surgery and will subside, permanent hoarseness or loss of vocal volume is a potential danger.*
  d. *Tetany:* Assess for manifestations of latent tetany due to calcium deficiency, including tingling of toes, fingers, and lips; muscular twitches; positive Chvostek's and Trousseau's signs; and decreased serum calcium levels. Serum calcium levels will be monitored in the postoperative period. Keep calcium gluconate or calcium chloride available for immediate IV use, if necessary. *The parathyroid glands are located in and near the thyroid gland; surgery of the thyroid gland may injure or remove parathyroid glands, resulting in hypocalcemia and tetany. Tetany may occur in 1 to 7 days after thyroidectomy.*

CASE STUDY & NURSING CARE PLAN A Patient with Graves' Disease

Mrs. Juanita Manuel is a 33-year-old mother of four small children. She is a second-year student at the local community college, within one semester of completing the requirements for an associate's degree in early childhood education. For the past 3 months, Mrs. Manuel has been constantly hungry and has eaten more than usual, but she has still lost 6.8 kg (15 lb). She has repeated bouts of diarrhea and often feels nauseated. Her hands shake, she can feel her heart beating rapidly, and she finds herself laughing or crying for no apparent reason.

Mrs. Manuel makes an appointment with her family physician. The nurse at the office completes a health history and physical assessment. When asked how she has been feeling, Mrs. Manuel replies, "I don't know what's wrong with me—but I keep losing weight and I cry at the drop of a hat. I am so hot all the time, and I've never had that problem before."

ASSESSMENT

The health history indicates that although her appetite has increased, Mrs. Manuel has lost 6.8 kg (15 lb). She states that she has had diarrhea, nausea, palpitations, heat intolerance, and mood changes. Physical assessment findings include the following: T 38.3°C (101°F), P 110 bpm, R 24/min, and BP 162/86 mmHg. Her skin is moist and warm, her hair thin and fine. She has visible tremors in her hands. Her eyeballs protrude, and she is unable to close her eyelids completely. Her thyroid is enlarged and palpable. Diagnostic tests reveal the following abnormal results: T_3, 350 g/dL (normal range: 80 to 200 ng/dL), T_4, 15.1 mg/dL (normal range: 5 to 12 mg/dL). A thyroid scan demonstrates an enlarged thyroid with increased iodine uptake. After the medical diagnosis of Graves' disease is made, Mrs. Manuel is started on the antithyroid medication propylthiouracil, 150 mg orally every 8 hours.

DIAGNOSES

- *Risk for Imbalanced Nutrition: Less Than Body Requirements* related to weight loss of 6.8 kg (15 lb), with present weight 10% less than normal for height
- *Diarrhea* related to increased peristalsis as evidenced by 8 to 10 liquid stools per day
- *Risk for Impaired Vision* related to an inability to close the eyelids completely
- *Anxiety* related to a lack of knowledge about disease process

EXPECTED OUTCOMES

- Patient will gain at least 0.45 kg (1 lb) every 2 weeks.
- Patient will regain normal bowel elimination patterns.
- Patient will maintain normal vision (with no evidence of corneal damage) and verbalize measures to protect her eyes.
- Patient will verbalize medical treatment and self-care needs.
- Patient will verbalize a decrease in anxiety.

PLANNING AND IMPLEMENTATION

- Request that she keep a record of daily weight.
- Discuss adopting a high-kilocalorie diet. Identify food likes and dislikes, as well as foods that increase diarrhea, before instituting a plan to increase food intake.
- Request that she keep a stool chart, noting the time, type, and precipitating factors for diarrhea stools. Teach comfort measures for irritated anal area (clean washcloth and soap, nonirritating ointment).
- Teach how to apply eyedrops (artificial tears).
- Explain the need to elevate the head of the bed to 45 degrees at night, and tape eye shields over eyes before sleep.
- Teach about Graves' disease, the medication's effects and side effects, and the need for continued medical care.

EVALUATION

By her next office visit, Mrs. Manuel has gained 0.45 kg (1 lb) and has discussed her dietary needs with the nurse and her husband. She is having diarrhea less often. She has safely applied the eyedrops and states that she uses the eye shields and elevates the head of her bed at night. The office nurse reviewed the written and verbal information about Graves' disease and the medication prescribed. Mrs. Manuel verbalizes her understanding, stating, "I'll always take my medicine—I never want to feel like that again!" She says that she feels much less anxious now that she understands what has happened.

Clinical Reasoning in Patient Care

1. What is the pathophysiologic basis for Mrs. Manuel's abnormal vital signs?
2. What is the rationale for having the patient with exophthalmos elevate the head of the bed at night?
3. Outline a teaching plan that could be given to patients for home care following a subtotal thyroidectomy.

See Evaluating Your Response in Appendix B.

care provided. The nurse should be aware of individual state laws regarding delegation published in state board of nursing rules prior to delegating specific tasks.

Continuity of Care

Patients with hyperthyroidism primarily provide self-care at home. Teaching is individualized to meet the patient's needs. Address the following topics:

- The patient taking oral medications must understand the need for lifelong treatment.
- The patient who has a thyroidectomy requires information about postoperative wound care.
- The patient having radioactive iodine therapy needs to know the manifestations of hypothyroidism.
- Depending on the age of the patient and the support systems available, referral to community healthcare agencies may be necessary.
- In addition, suggest the following resources: American Thyroid Association, Thyroid Foundation of Canada, and Endocrine Society.

THE PATIENT WITH HYPOTHYROIDISM

Hypothyroidism is a disorder that results when the thyroid gland produces an insufficient amount of TH. Because a decrease in TH levels decreases metabolic rate and heat production, hypothyroidism affects all body systems. Hypothyroidism is common in women between ages 30 and 60, with the incidence increasing after age 50. However, the disorder can occur at any stage of life. Careful evaluation of manifestations is important in the older adult because manifestations of hypothyroidism are often thought to be the result of aging instead of a pathologic process. The chronic, untreated hypothyroid state in adults is termed **myxedema**, with characteristic accumulation of nonpitting edema in the connective tissues throughout the body. The edema is the result of water retention in mucoprotein (hydrophilic proteoglycans) deposits in the interstitial spaces. The face of a patient with myxedema appears puffy, the tongue is enlarged, and the voice is hoarse and husky (Grossman & Porth, 2014).

Pathophysiology and Manifestations

Hypothyroidism may be either primary or secondary. Primary hypothyroidism (which is more common) may be caused by congenital defects in the gland, loss of thyroid tissue following treatment for hyperthyroidism with surgery or radiation, antithyroid medications, Hashimoto's thyroiditis, or endemic iodine deficiency. The cardiac drug amiodarone (Cordarone), which contains iodine, is increasingly being implicated in causing thyroid problems, especially hypothyroidism (Grossman & Porth, 2014). Anabolic steroids, androgens, lithium, phenytoin, propranolol, interferon alpha, and interleukin-2 decrease T_4. The antithyroid drugs propylthiouracil and methimazole decrease T_4 level. Secondary hypothyroidism may result from pituitary TSH deficiency or peripheral resistance to thyroid hormones (McPhee et al., 2012). Hypothyroidism has a slow onset, with manifestations occurring over months or even years. With treatment, the mental and physical manifestations rapidly reverse in patients of all ages.

When TH production decreases, the thyroid gland enlarges in a compensatory attempt to produce more hormone. The goiter that results is usually a simple or nontoxic form. People living in certain areas of the world where the soil is deficient in iodine, the substance necessary for TH synthesis and secretion, are more prone to become hypothyroid and develop simple goiter.

Patients with hypothyroidism characteristically have a goiter, fluid retention and edema, decreased appetite, weight gain, constipation, dry skin, dyspnea, pallor, hoarseness, and muscle stiffness. Many patients have a decreased sense of taste and smell, menstrual disorders, anemias, and cardiac enlargement. The pulse is typically slow. Deficient amounts of TH cause abnormalities in lipid metabolism, with elevated serum cholesterol and triglyceride levels. As a result, the patient is at increased risk for atherosclerosis and cardiac disorders. Decreased renal blood flow and glomerular filtration rate reduce the kidney's ability to excrete water, which may cause hyponatremia. Sleep apnea is more common in patients with hypothyroidism. The Multisystem Effects of Hypothyroidism are illustrated on page 484.

IODINE DEFICIENCY

Iodine is necessary for TH synthesis and secretion. Iodine deficiency may result from certain goitrogenic drugs (which block TH synthesis); lithium carbonate, used to treat bipolar mental disorders; and antithyroid drugs. Goitrogenic compounds in foods such as turnips, rutabagas, and soybeans may also block TH synthesis if consumed in sufficient quantities. In areas of the world where the soil is deficient in iodine, dietary intake of iodine may be inadequate. The use of iodized salt has reduced this risk in the United States.

HASHIMOTO'S THYROIDITIS

Hashimoto's thyroiditis is the most common cause of goiter and primary hypothyroidism. In this autoimmune disorder, antibodies develop that destroy thyroid tissue. Functional thyroid tissue is replaced with fibrous tissue, and TH levels decrease. In addition, decreasing levels of TH in the early stages of the disease prompt the gland to enlarge to compensate, causing a goiter. However, as the disease progresses, the thyroid gland becomes smaller. This disorder is more common in women and has a familial link.

MYXEDEMA COMA

Myxedema coma is a life-threatening complication of long-standing, untreated hypothyroidism. It is characterized by severe metabolic disorders (hyponatremia, hypoglycemia, lactic acidosis), hypothermia, cardiovascular collapse, impaired cognition, and coma. These patients are extremely sensitive to opioids and may die from normal doses. Myxedema coma usually occurs in the elderly and may be precipitated by the use of central nervous system depressants, pneumonia, heart failure, gastrointestinal bleeding, stroke, or other factors that impair respirations (Jameson & Weetman, 2012). The treatment of myxedema coma addresses the precipitating factors and manifestations and involves maintaining a patent airway; maintaining fluid, electrolyte, and acid–base balance; maintaining cardiovascular status; increasing body temperature; and increasing TH levels. Even with intensive treatment, the mortality rate is high (Jameson & Weetman, 2012).

●○● INTERPROFESSIONAL CARE

The treatment of the patient with hypothyroidism focuses on diagnosis, prevention or treatment of complications, and replacement of the deficient TH. With early and continued treatment, both appearance and mental function return to normal.

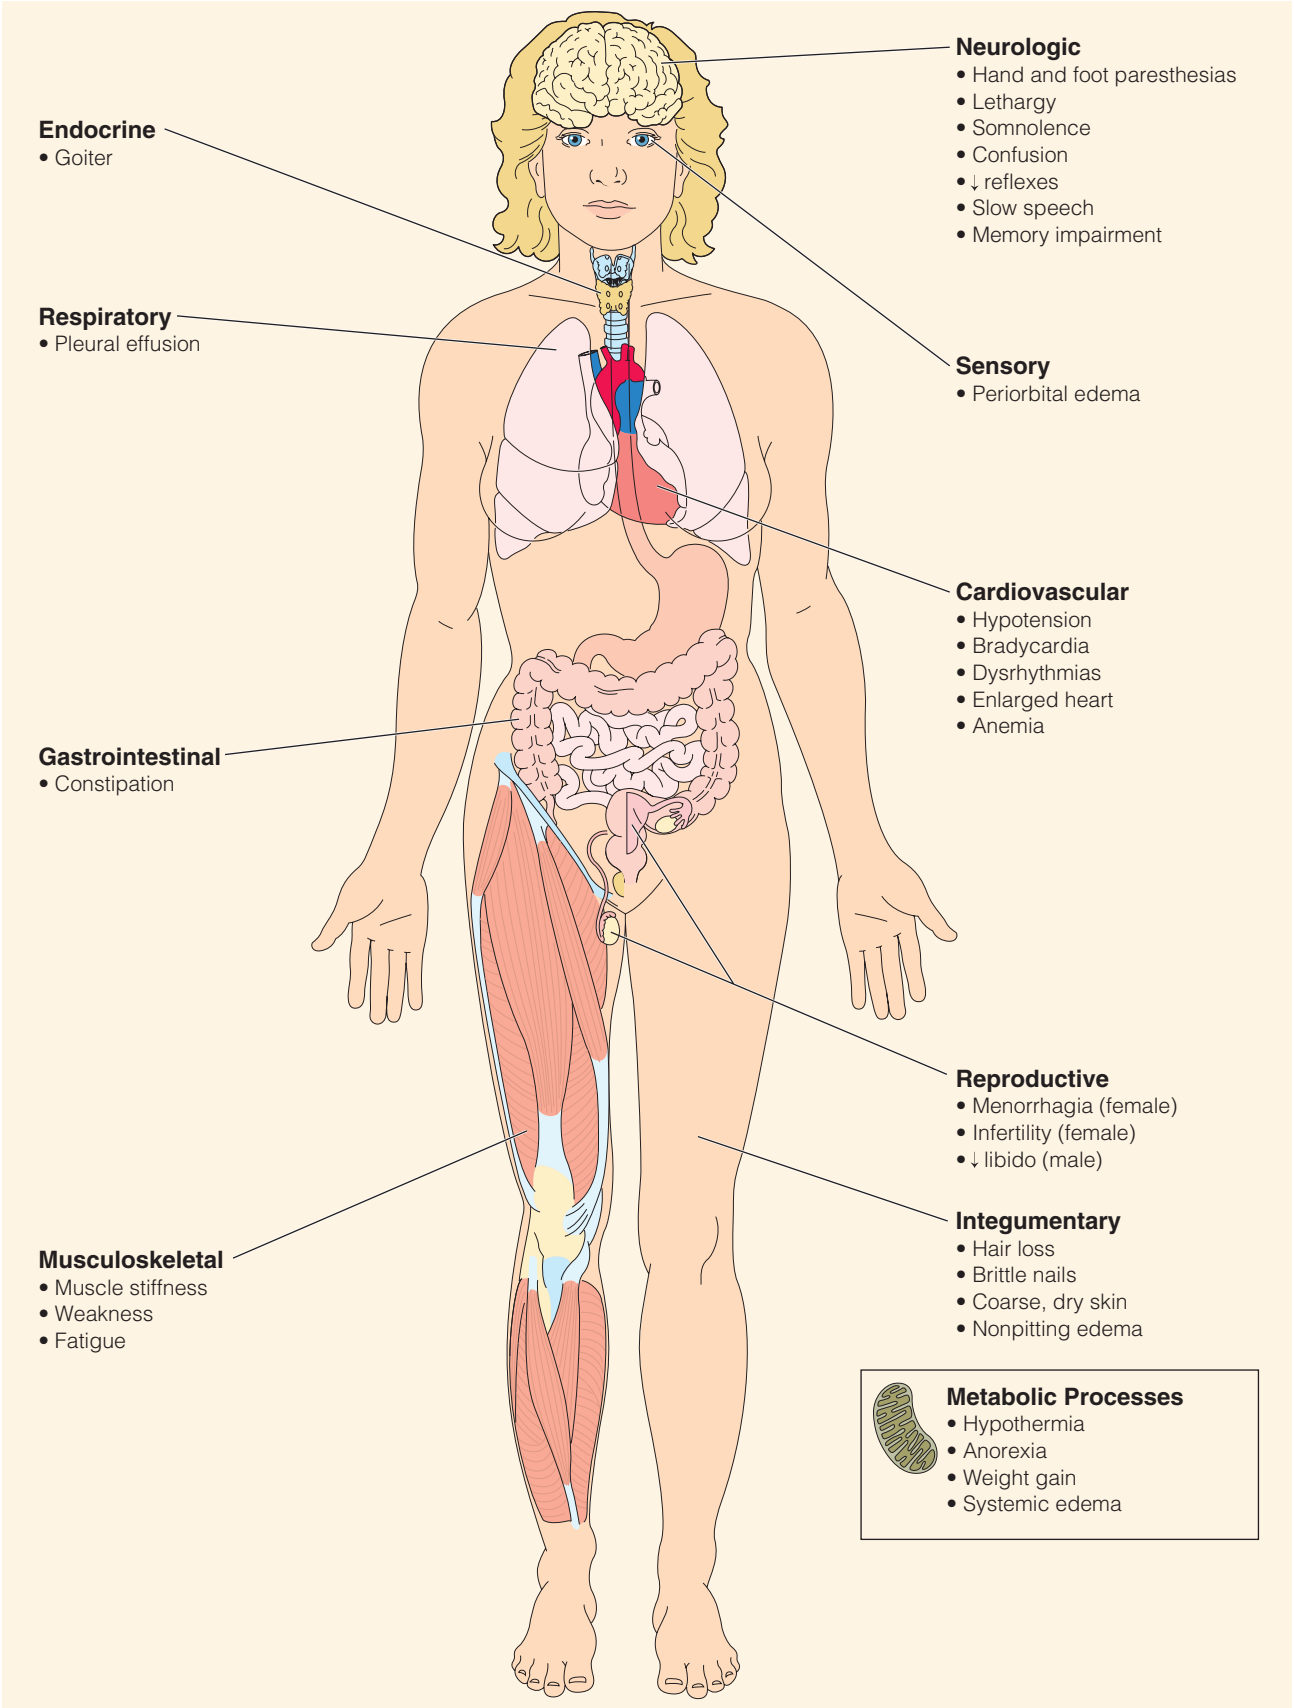
DIAGNOSIS

Hypothyroidism is diagnosed by the clinical manifestations and by a decrease in TH, especially T_4. TSH concentration often is increased because the negative hormonal feedback from TH is lost. The same laboratory and diagnostic tests used to diagnose hyperthyroidism are also used to diagnose hypothyroidism, with opposite results in most cases (refer to Table 19–1). Refer to Chapter 18 for information on specific thyroid tests. Other laboratory tests associated with the diagnosis of hypothyroidism include elevated serum LDL cholesterol, triglycerides, and lipoproteins. Anemia, hypoglycemia, and hyponatremia are also common.

MEDICATIONS

Hypothyroidism is treated with medications that replace TH. *Levothyroxine* (thyroxine, T_4) is the treatment of choice. Medications commonly used to treat hypothyroidism and their nursing implications are shown in the Medication Administration box on page 485. In the older adult, an age-related decrease in serum albumin and renal excretion can increase the amount of available drug and cause an exaggerated pharmacologic effect. Therefore, the older patient may require less thyroid medication than a younger patient.

SURGERY



If a patient with hypothyroidism has a goiter large enough to cause respiratory difficulties or dysphagia, a subtotal thyroidectomy may be performed.

●○● NURSING CARE

Health Promotion

One of the most critical factors in preventing hypothyroidism is education of the public about the necessity of an adequate dietary intake of iodine. The use of iodized salt meets the requirements for hormone production. It is important to teach patients the importance of regular healthcare provider visits and medication intake.

MULTISYSTEM EFFECTS OF Hypothyroidism

MEDICATION ADMINISTRATION

Hypothyroidism

THYROID PREPARATIONS

levothyroxine sodium (T_4) (Levoxyl, Levothroid, Synthroid)

liothyronine sodium (T_3) (Cytomel)

liotrix (T_3–T_4) (Euthyroid, Thyrolar)

Thyroid preparations increase blood levels of TH, thus raising the patient's metabolic rate. As a result, cardiac output, oxygen consumption, and body temperature increase. Levothyroxine speeds the elimination of vitamin K–dependent clotting factors, enhancing the effects of warfarin (Coumadin). Patients are at increased risk of bleeding if warfarin dosages are not appropriately reduced. The dosage depends on the drug chosen and the patient's degree of thyroid dysfunction, sensitivity to TH, age, body size, and health. The older adult may require lower doses.

Nursing Responsibilities

- Give 1 hour before meals or 2 hours after meals for best absorption.
- Thyroid preparations potentiate the effect of anticoagulant drugs. If the patient is also receiving an anticoagulant, monitor for bruising, bleeding gums, and blood in the urine.
- Thyroid medications potentiate the effect of digitalis. If the patient is also receiving a digitalis preparation, monitor for signs of digitalis toxicity.
- Monitor for manifestations of coronary insufficiency: chest pain, dyspnea, tachycardia.
- If the patient has insulin-dependent diabetes, monitor the effects of insulin. The effect of the insulin may change as thyroid function increases.
- During dose adjustment, take pulse before administering drug. Report pulse > 100 bpm.

Health Education for the Patient and Family

- Do not substitute brands of drugs or use generic equivalents without the physician's approval.
- The medications must be taken for the rest of your life.
- Report manifestations of excess thyroid hormone to the physician: excess weight loss, palpitations, leg cramps, nervousness, or insomnia.
- If you have diabetes and use insulin, monitor blood glucose levels closely; the thyroid medications may alter the amount of insulin required.
- Thyroid preparations increase the risk of iodine toxicity. Do not use iodized salt or over-the-counter drugs containing iodine.
- If you are also taking an anticoagulant, report any signs of bleeding.
- Report any changes in menstrual periods.
- Take the thyroid preparation in the morning 30 minutes before eating to decrease the possibility of insomnia; take other medications such as calcium carbonate, iron, or antacids at least 4 hours before or after taking thyroid drugs; these medications may prevent absorption.
- Closely monitor blood pressure and pulse (older patients).
- Avoid excessive intake of foods that are known to inhibit TH utilization such as walnuts and high-fiber foods.

Note: Medications identified in *italics* are among the 200 most frequently prescribed drugs in the US.

Assessment

Collect the following data through the health history and physical examination. Further focused assessments are described with nursing interventions that follow. When assessing the older patient, be aware of normal changes with aging, as described in Chapter 18.

- *Health history:* pituitary diseases, history of hyperthyroidism and treatment with medications or radioactive iodine, thyroid surgery, treatment of head or neck cancer with radiation, diet, use of iodized salt, bowel elimination, depression, muscle or joint aching, cold intolerance, respiratory difficulties, heavy menstrual periods.
- *Physical assessment:* muscle strength, deep tendon reflexes, vital signs, cardiovascular and peripheral vascular systems, integument, thyroid gland, weight.

Priorities of Care

In planning and implementing care for patients with hypothyroidism, the nurse takes into account that the disorder affects all organ systems. Although many nursing diagnoses might be valid, the next section focuses on patient problems with cardiovascular function, elimination, and skin integrity. See the accompanying Case Study & Nursing Care Plan on page 486.

Diagnoses, Outcomes, and Interventions

Decreased Cardiac Output

A TH deficit causes a reduction in heart rate and stroke volume, resulting in decreased cardiac output. There may also be an accumulation of fluid in the pericardial sac (from the edema characteristic of hypothyroidism), and coronary artery disease may be present, further compromising cardiac function.

Expected Outcome: Patient's blood pressure, rate and rhythm of apical and peripheral pulses, respiratory rate and breath sounds, and temperature will be within normal ranges. Patient's extremities will be warm.

- Monitor blood pressure, rate and rhythm of apical and peripheral pulses, respiratory rate, and breath sounds. *Hypotension indicates decreasing peripheral blood flow. Fluid in the pericardial sac restricts cardiac function. Monopolysaccharide deposits in the respiratory system decrease vital capacity and hypoventilation.*
- Suggest the patient avoid chilling; increase room temperature, use additional bed covers, and avoid drafts. *Chilling increases metabolic rate and puts increased stress on the heart.*
- Explain the need to alternate activity with rest periods. Ask the patient to report any breathing difficulties, chest pain, heart palpitations, or dizziness. *Activity increases demands on the heart and should be balanced with rest. Manifestations of cardiac stress include dyspnea, chest pain, palpitations, and dizziness.*

Constipation

The hypothyroid patient is likely to have a reduced appetite and decreased food intake, a diminished activity level because of muscle aches and weakness, and reduced peristalsis to the point that fecal impactions may occur.

Expected Outcome: Patient's bowel sounds will be normal and usual bowel habits will be restored.

- Encourage a fluid intake of up to 2000 mL/day. Discuss preferred liquids and the best times of day to drink fluids. If kilocalorie

CASE STUDY & NURSING CARE PLAN A Patient with Hypothyroidism

Jane Lee is a 60-year-old retired nurse living with her husband and daughter on a farm that has been in the family for four generations. Mrs. Lee has gained 4.5 kg (10 lb) in the past few months, even though she is rarely hungry and eats much less than normal. She is always tired and weak—so tired that she has not even been able to help with the chores on the farm or do housework. She is concerned about her appearance and the way she sounds when she talks. Her face is puffy, and her tongue always feels thick.

ASSESSMENT

Brian Henning, RN, completes the health assessment for Mrs. Lee at the health center. He finds that she now weighs 68 kg (150 lb), an increase of 4.5 kg (10 lb) over her weight at her last visit 6 months earlier. Mrs. Lee states that she always feels cold, tired, and weak. She states that she is constipated, has difficulty remembering things, and looks different. Physical assessment findings include a palpable and bilaterally enlarged thyroid; dry, yellowish skin; nonpitting edema of the face and lower legs; and slow, slurred speech. Diagnostic tests revealed the following abnormal findings: T_3, 56 ng/dL (normal range: 80 to 200 ng/dL); T_4, 3.1 (normal range: 5 to 12 mg/dL); TSH increased. The medical diagnosis of hypothyroidism is made, and Mrs. Lee is started on levothyroxine 0.05 mg daily.

DIAGNOSES

- *Constipation* related to decreased peristalsis, as evidenced by hard, formed stools every 4 days
- *Impaired Verbal Communication* related to changes in speech patterns and enlarged tongue
- *Situational Low Self-Esteem* related to changes in physical appearance and activity intolerance

EXPECTED OUTCOMES

- Patient will regain normal bowel elimination patterns, having a soft, formed stool at least every other day.
- Patient will experience improvement in verbal communication.
- Patient will regain positive self-esteem as medication reduces physical changes and fatigue.

PLANNING AND IMPLEMENTATION

- Teach to increase fluids, bulk, and fiber in the diet to help regain a normal bowel elimination pattern of a soft, formed stool every other day.
- Take medication as prescribed and do not expect immediate reversal of manifestations affecting speech.
- Plan activities around rest periods. Encourage husband and daughter to help with housecleaning and cooking.

EVALUATION

On return to the health center 2 months later, Mrs. Lee reports that she is no longer constipated but that she is continuing to drink six glasses of water and eating oatmeal every day. She no longer feels cold, is regaining her normal energy, and even feels well enough to plant her garden. Her speech is clear and easy to understand.

Clinical Reasoning in Patient Care

1. What physical changes that normally occur with aging are similar to the manifestations of hypothyroidism?
2. Describe the factors that put Mrs. Lee's safety at risk. What alterations in her home environment would you suggest to promote safety until the prescribed medication takes effect?
3. The patient taking oral thyroid medications may develop hyperthyroidism. List the manifestations you would include in a teaching plan to signal this condition.

See Evaluating Your Response in Appendix B.

intake is restricted, ensure that liquids have no or low kilocalories. *Sufficient fluid intake is necessary to promote proper stool consistency.*

- Discuss ways to maintain a high-fiber diet. *Diets high in fiber and fluid produce soft stools. Fiber that is not digested absorbs water, which adds bulk to the stool and assists in the movement of fecal material through the intestines. High-fiber foods include beans, fruits, breads, cereals, popcorn, and rice. Consult nutritional labels for fiber content. Instruct not to eat high-fiber foods within 4 hours of taking a thyroid hormone medication. These foods decrease absorption of thyroid hormone medications.*
- Encourage activity as tolerated. *Activity influences bowel elimination by improving muscle tone and stimulating peristalsis.*

Risk for Impaired Skin Integrity

The patient with hypothyroidism is at risk for impaired skin integrity related to the accumulation of fluid in the interstitial spaces and to dry, rough skin. Decreased peripheral circulation, decreased activity levels, and slow wound healing further increase the risk.

Expected Outcome: Skin will be warm, moist, and intact without evidence of edema. Skin wounds will heal normally.

- Monitor skin surfaces for redness or lesions, especially if the patient's activity is greatly reduced. Use a pressure ulcer risk assessment scale to identify patients at risk. *Hypothyroidism causes dry, rough, edematous skin conditions that increase the risk of skin breakdown.*
- Provide or teach the immobile patient measures to promote optimal circulation:
  - Use a turning schedule if the patient is on bed rest, or teach the patient to change position every 2 hours.
  - Limit the time for sitting in one position; shift weight or lift the body using arm rests every 20 to 30 minutes.
  - Use pillows, pads, or sheepskin or foam cushions for bed and/or chair.
  - Teach and implement a schedule of range-of-motion exercises.

  Prolonged pressure, especially in patients with edema and circulatory impairment, can occlude capillaries and cause hypoxic tissue damage.
- Provide or teach the patient measures to maintain skin integrity:
  - Take baths only as necessary; use warm (not hot) water.
  - Use gentle motions when washing and drying skin.
  - Use alcohol-free skin oils and lotions.

  Dry skin and edema increase the risk of skin breakdown. Hot water, rough massage, and alcohol-based preparations may increase skin dryness, further impairing the body's ability to maintain skin integrity.

Delegating Nursing Care Activities

Often, dietary teaching is referred to the dietitian, and skin care and hygiene are delegated to assistive personnel. The professional nurse follows up on delegated activities. Assessments and evaluations of treatment are assessed by the nurse and communicated to other members of the healthcare team through documentation.

Moving Evidence into Action

Hypothyroid

Hypothyroid is positively associated with an increased risk for heart disease, metabolic syndrome (prediabetes), and type 2 diabetes.

Recent research is examining the correlation between hypothyroid with the prevalence of heart disease, metabolic syndrome (prediabetes), and type 2 diabetes. Many research studies have correlated hypothyroidism with hyperlipidemia, a cause of heart disease. In a prospective study, Saxena et al. (2013) administered levothyroxine (Synthroid) to subjects that had either subclinical or overt hypothyroidism. Both groups had improvement in lipid profiles during the study period. The researchers reported that many participants even had a return to normal lipid profiles. Although many of the participants were reported as overweight or obese, treatment with levothyroxine (Synthroid) did not cause significant weight loss in this study.

Studies have also found a positive correlation between hypothyroidism and multiple risk factors such as hypertension, increased fasting blood glucose, increased cortisol levels, increased lipids, obesity, and insulin resistance. All of these factors increase risk for heart disease, metabolic syndrome (prediabetes), and type 2 diabetes. Purvi and Ranjana (2013) used Spearman's coefficient of correlation to compare a number of risk factors including: fasting blood sugar, triiodothyronine, thyroxine, thyroid stimulating hormone, insulin, C-peptide, lipid profile, apo-B and apo-A1. Findings indicated that participants with hypothyroid had an increased prevalence of all of these cardiovascular and diabetes risk factors.

Implications for Nursing

As the prevalence of heart disease and type 2 diabetes is increasing in the United States, there is more focus on prevention of each condition. For patients with hypothyroid, appropriate treatment with levothyroxine (Synthroid) can lessen or in some cases prevent these risk factors, so it is important to assess the patient's level of understanding and educate when necessary about the appropriate use and timing of Synthroid. Nurses can also help to educate the patient with hypothyroid about the risk for heart disease and diabetes and prevention of these risk factors through lifestyle management.

Moving Knowledge into Action

1. What assessment findings could the nurse monitor for to signal that a patient with hypothyroid is having complications?
2. What type of teaching is important to assist the patient in preventing comorbidities?

Communication of assessments and collaboration of the healthcare team is essential to providing quality care to the patient.

Continuity of Care

Patients with hypothyroidism require lifelong care, primarily at home. Address the following topics:

- The need to take medications for the rest of one's life
- The need for periodic dosage reassessments
- If the patient is older or does not have a support system, helpful community resources
- Additional resources are the same as for the patient with hyperthyroidism.

THE PATIENT WITH CANCER OF THE THYROID

Approximately 60,220 new cases of thyroid cancer were diagnosed and it accounted for about 1850 cancer deaths in 2013 (National Cancer Institute, 2014). The most consistent risk factor is exposure to ionizing radiation to the head and neck during childhood. For example, many adults in their 60s, 70s, and 80s received x-ray treatments for colds, tonsillitis, acne, and sinus infections during childhood.

Of the several types of thyroid cancer, the most common types are listed here:

- *Papillary thyroid carcinoma* is the most common thyroid malignancy (National Cancer Institute, 2014). It is usually detected as a single nodule, but may arise from a multinodular goiter. It is most often diagnosed in women between ages 30 and 50. Risks for the development of this form are exposure to external x-ray treatments to the head or neck as a child, childhood exposure to radioactive isotopes of iodine in nuclear fallout, and a family history. Papillary thyroid carcinoma is the least aggressive type, but does metastasize to local and regional lymph nodes and lungs.
- *Follicular thyroid cancer* is the second most common thyroid malignancy. It is diagnosed at a slightly older age (40 to 60) than papillary and more commonly in women. This form is more aggressive than papillary, with potential for vascular invasion and spread to lung and bone. Exposure to radiation is not considered a risk factor for this type of thyroid cancer.
- *Medullary thyroid cancer* arises from the cells of the thyroid that produce the hormone calcitonin; these cells do not uptake iodine and, therefore, are not susceptible to treatment with radioactive iodine. Individuals with a family history of thyroid cancer have a change in a gene named *RET* and this can be passed from parent to child.

Thyroid cancer is manifested by a palpable, firm, nontender nodule in the thyroid. If undetected, the tumor may grow and impinge on the esophagus or trachea, causing difficulty with swallowing or breathing. Most people with thyroid cancer do not have elevated thyroid hormone levels. The diagnosis is made by measuring thyroid hormones, performing thyroid scans, and by fine-needle biopsy of the nodule. The usual treatment is subtotal or total thyroidectomy. TSH suppression therapy with levothyroxine may be conducted prior to surgery. Radioactive iodine therapy (^{131}I) and chemotherapy are additional therapeutic options. Although standard chemotherapy is not used often, new biologic chemotherapies offer promise of remission or cure for the more aggressive or refractory types of thyroid cancer (Jameson & Weetman, 2012). Nursing care for the patient with cancer is discussed in Chapter 14.

Disorders of the Parathyroid Glands

Disorders of the parathyroid glands, hyperparathyroidism and hypoparathyroidism, are not as common as those of the thyroid gland. Hypercalcemia and hypocalcemia (the primary results of alterations in parathyroid function) are discussed in Chapter 10.

THE PATIENT WITH HYPERPARATHYROIDISM

Hyperparathyroidism results from an increase in the secretion of parathyroid hormone (PTH), which regulates normal serum levels of calcium. The increase in PTH affects the kidneys and bones, resulting in increased resorption of calcium and excretion of phosphate by the kidneys (increasing the risk of hypercalcemia and hypophosphatemia), increased bicarbonate excretion and decreased acid excretion by the kidneys (increasing the risk of metabolic acidosis and hypokalemia), increased release of calcium and phosphorus by bones with resultant bone decalcification, and deposits of calcium in soft tissues and the formation of renal calculi.

Pathophysiology and Manifestations

Hyperparathyroidism occurs more often in older adults and is three times more common in women. The disorder itself is not common. Primary hyperparathyroidism occurs when there is hyperplasia or an adenoma in one of the parathyroid glands. Secondary hyperparathyroidism is a compensatory response to chronic hypocalcemia. The tertiary form is most often seen in patients with chronic renal failure.

Many patients with hyperparathyroidism are asymptomatic. When manifestations occur, they are related to hypercalcemia and various musculoskeletal, renal, and gastrointestinal manifestations. Bone reabsorption results in pathologic fractures, while elevated calcium levels alter neural and muscular activity, leading to muscle weakness and atrophy. Proximal renal tubule function is altered, and metabolic acidosis, renal calculi formation, and polyuria occur.

Manifestations of the effect of hypercalcemia on the gastrointestinal tract include abdominal pain, constipation, anorexia, and peptic ulcer formation. Hypercalcemia also affects the cardiovascular system, causing dysrhythmias, hypertension, and increased sensitivity to cardiotonic glycosides (e.g., digitalis preparations).

●○● INTERPROFESSIONAL CARE

Hyperparathyroidism is diagnosed by excluding all other possible causes of hypercalcemia, by at least a 6-month history of manifestations, and by laboratory analysis of levels of serum calcium and PTH levels (McPhee et al., 2012).

Treatment of hyperparathyroidism focuses on decreasing the elevated serum calcium levels. Patients with mild hypercalcemia are urged to drink fluids and keep active. They should avoid immobilization, thiazide diuretics, large doses of vitamins A and D, antacids containing calcium, and calcium supplements. Severe hypercalcemia requires hospitalization and intensive treatment with intravenous saline. Medications to inhibit bone resorption and reduce hypercalcemia, such as pamidronate (Aredia), alendronate (Fosamax), and zoledronate (Zometa), are used for short-term treatment, improve bone density, and may relieve bone pain. Calcitonin, a hormone produced by the thyroid gland, decreases plasma levels of calcium by inhibiting bone resorption and increasing calcium excretion by the kidney (Grossman & Porth, 2014). A form of calcitonin from salmon is available as a nasal spray or by IM or subcutaneous injection. A medication for patients with hyperparathyroidism secondary to renal failure or parathyroid cancer is a calcimimetic. This drug increases the sensitivity of the calcium-sensing receptors of the parathyroid gland to serum calcium. The effect is decreased secretion of PTH and reduced serum calcium and phosphorus.

Surgical removal of the parathyroid glands affected by hyperplasia or adenoma treats primary hyperparathyroidism. The preoperative and postoperative nursing care of the patient having surgery of the parathyroids is essentially the same as that for the patient having a thyroidectomy. Manipulation of the thyroid while removing the parathyroids may result in TH release, causing increased cardiac rate and stroke volume.

●○● NURSING CARE

Nursing care of the patient with hyperparathyroidism focuses on its effects on calcium balance: hypercalcemia and bone resorption with an increased risk for pathologic fractures. Nursing care of the patient with hypercalcemia is discussed in Chapter 10. The patient also is at risk for developing kidney stones; see Chapter 27 for nursing care for the patient with renal calculi.

THE PATIENT WITH HYPOPARATHYROIDISM

Hypoparathyroidism results from abnormally low PTH levels. The most common cause is damage to or inadvertent removal of all of the parathyroid glands during thyroidectomy. The lack of circulating PTH causes hypocalcemia and an elevated blood phosphate level.

Pathophysiology and Manifestations

Reduced levels of PTH result in impaired renal tubular regulation of calcium and phosphate. In addition, decreased activation of vitamin D results in decreased absorption of calcium by the intestines. The low calcium levels cause changes in neuromuscular activity, affecting peripheral motor and sensory nerves. Hypocalcemia lowers the threshold for nerve and muscle excitability; a slight stimulus anywhere along a nerve or muscle fiber initiates an impulse.

The neuromuscular manifestations that result include numbness and tingling around the mouth and in the fingertips, muscle spasms of the hands and feet, convulsions, and laryngeal spasms.

MANIFESTATIONS OF HYPOPARATHYROIDISM

MUSCULOSKELETAL SYSTEM
- Muscle spasms
- Facial grimacing
- Carpopedal spasms
- Tetany or convulsions

INTEGUMENTARY SYSTEM
- Brittle nails
- Hair loss
- Dry, scaly skin

GASTROINTESTINAL SYSTEM
- Abdominal cramps
- Malabsorption

CARDIOVASCULAR SYSTEM
- Dysrhythmias

CENTRAL NERVOUS SYSTEM
- Paresthesias (lips, hands, feet)
- Mood disorders (irritability, depression, anxiety)
- Hyperactive reflexes
- Psychosis
- Increased intracranial pressure

Tetany, a continuous spasm of muscles, is the primary symptom of hypocalcemia. In severe cases of tetany, death may occur. Assessments for tetany include Chvostek's sign and Trousseau's sign (refer to Chapter 18). The manifestations of hypoparathyroidism are summarized in the box on page 489.

●○● INTERPROFESSIONAL CARE

Hypoparathyroidism is diagnosed by low serum calcium levels and high phosphorous levels in the absence of renal failure, an absorption disorder, or a nutritional disorder.

Treatment of hypoparathyroidism focuses on increasing calcium levels. Intravenous calcium gluconate is given immediately to reduce tetany. Long-term therapy includes supplemental calcium, increased dietary calcium, and vitamin D therapy.

●○● NURSING CARE

Calcium imbalance (hypocalcemia) is the primary manifestation of hypoparathyroidism and the nursing care focus. Nursing care for the patient with hypocalcemia is discussed in Chapter 10.

Disorders of the Adrenal Glands

The paired adrenal glands are made up of two distinct regions, the cortex (outer portion) and medulla (inner portion), each producing hormones with whole body effects. Hormones of the adrenal cortex are essential to life. They maintain homeostasis in response to stressors. Disorders of the adrenal cortex result in complex physical, psychologic, and metabolic alterations that are potentially life threatening. Hormones of the adrenal medulla are not essential to life, because the sympathetic nervous system produces similar body responses. The primary adrenal disorders are hyperfunction and hypofunction of the adrenal cortex and hyperfunction of the adrenal medulla.

THE PATIENT WITH CUSHING'S SYNDROME

Cushing's syndrome (hypercortisolism) is a chronic disorder caused by excessive amounts of circulating cortisol. Cushing's syndrome is more common in women, with the average age of onset between 30 and 50 years. However, the disorder may occur at any age, especially as the result of pharmacologic therapy. People who take corticosteroids for long periods of time (e.g., for the treatment of arthritis, after an organ transplant, or as an adjunct to chemotherapy) are at increased risk for developing the disorder.

Pathophysiology

Cushing's syndrome may be the result of various causes. The most common etiologies of the disorder are as follows:

- Iatrogenic Cushing's syndrome results from long-term therapy with potent pharmacologic glucocorticoid (corticosteroid) preparations. This is the most common cause of Cushing's syndrome (Arlt, 2012).
- The pituitary form, with ACTH hypersecretion leading to hypercortisolism (*Cushing's disease*), accounts for about 40% of all cases of Cushing's syndrome (McPhee et al., 2012). It is most commonly caused by a small pituitary adenoma. This form of Cushing's syndrome occurs three times more frequently in women than in men.
- The adrenal form results from excessive cortisol secretion by a benign or malignant adrenal tumor. In most cases, the tumor is unilateral (McPhee et al., 2012). The excess secretion suppresses pituitary ACTH production, resulting in atrophy of the uninvolved adrenal cortex.
- The ectopic form is caused by ACTH-secreting tumors (such as small-cell lung cancer). In some cases, the source of excess ACTH secretion cannot be identified.

Manifestations

The manifestations of Cushing's syndrome result from an excess of cortisol, which leads to exaggerated cortisol actions. Obesity and a redistribution of body fat result in fat deposits in the abdominal region (central obesity), fat pads under the clavicle, a "buffalo hump" over the upper back, and a round moon face (Figure 19–3 ■). Changes in protein metabolism cause muscle weakness and wasting, especially in the extremities. Glucocorticoid excess inhibits fibroblasts, resulting in loss of collagen and connective tissue. Thinning of skin, abdominal striae (reddish purple stretch marks), easy bruising, poor wound healing, and frequent skin infections result. Glucose metabolism is altered in the majority of patients, and diabetes mellitus may occur. Electrolyte imbalances also occur with the increased hormone levels. Changes in calcium absorption result in osteoporosis, compression fractures of the vertebrae, fractures of the ribs, and renal calculi. Hypokalemia and hypertension occur as potassium is lost and sodium is retained. Inhibited immune responses increase the risk of infection, and increased gastric acid secretion increases the risk of peptic ulcers. Emotional changes range from depression to psychosis. In women, increasing androgen levels cause hirsutism (excessive facial hair in particular), acne, and menstrual irregularities. The manifestations with related pathophysiology of Cushing's syndrome are outlined in the box on page 490.

The complications of untreated Cushing's syndrome include electrolyte imbalances (hyperglycemia, hypernatremia, and hypokalemia), hypertension, and emotional disturbances. Increased susceptibility to infections is also a factor. Compression fractures from osteoporosis and aseptic necrosis of the femoral head may result in serious disability. If the patient undergoes a bilateral adrenalectomy as a treatment for Cushing's syndrome, an acute deficit of cortisol (Addisonian crisis) may result.

●○● INTERPROFESSIONAL CARE

The treatment of Cushing's syndrome includes medications, radiation therapy, or surgery, depending on the etiologic origin of the disorder.

DIAGNOSIS

Cushing's syndrome is diagnosed through a variety of diagnostic tests. In addition to the laboratory tests described in Chapter 18 and in Table 19–2, a dexamethasone suppression test may be performed to differentiate between adrenal hyperplasia due to excess ACTH secretion (Cushing's disease) and adrenal cancer. If the dexamethasone test is positive, a test for urinary free cortisol is made. This measures the amount of cortisol in the urine over 24 hours. Other diagnostic

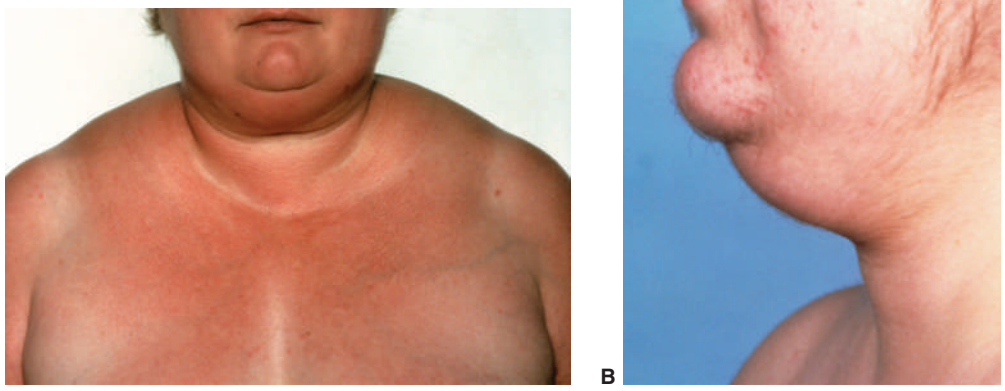


Figure 19–3 ■ Among the manifestations of Cushing's syndrome are central obesity; fat deposits around the upper back (A); the face (B); and clavicle; hirsutism; dilation of capillaries; and purple or red striae (due to weight gain).
Source: A, Wellcome Image Library; B, Custom Medical Stock.

studies, including a CT scan or MRI of the abdomen, may be conducted to assess the adrenal gland for tumors.

MEDICATIONS

Cushing's syndrome that results from a pituitary tumor is treated by medications as an adjunct to surgery or radiation. Medications are also used for patients with inoperable pituitary or adrenal malignancies. Although the drugs control manifestations, they do not effect a cure. Examples of some commonly prescribed drugs follow:

- Mitotane directly suppresses activity of the adrenal cortex and decreases peripheral metabolism of corticosteroids. It is used to treat metastatic adrenal cancer.
- Aminoglutethimide or ketoconazole (or both) inhibit cortisol synthesis by the adrenal cortex and may be administered to patients with ectopic ACTH-secreting tumors that cannot be surgically removed.
- Somatostatin analog (octreotide) suppresses ACTH secretion in some patients.

PATHOPHYSIOLOGY LINKAGE

Cushing's Syndrome

Manifestations	Pathophysiology
Weight gain, abdominal fat deposits (central obesity), fat pads on the upper back ("buffalo hump"), and a round face ("moon face")	Altered fat metabolism with increased breakdown of fats to fatty acids and redistribution of body fat.
Muscle weakness and wasting, especially in the extremities	Altered protein metabolism with protein catabolism and mobilization of amino acids for gluconeogenesis.
Thinning of skin, abdominal striae (purple "stretch marks"), easy bruising, poor wound healing	Increased protein breakdown with loss of collagen and connective tissues in skin and subcutaneous tissues.
Osteoporosis, compression fractures of the vertebrae, rib fractures	Loss of bone proteins and altered calcium balance with increased resorption of calcium from bone.
Increased susceptibility to infections	Inhibition of inflammatory and immune responses.
Hypertension, hypokalemia, and hypernatremia	Mineralocorticoid effects cause increased potassium excretion and sodium retention by the kidneys.
Hyperglycemia, polyuria, polydipsia	Altered carbohydrate metabolism with increased gluconeogenesis.
Increased risk for deep venous thrombosis	Altered coagulation due to excess cortisol.
Increased risk of gastric ulcers	Increased gastric acid secretion in response to excess cortisol.
Hirsutism (excessive hair growth), acne, menstrual irregularities	Altered feedback mechanisms lead to suppression of gonadotropins and increased androgen levels.
Emotional instability	Excess levels of glucocorticoids.

TABLE 19–2 Laboratory Findings in Adrenal Disorders

	Test	Normal Values	Hyperfunction (Cushing's Syndrome)	Hypofunction (Addison's Disease)
Serum	Cortisol	8 a.m. to 10 p.m.: 138–635 mmol 4 p.m. to 6 p.m.: 83–359 mmol	Increased	Decreased
	Blood urea nitrogen (BUN)	5–25 mg/dL	Normal	Increased
	Sodium	135–145 mEq/L	Increased	Decreased
	Potassium	3.5–5.0 mEq/L	Decreased	Increased
	Glucose	70–110 mg/dL	Increased	Decreased
Urine	Urinary free cortisol (UFS)	10–50 mcg/24 h	Increased	Low/absent
	17-hydroxy-corticosteroids (17-OHCS)	Male: 3-12 mcg/24h Female: 2-10 mg/24 h	Increased	Decreased
	17-ketosteroids (17-KS)	Male: 5–25 mg/24 h Female: 5–15 mg/24 h Age > 65: 4–8 mg/24 h	Increased	Decreased

SURGERY

When Cushing's syndrome is caused by an adrenal cortex tumor, an adrenalectomy may be performed to remove the tumor. Only one adrenal gland is usually involved; however, if an ACTH-producing ectopic tumor is involved, a bilateral adrenalectomy is performed. Lifelong hormone replacement is necessary if both adrenal glands are removed. See the box on page 492 for nursing care of the patient undergoing adrenalectomy.

Surgical removal of the pituitary gland (hypophysectomy) is indicated when Cushing's syndrome is the result of a pituitary disorder. The gland is removed either by a transsphenoidal route or by a craniotomy.

●○● NURSING CARE

Health Promotion

Stress the importance of taking corticosteroid medications as ordered to reduce the risk of developing Cushing's syndrome for patients with acute or chronic inflammation. The risk of abruptly discontinuing the medications also is an essential component of teaching.

Assessment

Collect the following data through the health history and physical examination. Further focused assessments are described with nursing interventions later.

- *Health history:* history of pituitary, adrenal, pancreatic, or pulmonary tumor; frequent infections; gastrointestinal bleeding; stress fractures; pain; changes in weight or fat distribution; change in height; fatigue; weakness; change in appearance; bruising; skin infections; menstrual history; sexual function
- *Physical assessment:* vital signs, behavior, appearance, fat distribution, face, skin, hair quantity and distribution, muscle size and strength, gait.

Moving Knowledge into Action

1. What assessment findings would be expected with Cushing's syndrome?
2. List the assessments that nurses can observe to determine body fluid balance.

Priorities of Care

The nurse caring for the patient with Cushing's syndrome must take a holistic approach to plan and implement interventions for a wide variety of responses, including problems related to fluid and electrolyte balance, injury, infection, and body image. See the Case Study & Nursing Care Plan on page 496.

Diagnoses, Outcomes, and Interventions

Fluid Volume Excess

The excess cortisol secretion associated with Cushing's syndrome results in sodium and water reabsorption, causing fluid volume excess (Grossman & Porth, 2014). The patient will have weight gain, edema, and hypertension.

Expected Outcome: Patient's blood pressure and weight will be within normal limits; no jugular vein distention or edema will be present.

- Ask the patient to weigh at the same time each day, and maintain a record of results. *Body weight is an accurate indicator of fluid status. One liter of fluid retention corresponds to about 1 kg (2.2 lb) of body weight.*
- Monitor blood pressure, rate and rhythm of pulse, respiratory rate, and breath sounds. Assess for peripheral edema and jugular vein distention. *Extracellular fluid volume excess resulting from sodium and water retention is manifested by hypertension and a bounding, rapid pulse. There may also be crackles and wheezes, dependent edema, and venous distention.*
- Teach the patient and family the reasons for restricting fluid and the importance of limiting fluids if ordered. *Restricting fluid can help decrease the risk of fluid volume excess. Involving the patient and*

NURSING CARE OF THE PATIENT

Having an Adrenalectomy

PREOPERATIVE CARE

- Request a dietary consultation with the patient to discuss a diet high in vitamins and proteins. If hypokalemia exists, include foods high in potassium. *Glucocorticoid excess increases catabolism. Vitamins and proteins are necessary for tissue repair and wound healing following surgery*.
- Use medical and surgical asepsis when providing care and treatments. *Cortisol excess increases the risk of infection*.
- Monitor the results of laboratory tests of electrolytes and glucose levels. *Electrolyte and glucose imbalances are corrected before the patient has surgery*.
- Teach the patient to turn, cough, and perform deep-breathing exercises. *Having the patient practice and demonstrate the activities increases postoperative compliance*.

POSTOPERATIVE CARE

- Take and record vital signs, measure intake and output, and monitor electrolytes on a frequent schedule, especially during the first 48 hours after surgery. *Removal of an adrenal gland, especially a bilateral adrenalectomy, results in adrenal insufficiency. Addisonian crisis and hypovolemic shock may occur. Cortisol is often given on the day of surgery and in the postoperative period to replace inadequate hormone levels. Intravenous fluids are also administered*.
- Assess body temperature, white blood cell (WBC) levels, and wound drainage. Change dressings using sterile technique. *Impaired wound healing increases the risk of infection in patients with adrenal disorders. Use aseptic technique to decrease this risk*.
- Assess respiratory rate, rhythm, depth, and effort. Assist the patient with coughing and deep breathing. *Although they are important for all surgical patients, these activities are even more important for the patient who is at risk for infection.*

family in the plan of care and teaching the rationale for interventions help the patient achieve goals.

Risk for Injury

The patient with Cushing's syndrome is at risk for injury from several causes. Excess cortisol causes increased absorption of calcium and demineralization of bones, resulting in risk of pathologic fractures. Muscle weakness and fatigue are common, increasing the potential for accidental falls.

Expected Outcome: Patient will be aware of accommodations to prevent injuries and will be free from injuries.

Teach the patient and caregivers the following:

- Keep unnecessary clutter and equipment out of the way and off the floor.
- Ensure adequate lighting, especially at night.
- Use assistive devices for ambulation or to ask for help if needed.
- Be sure corrective lenses are available and clean.
- Use nonskid slippers or shoes.
- Watch for signs of fatigue (increased pulse and respirations); plan rest periods.

  A well-lighted environment free of clutter decreases the risk of falls and injury. Sensory and motor deficits increase the risk of falls; corrective lenses, assistive devices, and nonslip footwear can decrease this risk. Rest relieves fatigue. To reduce energy expenditure, include alternating periods of rest and activity in daily schedules.

Risk for Infection

Elevated cortisol levels impair the immune response and put the patient with Cushing's syndrome at increased risk for infection. Increased cortisol also affects protein synthesis, causing delayed wound healing, and inhibits collagen formation, which results in epidermal atrophy, further inhibiting resistance to infection. In addition, impaired blood flow to edematous tissue results in altered cellular nutrition, which increases the potential for infection.

Expected Outcome: The patient will be aware of measures to prevent infections. The patient will be free from infections.

- Place the patient with Cushing's syndrome who requires hospitalization in a private room, and limit visitors.
- Monitor vital signs and verbalizations of subjective manifestations (e.g., the patient's response to "How do you feel?") every 4 hours. *Increased body temperature and pulse are systemic indicators of infection; however, because Cushing's syndrome impairs the normal inflammatory response, the usual indicators of inflammation may not be present.*
- Use principles of medical and sterile asepsis when caring for the patient, conducting procedures, or providing wound care. *Impaired skin and tissues make aseptic techniques even more necessary to decrease the risk of infection. Intact skin is the first line of defense against infection; if invasive procedures are performed or a wound is present, this defense is lost.*
- If wounds are present, assess the color, odor, and consistency of wound drainage, and look for increased pain in and around the wound. *Cortisol excess delays wound healing and closure.*
- Teach the importance of increasing intake of protein and vitamins C and A. *Protein, vitamin C, and vitamin A are necessary to collagen formation; collagen helps support and repair body tissues.*
- Encourage recommended vaccinations.

SAFETY ALERT

A generalized feeling of malaise may be the primary manifestation of infection, especially in the older adult.

Disturbed Body Image

The patient with Cushing's syndrome has obvious physical changes in appearance. The abnormal fat distribution, moon face, buffalo hump, striae, acne, and facial hair (in women) all contribute to disruptions in the way patients with this disorder perceive themselves.

Expected Outcome: Patient will discuss physical changes and ways to adapt to them. Patient will verbalize an understanding that physical changes are expected to improve with treatment of Cushing's syndrome.

- Encourage patients to express feelings and to ask questions about the disorder and its treatment. *The loss of one's normal body image may prompt feelings of hopelessness, powerlessness, anger, and depression. Understanding the disease and adapting to changes from that disease are the first steps in regaining control of one's own body.*

- Discuss strengths and previous coping strategies. Enlist the support of family or significant others in reaffirming the patient's worth. *Disturbances in body image are often accompanied by low self-esteem. Self-esteem derives from one's perception of competence and from appraisals of others.*
- Discuss signs of progress in controlling manifestations; for example, decreased facial edema or increased activity tolerance. *Many physical changes from cortisol excess disappear with treatment. Clearly communicate this fact, because the patient may believe changes are permanent.*

Delegating Nursing Care Activities

The registered nurse performs the preoperative and postoperative assessments. These assessments are particularly important for identifying potential complications during and after surgery. Tasks that are often delegated include blood glucose measurements, toileting, and repositioning. The registered nurse develops the plan of care, provides teaching, coordinates the healthcare team, and evaluates the results of care provided. The nurse should be aware of individual state laws regarding delegation published in state board of nursing rules prior to delegating specific tasks.

Continuity of Care

The patient with Cushing's syndrome requires education about self-care at home specific to the type of treatment given. Address the following topics:

- Safety measures to prevent falls if fatigue, weakness, and osteoporosis are present.
- Taking medications as prescribed, with information about side effects. Patients often require medications for the rest of their lives, and dosage changes are highly likely.
- Having regular health assessments.
- Wearing a medical alert ID indicating the patient has Cushing's syndrome.
- Helping the older patient with referrals to social services or community health services because of the complexity of the treatment and care required.
- Providing helpful resources: American Association of Clinical Endocrinologists and Endocrine Society.

THE PATIENT WITH CHRONIC ADRENAL INSUFFICIENCY

Chronic adrenal insufficiency is an uncommon disorder resulting from destruction or dysfunction of the adrenal cortex. The result is chronic deficiency of cortisol, aldosterone, and adrenal androgens, accompanied by skin pigmentation. It can occur at any age, although it is usually diagnosed in young adults (Arlt, 2012).

Pathophysiology

There are many possible causes of adrenal insufficiency. The etiologies include the following:

- Autoimmune destruction of the adrenals is the most common cause of primary adrenal insufficiency (**Addison's disease**). It may occur alone, or as part of a polyglandular autoimmune syndrome (PGA). Type 2 PGA is seen in adults (usually women), often associated with autoimmune thyroid disease (usually hypothyroidism), type 1 diabetes, primary ovarian or testicular failure, and pernicious anemia.
- The adrenal glands also may be destroyed by infection (tuberculosis is a common cause of Addison's disease in developing countries), sepsis, metastatic cancer, hemorrhage, or heparin-induced thrombocytopenia (HIT).
- Adrenoleukodystrophy is an X-linked disorder characterized by an accumulation of very long chain fatty acids in the adrenal cortex, testes, brain, and spinal cord.
- An ACTH deficit (secondary adrenal insufficiency) can result from pituitary tumors, pituitary surgery or irradiation, and the use of exogenous steroids.
- Abrupt withdrawal from long-term, high-dose steroid therapy can cause acute adrenal insufficiency.

Because the adrenal cortex has significant reserve capacity, initial manifestations may not be apparent. Basal glucocorticoid secretion is normal, but does not increase in response to stress and surgery. Trauma or infection can precipitate an adrenal crisis. As the destruction of the adrenal cortex continues, even basal secretion of glucocorticoids and mineralocorticoids is deficient. Decreasing plasma cortisol reduces the feedback inhibition of pituitary ACTH and, hence, plasma ACTH rises.

Acute secondary adrenocortical insufficiency occurs when either large doses or prolonged therapy with corticosteroids is abruptly withdrawn. Corticosteroids are used for their anti-inflammatory and immunosuppressive effects to treat diseases such as arthritis and asthma. High levels of circulating corticosteroids suppress the hypothalamic-pituitary-adrenal feedback mechanism, and cause atrophy of the adrenal glands. If the steroid medications are suddenly discontinued, the glands cannot effectively respond to the reduced level of circulating glucocorticoids.

Manifestations

The onset of Addison's disease is slow in most cases; the patient experiences manifestations after about 90% of the function of the gland is lost. The primary manifestations are the result of elevated ACTH levels and decreased aldosterone and cortisol. Aldosterone deficiency affects the ability of the distal tubules of the nephron to conserve sodium. Sodium is lost, potassium is retained, extracellular fluid is depleted, and the blood volume is decreased. Postural hypotension and syncope are common, and hypovolemic shock may occur. Hyponatremia causes dizziness, confusion, and neuromuscular irritability. Hyperkalemia causes cardiac dysrhythmias. See the manifestations box on page 494.

Cortisol insufficiency also causes decreased hepatic gluconeogenesis with hypoglycemia. The patient tolerates stress poorly and experiences lethargy, weakness, anorexia, nausea, vomiting, and diarrhea. The increased ACTH levels stimulate hyperpigmentation in more than 90% of patients with Addison's disease (Grossman & Porth, 2014). In Caucasian patients, the skin looks deeply suntanned or bronzed in both exposed and unexposed areas.

ADDISONIAN CRISIS

Addisonian crisis is a life-threatening acute adrenal insufficiency. The disorder is chronic after the acute episode resolves.

Addisonian crisis is most commonly precipitated by major stressors, especially if the disease is poorly controlled. Triggers

MANIFESTATIONS OF ADDISON'S DISEASE

INTEGUMENTARY SYSTEM
- Delayed wound healing
- Hyperpigmentation

CARDIOVASCULAR SYSTEM
- Postural hypotension
- Dysrhythmias
- Tachycardia

CENTRAL NERVOUS SYSTEM
- Lethargy
- Tremors
- Emotional lability
- Confusion

MUSCULOSKELETAL SYSTEM
- Weakness
- Muscle wasting
- Joint pain
- Muscle pain

GASTROINTESTINAL SYSTEM
- Anorexia
- Nausea and vomiting
- Diarrhea

REPRODUCTIVE SYSTEM
- Menstrual changes

METABOLIC EFFECTS
- Hyperkalemia
- Hyponatremia
- Hypoglycemia

include surgery, acute systemic illness, and trauma. Addisonian crisis may occur in patients who are abruptly withdrawn from corticosteroid medications or who have hemorrhage into the adrenal glands from either septicemia or anticoagulant therapy.

The primary manifestations of the crisis develop rapidly and are a high fever; weakness; severe, penetrating pain in the abdomen, lower back, and legs; severe vomiting; diarrhea; hypotension; and circulatory collapse, shock, and coma. See the manifestations box, above.

Treatment of the crisis is rapid intravenous replacement of fluids and glucocorticoids. Fluid balance is usually restored in 4 to 6 hours.

●○● INTERPROFESSIONAL CARE

The patient with Addison's disease requires early diagnosis and treatment. Medical treatment includes glucocorticoid and mineralocorticoid replacement therapy.

DIAGNOSTIC TESTS

Addison's disease is diagnosed through findings of decreased levels of cortisol, aldosterone, and urinary 17-ketosteroids (17-KS). Dehydration may result in increased hematocrit and blood urea nitrogen (BUN). Blood glucose levels are decreased, and potassium is increased. A list of laboratory findings in Addison's disease is shown in Table 19–2. The following diagnostic tests are used:

- *Serum cortisol levels,* which are decreased in adrenal insufficiency
- *Blood glucose levels,* which are decreased in adrenal insufficiency
- *Serum sodium levels,* which are decreased in adrenal insufficiency
- *Serum potassium levels,* which are increased in adrenal insufficiency
- *BUN levels,* which are increased in adrenal insufficiency
- *Urinary 17-hydroxycorticoids (17-OHCS)* and *17-KS levels,* which are decreased in adrenal insufficiency
- *Plasma ACTH levels,* which are increased in primary adrenal insufficiency (adrenal gland does not produce cortisol), but decreased in secondary adrenal insufficiency (ACTH not adequately produced by the pituitary)
- *ACTH stimulation test,* which is the most specific diagnostic test for Addison's disease (Cortisol levels rise with pituitary deficiency but do not rise in primary adrenal insufficiency.)
- *CT scans* of the head, which identify any intracranial lesion impinging on the pituitary gland.

MEDICATIONS

The primary medical treatment of Addison's disease is replacement of corticosteroids and mineralocorticoids, accompanied by increased sodium in the diet. Hydrocortisone (Cortef, others) is given orally to replace cortisol; fludrocortisone (Florinef) is given orally to replace mineralocorticoids. Nursing responsibilities in cortisol replacement are given in the Medication Administration box.

●○● NURSING CARE

Health Promotion

Health promotion related to adrenal insufficiency focuses on teaching patients about the risks associated with abruptly withdrawing prolonged or high dose corticosteroid drugs. Interventions for the patient with Addison's disease focus on careful assessments when the patient is under significant physiologic stress. Teaching to prevent or treat an Addisonian crisis is essential.

Assessment

Collect the following data through the health history and physical examination. Further focused assessments are described with nursing interventions in the following text.

- *Health history:* weight loss, changes in skin color, nausea and vomiting, anorexia, diarrhea, abdominal pain, weakness, amenorrhea, changes in sexual desire, confusion, and intolerance of stress
- *Physical assessment:* height and weight, vital signs, skin, hair quality and distribution, muscle size and strength.

Priorities of Care

The patient with Addison's disease requires nursing care for a wide variety of responses to the decrease in cortisol levels. Nursing diagnoses discussed in the next section are directed toward problems with fluid and electrolyte balance and compliance with lifelong self-care. See the Case Study & Nursing Care Plan on page 496.

Diagnoses, Outcomes, and Interventions

Deficient Fluid Volume

Fluid volume deficit in the patient with Addison's disease results from loss of water and sodium, as well as from vomiting and diarrhea. Extracellular fluid volume deficit, decreased cardiac output, hypotension, and hypovolemic shock may occur, especially in crisis situations. Interventions for this diagnosis are outlined for the patient who is hospitalized.

MEDICATION ADMINISTRATION

Addison's Disease

CORTICOSTEROID REPLACEMENTS

cortisone (Cortone, Cortogen)
hydrocortisone (Cortisol, Hydrocortone, Cortef)
fludrocortisone acetate (Florinef, F-Cortef)
dexamethasone (Decadron, Hexadrol, Dexasone)
prednisone (Meticorten, Deltasone, Orasone)
prednisolone (Meticortelone)
methylprednisolone (Medrol, Solu-Medrol)

Corticosteroids are used for replacement therapy in acute and chronic adrenal insufficiency. These drugs have anti-inflammatory and immunosuppressant effects. They also facilitate coping with stress.

Because corticosteroids are immunosuppressants, their use is contraindicated when an infection is suspected; they also mask the signs of infection. Immunizations with live vaccines should not be attempted. Corticosteroids are contraindicated in many other disorders, including peptic ulcer, Cushing's syndrome, cardiac disease, hyperthyroidism, hypothyroidism, and tuberculosis. Concurrent use with NSAIDs is not recommended because of the combined effect on the gastrointestinal tract.

When these drugs are administered in small doses for replacement therapy, side effects are uncommon. Large doses or prolonged therapy may cause a Cushing's-like syndrome, with atrophy of the adrenal cortex. Older patients, especially postmenopausal women, are more prone to develop hypertension and osteoporosis when undergoing glucocorticoid therapy. These drugs are used with caution in children and the older adult and are not usually administered to pregnant women.

Nursing Responsibilities

- Establish baseline data, including mental status, neurologic function, vital signs, and weight.
- Identify medications that might interact with corticosteroids: antidiabetic agents, cardiac glycosides, oral contraceptives, anticoagulants, NSAIDs.
- Document and report increased blood pressure, edema or weight gain, bleeding or bruising, weakness, or manifestations of Cushing's syndrome.
- Administer oral forms of the drug with food to minimize its ulcerogenic effect.
- Monitor electrolyte levels for increased sodium and decreased potassium.
- Monitor capillary blood glucose for hyperglycemia in the patient with diabetes.

Health Education for the Patient and Family

- Take medications with food or milk, and report any gastric distress or dark stools.
- People with adrenal insufficiency need to take the medications for the rest of their lives.
- Consume a diet that is low in potassium, and higher in sodium and protein.
- Weigh yourself each day at the same time, and report any consistent weight gain, which indicates fluid retention.
- Use safety measures in the home to prevent falls and injuries.
- Corticosteroids may impair the effectiveness of oral contraceptives.
- Take the medication regularly and continuously. *Abruptly discontinuing the medication is dangerous.*
- Obtain a medical alert bracelet.
- Monitor for increased stressors (infection, dental work, personal crisis) and increase the dose as indicated by the physician.
- Anticoagulant drugs or insulin may decrease the effectiveness of corticosteroids.
- Report the following to the physician: dizziness on sitting or standing, nausea and vomiting, pain, thirst, feelings of anxiety, malaise, infections.

Note: Drugs identified in *italics* are among the 200 most commonly prescribed medications in the U.S.

Expected Outcome: Patient's fluid balance will return to normal following treatment: Blood pressure will be normal, urine will be light amber with normal specific gravity, postural hypotension will be absent, and weight will return to baseline.

- Monitor intake and output, and assess for signs of dehydration: dry mucous membranes; thirst; poor skin turgor; sunken eyeballs; scanty, dark urine; increased urine specific gravity; weight loss; and increased hemoconcentration (increased hematocrit and BUN). *Glucocorticoid and mineralocorticoid depletion causes fluid volume deficit. Fluid volume deficit may reach crisis levels if undetected, causing altered tissue perfusion and hypovolemic shock.*
- Monitor cardiovascular status: Take and record vital signs, assess character of pulses, and monitor potassium levels and ECGs. *Fluid volume deficit may lead to hypotension and a rapid, weak, or thready pulse. As aldosterone levels fall, renal excretion of potassium decreases, increasing blood levels of potassium.*
- Weigh the patient daily at the same time and in the same clothing. *Dehydration is manifested by weight loss.*
- Encourage an oral fluid intake of 3000 mL/day and an increased salt intake. *Cortisol deficiency increases fluid loss, leading to extracellular fluid volume depletion. Oral fluid replacement is necessary to balance this loss. An increase in dietary sodium can decrease the hyponatremia characteristic of adrenal insufficiency.*
- Teach to sit and stand slowly, and provide assistance as necessary. *Extracellular fluid volume deficit causes orthostatic hypotension, dizziness, and possible loss of consciousness. These manifestations increase the risk of injury from falls.*

SAFETY ALERT

Hyperkalemia causes changes in cardiac muscle function, which are reflected in ECG changes.

Risk for Ineffective Therapeutic Regimen Management

Patients with Addison's disease must learn to provide lifelong self-care that involves varied components: medications, diet, and recognizing and responding to responses to stress. Changes in lifestyle are difficult to maintain permanently.

Expected Outcome: Patient and close family members will have the knowledge necessary to manage Addison's disease and demonstrate ability to manage medications competently.

- Teach the effects of illness and treatment. Discuss patient and family concerns. *Lack of knowledge about the illness, as well as the possibility of complications from disregarding or altering the treatment, can negatively affect compliance.*

CASE STUDY & NURSING CARE PLAN A Patient with Addison's Disease

A 51-year-old unemployed salesman, Don Sardoff, is brought to the emergency department (ED) by his wife, Ellen, at 8 a.m. Mrs. Sardoff tells the ED nurse that her husband has not been feeling well for the past week, but that when he got up this morning, he was so weak he couldn't dress himself and didn't know where he was. Mrs. Sardoff tells the nurse that her husband has been taking a cortisone drug for treatment of his rheumatoid arthritis for the past 2 years, but notes, "We didn't have the money to buy it this month."

ASSESSMENT

On admission to the ED, Mr. Sardoff is dehydrated, with dry oral mucous membranes and tongue, poor skin turgor, and sunken eyeballs. His blood pressure is 94/44, and his pulse is rapid and thready. He is weak, dizzy, and disoriented about time and place. Diagnostic tests reveal the following abnormal findings at 8:30 a.m.:

- ECG: widening QRS complex and increased PR interval
- Sodium: 129 mEq/L (normal range: 135 to 145 mEq/L)
- Glucose: 54 mg/dL (normal range: 70 to 110 mg/dL)
- Potassium: 5.3 mEq/L (normal range: 3.5 to 5.3 mEq/L)
- Cortisol: 2 mg/dL (normal for a.m.: 5 to 23 mg/dL).

The medical orders for Mr. Sardoff include intravenous administration of 5% dextrose in normal saline (D_5NS) at 250 mL/h and hydrocortisone (Solu-Cortef) 200 mg. After the fluids and medication are initiated, Mr. Sardoff is moved to an in-hospital medical bed.

DIAGNOSES

- *Deficient Fluid Volume* related to hypovolemia secondary to adrenal insufficiency
- *Ineffective Tissue Perfusion: Peripheral* related to fluid volume deficit
- *Anxiety* related to lack of knowledge about the effects and treatment of adrenal insufficiency

EXPECTED OUTCOMES

- Patient will regain normal fluid balance.
- Patient will regain normal peripheral perfusion with blood pressure within normal range.
- Patient will verbalize knowledge of the causes and effects of adrenal insufficiency.

PLANNING AND IMPLEMENTATION

- Monitor intake and output closely.
- Take and record weight at the same time daily.
- Monitor blood pressure, pulses, and skin turgor every 2 hours until stable, then four times a day.
- Monitor electrolytes, and report abnormal results.
- Discuss a diet that is high in sodium, low in potassium, and has an increased fluid intake (3000 mL/day). Discuss the types of fluids desired and the best times for intake of increased fluids.
- Assist during activity to prevent falls.
- Provide verbal and written instructions, and encourage verbal feedback about the causes and effects of the disease, the effects of medications, the effects of not taking long-term cortisone drugs, the diet, and self-care at home.

EVALUATION

Following treatment for acute adrenal insufficiency, Mr. Sardoff is no longer dehydrated, and his blood pressure has returned to his normal reading of 132/88 mmHg. He is alert and oriented, and anxious to learn to care for himself at home. After dietary instructions and teaching for self-care that included his wife, Mr. Sardoff verbalizes an understanding of his illness and the need to take his medication carefully and accurately. A referral is made to a social worker for assistance with costs of medications.

Clinical Reasoning in Patient Care

1. Adrenal insufficiency is often diagnosed only when the patient becomes seriously ill in response to a stressor. Explain why this statement is or is not true.
2. Describe the physical assessments that are found in the severely dehydrated patient.
3. Outline a teaching plan for Mr. Sardoff with foods for a high-sodium, low-potassium diet.

See Evaluating Your Response in Appendix B.

- Include the following in the teaching plan:
  - Self-administration of steroids
  - The importance of carrying at all times an emergency kit containing parenteral cortisone and a syringe/needle
  - Wearing a medical alert bracelet that says "Adrenal insufficiency—takes hydrocortisone"
  - Increasing oral fluid intake and maintaining a diet high in sodium and low in potassium
  - The necessity of altering the medication dose when experiencing emotional or physical stressors
  - The importance of continuing healthcare.

  One of the most important components of caring for the patient with Addison's disease is teaching both the patient and family to provide care. The length of treatment and the side effects of medications can discourage adherence to the regimen.

Continuity of Care

The patient with Addison's disease provides self-care at home. One of the most important components of caring for the patient with Addison's disease is teaching both the patient and family to provide care. Family stability, an awareness of the serious nature of the disease, and the effectiveness of treatment all promote adherence. The length of treatment and the side effects of medications, however, can discourage adherence. In addition to the information in the teaching topics included in the preceding section, include the following topics:

- Referral to social worker, if appropriate
- Referral to community agencies for continued education and support
- Helpful resources: National Institute of Diabetes and Digestive and Kidney Diseases (Addison's disease), Endocrine Society, and American Association of Clinical Endocrinologists

THE PATIENT WITH PHEOCHROMOCYTOMA

Pheochromocytomas are tumors of chromaffin tissues in the adrenal medulla. These tumors, which are usually benign, produce catecholamines (epinephrine or norepinephrine) that stimulate the sympathetic nervous system. Although many organs are affected, the most dangerous effects are peripheral vasoconstriction and increased cardiac rate and contractility with resultant paroxysmal hypertension. Systolic blood pressure may rise to 200 to 300 mmHg, the diastolic to 150 to 175 mmHg. Attacks are often precipitated by physical,

emotional, or environmental stimuli. This condition, while rare, is life threatening.

A pheochromocytoma is diagnosed by increased levels of catecholamines and their metabolites (metanephrines) in the blood or urine, by x-ray studies, and by surgical exploration. Removal of the tumor(s) by adrenalectomy is the treatment of choice.

Disorders of the Pituitary Gland

The pituitary gland produces hormones that affect multiple body systems through regulation of endocrine function. Target tissues include the thyroid, adrenal cortex, ovary, uterus, mammary glands, testes, and kidneys. Disorders result from an excess or deficiency of one or more of the pituitary hormones due to a pathologic condition within the gland itself or to hypothalamic dysfunction.

Although disorders of the pituitary cause diverse and serious problems, they are not as common as disorders of other endocrine glands. Hyperpituitarism and hypopituitarism are discussed in this section.

THE PATIENT WITH DISORDERS OF THE ANTERIOR PITUITARY GLAND

Hyperfunction of the anterior pituitary gland, characterized by excess production and secretion of one or more trophic hormones, is usually the result of a pituitary tumor or pituitary hyperplasia. The most common cause of hyperpituitarism is a benign adenoma. The manifestations result from pressure on the optic nerve causing visual changes or an excess of growth hormone (GH), prolactin (PRL), ACTH, or TSH. Disorders related to excess growth hormone are discussed below.

Hypofunction of the anterior pituitary gland results in a deficiency of one or more of the gland's hormones. Conditions causing hypopituitarism include pituitary tumors; surgical removal of the pituitary gland; radiation; and pituitary infarction, infection, or trauma.

Pathophysiology and Manifestations

Growth hormone (somatotropin) is produced throughout life by cells in the anterior pituitary. GH stimulates the production of IGF-1 (an insulin-like growth factor) by the liver. GH is necessary for growth and also contributes to metabolic regulation. GH stimulates all aspects of cartilage growth, and one of its major effects is to stimulate the growth of the epiphyseal cartilage plates of long bones. In addition, other body tissues respond to the metabolic effect of GH and IGF-1 with increases in bone width and the growth of visceral and endocrine organs, skeletal and cardiac muscle, skin, and connective tissue. Gigantism and acromegaly result from overstimulation. Growth retardation and short stature result from deficient production of GH.

GIGANTISM

Gigantism occurs when GH hypersecretion begins before puberty and the closure of the epiphyseal plates. The person becomes abnormally tall, often exceeding 213 cm (7 ft) in height, but body proportions are relatively normal. Most often the result of a tumor, the condition is rare today as a result of improved diagnosis and treatment.

ACROMEGALY

Acromegaly, which literally means "enlarged extremities," occurs when sustained GH and IGF-1 hypersecretion begins during adulthood, most commonly because of pituitary tumors. IGF-1 causes most of the clinical manifestations of acromegaly (Grossman & Porth, 2014). When excess GH production develops in adulthood, the person does not grow taller because the long bone epiphyses are closed. As a result of excess GH, the small bones of the hands and feet, the membranous bones of the skull, connective tissue, and soft tissues continue to grow. The forehead enlarges, the maxilla lengthens, the tongue enlarges, and the voice deepens. Overgrowth of bone and soft tissue in the hands and feet causes patients to buy increasingly larger rings, gloves, and shoes.

Other manifestations of acromegaly include peripheral nerve damage from entrapment of nerves, headache, hypertension, heart failure, skin thickening and copious sweating, seizures, and visual disturbances. Changes in appearance are subtle and diagnosis is usually made 10 years or more after onset of GH hypersecretion. Impaired glucose tolerance and diabetes may develop. Arthralgias in the large joints develop secondary to the bone and connective tissue growth. Manifestations may be relieved by treatment that halts excessive GH and IGF-1 production.

●○● INTERPROFESSIONAL CARE

Acromegaly is treated by surgical removal or irradiation of the pituitary tumor. A transsphenoidal or transfrontal surgical procedure is most commonly used. Somatostatin receptor binding drugs (SRBDs) suppress the anterior pituitary gland and decrease GH levels. These are administered by injection, and gastrointestinal side effects are common for the first couple of weeks. Gallstones may occur within a year of beginning treatment. Growth hormone receptor antagonists lower IGF-1 production and are used if manifestations persist with SRBDs. Radiation therapy is used when GH-producing tumors persist despite surgery or become resistant to medical therapies (Somatostatin analogues, 2010).

●○● NURSING CARE

Patients with anterior pituitary disorders require interventions to help in coping with physical and emotional changes, as well as to prevent complications involving other organs and functions of the endocrine system. Nursing care for the patient having cranial surgery is discussed in Chapter 42.

THE PATIENT WITH DISORDERS OF THE POSTERIOR PITUITARY GLAND

Disorders of the posterior pituitary are related primarily to excessive or deficient antidiuretic hormone (ADH) secretion. The disorders discussed here are the syndrome of inappropriate ADH secretion and diabetes insipidus.

Pathophysiology and Manifestations

ADH, also known as vasopressin, regulates water excretion by the kidneys. Antidiuretic hormone is secreted in response to increased serum osmolality and decreased circulatory volume, which are monitored by osmoreceptors in the hypothalamus. When hyperosmolality or a low circulating volume occur, ADH secretion increases, and water is reabsorbed, thus restoring blood volume and reducing its osmolality. Hypo-osmolality suppresses ADH secretion, and renal water excretion increases.

SYNDROME OF INAPPROPRIATE ADH SECRETION

The **syndrome of inappropriate ADH secretion (SIADH)** is characterized by high levels of ADH with water retention and small amounts of concentrated urine output. This disorder may be caused by the ectopic production of ADH by malignant tumors (e.g., oat cell carcinoma of the lung, pancreatic carcinoma, leukemia, and Hodgkin's lymphoma). SIADH may occur with a head injury or CNS disorders such as stroke, pulmonary disease (including pneumonia or use of positive pressure ventilation), or as an adverse effect of medications such as selective serotonin reuptake inhibitors (SSRIs) used to treat depression, barbiturates, or anesthetics.

Manifestations of SIADH occur as a result of water retention, hyponatremia, and reduced serum osmolality. Water moves from the hypotonic plasma and the interstitial spaces into the cells. Despite fluid retention, the patient may experience thirst. Urinary output decreases and the urine becomes very concentrated.

Cerebral edema develops, causing early manifestations such as headache, nausea and vomiting. Changes in mental status or personality, lethargy, irritability, and seizures can follow if hyponatremia is significant. Weight gain may occur but usually no edema is present, because water is distributed between the intracellular and extracellular spaces.

Treatment addresses the low serum sodium and cerebral edema. Fluid intake is restricted to gradually reduce total body water. Besides keeping the patient safe, nursing care involves teaching the patient about restricting fluids to 1 L/day. Fluid restriction continues until the syndrome resolves or is corrected,. Diuretics such as furosemide are used to decrease fluid volume. Demeclocycline (Declomycin) is a tetracycline antibiotic that suppresses ADH activity, resulting in increased urine production. Lithium may be used because it decreases renal responsiveness to ADH. Vasopressin antagonists may be given for SIADH. These drugs are especially beneficial for SIADH in individuals with heart failure (McPhee et al., 2012).

An intravenous hypertonic solution of sodium chloride (3% saline) may be required if the sodium is critically low. IV replacement of sodium must be monitored carefully to prevent rapid infusion. Too rapid replacement of sodium can cause demyelination of the central nervous system, which results in permanent neurologic dysfunctions. The recommended rate of sodium infusion is 10 to 20 mEq/day (John & Day, 2012).

DIABETES INSIPIDUS

Diabetes insipidus is the result of ADH insufficiency. The two types are as follows:

- *Neurogenic diabetes insipidus* can either result from a disruption of the hypothalamus and pituitary gland (as from trauma, irradiation, or cranial surgery) or be idiopathic.
- *Nephrogenic diabetes insipidus* is a disorder in which the renal tubules are not sensitive to ADH. This may be familial in origin or the result of renal failure.

Diabetes insipidus may result from brain tumors or infections, pituitary surgery, cerebrovascular accidents, and renal and organ failure. It is also a complication of closed head trauma with increased intracranial pressure.

A deficit of ADH causes excretion of large amounts of dilute urine (*polyuria*), in some instances as much as 12 L/day. The patient has extreme thirst and drinks large volumes of water (*polydipsia*). If unable to replace the water loss, the patient becomes dehydrated and hypernatremic. Even though the serum osmolality is high, the urine is dilute and has a low specific gravity.

If this disorder is caused by cerebral injury, manifestations commonly appear 3 to 6 days after the initial injury and last for 7 to 10 days. Initial care of the patient is focused on correcting fluid deficits, normalizing the sodium levels, and replacing deficient ADH. Intake and output are measured carefully and fluid is often replaced based on a calculation that adds fluid losses from the prior hour to an hourly base rate of fluid. Rapid and careful fluid replacement is essential to prevent hypovolemia. Hypotonic solutions of sodium are used if the sodium level is high. High serum sodium can cause neurologic deficits and can result in seizures (refer to Chapter 10). Seizure precautions are indicated if serum sodium is critically high. ADH replacement is necessary and comes in a variety of preparations. Desmopressin (DDAVP) can be administered nasally or parenterally. Vasopressin (Pitressin) can be administered as a titrated IV infusion (John & Day, 2012). Diabetes insipidus may also be a chronic illness requiring lifelong treatment and care. See Table 19–3 for a comparison of posterior pituitary gland disorders.

●○● INTERPROFESSIONAL CARE

SIADH is treated by correcting underlying causes, treating the hyponatremia with intravenous hypertonic saline, and restricting oral fluids to less than 800 mL/day.

TABLE 19–3 Comparison of Posterior Pituitary Gland Disorders

SIADH	Diabetes Insipidus
Excessive ADH	Deficient ADH
Fluid volume excess	Fluid volume deficit
Hyponatremia: sodium < 135 mEq/L (low)	Hypernatremia: sodium > 145 mEq/L (high)
Serum osmolality < 275 mOsm/kg (low)	Serum osmolality > 295 mOsm/kg (high)
Urinary specific gravity > 1.010 (concentrated, dark)	Urinary specific gravity < 1.005 (very dilute)
Restrict fluid intake	Encourage fluid intake
Slow sodium replacement	IV fluid replacement (replaced milliliter for milliliter) if necessary
	ADH replacement
Demeclocycline (Declomycin) (oral agent) to suppress ADH activity	Desmopressin (DDAVP) (nasal spray) to replace deficient ADH

Diabetes insipidus is treated by correcting underlying causes, if possible. Other medical interventions include administering intravenous hypotonic fluids, increasing oral fluids, and replacing ADH hormone.

●○● NURSING CARE

Nursing care for the patient with SIADH and diabetes insipidus focuses on patient problems with fluid and electrolyte balance. See Chapter 10 for specific nursing interventions for the patient with fluid volume excess or deficit, hyponatremia, or hypernatremia.

CHAPTER HIGHLIGHTS

- **Hormones regulate growth, development, and metabolism. Homeostasis is dependent on a balanced level of each type of hormone. Not only do hormones affect organ function, but they also interact, and when excesses or deficits occur, manifestations of other endocrine disorders may result.**
- **Patients with endocrine disorders often experience life-altering changes that require nursing assessment, care, and follow-up with the goal of providing holistic care to the patient.**
- **Thyroid disorders are identified by their effects on metabolism: hyperthyroidism causes an increased metabolic rate, and hypothyroidism causes a decreased metabolic rate. Both can be life-threatening if ineffectively managed.**
- Thyroid disorders are the most common endocrine disorders. Occurring mainly among women, these diseases change body image and impose upsets to energy levels, creating fatigue and exhaustion.
- Diagnostic tests and therapies are available to identify and treat thyroid disorders. Surgery, radiation therapy, and medications support good quality of life, but the medications must be used throughout the lifetime.
- **The parathyroid glands regulate serum calcium levels. Manifestations of parathyroid disorders are primarily those related to hypercalcemia or hypocalcemia.**
- **Cushing's syndrome and Addison's disease are polar opposites. Treatment of one can create the manifestations of the other. Patients with these diseases require education to fully grasp the significance of the condition and the importance of adhering to the treatment plan.**
- The pituitary gland, in conjunction with the hypothalamus, is the master gland of the body. Pituitary disorders, therefore, can have wide-ranging effects. Excess growth hormone due to hyperfunction of the anterior pituitary in an adult causes acromegaly.
- **Disorders of the anterior pituitary may be manifested by the effects of excess growth hormone, whereas posterior pituitary disorders affect the production of antidiuretic hormone and affect fluid and electrolyte balance.**

TEST YOURSELF NCLEX-RN® REVIEW

1. The nurse is preparing teaching for a patient diagnosed with Graves' disease. What should the nurse explain about the etiology of this health problem?
   1. It is a genetic disorder.
   2. It is caused by an allergy.
   3. It occurs in response to an infection.
   4. It develops as an autoimmune response.

2. A patient with hyperthyroidism is scheduled to receive radioactive iodine. What should the nurse explain about the use of radioactive iodine in hyperthyroidism?
   1. The thyroid gland takes up iodine in any form.
   2. Radioactive iodine reduces the vascularity of the thyroid gland.
   3. Irradiation of the thyroid gland decreases the risk of hypothyroidism.
   4. Doses of radioactive iodine are too small to be hazardous to other body parts.

3. During a physical examination the nurse assesses a patient with hypothyroidism as having a goiter. What physiologic process caused the thyroid gland to enlarge?
   1. an increased dietary iodine intake
   2. a compensatory effort to produce more TH
   3. an excess of TH that stimulated thyroid follicles
   4. tissue hypertrophy in response to increased TH

4. While reviewing a medication list, the nurse learns that a new patient has taken cortisone as treatment for rheumatoid arthritis for several years. What endocrine disorder is the patient most at risk for developing?
   1. acromegaly
   2. hypothyroidism
   3. hyperthyroidism
   4. Cushing's syndrome

5. The nurse is teaching a patient with Addison's disease about the disease process. Which statement illustrates that the patient understands the teaching?
   1. "I wonder why I look suntanned all the time."
   2. "I know I should never alter my dose of medications."
   3. "I have purchased an emergency kit and keep it with me all the time."
   4. "I will be sure to stop taking my medications when I have an infection."
6. The nurse suspects that a patient with syndrome of inappropriate antidiuretic hormone secretion is experiencing hyponatremia. Which manifestation of hyponatremia did the nurse most likely assess?
   1. irritability
   2. weight loss
   3. constipation
   4. hyperkalemia
7. The home health nurse is planning care for a patient with hyperparathyroidism and osteoporosis. Which nursing diagnosis is the priority for this patient?
   1. *Fear*
   2. *Risk for Injury*
   3. *Social Isolation*
   4. *Risk for Chronic Low Self-Esteem*
8. The nurse is concerned that a patient is showing signs of hypercalcemia. What did the nurse assess in this patient?
   1. oliguria
   2. positive Chvostek's sign
   3. diminished bowel sounds
   4. hyperactive deep tendon reflexes
9. A patient recovering from a thyroidectomy is experiencing tingling around the mouth and fingertips. What should these manifestations suggest to the nurse?
   1. Addisonian crisis
   2. hypoparathyroidism
   3. Cushing's syndrome
   4. hyperparathyroidism
10. A female patient with Cushing's syndrome is distressed because of the appearance of abdominal stretch marks. What should the nurse explain to the patient about this skin change?
    1. Excessive mineralocorticoids reduce the absorption of calcium.
    2. Excessive glucocorticoids affect normal carbohydrate metabolism.
    3. Excessive glucocorticoids cause a loss of collagen and connective tissue.
    4. Excessive cortisol results in changes in protein metabolism and protein catabolism.

20 Nursing Care of Patients with Diabetes Mellitus

LEARNING OUTCOMES

1. Describe the prevalence and incidence of diabetes mellitus (DM).
2. Explain the pathophysiology, risk factors, manifestations, and complications of type 1 and type 2 DM.
3. Provide rationale for diagnostic tests used for screening, diagnosis, and monitoring of DM.
4. Discuss the nursing implications for insulin and oral hypoglycemic agents used to treat patients with DM.
5. Discuss best practices of self-care management of DM related to diet planning, sick day management, and exercise.
6. Compare and contrast the manifestations of hypoglycemia, diabetic ketoacidosis (DKA), and hyperosmolar hyperglycemic state (HHS).

CLINICAL COMPETENCIES

1. Assess blood glucose levels and patterns of hyper- and hypoglycemia in patients with DM.
2. Use assessed data, patient values, clinical expertise, and evidence to determine priority nursing diagnoses and select and implement individualized nursing interventions.
3. Administer oral and injectable medications used to treat DM knowledgeably and safely.
4. Provide individualized care to patients with hypoglycemia, diabetic ketoacidosis, and hyperosmolar hyperglycemic state.
5. Effectively communicate with and function within the interprofessional team to plan and provide patient care.
6. Provide appropriate teaching to facilitate self blood glucose monitoring, administration of oral and injectable hypoglycemic medications, diabetic diet, appropriate exercise, and effective foot care.
7. Adapt individual and cultural values and variations as well as expressed needs and preferences into the plan of care for patients with DM.
8. Revise plan of care as needed to provide effective interventions to promote, maintain, or restore normal glucose levels.

MAJOR CHAPTER CONCEPTS

- Diabetes mellitus (DM) is a very common condition with approximately 1.9 million new cases diagnosed each year in the United States. The long-term complications of diabetes, including cardiovascular disease, strokes, and kidney failure, are among the leading causes of death in this country.
- The onset, pathophysiology, and acute complications of type 1 and type 2 DM differ from one another. Unlike type 1 DM, in which the onset is often sudden, the development of type 2 DM starts with insulin resistance (prediabetes) that may be asymptomatic for many years.
- The incidence of type 2 DM is increasing in epidemic proportions in all racial and ethnic groups in the United States, often triggered by obesity and sedentary lifestyles.
- Tighter, intensive glycemic control is increasingly the focus of care of patients with hyperglycemia (patients with diabetes and prediabetes).
- Products to manage DM include insulins, noninsulin hypoglycemics, and blood glucose monitoring devices. Nurses must be familiar with these products and help patients become proficient in their use.
- Motivation for self-care by the patient with DM continues to be a challenge because treatment commonly includes lifestyle changes. Through education and support, patients can achieve control of DM and avoid complications.

urine ketone tests, *509*

Diabetes Mellitus

Diabetes mellitus (DM) is a common chronic disease of adults requiring continuing medical supervision and patient self-care education. However, depending on the type of DM and the age of the patient, both patient needs and nursing care may vary greatly. Consider the following examples:

- Cheryl Draheim is a 45-year-old schoolteacher. She developed DM at age 34 after an automobile crash caused severe pancreatic injuries. Ms. Draheim has always been very careful about taking her insulin, following her diet, and exercising regularly. However, she is beginning to notice that her vision is getting worse and that she is having increasing pain in her legs, especially after standing for long periods of time. Ms. Draheim says that sometimes she believes the disease controls her more than she controls it.
- Tom Chang is 53 years old. Early in his 40s, Tom was diagnosed with type 2 DM. Although Mr. Chang was taught about the disease and the importance of taking his oral medications, following his diet plan, and getting exercise, he rarely did more than take the medication. Five years ago, he was hospitalized for hyperglycemia and started taking insulin. Last year Mr. Chang had a stroke, leaving him unable to walk. Now, he has been admitted to the hospital for treatment of gangrene of the large toe on his left foot.
- Grace Staples is an independent 82-year-old woman who lives alone and happily takes care of her two cats. She is slightly overweight. Last year, during Ms. Staples's annual eye examination, eye changes typical for DM were found. She was referred to her family physician, who diagnosed type 2 DM and started her on oral medications. Ms. Staples sticks to her diet, walks a mile every day, and plans to live to be 100.

As illustrated in these examples, DM is not a single disorder but a group of chronic disorders of the endocrine pancreas, all categorized under a broad diagnostic label. The condition is characterized by inappropriate hyperglycemia caused by a relative or absolute deficiency of insulin or by cellular resistance to the action of insulin. Of the several classifications of DM, this chapter focuses on type 1 and type 2. Type 1 DM is the result of pancreatic islet cell destruction and a total deficit of circulating insulin; type 2 DM results from insulin resistance with a defect in compensatory insulin secretion.

DM has been recognized as a disease for centuries, but it was not until 1921 that techniques were developed for extracting insulin from pancreatic tissue and for measuring blood glucose. At the same time, researchers discovered that insulin, when injected, produces a dramatic drop in blood glucose. This meant that DM was no longer a terminal illness, because hyperglycemia could now be controlled. Since that time, oral hypoglycemic drugs, human insulin products, insulin pumps, home blood glucose monitoring, and transplantation of the pancreas or of pancreatic islet or beta cells have advanced the treatment and care of people with DM.

Patients with DM face lifelong changes in lifestyle and health status. Nursing care is provided in many settings for the diagnosis and care of the disease and treatment of complications. A major role of the nurse is that of educator in both hospital and community settings.

Incidence and Prevalence

Approximately 1.9 million new cases of DM are diagnosed each year in the United States. This chronic illness affects an estimated 25.8 million people; of that number, 18.8 million people have been diagnosed and an estimated 7 million are undiagnosed (National Institutes of Health [NIH], 2011). Additionally, 79 million Americans over the age of 20 (35% of U.S. adults) have prediabetes. The prevalence of DM (especially type 2 DM) among American adults is increasing rapidly and more younger adults are developing diabetes. Blacks and Native Americans are disproportionately affected by DM. See the Cultural Diversity feature.

DM is the seventh leading cause of death by disease in the United States, primarily because of the widespread cardiovascular effects that result in atherosclerosis, coronary heart disease, and stroke (Centers for Disease Control and Prevention [CDC], 2011). People with DM are two to four times more likely to have heart disease, and two to four times more likely to have a stroke than people who do not have the disease. DM is the leading cause of end-stage renal disease (kidney failure), and the major cause of newly diagnosed blindness. DM is the most frequent cause of nontraumatic amputations (NIH, 2011).

Americans with DM use a disproportionate share of the nation's healthcare services. They visit outpatient services and healthcare providers' offices more often than people who do not have the disease, and they require more frequent hospitalizations with more days of in-hospital treatment. The cost of illness and resulting loss of productivity for people with DM exceeds $174 billion per year, according to an estimate by the American Diabetes Association (NIH, 2011).

Overview of Endocrine Pancreatic Hormones and Glucose Homeostasis

The hormones produced by several different cells of the endocrine pancreas, along with hormones produced by the small intestine, are responsible for glucose homeostasis in the body.

HORMONES

The endocrine pancreas produces hormones necessary for the metabolism and cellular utilization of carbohydrates, proteins, and fats. The cells that produce these hormones are clustered in groups of cells called the islets of Langerhans. These islets have three different types of cells:

- *Alpha cells* produce the hormone *glucagon*, which stimulates the breakdown of glycogen in the liver, the formation of carbohydrates in the liver, and the breakdown of lipids in both the liver and adipose tissue. The primary function of glucagon is to decrease glucose oxidation and to increase blood glucose levels. Through **glycogenolysis** (the breakdown of liver glycogen) and **gluconeogenesis** (the formation of glucose from fats and proteins), glucagon prevents blood glucose from decreasing below a certain level when the body is fasting or in between meals. The action of glucagon is initiated in most people when blood glucose falls below about 70 mg/dL.
- *Beta cells* secrete the hormone *insulin*, which facilitates the movement of glucose across cell membranes into cells, decreasing blood glucose levels. Insulin prevents the excessive breakdown of glycogen in the liver and in muscle, facilitates lipid formation while

inhibiting the breakdown of stored fats, and helps move amino acids into cells for protein synthesis. After secretion by the beta cells, insulin enters the portal circulation, travels directly to the liver, and is then released into the general circulation. Circulating insulin is rapidly bound to receptor sites on peripheral tissues (especially muscle and fat cells) or is destroyed by the liver or kidneys. Insulin release is regulated by blood glucose; it increases when blood glucose levels increase, and it decreases when blood glucose levels decrease. When an individual eats food, insulin levels begin to rise in minutes, peak in 3 to 5 minutes, and return to baseline in 2 to 3 hours. Amylin is a glucose-regulating hormone secreted by the beta cells with insulin that affects postprandial (postmeal) glucose levels. It impairs glucagon secretion and slows the rate at which glucose travels to the small intestine for absorption.

- *Delta cells* produce *somatostatin*, which acts within the islets of Langerhans to inhibit the production of both glucagon and insulin. Somatostatin slows gastrointestinal motility, allowing more time for food to be absorbed.

In addition, the small intestine produces hormones that lower blood glucose following the intake of a meal. Glucagon-like peptide-1 (GLP-1) and glucose-dependent insulinotropic polypeptide (GIP) are secreted from the small intestine to increase insulin release after a meal has been ingested. This hormone-stimulated insulin increase following ingestion of food is called an incretin effect. An injectable form of these hormones, exenatide (Byetta), is an incretin mimetic used in the treatment of type 2 DM.

BLOOD GLUCOSE HOMEOSTASIS

All body tissues and organs require a constant supply of glucose; however, not all tissues require insulin for glucose uptake. The brain, liver, intestines, and renal tubules do not require insulin to transfer glucose into their cells. Skeletal muscle, cardiac muscle, and adipose tissue do require insulin for glucose movement into the cells.

Normal blood glucose is maintained in healthy people primarily through the actions of insulin and glucagon. Increased blood glucose levels, amino acids, and fatty acids stimulate pancreatic beta cells to produce insulin. As cells of cardiac muscle, skeletal muscle, and adipose tissue take up glucose, plasma levels of nutrients decrease, suppressing the stimulus to produce insulin. If blood glucose falls, glucagon is released to raise hepatic glucose output, raising glucose levels. Catecholamines (epinephrine, norepinephrine, and dopamine), growth hormone, cortisol, and glucagon (collectively referred to as *glucose counterregulatory hormones*) also stimulate an increase in blood glucose in times of hypoglycemia, stress, growth, or increased metabolic demand. The regulation of blood glucose levels by insulin and glucagon is illustrated in Figure 20–1 ■.

FOCUS ON CULTURAL DIVERSITY

Estimates of Prevalence of Diabetes Mellitus

- 10.2% (15.7 million) of all non-Hispanic Whites ages 20 years or older have DM.
- 18.7% (4.9 million) of non-Hispanic African Americans ages 20 years or older have DM.
- 11.8% of Hispanic/Latino Americans ages 20 years or older have DM. Rates of diabetes are lower among Cuban Americans and Central and South Americans (7.6%), and higher for Mexican Americans (13.3%) and Puerto Rican Americans (13.8%).
- 8.4% of Asian Americans ages 20 years or older have DM.
- 16.1% of American Indians and Alaska Natives have DM. The rate varies; only 5.5% of Alaska natives have DM, whereas 33.5% of Native Americans in southern Arizona have DM (CDC, 2011).

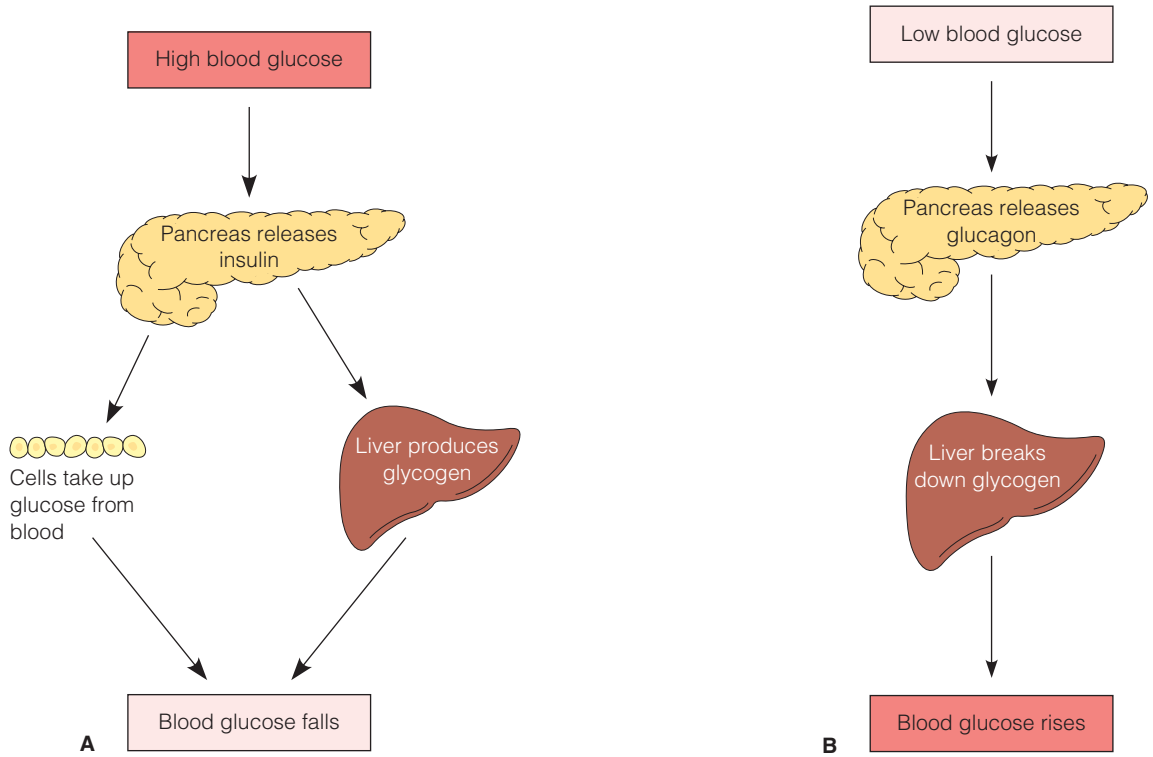

Figure 20–1 ■ Regulation (homeostasis) of blood glucose levels by insulin and glucagon. A, High blood glucose is lowered by insulin release. B, Low blood glucose is raised by glucagon release.

Pathophysiology of DM

DM is a group of metabolic diseases characterized by hyperglycemia resulting from defects in the secretion of insulin, the action of insulin, or both. Carbohydrate, fat, and protein metabolism are affected by the imbalance between insulin availability and insulin need. Cellular starvation occurs as the body is unable to move glucose into fat and muscle cells (Grossman & Porth, 2014).

There are four major types of DM. Type 1 DM (5% to 10% of diagnosed cases), type 2 DM (90% to 95% of diagnosed cases), gestational DM (2% to 5% of all pregnancies), and other specific types of DM (1% to 2% of diagnosed cases). The classification and characteristics of the four types are described in Table 20–1.

TYPE 1 DIABETES

Type 1 DM most often occurs before the age of 30 years (often in childhood and adolescence), but it may occur at any age, even in the 80s and 90s. This disorder is characterized by **hyperglycemia** (elevated blood glucose levels), a breakdown of body fats and proteins, and the development of **ketosis** (an accumulation of ketone bodies produced during the oxidation of fatty acids). Type 1 DM is the result of the destruction of the beta cells of the islets of Langerhans in the pancreas. When beta cells are destroyed, insulin is no longer produced. Although type 1 DM may be classified as either an autoimmune or idiopathic disorder, 90% of the cases are immune mediated. The disorder begins with insulitis, a chronic inflammatory process that occurs in response to the autoimmune destruction of islet cells. This process slowly destroys production of insulin, with the onset of hyperglycemia occurring when 80% to 90% of beta-cell function is lost. This process usually occurs over a long preclinical period. It is believed that both alpha-cell and beta-cell functions are abnormal, with a lack of insulin and a relative excess of glucagon resulting in hyperglycemia.

RISK FACTORS Genetic predisposition plays a role in the development of type 1 DM. Although the risk in the general population ranges from 1 in 400 to 1 in 1000, the child of an individual with DM has a 1 in 20 to 1 in 50 risk. Genetic markers that determine immune responses have been found in most people diagnosed with type 1 DM. Although the presence of these markers does not guarantee that the individual will develop type 1 DM, it does indicate increased susceptibility (Grossman & Porth, 2014).

Environmental factors are believed to trigger the development of type 1A DM. The trigger can be a viral infection (mumps, rubella, or coxsackievirus B4) or a chemical toxin, such as those found in smoked and cured meats. As a result of exposure to the virus or chemical, an abnormal autoimmune response occurs in which antibodies respond to normal islet beta cells as though they were foreign substances, destroying them. The manifestations of type 1 DM appear when approximately 90% of the beta cells are destroyed. However, manifestations may appear at any time during the loss of beta

TABLE 20–1 Classification and Characteristics of Diabetes Mellitus

	Classification	Characteristics
Type 1 DM	A. Immune mediated	Beta cells are destroyed, usually leading to absolute insulin deficiency. Markers to the immune destruction of the beta cells include islet cell autoantibodies (ICAs) and insulin autoantibodies (IAAs). The rate of beta-cell destruction is variable, usually more rapid in infants and children and slower in adults. Destruction of the beta cells has genetic predispositions and is also related to environmental factors as yet undefined.
	B. Idiopathic	Has no known etiologic causes. Most patients are of African or Asian descent. Is strongly inherited. Need for insulin may be intermittent.
Type 2 DM		May range from predominantly insulin resistance with relative insulin deficiency to a predominantly secretory defect with insulin resistance. There is no immune destruction of beta cells. Initially, and in some cases for the entire life, insulin is not necessary. Most people with this form are obese, or have an increased amount of abdominal fat. Risks for development include increasing age, obesity, and a sedentary lifestyle. Occurs more frequently in women who have had gestational DM, and in people with lipid disorders or hypertension. There is a strong genetic predisposition.
Other specific types	A. Genetic defects of beta cell	Hyperglycemia occurs at an early age (usually before age 25). This type is referred to as maturity-onset DM of the young (MODY).
	B. Genetic defects in insulin action	Are genetically determined. Dysfunctions may range from hyperinsulinemia to severe DM.
	C. Diseases of the exocrine pancreas	Acquired processes causing DM include pancreatitis, trauma, infection, pancreatectomy, and pancreatic cancer. Severe forms of cystic fibrosis and hemochromatosis may damage beta cells and impair insulin secretion.
	D. Endocrine disorders	Excess amounts of counterregulatory hormones (e.g., growth hormone, cortisol, glucagon, and epinephrine) impair insulin secretion, resulting in DM in people with Cushing's syndrome, acromegaly, and pheochromocytoma.
	E. Drug or chemical induced	Many drugs impair insulin secretion, precipitating DM in people with predisposing insulin resistance. Examples are nicotinic acid, glucocorticoids, thyroid hormone, thiazides, and phenytoin.
	F. Infections	Certain viruses may cause beta-cell destruction, including congenital measles, cytomegalovirus, adenovirus, and mumps.
Gestational diabetes mellitus (GDM)		Any degree of glucose intolerance with onset or first recognition during pregnancy.

cells if an acute illness or stress increases the demand for insulin beyond the reserves of the damaged cells. The actual cause and exact sequence are not completely understood, but research continues to identify the genetic markers of this disorder and to investigate ways of altering the immune response to prevent or cure type 1 DM.

Type 1B DM, a rare form, is strongly inherited and affects people of African and Asian descent. It is not an autoimmune disorder; beta-cell destruction varies and periods of ketoacidosis develop.

MANIFESTATIONS The manifestations of type 1 DM are the result of a lack of insulin to transport glucose across the cell membrane into the cells (Figure 20–2 ■). Glucose molecules accumulate in the circulating blood, resulting in hyperglycemia. Hyperglycemia causes serum hyperosmolality, drawing water from the intracellular spaces into the vascular circulation. The increased blood volume increases renal blood flow, and the hyperglycemia acts as an osmotic diuretic. The resulting osmotic diuresis increases urine output and causes loss of electrolytes (sodium and potassium). This condition is called **polyuria**. When the blood glucose level exceeds the renal threshold for glucose—usually about 180 mg/dL—glucose is excreted in the urine, a condition called **glucosuria**. The decrease in interstitial and later intracellular volume and the increased urinary output cause dehydration. The mouth becomes dry and thirst sensors are activated, causing the person to drink increased amounts of fluid (**polydipsia**).

Because glucose cannot enter the cell without insulin, energy production decreases. This decrease in energy stimulates hunger, and the person eats more food (**polyphagia**). Despite increased food intake, the person loses weight as the body loses water and breaks down fats and later proteins in an attempt to restore energy sources. Malaise and fatigue accompany the decrease in energy. Blurred vision is common, resulting from osmotic affects that cause swelling of the lenses of the eyes.

The classic manifestations are polyuria, polydipsia, and polyphagia, accompanied by weight loss, malaise, and fatigue, varying from slight to severe depending on the length of time the individual with type 1 DM goes without insulin. People with type 1 DM require an exogenous (external) source of insulin to maintain normal glucose metabolism. Without insulin, ketoacidosis rapidly threatens life. See the Multisystem Effects of Diabetes Mellitus illustration on page 507.

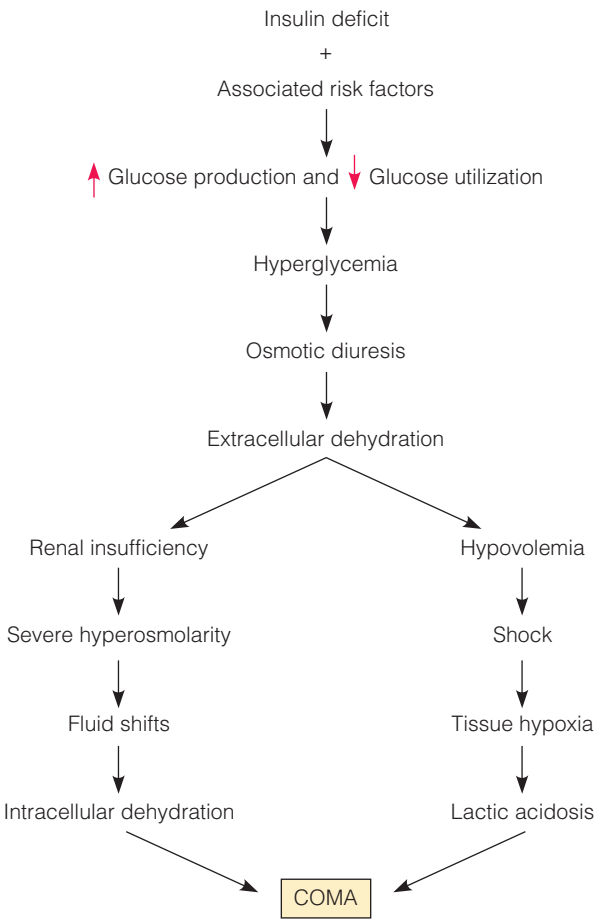

Figure 20–2 ■ Pathophysiologic results of type 1 DM.

TYPE 2 DIABETES

Type 2 DM is a condition of fasting hyperglycemia that occurs despite the availability of endogenous insulin. Type 2 DM can occur at any age but it is more often seen in middle age and older people. It is the most common form of DM. Heredity plays a role in its transmission, and the development of the disease is closely linked to lack of exercise and obesity. The level of insulin produced varies in type 2 DM, and despite its availability, insulin function is impaired by insulin-resistance in peripheral tissues. The liver produces more glucose than normal, dietary carbohydrates are not metabolized well, and eventually the pancreas secretes less than adequate amounts of insulin (Grossman & Porth, 2014). Insulin production usually is sufficient to prevent the breakdown of fats with resultant ketosis; thus, type 2 DM is characterized as a nonketotic form of DM. However, the function of insulin available is not sufficient to lower blood glucose levels through the uptake of glucose by muscle and fat cells. Treatment usually begins with prescriptions for weight loss and increased activity. If these changes can be sustained, no further treatment will be necessary for many individuals. Medications are begun when lifestyle changes are insufficient or cannot be maintained. Often, a combination of insulin and oral medication is used to achieve the best glycemic control in the patient with type 2 DM. New medications are aimed at treating specific pathologies that cause specific complications (Kulkarni et al., 2011).

PREDIABETES AND METABOLIC SYNDROME A major factor in the development of type 2 DM is cellular resistance to the effect of insulin. Insulin resistance occurs as much as 10 to 20 years before the onset of diabetes and is closely related to central obesity and lack of exercise. In obesity, insulin has a decreased ability to influence glucose absorption and metabolism by the liver, skeletal muscles, and adipose tissue. Increasing age, physiologic stress (as a result of illness and chronic stress), and some medications contribute to insulin resistance. **Metabolic syndrome** causes insulin resistance and leads to type 2 diabetes. It is characterized by a group of abnormalities:

- Central obesity, defined as waist circumference larger than 40 inches in men, or larger than 35 inches in women
- Hypertension, defined as blood pressure over 130/85 mmHg in adults
- Abnormal lipid panel with triglyceride levels over 150 mg/dL, high LDL, HDL less than 40 mg/dL in men or less than 50 mg/dL in women
- Fasting blood glucose greater than 100 mg/dL
- Hyperinsulinemia, which is often characterized by dark, thick, velvety skin in body folds and creases (acanthosis nigricans) commonly seen on the back of the neck and under the arms.

Prediabetes is characterized by impaired glucose tolerance and is defined by an abnormal glucose tolerance test. Some people have impaired glucose tolerance but do not have metabolic syndrome, though many individuals have both metabolic syndrome and impaired glucose tolerance. Insulin resistance coupled with impaired glucose tolerance leads to hyperglycemia, which is known to occur at short intervals and gradually increase in severity and duration many years before the diagnosis of diabetes. Hyperglycemia results in diabetes complications; thus, approximately half of those newly diagnosed with type 2 DM already have complications (Kulkarni et al., 2011).

RISK FACTORS The major risk factors for type 2 DM are the following:

- History of DM in parents or siblings. Although there is no identified HLA linkage, the children of an individual with type 2 DM have a two- to fourfold increased risk of developing type 2 DM and a 30% risk of developing a glucose intolerance (the inability to metabolize carbohydrate normally).
- Obesity, defined as being at least 20% over desired body weight or having a body mass index (BMI) of at least 27 kg/m^2.
- Physical inactivity.
- Race/ethnicity.
- In women, a history of gestational DM, polycystic ovary syndrome, or delivering a baby weighing more than 9 lb.
- Prediabetes and metabolic syndrome.

MANIFESTATIONS The person with type 2 DM experiences a slow onset of manifestations and is often unaware of the disease until seeking healthcare for some other problem. The hyperglycemia in type 2 DM is usually not as severe as in type 1 DM because of the presence of insulin, but similar manifestations occur, especially polyuria and polydipsia. Polyphagia and weight loss are common, though the person is often obese at the time of diagnosis. Other manifestations are the result of hyperglycemia: blurred vision, fatigue, paresthesias, and skin infections.

DM in the Older Adult

Older adults most often develop type 2 diabetes as a result of increased insulin resistance and decreased production of insulin. The National Institute of Diabetes and Digestive and Kidney Diseases estimates that 26.9% of the U.S. population over the age of 65 have DM (NIH, 2011). It is predicted that the number of older adults with DM will continue to increase because the incidence of the disease increases with age and because the number of people over age 65 is increasing.

The normal physiologic changes of aging may mask manifestations of the onset of DM. Manifestations of DM in older adults may not include the classic symptoms of polyuria and thirst. Conditions that signal potential complications of hyperglycemia, such as hypertension, periodontal disease, frequent infections, central arterial disease (i.e., carotid, cerebral, or coronary), peripheral arterial disease (i.e., impotence), slow gastric emptying (gastroparesis), and neuropathy, warrant screening presence of diabetes (American Diabetes Association [ADA], 2012a; Handelsman et al., 2011). Common problems in the older adult that make the diagnosis and management of DM more difficult are described in the Nursing Care of the Older Adult box. The older adult with DM also has a longer recovery period after surgery or serious illness. The benefits of tight glycemic control in an older adult with comorbid conditions versus the risks of hypoglycemia and decreased quality of life must be carefully balanced.

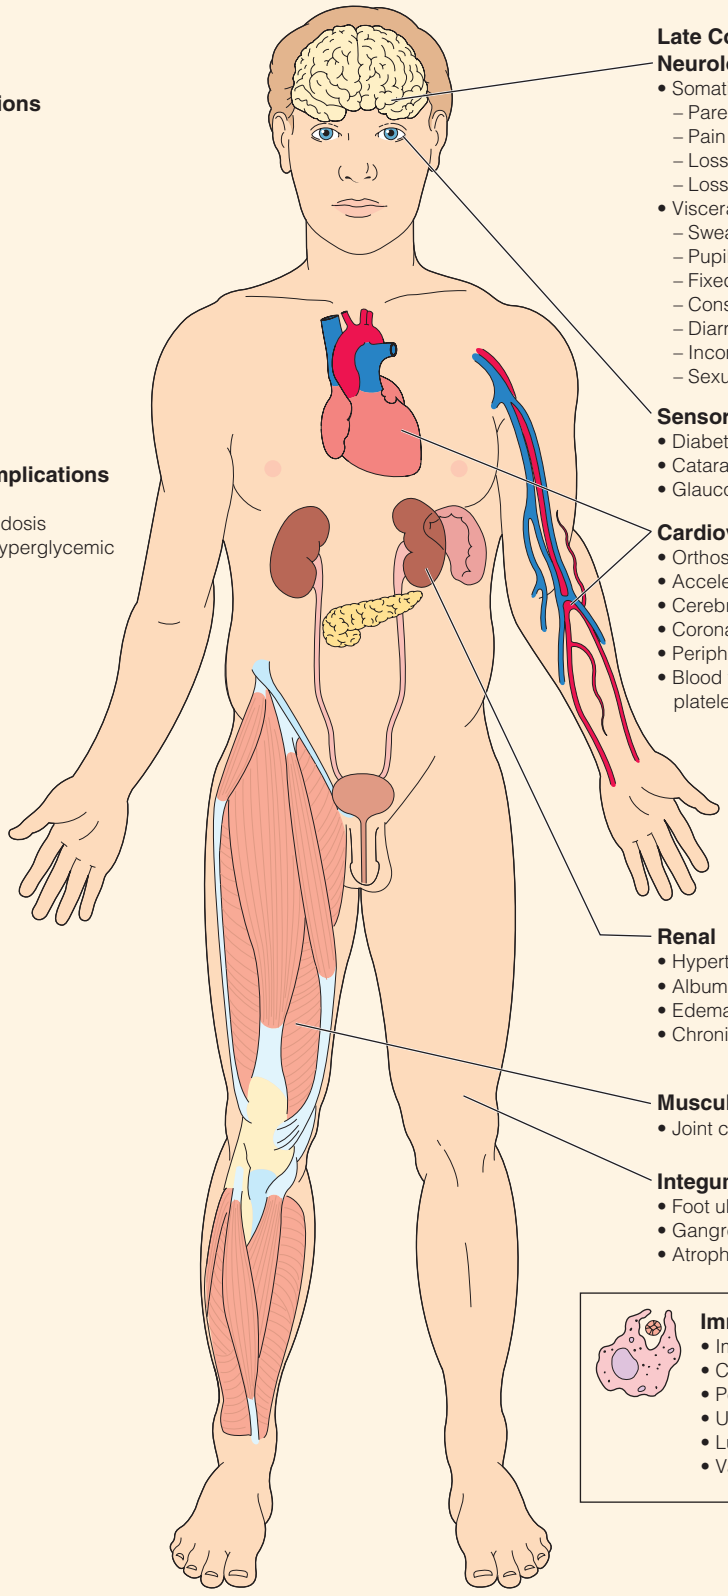
●○● INTERPROFESSIONAL CARE

Treatment of the patient with DM focuses on maintaining blood glucose at levels as nearly normal as possible through medications, dietary management, and exercise. The results of a 10-year DM Control and Complications Trial (DCCT), sponsored by the NIH, have significant implications for the management of type 1 DM. People in the study who kept their blood glucose levels close to normal by frequent monitoring, several daily insulin injections, and lifestyle changes that included exercise and a healthier diet reduced by 60% their risk for the development and progression of complications involving the eyes, the kidneys, and the nervous system. Patients with either type 1 DM or type 2 DM benefit from similar levels of control.

DIAGNOSIS

Diagnostic tests are conducted for screening purposes to diagnose DM, and ongoing laboratory tests are conducted to evaluate the effectiveness of diabetic management.

DIAGNOSTIC SCREENING The diagnostic criteria recommended by the American Diabetes Association (2014) have recently been updated and include the following:



1. A hemoglobin A_1C greater than or equal to 6.5%. This test should be performed using a method that is both National Glycohemoglobin Standardization Program (NGSP) certified and standardized to the DCCT assay.
2. Fasting plasma glucose (FPG) greater than or equal to 126 mg/dL (7.0 mmol/L). Fasting is defined as no caloric intake for 8 hours.
3. Two-hour PG greater than or equal to 200 mg/dL (11.1 mmol/L) during an oral glucose tolerance test (OGTT). The test should be performed with a glucose load containing the equivalent of 75 g anhydrous glucose dissolved in water.
4. A random plasma glucose greater than or equal to 200 mg/dL (11.1 mmol/L) in an individual with manifestations of hyperglycemia or hyperglycemic crisis.

Meeting Individualized Needs

Patients with Obesity after Gastrointestinal Surgery

Studies of patients with DM who have gastrointestinal surgery for morbid obesity show complete remission of type 2 DM in over three-quarters of cases. Laparoscopic adjustable gastric banding (LAGB) and Roux-en-Y gastric bypass (RYGB) result in remarkable reductions in blood glucose levels and Hgb A_1C. RYGB, which alters gastrointestinal anatomy, improves insulin sensitivity and is associated with total remission of DM in a significant percentage of patients (Buchwald et al., 2009). See Chapter 22 for more information about these procedures and related nursing care.

MULTISYSTEM EFFECTS OF
Diabetes Mellitus

Early Manifestations
- Type 1 DM
  - Polyuria
  - Polydipsia
  - Polyphagia
  - Weight loss
  - Glycosuria
  - Fatigue
- Type 2 DM
  - Polyuria
  - Polydipsia
  - Blurred vision

Progressive Complications
- Hyperglycemia
  - Diabetic ketoacidosis
  - Hyperosmolar hyperglycemic state
- Hypoglycemia

Late Complications

Neurologic
- Somatic neuropathies
  - Paresthesias
  - Pain
  - Loss of cutaneous sensation
  - Loss of fine motor control
- Visceral neuropathies
  - Sweating dysfunction
  - Pupillary constriction
  - Fixed heart rate
  - Constipation
  - Diarrhea
  - Incomplete bladder emptying
  - Sexual dysfunction

Sensory
- Diabetic retinopathy
- Cataracts
- Glaucoma

Cardiovascular
- Orthostatic hypotension
- Accelerated atherosclerosis
- Cerebrovascular disease (stroke)
- Coronary artery disease (MI)
- Peripheral vascular disease
- Blood viscosity and platelet disorders

Renal
- Hypertension
- Albuminuria
- Edema
- Chronic kidney disease

Musculoskeletal
- Joint contractures

Integumentary
- Foot ulcers
- Gangrene of the feet
- Atrophic changes

Immune System
- Impaired healing
- Chronic skin infections
- Periodontal disease
- Urinary tract infections
- Lung infections
- Vaginitis

NURSING CARE OF THE OLDER ADULT

Diabetes Mellitus

Health Problem/Complication	Implications for Nursing Care
Urinary incontinence	The older adult may assume urinary incontinence is a normal part of aging. Consequently, polyuria, a classic manifestation of DM, often is ignored.
Decreased ability to recognize thirst	The thirst response decreases with aging so the patient may not experience polydipsia, a classic manifestation of DM. This further increases the risk of dehydration and electrolyte imbalances.
Decreased hunger and weight loss	Polyphagia, a classic manifestation of DM, may not be evident. The aging process, medications, depression, or lack of socialization may decrease hunger. Weight loss may be gradual and go unnoticed.
Fatigue and depression	Fatigue and depression are common symptoms of DM but may be blamed on increased age.
Hypoglycemia	The older adult may have either very mild manifestations or none at all, or there may be an inability to sense or respond to hypoglycemia. As a result, hypoglycemia is often ignored until it causes serious adverse effects.
Peripheral neuropathy	Manifestations may be thought to be due to arthritis, and over-the-counter drugs often are used to self-medicate. The risk of falls increases, as does the risk of gangrene and amputation.
Peripheral vascular disease	May go undetected if the person does not get enough exercise to cause claudication. May also impair abilities to climb stairs and walk.
Diabetic retinopathy	May be undetected if the person has cataracts. Patients with diabetes also have an increased incidence of cataracts and glaucoma. Deficits in vision threaten independence, mobility, and social interactions. Yellowing of the lens with age makes it difficult to read colored test strips; numeric meters are preferable. Filling insulin syringes may be impossible for the patient with macular degeneration or other causes of visual loss.
Hypertension	Treatment with diuretics may further impair glucose tolerance and result in electrolyte imbalances.
Persistent pain	Arthritic pain and stiffness may impair the older adult's ability to perform glucose testing and self-administer medications. Depression from chronic pain, inactivity, and loss of appetite may interfere with DM self-care as well.
Parkinson's disease	The tremors and rigidity of this disease make self-care involving fine and gross motor skills difficult.
Polypharmacy	Older adults commonly take more than one type of medication and are at increased risk for problems relating to drug interactions.
Cognitive impairment	Delirium or dementia can prevent the patient from communicating or performing self-care.

When using these criteria, the following levels are used for the FPG:

- Normal fasting glucose ≤ 100 mg/dL (6.1 mmol/L)
- Impaired fasting glucose (IFG) = 100 to 126 mg/dL (6.1 to 7.0 mmol/L)
- Diagnosis of DM = > 126 mg/dL (7.0 mmol/L).

When using these criteria, the following levels are used for the OGTT:

- Normal glucose tolerance = 2-hr PG < 140 mg/dL (7.8 mmol/L)
- Impaired glucose tolerance (IGT) = 2-hr PG ≥ 140 (7.8 mmol/L) and < 200 mg/dL (11.1 mmol/L)
- Diagnosis of DM = 2-hr PG ≥ 200 mg/dL (11.1 mmol/L).

PREDIABETES A hemoglobin A_1C level of 5.7% to 6.4% indicates a high risk for developing diabetes and vascular disease (peripheral vascular disease, acute myocardial infarction, and stroke), and is a marker for prediabetes. The ADA (2012a) and the American Association of Clinical Endocrinologists (2013) have issued specific recommendations to delay or prevent the onset of type 2 diabetes. Weight loss and increased physical activity to at least 150 minutes per week are essential. In addition, annual monitoring for the onset of diabetes is suggested, and treatment with metformin to prevent or delay the onset of type 2 diabetes should be considered.

DIAGNOSTIC TESTS TO MONITOR DM MANAGEMENT Diagnostic tests used to monitor DM include a fasting blood glucose (FBG), an oral glucose tolerance test (OGTT), and a glycosylated hemoglobin (A_1C). Normal values for these tests as well as nursing implications are described in Chapter 18.

Other tests that may be used are urine tests for glucose, ketones, and albumin. Urine analysis for increased glucose and ketones indicates hyperglycemia and ketosis. Urine tests for albumin are used to detect the early onset of kidney damage. Serum cholesterol and lipid levels identify those individuals at risk for cardiovascular disease.

SELF-MONITORING

It is essential for patients with insulin-dependent diabetes to monitor their condition daily by testing glucose levels. Direct measurement of blood glucose is widely used in all types of healthcare settings and in the home. Urine tests for ketones are also recommended for patients with type 1 DM, and occasionally for those with type 2 DM who no

Moving Knowledge into Action

1. Imagine you have just been diagnosed with type 1 DM. Make a list of the questions you would have and the areas that would cause you the most difficulty in complying with your medical care.
2. How would you respond if your patient with diabetes tells you, "Sometimes I eat whatever I want to for several days." What do you think this behavior indicates?

longer produce insulin. Ketone measurement is especially beneficial to determine whether ketosis (breakdown of fats) is occurring.

URINE TESTING FOR KETONES AND GLUCOSE **Positive urine glucose** is suggestive of a blood glucose level over 180 to 200 mg/dL (the renal threshold). Urine glucose testing is no longer recommended for the patient with diabetes who is self-managing the condition. The blood glucose level is likely to be drastically different than a urine level because urine may sit in the bladder for several hours. Additionally, if the result is glucose negative, then the blood glucose could be normal, hyperglycemic (up to 180 mg/dL), or hypoglycemic (less than 70 mg/dL). **Urine ketone tests** should be used by people with type 1 diabetes especially under times of physiologic stress (i.e., infections, disease) and emotional stress. During these times, an individual with type 1 diabetes may become rapidly hyperglycemic with a relative insulin deficiency and switch to using fats for energy. This abnormal process can be measured with the by-product of fat metabolism, ketones. Positive urine ketone excretion is the beginning of diabetic ketoacidosis.

SELF-MONITORING OF BLOOD GLUCOSE Self-monitoring of blood glucose (SMBG) allows the individual with DM to monitor and achieve metabolic control and decrease the complications associated with both hypoglycemia and hyperglycemia. The ADA recommends that all patients with DM be taught some method of monitoring glycemic control. The timing of SMBG is highly individualized, depending on the person's diagnosis, general disease control, and physical state. SMBG is recommended three or more times a day for patients with type 1 DM using multiple insulin injections or insulin pump therapy. Monitoring by patients with type 2 DM who are not using insulin should be sufficient to help them reach glucose goals. Postprandial blood glucose is often the most useful information for evaluating level of glycemic control in the patient with type 2 DM (ADA, 2012a). If patients were to check only their fasting glucose, they would be unaware of the postprandial results.

When adding or modifying therapy, patients with both types of DM should test more often than usual. SMBG is also useful when an individual is ill or pregnant, or has manifestations of hypoglycemia or hyperglycemia. Both hypoglycemia and hyperglycemia may contribute to complications and decrease quality of life. With the information assessed with SMBG, patients can alter their diet, their physical activity, and even their medication to control blood glucose and the risk for complications.

The ADA annually publishes a comprehensive list of currently available blood glucose monitoring machines and strips with approximate prices in *Diabetes Forecast.* Most medical insurance policies cover the cost of these machines and the test strips. Many companies, however, provide a machine free of cost, but the testing supplies are specific to each machine, which obligates the recipient to purchase supplies for that machine.

The following equipment is needed for SMBG:

- Some type of lancet device to perform a fingerstick for obtaining a drop of blood (such as an Autolet, Penlet, or Soft Touch).
- A blood glucose monitor (e.g., Glucometer, Accu-Chek, or One Touch). The manufacturer's instructions must be followed carefully even though the procedure for SMBG has been simplified such that most glucose monitors are very simple to use (Figure 20–3 ■).
- Test strips that are specific to the glucose monitor being used (e.g., Accu-Chek Aviva).

Figure 20–3 ■ A portable glucometer is used by the patient or caregivers to provide accurate blood glucose measurements.
Source: Lisa S/shutterstock.

A newer technology is continuous blood glucose monitoring (CGM). A CGM device has a sensor that is inserted under the skin and measures glucose readings every few minutes. This sensor provides a continuous glucose reading and warns the patient with diabetes with an alarm for when glucose levels are high or low (Figure 20–4 ■). The CGM reveals patterns of glycemic control useful for the patient or healthcare provider to make treatment decisions. The data are downloaded to computer- or Internet-based applications and various reports such as daily trends, trends at a certain time of day, and long-term trends can be analyzed. Fingerstick measurements are still required to calibrate CGMs (McPhee et al., 2012).

FACTORS THAT AFFECT GLUCOSE METER PERFORMANCE According to the U.S. Food and Drug Administration (FDA), several factors affect the accuracy of blood glucose test results. The quality of the meter and test strips and the training on how to use the meter contribute to the degree of accuracy. Other factors can create falsely positive or negative readings.

HEMATOCRIT Patients with very high hematocrit values will usually test falsely low in blood glucose, and patients with very low hematocrit will test falsely higher. Anemia and sickle cell disease are two conditions that can affect hematocrit values.

Figure 20–4 ■ Dexcom continuous glucose monitor showing a current glucose of 90 mg/dL and glucose trends during the preceding 3 hours.
Source: Courtesy Dexcom, Inc.

OTHER SUBSTANCES Isopropyl alcohol, which is frequently used to clean the skin, will alter the results if it mixes with the blood sample, as will food residue on the skin and some lotions. Uric acid (a natural substance in the body that can be more concentrated in some people with DM), glutathione (an antioxidant also called GSH), and ascorbic acid (vitamin C) are known to interfere. Meters and supplies vary in sensitivity to medications.

USING CORRECT SUPPLIES AND SAMPLE VOLUME The test strips must be compatible with the glucose meter, not outdated, and stored according to directions. Insufficient amounts of blood on the testing strip will cause a testing error.

MEDICATIONS

The pharmacologic treatment for DM depends on the type of DM. People with type 1 must have insulin; those with type 2 may be able to control glucose levels with an oral hypoglycemic medication, but they may require insulin if control is inadequate or if they are subjected to a stressor, such as surgery.

INSULIN The person with type 1 DM requires a lifelong exogenous source of the insulin hormone to maintain life. Insulin is not a cure for DM; rather, it is a means of controlling hyperglycemia. People with type 2 DM take insulin to control glucose levels when oral medications and/or diet and exercise are ineffective. Insulin needs are increased during times of increased metabolism as can occur in the following situations:

- People who are experiencing physical stress (such as an infection or surgery) or who are taking corticosteroids
- Women with gestational DM
- People with diabetic ketoacidosis (DKA) or hyperosmolar hyperglycemic state (HHS)
- People who are ill and have an altered diet and exercise routine.

SOURCES OF INSULIN Preparations of insulin are derived from recombinant DNA technology to form biosynthetic human insulin. Insulin analogs have been developed by modifying the amino acid sequence of the insulin molecule. Although pork and beef derived insulins were used in the past, today's insulin is derived from human DNA.

INSULIN PREPARATIONS Insulins are available in rapid-acting, short-acting, intermediate-acting, and long-acting preparations. Examples of various trade names and times of onset, peak, and duration of action are listed in Table 20–2.

Insulin lispro (Humalog) is a human insulin analog and is classified as a rapid-acting or ultra-short-acting insulin. Compared to regular insulin, lispro has a more rapid onset (less than 15 minutes), an earlier peak of glucose lowering (30 to 60 minutes), and a shorter duration of activity (3 to 4 hours). This means that lispro should be administered within 15 minutes before a meal (as compared to 30 minutes before as recommended for regular insulin). Because of its shorter duration, lispro is much less likely than regular insulin to cause nocturnal hypoglycemia. Patients using rapid-acting insulin usually also require concurrent use of a longer-acting insulin product.

Regular insulin is unmodified insulin, classified as a short-acting insulin. Regular insulin is clear in appearance and is used for subcutaneous injection as well as IV insulin therapy. While other insulins may also be clear, not all are appropriate for IV administration. Regular insulin is used in insulin infusions, as an IV bolus, or subcutaneously alone or in combination with intermediate-acting insulins to provide better glucose control. Only clear, short-acting insulins—regular, aspart, lispro, and glulisine—can be administered mixed with an intermediate- or long-acting insulin. Short- or rapid-acting insulins are used in insulin pumps so that if pump therapy is stopped the effect of the insulin rapidly declines.

The onset, peak, and duration of action of insulin can be changed by changing the insulin molecule or by adding protamine, a protein that slows insulin absorption. NPH insulin contains protamine to prolong its action, and it is classified as an intermediate-acting insulin. NPH insulin preparations appear cloudy when properly mixed prior to injection. Protamine is a foreign substance and may cause hypersensitivity reactions. Fixed-dose combinations of NPH insulin with a short-acting insulin are available to simplify administration.

Insulin detemir (Levemir) and insulin glargine (Lantus) are long-acting insulins, with a duration of action up to 24 hours. While these insulins are clear preparations, they must not be mixed with other insulins and cannot be used in insulin pumps. Doses may be administered once or twice daily. Insulin glargine is used to treat patients with both type 1 and type 2 DM. It has a relatively constant

TABLE 20–2 Insulin Preparations

Preparation	Name	Onset (h)	Peak (h)	Duration (h)
Rapid acting	lispro (Humalog)	0.25	1–1.5	3–4
	aspart (NovoLog)	0.25	40–50 min	3–5
	glulisine (Apidra)	0.25	1–1.5	3–5
Short acting	regular (Novolin-R, Humulin-R)	0.5–1.0	2–3	4–6
Intermediate acting	NPH (Humulin N, Novolin N)	2	6–8	12–16
	detemir (Levemir)	Gradual	6–8	17–24
Long acting	glargine (Lantus)	1.1	3–4	10–24
COMBINATIONS:				
NPH and regular insulins	Humulin 50/50	0.5	3	22–24
	Humulin 70/30	0.5	4–8	24
	Novolin 70/30	0.5	4–8	24
Insulin aspart and insulin aspart protamine	Novolog Mix 70/30	0.25	4–8	24
Insulin lispro protamine and insulin lispro	Humalog Mix 75/25	0.25	4–8	24

effect (meaning it does not have a peak time of effect). It is not recommended for use in pregnancy.

SAFETY ALERT

Insulin glargine and insulin detemir are clear, unlike NPH insulins. Do not mistake these for regular insulin. Do not mix with any other insulins. Do not inject IV, only subcutaneously.

CONCENTRATIONS OF INSULIN Insulin is dispensed as 100 units/mL (U-100) and 500 units/mL (U-500) in the United States. U-100 is the standard insulin concentration used; there are 100 units of insulin in 1 mL. U-500 insulin is only used in rare cases of insulin resistance when patients require very large doses.

INSULIN ADMINISTRATION Nursing implications for administering insulin are outlined in the Medication Administration box and further discussion follows in the chapter. The considerations for administering insulin include routes of administration, syringe and needle selection, preparing the injection, sites of injection, mixing insulins, and insulin regimens.

ROUTES OF ADMINISTRATION All insulins are given parenterally. Regular insulin is given by both subcutaneous and IV routes; all others are given only subcutaneously. If the IV route is not available, regular insulin may also be administered IM in an emergency situation.

CONTINUOUS SUBCUTANEOUS INSULIN INFUSION Regular or rapid-acting insulins are used in continuous subcutaneous insulin infusion (CSII) devices, often called insulin pumps (e.g., OmniPod, MiniMed, Disetronic pumps). CSII devices have a small pump that holds a reservoir of insulin, connected to a subcutaneous needle. The pump is about the size of a small cell phone and can be worn on a belt or tucked into a pocket. The needle is placed in the skin, usually in the abdomen, and is changed routinely. This device delivers

MEDICATION ADMINISTRATION

Insulin

Nursing Responsibilities

- Discard vials of insulin that have been open for more than 30 days or whose expiration date has passed.
- Refrigerate extra insulin vials not currently in use (at about 4°C [40°F]), but do not freeze them.
- Store insulin in a cool place, and avoid exposure to temperature extremes or sunlight.
- Discard any vials with discoloration, clumping, granules, or solid deposits on the sides.
- If breakfast is delayed, also delay the administration of rapid-acting insulin.
- Monitor and maintain a record of blood glucose readings 30 minutes before each meal and bedtime (or as prescribed).
- Monitor food intake, and notify the healthcare provider if food is not being consumed.
- Monitor serum potassium and creatinine.
- Observe injection sites for manifestations of hypersensitivity, lipodystrophy, and lipoatrophy.
- If manifestations of hypoglycemia occur, confirm by testing blood glucose level, and administer an oral source of a fast-acting carbohydrate, such as 4 ounces of juice with six crackers, or 8 ounces of skim milk. Hypoglycemic manifestations are described later under complications, but commonly include feelings of shakiness, hunger, and/or nervousness accompanied by sweating, tachycardia, or palpitations.
- If manifestations of hyperglycemia occur, confirm by testing blood glucose level, and notify the healthcare provider to obtain supplemental insulin or a change in oral medication therapy.

Health Education for the Patient and Family

- Teach about the manifestations of DM.
- Demonstrate self-administration of insulin, with a return demonstration:
  a. Wash hands carefully.
  b. Have a vial of insulin, the insulin syringe with needle, and alcohol pads ready to use.
  c. Remove the cover from the needle.
  d. Fill the syringe with an amount of air equal to the number of units of insulin, and insert the needle into the vial.
  e. Push air into the vial, invert the vial, and withdraw the prescribed units of insulin.
  f. Replace the cover over the needle.
  g. Wipe the selected site with alcohol. The injection is less likely to be painful if the alcohol is allowed to dry.
  h. Pinch up a fold of skin, and insert the needle into the tissue at the recommended angle.
  i. Insert the insulin.
  j. Withdraw the needle; if desired, apply firm pressure to the site for a few seconds.
  k. Recap the needle. Many people with DM reuse disposable syringes with attached needles without adverse effects. The primary reason for discarding after several uses is that the needle becomes dull and makes the injection painful.
  l. Insulin pens may be more convenient to use. The dose is selected with a dial on the pen. Needles should be changed with each use. Insulins, except for commercially mixed ones such as 70/30, cannot be mixed in a pen.
- Follow instructions for mixing insulins.
- Always keep an extra vial or cartridge of insulin available; refrigerate insulins not in use. Discard insulin pens kept at room temperature for current use at 28 days. Discard vials of insulin kept at room temperature for 30 days. Stored, refrigerated vials and cartridges should be discarded if their expiration date is exceeded.
- Always have a vial of regular insulin available for emergencies.
- Be aware of the signs of hypersensitivity responses, hypoglycemia, and hyperglycemia.
- Keep a source of glucose available at all times to treat hypoglycemia, if it occurs. Eat within 15 minutes of injecting rapid-acting insulins.
- Vision may be blurred during the first 6 to 8 weeks of insulin therapy; this is the result of fluid changes in the eye and should clear up in 8 weeks.
- Avoid alcoholic beverages, which may cause hypoglycemia.
- Follow these guidelines for sick days:
  a. Never omit insulin.
  b. Always monitor blood glucose and urine ketones at least every 2 to 4 hours.
  c. Always drink plenty of fluids, try to drink at least one glass of water or other calorie-free, caffeine-free liquid each hour.
  d. Get as much rest as possible.
  e. Contact the healthcare provider if there is persistent fever, vomiting, shortness of breath, severe pain in the abdomen, dehydration, loss of vision, chest pain, persistent diarrhea, blood glucose levels above 250 mg/dL, or ketones in the urine.
- Establish a plan for rotating injection sites, and observe closely for changes in tissues such as hardness, dimpling, or sunken areas.

a constant amount of programmed insulin (basal dose) throughout each 24-hour period, and also delivers a bolus of insulin before meals.

Programming the amount of insulin to be delivered with a pump is determined by frequent blood glucose monitoring. Several different pumps are available, and each has rechargeable batteries, a syringe, a programmable computer, and a motor and drive mechanism. The rapid-acting insulin analog lispro is an appropriate insulin for insulin pumps, and short-acting regular insulin may be used. Lispro is not approved for use during pregnancy.

Many people with DM believe the pump allows more normal regulation of blood glucose and provides greater lifestyle flexibility. Pumps are as safe as multiple-injection therapy when recommended procedures are followed. A potential complication is an undetected interruption in insulin delivery, which may result in the rapid onset of DKA. The needle site must be kept clean and changed on a regular basis (usually every 7 days) to prevent inflammation and infection. Although the patient who chooses an insulin pump has more to learn, many are very satisfied with having more normal glucose control.

CORRECTIONAL DOSES OF INSULIN Maintaining normal blood glucose prior to and during hospitalization decreases the risk of postoperative infections and shortens hospital stays. Healing is impaired when hemoglobin is glycosylated (linked with a sugar molecule) because glycosylated Hgb has an increased affinity for oxygen, putting tissues at risk for ischemia, and decreases the effectiveness of white blood cells (increasing the risk of infection).

Treatment of hospitalized patients with type 1 and type 2 DM requires a medication regimen that is responsive to glycemic changes secondary to the admitting condition and its treatment, including surgery (Kadoi, 2010).

People with type 2 DM may not be able to manage with oral medications during hospitalization because of the risk of hypoglycemia from not eating and the slow response of these medications to correct hyperglycemia. Significant hyperglycemia during hospitalization is also likely due to increased metabolic demand and stress hormones. Researchers have found significantly less mortality and significantly reduced complications such as infections and acute kidney injury, as well as decreased time on mechanical ventilation, and decreased length of ICU stays when normal blood glucose levels (80 to 110 mg/dL) were maintained. However, periods of hypoglycemia of less than 40 mg/dL also increase mortality (NICE-SUGAR Study Investigators, 2009). Current recommendations for critically ill patients are to keep the blood glucose between 110 and 140 mg/dL for patients who otherwise have good glycemic control if it is safe to do so without risk of significant hypoglycemia. In many critically ill patients with a history of poor glycemic control, a range of 140 to 180 mg/dL may be appropriate. For those who are hospitalized (but not critically ill) pre-meal glucose levels should be less than 140 mg/dL and random levels should be below 180 mg/dL (ADA, 2012a).

The latest recommendations are to control hyperglycemia in hospitalized patients (including those taking oral medications at home) with insulin. Hyperglycemia is best managed with a basal dose of insulin, pre-meal insulin, and correctional doses. The basal dose is once or twice daily subcutaneous insulin such as insulin glargine (once daily) or NPH (twice daily). The prandial or mealtime dose is a short- or rapid-acting dose of insulin given before meals. Correctional doses are calculated based on food intake and prior hyperglycemia and hypoglycemia episodes. The mealtime short-acting insulin dose is corrected (either increased or decreased) to prevent hyperglycemic or hypoglycemic episodes (Handelsman et al., 2011). See Box 20–1 for methods to calculate basal, prandial, and correction doses for hospitalized patients on scheduled subcutaneous insulin doses and patients with insulin pumps.

SYRINGE AND NEEDLE SELECTION Insulin is administered by sterile, single-use needles and either disposable insulin syringes or a multiple-dose insulin pen (Figure 20–5 ■), calibrated in units per milliliter. This means that in U-100 insulin, there are 100 units of insulin in 1 mL. Syringes for administering U-100 insulin can be purchased in either a 0.3-mL (30 U), 0.5-mL (50 U), or 1.0-mL (100 U) size. The advantage of the 0.3- and 0.5-mL sizes is that the distance between unit markings is greater, making it easier to see and measure the dose accurately.

Some hospitals and many patients are using insulin pens instead of insulin syringes to administer insulin. The pens, either reusable or disposable, contain prefilled cartridges of insulin; the desired dose is adjusted on the pen's dial prior to injection. A disposable needle is replaced for each injection. Insulin pens are convenient to use, eliminating the need to carry an insulin vial and fill a syringe. The insulin in the cartridges is more stable than insulin packaged in vials. The prefilled syringe currently in use may be stored at room temperature and must be discarded at 28 days. Cartridges not in current use may be stored in the refrigerator.

Other special injection products are available for people with physical handicaps. These products include automatic injectors and jet spray injectors. Prefilled syringes or pens are useful for people who are visually impaired or traveling.

PREPARING THE INJECTION The vial of insulin currently being used may be kept at room temperature for up to 30 days. Stored vials should be kept in the refrigerator and brought to room temperature prior to administration.

Regular insulin does not require mixing. If the solution is cloudy or discolored, the vial should be discarded. Modified insulin such as NPH insulin must be mixed to disperse the particles evenly throughout the solution. Mix the vial by gently rolling it between the hands.

BOX 20–1 Methods for Calculating Basal, Prandial, and Correction Doses of Insulin

INSULIN TOTAL DAILY DOSE (ITDD)

1. The total amount of insulin that the patient administered daily by injection (rapid- or short-acting with intermediate- or long-acting); for example, 48 units (30 units NPH and 18 units regular insulin)
   OR
2. 0.5 to 1 unit/kg (normal kidney/liver function already on insulin); for example, 48 units for a 96-kg patient
   OR
3. 0.3–0.5 unit/kg (reduced kidney/liver function or initial insulin therapy); for example, 30 units for a 96-kg patient.

Test blood glucose with test strip before meals and at bedtime.

BASAL DOSE: 40%–50% OF THE ITDD

1. *Insulin pump:* Multiply the ITDD by 50% (e.g., 48.0 × 0.5 = 24 units). The basal insulin pump dose for this patient is 24 units. Divide the basal insulin pump dose by 24 to get the hourly basal pump dose and rate (24/24 = 1.0 unit/hour). Use rapid-acting or regular insulin.
2. *Subcutaneous insulin:* Multiply the ITDD by 50% (e.g., 48.0 × 0.5 = 24 units). This will be administered as one insulin subcutaneous injection of long-acting insulin (e.g., insulin glargine) daily or twice daily injections of 12 units each of intermediate-acting insulin (e.g., NPH).

Correction doses may be needed if the patient is hypoglycemic or hyperglycemic.

MEALTIME BOLUS DOSE

1. *Insulin pump:* To calculate bolus doses, the remaining 50% of the ITDD is divided by four doses according to the patient's meal plan for the day. To calculate the units for each of these four daily bolus doses, multiply the percent of each meal bolus times the total daily insulin pump dose. For example, for 48 units for a total daily dose:
   Breakfast dose is 20% (or 0.2) × 48 units = 10 units
   Lunch dose is 10% (or 0.1) × 48 units = 5 units
   Dinner dose is 15% (or 0.15) × 48 units = 8 units
   Bedtime snack dose is 5% (or 0.05) × 48 = 2 units
   Correction doses may be needed if the patient is hypoglycemic or hyperglycemic.
2. *Subcutaneous insulin mealtime dose:* Divide half of the ITDD into three mealtime doses.
   Breakfast = 8 units; lunch = 8 units; supper = 8 units. No bedtime dose is given.
   Rapid-acting insulin (regular or aspart) is given in conjunction with the meal.

MEALTIME CORRECTION DOSE

A mealtime correction dose of insulin may be given before hyperglycemia develops. It is given with the mealtime bolus dose of rapid-acting insulin.

1. Test blood glucose prior to each meal. If blood glucose level is less than 70 mg/dL or the patient is symptomatic for hypoglycemia, follow hypoglycemia protocol.

71–100	No correction dose needed.
101–150	Add 2 or 3 units if mealtime dose is greater than 20 units.
151–200	Add 4 units if mealtime dose is greater than 20 units.
201–250	Add 6 units if mealtime dose is greater than 20 units.
251–300	Add 8 units if mealtime dose is greater than 20 units.
> 300	Add 10 units if mealtime dose is greater than 20 units.

Note: When correction doses are needed, the scheduled doses of rapid-acting insulin need to be reordered at higher doses.

It is critical that no air bubbles remain in the prepared dose, because even a small bubble can displace several units of insulin.

SITES OF INJECTION Although in theory any area of the body with subcutaneous tissue may be used for injections of insulin, certain sites are recommended (Figure 20–6 ■). The rate of absorption and peak of action of insulin differ according to the site. The site that allows the most rapid absorption is the abdomen, followed by the subcutaneous tissue of the upper arm, thigh, and hip. Insulin sites are rotated with each injection. See Box 20–2 for techniques to minimize painful injections.

When administering insulin, gently pinch a fold of skin and inject the needle at a 90-degree angle. If the person is very thin, a 45-degree angle may be required to avoid injecting into muscle. Aspiration to

BOX 20–2 Techniques to Minimize Painful Injections

- Inject insulin that is at room temperature.
- Take care not to bend the needle before injection.
- Wait until alcohol on the skin completely dries before injecting the insulin.
- Quickly penetrate the skin with the needle.
- Don't change the direction of the needle during insertion or withdrawal.
- Don't reuse needles, they become dull with repeated use.

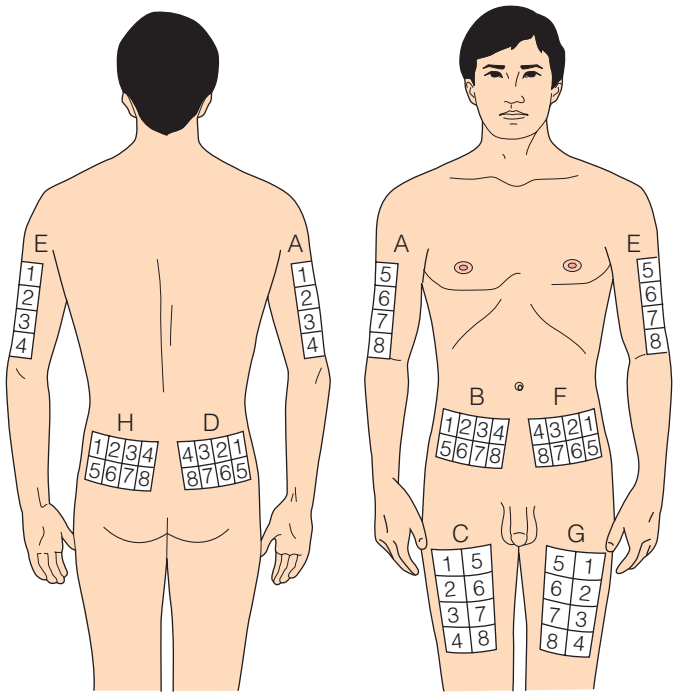

Figure 20–6 ■ Sites of insulin injection. The abdomen is the preferred site.

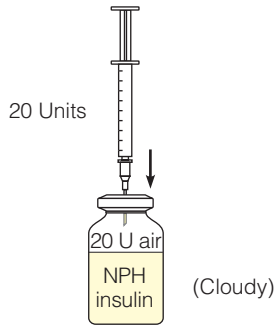
check for blood is not necessary. Do not massage the site after administering the injection, because this may interfere with absorption. Rotation of sites with body regions is recommended. The distance between injections should be about 1 inch (avoiding the area within a 2-inch radius around the umbilicus). Insulin should not be injected into an area to be exercised (such as the thigh before a vigorous walk) or to which heat will be applied; exercise or heat may increase the rate of absorption and cause a more rapid onset and peak of action.

LIPODYSTROPHY Lipodystrophy (hypertrophy of subcutaneous tissue) or lipoatrophy (atrophy of subcutaneous tissue) may result if the same injection sites are used repeatedly. The tissues become hardened and have an orange-peel appearance. The use of refrigerated insulin may trigger the development of tissue atrophy or hypertrophy. These problems rarely occur, however, with the use of human insulins. Lipodystrophy and lipoatrophy alter insulin absorption, delaying its onset or retaining the insulin in the tissue for a period of time instead of allowing it to be absorbed into the body. Lipodystrophy usually resolves if the area is unused for a minimum of 6 months.

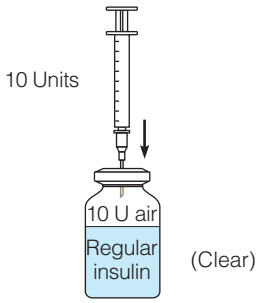
MIXING INSULINS When an individual with DM requires more than one type of insulin, mixing is recommended to avoid administering two injections per dose. Two different types of insulin are administered, because a single dose of intermediate-acting or long-acting insulin rarely provides adequate control of blood glucose levels. The procedure for mixing insulins is described in Box 20–3. Following are some general guidelines:

- Commercially mixed insulins are recommended if the insulin ratio is appropriate for the requirements of the patient.
- Glargine and detemir insulin cannot be mixed with other insulins.
- NPH insulin may be mixed only with regular insulin.
- Always withdraw regular insulin first to avoid contaminating the regular insulin with intermediate-acting insulin.



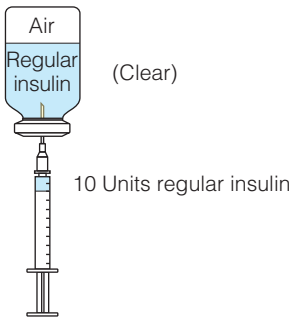
INSULIN REGIMENS Individualizing the appropriate insulin dosage is achieved through a balance among insulin, diet, and exercise. For most people with DM, the timing of insulin action requires two or more injections each day, often a mixture of rapid-acting and intermediate-acting insulins. Timing of the injections depends on blood glucose levels, food consumption, exercise, and types of insulin used. The objective is to avoid daytime and nighttime hypoglycemia while achieving adequate blood glucose control. Typical insulin regimens are outlined in Table 20–3.

HYPERSENSITIVITY RESPONSES When injected, insulin may cause local and systemic hypersensitivity responses. Manifestations of local reactions are a hardening and reddening of the area that develops over several hours. Local reactions result from a contaminant in the insulin and are more likely to occur when less purified insulin products are used.

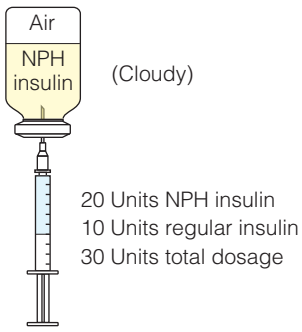


Systemic reactions occur rapidly and are characterized by widespread red, intensely pruritic welts. Respiratory difficulty may occur. Systemic responses are due to an allergy to the insulin itself. The patient can be desensitized by administering small doses of human insulin, followed by progressively larger doses.

BOX 20–3 Mixing Insulins: 10 Units of Regular and 20 Units of NPH

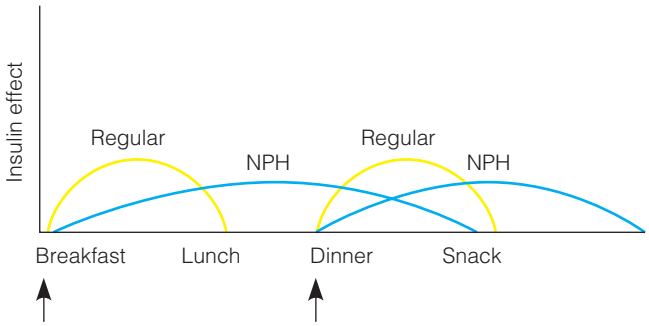


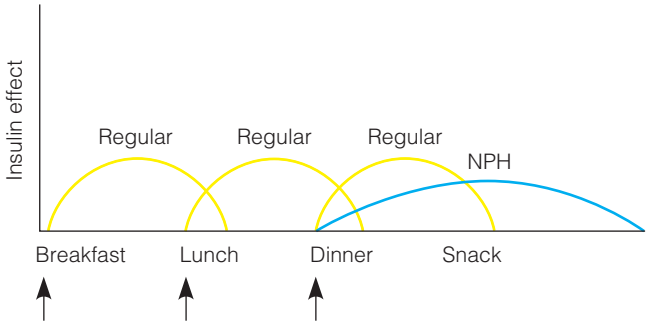
1. Wash hands.
2. Inspect regular insulin for clarity.
3. Gently rotate NPH insulin to mix well.
4. Wipe off the top of both vials with an alcohol pad.
5. Draw 20 units of air into the syringe, and inject air into the NPH vial (Figure *A*). Withdraw needle. The vial should remain upright (not inverted) when adding air to the vial.
6. Draw 10 units of air into the syringe, and inject air into the regular vial (Figure *B*).
7. Invert the vial, and withdraw 10 units of regular insulin (Figure *C*). Withdraw the needle.
8. Insert the needle into the NPH vial, and carefully withdraw 20 units of NPH insulin (Figure *D*).
9. Don disposable gloves.
10. Administer the insulin.
11. Discard gloves, wash hands, and properly dispose of the syringe.
12. Document insulin administration.

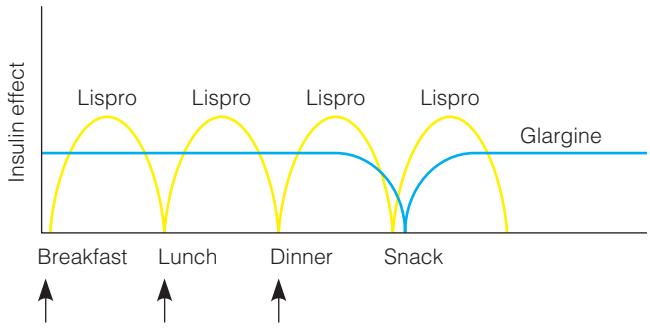


A Injecting air into the NPH vial.

B Injecting air into the regular insulin vial.







C Withdrawing regular insulin.

D Withdrawing NPH insulin.

TABLE 20–3 Insulin Regimens

Regimen	Insulin Type*	General Information
Two injections per day 	NPH or NPH/R before breakfast and dinner	This regimen is the least complex of those aiming to mimic normal pancreatic function; the person must have a fairly rigid schedule of food intake and exercise.
Three or four injections per day 	R before each meal; NPH at dinner or bedtime	This regimen more closely mimics normal pancreatic function; it allows greater choice in mealtimes and exercise. However, each preprandial dose of R must be determined by blood glucose tests.
Four or more injections per day 	Rapid-acting insulin (i.e., Humalog) before each meal; insulin glargine (i.e., Lantus) once daily in the evening	This regimen mimics normal pancreatic function the best; it allows greater choice in mealtimes and exercise. Each preprandial dose of rapid-acting insulin must be determined by blood glucose tests.

Note: *Insulin types are abbreviated as follows: NPH = intermediate acting, R = regular, RA = rapid acting, LA = long acting.

HYPOGLYCEMIC AGENTS Hypoglycemic agents are used to treat people with type 2 DM. Nursing implications for this category of drugs are discussed in the Medication Administration box on page 516. These medications lower blood sugar by stimulating or increasing insulin secretion, preventing breakdown of glycogen to glucose by the liver, and increasing peripheral uptake of glucose by making cells less resistant to insulin. Peripheral uptake refers to uptake by muscles and fat in the arms and legs rather than in the trunk. Some hypoglycemic agents keep blood sugar low by blocking absorption of carbohydrates in the intestines. A hypoglycemic agent that is only available as an injectable is exenatide (Byetta). It has several modes of action: (1) It signals the pancreas to make insulin when nutrients are ingested and stop insulin release as blood sugar normalizes, (2) it stops liver conversion of glycogen to glucose, and (3) it decreases absorption of sugar from the intestines.

ASPIRIN THERAPY Cardiovascular disease is the most common cause of morbidity and mortality in people with DM (Handelsman et al., 2011). It is recommended that a once-daily dose of 81 to 160 mg of enteric-coated aspirin be considered as primary prevention for patients at risk for heart disease (Handelsman et al., 2011). Aspirin therapy is contraindicated for patients with aspirin allergy, bleeding tendency, anticoagulant therapy, recent gastrointestinal bleeding, or active liver disease.

NUTRITION

Nutrition therapy is an integral part of diabetes management and metabolic control in adults. The management of DM requires a

balance between the intake of nutrients, the expenditure of energy, and the dose and timing of insulin or oral antidiabetic agents. The goals for dietary management for adults with DM, based on guidelines established by the ADA, are as follows:

- Promote and support healthy eating patterns that include a variety of nutrient-dense foods in appropriate portions.
- Achieve and maintain blood glucose levels with an HbA1C <7% or individualized for the patient based on age, duration of diabetes, health history, and other health conditions.
- Achieve and maintain optimal serum lipid levels to reduce the risk of vascular disease.
- Achieve and maintain blood pressure levels in the normal range.
- Achieve and maintain body weight goals.
- Prevent or at least slow the rate of development of complications of DM.
- Address individual nutrition needs, taking into account personal and cultural preferences, health literacy, access to healthful food choices, and willingness to change.

MEDICATION ADMINISTRATION

Noninsulin Hypoglycemic Agents

SULFONYLUREAS

glimepiride (Amaryl)

glipizide (Glucotrol, Glucotrol XL)

glyburide (DiaBeta, Micronase)

tolazamide (Tolinase)

tolbutamide (Orinase)

These drugs are used primarily to treat mild, nonketotic type 2 DM in people who are not obese. These patients cannot control the manifestations by diet alone, but they do not require insulin. Glyburide, glipizide, and glimepiride are 100 to 200 times more potent than tolbutamide. The drugs act by stimulating the pancreatic cells to secrete more insulin and by increasing the sensitivity of peripheral tissues to insulin. Dose adjustments must be made gradually and therefore these drugs are not useful for meeting acute changes that occur in illness or surgery. The most common side effect is hypoglycemia and this is exacerbated by NPO status. These drugs are also associated with weight gain. These drugs are usually suspended during hospitalization (ADA, 2014).

BIGUANIDES

metformin (Glucophage)

Metformin reduces both the FBG and the degree of postprandial hyperglycemia in patients with type 2 DM. It primarily decreases the overproduction of glucose by the liver, and may also make insulin more effective in peripheral tissues. If renal insufficiency develops, metformin must be discontinued. It is used as an adjunct to diet, especially in patients who are obese or not responding to the sulfonylureas. Because of an increased risk of metformin-induced lactic acidosis, metformin is usually suspended during hospitalization. It should be discontinued temporarily before and for 48 hours after using intra-arterial iodinated contrast media for diagnostic imaging and anesthesia due to a small but significant risk of renal failure. In the Diabetes Prevention Program, some people treated with metformin reduced their risk of developing DM. An ADA panel recommends metformin for prevention for high-risk individuals (those with combined IGT and IFG, BMI greater than 35, and under 60 years of age with at least one other risk factor for DM). Lifestyle changes including diet and regular moderate exercise are part of preventing or delaying the onset of DM (ADA, 2014).

ALPHA-GLUCOSIDE INHIBITORS

acarbose (Precose)

miglitol (Glyset)

These drugs work locally in the small intestine to slow carbohydrate digestion and delay glucose absorption. As a result, postprandial glucose and glycosylated hemoglobin are better controlled, reducing the risk of long-term complications. They do not cause hypoglycemia, but diminishing gastrointestinal side effects such as flatulence, diarrhea, and abdominal discomfort may occur.

MEGLITINIDES

nateglinide (Starlix)

repaglinide (Prandin)

This is a new class of oral medications for treatment of type 2 DM. They stimulate rapid and short-duration insulin secretion from the pancreatic beta cells to decrease spikes in glucose following meals and also reduce the overall blood glucose level. They should be taken shortly before meals; without a meal, hypoglycemia is a risk. Side effects may occur and diminish with nateglinide; these include nausea, vomiting, diarrhea, joint pain, and flu-like symptoms. Repaglinide is associated with temporary weight gain, diarrhea, and joint pain.

INCRETIN MIMETICS

exenatide (Byetta), injectable only

This medication signals the pancreas to make the right amount of insulin after meals to help lower blood sugar closer to normal levels. It limits liver conversion of glycogen to glucose, and slows the rate at which sugar enters the bloodstream, avoiding high blood sugar spikes.

DPP-4 INHIBITORS

sitagliptin (Januvia)

saxagliptin (Onglyza)

These drugs slow inactivation of incretin hormones and stabilize blood glucose levels by decreasing liver release of glucose and increasing insulin secretion. Side effects may include headache, nasopharyngitis, and urinary tract infections; there may also be allergic-like reactions such as rash and hives. They are taken once daily in combination with diet and exercise.

SYNTHETIC AMYLIN HORMONE

pramlintide (Symlin)

This medication is a synthetic form of amylin, a hormone co-secreted with insulin from the beta cells in the pancreas. It complements the role of insulin in limiting glucose levels by delaying gastric emptying and suppressing glucagon secretion after food intake. Patients with type 1 DM almost totally lack this hormone. It is used with insulin as a subcutaneous injection at mealtime for type 1 and type 2 DM and increases the risk of severe hypoglycemia.

Nursing Responsibilities

- Assess patients taking oral hypoglycemic agents closely for the first 7 days to determine therapeutic response.
- Alpha-glucosidase inhibitors should be administered with food. Most other oral hypoglycemic agents are taken 30 minutes before a meal.
- Teach the patient the importance of maintaining a prescribed diet and exercise program.
- Monitor for hypoglycemia if the patient is also taking nonsteroidal anti-inflammatory agents (NSAIDs), sulfonamide antibiotics, ranitidine, cimetidine, or beta-blockers; these drugs intensify the action of sulfonylureas.
- Monitor for hyperglycemia if the patient is also taking calcium channel blockers, oral contraceptives, glucocorticoids, phenothiazines, or thiazide diuretics; these drugs decrease the hypoglycemic responses to sulfonylureas.

MEDICATION ADMINISTRATION (*continued*)

- Assess for side effects: nausea, heartburn, diarrhea, dizziness, fever, headache, jaundice, skin rash, urticaria, photophobia, thrombocytopenia, leukopenia, or anemia.
- If the patient is to have a thyroid test, determine whether the drug has been taken; sulfonylureas interfere with the uptake of radioactive iodine.
- Monitor for hypoglycemia with concurrent administration of an oral antidiabetic agent and insulin.
- Temporarily hold metformin for 2 days prior to injection of any radiocontrast agent to avoid potential lactic acidosis if renal failure occurs.

Health Education for the Patient and Family

- Maintain prescribed diet and exercise regimen.
- You may need insulin if you have surgery, trauma, fever, or infection.
- Follow instructions to monitor blood glucose.
- Report illness or side effects to the healthcare provider.
- Undergo periodic laboratory evaluations as prescribed by your healthcare provider.
- Avoid alcohol intake, which may cause a reaction involving flushing, palpitations, and nausea.
- The medication interferes with the effectiveness of oral contraceptives; other birth control measures may be required.
- Mild manifestations of hyperglycemia may appear if a different agent is begun.
- Take medications as prescribed; for example, once a day at the same time each day. If you are taking acarbose, take the pill with the first bite of food at breakfast, lunch, and dinner.

Note: Medications identified in italics are among the 200 most frequently prescribed drugs in the US.

- Limit food choices only when research-based evidence supports doing so to maintain a positive outlook on food and the pleasure of eating.
- Provide practical tools for meal planning instead of focusing on individual nutrients (Evert et al., 2013).
- Meal planning should follow the recommended daily allowances of all nutrients. Monitoring carbohydrate intake is a key factor to maintaining glycemic control (ADA, 2012a).

CARBOHYDRATES The ADA recommends that carbohydrate intake be individualized to the patient's needs, with carbohydrate counting or estimating an important strategy to achieve glycemic goals (Evert et al., 2013). This group of nutrients consists of plant foods (grains, fruits, vegetables), milk, and some dairy products. Carbohydrates can be divided into simple sugars and complex carbohydrates. The glycemic index refers to the rate at which a food raises blood glucose, and determines the need for insulin. Proponents of low-carbohydrate diets use the glycemic index as the scientific foundation for decreasing intake of foods with a high glycemic index. However, many factors affect the digestion of carbohydrates; to date, research does not support using the glycemic index as a basis for therapy. The ADA recommends the majority of carbohydrate intake be from vegetables, fruits, whole grains, legumes, and dairy products.

The use of sucrose as part of the total carbohydrate content in the diet does not impair blood glucose control in people with DM. Dietary fructose (from fruits and vegetables or from fructose-sweetened foods) produces a smaller rise in plasma glucose than sucrose and most starches, so it may offer an advantage as a sweetening agent. However, foods with added sugars often have less nutrient value than other carbohydrates, so amounts used should be limited.

PROTEIN As with carbohydrates, goals for dietary protein intake are individualized. Protein has 4 kcal per gram. Sources of protein should be low in fat, low in saturated fat, and low in cholesterol to reduce cardiovascular risk factors. Evidence that restricting dietary protein intake delays development of kidney disease in patients with DM is inconclusive (Evert et al., 2013).

FATS Dietary fats should be low in saturated fat, trans fatty acids, and cholesterol. Saturated and trans fatty acids are the principal dietary determinants of plasma LDL cholesterol. Saturated fats should be no higher than 10% of the total kilocalories allowed per day, intake of trans fatty acids should be minimal, and dietary cholesterol intake less than 300 mg per day. Fat has 9 kilocalories per gram. Sources of the different types of fat include the following:

- ***Saturated fat:*** animal meats (butter fats, lard, bacon), cocoa butter, coconut oil, palm oil, and hydrogenated oils
- ***Polyunsaturated fat:*** oils of corn, safflower, sunflower, soybean, sesame seed, and cottonseed
- ***Trans fatty acids:*** partially hydrogenated vegetable oils such as shortenings and animal fats (Trans fats lower HDL cholesterol and increase LDL cholesterol, leading to coronary heart disease.)
- ***Monosaturated fat:*** peanut oil, olive oil, and canola oil.

Limiting fat and cholesterol intake may help prevent or delay the onset of atherosclerosis, a common complication of DM. There is evidence to support recommending a Mediterranean-style diet rich in monounsaturated fatty acids (MUFAs) for patients with type 2 DM (Evert et al., 2013).

FIBER Dietary fiber may be helpful in treating or preventing constipation and other gastrointestinal disorders, including colon cancer. It also helps provide a feeling of fullness, and large amounts of soluble fiber may be beneficial to serum lipids. Soluble fiber is found in dried beans, oats, barley, and in some vegetables and fruits (e.g., peas, corn, zucchini, cauliflower, broccoli, prunes, pears, apples, bananas, oranges). Insoluble fiber, which is found in wheat, corn, and in some vegetables and fruits (e.g., carrots, brussels sprouts, eggplant, green beans, pears, apples, strawberries), does facilitate intestinal motility and give a feeling of fullness.

The ideal level of fiber has not been determined, but an intake of 14 g/1000 kcal per day is recommended (ADA, 2012a). An increase in fiber may cause nausea, diarrhea or constipation, and increased flatulence, especially if the person does not also increase fluid intake. Fiber should be increased gradually.

SODIUM Although the body requires sodium, most people consume much more than is needed each day, especially in processed foods. The recommended daily intake is 1000 mg of sodium per 1000 kcal, not to exceed 2000 mg per day, with lower levels (1500 mg)

for people with hypertension. The primary concern with sodium is its association with hypertension, a common health problem in people with DM. It is suggested that table salt (which is 40% sodium) and processed foods high in sodium be avoided in the DM meal plan.

SWEETENERS The diet plan for people with DM restricts the amount of refined sugars. As a result, many people use noncaloric sweeteners and foods or drinks made with noncaloric sweeteners. The FDA has approved commercially produced nonnutritive sweeteners. Although questions have been raised about the safety of these substances in laboratory animal studies, they are considered safe for use by humans, when consumed in small amounts. Included in this category of sweeteners are saccharin (Sweet & Low), aspartame or neotame (NutraSweet, Equal), sucralose (Splenda), and acesulfame potassium (Sunette). The nonnutritive sweeteners have negligible amounts of or no kilocalories, do not produce dental caries, and produce very little or no changes in blood glucose levels.

People with DM also use nutritive sweeteners, including fructose, sorbitol, and xylitol. The kilocalorie content of these substances is similar to that of table sugar (sucrose), but they cause less elevation in blood glucose. They are often included in foods labeled as "sugar free." Sorbitol may cause flatulence and diarrhea.

Researchers are continuing to study the safety and effectiveness of the sweeteners. In addition, the FDA recommends that the food industry label products with the amount of each ingredient in milligrams per serving and the number of servings per container. When teaching patients about diet, the nurse should include information about the kilocalorie content of sweeteners and the meaning of such terms as *sugar free* and *dietetic* on labels.

ALCOHOL Although drinking alcoholic beverages is not encouraged, neither is it totally prohibited for the patient with DM. Alcohol consumption may potentiate the hypoglycemic effects of insulin and oral agents. The ADA recommends that men with DM consume no more than two drinks and women with DM no more than one drink per day. The following list provides guidelines for people who include alcohol in their diet plan:

- The signs of intoxication and hypoglycemia are similar; thus, the person with type 1 DM is at increased risk for an insulin reaction.
- Two oral hypoglycemic agents (chlorpropamide and tolbutamide) may interact with the alcohol, causing headache, flushing, and nausea.
- Liqueurs, sweet wines, wine coolers, and sweet mixers contain large amounts of carbohydrate.
- Light beer is the recommended alcoholic drink.
- Alcohol should be consumed with meals and added to the daily food intake.

MEAL PLANNING Several different systems for meal planning are available to the person with DM. These systems include a consistent-carbohydrate DM meal plan, exchange lists, point systems, food groups, carbohydrate counting, and calorie counting. No matter what system is used, however, it must take into account the person's individualized eating habits, diet history, food values, and special needs. Altering eating patterns is often one of the most difficult tasks of DM management; careful consideration of individualized preferences enhances the ability of the patient with diabetes to manage glycemic control. Although the ADA recommends that a registered dietitian provide the nutrition prescription, nurses should know what is prescribed and be able to reinforce teaching and answer questions.

THE CONSISTENT-CARBOHYDRATE DM MEAL PLAN The consistent-carbohydrate DM meal plan, which is replacing the traditional exchange list plan, focuses on carbohydrate content. The patient eats a similar amount of carbohydrates at each meal or snack each day, based on an individual diet prescription and the federal government's MyPlate recommendations. Carbohydrates in a meal have the most effect on postprandial (after meals) blood glucose levels. They also determine, to a greater extent than do proteins and fats, insulin requirements before meals. Patients may be taught to count carbohydrates so they can administer 1 unit of regular insulin or insulin lispro for each 10 or 15 g of carbohydrate eaten at a meal. This method provides a better connection between food, medications, and exercise.

THE EXCHANGE LISTS The exchange list diet is based on an individual's ideal (or reasonable) weight, activity level, and age. These factors determine the total kilocalories that the person may consume each day. After the calories have been determined, the proportions of carbohydrates, proteins, and fats are calculated, using guidelines established by the American Diabetes Association and the American Dietetic Association.

The distribution of foods throughout the day is based on exchange lists. The name and quantity of food that make up one exchange (or serving) are listed; standard household measurements are used. One food portion on the list can be substituted (exchanged) for another with very little difference in calories or amount of carbohydrates, proteins, and fats. The meal plan prescribes how many exchanges are allowed for each food group per meal and snacks.

DIET PLAN FOR INSULIN-DEPENDENT DM Diet and insulin prescriptions must be integrated for optimal energy metabolism and the prevention of hyperglycemia or hypoglycemia. The goals of the diet plan are to achieve optimal glucose and lipid levels and maintain overall health and a reasonable body weight. To meet these goals, the following strategies must be implemented:

- Glucose regulation requires correlating eating patterns with insulin onset and peak of action.
- Meals, snacks, and insulin regimens should be based on the person's lifestyle.
- Meal planning depends on the specific insulin regimen prescribed.
- Snacks are an important consideration in relation to the amount and timing of exercise.
- SMBG levels help the patient make adjustments for planned and unplanned changes in routines.

DIET PLAN FOR TYPE 2 DM The goals of the diet plan are to achieve glycemic targets, maintain overall health, prevent or delay complications, and attain or maintain reasonable body weight. Because the majority of these patients are overweight, weight loss is important and facilitates achieving the other goals.

In addition to decreasing kilocalories, it is recommended that the patient consume three small meals of equal size, evenly spaced approximately 4 to 5 hours apart, with one or two snacks. The person with type 2 DM should also limit fat intake, and consume many healthy vegetables and fruits, especially those that contain more fiber.

SICK-DAY MANAGEMENT When the person with DM is sick or has surgery, blood glucose level increases due to high metabolic needs. The person often mistakenly alters or omits the insulin dose in response to decreased food intake, causing hyperglycemia (sometimes severe). The guidelines for dietary management during illness focus on preventing dehydration and providing nutrition to promote recovery. In general, sick-day management includes the following:

- Monitoring blood glucose at least four times a day throughout an illness
- Testing urine for ketones if blood glucose is greater than 240 mg/dL
- Continuing to take the usual insulin dose or oral hypoglycemic agent, and adding correctional insulin doses as prescribed by the healthcare provider
- Consuming 8 oz of fluid each hour (Sugar-free beverages should be consumed if hyperglycemia is present.)
- Substituting easily digested liquids or soft foods if solid foods are not tolerated (The substituted liquids and foods should be carbohydrate equivalents, for example, 1/2 cup sweetened gelatin, 1/2 cup fruit juice, one Popsicle, 1/4 cup sherbet, and 1/2 cup regular soft drink.)
- Calling the healthcare provider if the patient is unable to eat for more than 24 hours, if vomiting and diarrhea last for more than 6 hours, or if urine ketones are moderate or large for more than 4 hours.

DIET PLAN FOR THE OLDER ADULT The majority of older adults with diabetes have type 2 DM and should follow the general guidelines for that diet plan. However, special considerations for the older adult are important if the diet plan is to be followed, including dietary likes and dislikes, changes in taste perception, dental health, available income, and who prepares the food. Other factors to consider in planning the diet for the older adult include the age-related decline in kilocalorie requirements, decline in physical activity due to age and/or chronic illnesses, and the onset or progression of other chronic illnesses. The older adult who is overweight should reduce kilocalorie intake to ensure weight loss, but at the same time, careful monitoring for malnutrition is necessary.

EXERCISE

The third component of DM management is a regular exercise program consisting of at least 150 minutes per week (ADA, 2012a). The benefits of exercise are the same for everyone, with or without DM: improved physical fitness, improved emotional state, weight control, and improved work capacity. In people with DM, exercise increases the uptake of glucose by muscle cells, potentially reducing the need for insulin. Exercise decreases cholesterol and triglycerides, reducing the risk of cardiovascular disorders. People with DM should consult their primary healthcare provider before beginning or changing an exercise program. The ability to maintain an exercise program is affected by many different factors, including fatigue and glucose levels. It is as important to assess the person's usual lifestyle before establishing an exercise program as it is before planning a diet. Factors to consider include the patient's usual exercise habits, living environment, and community programs. The exercise that the person enjoys most is probably the one that he or she will continue throughout life. Instruct the patient to use proper footwear, inspect the feet daily and after exercise, avoid exercising in extreme heat or cold, and avoid exercising during periods of poor glucose control.

TYPE 1 DM In the person with type 1 DM, glycemic responses to exercise vary according to the type, intensity, and duration of the exercise. Other factors that influence responses include the timing of exercise in relation to meals and insulin injections, and the time of day of the activity. Unless these factors are integrated into the exercise program, the person with type 1 DM has an increased risk of hypoglycemia and hyperglycemia. General guidelines for an exercise program follow:

- Patterns of hyperglycemia or hypoglycemia during exercise should be recognized and treated.
- The risk of exercise-induced hypoglycemia is lowest before breakfast, when free-insulin levels tend to be lower than they are before meals later in the day or at bedtime.
- Exercise should be moderate and regular; brief, intense exercise tends to cause hyperglycemia (due to release of stress hormones), and exercise can also lead to hypoglycemia.
- Exercising at a peak insulin action time may lead to hypoglycemia.
- SMBG is essential before, during, and after exercise.
- Food intake may need to be increased during exercise to treat hypoglycemia.
- Fluid intake, especially water, is essential.

Young adults may continue participating in sports with some modifications in diet and insulin dosage. Athletes should begin training slowly, extend activity over a prolonged period, take a carbohydrate source (such as a drink consisting of 5% to 10% carbohydrate), and monitor blood glucose levels for possible adjustments. In addition, a snack should be available. It may be necessary to omit the usual regular insulin dose prior to an athletic event; even if the athlete is hyperglycemic at the beginning of the event, blood glucose levels will fall during exercise.

TYPE 2 DM An exercise program for the person with type 2 DM is especially important. The benefits of regular exercise include weight loss in those who are overweight, improved glycemic control, increased well-being, socialization with others, and a reduction of cardiovascular risk factors. A combination of diet, exercise, and weight loss may decrease the need for oral hypoglycemic agents if it can be maintained. This decrease is due to an increased sensitivity to insulin, increased kilocalorie expenditure, and increased self-esteem.

General guidelines for an exercise program follow:

- Before beginning the program, have a medical screening.
- Begin the program slowly, and gradually increase intensity and duration.
- Exercise at least 150 minutes a week in regular sessions (30 minutes, five times per week).
- Include resistance exercise (muscle strengthening) and aerobic exercises in the program.

TREATMENTS

SURGERY Surgical management of DM includes surgically revising the GI tract as well as replacing or transplanting the pancreas, pancreatic cells, or beta cells. Many researchers believe that transplantation of the tail of the pancreas is a promising technique for achieving long-term disease control. Islet cell transplantation has

also had moderate success, and research is continuing. A patient with diabetes can receive a portion of a pancreas from a living relative, sometimes along with a kidney transplant. Transplants of more than one organ survive better than solo transplants (ADA, 2012b). Patients receiving organ transplants will receive medications for the rest of their lives to prevent immune rejection of the organ.

Surgery is a stressor that often alters self-management and glycemic control in people with DM. In response to stress, levels of catecholamines, cortisol, glucagon, and growth hormones increase, as does insulin resistance. Hyperglycemia occurs, and protein stores are decreased. In addition, diet and activity patterns change, and medication types and dosages vary. Periods of hyperglycemia result in increased risk for postoperative infection, delayed wound healing, fluid and electrolyte imbalances, and DKA (Handelsman et al., 2011).

Preoperatively, all patients should be in the best possible metabolic state. Screening for complications and regular blood glucose monitoring are part of preoperative preparation. Oral hypoglycemic agents may be withheld for 1 or 2 days before surgery. Regular insulin is often administered to the patient with type 2 DM and those with prediabetes (hyperglycemia but not diagnosed with DM) during the perioperative period. All patients with hyperglycemia follow a carefully prescribed insulin regimen individualized to specific needs.

Patients with diabetes who are critically ill in the perioperative period should receive IV glucose and insulin infusion in an intensive care unit. The target blood glucose level during surgery is between 110 and 140 mg/dL. This avoids hypoglycemia, which is difficult to detect under anesthesia, and prevents glycosuria, dehydration, and impaired wound healing (Handelsman et al., 2011).

The surgical procedure should be scheduled for as early as possible in the morning to minimize the duration of fasting. If food intake is restricted after surgery, intravenous dextrose is often prescribed, accompanied by subcutaneous regular insulin for the non–critically ill surgical patient. Insulin doses are adjusted to blood glucose levels. Although kilocalorie intake is decreased postoperatively, physiologic stress can increase insulin requirements. Glucose control is also affected postoperatively by nausea and vomiting, anorexia, and gastrointestinal suction.

During the postoperative period, the patient with type 2 DM may continue to require insulin or may resume oral medications, depending on glucose control. The patient with type 1 DM may require reduced insulin as healing progresses and stress diminishes. Regular blood glucose monitoring is essential, as are assessments for hypoglycemia.

Complications of Diabetes Mellitus

The person with DM, regardless of type, is at increased risk for complications involving many different body systems. Alterations in blood glucose levels, alterations in the cardiovascular system, neuropathies, an increased susceptibility to infection, and periodontal disease are common. In addition, the interaction of several complications can cause problems of the feet. Periods of hyperglycemia lead to many of the chronic complications of diabetes. The Multisystem Effects of Diabetes Mellitus illustration on page 507 shows the progression from cardinal signs to acute and late complications for the patient with DM. A discussion of each of these complications follows; related interprofessional care and nursing care are discussed later in the chapter.

ACUTE COMPLICATIONS: ALTERATIONS IN BLOOD GLUCOSE LEVELS

The mechanisms maintaining normal blood glucose levels are impaired in the patient with diabetes. As a result, problems with either hyperglygemia or hypoglycemia can develop, often rapidly.

HYPERGLYCEMIA The person with DM may experience relatively brief and transient episodes of hyperglycemia (the dawn phenomenon and the Somogyi phenomenon) as well as the acute complications of diabetic ketoacidosis (DKA) and hyperosmolar hyperglycemic state (HHS).

The Somogyi phenomenon is a combination of hypoglycemia during the night with a rebound morning rise in blood glucose to hyperglycemic levels. The hypoglycemia stimulates release of counterregulatory hormones (epinephrine, cortisol, glucagon, and growth hormone), which stimulate gluconeogenesis and glycogenolysis and inhibit peripheral glucose use, leading to hyperglycemia and insulin resistance. Using larger insulin doses to treat the hyperglycemia can induce a cycle of nocturnal hypoglycemia followed by early morning hyperglycemia (Grossman & Porth, 2014).

The dawn phenomenon is a rise in blood glucose between 4 a.m. and 8 a.m. that is not a response to hypoglycemia. This condition occurs in people with both type 1 and type 2 DM. The exact cause is unknown. Increased insulin clearance, decreased sensitivity to insulin, and nocturnal increases in growth hormone are believed to contribute to the dawn phenomenon.

DIABETIC KETOACIDOSIS **Diabetic ketoacidosis (DKA)** develops when there is a deficiency of insulin; this results in glucose deficiency at the cellular level. As the pathophysiology of untreated type 1 DM continues, the glucose deficit causes fat stores to break down to provide energy, resulting in mobilization of fatty acids with a subsequent ketosis (refer to Figure 20–2). The lack of cellular glucose causes production of counterregulatory hormones (catecholamines, glucagon, cortisol, and growth hormone). Glucose production by the liver increases, peripheral glucose use decreases, fat mobilization increases, and ketogenesis (ketone formation) is stimulated. Increased glucagon levels activate the gluconeogenic and ketogenic pathways in the liver. In the presence of insulin deficiency, hepatic overproduction of beta-hydroxybutyrate and acetoacetic acids (ketone bodies) causes increased ketone concentrations and an increased release of free fatty acids. As a result of a loss of bicarbonate (which occurs when the ketone is formed), bicarbonate buffering does not occur, and metabolic acidosis develops. Severe hyperglycemia results in osmotic diuresis, which leads to dehydration and loss of electrolytes. If left untreated, fluid volume deficit leads to poor tissue perfusion and lactic acidosis, further complicating the metabolic acidosis. Depression of the central nervous system (CNS) from the accumulation of ketones, the resulting acidosis, and severe dehydration may cause coma and death if left untreated (Adams & Urban, 2013). The impact of DKA is illustrated in Figure 20–7 ■.

DKA also may occur in an individual with diagnosed DM when energy requirements increase during physical or emotional stress. Stress states initiate the release of counterregulatory hormones (catecholamines, glucagon, cortisol, and growth hormone). The person who is sick, has an infection (the most frequent cause of DKA), or who decreases or omits insulin doses is at a greatly increased risk for developing DKA.

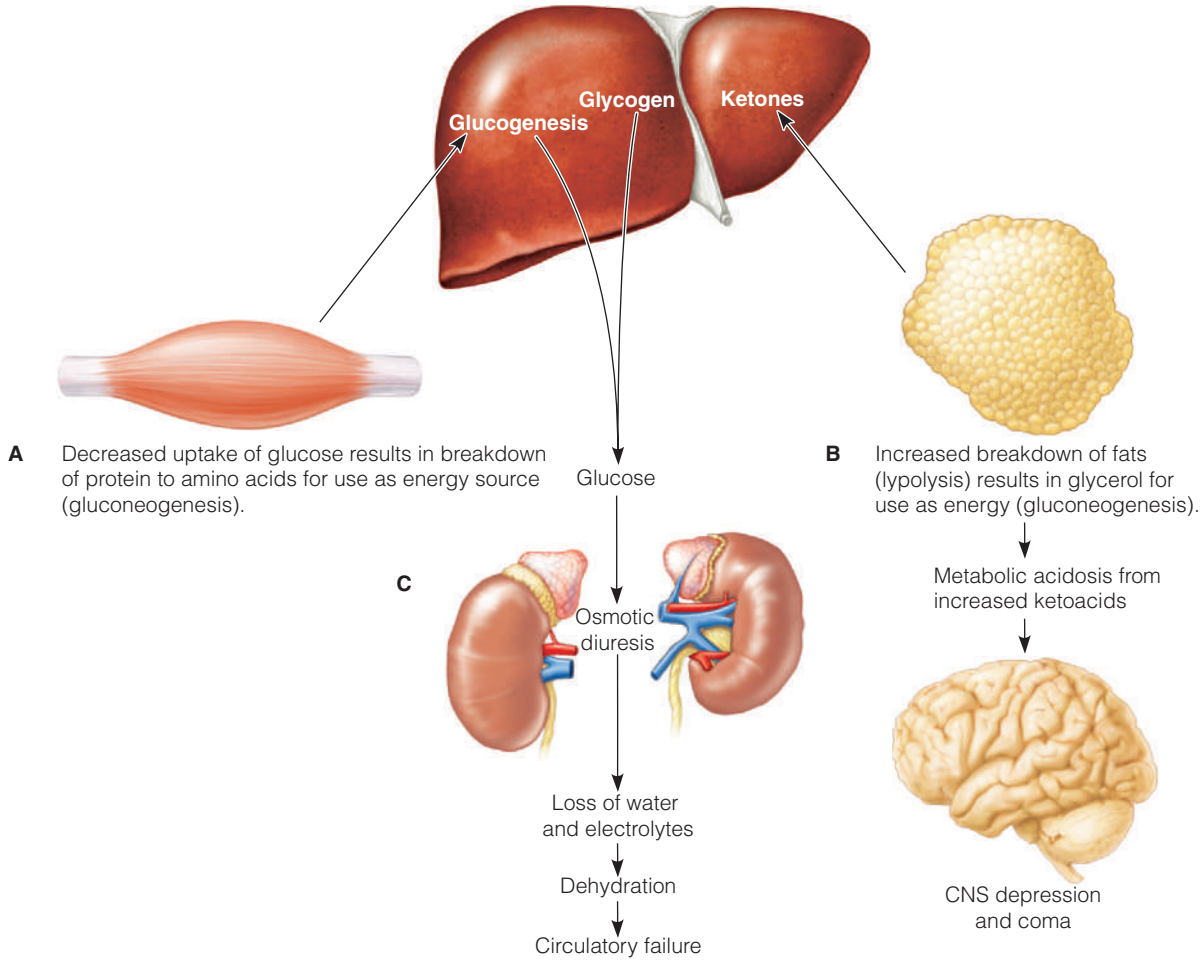


Figure 20–7 ■ DKA impact.

DKA involves four metabolic problems:

- Hyperosmolarity from hyperglycemia and dehydration
- Metabolic acidosis from an accumulation of ketoacids (and lactic acids if severe)
- Extracellular volume depletion from osmotic diuresis
- Electrolyte imbalances (such as loss of potassium and sodium) from osmotic diuresis.

Manifestations of DKA result from severe dehydration and acidosis. These manifestations are summarized in the accompanying box. Laboratory findings include the following:

- Blood glucose levels higher than 250 mg/dL
- Plasma pH less than 7.3
- Plasma bicarbonate less than 15 mEq/L
- Presence of serum ketones
- Presence of urine ketones and glucose
- Abnormal levels of serum sodium, potassium, and chloride.

MANIFESTATIONS OF DIABETIC KETOACIDOSIS (DKA)

DEHYDRATION (FROM HYPERGLYCEMIA)
- Thirst
- Warm, dry skin with poor turgor
- Soft eyeballs
- Dry mucous membranes
- Weakness
- Malaise
- Rapid, weak pulse
- Hypotension

METABOLIC ACIDOSIS (FROM KETOSIS)
- Nausea and vomiting
- Ketone (fruity, alcohol-like) breath odor
- Lethargy
- Coma

OTHER MANIFESTATIONS
- Abdominal pain (cause unknown)
- Kussmaul's respirations (increased rate and depth of respirations, with a longer expiration to blow off carbon dioxide; a compensatory response to acidosis)

INTERPROFESSIONAL CARE

DKA requires immediate medical attention. Admission to the hospital is appropriate when the person has a blood glucose of greater than 250 mg/dL, a decreasing pH, and ketones in the urine. If the patient is alert and conscious, fluids may be replaced orally. In the first 12 hours of treatment, adults usually require 8 to 10 L of fluid to replace losses from polyuria and vomiting. The initial fluid replacement may beaccomplished by administering 0.9% saline solution at a rate of 500 to 1000 mL/h. After 2 to 3 hours (or when blood pressure is returning to normal), the administration of 0.45% saline at 200 to 500 mL/h may continue for several more hours. When the blood glucose levels reach 250 mg/dL, dextrose is added to IV solutions to prevent rapid decreases in glucose. There is a risk of fatal cerebral edema if the blood glucose is lowered too quickly or fluids are given too rapidly or excessively.

Regular intravenous insulin is used in the management of DKA. Nursing responsibilities for the patient receiving intravenous insulin are described in the Medication Administration box. When renal function and blood pressure are restored, potassium and sodium can be corrected. The electrolyte imbalance of primary concern is depletion of body stores of potassium. Initially, serum potassium levels may be normal, but they decrease during treatment as a result of intracellular potassium deficits. Insulin causes potassium to be shifted into the cells, causing serum hypokalemia. In DKA (and from rehydration), the body loses potassium from increased urinary output, acidosis, catabolic state, and vomiting or diarrhea. Potassium replacement is begun early in the course of treatment, usually by adding potassium to the rehydration fluids. Replacement is essential for preventing cardiac dysrhythmias secondary to hypokalemia. Cardiac rhythms are monitored continuously and potassium levels must be monitored every 2 to 4 hours.

HYPEROSMOLAR HYPERGLYCEMIC STATE (HHS) The metabolic problem called **hyperosmolar hyperglycemic state (HHS)** occurs in people who have type 2 DM. HHS is characterized by a plasma osmolarity of 320 mOsm/L or greater (the normal range is 280 to 300 mOsm/L), greatly elevated blood glucose levels (often over 600 mg/dL and sometimes over 1000 mg/dL), and altered levels of consciousness. HHS is a serious, life-threatening medical emergency and has a higher mortality rate than DKA. Mortality is high as a result of severe osmotic diuresis resulting in dehydration and electrolyte deficits. Additionally, patients with HHS are usually older and have other medical problems such as heart failure. The precipitating factors associated with HHS include infection, medications that cause hyperglycemia, therapeutic procedures, acute illness, and chronic illness (Box 20–4). The manifestations of this disorder may be slow to appear, with onset ranging from 24 hours to 2 weeks. The manifestations are initiated by hyperglycemia, which causes osmotic diuresis. With increased urine output, plasma volume decreases. The resulting decreased perfusion causes the glomerular filtration rate (GFR) to drop and can lead to acute kidney injury. Some patients with type 2 DM have chronic HHS resulting from very poor control of hyperglycemia.

Serum hyperosmolarity results in severe dehydration, reducing intracellular water in all tissues, including the brain. The person has dry skin and mucous membranes, extreme thirst, and altered levels of consciousness (progressing from lethargy to coma). Neurologic deficits may include hyperthermia, motor and sensory impairment, positive Babinski's sign, and seizures. Metabolic acidosis is not usually part of the pathology; despite elevated blood glucose, sufficient insulin is present to prevent metabolism of fats. However, if dehydration is severe, it leads to decreased tissue perfusion and lactic acidosis will result. Treatment is directed toward correcting fluid and electrolyte imbalances, lowering blood glucose levels with insulin, and treating underlying conditions.

BOX 20–4 Factors Associated with Hyperosmolar Hyperglycemic State

MEDICATIONS
- Glucocorticoids
- Diuretics
- Beta-adrenergic blocking agents
- Immunosuppressants
- Chlorpromazine
- Diazoxide

THERAPEUTIC PROCEDURES
- Peritoneal dialysis
- Hemodialysis
- Hyperosmolar alimentation (oral or parenteral)
- Surgery

ACUTE ILLNESS
- Infection
- Gangrene
- Urinary tract infection
- Burns
- Gastrointestinal bleeding
- Myocardial infarction
- Pancreatitis
- Stroke

CHRONIC ILLNESS
- Kidney disease
- Cardiac disease
- Hypertension
- Previous stroke
- Alcoholism

INTERPROFESSIONAL CARE

HHS is a serious, life-threatening metabolic condition. The patient admitted to the intensive care unit for treatment typically manifests blood glucose levels over 600 mg/dL, dehydration with increased serum osmolarity, and altered levels of consciousness or seizures. Treatment is similar to that of DKA: correcting fluid and electrolyte

MEDICATION ADMINISTRATION

Intravenous Insulin

General Guidelines
- Regular insulin may be given by bolus injection undiluted directly into the vein.
- Insulin infusions are diluted in 0.9% saline or 0.45% saline solution and are always administered using an IV pump to regulate the rate of infusion.
- Because glass or plastic infusion containers and plastic tubing may reduce insulin potency by at least 20% and possibly by up to 80% before the insulin reaches the venous system, 50 mL of the insulin solution should be flushed through the intravenous tubing prior to starting the infusion.

Nursing Responsibilities
- Monitor blood glucose levels at least hourly.
- Flush the intravenous tubing with 50 mL of insulin mixed with normal saline solution to saturate binding sites on the tubing before administering the insulin to the patient; this step increases the amount of insulin delivered during the first few hours.
- Do not discontinue the intravenous infusion until subcutaneous administration of insulin is resumed.
- Monitor for manifestations of hypoglycemia and hyperglycemia.
- Ensure that D_{50} is readily available as an antidote for hypoglycemia.

imbalances and providing insulin to lower hyperglycemia. In general, treatment modalities include the following:

- Establishing and maintaining adequate ventilation
- Correcting shock with adequate intravenous fluids
- Instituting nasogastric suction if comatose to prevent aspiration
- Maintaining fluid volume with intravenous isotonic or colloid solutions
- Administering potassium intravenously to replace losses
- Administering insulin to reduce blood glucose, usually discontinuing administration when blood glucose levels reach 250 mg/dL. (Because ketosis is not present, there is no need to continue insulin, as with DKA.)

HYPOGLYCEMIA **Hypoglycemia** (low blood glucose levels) is common in people with type 1 DM and occasionally occurs in people with type 2 DM who are treated with certain oral hypoglycemic agents. This condition is sometimes referred to as insulin shock, insulin reaction, or "the lows" in patients with type 1 DM. Hypoglycemia results primarily from a mismatch between insulin intake (e.g., an error in insulin dose), physical activity, and lack of carbohydrate availability (e.g., omitting a meal). The intake of alcohol and drugs such as chloramphenicol (Chloromycetin), Coumadin, monoamine oxidase (MAO) inhibitors, probenecid (Benemid), salicylates, and sulfonamides can also cause hypoglycemia.

The manifestations of hypoglycemia (refer to the Manifestations box) result from a compensatory autonomic nervous system (ANS) response and from impaired cerebral function due to a decrease in glucose available for use by the brain. The manifestations vary, particularly in older adults. The onset is sudden, and blood glucose is usually less than 60 mg/dL. Severe hypoglycemia may cause death. Table 20–4 compares DKA, HHS, and hypoglycemia.

People who have type 1 DM for 4 or 5 years fail to secrete glucagon in response to a decrease in blood glucose. They then depend on epinephrine to serve as a counterregulatory response to hypoglycemia. However, this compensatory response can become absent or blunted. As a result, the person with type 1 diabetes does not experience typical manifestations of hypoglycemia; the first symptoms include fatigue and inability to think followed by loss of consciousness and seizures. The individual with type 1 diabetes should always have glucagon available and close family members (or significant others) and coworkers should be familiar with its administration.

INTERPROFESSIONAL CARE FOR HYPOGLYCEMIA

Mild Hypoglycemia When mild hypoglycemia occurs, immediate treatment is necessary. People experiencing hypoglycemia should take about 15 g of a rapid-acting sugar. This amount of sugar is found, for example, in three glucose tablets, 1/2 cup (4 ounces) of fruit juice or regular soda, 8 oz of skim milk, five Life Savers candies, three large marshmallows, or 3 tsp of sugar or honey. Sugar should not be added to fruit juice. Adding sugar to the fruit sugar already in the juice could cause a rapid rise in blood glucose, with persistent hyperglycemia.

If the manifestations continue, the 15/15 rule should be followed: Wait 15 minutes, monitor blood glucose (BG), and, if it is low, eat another 15 g of carbohydrate. This procedure can be repeated until blood glucose levels return to normal (ADA, 2012a). BG should be tested 1 hour after the BG has reached ≥ 70 mg/dL because BG levels may start to fall again after 1 hour. People with DM should have some source of carbohydrate readily available at all times so that hypoglycemic manifestations can be quickly reversed. If hypoglycemia occurs more than two or three times a week, the DM management plan should be adjusted.

Severe Hypoglycemia People with DM who have severe hypoglycemia should seek medical attention. The criteria for hospitalization are one or more of the following:

- Blood glucose is less than 50 mg/dL, and the prompt treatment of hypoglycemia has not resulted in recovery of sensorium.
- The patient has coma, seizures, or altered behavior.
- The hypoglycemia has been treated, but a responsible adult cannot be with the patient for the following 12 hours.
- The hypoglycemia was caused by a sulfonylurea drug.

If the patient is conscious and alert, 10 to 15 g of an oral carbohydrate may be given. If the patient has altered levels of consciousness, parenteral glucose or glucagon is administered. Fifty percent dextrose (D_{50}) is administered by intravenous push. This is the most rapid method of increasing BG levels. Glucagon is an antihypoglycemic agent that raises blood glucose by promoting the conversion of hepatic glycogen to glucose. It is used in severe insulin-induced hypoglycemia (usually outside of the hospital setting) and may be given in the recommended dose of 1 mg by the subcutaneous or intramuscular route. Glucagon has a short period of action; an oral (when the patient is conscious) or intravenous carbohydrate should be administered following the glucagon to prevent a recurrence of hypoglycemia. If the patient has been unconscious, glucagon may cause vomiting when consciousness returns.

Chronic Complications

Although the underlying mechanisms of the vascular, neurologic, and other complications of diabetes are not yet well understood, it is clear that the level of chronic hyperglycemia correlates well with their development. Increased intracellular glucose levels affect cell

MANIFESTATIONS OF HYPOGLYCEMIA

MANIFESTATIONS CAUSED BY RESPONSES OF THE AUTONOMIC NERVOUS SYSTEM

- Hunger
- Nausea
- Anxiety
- Pale, cool skin
- Sweating
- Shakiness
- Irritability
- Rapid pulse
- Hypotension

MANIFESTATIONS CAUSED BY IMPAIRED CEREBRAL FUNCTION

- Strange or unusual feelings
- Headache
- Difficulty in thinking
- Inability to concentrate
- Change in emotional behavior
- Slurred speech
- Blurred vision
- Decreasing levels of consciousness
- Seizures
- Coma

TABLE 20–4 DKA, HHS, and Hypoglycemia Compared

		DKA	HHS	Hypoglycemia
DM Type		Primarily type 1	Type 2	Both
Onset		Slow	Slow	Rapid
Cause		↓ Insulin Infection	↓ Insulin Older age	↑ Insulin Omitted meal/snack Error in insulin dose
Risk factors		Surgery Trauma Illness Omitted insulin Stress	Surgery Trauma Illness Dehydration Medications Dialysis Hyperalimentation	Surgery Trauma Illness Exercise Medications Lipodystrophy Renal failure Alcohol intake

proteins and result in the release of abnormal metabolic end-products (Powers, 2012). The abnormal glycoproteins are believed to damage basement membranes, affecting the eyes, kidneys, and circulation (Grossman & Porth, 2014).

ALTERATIONS IN THE CARDIOVASCULAR SYSTEM

The relationship between hyperglycemia and vascular complications is now clear. The effect of hyperglycemia from impaired glucose tolerance and insulin resistance sets off an inflammatory process in the vascular endothelial lining. Proinflammatory cytokines are released in the presence of hyperglycemia, and they start a cascade that increases insulin resistance, increases hyperglycemia, and causes inflammatory damage in the endothelium. Polyol pathways are created, and oxidative stress at the cellular level occurs. Abnormal metabolic end products, vascular endothelial growth factor, and angiopoietin are also thought to contribute to vascular damage (Rambhade et al., 2011).

MACROVASCULAR COMPLICATIONS

Macrovascular damage is manifested through atherosclerosis and often results in hypertension, coronary artery damage, cerebral artery and carotid artery damage, and peripheral arterial damage (Rambhade et al., 2011). People with undiagnosed diabetes often seek treatment for a vascular complication such as acute myocardial infarction or manifestations of peripheral vascular disease before the diagnosis of type 2 diabetes. The metabolic syndrome, a known risk factor for diabetes, is a major risk factor for macrovascular disease as well.

CORONARY ARTERY DISEASE Coronary artery disease is a major risk factor in the development of myocardial infarction in people with DM, especially in the middle to older adult with type 2 DM. Coronary artery disease is the most common cause of death in people with type 2 DM (McPhee et al., 2012). People with DM who have myocardial infarction are more prone to develop heart failure as a complication of the infarction and are also less likely to survive in the period immediately following the infarction.

HYPERTENSION Hypertension affects 75% of all people with DM, and is a major risk factor for cardiovascular disease and microvascular complications such as retinopathy and nephropathy. Hypertension may be reduced by weight loss, exercise, avoiding or stopping smoking, and decreasing sodium intake and alcohol consumption. In addition, treatment with antihypertensive medications is necessary.

STROKE (CEREBROVASCULAR ACCIDENT) People with DM, especially older adults with type 2 DM, are two to four times more likely to have a stroke than those who do not have DM (CDC, 2011). Atherosclerosis of the cerebral vessels develops at an earlier age and is more extensive in people with DM (Rambhade et al., 2011).

The manifestations of stroke or transient ischemic attacks are often similar to those of hypoglycemia or HHS: blurred vision, slurred speech, weakness, and dizziness. Manifestations that are different with stroke include unilateral facial droop, weakness, or paralysis. People with these manifestations require immediate medical attention.

PERIPHERAL VASCULAR DISEASE Peripheral vascular disease of the lower extremities accompanies both types of DM, and is related to hyperglycemia. Atherosclerosis of vessels in the legs of people with DM begins at an earlier age and advances more rapidly than in the general population. It is equally common in both men and women. Impaired peripheral arterial circulation impairs tissue perfusion and leads to intermittent claudication (pain) in the lower legs and ulcerations of the feet. (See the accompanying box for manifestations of peripheral vascular disease.)

Vascular damage, as well as alterations in neurologic function and increased risk of infection, can result in gangrene (necrosis, or the death of tissue). Gangrene from DM is the most common cause of nontraumatic amputations of the lower leg. In people with DM, dry gangrene is most common, manifested by cold, dry, shriveled, and black tissues of the toes and feet. The gangrene usually begins in the toes and moves proximally into the foot. (Peripheral vascular disease is discussed in Chapter 32.)

MANIFESTATIONS OF PERIPHERAL VASCULAR DISEASE

- Loss of hair on lower leg, feet, and toes
- Atrophic skin changes: shininess and thinning
- Cold feet
- Feet and ankles darker than leg
- Dependent rubor, blanching on elevation
- Thick toenails
- Diminished or absent pulses
- Nocturnal pain
- Pain at rest, relieved by standing or walking
- Intermittent claudication
- Patchy areas of gangrene on feet and toes

MICROVASCULAR COMPLICATIONS

Microvascular changes include capillary leak, microthromboses, and decreased transport of oxygen and glucose to the cells. The basement membrane of smaller blood vessels and capillaries thickens, eventually leading to decreased tissue perfusion. (The basement membrane is the structure that supports and serves as the boundary around the space occupied by epithelial cells.) Alterations in the microcirculation affect all body tissues.

DIABETIC RETINOPATHY Diabetic retinopathy is the name for the changes in the retina that occur in the person with DM. Microvascular damage and hemorrhages lead to scarring of the retina. Diabetic retinopathy is the leading cause of blindness in people between ages 20 and 74 (CDC, 2011). If exudate, edema, hemorrhage, or ischemia occurs near the fovea, the person experiences visual impairment. In addition, the person with DM is at increased risk for developing cataracts (opacity of the lens) as a result of increased glucose levels within the lens itself. Screening for retinopathy is important, as laser photocoagulation surgery has proven beneficial in preventing loss of vision.

DIABETIC NEPHROPATHY Diabetic nephropathy results from microvascular disease of the kidneys and is characterized by the presence of albumin in the urine, hypertension, and progressive renal insufficiency. The most common cause of renal failure in the United States is diabetes (CDC, 2011).

Microvascular damage results in thickening of the basement membrane of the glomeruli and eventually impairs renal function. Glomerulosclerosis thickens the basement membrane and simultaneously makes it functionally leaky, allowing large molecules such as protein to be lost in the urine. Kimmelstiel-Wilson syndrome is a type of glomerulosclerosis found only in people with DM. In advanced nephropathy, tubular atrophy occurs, and end-stage renal disease results. (Renal failure is discussed in Chapter 28.)

The first indication of nephropathy is microalbuminuria, an abnormal level of albumin in the urine. Without specific interventions, people with DM with sustained microalbuminuria will develop nephropathy, accompanied by hypertension. People with type 2 DM often have microalbuminuria and nephropathy shortly after diagnosis of diabetes is made, because prediabetes (or undiagnosed diabetes) with intermittent hyperglycemia has been present and untreated for many years. Because the hypertension accelerates the progress of diabetic nephropathy, aggressive antihypertensive management should be instituted. Management includes control of hypertension with ACE inhibitors, weight loss, reduced salt intake, and exercise.

DIABETIC NEUROPATHIES

Peripheral and visceral neuropathies are disorders of the peripheral nerves and the autonomic nervous system. In people with DM, these disorders are often called diabetic neuropathies. The etiology of diabetic neuropathies involves (1) a thickening of the walls of the blood vessels that supply nerves, causing a decrease in nutrients; (2) demyelinization of the Schwann cells that surround and insulate nerves, slowing nerve conduction; and (3) the formation and accumulation of sorbitol within the Schwann cells, impairing nerve conduction. The manifestations depend on the location of the lesions.

The peripheral neuropathies (also called *somatic neuropathies*) include polyneuropathies and mononeuropathies. *Polyneuropathies*, the most common type of neuropathy associated with DM, are bilateral sensory disorders. The manifestations appear first in the toes and feet and progress upward. The fingers and hands may be involved, but usually only in later stages of DM. The manifestations of polyneuropathy depend on the nerve fibers involved. The lack of sensation prevents awareness of injury and for this reason, people with diabetes must be taught to visually inspect their feet and legs daily, looking for evidence of injury.

The person with polyneuropathy commonly has distal paresthesias (a change in sensation, such as numbness or tingling); pain described as aching, burning, or shooting; and feelings of cold feet. Other manifestations may include impaired sensations of pain, light touch, two-point discrimination, and vibration. There is no specific treatment for polyneuropathy.

Mononeuropathies are isolated peripheral neuropathies that affect a single nerve. Depending on the nerve involved, manifestations may include the following:

- Palsy of the third cranial (oculomotor) nerve, with headache, eye pain, and an inability to move the eye up, down, or medially
- Radiculopathy, with pain over a dermatome and loss of cutaneous sensation, most often located in the chest
- Diabetic femoral neuropathy, with motor and sensory deficits (pain, weakness, areflexia) in the anterior thigh and medial calf
- Entrapment or compression of the medial nerve at the wrist, resulting in carpal tunnel syndrome with pain and weakness of the hand; the ulnar nerve at the elbow, with weakness and loss of sensation over the palmar surface of the fourth and fifth fingers; and the peroneal nerve at the head of the fibula, with foot drop.

VISCERAL NEUROPATHIES The visceral neuropathies (*autonomic neuropathies*) cause various manifestations, depending on the area of the ANS involved. These neuropathies may include the following:

- Sweating dysfunction, with an absence of sweating (anhidrosis) on the hands and feet and increased sweating on the face or trunk.
- Abnormal pupillary function, most commonly seen as constricted pupils that dilate slowly in the dark.
- Cardiovascular dysfunction, resulting in such abnormalities as a fixed cardiac rate that does not change with exercise, postural hypotension, and a failure to increase cardiac output or vascular tone with exercise.
- Gastrointestinal dysfunction, with changes in upper GI motility (**gastroparesis**) resulting in dysphagia, anorexia, heartburn, nausea and vomiting, and slowed digestion with altered blood glucose control. Constipation is one of the most common GI manifestations associated with DM, possibly a result of hypomotility of the bowel. Diabetic diarrhea is not as common, but it does occur and is often associated with fecal incontinence during sleep due to a defect in internal sphincter function.
- Genitourinary dysfunction, resulting in changes in bladder function and sexual function. Bladder function changes include an inability to empty the bladder completely, loss of sensation of bladder fullness, and an increased risk of urinary tract infections. Sexual dysfunctions in men include ejaculatory changes and impotence. Sexual dysfunctions in women include changes in arousal patterns, vaginal lubrication, and orgasm. Alterations in sexual function in people with DM are the result of both neurologic and vascular changes.

MOOD ALTERATIONS Individuals with DM, both type 1 and type 2, endure the chronic strains of living with complex self-care and are at increased risk for depression and DM-specific emotional distress. The management of diabetes can create financial, emotional, and social distress. Depression affects the ability to self-manage DM; depressed patients may forget to take their medications or run out of medications because they forget to refill their prescriptions in a timely manner. Treating depression has been associated with better control of serum glucose, so screening for depression is an important part of assessing the individual's ability to manage the disease. Tests to identify the scope of depression are available (ADA, 2012a).

Interventions to help patients with depression include antidepressant medications and psychotherapy focused on restoring logical thinking and problem-solving skills. Nurses can assist depressed patients by correcting misconceptions about depression, identifying individual strengths in managing DM, acknowledging negative feelings that may be expressed, suggesting problem-solving behaviors to better manage the disease, and referring to appropriate resources.

INCREASED SUSCEPTIBILITY TO INFECTION

The person with DM has an increased risk of developing infections. Vascular and neurologic impairments, hyperglycemia, inflammation, and altered neutrophil function are responsible for increased susceptibility to infections (Adams & Urban, 2013).

The person with DM may have sensory deficits resulting in inattention to trauma, and vascular deficits that decrease circulation to the injured area; as a result, healing is slowed. Nephrosclerosis and inadequate bladder emptying with retention of urine predispose the person with DM to pyelonephritis and urinary tract infections. Bacterial and fungal infections of the skin, nails, and mucous membranes are common. Surgical patients with a blood glucose value greater than 140 mg /dL have higher infection rates (Kadoi, 2010).

PERIODONTAL DISEASE Although periodontal disease does not occur more often in people with DM, it does progress more rapidly, especially if the DM is poorly controlled. Vascular changes in the gums coupled with periods of hyperglycemia increase the risk of infection and decrease the localized response to infection. As a result, gingivitis (inflammation of the gums) and periodontitis (inflammation of the bone underlying the gums) occur.

COMPLICATIONS INVOLVING THE FEET

The high incidence of foot problems and amputations in people with DM is the result of angiopathy, neuropathy, and infection. People with DM, especially those who are not meeting recommended glycemic goals, are at high risk for amputation of a lower extremity.

Atherosclerosis and microvascular changes in the lower extremities of the person with DM impair tissue perfusion and oxygenation. The smaller blood vessels located below the knee are most affected with occlusions in the large, medium, and small arteries of the lower legs and feet. Multiple occlusions with decreased blood flow result in the manifestations of peripheral vascular disease

Diabetic neuropathy impairs the sense of touch and perception of pain. As a result, the person with DM may experience foot trauma without being aware of it. Healing is impaired by the effects of DM and poor tissue perfusion, increasing the risk for ulceration and infection (see Figure 20–8 ■).

The most common sources of foot trauma in the individual with DM are cracks and fissures caused by dry skin or infections such as athlete's foot, blisters caused by improperly fitting shoes, pressure from stockings or shoes, ingrown toenails, and direct trauma (cuts, bruises, or burns). An individual with diabetic neuropathy may not be aware that these injuries have occurred. In addition, when a part of the body loses sensation, the individual tends to dissociate from or ignore the part, so an injury may go unattended for days or weeks. The injury may even be forgotten entirely.

Foot lesions usually begin as a superficial skin ulcer. In time, the ulcer extends deeper into muscles and bone, leading to abscess or osteomyelitis. Gangrene can develop on one or more toes; if untreated, the whole foot eventually becomes gangrenous. (Care of the feet, an essential part of patient and family education, is discussed later in the chapter.)

●○● NURSING CARE

Diabetes mellitus is a chronic condition and the plan of care is dedicated to preventing complications and maintaining or improving quality of life. The responses of the person with DM to the illness are often complex and individual, involving multiple body systems. Assessments, planning, and implementation differ for the person with newly diagnosed DM, the person with long-term DM, and the person with acute complications of DM. The plan of care and content of teaching also differ according to the type of DM, the person's age and culture, and the person's intellectual, psychologic, and social resources. Nurses who are DM specialists and generalists are relied on to teach patients to successfully manage living with DM. To teach and support patients in their efforts to manage DM, all nurses need to understand DM, learn effective behavioral change strategies, and know appropriate interventions. The Moving Evidence into Action box on page 528 describes a nursing study of the effect of resilience in diabetes self-care.

Health Promotion

Health promotion activities primarily focus on preventing the onset and complications of DM. The prevention of type 2 diabetes has been shown in randomized controlled trials to be achievable in a significant number of individuals at risk. A combination of lifestyle changes (weight loss and increased physical activity) and medications (especially metformin) prevents or delays the onset of type 2 DM (ADA, 2012a). Prevention of progression to DM is dependent on at-risk individuals accepting responsibility for learning and sustaining lifestyle changes through self-management education, counseling, and coaching. Blood glucose screening at 3-year intervals beginning at age 45 is recommended for those not in the high-risk group.

Assessment

The following data are collected through the health history and physical examination. Further focused assessments are described below with nursing interventions. When assessing the older patient, be aware of normal aging changes in all body systems that may alter interpretation of findings.

- ***Health History:*** family history of DM; history of hypertension or other cardiovascular problems; history of any change in vision (e.g., blurring) or speech, dizziness, numbness or tingling in hands or feet; pain when walking; frequent voiding; change in weight, appetite, infections, and healing; problems with gastrointestinal function or urination; or altered sexual function
- ***Physical Assessment:*** height/weight ratio, vital signs, visual acuity, cranial nerves, sensory ability (touch, hot/cold, vibration) of extremities, peripheral pulses, skin and mucous membranes (hair loss, appearance, lesions, rash, itching, vaginal discharge).

Priorities of Care

The priorities of care for the patient with DM are to maintain function, prevent complications, and teach self-management. Teaching the patient and significant others to manage the disease is vital to achieving long-term glycemic targets. Although the patient with an acute or chronic complication of DM may require focused nursing interventions to restore functional health, teaching to maintain health and prevent future complications remains a priority of nursing care.

Moving Evidence into Action

Resilience and Diabetes Outcomes in African American Women

When compared with Caucasian women, African American women are more likely to be diagnosed with type 2 diabetes mellitus, more likely to experience complications of the disease, and also have a lower life expectancy (DeNisco, 2011). The diagnosis of diabetes can have significant physical, psychologic, social, lifestyle, and potentially economic impacts on the individual.

Optimal glycemic control is clearly recognized to reduce the risk of complications and an early death due to DM. The abilities to access healthcare, self-manage the disease, and perform specific tasks and behaviors influence glycemic control. These abilities, in turn, may be influenced by the resilience of the individual. Resilience can be defined as a positive adjustment or adaptation to adversity such as a devastating illness or loss (DeNisco, 2011). This personality characteristic moderates the negative effects of stress and promotes adaptation.

Using a convenience sample of 71 Black women ranging in age from 33 to 85 years, DeNisco (2011) measured resilience levels. Resilience was then correlated with demographic and personal characteristics, and with glycosylated hemoglobin levels. Participants with higher resilience scores had significantly lower HbA1C levels, indicating better glycemic control.

Implications for Nursing

A holistic approach to care that provides psychologic, emotional, and social support is important for the patient with DM. Helping the patient focus on planning, goal setting, problem solving, and mastery of physical and psychologic self-care is one way of building resilience.

Moving Knowledge into Action

1. You are caring for two patients with DM who are receiving home care for complications of long-term DM. One patient follows the medical regimen faithfully, the other adapts it to his own schedule and needs.
2. What differences can you identify in your own reaction to these two different patients?
3. How would these reactions affect your relationship with the patients?

Evidence for Nursing Care

The Patient with Type 1 DM

Selected resources that nurses may find helpful when planning evidence-based nursing care follow.

- Blount, A. M., & Largay, J. (2011). Insulin pump therapy for the patient with diabetes. *Clinician Reviews, 21*(11), 26–31.
- Garg, S. K., & Hirsch, I. B. (2011). Self-monitoring of blood glucose. *International Journal of Clinical Practice, 170*(Suppl.), 1–9.

Diagnoses, Outcomes, and Interventions

Although many different nursing diagnoses are appropriate for the individual with DM, those discussed in this section address actual or potential problems with skin integrity, infection, injury, sexuality, and coping. See the accompanying Case Study & Nursing Care Plan for more information.

Risk for Impaired Skin Integrity

The person with DM is at increased risk for altered skin integrity as a result of changes in sensation and decreased tissue perfusion. In addition, an open lesion is more prone to infection and delayed healing. Impaired skin and tissue integrity, with resultant gangrene, is especially common in the feet and lower extremities.

Expected Outcomes: Patient's skin will remain intact without evidence of wounds or ulcers. Patient will demonstrate preventive foot care and will manage wounds as instructed. Patient will maintain glycemic control to promote healing. The patient's caregiver will manage wounds as instructed.

- Conduct baseline and ongoing assessments of the feet:
  - Musculoskeletal assessment, including foot and ankle joint range of motion, bone abnormalities (bunions, hammertoes, overlapping digits), gait patterns, use of assistive devices for walking, and abnormal wear patterns on shoes
  - Neurologic assessment, including sensations of touch and position, pain, and temperature
  - Vascular assessment, including lower-extremity pulses, capillary refill, color and temperature of skin, lesions, and edema
  - Hydration status, including dryness or excessive perspiration
  - Lesions, fissures between toes, corns, calluses, plantar warts, ingrown or overgrown toenails, redness over pressure points, blisters, cellulitis, or gangrene.

  Peripheral neuropathies may result in altered pain perception, loss of deep tendon reflexes, loss of cutaneous pressure and position sensation, foot drop, changes in the shape of the foot, and changes in bones and joints. Peripheral vascular disease may cause intermittent claudication, absent pulses, delayed venous filling on elevation, dependent rubor, and gangrene. Injuries, lesions, and changes in skin hydration potentiate infections, delayed healing, and tissue loss in the person with DM.
- Teach foot hygiene. Wash the feet daily with lukewarm water and mild hand soap; pat dry, and dry well between the toes. Use a thermometer to test the water temperature in the shower or bath before stepping in. Apply a very thin coat of lubricating cream if dryness is present (but not between the toes). *Proper hygiene decreases the chance of infection. Temperature receptors may be impaired, so the water should always be tested before use.*
- Discuss the importance of not smoking if patient smokes. *Nicotine in tobacco causes vasoconstriction, further decreasing the blood supply to the feet.*
- Discuss the importance of maintaining blood glucose levels through diet, medication, and exercise. *Hyperglycemia is associated with a higher risk for the chronic complications of DM, including peripheral vascular disease and neuropathy.*
- Conduct and reinforce foot care teaching sessions as often as necessary (see the accompanying box). Use a variety of methods, including demonstration, return demonstration, audiovisual aids, and written lists. If the person is wearing shoes and socks, ask him or her to remove them to practice foot care effectively. If the person has visual deficits, is obese, or cannot reach the feet, teach the caregiver how to inspect and care for the feet. *Foot care is a priority in DM management to prevent serious problems. Many people with DM are unaware of lesions or injury until infection and compromised circulation are far advanced.*

SAFETY ALERT

Suggest the use of a hand mirror to check the bottom of the feet and the back of the heels.

Risk for Infection

The person with DM is at increased risk for infection due to vascular insufficiency that limits tissue perfusion, an inhibited inflammatory response, neurologic abnormalities that limit the awareness of trauma, and increased susceptibility to bacterial and fungal infections, especially in the presence of hyperglycemia.

Expected Outcomes: Patient will be free from infection. Patient will treat infections per provider advice.

- Use and teach meticulous hand hygiene. *Hand hygiene is the single most effective method for preventing the spread of infection.*
- Monitor for manifestations of infection: increased temperature, pain, malaise, swelling, redness, discharge, cough. *Early diagnosis and treatment of infections can control their severity and decrease complications.*
- Discuss the importance of meticulous skin care. Keep the skin clean and dry, using lukewarm water and mild soap. *People with DM are more prone to develop furuncles and carbuncles; the infection often increases the need for insulin. Clean, intact skin and mucous membranes are the first line of defense against infection.*
- Teach dental health measures:
  - Obtain a dental examination every 4 to 6 months.
  - Maintain careful oral hygiene, which includes brushing the teeth with a soft toothbrush and fluoridated toothpaste at least twice a day and flossing as recommended.
  - Be aware of the manifestations requiring dental care: bad breath; unpleasant taste in the mouth; bleeding, red, or sore gums; and tooth pain.
- If dental surgery is necessary, monitor for need to make adjustments in insulin. *All people with DM need to be taught proper oral hygiene, the risk of periodontal disease, and the importance of obtaining dental care for manifestations of oral or dental problems.*
- Teach women about the manifestations and preventive measures for vaginitis caused by *Candida albicans*. The manifestations are an odorless, white or yellow cheeselike discharge and itching. *DM is a predisposing factor for* Candida albicans *vaginitis, the most common form of vaginitis. Poor personal hygiene and wearing clothing that keeps the vaginal area warm and moist increase the risk of vaginitis. The infection may spread to the urinary tract, resulting in urinary tract infections; preventing and treating vaginitis decrease this risk.*

SAFETY ALERT

Teach women with DM to prevent urinary tract infection (UTI) by maintaining good personal hygiene, wiping front to back after voiding, wearing cotton underwear, avoiding tight jeans and nylon pantyhose, and avoiding douching.

Risk for Injury

The person with DM is at risk for injury from multiple factors. Neuropathies may alter sensation, gait, and muscle control. Cataracts or retinopathy may cause visual deficits. Hyperglycemia often causes osmotic changes in the lens of the eye, resulting in blurred vision. In addition, significant changes in blood glucose alter levels of consciousness and may cause seizures. The impaired mobility, sensory

Meeting Individualized Needs

Foot Care Teaching Session

BUYING AND WEARING SHOES AND STOCKINGS

- Shoes should allow 1/2 to 3/4 inch of room for toes to spread out and wiggle. The lining and inside stitching should be smooth, and the insole soft with good arch support. The sole should be flexible and cushion the foot. The heel should fit snugly.
- Do not wear open-toed shoes, sandals, high heels, or flip-flops; they increase the risk of trauma.
- Buy shoes late in the afternoon, when feet are at their largest; always buy shoes that feel comfortable and do not need to be "broken in."
- Shoes made of natural fibers (leather, canvas) allow perspiration to escape.
- Check the shoes before each wearing for foreign objects, wrinkled insoles, and cracks that might cause lesions.
- Stockings made of wool or cotton allow perspiration to dry.
- Do not wear garters, knee stockings, or panty hose; they may interfere with circulation.
- Wear insulated boots in the winter.

INSPECTING THE FEET

- Check the feet, including between the toes, daily for red areas, cuts, blisters, corns, calluses, or cracks in the skin.
- Check the skin of the feet for dry or damp areas.
- Use a mirror to check each sole and the back of each heel.
- If you are unable to inspect the feet daily, be sure that someone else does so.

CARE OF TOENAILS

- Cut the toenails after washing, when they are softer and easier to trim.
- Cut the nails straight across with a clipper, and smooth edges and corners with an emery board.
- Do not use razor blades to trim the toenails or callouses.
- If you are unable to see well or to reach the feet easily, have someone else trim the nails. If the nails are very thick or ingrown, if the toes overlap, or if circulation is poor, get professional care from a podiatrist.

GENERAL INFORMATION

- Never go barefoot. Wear slippers when leaving the bed during the night.
- Do not use commercial corn medicines or pads, chemicals (such as boric acid, iodine, or hydrogen peroxide), or over-the-counter cortisone medications on the feet.
- Do not put heating pads, hot water bottles, or ice packs on the feet. If the feet become cold at night, wear socks or use extra blankets.
- Do not allow the feet to become sunburned.
- Do not put tape on the feet.
- Do not sit with the legs crossed at the knees or ankles.

deficits, and neurologic effects of complications of DM increase the risk of accidents, burns, falls, and trauma.

Expected Outcomes: Patient will be free from injury. Patient will demonstrate an understanding of techniques to prevent injury, and will implement safety measures in the home to prevent injury. The patient (and close caregivers) will demonstrate knowledge of diabetes, how to meet glycemic goals, and how to prevent diabetic emergencies.

- Assess factors that increase the risk of injury: blurred vision, cataracts, decreased adaptation to dark, decreased tactile sensitivity, hypoglycemia, hyperglycemia, dehydration, joint immobility, unstable gait. *A knowledge base is necessary to develop an individualized plan of care. The risk of injury increases with the number of factors identified.*
- Reduce environmental hazards in the healthcare facility, and teach the patient about safety in the home and in the community.

CASE STUDY & NURSING CARE PLAN A Patient with Type 1 DM

Jim Meligrito, age 24, is a nursing student at a large university. Mr. Meligrito works 20 hours a week as a campus student security guard. His working hours are 8 p.m. to midnight, five nights a week. He lives with his father, who is also a student. Neither of the two men likes to cook, and they usually eat "whatever is handy." Mr. Meligrito has smoked 8 to 10 cigarettes a day for 5 years. He was diagnosed with type 1 DM at age 12. Although his insulin dosage has varied, he currently takes a total of 32 units of insulin each day, 10 units of NPH and 6 units of regular insulin each morning and evening. He monitors his blood glucose about three times a week. He feels that he is too busy for a regular exercise program and that he gets enough exercise in clinicals and in weekend sports activities. He has not seen a healthcare provider for over a year.

One day during a 6-hour clinical experience, Mr. Meligrito notices that he is urinating frequently, is thirsty, and has blurred vision. He is very tired but blames all his manifestations on drinking a couple of beers and having only 4 hours of sleep the night before while studying for an examination and also on the stress he has been under lately from school and work. When he remembers that he had forgotten to take his insulin that morning, he realizes he must have hyperglycemia but decides that he will be all right until he gets home in the afternoon. Around noon, he begins having abdominal pain, feels weak, has a rapid pulse, and vomits. When he reports his physical manifestations to his clinical instructor, she sends him immediately to the hospital emergency department, accompanied by another student.

ASSESSMENT

As soon as Mr. Meligrito arrives at the emergency department, his blood glucose level is measured at 400 mg/dL. Urine samples and additional blood samples are sent to the laboratory for analysis. Blood glucose is 430 mg/dL, Hgb A1C is 9.5%, urine shows the presence of ketones, electrolytes are normal, and pH is 7.1. His vital signs are as follows: T 37.2°C (99°F), P 140 bpm, R 28/min, and BP 102/52 mmHg. An intravenous infusion of 1000 mL normal (0.9%) saline with 20 mEq of KCl is started at a rate of 400 mL/h. Intravenous regular insulin at 5 units/h (diluted in 0.9% saline) is begun. Hourly blood glucose monitoring is initiated. Mr. Meligrito is nauseated and lethargic but remains oriented. Three hours later, he has a blood glucose level of 120 mg/dL, and his pulse and blood pressure are normal. He is dismissed from the emergency department after making an appointment for the next morning with the hospital's DM nurse educator. When he meets with the DM educator, he says that he no longer feels in control of the DM or his future goal to become a nurse anesthetist.

DIAGNOSIS

- *Ineffective Self-Health Management* related to control of blood glucose as evidenced by recent episode of DKA and elevated Hgb A_1C
- *Powerlessness* related to a perceived lack of control of DM due to present demands on time
- *Deficient knowledge* related to self-management of DM
- *Risk for Ineffective Role Performance* related to uncertainty about capacity to achieve desired role as registered nurse

EXPECTED OUTCOMES

- Patient will identify those aspects of DM that can be controlled and participate in making decisions about self-managing care.
- Patient will demonstrate an understanding of DM self-management through planned medication, diet, exercise, and blood glucose self-monitoring activities.
- Patient will explore and clarify his perceptions of his role as a student nurse, verbalizing his ability to meet his expectations.

PLANNING AND IMPLEMENTATION

- Mutually establish specific and individualized short-term and long-term goals for self-management of blood glucose.
- Provide patient with opportunities to express feelings about himself and his illness.
- Explore perceptions of the patient's own ability to control his illness and his future, and clarify these perceptions by providing information about resources and support groups.
- Facilitate decision-making abilities in the patient for self-managing his prescribed treatment regimen.
- Provide positive reinforcement for increasing involvement in self-care activities.
- Provide relevant learning activities about insulin administration, dietary management, exercise, self-monitoring of blood glucose, and healthy lifestyle.

EVALUATION

After taking an active part in the weekly educational meetings for 2 months, Mr. Meligrito has greatly enhanced his understanding of and compliance with self-management of his DM. He states that he finally understands how insulin, food, and exercise affect his body, having previously thought they were "too hard to control." He decides to perform self-management activities one week at a time, rather than think too far into (and thereby feel overwhelmed by) the future. Both son and father have developed a workable meal schedule and weekly grocery list, and they have begun eating breakfast and dinner together. Mr. Meligrito and a friend have arranged to walk 2 to 3 miles three times a week on a community hiking trail. To gain a sense of control over his illness, he has worked out a schedule that allows time for school, healthcare, and himself.

Clinical Reasoning in Patient Care

1. What is the pathophysiologic basis for the changes in temperature, pulse, respirations, and blood pressure that occurred on Mr. Meligrito's admission to the hospital emergency department?
2. How can smoking and poor self-management of DM increase the risk of long-term complications?
3. Is powerlessness a common response to a chronic illness? Why or why not?
4. Consider that you are teaching Mr. Meligrito and another patient, Mr. McDaniel (age 75, newly diagnosed with type 2 DM). What components of your teaching plan would be the same and what components would be different?

See Evaluating Your Response in Appendix B.

In the Healthcare Facility

- Orient the patient to new surroundings on admission.
- Keep the bed at the lowest level.
- Keep the floors free of objects.
- Use a night-light.
- Use a thermometer to check the temperature of the bath or shower water before the patient uses it.
- Instruct the patient to wear shoes or slippers when out of bed.
- Monitor blood glucose levels regularly.
- Monitor for side effects of prescribed medications, such as dizziness or drowsiness.

In the Home and Community

- Use a night-light, preferably one with a soft, nonglare bulb.
- Turn the head away when switching on a bright light.
- Avoid looking directly into headlights when driving at night.
- Use a thermometer to test the temperature of the bath or shower water before use.
- Wear shoes and slippers with nonskid soles.
- Do not use throw rugs.
- Install hand grips in the tub and shower and next to the toilet.
- Wear a seat belt when driving or riding in a car.

  Strange environments and the presence of hazardous environmental factors increase the risk of falls or other accidents. Glare is often responsible for falls in people with visual deficits. The nurse can reduce factors that increase the risk of injury by implementing care and teaching safe practices during the activities of daily life.
- Monitor for and teach the patient and family to recognize and seek care for the manifestations of DKA in the patient with type 1 DM: hyperglycemia, thirst, headaches, abdominal pain, nausea and vomiting, increased urine output, ketonuria, dehydration, and decreasing level of consciousness. *Blood glucose levels increase if the insulin need is unmet or insufficiently met; the cellular use of fats for fuel results in ketosis. Osmotic diuresis increases urinary output, resulting in thirst and dehydration.*
- Monitor for and teach the patient and family to recognize and seek care for the manifestations of HHS in the patient with type 2 DM: extreme hyperglycemia, increased urinary output, thirst, dehydration, hypotension, seizures, and decreasing level of consciousness. *HHS is a life-threatening condition requiring recognition and treatment.*
- Monitor for and teach the patient and family to recognize and treat the manifestations of hypoglycemia: low blood glucose, anxiety, headache, uncoordinated movements, sweating, rapid pulse, drowsiness, and visual changes. Teach patient and family to carry some form of rapid-acting sugar source at all times. *Severe hypoglycemia causes a decrease in the level of consciousness. The decrease in blood glucose most often results from too much insulin, too little food, or too much exercise.*
- Recommend that the patient wear a medical alert bracelet or necklace identifying self as an individual with DM. *In case of sudden, severe illness or accident, a medical alert bracelet can allow immediate medical attention for DM to be instituted.*

Sexual Dysfunction

Sexuality is a complex and inseparable part of every person. It involves not only physical sexual activities but also an individual's self-perception as male or female, roles and relationships, and attractiveness and desirability. Changes in sexual function and in sexuality have been identified in both men and women with DM.

Alterations in erectile ability occur in approximately 50% of all men with DM. The incidence of impotence increases with the duration of the DM and is often associated with peripheral neuropathy and vascular disease. Libido is usually unaffected, even when impotence is present. Women with DM also have alterations in sexual function, although the reason is less clear. The problems reported by women involve decreased desire and decreased vaginal lubrication. Women with DM are also at increased risk for vaginitis and may avoid sexual intercourse in order to avoid pain.

Expected Outcome: The patient and his or her significant other will verbalize knowledge of sexual function, the potential effects of DM, and options if dysfunction is present.

- Include a sexual history as part of the initial and ongoing assessment of the patient with DM. A specific history form may be used that addresses sexual development, personal and family values, current sexual practices and concerns, and changes desired. Ask a nonthreatening, open-ended question to elicit information, such as "Tell me about your experience with sexual function since you have been diagnosed with DM." *Obtaining accurate information to assess the sexual health of a patient is necessary before counseling can begin or referrals can be made. Patients may not discuss problems with sexual function unless the nurse initiates the conversation.*
- Provide information about the actual and potential physical effects of DM on sexual function. Discuss the effect of poor control of blood glucose on sexual function as part of any teaching plan. *Patients benefit from basic information about male and female anatomy and the sexual response cycle, and how DM can affect this part of the body. Changes in blood glucose levels not only may cause changes in desire and physical response but also may alter sexual responses as a result of depression, anxiety, and fatigue.*
- Provide counseling or make referrals as appropriate. The nurse is responsible for knowing about sexuality and sexual health throughout the life span and provides information based on knowledge of the effects of illness and treatment on sexual function. For example, men who are impotent may regain the ability to have sexual intercourse through penile implants, suction apparatus, the use of drugs that facilitate gaining and maintaining an erection, such as sildenafil citrate (Viagra), or injections of medications (such as yohimbine, an alpha$_2$-adrenergic blocker) that increase vascular blood flow into the corpus of the penis. Women with decreased vaginal lubrication can decrease painful intercourse by using vaginal lubricants (such as K-Y Jelly) or estrogen creams. *The nurse may make specific suggestions to facilitate positive sexual functioning, referring the patient to the appropriate healthcare provider as necessary for intensive therapy.*

Ineffective Coping

Coping is the process of responding to internal or environmental stressors or potential stressors. When coping responses are ineffective, the stressors exceed the individual's available resources for

responding. The person diagnosed with DM is faced with lifelong changes in many parts of his or her life. Diet, exercise habits, and medications must be integrated into the person's lifestyle and be carefully controlled. Daily injections may be a reality. Fear of potential complications and of negative effects on the future is common.

If the person is unable to cope successfully with these changes, emotional stress can interfere with glycemic control. In addition, unsuccessful coping often results in noncompliance with prescribed treatment modalities, further impairing glycemic control and increasing the potential for acute and chronic complications.

Expected Outcome: Patient will follow the prescribed treatment plan, using available personal, family, and community resources as needed.

- Assess the patient's psychosocial resources, including emotional resources, support resources, lifestyle, and communication skills. *Chronic illness affects all dimensions of an individual's life, as well as the lives of family members and significant others. A comprehensive assessment of strengths and weaknesses is the first step in developing an individualized plan of care to facilitate coping.*
- Explore with the patient and family the effects (actual and perceived) of the diagnosis and treatment of DM on finances, occupation, energy levels, and relationships. *Common frustrations associated with DM are the disease itself, the treatment modalities, and the healthcare system. Effective coping involves maintaining a healthy self-concept and satisfying relationships, emotional balance, and handling emotional stress.*
- Teach constructive problem-solving techniques. *Problem-focused behaviors include setting attainable and realistic goals, learning about all aspects of the problem, learning new procedures or skills that increase self-esteem, and reaching out to others for support.*
- Provide information about support groups and resources, such as suppliers of products, journals, books, and cookbooks for people with DM. *Sharing with others who have similar problems provides opportunities for mutual support and problem solving. Using available resources improves the ability to cope.*

Delegating Nursing Care Activities

The professional nurse may delegate nursing care activities such as doing blood glucose checks, providing hygiene, assisting with feeding, and assisting with physical activity. The professional nurse assesses the patient on admission (or transfer of care), preoperatively, postoperatively, and on discharge. The professional nurse also provides teaching and develops the plan of care, coordinates the healthcare team, and evaluates the results of care provided.

Continuity of Care

Teaching the patient and family to self-manage DM is a healthcare team responsibility. Nurses are very important resources and must be knowledgeable and up to date on their understanding of DM care. Even when a formal teaching plan is developed and implemented by diabetes nurse educators, all nurses must be able to reinforce knowledge and answer questions. Teaching is necessary for both the person who is newly diagnosed and for the person who has had DM for years. In fact, the latter may need almost as much teaching as the newly diagnosed person. Products for DM care, especially insulins, have changed dramatically and knowledge about risk reduction to prevent complications has increased.

The American Diabetes Association recommends that teaching be carried out on three levels. The first level focuses on survival skills, with the person learning basic knowledge and skills to be able to provide DM management for the first week or two while adjusting to the idea of having the disease. The second level focuses on home management, emphasizing self-reliance and independence in the daily management of DM. The third level aims at improving lifestyle and educating patients to individualize self-management of the illness.

Teaching may need to be adapted to the older adult. Because many patients with diabetes are older, considering the special needs of this population is essential. Uncontrolled DM in the older adult increases the potential for functional loss, social disengagement, and increased morbidity and mortality. Education for self-care allows the older adult to be more actively involved in his or her DM management and decreases the potential for acute and long-term complications from the disease. Considerations for teaching the older adult with DM include the following:

- Changes in diet may be difficult to implement for many reasons. Balanced meals at regular intervals may not have been part of the patient's lifestyle. Purchasing, storing, and preparing foods may be a problem. Changes in taste sensation may cause the patient to increase the use of salt and sugar.
- Exercise is important and must be individualized for any physical limitations imposed by other chronic illnesses, such as arthritis, Parkinson's disease, chronic respiratory diseases, and/or cardiovascular diseases.
- The diagnosis of a chronic illness threatens independence and self-worth. The older adult with DM may now have to depend on others for help in meeting self-care needs.
- Money to purchase medications and supplies often must be taken out of a fixed income.
- Visual deficits may impair safe insulin administration. Visual deficits also interfere with blood glucose monitoring, food preparation, exercises, and foot care.

The nurse and patient should mutually establish goals based on the assessment data. Inquiries about patient and family priorities can be made effectively with the simple question "What concerns you most about having diabetes?" The topics of concern range from medications to economics. Addressing topics of greatest concern first increases the patient's and family's confidence that the information provided will be useful. It is equally important for family members to understand that the responsibility for daily management lies with the patient and that the primary role of the family is supportive. The patient is the person with the disease, and it is the patient who each day must take medications or inject insulin, test blood or urine, calculate and balance foods, exercise, adjust medications, inspect the body for injury, and determine whether and when medical assistance is needed. However, family members require the same knowledge so that they can provide emotional support as well as physical care if necessary.

The following should be included in teaching the patient and family about care at home:

- Information about normal metabolism, DM, and how DM changes metabolism
- Diet plan: how diet helps keep blood glucose in normal range; number of kilocalories required and why; amount of

carbohydrates, meats, and fats recommended and why; and how to calculate the diet, integrating personal food preferences
- Exercise: how it helps lower blood glucose, the importance of a regular program, types of exercise, integrating personal exercise preferences, how to handle increased activity
- Self-monitoring of blood glucose: how to perform the tests accurately, how to care for equipment, what to do for high or low blood glucose levels
- Medications:
  - Insulin: type, dosage, mixing instructions (if necessary), times of onset and peak actions, how to get and care for equipment, how to give injections, where to give injections
  - Oral agents: type, dosage, side effects, interaction with other drugs
- Manifestations of acute complications of hypoglycemia and hyperglycemia; what to do when they occur
- Hygiene: skin care, dental care, foot care
- Sick days: what to do about food, fluids, and medications
- Helpful resources: American Diabetes Association, Juvenile Diabetes Research Foundation, American Dietetic Association, National Diabetes Information Clearinghouse, Indian Health Service, and National Council of La Raza.

CHAPTER HIGHLIGHTS

- **Diabetes mellitus (DM) is a very common condition with approximately 1.9 million new cases diagnosed each year in the United States. The long-term complications of diabetes, including cardiovascular disease, strokes, and kidney failure, are among the leading causes of death in this country.**
- **The onset, pathophysiology, and acute complications of type 1 and type 2 DM differ from one another. Unlike type 1 DM, in which the onset is often sudden, the development of type 2 DM starts with insulin resistance (prediabetes) that may be asymptomatic for many years.**
- Type 1 DM is the result of pancreatic islet cell destruction and a total deficit of circulating insulin; type 2 DM results from insulin resistance with a defect in compensatory insulin secretion.
- **The incidence of type 2 DM is increasing in epidemic proportions in all racial and ethnic groups in the United States, often triggered by obesity and sedentary lifestyles.**
- An estimated 50% of individuals newly diagnosed with type 2 DM have already developed complications secondary to hyperglycemia.
- **Tighter, intensive glycemic control is increasingly the focus of care of patients with hyperglycemia (patients with diabetes and prediabetes).**
- **Products to manage DM include insulins, noninsulin hypoglycemics, and blood glucose monitoring devices. Nurses must be familiar with these products and help patients become proficient in their use.**
- **Motivation for self-care by the patient with DM continues to be a challenge because treatment commonly includes lifestyle changes. Through education and support, patients can achieve control of DM and avoid complications.**

TEST YOURSELF NCLEX-RN® REVIEW

1. Through genetic testing a patient learns of having markers that indicate immune destruction of the beta cells. Which health problem is this patient prone to developing?
   1. type 2 diabetes mellitus
   2. maturity-onset diabetes mellitus
   3. idiopathic type 1 diabetes mellitus
   4. immune-mediated type 1 diabetes mellitus
2. The nurse is preparing to instruct a patient with type 1 diabetes mellitus on the complication of diabetic ketoacidosis. Which pathologic process should the nurse review with the patient about this complication?
   1. A decreased amount of glucagon causes low protein levels.
   2. An excess amount of insulin drives all glucose into the cells.
   3. A deficit of insulin causes fat stores to be used as an energy source.
   4. An increase occurs in the breakdown of glucose molecules with hypoglycemia.
3. The nurse is reviewing the health histories of newly admitted patients for the risk of developing endocrine disorders. Which patient would be most at risk for the development of type 2 diabetes mellitus?
   1. middle-aged man who maintains normal weight
   2. woman age 70 who is overweight and sedentary
   3. young adult who is a professional basketball player
   4. middle-aged woman who is the sole caretaker of her parents
4. The nurse identifies the nursing diagnosis *Risk for Injury* as appropriate for a patient with type 2 diabetes mellitus because of peripheral neuropathy involving both feet. Which assessment would support this diagnosis?
   1. loss of normal reflexes
   2. normal sensation to touch
   3. states “I can’t feel my feet anymore.”
   4. states “I have been having chest pain.”

5. The nurse is providing discharge instructions to a patient with type 2 diabetes mellitus. Which patient statement indicates teaching about foot care at home has been successful?
   1. "I always buy my shoes as soon as the stores open."
   2. "I will walk barefooted as long as I am in the house."
   3. "I will check my feet for cuts and bruises every night."
   4. "If I get a blister, I will just put alcohol on it and bandage it."
6. The nurse is preparing a teaching session on insulin for a group of patients newly diagnosed with type 1 diabetes mellitus. Which safety feature should the nurse emphasize when discussing insulin glargine (Lantus) and insulin detemir (Levemir)?
   1. These insulins are clear like regular insulin.
   2. These insulins are activated by vigorous agitation.
   3. These insulins are combined with glucose to raise energy levels.
   4. These insulins are subject to being inactivated by light and must be kept cold.
7. The nurse is preparing an insulin infusion for a patient in diabetic ketoacidosis (DKA). Which type of insulin should the nurse use to make this intravenous infusion?
   1. NPH
   2. regular
   3. glargine
   4. Humalog
8. The nurse is reviewing laboratory values and notes that a patient will soon begin treatment for diabetes mellitus. Which glycosylated hemoglobin (A_1C) level is on the patient's medical record?
   1. 1.7%
   2. 3.4%
   3. 5.2%
   4. 6.8%
9. A patient who is prescribed insulin for diabetes control is scheduled for surgery in the morning. What should the nurse anticipate regarding the prescribed morning regular insulin dose?
   1. It will be given intravenously.
   2. It should be chilled to slow absorption.
   3. It will be given at the usual prescribed dose.
   4. It should be combined with long-acting insulin.
10. The nurse is teaching a patient with type 1 diabetes mellitus how to self-administer the daily prescribed insulin. In which body area should the nurse teach that the most rapid absorption of the medication occurs?
    1. hip
    2. thigh
    3. deltoid
    4. abdomen

UNIT

5 Building Clinical Competence

Responses to Altered Endocrine Function

CLINICAL SCENARIO

Directions: *Read the following clinical scenarios and answer the questions that follow. To complete this exercise successfully, you will utilize not only knowledge of the content in this unit, but also principles related to priority setting and maintaining patient safety.*

You have been assigned to work with the following four patients for the 0700 shift on a medical-surgical unit. Significant data obtained during report is as follows:

- Mr. Blew is a 54-year-old who is admitted with complaints of polydipsia, polyuria, and polyphagia. There is a fruity odor to his breath and he seems confused at times. Vital signs on admission are temperature 37.2°C (99°F), pulse 90 bpm, respirations 30/min and deep, and blood pressure 110/68 mmHg. His blood glucose is 650 mg/dL on admission at 0630.
- Mrs. Rant is a 65-year-old who is admitted with severe back pain in the flank area on the right side, nausea, and vomiting. She is being evaluated for renal calculi. She has a history of hyperparathyroidism. Vital signs are temperature 36.4°C (97.6°F) with clammy skin, pulse 100 bpm, respirations 24/min, and blood pressure of 168/94 mmHg. She is requesting pain medication for the back pain.
- Mrs. Fox is an 86-year-old who was transferred from the medical ICU yesterday. She was admitted after being found in a comatose state by her daughter. On admission her blood sugar was 45 mg/dL, serum sodium was 128 mEq/L, temperature was 35.9°C (96.6°F), and she had a heart rate of 50 bpm. Vital signs this a.m. are temperature 36.9°C (98.4°F), pulse 78 bpm, respirations 18/min, and blood pressure 140/86 mmHg. She is due for electrolytes to be drawn at 0730.
- Mr. Rite is a 56-year-old who was admitted 4 days ago after falling from a ladder and hitting his head. He is complaining of a headache and thirst even after drinking 2000 mL of fluids during the night. Vital signs are temperature 37.8°C (100°F), pulse 98 bmp, respirations 14/min, and blood pressure 114/84 mmHg.

CLINICAL REASONING

1. Why should Mr. Rite's complaint of headache and intense thirst be further investigated?

Priority Setting

2. In what order would you visit these patients after report?

A. _____
B. _____
C. _____
D. _____

Health Promotion

3. Besides diet and medication administration related to the new diagnosis of diabetes mellitus, what other teaching is necessary for Mr. Blew in order for him to maintain a high level of health?

4. Dietary teaching for Mrs. Rant related to hyperparathyroidism should include which of the following?

A. Increase fluids in the diet and avoid taking vitamin D supplements.
B. Increase potassium in the diet and avoid taking vitamin C supplements.
C. Decrease sodium in the diet and take vitamin B_6 supplements.
D. Decrease phosphorus in the diet and take vitamin A supplements.

Nursing Process

5. If Mr. Blew's blood glucose drops to 50 mg/dL, which manifestations might he exhibit?

A. bradycardia, nausea, and vomiting
B. tachycardia, hypotension, and shakiness
C. thirst, diarrhea, and fatigue
D. hypertension, edema, and dyspnea

6. Which laboratory studies would be conducted for Mr. Blew to monitor his diabetes management? (Select all that apply.)

A. fasting blood glucose
B. glycosylated hemoglobin (Hb A1c)
C. complete blood cell count
D. serum electrolytes
E. serum cholesterol and triglyceride levels

Communication

7. Mr. Blew understands diabetic teaching implemented by the nurse when he states which of the following?

A. "I will check my blood glucose each morning before breakfast."
B. "If I follow my prescribed diet, I will not have to check my blood sugar."
C. "If my blood glucose drops below 60, I can drink 4 ounces of fruit juice to raise it."
D. "If my blood sugar is over 200, I can eat graham crackers to lower it."

8. Mrs. Fox's daughter asks if her mother will be able to go home alone or if she will need to be sent to a nursing home to live. How will you answer?

Delegation

9. Which care activities can be delegated to unlicensed assistive personnel (UAP) for each patient?

Interprofessional Care

10. Which of the following collaborative interventions should the nurse anticipate in caring for Mr. Blew's diabetic ketoacidosis?

A. preparing a continuous vasopressin infusion
B. obtaining an order for blood glucose levels every 2 to 4 hours
C. initiating a continuous infusion of regular insulin mixed in 5% dextrose/water
D. instituting an intravenous infusion of 0.9% normal saline at a rate of 250 mL/h.

Continuity of Care

11. A prescription for levothyroxine sodium (Synthroid) is given to Mrs. Fox after being diagnosed with hypothyroidism. The patient voices understanding of how to take the medication when she states which of the following?

A. "I must take the medication with meals."
B. "I must take my pulse before taking the medication and report to the doctor a pulse greater than 100."
C. "I will only need to take this medication until my thyroid blood levels are back to normal."
D. "I can eat any food I choose as foods do not interfere with the medications."

Safety

12. Which of the following interventions is most clearly focused at Mrs. Rant's safety related to her hyperparathyroidism?

A. Place the patient on a fluid restriction.
B. Assess for Chvostek's sign once each shift.
C. Maintain bed rest with bathroom privileges only.
D. Institute continuous cardiac rhythm monitoring.

Quality Improvement

13. Which of the following can affect the accuracy of glucose meter performance for self-monitoring of blood glucose? (Select all that apply.)

A. presence of dehydration
B. adequate blood sample on the test strip
C. proper training on use of the blood glucose meter
D. use of excessive isopropyl alcohol to clean the skin
E. test strips that have been stored outside the original container

Informatics

14. When caring for Mr. Blew, you wish to verify the latest clinical guideline recommendations for the patient with diabetes mellitus. What would your best action be?

A. Ask your coworkers what they know about diabetes mellitus guidelines.
B. Get a textbook from the nursing lounge on the unit to look up diabetes.
C. Using a link in the electronic medical record, research diabetes mellitus guidelines at the National Guidelines Clearinghouse website.
D. Review some nursing journals you found on the unit for an article related to diabetes.

UNIT

Responses to Altered Gastrointestinal Function

21 Assessing the Gastrointestinal System 538

22 Nursing Care of Patients with Nutritional Disorders 563

23 Nursing Care of Patients with Upper Gastrointestinal Disorders 588

24 Nursing Care of Patients with Bowel Disorders 625

25 Nursing Care of Patients with Gallbladder, Liver, and Pancreatic Disorders 692

Nutritional–Metabolic and Elimination Patterns

The structure and functions of the gastrointestinal tract directly affect the ability to ingest, digest, and absorb nutrients, nutritional status, and patterns of fecal elimination.

21 Assessing the Gastrointestinal System

LEARNING OUTCOMES

1. Discuss the function of nutrients absorbed in the gastrointestinal (GI) system.
2. Describe the anatomy, physiology, and functions of the GI system and the accessory digestive organs.
3. Identify focused topics to consider during a health history interview of the patient with GI disorders.
4. Explain techniques used for assessing nutritional status and GI function.
5. Describe normal variations in GI assessment findings for the older adult.
6. Identify abnormal findings that may indicate alterations in GI function.
7. Give examples of common genetic disorders of the GI system.

CLINICAL COMPETENCIES

1. Conduct and document a health history for patients who have or are at risk for alterations in GI function, eliciting patient values, preferences, and expressed needs as part of the interview.
2. Conduct and document a physical assessment of nutritional status and the GI system demonstrating sensitivity and respect for dietary habits related to culture and individual belief systems.
3. Provide supportive nursing care for patients undergoing invasive diagnostic procedures.
4. Monitor the results of diagnostic tests and report abnormal findings.

MAJOR CHAPTER CONCEPTS

- Overall health status is influenced by proper nutrition and a balanced diet.
- The etiology of many common illnesses is influenced by diet and nutrition, thereby making the nurse's role increasingly important in terms of conducting health assessments aimed at detecting early disease processes and teaching that promotes healthy dietary habits.

EQUIPMENT NEEDED

- Stethoscope
- Balance scale with height measuring attachment
- Tape measure
- Skinfold calipers
- Water-soluble lubricant
- Occult blood test, such as Occultest or Hemoccult II
- Disposable gloves

The GI system consists of the mouth, pharynx, esophagus, stomach, small intestine, and large intestine. The accessory digestive organs include the liver, gallbladder, and pancreas (Figure 21–1 ■). **Nutrition** is the process by which the body, via the GI system and the accessory digestive organs, ingests, absorbs, transports, uses, and eliminates nutrients in food.

NUTRIENTS

Nutrients are substances found in food that are used by the body to promote growth, maintenance, and repair. The categories of nutrients are carbohydrates, proteins, fats, vitamins, minerals, and water.

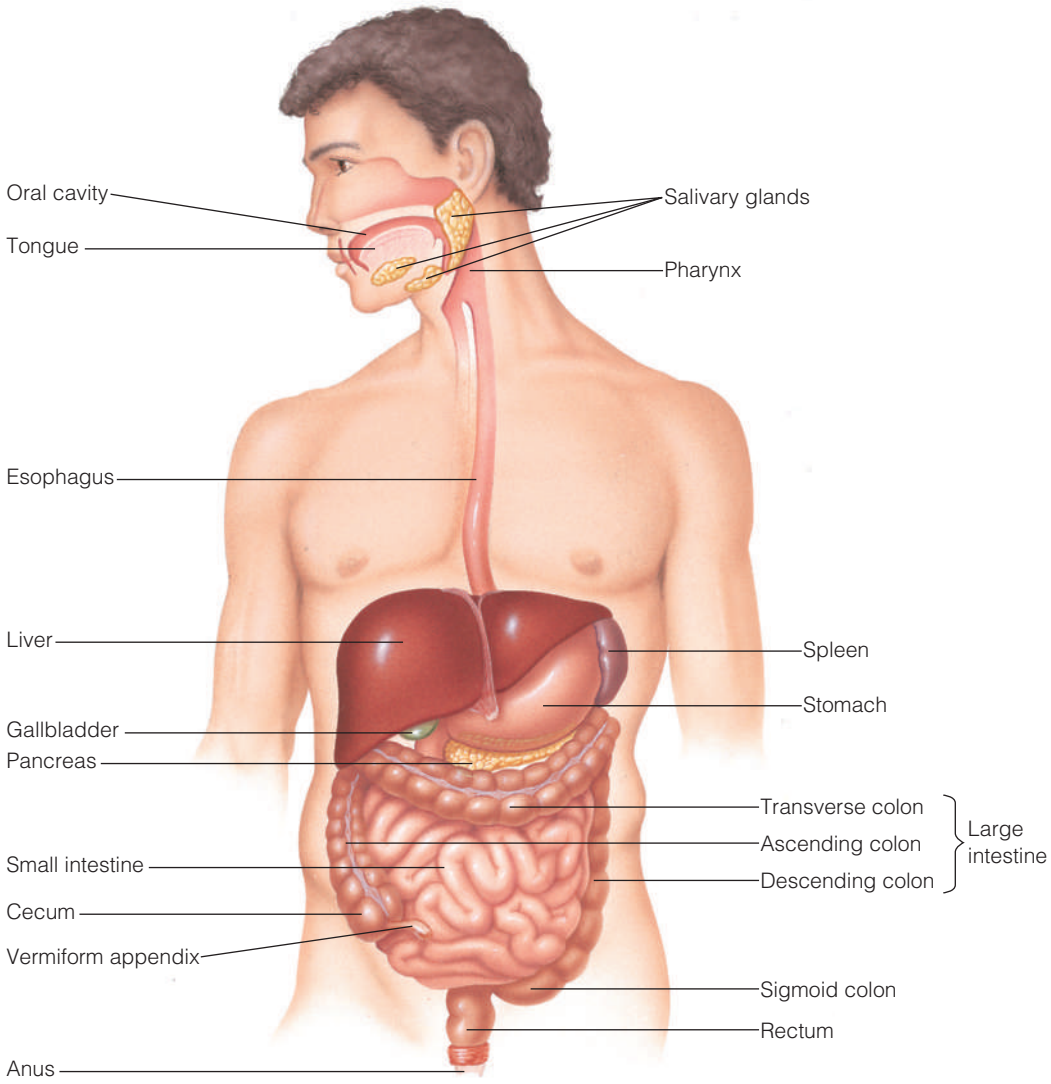

Figure 21–1 ■ Organs of the gastrointestinal system and accessory digestive organs.

Carbohydrates

The primary sources of carbohydrates (sugars and starches) are plant foods. Monosaccharides and disaccharides come from milk, sugar cane, sugar beets, honey, and fruits. Polysaccharide starch is found in grains, legumes, and root vegetables. Following ingestion, digestion, and metabolism, carbohydrates are converted primarily to glucose, the molecule body cells use to make adenosine triphosphate (ATP). Excess glucose in the healthy person is converted to glycogen or fat. Glycogen is stored in the liver and muscles; fat is stored as adipose tissue.

Excess intake of carbohydrates over time can result in obesity, dental caries, and elevated plasma triglycerides. In comparison, long-standing carbohydrate deficiencies lead to tissue wasting from protein breakdown and metabolic acidosis from an excess of ketones as a by-product of fat breakdown.

Proteins

Proteins are classified as either complete (high value) or incomplete. Complete proteins are found in animal products such as eggs, milk, milk products, and meat. They contain the greatest amount of amino acids and meet the body's requirements for tissue growth and maintenance. Incomplete proteins are found in legumes, nuts, grains, cereals, and vegetables. These sources are low in or lack one or more of the amino acids essential for building complete proteins.

The body uses proteins to build many different structures, including skin keratin, the collagen and elastin in connective tissues, and muscles. They also are used to make enzymes, hemoglobin, plasma proteins, and some hormones.

Healthy people with adequate caloric intake have an equal rate of protein synthesis and protein breakdown and loss, reflected as nitrogen balance. If the breakdown and loss of proteins exceed intake, a negative nitrogen balance results. This may be due to starvation, altered physical states (e.g., from injury or illness), or altered emotional states (such as depression or anxiety). A positive nitrogen balance, which results when protein intake exceeds breakdown, is normal during growth, tissue repair, and pregnancy. Anabolic steroids affect the rate of protein use; for example, the adrenal corticosteroids are released in times of stress to increase protein breakdown and conversion of amino acids to glucose. Excessive intake of proteins may lead to obesity, whereas deficits cause weight loss and tissue wasting, edema, and anemia.

Fats (Lipids)

Fats (lipids) include phospholipids, steroids (such as cholesterol), and neutral fats, more commonly known as triglycerides. Triglycerides are the most abundant fats in the diet and the major form of stored fat in the body. Triglycerides exist with a mix of saturated or unsaturated fatty acids. Saturated fatty acids are found in animal products (milk and meats) and in some plant products (such as coconut). Trans fatty acids behave like saturated fats in the body but have a greater detrimental effect on health. Unsaturated fats include both monounsaturated fats and polyunsaturated fats. Omega-3 and omega-6 fatty acids are classifications of polyunsaturated fatty acids. Unsaturated fats are found in seeds, nuts, most vegetable oils, and some fish oils. Sources of cholesterol include meats, milk products, and egg yolks.

When a person consumes more fats than the body requires, the excess is stored as adipose tissue, increasing the risk of obesity and other chronic illnesses, including cardiovascular disease. A deficit of fats may cause excessive weight loss and skin lesions.

Fats are a necessary part of the structure and function of the body. For example,

- Phospholipids are a part of all cell membranes.
- Triglycerides are the major energy source for hepatocytes and skeletal muscle cells.
- Dietary fats facilitate absorption of fat-soluble vitamins.
- Linoleic acid, an essential fatty acid, helps form prostaglandins, regulatory molecules that assist in smooth muscle contraction, maintenance of blood pressure, and control of inflammatory responses.
- Cholesterol is the essential component of bile salts, steroid hormones, and vitamin D.
- Adipose tissue serves as a protection around body organs, as a layer of insulation under the skin, and as a concentrated source of fuel for cellular energy.

VITAMINS

Vitamins are organic compounds that facilitate the body's use of carbohydrates, proteins, and fats. All of the vitamins except vitamins D and K must be ingested in foods or taken as supplements. Vitamin D is made by ultraviolet irradiation of cholesterol molecules in the skin. Vitamin K is synthesized by bacteria in the intestine.

Vitamins are categorized as either fat soluble or water soluble. The fat-soluble vitamins (A, D, E, and K) bind to ingested fats and are absorbed as the fats are absorbed. Water-soluble vitamins (the B complex and C) are absorbed with water in the GI system (however, vitamin B_{12} must become attached to intrinsic factor to be absorbed). Fat-soluble vitamins are stored in the body, and excesses may cause toxicity; water-soluble vitamins in excess of body requirements are excreted in the urine.

The recommended amounts of vitamins are labeled by the National Academy of Sciences as **dietary reference intakes (DRIs)** per day. The use of supplemental nutrients has become a common practice among the general population and there is increased use of dietary supplements containing high doses of some vitamins. Consequently, scientists are realizing the potential toxicity of higher doses and have established a **tolerable upper intake level (UL)** for some nutrients.

The source, function, and minimum daily recommended intake levels are provided for each vitamin in Table 21–1 and Table 21–2. The recommended DRIs serve as a reference point and should be individualized to each person's lifestyle, medical status, and current knowledge of research about vitamins. Note also that DRIs differ by recommending source.

Minerals

Minerals work with other nutrients to maintain the structure and function of the body. An adequate supply of calcium, phosphorus,

TABLE 21–1 Recommended Daily Intake of Fat-Soluble Vitamins

Name	Source	Function	Minimum Recommended Daily Intake (M = Men, W = Women)
Vitamin A (retinol)	• Fish liver oils • Egg yolk • Liver • Fortified milk • Margarine	Necessary for vision, integrity of skin and mucous membranes, cell membrane function, and reproductive function	M = 900 mcg W = 700 mcg
Vitamin D	• The action of sunshine on cholesterol in the skin	Necessary for blood calcium homeostasis (in turn necessary for blood clotting), bone formation, and neuromuscular function	M and W, 50 years and under = 5 mcg M and W, 51–70 years of age = 10 mcg M and W, 70+ years of age = 15 mcg
Vitamin E	• Vegetable oils • Margarine • Whole grains • Dark green, leafy vegetables	As an antioxidant, helps prevent the oxidation of vitamins A and C in the intestines and decreases the oxidation of unsaturated fatty acids to facilitate cell membrane integrity	M and W = 15 mg
Vitamin K	• Synthesized by coliform bacteria in the large intestine • Green, leafy vegetables • Cabbage • Cauliflower • Pork	Essential for the formation of clotting proteins in the liver	M = 120 mcg W = 90 mcg

TABLE 21–2 Estimated Average Requirements of Water-Soluble Vitamins

Name	Source	Function	Minimum Recommended Daily Intake (M = Men, W = Women)
Thiamin (vitamin B_1)	• Lean meats • Liver • Eggs • Green, leafy vegetables • Legumes • Whole grains	An essential coenzyme for carbohydrate metabolism and use; also for healthy function of nerves, muscles, and the heart	M = 1.2 mg W = 1.1 mg
Riboflavin (vitamin B_2)	• Liver • Egg white • Whole grains • Meat • Poultry • Fish • Milk	Involved in the catabolism and use of carbohydrates, fats, and proteins; the use of other B vitamins; is important for the production of adrenal hormones	M = 1.3 mg W = 1.1 mg
Vitamin B_6	• Meat • Poultry • Fish • Potatoes • Tomatoes • Sweet potatoes • Spinach	Necessary for amino acid metabolism, formation of antibodies, and formation of hemoglobin	M = 1.4 mg W = 1.3 mg
Vitamin B_{12}	• Liver • Meat • Poultry • Dairy foods (except butter) • Eggs	Essential for the production of nucleic acids and red blood cells in the bone marrow; also plays an important role in the use of folic acid and carbohydrates, and in healthy function of the nervous system	M and W = 2.4 mcg
Vitamin C (ascorbic acid)	• Citrus fruits • Potatoes • Tomatoes • Green leafy vegetables	Acts as an antioxidant and vasoconstrictor; also serves in the formation of connective tissue, conversion for cholesterol to bile salts, iron absorption and use, and conversion of folic acid to an active form	M = 75 mg W=60 mg
Niacin (nicotinamide)	• Meat • Poultry • Fish • Liver • Peanuts • Green, leafy vegetables	Plays an important role in the metabolism of carbohydrates and fats; inhibits cholesterol synthesis; important for integumentary, nervous, and digestive system health; assists in the manufacture of reproductive hormones	M = 16 mg W = 14 mg
Biotin	• Liver • Eggs • Nuts • Legumes	Essential for the catabolism of fatty acids and carbohydrates, and helps dispose of the waste products of protein catabolism	M and W = 30 mcg
Pantothenic acid	• Meats • Whole grains • Egg yolk • Liver • Yeast • Legumes	Assists in the synthesis of steroids and of the heme in hemoglobin; is essential for the metabolism of carbohydrates and fats, and for the manufacture of reproductive hormones	M and W = 5 mg
Folate (folic acid)	• Liver • Dark green vegetables • Lean beef • Eggs • Veal • Whole grains • Synthesized by bacteria in the intestine	The basis of a coenzyme necessary to the manufacture of nucleic acids and so is essential for the formation of red blood cells, growth and development, and nervous system health	M = 400 mcg W = 400 mcg

potassium, sulfur, sodium, chloride, and magnesium—as well as other trace elements such as iron, iodine, copper, and zinc—is necessary to health. Most minerals in the body are found in body fluids or are bound to organic compounds. The best sources of minerals are vegetables, legumes, milk, and some meats. The recommended daily intake for minerals is outlined in Table 21–3.

Anatomy, Physiology, and Functions of the GI System

The GI system is a continuous hollow tube, extending from the mouth to the anus. Once foods are placed in the mouth, they are subjected to a variety of digestive processes that move them and break them down into end products that can be absorbed from the lumen of the small intestine into the blood or lymph. These processes are ingestion of food; movement of food and wastes; secretion of mucus, water, and enzymes; mechanical and chemical digestion of food; and absorption of digested food.

The Mouth

The mouth, also called the oral or buccal cavity, is lined with mucous membranes and is enclosed by the lips, cheeks, palate, and tongue (Figure 21–2 ■).

The lips and cheeks are skeletal muscle covered externally by skin. Their function is to keep food in the mouth during chewing. The palate consists of the hard palate and the soft palate. The hard palate covers bone in the roof of the mouth and provides a hard surface against which the tongue forces food. The soft palate, extending from the hard palate and ending at the back of the mouth as a fold called the uvula, is primarily muscle. When food is swallowed, the soft palate rises as a reflex to close off the oropharynx.

The tongue, composed of skeletal muscle and connective tissue, contains mucous and serous glands, taste buds, and papillae. The tongue mixes food with saliva during chewing, forms the food into a bolus (a mass), and initiates swallowing. Some papillae provide surface roughness to facilitate licking and moving food; other papillae house the taste buds.

Saliva moistens food so it can be made into a bolus, dissolves food chemicals so they can be tasted, and provides enzymes (such as amylase) that begin the chemical breakdown of starches. Saliva is produced by salivary glands (parotid, submaxillary, and sublingual), most of which lie superior or inferior to the mouth and drain into it. Adults have 32 permanent teeth. The teeth chew (masticate) and grind food to break it down into smaller parts, mixed with saliva.

TABLE 21–3 Recommended Daily Intake of Minerals

Name	Minimum Recommended Daily Intake (M = Men, W = Women)
Calcium	M and W = 1000 mg, W > menopause = 1200 mg
Phosphorus	M and W = 700 mg
Iron	M = 8 mg, W = 18 mg
Zinc	M = 11 mg, W = 8 mg
Molybdenum	M and W = 45 mcg
Chromium	M = 35 mcg, W = 25 mcg
Iodine	M and W = 150 mcg
Selenium	M and W = 55 mcg
Magnesium	M=420 mg, W = 320 mg
Copper	M and W = 900 mcg
Potassium	M and W = 4700 mg
Chloride	M and W = 1500–2000 mg, depending on health status
Sodium	M and W = 1100–3000 mg, depending on health status

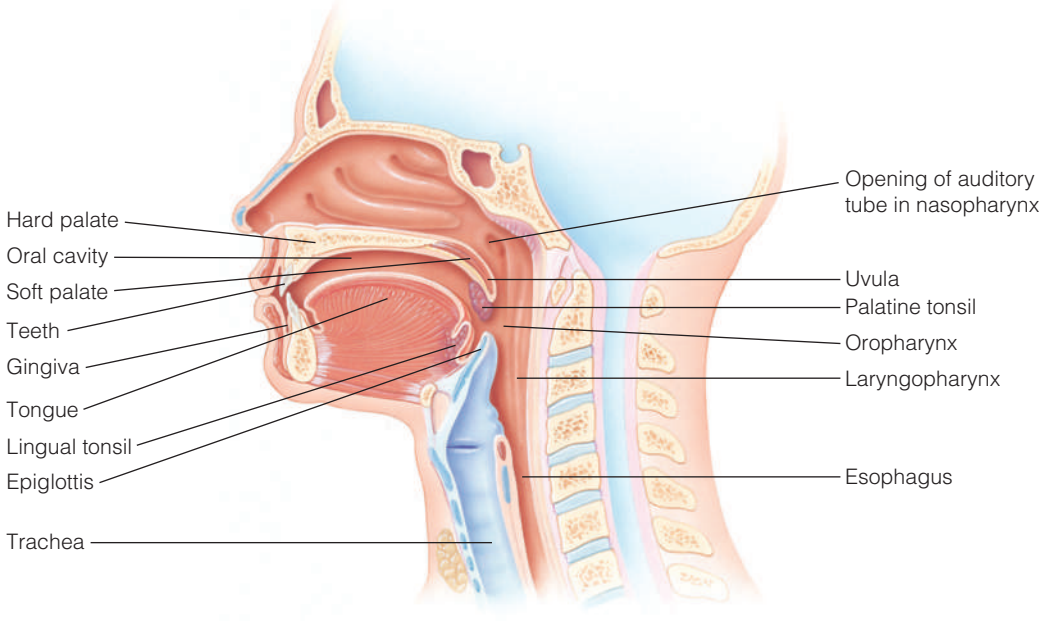

Figure 21–2 ■ Structures of the mouth, the pharynx, and the esophagus.

The Pharynx

The pharynx consists of the oropharynx and the laryngopharynx (refer to Figure 21–2). Both structures provide passageways for food, fluids, and air. The pharynx is made of skeletal muscles and is lined with mucous membranes. The skeletal muscles move food to the esophagus via the pharynx through peristalsis (alternating waves of contraction and relaxation of involuntary muscle). The mucosa of the pharynx contains mucous-producing glands that provide fluid to facilitate the passage of the bolus of food as it is swallowed.

The Esophagus

The esophagus, a muscular tube about 25 cm (10 in.) long, serves as a passageway for food from the pharynx to the stomach (refer to Figures 21–1 and 21–2). The epiglottis, a flap of cartilage over the top of the larynx, keeps food out of the larynx during swallowing. The esophagus descends through the thorax and diaphragm, entering the stomach at the cardiac orifice. The gastroesophageal sphincter surrounds this opening. This sphincter, along with the diaphragm, keeps the orifice closed when food is not being swallowed.

The Stomach

The stomach, located high on the left side of the abdominal cavity, is connected to the esophagus at the upper end and to the small intestine at the lower end (Figure 21–3 ■). Normally about 15–25 cm (10–15 in.) long, the stomach is a distensible organ that can expand to hold up to 4 L of food and fluid. The stomach may be divided into the cardiac region, fundus, body, and pylorus. The pyloric sphincter controls the emptying of the stomach into the duodenal portion of the small intestine. The stomach is a storage reservoir for food, continues the mechanical breakdown of food, begins the process of protein digestion, and mixes the food with gastric juices into a thick fluid called *chyme*.

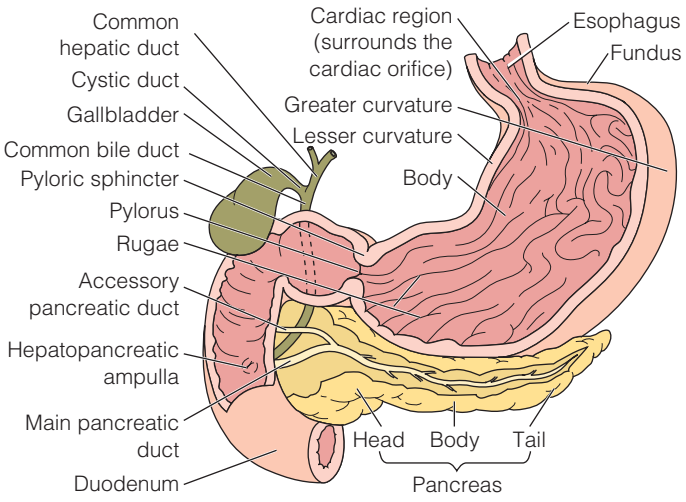

Figure 21–3 ■ The internal anatomic structures of the stomach, including the pancreatic, cystic, and hepatic ducts; the pancreas; and the gallbladder.

The stomach is lined with columnar epithelial, mucous-producing cells. Millions of openings in the lining lead to gastric glands that can produce 4 to 5 L of gastric juice each day. The gastric glands contain a variety of secretory cells that produce substances to protect the stomach from being digested by gastric juice, secrete hydrochloric acid and intrinsic factor, and help regulate gastric motility.

The secretion of gastric juice is under both neural and endocrine control. Stimulation of the parasympathetic vagus nerve increases secretory activity; in contrast, stimulation of sympathetic nerves decreases secretions. Mechanical digestion is accomplished by peristaltic movements that churn and mix the food with the gastric juices to form chyme. After a person eats a well-balanced meal, the stomach empties completely in approximately 4 to 6 hours. Gastric emptying depends on the volume, chemical composition, and osmotic pressure of the gastric contents. The stomach empties large volumes of liquid content more rapidly, while gastric emptying is slowed by solids and fats.

The Small Intestine

The small intestine begins at the pyloric sphincter and ends at the ileocecal junction at the entrance of the large intestine (refer to Figure 21–1). The small intestine is about 6 m (20 ft) long but only about 2.5 cm (1 in.) in diameter. This long tube hangs in coils in the abdominal cavity, suspended by the mesentery and surrounded by the large intestine. The small intestine has three regions: the duodenum, the jejunum, and the ileum. The duodenum begins at the pyloric sphincter and extends around the head of the pancreas for about 25 cm (10 in.). Both pancreatic enzymes and bile from the liver enter the small intestine at the duodenum. The jejunum, the middle region of the small intestine, extends for about 2.4 m (8 ft). The ileum, the terminal end of the small intestine, is approximately 3.6 m (12 ft) long and meets the large intestine at the ileocecal valve.

Food is chemically digested and most of it absorbed as it moves through the small intestine. Circular folds containing villi (finger-like projections of the mucosa cells) and microvilli (tiny projections of the mucosa cells) increase the surface area of the small intestine to enhance absorption of food. Although up to 10 L of food, liquids, and secretions enter the GI system each day, less than 1 L reaches the large intestine.

Enzymes in the small intestine break down carbohydrates, proteins, lipids, and nucleic acids. Pancreatic amylase acts on starches, converting them to maltose, dextrins, and oligosaccharides; the intestinal enzymes dextrinase, glucoamylase, maltase, sucrase, and lactase further break down these products into monosaccharides. Pancreatic enzymes (trypsin and chymotrypsin) and intestinal enzymes continue to break down proteins into peptides. Pancreatic lipases digest lipids in the small intestine. Triglycerides enter as fat globules and are coated by bile salts and emulsified. Nucleic acids are hydrolyzed by pancreatic enzymes and then broken apart by intestinal enzymes. Both pancreatic enzymes and bile are excreted into the duodenum in response to the secretion of secretin and cholecystokinin, hormones produced by the intestinal mucosa cells when chyme enters the small intestine.

Nutrients are absorbed through the mucosa of the intestinal villi into the blood or lymph by active transport, facilitated transport,

and passive diffusion. Almost all food products and water, as well as vitamins and most electrolytes, are absorbed in the small intestine, leaving only indigestible fibers, some water, and bacteria to enter the large intestine.

The Large Intestine

The large intestine (colon) begins at the ileocecal valve and terminates at the anus (Figure 21–4 ■). It is about 1.5 m (5 ft) long. The large intestine includes the cecum, the appendix, the colon, the rectum, and the anal canal. The colon is divided into ascending, transverse, and descending segments. The rectum is a mucosa-lined tube approximately 12 cm (4.7 in.) in length (Figure 21–5 ■). The rectum ends at the anal canal, which terminates at the anus, a hairless, dark-skinned area. The anorectal junction separates the rectum from the anal canal and may be the site of internal hemorrhoids (clusters of dilated veins in swollen anal tissue).

The major function of the large intestine is to eliminate indigestible food residue from the body. The large intestine absorbs water, salts, and vitamins formed by the food residue and bacteria. The semiliquid chyme that passes through the ileocecal valve is formed into feces as it moves through the large intestine by peristalsis. Goblet cells lining the large intestine secrete mucus to facilitate the lubrication and passage of feces.

The defecation reflex is initiated when feces enter the rectum and stretch the rectal wall. This spinal cord reflex causes the walls of the sigmoid colon to contract and the anal sphincters to relax. This reflex can be suppressed by voluntary control of the external sphincter. Closing the glottis and contracting the diaphragm and abdominal muscles to increase intra-abdominal pressure (**Valsalva's maneuver**) facilitates expulsion of feces. Prolonged suppression of defecation can result in a weakened reflex that may in turn lead to constipation (infrequent and often uncomfortable passage of hard, dry stool). Frequent bouts of constipation may lead to external hemorrhoids.

The Accessory Digestive Organs

The liver, gallbladder, and exocrine pancreas are accessory digestive organs. The liver produces bile, necessary for fat digestion and absorption, and stores it in the gallbladder. The liver also receives nutrients absorbed by the small intestine and metabolizes or synthesizes these nutrients so they are in a form that can be used by the cells of the body. The exocrine pancreas produces enzymes necessary for digestion of fats, proteins, and carbohydrates.

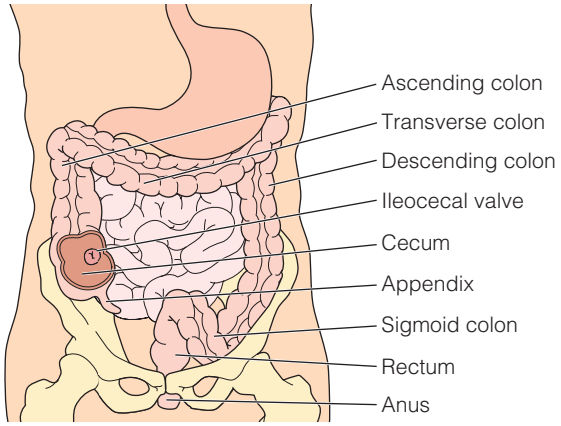

Figure 21–4 ■ Anatomy of the large intestine.

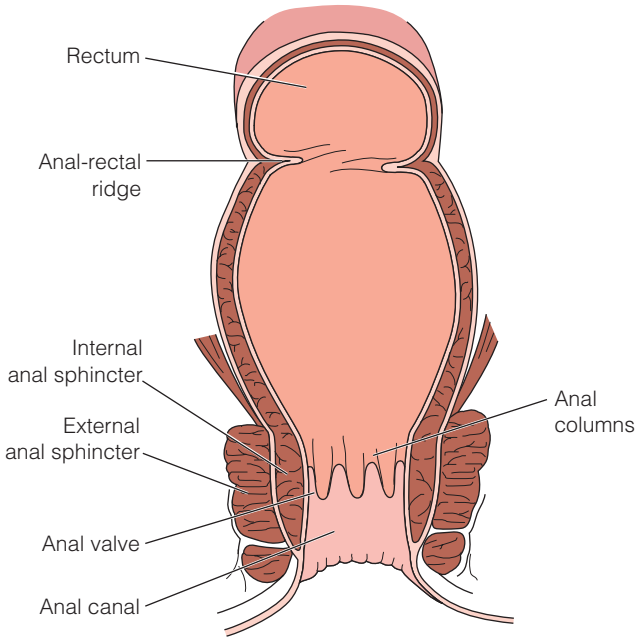

Figure 21–5 ■ Structure of the rectum and anus.

THE LIVER AND GALLBLADDER

The liver weighs about 1.4 kg (3 lb) in the average-sized adult. It is located in the right side of the abdomen, inferior to the diaphragm and anterior to the stomach (refer to Figure 21–1). A mesenteric ligament separates the right and left lobes and suspends the liver from the diaphragm and anterior abdominal wall. The liver is encased in a fibroelastic capsule, called the Glisson capsule. This capsule contains blood vessels, lymphatics, and nerves.

Liver tissue consists of units called lobules, which are composed of plates of hepatocytes (liver cells). A branch of the hepatic artery, a branch of the hepatic portal vein, and a bile duct communicate with each lobule. Sinusoids, blood-filled spaces within the lobules, are lined with Kupffer cells. These phagocytic cells remove debris from the blood.

Bile production is the liver's primary digestive function. **Bile** is a greenish, watery solution containing bile salts, cholesterol, bilirubin, electrolytes, water, and phospholipids. These substances are necessary to emulsify and promote the absorption of fats. Liver cells make from 700 to 1200 mL of bile daily. When bile is not needed for digestion, the sphincter of Oddi (located at the point at which bile enters the duodenum) is closed, and the bile backs up the cystic duct into the gallbladder for storage. Bile is concentrated and stored in the gallbladder, a small sac cupped in the inferior surface of the liver. When food containing fats enters the duodenum, hormones stimulate the gallbladder to secrete bile into the cystic duct. The cystic duct joins the hepatic duct to form the common bile duct, from which bile enters into the duodenum (refer to Figure 21–3).

The major digestive and metabolic functions of the liver are outlined in Box 21–1. These functions require a large amount of blood, with the liver receiving blood from both venous and arterial blood vessels. The hepatic artery, branching from the abdominal aorta,

BOX 21–1 Major Metabolic and Digestive Functions of the Liver

- Secretes bile.
- Stores fat-soluble vitamins (A, D, E, and K).
- Metabolizes bilirubin.
- Stores blood and releases blood into the general circulation during hemorrhage.
- Synthesizes plasma proteins to maintain plasma oncotic pressure.
- Synthesizes prothrombin, fibrinogen, and factors I, II, VII, IX, and X, which are necessary for blood clotting.
- Synthesizes fats from carbohydrates and proteins to be used either for energy or stored as adipose tissue.
- Synthesizes phospholipids and cholesterol necessary for the production of bile salts, steroid hormones, and plasma membranes.
- Converts amino acids to carbohydrates through deamination.
- Releases glucose during times of hypoglycemia.
- Takes up glucose during times of hyperglycemia and stores it as glycogen or converts it to fat.
- Alters chemicals, foreign molecules, and hormones to make them less toxic.
- Inactivates drugs by removing and breaking down circulating drugs, thereby limiting the duration of their effects.
- Stores iron as ferritin, which is released as needed for the production of red blood cells.

provides oxygenated blood at the rate of 400 to 500 mL/min. The hepatic portal vein delivers about 1000 to 1200 mL/min of deoxygenated blood to the liver from the inferior and superior mesenteric veins and the splenic vein.

THE EXOCRINE PANCREAS

The pancreas, a gland located between the stomach and small intestine, is the primary enzyme-producing organ of the digestive system. It is a triangular gland extending across the abdomen, with its tail next to the spleen and its head next to the duodenum (refer to Figure 21–3). The body and tail of the pancreas are retroperitoneal, lying behind the greater curvature of the stomach. The pancreas is actually two organs in one, having both exocrine and endocrine structures and functions. The exocrine portion of the pancreas, through secretory units called acini, secretes alkaline pancreatic juice containing many different enzymes. The acini, clusters of secretory cells surrounding ducts, drain into the pancreatic duct. The pancreatic duct joins with the common bile duct just before it enters the duodenum (so that pancreatic juice and bile from the liver enter the small intestine together).

The pancreas produces from 1 to 1.5 L of pancreatic juice daily. Pancreatic juice is clear and has a high bicarbonate content. This alkaline fluid neutralizes the acidic chyme as it enters the duodenum, optimizing the pH for intestinal and pancreatic enzyme activity. The secretion of pancreatic juice is controlled by the vagus nerve and the intestinal hormones secretin and cholecystokinin. Pancreatic juice contains enzymes that aid in the digestion of all categories of foods: Lipase promotes fat breakdown and absorption; amylase completes starch digestion; and trypsin, chymotrypsin, and carboxypeptidase are responsible for half of all protein digestion. Nucleases break down nucleic acids.

METABOLISM

After carbohydrates, fats, and proteins are ingested, digested, absorbed, and transported across cell membranes, they must be metabolized to produce and provide energy to maintain life. Metabolism is the process of biochemical reactions occurring in the body's cells. Metabolic processes are either catabolic or anabolic. Catabolism involves the breakdown of complex structures into simpler forms, for example, the breakdown of carbohydrates to produce ATP, an energy molecule that fuels cellular activity. In the process of anabolism, simpler molecules combine to build more complex structures; for example, amino acids bond to form proteins.

The biochemical reactions of metabolism produce water, carbon dioxide, and ATP. The energy value of foods is measured in kilocalories (kcal). A kilocalorie is defined as the amount of heat energy needed to raise the temperature of 1 kilogram (kg) of water 1 degree centigrade.

ASSESSING GASTROINTESTINAL FUNCTION

The GI system is assessed by findings from diagnostic tests, consideration of a patient's genetics, a health assessment interview to collect subjective data, and a physical assessment to collect objective data.

Diagnostic Tests

The results of diagnostic tests of nutritional status and GI function are used to support the diagnosis of a specific disease, to provide information to identify or modify the appropriate medication or therapy used to treat the disease, and to help nurses monitor the patient's responses to treatment and nursing care interventions. Diagnostic tests to assess nutritional status and function of the GI system and the accessory organs are described later in this chapter.

Regardless of the type of diagnostic test, the nurse is responsible for explaining the procedure and any special preparation needed, ensuring the consent form is signed (if necessary), supporting the patient during the examination as necessary, documenting the procedure as appropriate, and monitoring the results of the test. The nurse is also responsible for postprocedure care and patient teaching for self-care at home.

Genetic Considerations

When conducting a health assessment interview and physical assessment, it is important for the nurse to consider genetic influences on the health of the adult. During the health assessment interview, ask about family members with known abnormalities of copper accumulation in the body, hypercholesteremia, abnormal cholesterol or fat metabolism, obesity, or cancer of the pancreas, colon, or rectum. During the physical assessment, assess for any manifestations that might indicate a genetic disorder (see the Genetic Considerations box). If data are found to indicate genetic risk factors or alterations, ask about genetic testing and refer for appropriate genetic counseling and evaluation.

Nutrition Screening and Assessment

A complete nutritional assessment is comprised of three components: a nutrition history, a physical assessment, and laboratory measurements.

GENETIC CONSIDERATIONS

Examples of Gastrointestinal Disorders

- An autosomal recessive disorder, Wilson's disease is an abnormality of copper transport, resulting in copper accumulation and toxicity to the liver and grain. It causes neurologic disease in adults.
- Tangier disease is a disease of cholesterol transport, leading to characteristic orange tonsils, very low levels of high-density lipoprotein, and an enlarged liver and spleen.
- Hypercholesterolemia has a familial tendency.
- About 90% of human pancreatic cancers show a chromosome defect.
- Obesity is believed to result from a variety of factors, including genetics.
- Colon cancer is one of the most common inherited cancer syndromes.
- Familial adenomatous polyposis (FAP) and hereditary nonpolyposis colorectal cancer (HNPCC) are inherited disorders in which there is progressive development of colorectal adenomas. Unless treated, colorectal cancer inevitably occurs by the fourth or fifth decade of life.
- HNPCC, also called Lynch syndrome, is a type of inherited cancer of the GI system, especially the colon and rectum. Colon polyps occur at an early age and are more likely to become malignant.
- In about 20% of cases, Crohn's disease (an inflammatory bowel disease) appears to be familial in origin.
- Celiac disease (CD) is a genetic, inheritable disease responsible for the malabsorption of nutrients, resulting in malnutrition. If people with CD eat certain types of proteins (glutens, found in wheat, barley, rye, and oats), an autoimmune response causes damage to the small intestine, so that nutrients are not absorbed.
- Gaucher disease, more common in descendants of Jewish people from eastern Europe, results in lack of an enzyme to break down fats. Fats accumulate in the liver, spleen, and bone marrow, causing pain, fatigue, jaundice, bone damage, anemia, and even death.

NUTRITION HISTORY

An interview to establish baseline dietary habits and preferences and to identify problems with nutrition and GI function may be conducted during a health screening. The interview may be part of a total health assessment or may focus on a chief complaint such as nausea or unexplained weight loss. A food frequency questionnaire can be used to assess usual intake of foods and food groups over time. If the patient has a health problem involving the GI system, analyze its onset, characteristics, and course; severity; precipitating and relieving factors; and any associated symptoms, noting the timing and circumstances. For example, the nurse may ask the patient the following:

- What is your usual dietary intake pattern during a 24-hour period?
- Has your usual dietary intake pattern changed recently?
- Have you had any episodes of indigestion, nausea, vomiting, diarrhea, or constipation? If so, describe the appearance of what was vomited or the stools and anything that makes these problems better or worse. How long have you had these problems?
- Have you ever had bleeding from your rectum? If so, describe the amount and color of the blood (for example, was it bright red or dark red?).

When collecting information about the patient's current health status, the nurse should inquire about the following:

- Have there been any changes in weight, appetite, and the ability to taste, chew, or swallow? What is the patient's perception of the role of nutrition in maintaining health?
- Who buys and prepares the food?
- What medications (prescribed, over-the-counter, or vitamins) is the patient currently taking? Does the patient take any vitamins, herbal supplements, or other "health food" items?
- Does the patient consume alcohol (how much and type)?
- Does the patient have braces, bridges, or dentures? If so, what self-care measures are used for such appliances?
- What are the patient's oral hygiene practices and frequency of dental visits?
- What is the patient's typical bowel elimination pattern?

If the patient has experienced nausea or vomiting, ask whether the vomitus contains bright red blood, dark (old) blood, bile, or fecal material. If the patient is very thin or verbalizes concerns about body size incongruent with the ratio of height to weight, ask whether the patient induces vomiting or uses laxatives to control weight. Ask about any medical conditions that may influence the patient's bowel elimination pattern, such as a stroke or spinal cord impairment, inflammatory GI diseases, endocrine disorders, and allergies. Note any recent travel to other countries. Assess the patient's lifestyle for any patterns of psychologic stress and/or depression, which may alter bowel elimination. Depression may be associated with constipation, whereas diarrhea (frequent passage of loose, watery stools) may occur in situations of high stress and anxiety. Explore the patient's activities of daily living (ADLs), including exercise, sleep–rest patterns, and dietary and fluid intake. Ask the patient to describe the frequency and character of stools. Ask about any history of diarrhea, constipation, or bleeding from the rectum, and collect information about the use of medications, laxatives, suppositories, or enemas. Anticholinergic drugs, antihistamines, tranquilizers, or narcotics may cause constipation.

Determine whether the patient has had any lower abdominal pain or rectal pain. Crampy, colicky pains occur with diarrhea and/or constipation. A sudden onset of lower abdominal cramping occurs in obstruction of the colon. Left lower abdominal pain is associated with diverticulitis. Rectal pain may occur with stool retention and/or hemorrhoids.

If the patient has an **ostomy** (surgical opening into the bowel), ask about skin care problems, consistency of stool, foods that cause problems with diarrhea or **flatus** (intestinal gas), the number of times that the patient empties the appliance bag each day, and irrigation habits. It is also important to explore the patient's feelings about the appliance.

Explore any family history of colon cancer, colitis, gallbladder disease, or malabsorption syndromes, such as lactose intolerance and celiac sprue. Assess the patient's risk factors for cancer, including age greater than 50; family member with colon cancer; history of endometrial, ovarian, or breast cancer; and previous diagnoses of colon inflammation, polyps, or cancer.

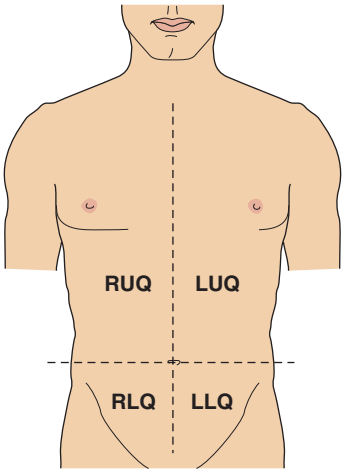
Ask the patient to describe any heartburn, indigestion, abdominal discomfort, or pain. Explore the location of the pain, the type of pain, the time it occurs, foods that aggravate or relieve it, and how it is relieved. Abdominal pain is often referred to other sites. For example, a patient with a liver disorder may experience pain over the right shoulder (Kehr's sign). Epigastric (middle upper abdominal) pain is experienced in cases of acute gastritis, obstruction of the small intestine, and acute pancreatitis. Pain in the right upper quadrant is associated with cholecystitis. Pain in the left upper quadrant may be related to a gastric ulcer.

The health history should include questions about any prior surgeries or trauma of the GI system. Explore the past history of any medical condition that may affect the patient's ingestion, digestion, and/or metabolism (for example, Crohn's disease, diabetes mellitus, irritable bowel syndrome, peptic ulcers, or pancreatitis). Other areas significant to assessment are food allergies (especially to milk, which is evidenced as lactose intolerance with abdominal cramping, excessive flatus, and loose stools) and a family history that may provide clues to increased risk for health problems.

In addition to other factors assessed in the health history, culture and ethnicity are important components of nutritional status and GI health. Nutritional diversity is common among cultural and ethnic groups and questions should be included to identify specific customs, food likes and dislikes, and how foods are prepared and served. For example, in some ethnic groups, dietary substances are used to protect health, such as eating raw garlic or onions (Spector, 2013). In other cultures, dietary balance is believed to be necessary to keep the body in balance or harmony. Nurses need to know about specific culturally related nutritional values and practices, and ask questions to identify health-related concerns specific to individualized dietary intake.

PHYSICAL ASSESSMENT

Physical assessment of the GI system may be performed as part of a total health assessment, as a focused assessment of patients with known or suspected health problems, in combination with assessment of the urinary and reproductive systems (problems that may cause manifestations similar to those of the GI system), or alone for patients with known or suspected health problems. The techniques of inspection, auscultation, percussion, and palpation are used. Palpation is the last method used in assessing the abdomen. Figure 21–6 ■ illustrates the four quadrants of the abdomen with the organs contained in each quadrant.



PRACTICE ALERT!

When assessing the abdomen, use palpation last, because pressure on the abdominal wall and contents may interfere with bowel sounds and cause pain, ending the examination.

Collect objective data by obtaining anthropometric measurements (height, weight, triceps skinfolds, and midarm circumference) and by examining the mouth and abdomen. Prior to the examination, collect all necessary equipment and explain techniques to the patient to decrease anxiety. Ask the patient to void.

The patient may be seated during assessment of the mouth, but is supine during the abdominal assessment. Have the patient turn to the left lateral (Sims') position for the rectal examination. The older patient or the patient with limited mobility may need assistance in assuming this position. The patient should be standing to assess for an inguinal hernia.

Explain what will happen during the examination, and encourage the patient to take deep, regular breaths to increase relaxation.

Right Upper Quadrant
Liver and gallbladder
Pylorus
Duodenum
Head of pancreas
Right adrenal gland
Portion of right kidney
Hepatic flexure of colon
Portions of ascending and transverse colon

Left Upper Quadrant
Left lobe of liver
Spleen
Stomach
Body of pancreas
Left adrenal gland
Portion of left kidney
Splenic flexure of colon
Portions of transverse and descending colon

Right Lower Quadrant
Lower pole of right kidney
Cecum and appendix
Portion of ascending colon
Bladder (if distended)
Right ovary and salpinx
Right spermatic cord
Right ureter

Left Lower Quadrant
Lower pole of left kidney
Sigmoid colon
Portion of descending colon
Bladder (if distended)
Left ovary and salpinx
Uterus (if enlarged)
Left spermatic cord
Left ureter

Midline
Aorta
Bladder
Uterus

◯ = Umbilicus

DIAGNOSTIC TESTS of the Gastrointestinal System

THE ESOPHAGUS AND STOMACH

Name of Test	Purpose and Description	Related Nursing Interventions
Barium swallow or upper GI series	These tests are conducted to diagnose esophageal varices, inflammation, ulcerations, hiatal hernia, foreign bodies, polyps, diverticula, and tumors of the esophagus, stomach, and duodenal bulb. The patient drinks 16–20 ounces of a chalky liquid (barium sulfate or meglumine diatrizoate [Gastrografin]) before the exam. These radiologic studies are done by observing the movement of a contrast medium with a fluoroscope (Figure 21–7 ■).	Instruct the patient not to eat or drink fluids or smoke for 8–12 h before the test. A low-residue diet may be ordered 2–3 days before the test. Tell the patient not to take narcotics or anticholinergic medications for 24 h pretest and not to take any medications for 8 h pretest. Following the test, ensure the patient eliminates the barium by taking laxatives and forcing fluids as appropriate because barium can cause fecal impaction. Inform patient stools may be light colored for several days.
Esophageal acidity, esophageal manometry, acid perfusion (Bernstein test) Normal esophageal pH: 5–6	Esophageal acidity is measured to diagnose problems of the lower esophageal sphincter and chronic reflux esophagitis. A catheter with a pH electrode is inserted into the esophagus through the mouth. The one-time measurement has been largely replaced by 24-hour pH monitoring. Esophageal manometry is done to measure esophageal sphincter pressure and peristaltic contractions for diagnosis of esophageal motility problems, such as achalasia. A manometric catheter with a pressure transducer is inserted into the esophagus through the mouth, and esophageal pressure is measured before and after swallowing. Acid perfusion (Bernstein test) tests are done to distinguish between gastric acid reflux and cardiac involvement. A catheter is inserted through the nose into the esophagus. A saline solution, followed by an hydrochloric acid (HCl) solution, is dripped into the catheter and the patient is asked to indicate when pain occurs. HCl is turned off, and saline is started until symptoms have subsided.	Food and fluid will be restricted 8–12 h prior to test. Instruct patient to avoid alcohol intake for 24 h prior to the exam. Assess medications: Results of the tests may be affected by antacids, anticholinergics, and H_2 inhibitors, which increase the pH, reducing acidity and causing false test results. Alcohol, cholinergics, adrenergic blockers, and corticosteroids may increase acidity and relax the lower esophageal sphincter.

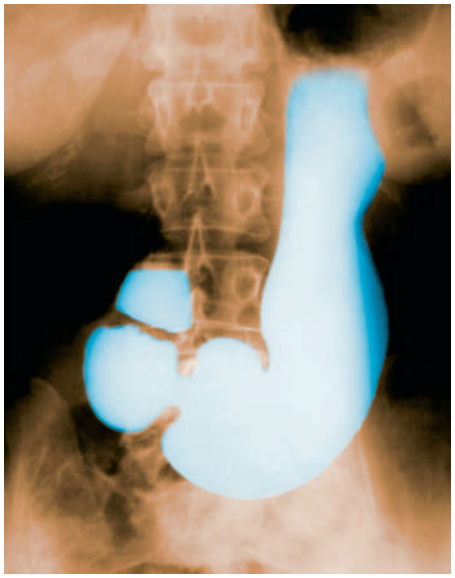

Figure 21–7 ■ A barium x-ray of a healthy stomach.

DIAGNOSTIC TESTS of the Gastrointestinal System (*continued*)

Name of Test	Purpose and Description	Related Nursing Interventions
Gastric analysis Normal values: Fasting: 1.0–5.0 mEq/L per hour Stimulation: 10–25 mEq/L per hour	This test is used to evaluate gastric secretions for an increase or decrease of free hydrochloric acid by inserting a nasogastric tube into the stomach and aspirating stomach fluids. A stimulation gastric analysis may follow, with a gastric stimulant (such as Histalog or pentagastrin) administered and several gastric samples aspirated.	Instruct the patient to not smoke, eat, or drink fluids for 8–12 h prior to the test. Assess medications and fluid intake: Anticholinergics, cholinergics, adrenergic blockers, antacids, steroids, alcohol, and coffee can alter results. Obtain baseline vital signs. Remove loose dentures. Insert nasogastric tube. Aspirate gastric contents at 15- to 20-minute intervals as ordered.
Gastric emptying studies	To evaluate the ability of the stomach to empty liquids or solids. In this nuclear imaging study, the patient is asked to eat a cooked egg containing ^{99m}Tc (solids) or to drink orange juice with ^{99m}Tc (liquids). Sequential images are recorded with a gamma camera every 2 minutes for up to an hour.	Explain to the patient that the substances contain only very small amounts of radioactivity and are not hazardous.
Magnetic resonance imaging (MRI)—stomach	An MRI of the stomach may be conducted to identify the source of gastric bleeding.	Inform the patient of the need to lie still during the examination. Assess for any metallic implants (such as pacemakers, clips on brain aneurysms, body piercings, tattoos, shrapnel). If present, notify imaging physician. Remove transdermal medication patches (both OTC and prescribed) unless otherwise ordered (U.S. Food and Drug Administration, 2009). Replace the patch following the procedure. Tell the patient to inform the staff about the patch when making the appointment and when completing the admission information. Ask if the patient is pregnant; if so, the test is not performed. Ask about claustrophobia; if a problem, sedation may be required.
Upper GI endoscopy (esophagogastroduodenoscopy [EGD]), gastroscopy	These tests directly visualize the mucous membrane lining of the esophagus, stomach, and duodenum. A flexible fiberoptic endoscope is used to visualize inflammations, ulcerations, tumors, or varices, and video imaging may illustrate gastric motility. They may also be combined with an ultrasound examination by attaching an ultrasound transducer to the endoscope.	Schedule this test at least 2 days after a barium swallow or upper GI series. Remove dentures and eyeglasses. Inform the patient not to eat food or drink fluids for 6–8 h before the procedure. Tell the patient that the procedure takes about 20–30 minutes and that a local anesthetic will be administered to the throat to help prevent discomfort. A sedative/tranquilizer, a narcotic analgesic, and atropine may be given before the procedure, and titrated intravenously during the procedure. After the procedure the patient is allowed to eat and drink as soon as he or she can swallow safely. Mild bloating, belching, or flatulence may occur after the procedure. Tell the patient to contact the physician postexamination for difficulty swallowing; epigastric, substernal, or shoulder pain; fever; vomiting blood; or having black tarry stools.
THE INTESTINES		
Name of Test	**Purpose and Description**	**Related Nursing Interventions**
Abdominal ultrasound	This test is used to identify abdominal masses, ascites, and disorders of the appendix. A lubricant gel is applied to the skin and a transducer is placed over the area of interest. High-frequency sound waves pass through the body structures and are recorded as they are reflected.	Tell the patient not to eat, drink, smoke, or chew gum for 6 h prior to the examination and to eat a fat-free meal the evening before the test. Ensure that the patient has not had any other tests that might interfere with results, such as an upper GI series.
Barium enema (Ba enema)	A barium enema is conducted to identify structural abnormalities of the colon and rectum. This fluoroscopic radiologic examination of the colon is done by administering a contrast medium rectally. Double-contrast or air-contrast studies are the examination of choice, with air being infused after the barium is evacuated.	The colon must be free from fecal material. Inform the patient to follow a clear liquid diet for 24 h and then to not eat or drink fluid for 8 h before the procedure. Instruct in the administration of the prescribed laxatives, enemas, or suppositories the evening before the procedure. Following the procedure, the patient should increase fluid intake and take a laxative, if prescribed. Stools may be white until all the barium is expelled.

(*continued*)

DIAGNOSTIC TESTS of the Gastrointestinal System (*continued*)

Name of Test	Purpose and Description	Related Nursing Interventions
Colonoscopy	A visual examination of the entire colon to the ileocecal valve is conducted to identify tumors, polyps, and inflammatory bowel disease and to dilate strictures. A flexible endoscope is inserted anally and advanced through the colon. Polyps are removed during the procedure to prevent future malignancies.	Tell the patient to follow the examining physician's order for preparation (this varies by physician or clinic), which may include a liquid diet the day prior to the examination, remaining NPO for 8 h before the procedure, and use of a bowel preparation, for example, citrate of magnesia, laxatives, or polyethylene glycol. Oral phosphate used for test preparation may compromise kidney function, especially in older adults, or those who are dehydrated, have kidney disease or colitis, or are taking medications that affect kidney function. Explain that sedation is usually given during the procedure and that polyps (if present) will be removed. Instruct the patient to refrain from eating prepared foods that contain olestra (a synthetic fat additive used in products such as potato chips); the chemical may cover tissue lesions and also cause adhesive plaques to form on the colonoscopy instruments. Inform the patient that after the procedure increased flatus is common, and to report to the healthcare provider any abdominal pain, chills, fever, rectal bleeding, or mucopurulent discharge. If polyps were removed, the patient should avoid high-fiber foods for 1–2 days and do no heavy lifting for 7 days.
Guaiac fecal occult blood test (G-FOBT)	In this test, feces are tested for occult (hidden) blood. This is often done as a screening test for colon cancer. A stool specimen may be sent to the laboratory, or the test may be done with a commercial kit such as Hemoccult II or Occultest.	When testing for occult blood with a commercial kit, place a smear of stool on the designated area and drop the reagent on the area. A blue color that develops in response to the reagent indicates the presence of blood. If the test is done at home, tell the patient to avoid (if recommended by the healthcare provider) taking aspirin, NSAIDs, anticoagulants, red meats, fish, broccoli and other high-fiber vegetables, mushrooms, vitamin C supplements, and iron supplements for 3 days prior to the stool collection.
Immunochemical fecal occult blood test (I-FOBT)	An I-FOBT is a test used to test for blood in the stool, and is considered to be more effective in detecting colon cancer than is the guaiac fecal occult blood test. A brush is used to collect water drops around the surface of a stool while it is still in the toilet bowl. The sample is then sent to the laboratory for analysis.	No special preparation is necessary. The specimen is collected and sent to the laboratory.
Magnetic resonance imaging (MRI)—abdominal	An abdominal MRI may be done to identify sources of GI bleeding and to stage colon cancer.	See previous information about MRI of the stomach.
Sigmoidoscopy	A sigmoidoscopy is a visual examination of the anus, rectum, and sigmoid colon to identify tumors, polyps, infections, inflammations, hemorrhoids, and fissures. The test is done using a flexible sigmoidoscope. Specimens are obtained and polyps removed during the procedure.	Instruct the patient to eat a clear liquid or light diet the evening before the procedure and to take prescribed laxatives. An enema or rectal suppository may be required the morning of the procedure. Explain to the patient that after the procedure large amounts of flatus may be expelled if air was instilled into the bowel, and to report any abdominal pain, fever, or rectal bleeding to the healthcare provider. If a polyp is removed, the patient should avoid heavy lifting for 7 days, and avoid high-fiber foods for 1–2 days.
Small-bowel series	This radiologic examination is done to diagnose abnormalities of the esophagus, stomach, and small intestine. The patient drinks a contrast medium and films are taken every 20 minutes until the medium reaches the terminal ileum. It may also be done in conjunction with an upper GI series or barium swallow.	Inform the patient that a low-residue diet should be eaten as prescribed (usually up to 48 h preprocedure), and not to eat for 8 h or drink fluids for 4 h before the test. Tell the patient about the procedure: It takes several hours to complete, and barium may be given orally, into the bowel via an endoscope, or through a weighted tube. Following the procedure the patient should increase oral fluid intake and take a prescribed laxative to facilitate evacuation of the barium. The stools will be white for up to 72 h after the examination; normal color will return when all the barium has been evacuated.
Stool specimen, stool culture	A sample of stool is collected for gross and microscopic examination, as well as for form, consistency, and color. Gross examination includes volume and water content, and the presence of any blood, pus, mucus, or excess fat. Microscopic examination identifies the presence of WBCs, unabsorbed fat, and parasites. When an enteric pathogen is suspected, a stool culture is done.	Ask the patient to provide a fresh stool sample. A sterile container should be used to collect a stool sample for a culture. Ask women of childbearing age if they are having their menstrual period; if so, note this on the laboratory request.

DIAGNOSTIC TESTS of the Gastrointestinal System (*continued*)

Name of Test	Purpose and Description	Related Nursing Interventions
Stool DNA test (sDNA)	This test involves examining a stool specimen for DNA changes. Premalignant polyps and malignant lesions of the bowel shed cells that have been identified as DNA markers for bowel and rectal cancer. The patient uses a kit containing an ice pack (that must be frozen for several hours before use), collects one bowel movement in a special container, then mails or brings the container with the ice pack in a provided box to the laboratory.	No special preparation is needed. Explain the procedure to the patient.
Virtual colonography (VC)	A VC is used to diagnose polyps, diverticulosis, and cancer and may not be as accurate as the traditional colonoscopy. Computers are used to produce two- and three-dimensional images of the colon on a screen. If abnormalities are found, a conventional colonoscopy may be needed (such as to remove polyps or do a biopsy).	The preparation for virtual colonography is essentially the same as that used for traditional colonoscopy. Inform the patient that a tube is inserted into the rectum, air is instilled to inflate the colon, and scans are taken.
THE GALLBLADDER AND PANCREAS		
Name of Test	**Purpose and Description**	**Related Nursing Interventions**
Abdominal ultrasound, hepatobiliary ultrasound, gallbladder ultrasound	Abdominal ultrasound is used to detect abdominal tumors, cysts, and ascites. Hepatobiliary ultrasound is used to visualize the biliary ducts, and to detect subphrenic abscesses, cysts, tumors, and cirrhosis of the liver. Gallbladder ultrasound is used to detect gallstones. These noninvasive procedures record ultrasound waves as they are reflected off body structures. A conductive gel is applied to the skin and a transducer placed on the area of interest.	Instruct the patient to remain NPO for 8–12 h prior to the test.
Cholangiography • Percutaneous transhepatic cholangiogram (PTC) • Surgical cholangiogram	A PTC is done to evaluate filling of the hepatic and biliary ducts. Using local anesthesia, the liver and bile duct are entered with a long needle (using fluoroscopy), bile is withdrawn, and a contrast medium is injected into the bile duct. During a surgical cholangiogram with general anesthesia, contrast medium is injected into the common bile duct to evaluate filling of the duct.	Assess for allergy to iodine, seafood, or x-ray dye (many contain iodine). Assess medications: Oral hypoglycemic agents are contraindicated for use with iodinated contrast. Monitor for bile leakage or hemorrhage following the tests.
Cholecystography (oral) (GB series)	This test is used to detect gallbladder stones, inflammation, tumors, and obstruction of the cystic duct. Radiopaque tablets (for example, iopanoic acid [Telepaque], sodium ipodate [Oragrafin], iodoalphionic acid [Priodax], or iodipamide meglumine [Cholografin]) are given the evening before the test; x-rays are taken the following morning. A high-fat meal may be given after the fasting x-rays are completed and further x-rays taken to determine how rapidly the GB expels the dye.	*If the patient is also having GI x-rays with barium, the GB tests should be done first, because barium would interfere with the test.* Instruct the patient to eat a fat-free diet 24 h prior to test. No food or fluids except sips of water should be taken 12 h before the test. Radiopaque tablets are to be taken 2 h after the evening meal. Assess for allergy to iodine, seafood, or x-ray dye (many contain iodine). Assess medications: Oral hypoglycemic agents are contraindicated for use with iodinated contrast.
Computed tomography (CT)	The CT scan produces a narrow x-ray beam that examines the body sections from 360 degrees. CT of the abdomen is useful in visualizing many pathologic conditions of the liver, biliary tract, pancreas, spleen, GI tract, and gallbladder. Oral contrast media may be used.	No special preparation is needed. Observe for signs and symptoms of allergic reaction to contrast media. If contrast media is used, encourage patient to increase fluid after exam to enhance excretion of dye.
Endoscopic retrograde cholangiopancreatography (ERCP)	An ERCP is done to directly visualize GI structures, and to retrieve gallstones from the distal common bile duct, dilate structures, and biopsy tumors. A fiberoptic endoscope is inserted through the mouth, esophagus, stomach, descending duodenum, and common bile ducts and pancreatic ducts. Contrast medium is injected into the ducts and structures are visualized.	Tell the patient not to drink fluids or eat for 8 h before the test. Assess patient for allergy to iodine, seafood, or x-ray dye (many contain iodine). Assess medications: Oral hypoglycemic agents are contraindicated for use with iodinated contrast. Assess gag reflex prior to giving food or fluids. If atropine was given, assess for manifestations of urinary retention. Tell the patient that a sore throat may be present for a few days after the test; suggest warm saline gargles to ease discomfort.
Magnetic resonance cholangiopancreatography (MRCP)	This noninvasive MRI study is done to evaluate the biliary and pancreatic ducts.	See previous information for MRI of the stomach.

(*continued*)

DIAGNOSTIC TESTS of the Gastrointestinal System (*continued*)

Name of Test	Purpose and Description	Related Nursing Interventions
Serum amylase Normal value: 30–170 units/L	This blood test is used to measure the secretion of amylase by the pancreas. It is used to diagnose acute pancreatitis, when amylase level peaks in 24 h and then drops to normal in 48–72 h.	No special preparation is needed.
Serum lipase Normal value: 20–180 units/L (norms vary among laboratories)	This blood test is used to measure the secretion of lipase by the pancreas.	No special preparation is needed.

THE LIVER

Name of Test	Purpose and Description	Related Nursing Interventions
Liver biopsy	A liver biopsy is performed to rule out metastatic cancer or to detect a cyst or cirrhosis of the liver. The procedure is considered minor surgery, and is done at a hospital. Using ultrasound, a biopsy needle is inserted into the liver and guided to the pathologic site. See Figure 21–8 ■.	Inform the patient to tell the physician about any anticoagulants taken, and to withhold aspirin and ibuprofen for a week before the procedure. Food and fluids are withheld for 4–6 h before the procedure. Assess and record baseline vital signs, and review prothrombin time and platelet count. Report abnormal findings. Administer vitamin K as prescribed. Ask the patient to void immediately before the procedure. After the needle is removed, pressure is applied; place the patient on the right side for 1–2 h to maintain pressure on the insertion site. Explain to the patient that pain may be experienced in the right shoulder as the local anesthetic loses effect, that the dressing will be assessed frequently, that food and fluids are withheld for 2 h after the biopsy, and that coughing, lifting, or straining should be avoided for 1–2 weeks. The patient will not be allowed to drive home, and must go directly to bed for 8–10 h (or as prescribed by the physician).

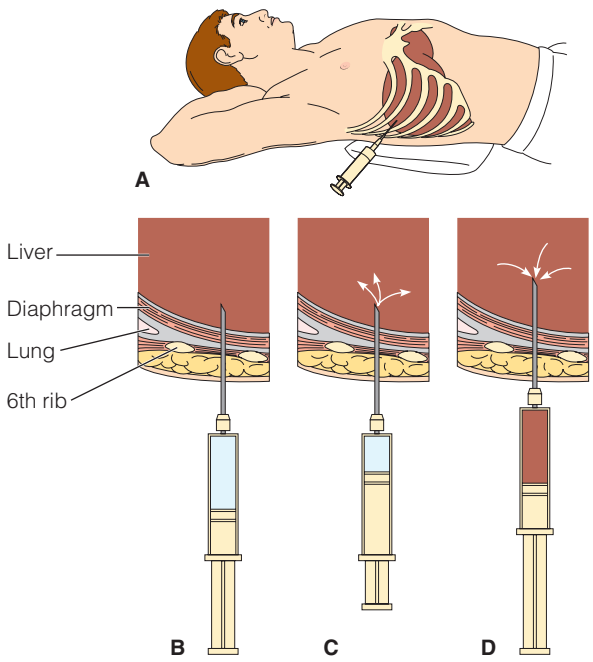

Figure 21–8 ■ Liver biopsy. A, The patient exhales completely, and then holds his or her breath. This brings the liver and diaphragm to their highest position. B, The biopsy needle is inserted into the liver. C, Approximately 1 mL of saline is injected to clear the needle of blood and tissue. D, The needle is advanced, and a tissue sample is aspirated. Pressure is applied to the site immediately after the needle is withdrawn. The specimen is sent to the laboratory for analysis.

Note: A wide variety of blood tests are used to diagnose and monitor liver disease. See Table 21–4.

TABLE 21–4 Liver Function Tests

Used to assess liver function, evaluate patients with jaundice, and detect liver disease such as hepatitis or alcoholic cirrhosis. Fasting is required for the bilirubin sample; samples for other liver function studies may be drawn without fasting. Water is permitted.

Note: All values are for adults.

Alanine aminotransferase (ALT or SGPT)	10–35 units/L
Alkaline phosphatase (ALP)	42–136 units/L
Aspartate aminotransferase (AST or SGOT)	8–38 units/L
Gamma-glutamyltransferase (GGT)	Women: 3–13 units/L Men: 4–23 units/L
Serum bilirubin	Total: 0.1–1.2 mg/dL Conjugated (direct): 0.1–0.3 mg/dL

Explain that during the rectal examination, it may feel as though the patient is about to have a bowel movement and sometimes flatus (gas) is passed. Assure the patient that this is normal. Ensure that the examination area is private and the patient is draped properly to prevent unnecessary exposure.

Physical assessment of the integumentary system, nervous system, musculoskeletal system, cardiovascular system, and respiratory system may reflect the patient's nutritional status. Table 21–5 summarizes abnormal nutritional assessment findings related to these body systems. Normal age-related findings for the older adult are summarized in the Nursing Care of the Older Adult box.

TABLE 21–5 Assessment Findings Due to Malnutrition

Body System	Assessment Findings
Nails	Soft and spoon shaped in iron deficiency. Splinter hemorrhages in vitamin C deficiency.
Hair	Dry, dull, and scarce in zinc, protein, and linoleic acid deficiencies.
Skin	Flaky and dry in vitamin A, vitamin B, and/or linoleic acid deficiency. Cracks and/or hyperpigmentation in niacin deficiency. Bruising in vitamin C or vitamin K deficiency. Poor wound healing.
Eyes	Eyes become dry and soft with decrease in vitamin A. Conjunctiva is pale with a decrease in iron, and red with a decrease in riboflavin.
Nervous system	Reflexes are decreased and patient may have peripheral neuropathies with thiamine deficiency. Patient may be irritable and/or disoriented with thiamine deficiency. Dementia, confusion, ataxia.
Musculoskeletal system	Muscle wasting is seen with deficits in protein, carbohydrate, and fat metabolism. Calf pain occurs with thiamine deficiency; joint pain may occur with vitamin C deficiency.
Cardiovascular system	Heart size and rate may increase with thiamine deficiency. Diastolic blood pressure may be increased with a high intake of fat. Lowered cardiac output and decreased blood pressure may occur with caloric deficiencies over a long time period.
GI system	Cheilosis (sores at corner of mouth) seen in vitamin B complex deficiencies, especially riboflavin. Stomatitis and spongy, bleeding gums may also be seen in malnutrition.

NURSING CARE OF THE OLDER ADULT

Age-Related Gastrointestinal Changes

Age-Related Change	Significance
Teeth: ↑ number of root cavities and cavities around existing dental work; tooth enamel harder and more brittle; dentin is more fibrous; tooth cusps flatten; root pulp shrinks; ↑ loss of bone supporting teeth	Increase in periodontal disease and tooth loss Increase in fractures of teeth Increased incidence of dentures
Gums: Gingiva retracts	Increase in periodontal disease
Taste: Less acute as tongue atrophies, especially for sweet sensations	Excessive seasoning of foods
Saliva: ↓ amount is produced (one-third of that produced in younger years)	Decreased ability to break down starches Swallowing may take longer
Esophageal motility: ↓ intensity of propulsive waves and slower emptying time, weaker gag reflex	Discomfort when swallowing food Increased risk of aspiration
Stomach: Mucosa atrophies, ↓ production of hydrochloric acid and pepsin leading to higher pH in stomach	Increase in incidence of gastric irritation
Liver: Less efficient handling of cholesterol	Increased incidence of gallstones
Small intestine: ↓ number of absorbing cells on intestinal wall, slowed fat absorption, faulty absorption of vitamin B_{12}, vitamin D, calcium, and iron	Decreased ability to absorb vitamins A, D, E, and K Increased risk of osteoporosis and fractures (↓ calcium and vitamin D) Increased risk of iron-deficiency anemia (weakness, lassitude, pallor) (↓ iron) Increased risk of pernicious anemia (weakness, dyspnea, glossitis, numbness, dementia, depression) (↓ vitamin B_{12})
Large intestine: ↓ mucous secretion and elasticity of the wall of the rectum, loss of tone in internal sphincter with decreased awareness of need to defecate	Increased tendency for constipation

Gastrointestinal Assessments

Technique/Normal Findings	Abnormal Findings
Anthropometric Assessment	
Weigh the patient and measure the patient's height. Compare the patient's actual weight to ideal body weight (IBW) (Table 21–6). *Weight should be appropriate to height as indicated on a standardized table.*	• A weight 10% to 20% less than ideal body weight indicates malnutrition. • A weight 10% above ideal body weight is considered overweight. • A weight 20% above ideal body weight is considered obese.
Measure BMI. Determine BMI by using the accompanying formula. *BMI should be between 19 and 25.*	• A BMI of 25–29.9 kg/m^2 indicates overweight. $\frac{\text{Weight in kilograms}}{\text{Height in meters}} = \text{BMI}$

TABLE 21–6 Example of a Height and Weight Table

	Height		Weight		
	Feet	Inches	Small Frame	Medium Frame	Large Frame
Men (ages 25–29)	5	2	128–134	131–134	138–150
	5	3	130–136	133–143	140–153
	5	4	132–138	135–145	142–156
	5	5	134–140	137–148	144–160
	5	6	136–142	139–151	146–164
	5	7	138–145	142–154	149–168
	5	8	140–148	145–157	152–172
	5	9	142–151	148–160	155–176
	5	10	144–154	151–163	158–180
	5	11	146–157	154–166	161–184
	6	0	149–160	157–170	164–188
	6	1	152–164	160–174	168–192
	6	2	155–168	164–178	172–197
	6	3	158–172	167–182	176–202
	6	4	162–176	171–187	181–207
Women (ages 25–29)	4	10	102–111	109–121	118–131
	4	11	103–113	111–123	120–134
	5	0	104–115	113–126	122–137
	5	1	106–118	115–129	125–140
	5	2	108–121	118–132	128–143
	5	3	111–124	121–135	131–147
	5	4	114–127	124–138	134–151
	5	5	117–130	127–141	137–155
	5	6	120–133	130–144	140–159

	6	0	138–151	148–162	158–179

Gastrointestinal Assessments (*continued*)

Technique/Normal Findings	Abnormal Findings
Measure triceps skinfold thickness (TSF). Find the midpoint between the patient's olecranon and acromion processes. Grasp the skin and fat, and pull it away from the muscle. Apply skinfold calipers for 3 seconds, and record the reading (Figure 21–9 ■). Repeat three times, and average the three readings. Compare the patient's reading to the standard values shown in Table 21–7. *TSF should be within normal range as compared to standard values.*	• Triceps readings are 10% or more below standards in malnutrition and 10% or more above standards in obesity or overnutrition.

TABLE 21–7 Values for Anthropometric Measurements

	Standard Value	
Measurement	**Male**	**Female**
Triceps skinfold thickness	12.5 mm	16.5 mm
Midarm circumference	29.3 cm	28.5 cm
Midarm muscle circumference	25.3 cm	23.2 cm

Figure 21–9 ■ Measuring the triceps skinfold thickness with calipers.

Measure midarm circumference (MAC). Find the midpoint between the patient's olecranon and acromion processes. Wind tape measure around arm (Figure 21–10 ■). Compare the patient's reading to the standard values shown in Table 21–7. *MAC should be within normal range as compared to standard values.*	• MAC decreases with malnutrition and increases with obesity.

Figure 21–10 ■ Measuring MAC with a tape measure.

Calculate midarm muscle circumference (MAMC). Use the patient's triceps skinfold measurement and midarm circumference readings to calculate the patient's MAMC using the accompanying formula. Compare the result to the standard values shown in Table 21–7. *MAMC should be within normal range as compared to standard values.*	• In mild malnutrition, the MAMC is 90% of the standard; in moderate malnutrition, 60% to 90%. In severe malnutrition (muscle wasting), the MAMC is less than 60% of the standard. $\text{MAMC} = \text{MAC} - (0.314 \times \text{TSF})$
Determine waist-to-hip ratio. With the patient standing, measure the waist, and then measure the hips midway between the iliac crest and the greater trochanter. Use the accompanying formula to calculate the waist-to-hip ratio. *Normal findings: females, waist ratio less than or equal to 0.80; males, waist ratio less than or equal to 1.0.*	• Females with a ratio greater than 0.80 and males with a ratio greater than 1.0 have a three to five times greater risk for having a heart attack or stroke $\frac{\text{Waist circumference}}{\text{Hip circumference}} = \text{waist-to-hip ratio}$

SAMPLE DOCUMENTATION

Assessment of Nutritional Status

Twenty-two-year-old female visiting health clinic for regular checkup. Height: 5 feet, 5 inches (165 cm); weight: 128 pounds (58 kg). BMI: 24. MAC: 28 cm. Waist-to-hip ratio: 0.6. Skin is warm, moist, and smooth without lesions other than well-healed scar on RLQ of abdomen from appendectomy, age 15. Oral mucosa and tongue pink and moist. No breath odor. All teeth present with evidence of dental care. Abdomen slightly concave when lying on back, bowel sounds present in all four quadrants, liver nonpalpable, tympany over lower abdomen on percussion.

(*continued*)

Gastrointestinal Assessments (*continued*)

Technique/Normal Findings	Abnormal Findings
Oral Assessment	
Inspect and palpate the lips. *Lips should be of normal color for race without lesions.*	• **Cheilosis** (painful lesions at corners of mouth) is seen with riboflavin and/or niacin deficiency. • Cold sores or clear vesicles with a red base are seen in herpes simplex 1.
Inspect and palpate the tongue. *Tongue should be pink, smooth, and have good turgor.*	• Atrophic smooth **glossitis** is characterized by a bright red tongue. It is seen in B_{12}, folic acid, and iron deficiencies. • Vertical fissures are seen in dehydration. • A black, hairy tongue may be seen following antibiotic therapy.
Inspect and palpate the buccal mucosa. *Mucosa should be moist, without lesions and of appropriate color.*	• **Leukoplakia** (small white patches) may be a sign of a premalignant condition. • A reddened, dry, swollen mucosa may be seen in stomatitis. • Candidiases (white cheesy patches that bleed when scraped) may be seen in immune-suppressed patients receiving antibiotics or chemotherapy and in terminally ill patients.
Inspect and palpate the teeth. *Teeth should be in a state of good hygiene without caries.*	• Cavities and excessive plaque are seen with poor nutrition and/or poor oral hygiene.
Inspect and palpate the gums. *Gums should be of even color without swelling.*	• Swollen, red gums that bleed easily (**gingivitis**) are seen in periodontal disease, vitamin C deficiencies, or with hormonal changes.
Inspect the throat and tonsils. *Tonsils (if present) should be of appropriate color and size.*	• In acute infections, tonsils are red and swollen and may have white spots.
Note the patient's breath. *Breath should not have unusual or foul odors.*	• Sweet, fruity breath is noted in diabetic ketoacidosis. • Acetone breath may be a sign of uremia. • Foul breath may result from liver disease, respiratory infections, and poor oral hygiene.

Abdominal Assessment

Technique/Normal Findings	Abnormal Findings
Inspect abdominal contour, skin integrity, venous pattern, and aortic pulsation (see Box 21–2). *Abdomen should be slightly concave or rounded with intact skin. There should not be distended veins or obvious aortic pulsations.*	• Generalized abdominal distention may be seen in gas retention or obesity. • Lower abdominal distention is seen in bladder distention, pregnancy, or ovarian mass. • General distention and an everted umbilicus are seen with ascites and/or tumors. • A scaphoid (sunken) abdomen is seen in malnutrition or when fat is replaced with muscle. • **Striae** (whitish-silver stretch marks) are seen in obesity and during or after pregnancy. • Spider angiomas may be seen in liver disease. • Dilated veins are prominent in cirrhosis of the liver, ascites, portal hypertension, or venocaval obstruction. • Pulsation is increased in aortic aneurysm.

BOX 21–2 Guidelines for Assessing the Abdomen

Ask the patient to empty the bladder before beginning the examination. Assist the patient to the dorsal recumbent (supine) position, with a small pillow under the head, a pillow under the knees (if desired), and the arms at the sides of the body. Warm the stethoscope before applying it to the patient's skin. Ask the patient to point to areas that are painful, and explain that those areas will be examined last. Expose the abdomen from below the breasts to the pubic symphysis, and drape the patient's thoracic and genital areas. When you document your findings, specify the location by abdominal quadrant.

General guidelines for abdominal assessment are as follows:

1. Inspect the abdomen under a good light source that is shining across the abdomen. Sit at the right side of the patient, and note symmetry, distention, masses, visible peristalsis, and respiratory movements. If masses are detected, ask the patient to take a deep breath, which decreases the size of the abdominal cavity and makes any abnormality more visible.
2. Auscultate each quadrant of the abdomen, using the diaphragm of the stethoscope. Listen for bowel sounds, arterial bruits, venous hums, and friction rubs.
3. Percuss several areas within each quadrant of the abdomen, using a systematic path. (For example, always begin in the lower left quadrant, then proceed to the lower right quadrant, upper right quadrant, and upper left quadrant, respectively). The predominant percussion tones for the entire abdomen are tympany and dullness. Tympany is present over gas-filled intestines. Dullness is present over the liver, the spleen, an enlarged kidney, or a full stomach. Percuss for fluid, gaseous distention, and masses.
4. Palpate each quadrant of the abdomen for shape, position, mobility, size, consistency, and tenderness of the major abdominal organs. Begin this part of the assessment with light palpation, and increase the depth of palpation to elicit tenderness or better identify organ size and shape. Only nurses with considerable experience should conduct deep palpation. Remember to palpate areas of indicated tenderness last and to use gentle pressure. Palpation may be difficult or impossible if the patient exhibits muscle guarding from pain or is ticklish. The gallbladder and the spleen are normally not palpable.

Abdominal Assessment (*continued*)

Technique/Normal Findings	Abnormal Findings
Auscultate all four quadrants of the abdomen with the diaphragm of the stethoscope (Figure 21–11 ■). Begin in the lower right quadrant, where bowel sounds are almost always present. If bowel sounds are not heard, ask a colleague to check your findings. *Normal bowel sounds (gurgling or clicking) occur every 5–15 seconds. Listen for at least 5 minutes in each of the four quadrants to confirm the absence of bowel sounds.*	• **Borborygmus** (hyperactive high-pitched, tinkling, rushing, or growling bowel sounds) is heard in diarrhea or at the onset of bowel obstruction. • Bowel sounds may be absent later in bowel obstruction, with an inflamed peritoneum, and/or following surgery of the abdomen.

Figure 21–11 ■ Auscultating the abdomen with the diaphragm of the stethoscope.

Auscultate the abdomen for vascular sounds with the bell of the stethoscope (Figure 21–12 ■). *No sounds (bruits, venous hum, or friction rub) other than bowel sounds should be auscultated.*	• **Bruits** (blowing sound due to restriction of blood flow through vessels) may be heard over constricted arteries. A bruit over the liver may be heard in hepatic carcinoma. • A venous hum (continuous medium-pitched sound) may be heard over a cirrhotic liver. • Friction rubs (rough grating sounds) may be heard over an inflamed liver or spleen.

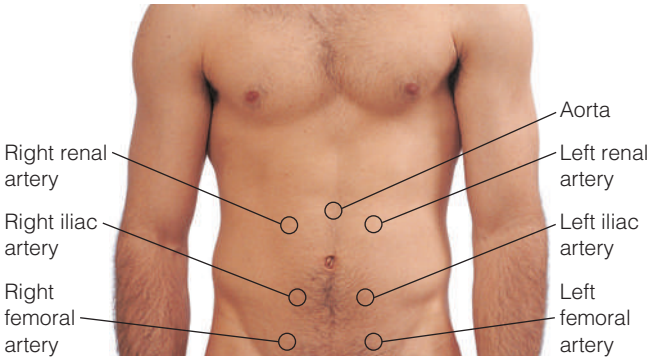

Figure 21–12 ■ Location of placement of the stethoscope for auscultation of arteries of the abdomen.

Percuss the abdomen in all four quadrants (Figure 21–13 ■). *Normally, tympany is heard over the stomach and gas-filled bowels.*	• Dullness is heard when the bowel is displaced with fluid or tumors or filled with a fecal mass.

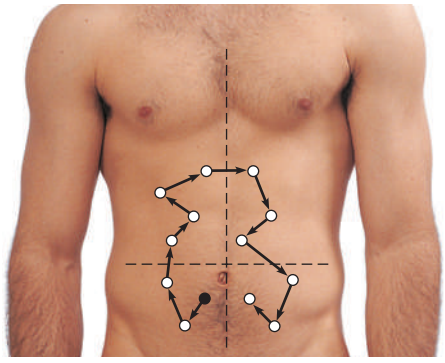

Figure 21–13 ■ Location of sites for systematic percussion of all four quadrants.

(*continued*)

Abdominal Assessment (*continued*)

Technique/Normal Findings	Abnormal Findings
Percuss the liver (see Box 21–3 for guidelines for liver percussion and palpation; see Figure 21–14 ■ for landmarks). *The lower border of liver dullness is located at the costal margin to 1–2 cm below.*	• In cirrhosis and/or hepatitis, the liver is greater than 6–10 cm in the MCL and greater than 4–8 cm in the midsternal line (MSL).

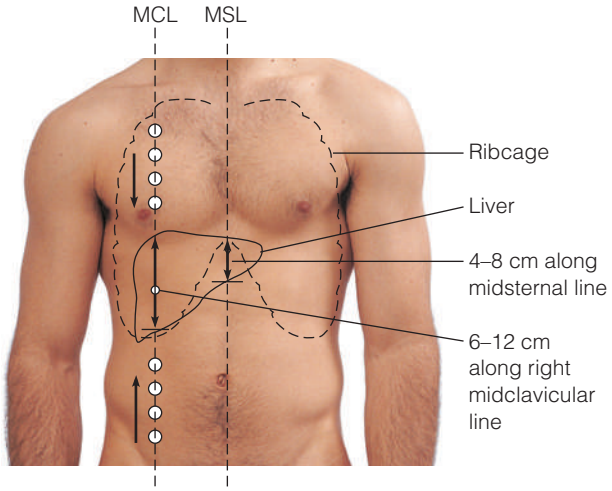

Figure 21–14 ■ Anatomic location of the liver, with the midclavicular line (MCL) and midsternal line (MSL) superimposed. The normal liver span is 6 to 12 cm.

BOX 21–3 Guidelines for Percussing and Palpating the Liver

The size of the liver may be determined by percussion and palpation, as follows:

1. Percuss, in the midclavicular line (MCL), beginning below the umbilicus (refer to Figure 21–14). Begin to percuss over a region of tympany, and move upward. The first dull percussion tone occurs at the lower border of the liver. Determine the upper liver border by beginning percussion over an area of lung resonance (in the MCL) and percussing downward to the first dull tone, usually at the 5th to 7th interspace. Mark each of these locations and measure the distance from one mark to the other to determine liver size. The normal liver size is 6 to 12 cm in the MCL; however, men have larger livers than women.
2. Conduct bimanual palpation of the liver by placing your left hand under the patient at the level of the 11th to 12th ribs and applying upward pressure. Place your right hand below the costal margin, ask the patient to take a deep breath, and palpate for the liver border. The liver is not normally palpable in a healthy adult, although it may be in very thin people.

Percuss the spleen for dullness posterior to the midaxillary line at the level of the 6th to 11th rib (Figure 21–15 ■). *The spleen is percussed as an oval area of dullness approximately 7 cm wide near the left 10th rib and slightly posterior to the midaxillary line.*	• A large area of dullness that extends to the left anterior axillary line on inspiration is associated with an enlarged spleen and may be related to trauma, infection, or mononucleosis.

Figure 21–15 ■ Percussing the spleen.

Abdominal Assessment (*continued*)

Technique/Normal Findings	Abnormal Findings
Percuss for shifting dullness (Figure 21–16 ■). *If ascites is not present, the borders between tympany and dullness remain relatively constant despite position changes.*	• In a patient with ascites, the level of dullness increases when the patient turns to the side.

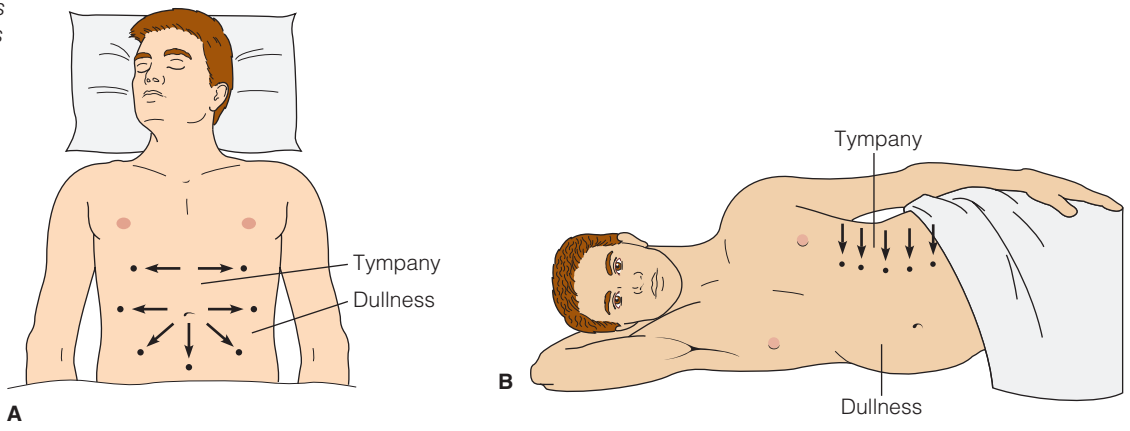

Figure 21–16 ■ Percussing for shifting dullness in ascites. A, Common percussion tones when the patient is lying supine; B, changes in percussion tones (shifting dullness) when the patient turns to the side.

Palpate the abdomen in all four quadrants (Figure 21–17 ■). If the patient tightens the abdominal muscles (called "guarding"), flexing the knees may relax the muscles. *There should be no abdominal masses or pain on palpation.*	• In cases of peritoneal inflammation, palpation causes abdominal pain and involuntary muscle spasms. • Abnormal masses include aortic aneurysms, neoplastic tumors of the colon or uterus, and a distended bladder or distended bowel due to obstruction. • A rigid, boardlike abdomen may be palpated when the patient has a perforated duodenal ulcer.

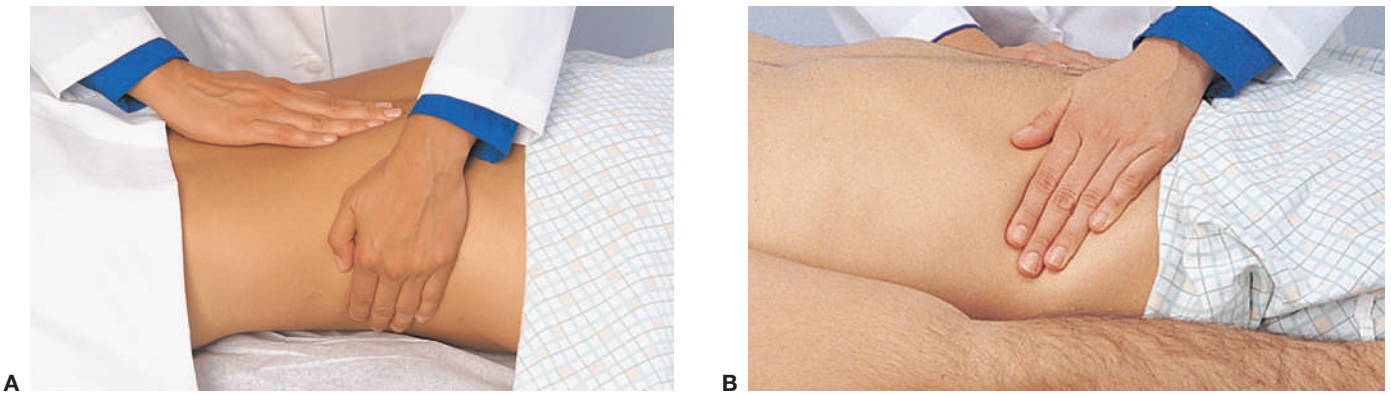

Figure 21–17 ■ Light to moderate palpation of the abdomen. A, In light palpation, the examiner, keeping the fingers approximated, gently depresses the abdominal wall about 1 cm to assess for large masses, slight tenderness, and muscle guarding. B, The examiner performs moderate palpation by using the palm or the side of the hand to depress the abdominal wall to a slightly greater depth than in light palpation. This technique is useful for assessing abdominal organs that move with respiration (such as the liver and the spleen).

Use a circular motion to move the abdominal wall over underlying structures. Feel for masses and note any tenderness or pain the patient may have during this part of the exam. Palpate lightly at first (0.5 to1.5 in.), then deeply (1.5 to 2 in.) with caution. If a mass is palpated, ask the patient to raise head and shoulders. A mass in the abdomen may become more prominent with this maneuver, as will a ventral abdominal wall hernia. If the mass is no longer palpable, it is deeper in the abdomen. *There should be no palpable masses or pain.*

SAFETY ALERT

A patient with abdominal pain may not tolerate any level of palpation. Never use deep palpation in a patient who has had a pulsatile abdominal mass, renal transplant, polycystic kidneys, or is at risk for hemorrhage.

(*continued*)

Abdominal Assessment (*continued*)

Technique/Normal Findings	Abnormal Findings
Palpate for rebound tenderness. Press the fingers into the abdomen slowly and release the pressure quickly. *Releasing pressure should not cause or increase pain.*	• In peritoneal inflammation, pain occurs when the fingers are withdrawn. • Right upper quadrant pain occurs with acute cholecystitis. • Upper middle abdominal pain occurs with acute pancreatitis. • Right lower quadrant pain occurs with acute appendicitis. • Left lower quadrant pain is seen in acute diverticulitis.
Palpate the liver. Box 21–3 provides guidelines for liver assessment (also see Figure 21–18 ■). Note whether the patient guards the abdomen or reports any sharp pain, especially on inspiration. *The abdomen should be nontender, and the liver is usually nonpalpable.*	• An enlarged liver with a smooth, tender edge may indicate hepatitis or venous congestion. • An enlarged, nontender liver may be felt in a malignant condition. • The patient with inflammation of the gallbladder feels sharp pain on inspiration and stops inspiring. This is called Murphy's sign.

Figure 21–18 ■ Palpating the liver with the bimanual method.

Inguinal Area Assessment	
Inspect the inguinal area for bulges after asking the patient to bear down. *The inguinal area is normally free of bulges.*	• Bulges that appear in the inguinal area when the patient bears down may indicate a **hernia** (a defect in the abdominal wall that allows abdominal contents to protrude outward).
Palpate the inguinal area with the gloved hand. Ask the patient to shift weight to the left to palpate the right inguinal area and vice versa. Place your right index finger upward into the inguinal area and ask the patient to bear down or cough. *Bulging or masses are normally not palpable.*	• A bulge or mass may indicate a hernia.

Perianal Assessment	
Inspect the perianal area. Wearing gloves, spread the patient's buttocks apart. Observe the area, and ask patient to bear down as if trying to have a bowel movement. *The perianal area should be intact, without obvious lesions.*	• Swollen, painful, longitudinal breaks in the anal area may appear in patients with anal fissures. (These are caused by the passing of large, hard stools or by diarrhea.) • Dilated anal veins appear with hemorrhoids. • A red mass may appear with prolapsed internal hemorrhoids. • Doughnut-shaped red tissue at the anal area may appear with a prolapsed rectum.
Palpate the anus and rectum.	
Lubricate the gloved index finger and ask the patient to bear down. Touch the tip of your finger to the patient's anal opening. Flex the index finger, and slowly insert it into the anus, pointing the finger toward the umbilicus (Figure 21–19 ■). Rotate the finger in both directions to palpate any lesions or masses. *There should be no masses in the anus or rectum.*	• Movable, soft masses may be polyps. • Hard, firm, irregular embedded masses may indicate carcinoma.

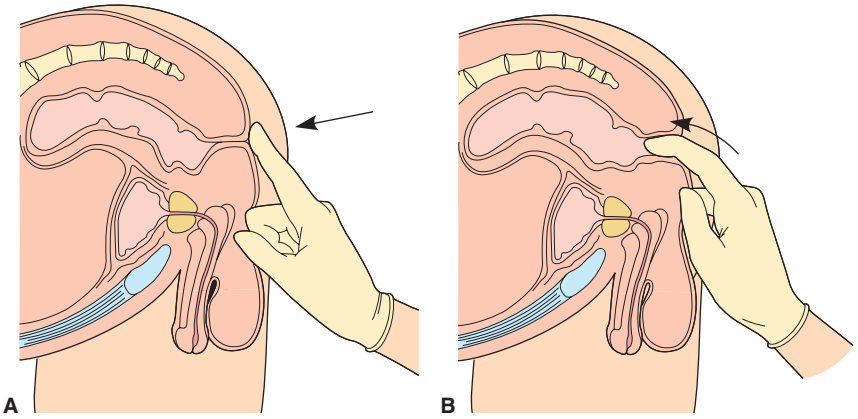

Figure 21–19 ■ Digital examination of the A, anus, and B, rectum.

Abdominal Assessment (*continued*)

Technique/Normal Findings	Abnormal Findings
Fecal Assessment	
Inspect the patient's feces. After palpating the rectum, withdraw your finger gently. Inspect any feces on the glove. Note color and/or presence of blood. Also use gloved fingers to note consistency. *Stool should be soft with no blood present.*	• See Box 21–4 for information about stool characteristics.
Test the feces for occult blood. Use a testing kit such as Occultest or Hemoccult II. *There should be no occult blood in the feces.*	• A positive occult blood test requires further testing for colon cancer or GI bleeding due to peptic ulcers, ulcerative colitis, or diverticulosis.
Note the odor of the feces. *No distinctly foul odors should be present.*	• Distinctly foul odors may be noted with stools containing blood or extra fat or in cases of colon cancer.

SAMPLE DOCUMENTATION

Abdominal Assessment

Seventy-two-year-old female, currently a resident in an extended care facility, states she has not had a bowel movement for a week, and normally has one every other day. She also says she has lost her appetite and "just feels terrible." Abdominal assessment reveals a firm, slightly distended abdomen. Bowel sounds are active with gurgles in all four quadrants. Slight dullness to percussion in LLQ (sigmoid colon). States she has some generalized abdominal discomfort with moderate palpation. Hard stool present in rectum. Stool negative for occult blood.

BOX 21–4 Assessing Stool Characteristics

Inspect feces for color, odor, and consistency after the rectal exam or after defecation. Both hands are gloved.

COLOR

- Blood *on* the stool results from bleeding from the sigmoid colon, anus, or rectum. Blood *within* the stool indicates bleeding from the colon due to ulcerative colitis, diverticulosis, or tumors. Black, tarry stools, called **melena**, occur with upper GI bleeding. Oral iron may turn stools black and mask melena.
- Grayish or whitish stools can result from biliary obstruction due to lack of bile in stool.
- Greasy, frothy, yellow stools, called **steatorrhea**, may appear with fat malabsorption.

ODOR

- Distinct, foul odors may be noted with stools containing blood or extra fat or in cases of colon cancer.

CONSISTENCY

- Hard stools or long, flat stools may result from a spastic colon or bowel obstruction due to a tumor or hemorrhoids. Hard stools may also result from ingestion of oral iron.
- Mucousy, slimy feces may indicate inflammation and occur in irritable bowel syndrome.
- Watery, diarrhea stools appear with malabsorption problems, irritable bowel syndrome, emotional or psychologic stress, ingestion of spoiled foods, or lactose intolerance.

CHAPTER HIGHLIGHTS

- **Overall health status is influenced by proper nutrition and a balanced diet.**
- **The etiology of many common illnesses is influenced by diet and nutrition, thereby making the nurse's role increasingly important in terms of conducting health assessments aimed at detecting early disease processes and teaching that promotes healthy dietary habits.**
- The gastrointestinal system including the mouth, pharynx, esophagus, stomach, small intestine, large intestine, and the accessory digestive organs; liver, gallbladder and pancreas plays a critical role in providing nutrition to all other systems thereby influencing homeostasis of the body.
- Manifestations of dysfunctions and disorders affecting the gastrointestinal system may be detected during a general health assessment as well as during focused assessment of the gastrointestinal system.
- As a member of the interprofessional health care team, the nursing role involves preparing the patient for diagnostic tests and monitoring results.

TEST YOURSELF NCLEX-RN® REVIEW

1. The nurse is preparing educational materials for a patient with a low serum albumin level. Which foods should the nurse instruct as being complete proteins? (Select all that apply.)
   1. milk
   2. eggs
   3. fruits
   4. butter
   5. vegetables
2. The nurse suspects a patient recovering from surgery is deficient in vitamin K. What did the nurse most likely assess in this patient? (Select all that apply.)
   1. bruising
   2. slow peristalsis
   3. poor wound healing
   4. surgical wound bleeding
   5. evidence of keloid formation
3. The nurse notes that a patient's serum amylase level is elevated. For which health problem should the nurse plan patient care?
   1. cheilosis
   2. gallstones
   3. gastric reflux
   4. acute pancreatitis
4. While assessing the oral cavity, the nurse notes that an older patient has obvious caries and difficulty swallowing. When asked about eating, the patient states frequent issues with a dry mouth. Which health problem is this patient at risk for developing?
   1. acute pain
   2. risk for infection
   3. nutritional deficit
   4. altered elimination
5. The nurse is conducting a physical examination of a patient with ascites. Which sound should the nurse expect to hear when percussing this patient's abdomen?
   1. flatness
   2. resonance
   3. shifting dullness
   4. alternating amplitude
6. A patient is upset to learn after a sigmoidoscopy that internal hemorrhoids were found. What should the nurse explain about this health problem?
   1. "They are part of the lymphatic system."
   2. "They are part of the arteries of the body."
   3. "They are swollen veins in the anal canal."
   4. "They are just bits of tissue that occur for no reason."
7. The nurse is completing an assessment for a patient with an ostomy. Which questions should the nurse include when conducting this assessment? (Select all that apply.)
   1. "Has your appetite changed lately?"
   2. "Do any particular foods cause flatus?"
   3. "What is the consistency of your stools?"
   4. "What does the skin around the stoma look like?"
   5. "Have you had any bleeding from your hemorrhoids?"
8. The healthcare provider suspects a patient is experiencing gastrointestinal effects from parasites. For which diagnostic test should the nurse prepare this patient to confirm the diagnosis?
   1. colonoscopy
   2. barium enema
   3. stool specimen
   4. CT of the abdomen
9. A patient learns that during a colonoscopy two polyps were removed. Why is the removal of these structures important?
   1. Helps to identify genetic disorders.
   2. Prevents the development of cancer.
   3. Facilitates further examination of the bowel.
   4. Decreases future problems with constipation.
10. While conducting a health history, the nurse asks a patient if any family members had or have colon cancer. Is this question important for the nurse to ask?
    1. Yes, but it should wait for further diagnostic testing.
    2. Yes, because colon cancer is a common inherited disorder.
    3. No, because colon cancer is rarely found in family members.
    4. No, because this question should only be asked by physicians.

See Test Yourself answers in Appendix B.

22 Nursing Care of Patients with Nutritional Disorders

LEARNING OUTCOMES

1. Describe the pathophysiology and clinical manifestations of common nutritional disorders.
2. Identify risk factors for nutritional disorders and nursing measures to reduce those risks.
3. Identify causes, effects, and complications of nutritional disorders on general patient health status.
4. Describe effective interprofessional care for patients with nutritional disorders.
5. Develop strategies to promote nutrition for patient populations.

CLINICAL COMPETENCIES

1. Assess and monitor the health status of patients with nutritional disorders, recognizing and reporting unexpected manifestations or responses to treatment.
2. Use technology and information management tools to provide preventive interventions and health teaching for patients and populations at risk for developing complications resulting from nutritional disorders.
3. Using assessment data, research, and current standards of practice, plan and implement evidence-based nursing care for patients with nutritional disorders.
4. Administer medications and enteral and parenteral nutrition knowledgeably and safely.
5. Collaborate and coordinate with the patient and other members of the interprofessional care team to prioritize and implement care.
6. Incorporate cultural values and customs and personal preferences into the plan of care for patients with nutritional disorders.
7. Use holistic data to plan and provide care and to evaluate care and responses to interventions focused on health teaching and health coaching.

MAJOR CHAPTER CONCEPTS

- Developmental, genetic, sociocultural, psychologic, and physiologic factors may play a role in nutritional disorders. Consequently, a holistic approach to nursing care is vital.
- Obesity and malnutrition, the major nutritional disorders in the world today, affect many systems and organs. Nutritional disorders are associated with serious comorbidity and life-threatening complications. They often cause serious health problems, such as hypertension, heart disease, fluid and electrolyte imbalances, disability, and death.
- Patients with nutritional disorders require complex, skilled nursing care within the context of an interprofessional team.
- The nursing role involves coordinated and interprofessional care emphasizing health screening and teaching.
- Effective treatment of nutritional disorders involves physical, social, cognitive, and behavioral nursing action over time and should include relapse prevention interventions.

THE PATIENT WITH OBESITY

Obesity, an excess of adipose tissue, is one of the most prevalent, preventable health problems in the United States. Obesity has serious physiologic and psychologic consequences, and is associated with increased morbidity and mortality. It contributes to poor health-related quality of life to a greater extent than smoking, excess alcohol use, or poverty. The prevalence of obesity in the United States is high, exceeding 30% in adult men and women. The obesity epidemic has prompted rapid growth in **bariatrics**, the healthcare science that focuses on patients who are extremely obese. Obesity is associated with comorbid conditions such as coronary heart disease, type 2 diabetes mellitus, and various types of cancer, gallstones, and disability. These comorbid health problems are associated with higher use of healthcare services and costs among patients with obesity. Obesity is also associated with an increased risk for death, particularly in adults younger than 65 years of age. Health-related problems associated with obesity are listed in Table 22–1.

Although obesity is often defined by weight, it is more accurately defined by the **body mass index (BMI)**, an indirect measure of the amount of body fat, or adipose tissue. Adipose tissue is created when energy consumption exceeds energy expenditure. A BMI of 25 to 29.9 kg/m^2 is classified as *overweight*; obesity is a BMI of 30 kg/m^2 or greater (Centers for Disease Control and Prevention [CDC], 2012). The terms *overweight* and *obese* are not mutually exclusive; a patient who is obese also is overweight.

TABLE 22–1 Health-Related Problems Associated with Obesity

Body System	Obesity-Related Problems
Cardiovascular	Atherosclerosis, hypercholesterolemia
	Coronary heart disease
	Heart failure
	Hypertension
	Stroke
	Varicosities
	Venous thrombosis
Respiratory	Asthma
	Sleep apnea

	Hiatal hernia
	Colon cancer
Genitourinary	Prostate cancer
	Stress incontinence
Musculoskeletal	Low back pain
	Muscle strains and sprains
	Osteoarthritis
Endocrine and reproductive	Diabetes mellitus, type 2
	Breast and endometrial cancers
	Polycystic ovarian syndrome
	Complications of pregnancy
Other	Depression
	Metabolic syndrome
	Postoperative complications

FAST FACTS

Prevalence of overweight and obesity in the United States:

- Women
  - Black: 78.2%
  - Hispanic: 76.1%
  - White: 61.2%
- Men
  - Black: 68.5%
  - Hispanic: 79.3%
  - White: 72.6%

Incidence and Prevalence

More than 30% of the adult population in the United States is obese; two-thirds of all adults in the United States are overweight. Approximately 1 in 20 Americans has a BMI greater than 40 kg/m^2 (Moyer, 2012). The prevalence of obesity is higher in women and in economically disadvantaged people of all races. While the prevalence of overweight has been increasing since 1960, the prevalence of obesity is increasing to a greater extent, particularly during the past 10 to 15 years (Moyer, 2012). Of particular concern is the increasing incidence of obesity in children and young adults. The prevalence of overweight and obesity varies among ethnic and cultural groups. Adults of Asian heritage generally have a lower incidence of overweight and obesity. See the accompanying Focus on Cultural Diversity box.

Risk Factors

Many factors contribute to obesity, including genetic, physiologic, psychologic, environmental, and sociocultural factors. Recent genetic research provides emerging understanding into the genesis of obesity; however, environmental influence remains the primary contributor to this worldwide health problem (Grossman & Porth, 2014). There is a strong correlation between the weight of adopted children and their biologic parents, in addition identical twins tend to have similar BMIs, whether raised together or apart. Although several genes that contribute to appetite and fat deposition have been identified, obesity as a purely genetic condition is rare (Longo et al., 2013).

Physical inactivity is a significant factor contributing to obesity. Inactive people may consume fewer calories than active people and continue to gain weight due to lack of energy expenditure. Cultural and environmental factors such as reliance on the automobile for transportation and increased time spent using the computer contribute to decreased energy expenditure among adults in the United States. Increased time spent watching television is seen as a major contributing factor to the increased incidence of obesity among children and adolescents (Longo et al., 2013).

Recent epidemiologic studies indicate the most significant factor contributing to the obesity epidemic is the increased access to

FOCUS ON CULTURAL DIVERSITY

Obesity

Increased rates of obesity are being seen in African American and Hispanic groups, particularly in women (Flegal et al., 2012). Research suggests differences in perception of body image and weight-related concerns play a role and many theories have been considered. It is not yet clear how cultural food choices and accepted cultural behaviors impact these rates (Grossman & Porth, 2014). A sedentary lifestyle also contributes to the rate of obesity.

inexpensive and appealing obesogenic types of foods (Grossman & Porth, 2014). Environmental influences, such as an abundant and readily accessible food supply, fast-food restaurants, advertising, and vending machines, contribute to increased food intake. Sociocultural influences that contribute to obesity include increased consumption of restaurant meals, overeating at family meals, rewarding behavior with food, religious and family gatherings that promote food intake, and sedentary lifestyles. Socioeconomic status tends to correlate with the risk for overweight and obesity: In the United States, women with low incomes are more likely to be obese than those of higher socioeconomic status (Ogden et al, 2010). The association between socioeconomic status and obesity is less clear in men.

Psychologic factors, such as low self-esteem, also play a role in obesity. Low self-esteem may precipitate unhealthy eating behaviors, and the resulting weight gain in turn may diminish self-image even further. A person may overeat as a result of anxiety, depression, guilt, or boredom, or as a means of getting attention. Some experts characterize overeating as a food addiction and as a coping mechanism for stressful life events.

Overview of Normal Physiology

All body activities require energy, including activities of daily living, as well as those necessary to maintain cell and tissue function. **Nutrients** in food (or enteral or parenteral feedings) provide this energy and are the building blocks for growth and tissue repair. The body stores excess nutrients and energy (measured as kilocalories) to meet the body's needs when required nutrients are unavailable. This ability to store and release energy is important to maintaining body function. A significant portion of daily energy expenditure is fixed: More than 70% of the energy expended each day goes to maintaining the **basal metabolic rate (BMR)**, essentially the "cost" (in kilocalories) of being alive. Physical activity accounts for only 5% to 10% of the energy spent daily (Longo et al., 2013).

Energy is primarily stored as fat in adipose tissue. Although mature fat cells (adipocytes) do not multiply, the immature cells in adipose tissue can multiply, particularly when exposed to estrogen during puberty, in late adolescence, during breast-feeding, and in middle-aged adults who are overweight. Fat cells store excess energy as **triglycerides**, formed from dietary fats and carbohydrates. The body breaks down the triglycerides in fat cells when needed to provide energy (Grossman & Porth, 2014).

Pathophysiology

Obesity occurs when excess calories are stored as fat. It can result from excess energy intake, decreased energy expenditure, or a combination of both. The etiology of obesity is not as simple as excess kilocalorie intake in relation to energy expenditure.

Energy intake and energy expenditure are regulated by a complex interaction of endocrine and neural signals. In the absence of external influences, these regulatory mechanisms increase appetite and reduce energy expenditure when weight loss occurs, and suppress appetite and increase energy expenditure after overfeeding. In a society where food is abundant and physical activity is limited, the latter is less effective.

Appetite, which affects food intake, is regulated by the central nervous system (CNS) and by emotional factors. The hunger center in the hypothalamus stimulates appetite in response to stimuli such as hypoglycemia and peptides produced in the gut. As nutrient levels rise, the satiety center (also in the hypothalamus) sends a message to stop eating. Gastrointestinal filling and hormonal factors also signal *satiety* (a sensation of fullness). Appetite may have little relationship to hunger or physical signals, however; some people eat to relieve depression or anxiety.

Several hormones are involved in regulating obesity, including thyroid hormone, insulin, and leptin (a peptide produced by fatty tissue that suppresses appetite and increases energy expenditure). Some studies suggest that leptin resistance is a cause of obesity. Insulin is associated with body fat distribution. The two major types of body fat distribution are upper body and lower body obesity.

Upper body obesity (*central obesity*) is identified by a waist-to-hip ratio of greater than 1 in men or 0.8 in women. People with upper body obesity tend to have more intra-abdominal fat and higher levels of circulating free fatty acids (Grossman & Porth, 2014). As a result, upper body obesity is associated with a greater risk of complications such as hypertension, abnormal blood lipid levels, heart disease, stroke, and elevated insulin levels. Men tend to have more intra-abdominal fat than women, although women develop a central fat distribution pattern after menopause.

Lower body obesity (*peripheral obesity*), in which the waist-to-hip ratio is less than 0.8, is more commonly seen in women. The risk for hyperinsulinemia, abnormal lipids, and heart disease is lower in people with lower body obesity than in those with upper body obesity. Lower body obesity, however, may be more difficult to treat.

Sarcopenic obesity is associated with age-related loss of muscle mass and is described as the process of muscle loss combined with increased body fat (Benton, Whyte, & Dyal, 2011). Sarcopenic obesity leads to loss of strength and function, reduced quality of life, and early death. Limited physical activity, disuse syndrome, decreased resting metabolic rate, and changes in dietary requirements are all variables that contribute to the increase in sarcopenic obesity in older adults.

Complications of Obesity

Obesity is a major health risk factor, increasing the risk of mortality from all causes over that of normal-weight people. As obesity increases, so does the risk of dying.

CARDIOVASCULAR DISEASE

Many obese individuals have **metabolic syndrome**, a constellation of cardiovascular risk factors, including increased waist circumference, hypertension, elevated blood triglycerides and fasting blood glucose, and low HDL cholesterol. Metabolic syndrome is an identified risk factor for atherosclerosis and coronary heart disease (CHD).

Obesity is a significant risk factor for cardiovascular disease, including hypertension, CHD, and heart failure. The prevalence of hypertension in obese men and women is approximately twice that in people with a BMI of less than 25 (CDC, 2012). Several factors contribute to hypertension in individuals with obesity, including sodium retention with associated increased vascular resistance, blood volume, and cardiac output. The increases in blood pressure seen with obesity increase the risk for CHD and stroke.

Patients who are obese, particularly those who have abdominal obesity, often have a lipid profile that promotes atherosclerosis. Levels of low-density lipoprotein (LDL) and very low density lipoprotein (VLDL) cholesterol and triglycerides are increased, and levels of

high-density lipoprotein (HDL or desirable) cholesterol are reduced. Furthermore, adipose tissue secretes cytokines that stimulate the liver to produce C-reactive protein (CRP), now recognized as a risk factor for CHD.

Obesity increases the risk for heart failure. Left ventricular muscle mass increases, and the ventricle dilates in individuals with obesity, possibly related to increased blood volume and cardiac output.

RESPIRATORY DISORDERS

Overweight and obesity increase the risk for developing asthma and COPD in adults. The relationship between obesity and asthma is not clear, but may be related to genetic factors and the connection between obesity and inflammation. Obesity is the major risk factor for obstructive sleep apnea, intermittent airflow obstruction due to upper airway collapse during sleep. Not only is obesity a risk factor for sleep apnea, the reverse also may be true: It may predispose patients for weight gain (Dunham, 2013; Lawson & Pruitt, 2011).

DIABETES MELLITUS

Obesity increases the risk of insulin resistance and type 2 diabetes. While not all people who are obese develop diabetes, up to 80% of people with type 2 diabetes are obese. Both weight gain in adulthood and abdominal (central) obesity are positively correlated with the risk for developing type 2 diabetes (Longo et al., 2013).

OTHER DISORDERS

Obesity affects reproductive function in both men and women. Androgen (male sex hormone) levels are reduced in men with obesity; menstrual irregularities and polycystic ovarian syndrome (PCOS) are more common in women with obesity. PCOS is an additional risk factor for hyperinsulinemia and insulin resistance. Increased weight increases the risk for developing gallstones in both men and women. The risk for developing several types of cancer increases in obesity; these include colon, breast, and endometrial. Increased weight places abnormal stress on joints, increasing the prevalence of joint pain and osteoarthritis, particularly in weight-bearing joints (especially the knee joints). Refer to Table 22–1 for other health-related problems associated with obesity.

●○● INTERPROFESSIONAL CARE

The U.S. Preventative Services Task Force (USPSTF) recommends screening all adults for obesity and advocates for multicomponent behavioral interventions for adults with obesity (Moyer, 2012). Obesity treatment is far more complex than just reducing food consumption. Most experts recommend an individualized program of exercise, diet, and behavior modification designed to meet the patient's specific needs.

DIAGNOSIS

Although body weight may be used to identify obesity, measures of body fat are more accurate. Males at ideal body weight have 10% to 20% body fat, whereas females at ideal body weight have 20% to 30% body fat.

- *Body mass index* is used to identify excess adipose tissue. BMI is calculated by dividing the weight (in kilograms) by the height in meters squared (m^2). BMI calculations may not as accurately reflect the extent of adipose tissue in people who are highly muscular (e.g., body builders) or in those who have lost muscle mass (e.g., older adults). Box 22–1 classifies overweight and obesity by BMI.
- *Anthropometry* includes measurements of height, weight, bone size, and skinfold to estimate subcutaneous fat. See Chapter 21 for more information about anthropometric measurements.
- *Underwater weighing (hydrodensitometry)* is considered the most accurate way to determine body fat. This technique involves submerging the whole body and then measuring the amount of displaced water.
- *Bioelectrical impedance* uses a low-energy electrical impulse to determine the percentage of body fat by measuring the electrical resistance of the body.
- *Waist circumference* is measured to determine body fat distribution. Men with a waist measurement of 102 cm (40 in.) or greater, and women with a waist measurement of 88 cm (35 in.) or greater, have a higher risk for complications of obesity.

BOX 22–1 Classification of Overweight and Obesity by Body Mass

Classification	Obesity Class	BMI	Risk of Disease
Underweight		< 18.5	
Normal		18.5–24.9	
Overweight		25–29.9	Increased
Obesity	I	30–34.9	High
Obesity	II	35–39.9	Very high
Obesity	III	≥ 40	Extremely high

Other diagnostic tests may be done to help identify a physiologic cause of obesity, as well as complications of obesity:

- A *thyroid profile* is done to rule out thyroid disease.
- *Serum glucose* is measured to identify coexisting diabetes mellitus.
- *Serum cholesterol* is measured to assess for elevated levels.
- A *lipid profile* is ordered. HDL levels may be reduced in patients with obesity, whereas LDL levels are elevated.
- An *electrocardiogram (ECG)* is performed to detect effects of obesity on the heart, such as rate or rhythm disruptions, myocardial infarction, or heart enlargement.

MEDICATIONS

The USPSTF suggests consideration of weight loss medications when the patient's BMI is 30 kg/m^2 or greater than 27 kg/m^2 with a comorbid condition. Drug therapy is not recommended for cosmetic weight loss. When used in combination with behavioral intervention that includes diet and exercise, drugs can help promote weight loss. The 2012 USPSTF clinical guideline (Moyer, 2012) emphasize research indicates the best outcomes are achieved when medication is combined with comprehensive treatment. Treatment includes 12 to 26 sessions a year in which progress is monitored and behavior modification is taught to develop health dietary habits and regular exercise.

Orlistat (Xenical) is a lipase inhibitor, reducing fat absorption from the GI tract and leading to weight loss. It reduces blood glucose and total and LDL cholesterol levels, and lowers blood pressure. The

MEDICATION ADMINISTRATION

Drugs to Treat Obesity

APPETITE SUPPRESSANTS

phentermine (Adipex-P, Fastin, Ionamin, Obestin-30, Oby-Trim, others)

phentermine and topiramate extended release (Qsymia)

lorcaserin (Belviq)

Phentermine acts directly on the appetite-control center in the CNS to suppress the appetite and reduce hunger. Topiramate increases feelings of fullness and increases calorie burning.

Lorcaserin (Belviq) activates the serotonin 5-HT 2c receptor in the brain, which causes a person to feel full after eating smaller amounts of food.

These drugs may be used to treat obesity in patients with a BMI > 30 kg/m^2 and patients with a BMI > 27 kg/m^2 who have risk factors such as diabetes or hypertension.

Nursing Responsibilities

- Assess for contraindications, such as pregnancy or lactation, use of other appetite suppressants, impaired liver or kidney function, history of CHD, or alcohol abuse.
- Regularly monitor blood pressure and heart rate during treatment. Increases may indicate need to reduce dose or discontinue treatment.

Health Education for the Patient and Family

- Take as directed; do not exceed recommended dose. Do not take if you may be pregnant or are nursing.
- Take your last dose no later than 4 p.m. to avoid insomnia.
- You may experience difficulty sleeping, nervousness, or palpitations while taking this drug.
- Increase your fluid intake to reduce possible side effects of dry mouth and constipation.
- This drug does not replace diet and exercise for weight loss; continue to follow your prescribed regimen.

LIPASE INHIBITOR

orlistat (Alli, Xenical)

Orlistat inhibits lipases necessary for the breakdown and absorption of fat, thus decreasing the absorption of dietary fat. Its action is primarily local, within the GI tract, with few systemic effects.

Nursing Responsibilities

- Administer with meals or up to 1 hour following a meal.
- Provide a fat-soluble vitamin supplement (A, D, E, and K) daily. Separate administration time from orlistat by at least 2 hours.

Health Education for the Patient and Family

- Take as directed; do not increase dose. You may skip a dose if you do not consume a meal.
- Use in conjunction with a low-calorie, low-fat diet.
- Common gastrointestinal side effects include oily or fatty stools, flatulence, oily discharge, or frequent stools with difficulty controlling defecation. These side effects may diminish with time or increase if a meal high in fat is consumed.
- Notify your healthcare provider if you become pregnant while taking this medication.

adverse effects of orlistat relate to its inhibition of fat absorption: oily stools, flatulence, and fecal urgency. These effects tend to diminish when dietary fat intake is limited.

Lorcaserin (Belviq) activates the serotonin 5-HT 2c receptor in the brain, causing an individual to feel full after eating smaller amounts and therefore eating less. Coadministration with other drugs that increase serotonin levels can lead to serotonin syndrome or even neuroleptic malignant syndrome. Consequently, lorcaserin should be avoided or used with extreme caution for patients taking selective serotonin reuptake inhibitors (SSRIs), serotonin-norepinephrine reuptake inhibitors (SNRIs), monoamine oxidase inhibitors (MAOIs), triptans, bupropion, dextromethorphan, or St. John's wort.

Qsymia is a combination of phentermine, a sympathomimetic amine anorectic, and topiramate extended release, an antiepileptic drug. This medication suppresses appetite and increases feelings of fullness, making food taste less appealing. It also increases calorie burning (Cameron et al., 2012).

Other drugs used as appetite suppressants include amphetamines and nonamphetamines, and antidepressants such as bupropion (Wellbutrin, Zyban) and fluoxetine (Prozac). None of these drugs are approved for long-term use as appetite suppressants. Amphetamines carry a high abuse potential and are not approved for treating obesity. Nonamphetamines such as diethylpropion (Tenuate) and phentermine (Adipex-P) may be used, but these increase pulse rate and blood pressure.

TREATMENTS

Successful treatment of obesity (sustained achievement of normal body weight without adverse consequences) is rarely achieved. Research indicates most patients set unrealistic goals related to their ideal weight. The nurse should assist the patient to create attainable goals that incorporate achievement of improved health outcomes. Studies indicate reducing body weight by 5% to 10% will result in positive health outcomes such as decreased blood pressure and improved glucose tolerance and cholesterol levels (Brown & Wimpenny, 2011). Treatment focuses on reducing the health risks associated with obesity by changing both eating and exercise habits. A pound of body fat is equivalent to 3500 kcal. To lose 1 pound a person must reduce daily caloric intake by 500 kcal for 7 days or increase activity enough to burn the equivalent kilocalories. A weight loss goal of 1 to 2 pounds per week and a 10% reduction in body weight in 6 months of therapy is recommended (Moyer, 2012). The USPSTF recommends screening all adults for obesity and patients with a BMI of 30 kg/m^2 should be referred to intensive multicomponent behavioral interventions. A combination of physical activity, dietary therapy, behavior modification, pharmacology, and, in some cases, surgery is required to achieve and maintain weight loss. See Table 22–2 for treatment recommendations.

SAFETY ALERT

Lorcaserin should not be used with other medications that increase serotonin levels.

EXERCISE Exercise is a critical element in weight loss and maintenance. Physical activity increases energy consumption and promotes weight loss while preserving lean body mass. Physical activity improves physical fitness, decreases appetite, promotes self-esteem, and increases the basal metabolic rate. The CDC

TABLE 22–2 Treatment Recommendations for Overweight and Obesity

	BMI				
Treatment	**25–26.9**	**27–29.9**	**30–34.9**	**35–39.9**	**≥40**
Diet, exercise, and behavior modification	With two or more comorbidities[1]	With two or more comorbidities[1]	Yes	Yes	Yes
Pharmacotherapy[2]		With two or more comorbidities[1]	Yes	Yes	Yes
Surgery			With two or more comorbidities[1]		

[1]*For example, hypertension, hyperlipidemia, diabetes, and other obesity-related complications.*
[2]*Considered when 6 months of combined therapy has not produced a loss of 1 pound per week.*

Source: Adapted from National Institutes of Health; National Heart, Lung, and Blood Institute; North American Association for the Study of Obesity. (2000). *The practical guide: Identification, evaluation, and treatment of overweight and obesity in adults.* Bethesda, MD: National Institutes of Health.

recommends that all adults engage in both aerobic and muscle-strengthening activities each week. Table 22–3 outlines CDC activity recommendations and gives example activities to achieve goals. Activities should be spread throughout the week, and may be spread over the course of the day; however, it is important to expend moderate or vigorous effort for at least 10 minutes at a time when exercising (CDC, 2011).

Because fitness levels differ, patients may be taught to use their target heart rate or perceived exertion to measure the vigor of activities. The *target heart rate* is calculated based on maximum heart rate; in turn, maximum heart rate is estimated using the formula 220 minus age in years. For example, while the maximum heart rate for a 35-year-old is 185 beats per minute (bpm), it would be 155 bpm for someone who is 65 years old. While the target heart rate for the 35-year-old engaging in vigorous, intense activity would be 130 to 157 bpm, it would be 108 to 132 bpm for the older adult. Perceived exertion is a subjective rating of activity intensity, using self-evaluation of factors such as heart and respiratory rate, sweating, and muscle fatigue (CDC, 2011).

NUTRITION The diet is planned to create a daily 500- to 1000-kcal deficit. Ideally, the diet should be low in kilocalories and fat and contain adequate nutrients, minerals, and fiber. The patient should eat regular meals with small servings. A gradual, slow weight loss of no more than 1 to 2 pounds per week is recommended. This means a diet of 1000 to 1200 kcal/day for most women, and 1200 to 1600 kcal/day for most men. Fewer than 1200 kcal each day may lead to loss of lean tissue and nutritional deficiencies. The recommended diet generally is low in fat and high in dietary fiber (Table 22–4). Research shows equivalent weight loss among different diets (e.g., low-fat,

TABLE 22–3 CDC Physical Activity Recommendations for Adults

Activity	Recommendation	Examples
Aerobic activity:	Engage in moderate- or vigorous-intensity activity for at least the recommended amount of time weekly, or in an equivalent combination of moderate- and vigorous-intensity activity.	
• Moderate-intensity aerobic activity (target heart rate of 50% to 70% of maximum heart rate)	2 hours and 30 minutes (150 minutes) every week	• Walking fast • Water aerobics • Bicycle riding on level ground • Doubles tennis • Ballroom dancing • Pushing a lawn mower • General gardening
• Vigorous-intensity aerobic activity (target heart rate of 70% to 85% of maximum heart rate)	1 hour and 15 minutes (75 minutes) every week	• Race walking, jogging, running • Swimming laps • Singles tennis • Aerobic dancing • Bicycling 10 mph or faster • Heavy gardening (continuous hoeing or digging) • Hiking uphill
Muscle-strengthening activities	2 or more days per week: at least one set of 8 to 12 repetitions for all major muscle groups	• Lifting weights • Using resistance bands • Exercises that use body weight for resistance (push-ups, sit-ups) • Heavy gardening • Yoga

Source: Centers for Disease Control and Prevention (CDC). (2008). *Physical activity for everyone.* Atlanta, GA: Author.

TABLE 22–4 Recommended Nutrient Intake for Weight Loss

Nutrient	Recommended Intake
Calories	1000–1600 per day or approximately 500–1000 less than usual daily intake
Total fat	30% or less of total calories
Saturated fats	10% or less of total calories
Cholesterol	300 mg/day
Protein (from plant and lean animal sources)	Approximately 15% of total calories
Carbohydrate (complex carbohydrates from vegetables, fruits, and whole grains)	55% or more of total calories
Fiber (e.g., oat bran, legumes, barley, most fruits and vegetables)	20–30 g/day
Sodium chloride	< 2.4 g sodium or 6 g sodium chloride/day
Calcium	1000–1500 mg/day

(2000). *The practical guide: Identification, evaluation, and treatment of overweight and obesity in adults.* Bethesda, MD: National Institutes of Health.

BOX 22–2 Behavioral Change Strategies for the Patient with Obesity

CONTROLLING THE ENVIRONMENT
- Purchase low-calorie foods.
- Shop from a prepared list and on a full stomach.
- Keep all foods in the kitchen.
- Store all foods in the refrigerator or in the cabinets in opaque containers.
- Prepare exact portions of food to eliminate leftovers.
- Eat all foods in the same place.
- Avoid eating when watching television or reading.
- Develop behavioral strategies to maintain diet when eating out at restaurants, parties, and picnics.

CONTROLLING PHYSIOLOGIC RESPONSES TO FOOD
- Eat slowly by taking small bites, allowing 20 minutes for a meal.
- Eat a salad or drink a hot beverage before a meal.
- Chew each bite thoroughly and slowly.
- Put eating utensils or food down between bites.
- Concentrate on the eating process, savor the food.
- Stop eating with the first feelings of fullness.

CONTROLLING PSYCHOLOGIC RESPONSES TO FOOD
- Appreciate the aesthetic experience of eating.
- Use attractive dinnerware, and prepare a formal setting for eating.
- Use small plates and cups to make servings of food look larger.
- Concentrate on conversations and socialization during the meal.
- Use nonfood rewards for meeting a goal.
- Acknowledge small successes and improvements in all behavior.
- Substitute other activities for eating (e.g., reading, exercise, hobbies).

low-carbohydrate, or high-protein diets); adherence to the diet and participation in group sessions were shown to be the significant factors (Sacks et al., 2009). Excessive calorie restrictions can lead to failure to follow the prescribed diet, feelings of guilt, and overeating. Repeated cycles of weight loss and gain (sometimes called *yo-yo dieting*) may lead to a metabolic deficiency that makes subsequent weight loss efforts increasingly difficult.

Very low calorie diets (VLCD) are generally reserved for patients who have a BMI greater than 30 (Grossman & Porth, 2014). This type of program offers a protein-sparing modified fast (450 kcal/day) under close medical supervision (Grossman & Porth, 2014). VLCDs typically use commercially prepared formulas (liquid shakes or bars) to replace all food intake for several weeks or months, resulting in rapid weight loss while maintaining lean body mass. Exercise, nutrition, and behavior modification counseling should accompany the diet. Benefits include decreased blood pressure, blood glucose, and cholesterol and triglyceride levels, along with improved exercise tolerance. VLCD may not be appropriate for use in people over age 50 due to normal loss of lean body mass and adverse effects such as fatigue, constipation, nausea, diarrhea, and gallstone formation. In the long term, weight gain is common, and VLCD may be no more effective for weight loss than a diet that includes 800 to 1000 daily kcal (Grossman & Porth, 2014).

BEHAVIOR MODIFICATION Behavior modification is a critical component of successful weight management. Strategies such as keeping food records, eliminating cues that precipitate eating, and changing the act of eating are often helpful.

Recording food intake, amount, location of eating, and situations that induce eating often help the patient gain self-control. Researchers have found that most people who are overweight are stimulated to eat by external cues, such as the proximity to food and the time of day. In contrast, hunger and satiety are the cues that regulate eating in adults of normal weight. Strategies to control food cues include keeping food out of view, eliminating snack foods, and eating only in designated areas. See Box 22–2 for a list of behavior modification strategies.

Other strategies focus on helping patients examine factors such as lifestyle, personality, and environment that affect eating behaviors. The goal is to empower the individual who is overweight to choose activities that are not related to food.

Social support and group programs such as Weight Watchers, Overeaters Anonymous, and Take Off Pounds Sensibly (TOPS) promote weight loss success through peer support. Most organized programs require participants to pay a fee, which may improve compliance.

SURGERY Surgical treatment of obesity (*bariatric surgery*) generally is limited to patients who are extremely obese (BMI of over 40 kg/m^2) who have had previous unsuccessful attempts at weight loss or those with a BMI greater than 35 who have serious obesity-related problems such as type 2 diabetes, CHD, or severe sleep apnea (Gagnon & Sheff, 2012). In addition, patients must be able to tolerate surgery and be free of addiction to alcohol or other drugs. The benefits of surgery include major weight loss and improved blood pressure, plus a reduced risk of diabetes, sleep apnea, angina, heart failure, blood lipid levels, and venous disease. Bariatric surgery,

however, is not without risk, and the decision to undergo surgery is a significant one.

The three major categories of bariatric surgery are classified as restrictive, malabsorptive, or a combination of both (Dunham, 2013). Restrictive procedures include vertical gastroplasty and adjustable gastric banding (AGB). Malabsorptive procedures with a restrictive component include Roux-en-Y gastric bypass, vertical sleeve gastrectomy, and biliopancreatic diversion with duodenal switch. Surgeons sometimes use a combination of both restrictive and malabsorptive procedures and, in general, more weight loss is achieved with more complex procedures.

The most common bariatric surgical procedures are AGB, gastric bypass, gastric sleeve, and biliopancreatic bypass with duodenal switch. These procedures restrict stomach capacity, limiting food intake, and, in most cases, bypass a portion of the small intestine to restrict absorption of calories and nutrients. In many cases, they can be performed laparoscopically.

The Roux-en-Y gastric bypass (RYGB, Figure 22–1A ■), often called gastric bypass, a small stomach pouch is created to restrict food intake. A Y-shaped section of the jejunum is then attached to the pouch to allow food to bypass the lower stomach and duodenum. As a result, calorie and nutrient absorption is limited. The vertical sleeve gastrectomy (VSG, Figure 22–1B) was used as the first step in the biliopancreatic diversion with duodenal switch surgery (BPD-DS) but is often used as a stand-alone procedure for high-risk patients with severe obesity. The surgery involves removal of a large portion of the stomach, leaving only a gastric sleeve. The procedure restricts intake and slows digestion. The BPD-DS (Figure 22–1C) is a more complex procedure and carries a higher risk of nutritional deficiencies and is usually performed for patients with severe obesity. This surgery, which is irreversible, may be performed in two stages, with the majority of the stomach removed and a gastric sleeve created during the first stage. Additionally, the duodenum and jejunum are bypassed by connecting the ileum directly to the stomach pouch or just distal to the pyloric valve. The surgery both restricts intake and slows digestion and absorption. BPD-DS has been shown to result in substantial weight loss and significantly reduce the comorbidities associated with severe obesity (Dunham, 2013).

These surgeries that restrict nutrient intake and absorption produce rapid weight loss that is maintained over time. Many patients maintain a significant weight loss for 10 years or more, with improvement in obesity-associated health problems such as type 2 diabetes, hypertension, and sleep apnea. Because these procedures allow food to bypass the duodenum and jejunum, nutrient deficiencies are common, particularly of iron, calcium, vitamin B_{12}, and, possibly, the fat-soluble vitamins.

Restrictive procedures, such as adjustable gastric banding (AGB, Figure 22–1D), are safer and reversible, but generally less effective in the long term. In AGB, a hollow band of silicone rubber is placed around the upper (proximal) portion of the stomach. The band is inflated with saline solution to create a small stomach pouch with a narrow passage through to the rest of the stomach. The amount of band inflation can be adjusted using a port implanted under the skin. Few nutritional deficiencies are associated with restrictive bariatric procedures. Vomiting is a common postoperative risk with restrictive procedures. The band may slip or break, necessitating a return to surgery. Although patients typically lose about 50% of their excess body weight within the first year after these procedures, fewer maintain that weight loss over a 10-year period than those undergoing gastric bypass. The AGB is the safest of the available procedures and the FDA has approved the use of adjustable gastric bands for adults ages 18 and older with obesity. Vertical banded gastroplasty (VBG, Figure 22–1E) is a restrictive procedure sometimes referred to as *stomach stapling.* The surgeon cuts a small hole into the stomach a few inches below the esophagus and creates a small pouch by placing a line of staples to section off a small portion of the upper stomach. The pouch is anchored distally by a prosthetic band. The band slows digestion and the small stomach capacity gives the patient of feeling of early satiety. Although the risk for postoperative complications is high, the mortality rate for bariatric procedures is low (less than 1% for restrictive surgeries and up to 5% for combination procedures). Possible postoperative complications include anastomosis leak with peritonitis, abdominal wall hernia, gallstones, wound infections, deep venous thrombosis and pulmonary embolism, nutritional deficiencies, and gastrointestinal symptoms. Dumping syndrome, a common complication, which can be precipitated by a meal high in simple carbohydrates, may develop following gastric bypass surgeries. In dumping syndrome, stomach contents move rapidly through the small intestine, drawing fluid into the intestine by osmosis. Symptoms can arise 15 minutes to 2 hours after eating and generally last about 30 minutes. The patient experiences nausea, bloating, abdominal pain, diarrhea, weakness, sweating, tachycardia, and possibly syncope. Patients should be instructed to avoid foods high in simple carbohydrates. Meals should be small and liquids and solids should not be taken together. Patients who undergo laparoscopic RYGB and patients with preexisting hyperlipidemia or gastroesophageal reflux disease are at high risk for dumping syndrome.

Nursing care for the patient who has undergone bariatric surgery is substantially the same as for a patient who has undergone a gastric resection. See Chapter 23 for more information about gastric resection and associated nursing care. Bariatric patients have additional nursing care needs related to their obesity as discussed in the Moving Evidence into Action box.

MAINTAINING WEIGHT LOSS

Losing weight and maintaining that loss are two separate but related issues. Most experts agree that the majority of dieters regain lost weight within a 2-year period. The potential risks associated with regaining weight make maintenance a critical issue. Patients are encouraged to continue exercise, self-monitoring, and treatment support. Long-term weight loss and maintenance mean a lifelong commitment to significant lifestyle changes, including food and eating habits, activity and exercise routines, and behavior modification. Failure to maintain weight loss can lead to feelings of inadequacy, powerlessness, and hopelessness.

●○● NURSING CARE

Health Promotion

Maintaining a healthy weight throughout the life span begins in childhood. Children and teenagers who are obese continue to be so as adults. Promote healthy eating, including a diet rich in whole grains, fruits, and vegetables and low in fat. The USDA MyPlate program and the *Dietary Guidelines for Americans* (USDA Center

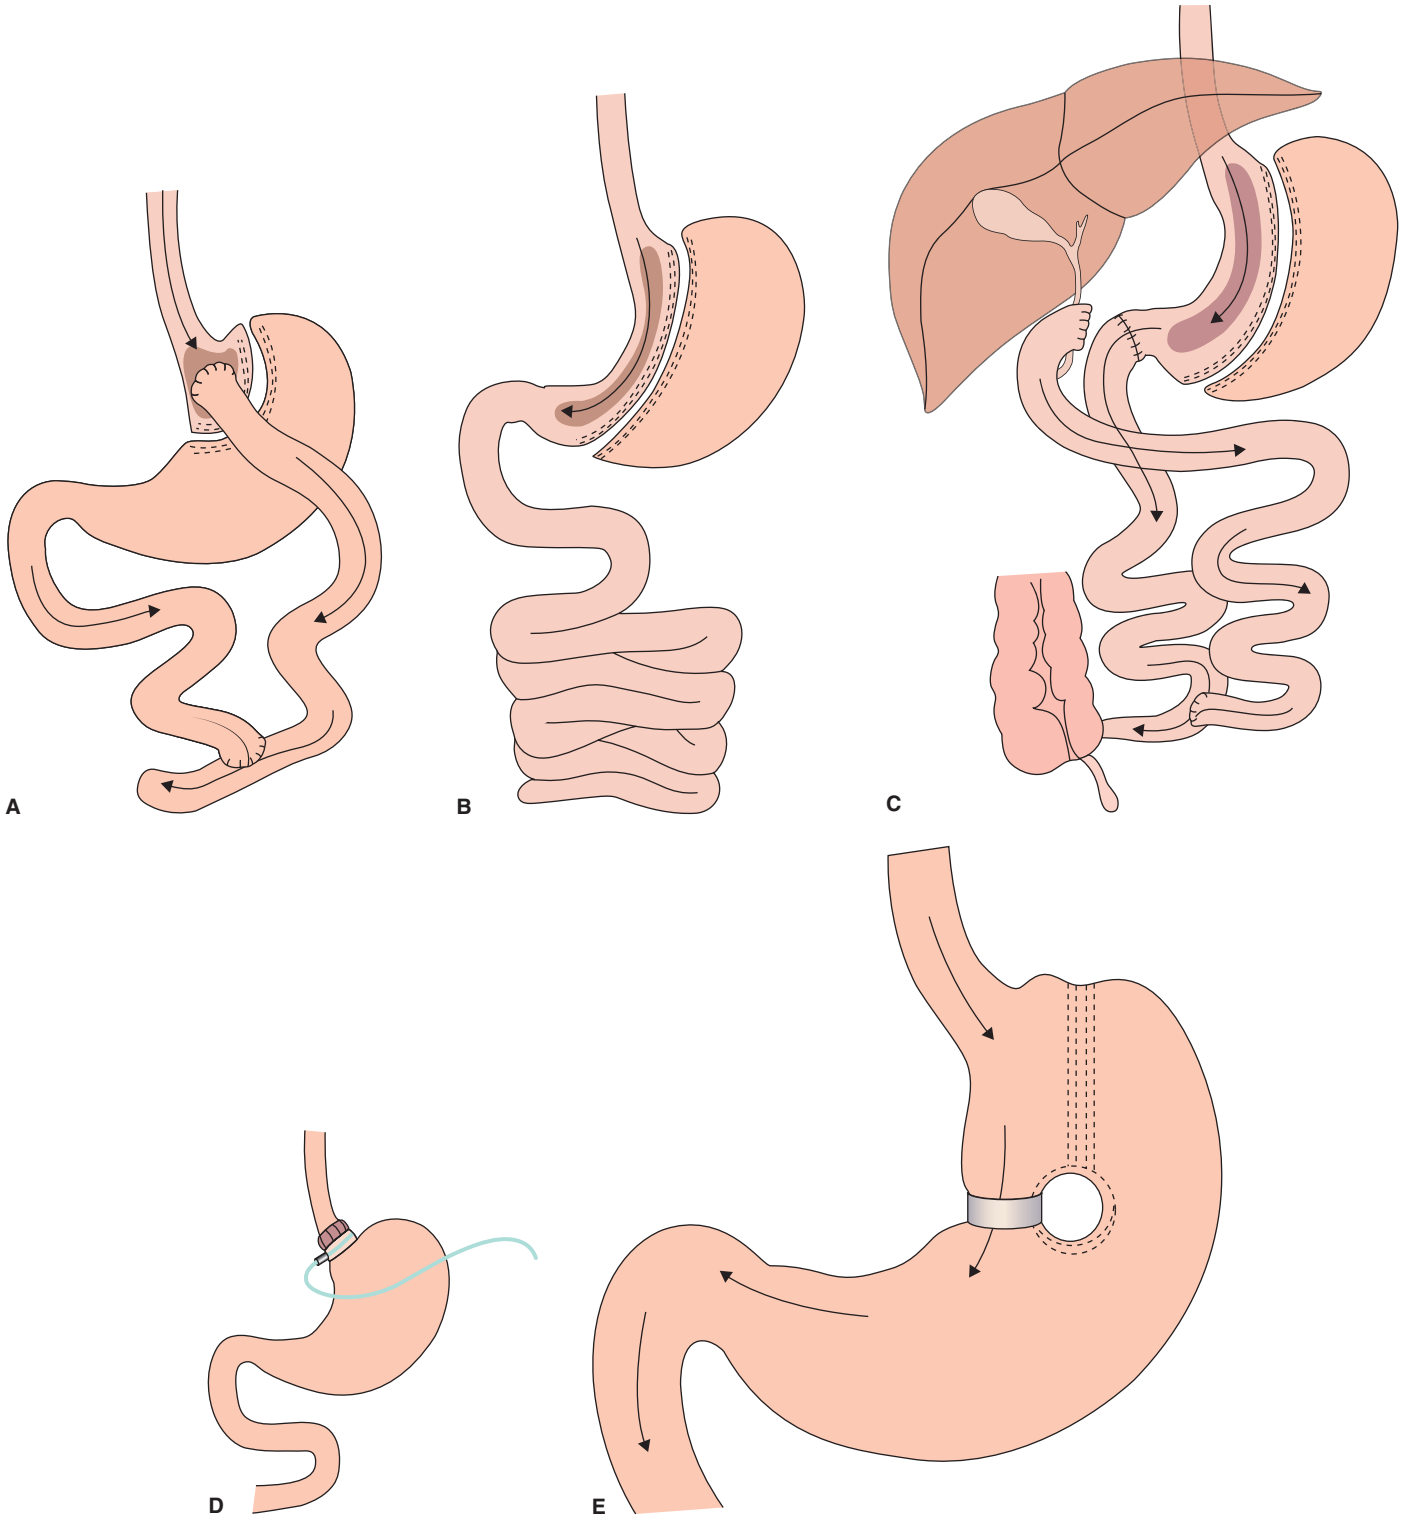

Figure 22–1 ■ Surgical procedures to treat obesity: A, Roux-en-Y gastric bypass, B, Vertical sleeve gastrectomy, C, Biliopancreatic diversion with duodenal switch, D, Adjustable gastric banding, E, vertical banded gastroplasty.

for Nutrition Policy and Promotion, 2011a, 2011b) provide visual guidance for appropriate food choices to maintain a healthy, well-balanced diet. Encourage all children and adults to maintain an active lifestyle, balance calories with daily energy requirements, avoid oversized portions, and emphasize fruits, vegetables, whole grains, and low-fat dairy in the diet. Nurses should encourage all patients to engage in at least 30 minutes of aerobic activity daily. Encourage parents to limit time children spend watching television, using the computer, and playing video games. Discuss the effects of smoking and excess alcohol use on nutrition and activity. To reduce weight gain commonly associated with aging, encourage patients to gradually reduce the amount of calories consumed.

Moving Evidence into Action

Self-Care for Patients Undergoing Bariatric Surgery

What are the most effective strategies to promote weight loss? The type and number of strategies are as diverse as the population, and bariatric surgery is becoming more common for patients who are morbidly obese. Patients initially lose large amounts of weight postoperatively. Unfortunately approximately 30% of these patients begin to gain weight 18 to 24 months after surgery (Wykowski & Krouse, 2013).

A comprehensive review of the literature was completed to identify which self-care variables are predictors of long-term weight loss (Wykowski & Krouse, 2013). Nine studies were reviewed and analyzed. The authors found common themes were evident across studies.

This review of the literature concludes individuals who undergo bariatric surgery need long-term follow-up in order to maintain significant, permanent lifestyle changes. Presurgical eating behaviors such as grazing and emotional eating and other behaviors associated with poor adherence to dietary advice must be addressed postoperatively. Continued encouragement to increase and maintain physical activity recommended during the preoperative period should be included in the postoperative plan of care. The authors conclude further nursing research is needed to identify which self-care activities are most important to implement postoperatively. Further studies should be conducted to determine which nursing interventions most effectively help patients to obtain and maintain their weight loss goals after surgery.

Implications for Nursing

Achieving and maintaining significant weight loss is a struggle for most patients who are overweight and obese and these challenges persist after bariatric surgery. Patients frequently seek advice from nurses and other healthcare practitioners about the best diet and the best way to meet their weight loss goals. Current evidence points to the importance of using an interprofessional approach to behavior change and weight loss: reduced calorie intake, regular exercise, and support groups or programs to help identify and maintain changes in eating behaviors.

Moving Knowledge into Action

1. Although research shows that reducing total calorie intake is more important than emphasizing or limiting intake of fats, carbohydrate, or protein, many people swear by a specific diet plan. What factors do you think contribute to the belief that one specific diet is more effective than another?
2. Exercise is consistently shown to be a significant factor in achieving and maintaining weight loss. How does exercise contribute to weight loss?
3. Develop a teaching plan to help a 54-year-old woman who recently underwent a laparoscopic adjustable banding procedure.

Evidence for Nursing Care

The Patient with Obesity

Selected resources that nurses may find helpful when planning evidence-based nursing care follow.

- Budd, G. M., Mariotti, M., Graff, D., & Falkenstein, K. (2011) Health care professionals' attitudes about obesity: An integrative review. *Applied Nursing Research, 24,* 127–137.
- Gagnon, L. E., & Sheff, E. K. (2013). Outcomes and complications after bariatric surgery. *American Journal of Nursing, 112*(9), 26–36.
- Phillips, J. (2013). Care of the bariatric patient in acute care. *Journal of Radiology Nursing, 32*(1), 21–31,

Assessment

Collect the following data through the health history and physical examination

- *Health history:* risk factors; current and usual weight; recent weight gains or losses; perception of weight and effect on health; usual diet and food intake; exercise/activity patterns; prior weight loss efforts and results; current medications; coexisting disorders such as cardiovascular disease and diabetes; tobacco use; family history of overweight, diabetes, and weight-related morbidity
- *Physical examination:* vital signs; weight (use a scale of adequate capacity) and height; skinfold measurements; waist-to-hip ratio; BMI; inspect skin under the breasts and abdominal folds.

Priorities of Care

- Nursing care priorities for the patient seeking treatment for obesity must be patient centered and holistic, focusing on the physiologic, psychologic, and sociologic responses to weight and appearance.
- Ensuring that the patient maintains adequate nutrition and participates in supportive interventions required to make necessary diet and exercise habits permanent should be the focus of nursing care.
- The nurse collaborates with the interprofessional team in assisting the patient with various treatment options to include diet, exercise, medication, and possibly surgery.
- Monitor anthropometric measurements regularly during treatment to include weight and BMI. Assess general well-being with each patient encounter including psychosocial status. Include diet recall, meat and snack patterns, food preparation methods, and dietary supplement use in assessment.
- Monitor vital signs including blood pressure and blood glucose if patient has type 2 diabetes.
- Assess for clinical manifestations of nutritional deficiency.
- Monitor for side effects and drug interactions for patients using weight loss medications.

SAFETY ALERT

Use of an inappropriately sized sphygmomanometer is a common source of error in measuring blood pressure in patients with obesity. Choose a cuff on which the width of the bladder is 40% of the circumference of the arm and the length of the bladder is sufficient to cover at least 65% of the arm circumference.

SAFETY ALERT

Patients with non–insulin-dependent diabetes may require insulin during the postoperative period. Review physician's orders and hospital protocols. Monitor for signs and symptoms of hypo- and hyperglycemia.

Diagnoses, Outcomes, and Interventions

Imbalanced Nutrition: More Than Body Requirements

Although many factors contribute to obesity, it always involves an imbalance of kilocalorie consumption to energy expenditure.

NURSING CARE OF THE PATIENT

Undergoing Bariatric Surgery

Patients who are severely obese and who undergo bariatric or general surgery have unique nursing care needs to ensure personal and caregiver safety.

- Obtain a thorough preoperative health history and physical assessment (including skin assessment). Note any limitations of mobility or assistive devices used. *Bariatric patients often have multiple chronic health problems that may affect postoperative assessment and recovery. Skinfolds are at high risk for fungal infections that may compromise immune protection. Knowing about and providing assistive devices to accommodate mobility limitations will help promote early postoperative mobilization and reduce the risk for complications.*
- Obtain equipment of appropriate size and weight capacity, including bed, mechanical lifts, expanded-capacity wheelchair, walker, commode, bedside chair (without arms), sphygmomanometer, and scale. Clearly label any equipment provided by the patient. *Appropriately sized equipment is vital to promote the patient's comfort and safety. Equipment made to meet the needs of patients who are within normal weight and BMI measurements may fail or the patient may not be able to sit or recline without the risk of falling.*
- Provide friction-reducing devices such as sliders, foam, or pressure-reducing mattresses. *Following surgery, mobility may be limited. Special equipment facilitates skin care while helping maintain patient and caregiver safety.*
- Ensure training and availability of nursing staff in adequate numbers to ensure patient and caregiver safety during position changes, transfers, and caregiving activities such as hygiene. *Even with use of appropriate lifts, sliders, and other devices, as many as six to eight caregivers may be necessary to safely move and transfer the bariatric patient.*
- Elevate the head of the bed. Apply a continuous positive airway pressure (CPAP) device as ordered. *Thoracic and abdominal fat may restrict lung capacity, particularly when the patient is supine. Elevating the head of the bed reduces the pressure of abdominal fat on the diaphragm. Patients who are obese are at risk for obstructive sleep apnea due to upper airway collapse; CPAP helps maintain upper airway patency.*
- Frequently monitor level of consciousness and respiratory status (rate, breath sounds, and oxygen saturation). *The postsurgical bariatric patient may sequester anesthetic agents in fatty tissue, increasing the risk for respiratory depression after surgery.*
- Initiate cardiac monitoring and compare heart rhythm to preoperative ECG. Promptly report changes in rate or rhythm, such as frequent premature ventricular contractions. *The patient with obesity is at significant risk for CHD; surgery and anesthesia place an additional risk for cardiovascular complications. Development of dysrhythmias not seen preoperatively may indicate myocardial ischemia, hypoxia, or electrolyte imbalance.*
- Assess peripheral pulses, skin color, and temperature of extremities. Apply elastic compression stockings or sequential compression device of appropriate size for the patient. Teach and remind to perform foot and leg exercises. *The patient with obesity is at significant risk for developing deep venous thrombosis due to alterations in clotting and immobility. Furthermore, multiple risk factors for atherosclerosis increase the likelihood of peripheral vascular disease and impaired circulation.*
- Assess pain level and analgesic effectiveness frequently. *Maintaining adequate pain relief is important to promote lung expansion and prevent respiratory complications in the bariatric patient.*
- Regularly monitor blood glucose levels, administering insulin as ordered. *Surgery is a physiologic stressor that causes increased cortisol levels that, in turn, can increase blood glucose levels.*
- Provide meticulous wound care, using strict aseptic technique and frequently assessing for signs of infection. *Excess adipose tissue impairs healing and immune function. Wound infection further delays healing and can be difficult to eradicate.*

Expected Outcome: Patient will achieve weight loss goal through behaviors that promote optimal nutritional habits and exercise.

- Encourage the patient to identify the factors that contribute to excess food intake. *Identification of cues to eating helps the patient eliminate or reduce these cues.*
- Establish realistic weight loss goals and exercise/activity objectives. *Small, reasonable goals, such as a loss of 1 to 2 pounds per week, increase the likelihood of success.*
- Assess the patient's knowledge and discuss diet plan options. Provide necessary teaching about diet. *Offering a selection of appropriate diet plans empowers the patient to choose a plan that best matches food preferences and lifestyle.*
- Discuss behavior modification strategies, such as self-monitoring and environmental management. *Behavior modification, diet, and exercise are critical to promoting successful, long-term weight loss.*
- Monitor weight loss, blood pressure, and laboratory data, including blood glucose and lipid levels. *Continuing assessment not only is important to evaluate the safety of weight loss strategies, but also to reinforce positive benefits of weight loss.* Refer to the Case Study and Nursing Care Plan on the following page.

Activity Intolerance

Patients with obesity may experience excess fatigue, tachycardia, and shortness of breath with activity due to the physiologic effects of excess weight as well as a sedentary lifestyle. A medical evaluation may be needed before beginning an exercise program.

Expected Outcome: Patient will improve activity tolerance as demonstrated by decreased reports of activity-related fatigue and improved changes in heart rate, blood pressure, and breathing rate.

- Assess current activity level and tolerance of that activity. Assess vital signs. *This provides baseline information when planning an activity program and assessing response to that activity.*
- After medical clearance, plan with the patient a program of regular, gradually increasing exercise. If desired, plan several 10- to 15-minute exercise periods over the course of the day. Develop plans for gradually increasing the duration and intensity of exercise. Consider a consultation with an exercise physiologist. *An individualized exercise program promotes activities within the patient's physical capabilities.*

Ineffective Therapeutic Regimen Management

Most patients who are overweight or obese experience some difficulty integrating all the components of a weight loss program into a daily routine. To be successful, the patient who is overweight must modify dietary intake in a world of daily temptations. There may be many obstacles to exercise, including a busy schedule, activity intolerance, impaired physical mobility, lack of equipment, and the embarrassment of being fat.

CASE STUDY & NURSING CARE PLAN A Patient with Obesity

Sam Elliott, age 57, has gained 30 pounds since his retirement 2 years ago. The most active thing he does each day is "puttering around" and "walking to the end of the driveway to get the mail." His 24-hour diet history includes juice, oatmeal, muffin, and coffee with cream for breakfast; donuts and coffee with friends midmorning; a bologna-and-cheese sandwich with chips and a root beer for lunch; and cheese, crackers, and wine before a dinner of meat, potatoes, vegetables, and dessert. He tells the nurse, "This is a pretty typical day. I have never had to diet. I just don't know how to get this weight off."

ASSESSMENT

Mr. Elliott is 173 cm (5′ 8″) tall and weighs 91.2 kg (201 lb). His BMI is 30.1 kg/m^2. His cholesterol is 240 mg/dL (normal 150 to 200 mg/dL) with an HDL of 37 mg/dL (normal male value > 45 mg/dL) and an LDL of 180 mg/dL (normal < 130 mg/dL). His BP is 138/90 mmHg. His fasting blood glucose is normal at 103 mg/dL. His ECG shows normal sinus rhythm. He reports fatigue and shortness of breath with activity. His healthcare provider has advised a weight loss of 30 pounds and a regular exercise program.

DIAGNOSES

- *Imbalanced Nutrition: More Than Body Requirements* related to food intake in excess of energy expenditure
- *Risk for Ineffective Therapeutic Regimen Management* related to knowledge deficit
- *Activity Intolerance* related to sedentary lifestyle

EXPECTED OUTCOMES

- Patient will lose 1 pound each week.
- Patient will walk 30 minutes 5 days each week.
- Patient will verbalize an understanding of the relationship between weight loss, weight control, and exercise.
- Patient will identify behavior modification strategies to avoid overeating.
- Patient will identify support systems for behavior modification.

PLANNING AND IMPLEMENTATION

- Assess weight and blood pressure once or twice each week.
- Discuss current eating habits and strategies to reduce fat and calorie intake.
- Discuss cues that promote eating. Identify strategies to eliminate or reduce eating cues.
- Teach to keep a food diary to examine and change eating habits.
- Discuss the role of regular exercise in weight loss and weight control. Instruct to maintain an exercise record to track the intensity and duration of activity.
- Discuss lifestyle and behavior modification strategies to promote successful weight loss and control.

EVALUATION

Two weeks after changing his diet and beginning to exercise, Mr. Elliott has lost 2 pounds. He has maintained a food diary. He has identified boredom as a cue to eating. In light of that fact, he has started volunteering at the local hospital, where he is working with children. He is walking for 30 minutes 5 days a week. He plans to increase his activity periods to 45 minutes. He verbalizes commitment to a lifelong plan of exercising and eating a low-fat diet. His BP has ranged from 132/76 to 136/84 mmHg. He plans to have the employee health nurse at the hospital check his weight and BP each week and to join Weight Watchers for ongoing support.

Clinical Reasoning in Patient Care

1. What are some possible pathophysiologic bases for Mr. Elliott's abnormal cholesterol, HDL, and LDL levels?
2. Develop a teaching plan for a group of men and women who are overweight.
3. Identify potential barriers to losing weight and strategies to reduce or eliminate these barriers.

See Evaluating Your Response in Appendix B.

Expected Outcome: Patient will implement resources to overcome barriers to incorporating healthy nutritional and exercise habits and will use identified behavioral and coping strategies to maintain dietary and exercise plan.

- Discuss ability and willingness to incorporate changes into daily patterns of diet, exercise, and lifestyle. *This provides data from which to set realistic goals with the patient.*
- Help the patient identify behavior modification strategies and support systems for weight loss and maintenance. *Weight loss and maintenance are most successful if the patient establishes lifestyle patterns that promote interest and motivation and thus exercise and diet management. Family and social support is critical to successful adherence to the therapeutic regimen.*
- Have the patient establish strategies for dealing with "stress" eating or interruptions in the therapeutic regime. *A sense of failure associated with overeating or lack of exercise can lead to further overeating. Identifying positive strategies to deal with these situations promotes self-acceptance and limits self-punishment through overeating.*

Chronic Low Self-Esteem

Most individuals who are overweight or obese verbalize the experience of ridicule (sometimes called *fat prejudice*), embarrassment, and health problems attributed to being fat. These experiences, coupled with problems such as finding attractive clothing or a chair large enough to sit on can affect self-esteem. Many patients report that fat jokes or comments contribute to a sense of negative self-worth.

Expected Outcome: Patient will demonstrate separation of self-perceptions from societal stigmas, describe personal strengths and attributes that will contribute to adhering to weight loss plan, and identify positive coping skills to be used for achieving weight loss and exercise goals.

- Encourage the patient to verbalize the experience of being overweight, and validate the patient's experience. *This provides baseline data to use in developing individualized interventions to address self-esteem issues.*
- Set small goals with the patient and offer positive feedback and encouragement. *Small goals provide more opportunities for success. Positive feedback and encouragement provide a comfortable environment in which to develop self-esteem.*
- Refer for counseling as appropriate. *Many patients benefit from counseling for issues related to self-esteem.*

Continuity of Care

Weight reduction involves interprofessional care provided in a variety of settings. Continuity of care is essential for establishing and maintaining the treatment plan and necessary lifestyle changes.

Weight loss and maintenance require a long-term commitment by the patient, family, and support systems. Address the following topics with the patient and family:

- Lifestyle changes are more effective than diets. Fad diets promote rapid weight loss but often are not nutritionally sound or may be difficult to maintain for a lifetime.
- All household members should consume a diet that is nutritionally sound, low in fat, and high in fiber.
- Establish realistic weight loss goals and a system of nonfood rewards for achieving each goal.
- Identify an exercise buddy or support system to promote continued physical activity.
- Expect occasional failures. Resume prescribed diet and exercise routine as soon as possible; the goal is long-term weight management.
- Community resources such as Weight Watchers, TOPS, or healthcare-based programs provide information, strategies, and support for successful weight management.

THE PATIENT WITH MALNUTRITION

Malnutrition results from inadequate intake of nutrients. An individual may lack major nutrients (calories, carbohydrates, proteins, and fats) or micronutrients such as vitamins and minerals. Malnutrition may be caused by inadequate nutrient intake; impaired absorption and use of nutrients; loss of nutrients due to diarrhea, hemorrhage, or renal failure; or increased metabolic needs (e.g., infection or physiologic stressors).

Incidence and Prevalence

Malnutrition is a widespread cause of disease and mortality throughout the world. It is endemic in regions affected by famine. Groups at risk for malnutrition in the United States include the young, poor, older adults, homeless, low-income women, and ethnic minorities. Even when food is plentiful, patients may be undernourished because of poor food choices.

It is estimated that one-third to one-half of all hospitalized patients are malnourished (Julian, 2013). Malnutrition may be present on admission or develop as a result of surgery or serious illness. Malnutrition increases both mortality and the incidence of complications in both medical and surgical patients.

Risk Factors

Risk factors for malnutrition include the following:

- Age—older adults are at greater risk for malnutrition due to a variety of factors (See the accompanying Meeting Individualized Needs box.)
- Poverty, homelessness, inadequate food storage and preparation facilities
- Functional health problems that limit mobility or vision
- History of weight loss of more than 20% of usual weight
- Oral or gastrointestinal problems that affect food intake, digestion, and absorption
- Inability to eat for 5 or more days
- Chronic pain or chronic diseases such as pulmonary, cardiovascular, renal, or endocrine disorders, or cancer
- Dementia, mental health disorders, eating disorders
- Medications or treatments that affect appetite
- Alcohol or drug addition
- Acute problems such as infection, surgery, or trauma.

Pathophysiology

Carbohydrates and fats in the diet are the body's primary energy source. Approximately 15% to 25% of the body is fat, the body's energy reservoir. The remainder (muscles, bones, other body tissues and organs) is lean body mass, metabolically active tissue. Proteins in the diet primarily are used to maintain this tissue. Glycogen and proteins in this lean body mass also act as energy stores.

When dietary intake of nutrients does not meet the body's energy needs, the body uses glycogen, body proteins, and lipids (fats) to support metabolism. In **starvation** (inadequate dietary intake), glycogen initially is used to provide energy. After the first 24 hours of starvation, gluconeogenesis (formation of glucose from proteins) is the major source of energy. As starvation continues, the body breaks down fats into free fatty acids and ketones, which provide energy for the brain. The size of all body compartments is reduced as body fats and muscle proteins are used to meet energy needs. As lean body mass is reduced, metabolically active tissue is lost, and energy expenditure decreases.

The stress of acute illness, surgery, or trauma produces a different response. The acute stress response produces a state of hypermetabolism and **catabolism** (cell and tissue breakdown). This hypermetabolic state increases energy expenditure and nutrient needs, resulting in **protein-calorie malnutrition (PCM)**. In PCM, both protein and calories are deficient. Lean body mass is broken down to meet these needs. If untreated, up to half of the body's protein stores can be used within 3 weeks. Visceral protein stores also are converted to

Meeting Individualized Needs

Nutrition for the Older Adult

Older adults are at greater risk for malnutrition than are younger people. Age-related changes that contribute to this problem include changes in taste and smell, poor oral health, loss of teeth or ill-fitting dentures, medication-related anorexia, and functional limitations that impair the ability to shop and cook. Older adults living on fixed incomes may not be able to afford well-balanced meals. Depression, social isolation, and loneliness often contribute to loss of appetite. Eating is a social event, and older adults who eat alone may not eat as well as those who share meals with companions.

Conduct a thorough assessment to determine nutritional status. Assess psychologic factors that influence eating habits, such as loneliness, isolation, and depression. Note the patient's general appearance and obtain a diet history, including information about foods and nutrients the patient consumes, and recent weight loss or gain. Review laboratory values, including complete blood count, total protein, prealbumin, and albumin levels.

TEACHING FOR HOME CARE

To maintain nutritional status, advise the older patient to do the following:

- Eat a well-balanced diet with fresh fruits and vegetables.
- Shop wisely to get the most value for the money.
- Avoid processed foods and foods high in fat.
- Drink adequate fluids.
- Exercise regularly.
- Contact local agencies for the availability of congregate meals (e.g., at local senior centers) or home-delivered meals (e.g., Meals-on-Wheels).

energy, with loss of protein from organs such as the liver, gastrointestinal tract, kidneys, and heart. Loss of protein from the liver affects its ability to produce plasma proteins. Immune cells decrease, and wound healing is impaired. Atrophy of gastrointestinal mucosa leads to malabsorption, further compounding the protein deficit. Myocardial contractility and cardiac output decline, and respiratory function is compromised (Grossman & Porth, 2014).

Two forms of severe malnutrition exist. Chronic protein deficiency with adequate calories to meet energy needs is called *kwashiorkor* and results from decreased protein intake and catabolism in acute and life-threatening illness. *Marasmus* refers to generalized starvation and occurs when both proteins and calories are insufficient to meet the body's needs. PCM is also known as marasmus.

Manifestations

The manifestations of malnutrition may vary among patients. Weight loss is the most apparent manifestation: The malnourished patient may have a body weight of less than 90% of ideal. Body mass also is reduced (refer to Box 22–1), as is skinfold thickness. Other manifestations include a wasted appearance, dry and brittle hair, and pale mucous membranes. Peripheral or abdominal edema may be present. Older adults may show general symptoms of frailty, including weakness, slow walking speed, low physical activity level, unintentional weight loss, and exhaustion. Manifestations of specific nutrient deficiencies may be present (see the accompanying Manifestations box). See the Multisystem Effects of Malnutrition feature on page 578.

Subcutaneous fat and muscle proteins are broken down in PCM, impairing mobility and increasing the risk for skin and tissue breakdown (pressure ulcers). Protein synthesis is inhibited and wound healing delayed. Serum albumin levels fall, leading to abdominal edema, diarrhea, and impaired nutrient absorption. Immune function is impaired, increasing the risk of infection. Cardiac output falls, and the risk for postural hypotension increases.

●○● INTERPROFESSIONAL CARE

The goal of treatment for the patient who is malnourished is to restore ideal body weight while replacing and restoring depleted nutrients and minerals. The patient's age, severity of malnutrition, and coexisting health problems help determine interventions. Treatment may include oral supplementation, tube feedings, or parenteral nutrition.

DIAGNOSIS

A nutrition screening tool can help identify patients at risk for malnutrition. As with obesity, the standard measurements to assess for malnutrition include height, weight, calculation of BMI, and skinfold measurements. A BMI of less than 18 to 20 kg/m^2 may indicate malnutrition. The following laboratory studies also may be ordered:

- *Serum albumin* is reduced in PCM, and may be below 3.0 g/dL.
- *Prealbumin* (also known as *transthyretin*) is a transport protein and precursor to albumin. It has a short (2-day) half-life and is sensitive to acute changes in nutritional status. A prealbumin level of less than 10 mg/dL indicates severe nutritional deficiency; a level lower than 5 mg/dL is seen in severe protein depletion (Kee, 2014).
- The *total lymphocyte count* is reduced in PCM.
- *Serum electrolytes* are measured. Potassium levels are low in severe malnutrition.

The following specialized procedures to evaluate the extent of malnutrition may be ordered:

- *Bioelectric impedance analysis* measures body fat and total body water.
- *Total daily energy expenditure* (which includes resting energy expenditure, energy needed for digestion, plus physical activity needs) may be measured to help determine the patient's calorie intake needs.

MEDICATIONS

Malnourished patients generally require supplemental vitamins and minerals to restore essential micronutrients. A multivitamin and mineral supplement may be given, or therapy may be tailored to correct specific deficiencies. See the Medication Administration box on page 579 for nursing implications of vitamin and mineral supplement use.

NUTRITION

Fluids and nutrients are carefully reintroduced in severely malnourished patients. Refeeding can precipitate fluid and electrolyte imbalances, heart failure, malabsorption, and diarrhea.

First, fluid and electrolyte imbalances are corrected, with particular attention paid to restoring normal potassium, magnesium, and calcium levels, as well as acid–base balance. Once fluid and

MANIFESTATIONS OF SPECIFIC NUTRIENT DEFICIENCIES

Deficiency	Assessment Data
Calorie	Weight loss Weakness, listlessness Loss of subcutaneous fat Muscle wasting
Protein	Thin or sparse hair Flaking skin Hepatomegaly
Vitamin A	Night blindness Altered taste and smell Dry, scaling, rough skin
Thiamine	Confusion, apathy Cardiomegaly, dyspnea Muscle cramping and wasting Paresthesias, neuropathy Ataxia
Riboflavin	Cheilosis, stomatitis Neuropathy, glossitis
Vitamin C	Swollen, bleeding gums Delayed wound healing Weakness, depression Easy bruising
Iron	Smooth tongue Listlessness, fatigue Dyspnea

electrolyte imbalances have been corrected, protein and calories are gradually reintroduced into the diet. Initial feedings are limited amounts (100 mL) of liquid formula to prevent diarrhea. Vitamin and mineral supplements at about twice the dietary reference intake (DRI) are provided along with refeeding. Fat and lactose are reintroduced into the diet last. Lactose intolerance may develop in severely malnourished patients; yogurt may be tolerated better than a milk-based formula.

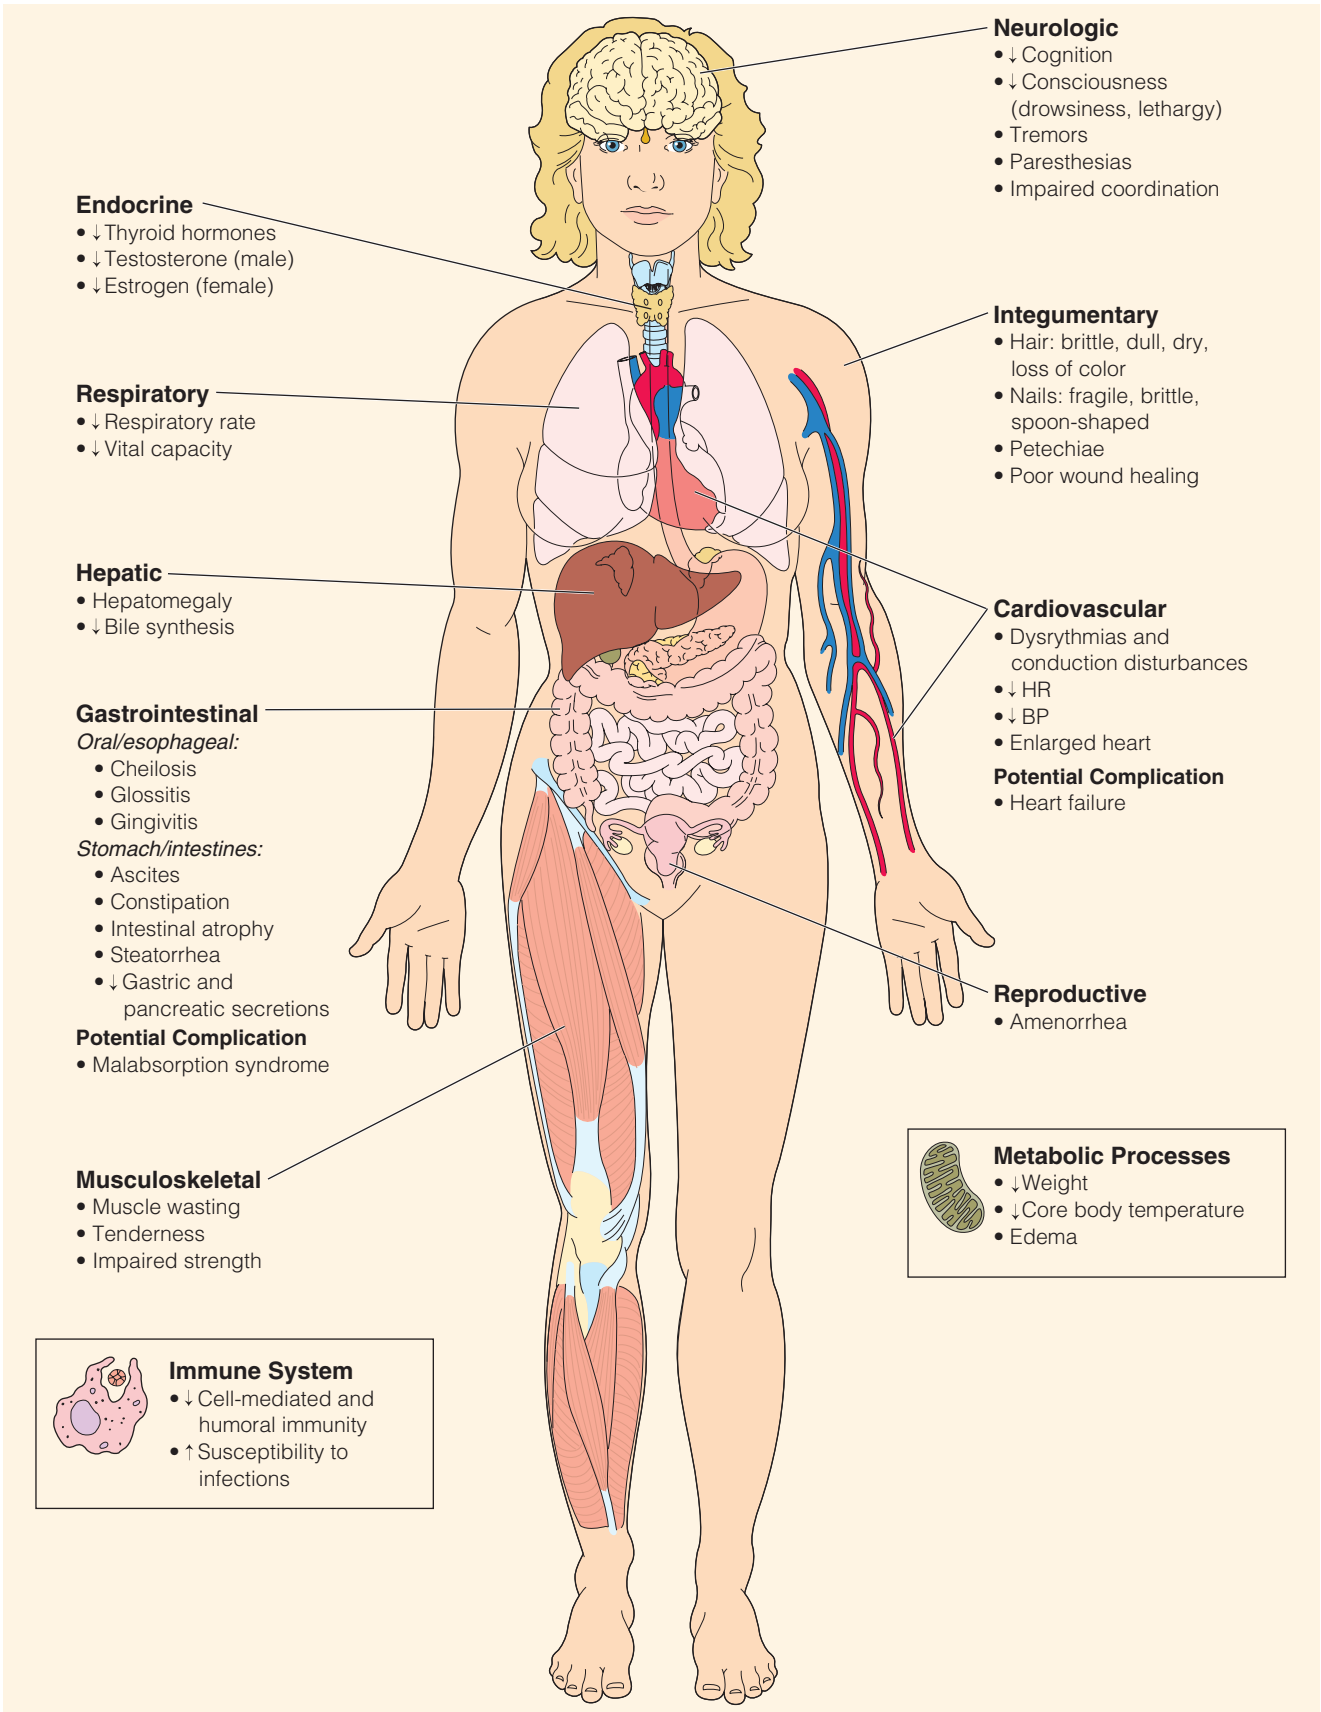
Food intake is gradually increased until the patient is able to consume about 5000 kcal/day, and is gaining 1.5 to 2.0 kg (3 to 5 lb) weekly. Commercially available nutritional supplements (such as Ensure or Sustacal) may supplement protein and calorie intake.

ENTERAL NUTRITION **Enteral nutrition**, or tube feeding, may be used to meet calorie and protein requirements in patients unable to consume adequate food. Significant evidence supports starting enteral nutrition rather than parental nutrition as early as possible to promote positive outcomes (Bailey et al., 2012). Indications for tube feedings include difficulty swallowing, unresponsiveness, oral or neck surgery or trauma, anorexia, or serious illness. Tube feedings may provide part or all of a patient's nutritional needs. Enteral feedings provide nutrients directly to the gut and other digestive organs, support immune function, promote blood flow to the gut, and support other functions of the GI tract such as the release of hormones and epidermal growth factor (Longo et al., 2013).

Tube feedings are usually administered through a soft, small-caliber nasogastric or nasoduodenal tube with a weighted tip. They also can be administered through a gastrostomy or jejunostomy tube. Small-bore feeding tubes are easily displaced; appropriate tube placement should be periodically checked by aspirating the tube and checking the pH of aspirated contents. A pH of 6 indicates the tube is in the jejunum. Most tube feeding formulas provide 1 kcal/mL with approximately 14% of the calories from protein, 60% from carbohydrates, and 25% to 30% from fat. Administering 1500 mL/day provides the recommended daily intake of all vitamins and minerals. Formulas that provide more calories per milliliter, more grams of protein, added fiber, or lower fat also are available (Table 22–5). Commercial products provide instructions for initiating therapy. Enteral feedings may initially be started with smaller volumes to prevent diarrhea, with the volume gradually increased to provide the required calories for maintenance and healing. Formulas may be administered as a bolus feeding or as a continuous-drip feeding regulated by a feeding pump.

Aspiration and diarrhea are the most common complications of enteral feedings. Continuous infusion of the formula reduces the risk of aspiration. The risk is reduced by placing the feeding tube in the jejunum rather than the stomach. To avoid aspiration, the nurse elevates the head of the bed at least 30 degrees during feeding and for at least 1 hour after feeding. Dual-lumen tubes that allow gastric suction with simultaneous instillation of an enteral feeding into the jejunum also reduce the risk for aspiration. Formulas that contain fiber can reduce the incidence of diarrhea. Fluid and electrolyte status is monitored carefully, and additional water is administered as needed.

PARENTERAL NUTRITION **Parenteral nutrition (PN)** is the intravenous administration of amino acids, often with added carbohydrates, fats, electrolytes, vitamins, and minerals. These hypertonic solutions usually are administered through a central vein, such as the subclavian vein (Figure 22–2 ■), particularly when therapy may be prolonged. A peripherally inserted central catheter (PICC) line may be used for short-term PN.



Although oral intake or enteral feeding is preferred over parenteral nutrition, PN is initiated when a patient's nutritional requirements cannot be met through diet or enteral feedings. Increasingly PN may be used concurrently with enteral nutrition. Patients who have undergone major surgery or trauma or are seriously undernourished are often candidates for PN. PN is used for both short- and long-term management of nutritional deficiencies.

To begin therapy, a peripheral or central venous catheter is inserted under aseptic conditions. The location of the catheter tip is confirmed by x-ray. Parenteral nutrition solutions are mixed in the pharmacy and commonly contain 3% to 11.4% amino acids (a mixture of essential and nonessential amino acids), 10% or more

TABLE 22–5 Selected Enteral Feeding Formulas

Formula Type	Contains	Examples
Complete—suitable for most patients requiring enteral feedings	• 1 kcal/mL • Protein: ~14% total kcal • Fat: ~30% total kcal • Carbohydrate: ~60% total kcal • Recommended daily intake of all minerals and vitamins in 1500 mL/day	Compleat, Ensure, Isocal, Nutren, Isolan, Sustacal, Resource
High-calorie complete—appropriate for patients on fluid restriction	As above; provides 1.5–2 kcal/mL	Ensure Plus, Sustacal HC, Comply, Nutren 1.5, Resource Plus, Isocal HCN, Magnacal, TwoCal HN
Complete lactose-free, high-residue—used to prevent/treat diarrhea, constipation	As above; provides fiber	Jevity, Profiber, Nutren 1.0 with fiber, Fiberlan, Sustacal with fiber, Ultracal, Ensure with fiber, FiberSource, Accupep HPF, others
Disease-specific formulas:		
Renal failure	Contain essential amino acids	Amin-Aid, Travasorb Renal, Aminess
Respiratory failure	Fat: >50% total kcal	Pulmocare, NutriVent
Liver failure with hepatic encephalopathy	High amounts of branched-chain amino acids	Hepatic-Aid II, Travasorb Hepatic

MULTISYSTEM EFFECTS OF Malnutrition

MEDICATION ADMINISTRATION

Vitamin and Mineral Supplements

FAT-SOLUBLE VITAMINS

vitamin A
vitamin D
vitamin E
vitamin K

The fat-soluble vitamins are absorbed in the gastrointestinal tract. Vitamins A and D are stored in the liver. All fat-soluble vitamins may become toxic if taken in excess amounts.

Nursing Responsibilities

- Monitor for manifestations of vitamin excess as well as for adverse effects from vitamin administration.
- Monitor carefully for hypersensitivity reactions during the parenteral administration. Have emergency equipment available.
- Administer vitamin A with food.
- Do not administer vitamin K intravenously.

Health Education for the Patient and Family

- Teach the importance of eating a well-balanced diet. If indicated, provide lists of foods high in specific vitamins.
- Caution that excessive intake of these vitamins may lead to toxicity.

WATER-SOLUBLE VITAMINS

vitamin C (ascorbic acid)
vitamin B complex:
thiamine (B_1)
riboflavin (B_2)
niacin (nicotinic acid)
pyridoxine hydrochloride (B_6)
pantothenic acid
biotin

These vitamins are used to prevent or treat deficiency problems. If the diet is deficient in one vitamin, it is usually deficient in other vitamins as well; therefore, multivitamin preparations are often administered. Most of these vitamins are well absorbed from the gastrointestinal tract.

Nursing Responsibilities

- Monitor for responses to replacement therapy.
- Monitor for hypersensitivity reactions from parenteral administration. Have emergency equipment available.

Health Education for the Patient and Family

- Do not exceed the recommended daily intake for the specific vitamin.

MINERALS

sodium
manganese
fluoride
magnesium
selenium
zinc
copper
potassium
chromium
iodine
calcium

Minerals are inorganic chemicals that are vital to a variety of physiologic functions. Also called trace elements, these minerals are part of a balanced diet. Recommended daily intakes have not been established for all mineral substances. The dosage of prescribed minerals depends on the specific deficiency, route of administration, and the patient's general health.

Nursing Responsibilities

- Monitor for manifestations of mineral imbalance.
- Prior to administration, dilute oral mineral preparations.
- Prior to the administration of iodine, assess for history of hypersensitivity to iodine or seafood; if hypersensitive, notify the physician.

Health Education for the Patient and Family

- Encourage the patient to avoid exceeding the known recommended daily intake of the mineral.
- Instruct the patient to take minerals other than fluoride and zinc with or after meals.

dextrose, and added electrolytes, minerals, and vitamins. Fat emulsions (lipids) may be added to the solution, although they often are administered separately. The sterility of the solution is maintained, and no medication is added to the solution after it is mixed or to the lumen through which the PN is being administered. When given separately, fat emulsions may be administered either through a peripheral vein or via the same intravenous catheter as PN. PN solutions are always administered with an infusion pump to ensure the correct rate of infusion.

COMPLICATIONS The patient receiving parenteral nutrition is at risk for fluid overload, infections, and metabolic and mechanical complications. Disruption of the skin barrier and administration of a solution high in glucose present a risk for infection in patients receiving PN. Infection may be local, limited to the insertion site or the catheter itself, or may be systemic. Meticulous sterile technique when inserting the catheter, preparing and administering PN solutions, and during site and catheter care reduces the risk for infection. Using a catheter impregnated with antiseptics and an in-line filter also reduce the risk for infection. The insertion site and the patient's temperature are monitored for evidence of infection. Cultures of the solution, catheter, and blood may be obtained if infection is suspected.

Glucose intolerance may develop, particularly early in the course of PN. The concentration of glucose in PN solutions may be gradually increased to reduce this risk. Blood and urine glucose levels are measured every 6 hours until insulin production adjusts to the increased glucose load. Patients with impaired kidney function or liver disease may develop excessively high blood urea nitrogen (BUN) levels or metabolic acidosis. Hyperlipidemia is a common complication of fat infusions; these solutions are given intermittently to allow fats to clear from the blood between infusions. Fluid overload or dehydration may develop, particularly in older adults. PN formulas can cause electrolyte shifts, with resulting imbalances.

Pneumothorax, brachial plexus injury, and improper position are possible mechanical complications of central venous catheter insertion. Once in place, a thrombus (clot) or fibrin sheath may form within or around the catheter. The catheter also can be mechanically occluded, or may dislodge, leak, or break and become an embolus.

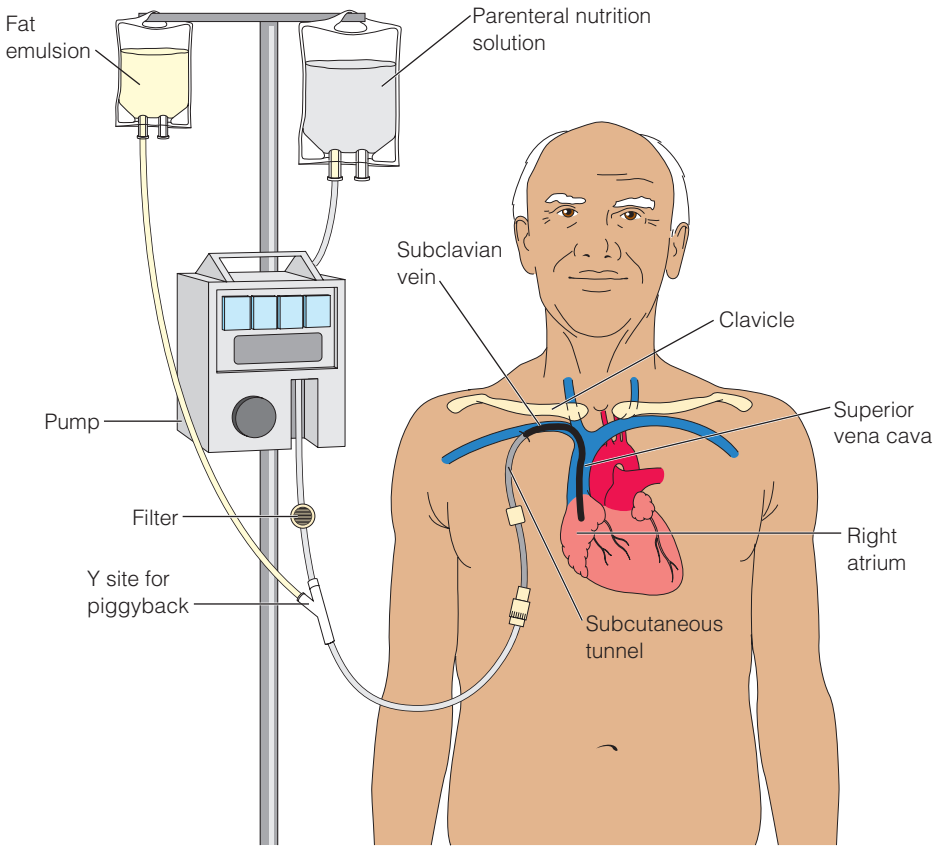


Figure 22–2 ■ Parenteral nutrition infusing through a catheter in the right subclavian vein

●○● NURSING CARE

Health Promotion

Aggressive nursing assessment and interventions can help prevent malnutrition associated with hospitalization or long-term care. In hospitalized patients, carefully monitor food intake. When the patient is placed on NPO status for surgery or tests, ask the care provider to restore diet orders as soon as possible. If allowed, encourage family members to provide favorite foods to promote intake. In long-term care settings, promote socialization during meals. Assess food likes and dislikes for patients, and provide foods they are likely to eat.

Assessment

Collect nutritional assessment data on admission and periodically (once or twice a week) during long-term institutionalization.

- *Health history:* usual daily dietary pattern (type and amount of foods consumed); usual weight and recent changes; appetite and food tolerance; specific food likes and dislikes; difficulty swallowing; problems such as anorexia, nausea, diarrhea, or constipation; history of surgery and/or chronic diseases (e.g., chronic lung disease) and medications.
- *Physical examination:* height, weight, skinfold thickness, BMI; vital signs; general appearance, muscle wasting, mobility; skin and mucous membranes; bowel sounds; laboratory studies.

Use of a nutritional assessment tool can help identify patients (older adults in particular) at risk for malnutrition.

Priorities of Care

- Obtain and document baseline indicators of nutritional status.
- Collaborate with physician, dietitian and pharmacy to develop an interprofessional treatment plan designed to correct acute fluid and electrolyte imbalances.
- Ensure patient is receiving supplemental nutritional support when appropriate.

Diagnoses, Outcomes, and Interventions

The complex effects of malnutrition on multiple body systems place the patient at high risk for a number of other problems. This section addresses problems with nutrition, infections, fluid volume, and skin integrity. See the Case Study & Nursing Care Plan feature on page 583 for the patient with malnutrition.

Imbalanced Nutrition: Less Than Body Requirements

The nurse plays a critical role in the ongoing assessment of a patient who is malnourished, while collaborating with the interprofessional team to provide nutritional therapies.

Expected Outcome: Patient will achieve consistent weight gain by practicing nutritional habits that restore physical health and functional capacity, will improve indicators of nutritional status such as laboratory values, and will demonstrate improved functional status and describe general well-being.

- If the patient is able to eat, provide an environment and nursing measures that encourage eating, for example, adequate staff

Evidence for Nursing Care

The Patient with Malnutrition

Selected resources that nurses may find helpful when planning evidence-based nursing care follow.

- DiMaria-Ghalili, R. (2012). *Nutrition in the elderly: Nutrition standard of practice protocol: Nutrition in aging.* New York, NY: Hartford Institute for Geriatric Nursing, New York University College of Nursing. Retrieved from www.consultgerirn.org/topics/nutrition_in_the_elderly/want_to_know_more
- Marshall, A. P., Cahill, N. E., Gramlick, L., MacDonald, G., Alberda, C., & Heyland, D. K. (2012). Optimizing nutrition in intensive care units: Empowering critical care nurses to be effective agents of change. *American Journal of Critical Care, 21*(3), 186–194.
- Skates, J. J., & Anthony, P. S. (2012). Identifying geriatric malnutrition in nursing practice: The Mini Nutritional Assessment (MNA®)—An evidence-based screening tool. *Journal of Gerontological Nursing, 38*(3), 18–27.

to assist with meals, sitting at the bedside or in a common area, and providing favorite foods. *Measures to promote a more normal and social dining experience support the patient's intake (DiMaria-Ghalili, 2012).*

- Eliminate foul odors, provide oral hygiene before and after meals, make meals appetizing, and offer frequent, small meals including preferred foods. Consult with the nutrition support team to provide adequate protein, calories, minerals, and vitamins. *Oral hygiene and a pleasant environment make food more appetizing. Small, frequent meals are generally more appealing and less overwhelming to a patient with anorexia. Many patients require complicated nutritional therapy such as enteral or parenteral therapy to meet nutritional needs.*
- Provide a rest period before and after meals. *Eating requires energy, and the malnourished patient may have decreased physical strength and energy.*
- Assess knowledge and provide appropriate teaching. *Lack of knowledge often contributes to undernutrition. Education empowers the patient to make healthy choices.*
- Start specialized nutritional support when a patient cannot, should not, or will not eat adequately and if the benefits of nutrition outweigh the associated risks. *Specialized nutritional support may be required to correct acute and life-threatening nutritional imbalances when malnourishment has been prolonged or during acute and critical illness.*

Risk for Infection

Patients who are malnourished have a much higher risk for infection than those who are well nourished. Malnutrition affects many components of the immune system, including the skin, mucous membranes, and lymph tissue and cells.

Expected Outcome: Patient will be free of signs and symptoms of infection.

- Monitor temperature and assess for manifestations of infection every 4 hours. *Although the baseline temperature may be subnormal in malnourished patients, any elevation from baseline may indicate infection. Manifestations of infection may include chills, malaise, erythema, and leukocytosis. Early detection of infection may prevent complications.*
- Maintain medical asepsis when providing care and surgical asepsis when carrying out procedures. *Hand hygiene is the best strategy to prevent the spread of pathogens. Sterile technique is required for procedures such as inserting central lines and changing dressings.*
- Teach the signs and symptoms of infection, hand hygiene, and factors that increase the risk for infection. *Knowledge empowers the patient to participate in self-care, thus reducing exposure to infectious pathogens.*

Risk for Deficient Fluid Volume

The patient with malnutrition may also have a fluid volume deficit. Difficulty swallowing food and fluids or administration of hyperosmolar nutritional solutions may lead to dehydration or electrolyte disturbances.

Expected Outcome: Patient will maintain adequate hydration status, and will not develop complications related to compromised hydration status.

- Monitor oral mucous membranes, urine specific gravity, level of consciousness, and laboratory findings every 4 to 8 hours. *Dry mucous membranes, increased urine specific gravity, decreased level of consciousness, and electrolyte imbalances may indicate dehydration.*
- Weigh daily and monitor intake and output. *Daily weights and intake and output measurements help monitor fluid balance.*
- If allowed, offer fluids frequently in small amounts, considering the patient's preferences. *Frequent, small amounts of fluids are better tolerated and promote adequate intake.*

Risk for Impaired Skin Integrity

Skin integrity depends on adequate nutrition. Loss of subcutaneous tissue and muscle increases the risk of pressure ulcers. In addition, healing is impaired in patients who are malnourished.

Expected Outcome: Patient will not exhibit signs of pressure ulcers.

- Assess skin every 4 hours. *Baseline and ongoing assessments allow prompt identification of early manifestations of skin breakdown.*
- Turn and reposition at least every 2 hours. Encourage passive and active range-of-motion exercises. *These measures reduce pressure and promote oxygenation of cells.*
- Keep skin dry and clean, and minimize shearing forces. Keep linens smooth, clean, and dry. Provide therapeutic beds, mattresses, or pads. *These nursing measures promote comfort and reduce the risk of skin breakdown.*

Delegating Nursing Care

- Conduct mealtime rounds to determine patients' needs for assistance with meals. *Identifying patients who need assistance with meals will ensure staff are available to help.*
- Ensure that unlicensed assistive personnel (UAP) keep fluids within patients' reach between mealtimes. *Medication and age can affect thirst sensation. Ensuring that fluids are accessible will remind the patient to sip fluids frequently.*
- Instruct UAP to enhance the environment by removing bedpans, urinals, and other equipment. *Ensuring that patients have*

pleasant surroundings at mealtime will increase the patient's appetite and improve nutritional intake.

- Instruct and monitor UAP adherence to swallowing precautions. *Failure to follow swallowing precautions can lead to aspiration.*

Continuity of Care

Periodic nutritional status assessment should be conducted for patients receiving nursing care in community-based settings. Nutritional status should be carefully assessed after hospitalization because multiple factors such as medications, functional limitations, and psychologic status can influence the intake, absorption, and digestion of nutrients. Community-dwelling older adults, homeless people, and other disadvantaged populations are at particular risk for being malnourished. See the accompanying Moving Evidence into Action box.

Patients with malnutrition may be cared for at home or in the hospital with diet, enteral, or parenteral therapy. Each year, it is more common to see patients managing tube feeding or PN at home. Teaching for the patient and family includes the following topics:

- Diet recommendations and use of nutritional supplements
- Where to obtain recommended foods and nutritional supplements
- If continuing enteral or parenteral nutrition, (1) how to prepare and/or handle solutions, (2) how to add them to either the feeding tube or central line, (3) how to manage infusion pumps, (4) how to care for the feeding tube or central catheter, (5) how to recognize and manage problems and complications, and (6) how and when to notify the healthcare provider of problems.

THE PATIENT WITH AN EATING DISORDER

Eating disorders are characterized by severely disturbed eating behavior and weight management. Eating disorders are more common in affluent societies where food is plentiful and occur in all sociaoconomic amd major ethnic groups. Eating disorders are manifested in both men and women. Women are slightly more affected than men (Grossman & Porth, 2014). **Anorexia nervosa** is characterized by a refusal to maintain a minimally normal body weight, a distorted body image, and an intense fear of gaining weight or of loss of control over food intake. Anorexia nervosa affects about 1% of women in the United States at some time in their lives (Longo et al., 2013). **Bulimia nervosa**, which affects 1% to 3% of women in the United States, is characterized by recurring episodes of binge eating followed by purge behaviors such as self-induced vomiting, use of laxatives or diuretics, fasting, or excessive exercise. *Eating disorder not otherwise specified* (EDNOS) is used as a diagnostic category for people who have eating disorder symptoms but do not meet the full category for anorexia nervosa or bulimia nervosa (Grossman & Porth, 2014). **Binge-eating disorder** is a subgroup of EDNOS and is believed to affect many more people than either anorexia or bulimia (Grossman & Porth, 2014). Binge-eating disorder is characterized by recurrent episodes of binge eating—eating an excessive amount of food during a defined period of time and a sense of loss of control over eating during binge episodes (Grossman & Porth, 2014).

Anorexia Nervosa

Anorexia nervosa typically begins during middle to late adolescence. Patients with anorexia nervosa have a distorted body image and irrational fear of gaining weight. Refusal to maintain body weight at or above a minimally normal level for height and body type is a common manifestation of anorexia nervosa. Patients maintain weight loss by restricted calorie intake, often accompanied by excessive exercise. Some may exhibit binge–purge behavior.

Although its cause is unknown, psychologic, biologic, genetic, and cultural risk factors have been identified for anorexia nervosa. A history of sexual or physical abuse and family history of mood disorders are nonspecific risk factors. Abnormal levels of neurotransmitters and other hormones may play a role. Genetic factors are suggested by a higher incidence within families and in the monozygotic twin of an affected individual. Women who develop anorexia nervosa tend to be obsessive and perfectionistic, and often feel inadequate or unable to maintain control in their lives. Family, social, or occupational (e.g., a career in modeling or ballet) pressures to maintain low body weight also contribute.

The manifestations and complications of anorexia nervosa are listed in the accompanying box. Patients who engage in binge–purge behavior have a higher risk for complications.

Bulimia Nervosa

Bulimia nervosa develops in late adolescence or early adulthood. Unlike patients with anorexia nervosa, the weight of patients with bulimia is within or above the normal range. Like anorexia nervosa, however,

Moving Evidence into Action

Patients with Malnutrition

The percentage of hospitalized patients with malnutrition is significant in Australia, Europe, the United Kingdom, and the United States. Malnutrition can increase complications, length of stay, mortality rates, and healthcare costs. A metasynthesis by Jefferies and colleagues (2011) identified appropriate nursing strategies that can reduce the prevalence of hospital malnutrition.

Implications for Nursing

As the nursing role becomes increasingly complex, direct patient care activities such as serving patients their meals are delegated to other nonnursing personnel, leaving the role of nursing activities related to patients' nutrition ill defined. This study identified eight recommended actions that nurses can use to support the oral nutrition of their patients. Highlights of these practices include creating a focused mealtime, managing mealtime environments, managing staff mealtimes, and developing a designated nutrition support nurse position to monitor and evaluate the implementation of nutrition related standards and policy.

Moving Knowledge into Action

1. What essential information should you collect from patients in the hospital to screen for those who are at risk for becoming malnourished?
2. This study identified eight standards that should be implemented in all care settings to prevent malnutrition. Describe nursing interventions that will reduce the prevalence of malnutrition of hospitalized patients.
3. Develop a teaching plan to prepare nonnursing assistive personnel to use the Mini-Nutritional Assessment Screening tool outlined in Box 22–3 for screening patients.

CASE STUDY & NURSING CARE PLAN A Patient with Malnutrition

Kyo Morris is an 88-year-old widow who lives alone. She typically rises early and has a cup of tea before spending her morning puttering in her garden. She consumes her main meal of the day at lunch, which usually includes rice and some vegetables. For dinner, she generally eats a bowl of rice with "whatever is in the refrigerator." Mrs. Morris admits to little interest in cooking or eating since her husband died 10 years ago and her group of friends has been "dying off too."

ASSESSMENT

Mrs. Morris weighs 43.1 kg (95 lb), is 160 cm (5′ 3″) tall, and has a BMI of 16.8. She reports weighing 53.5 kg (118 lb) 5 years ago. Her triceps skinfold thickness measurement is 11 mm (normal values for a female: >13 mm). Her skin is pale, and she appears thin and wasted. Her temperature is 36°C (97°F). Diagnostic test results include serum albumin 2.9 g/dL (normal 3.4 to 4.8 g/dL) and serum cholesterol 130 mg/dL (normal 150 to 200 mg/dL). A diagnosis of protein-calorie malnutrition is made, and a 1500 calorie per day diet is recommended.

DIAGNOSES

- *Imbalanced Nutrition: Less Than Body Requirements* related to lack of knowledge and inadequate food intake
- *Risk for Infection* related to protein-calorie malnutrition
- *Impaired Social Interaction* related to widowhood and reduced social support group

EXPECTED OUTCOMES

- Patient will gain at least 1 pound per week.
- Patient will verbalize understanding of nutritional requirements and identify strategies to incorporate requirements into daily diet after discharge.
- Patient will remain infection free, evidenced by normal vital signs.
- Patient will identify strategies to increase social interaction, such as participating in senior citizens' lunches at local senior center.

PLANNING AND IMPLEMENTATION

- Weigh weekly at a consistent time of day.
- Refer to dietitian for evaluation of nutritional needs.
- Teach about nutritional requirements, and plan an eating program that includes high-calorie, high-protein foods and supplements and reflects her food preferences. Encourage small, frequent meals.
- Encourage to keep a food intake diary.
- Teach strategies to reduce risks for infection.
- Provide information about communal meals available to seniors in the community, and help Mrs. Morris develop a plan to participate.

EVALUATION

One month later, Mrs. Morris has gained 3 pounds and reports feeling "more energetic." A friend is helping her shop to ensure that she purchases foods to maintain her protein, calorie, and nutrient intake. She has begun attending senior lunches twice a week, and is enjoying "being around people again." Although she still doesn't enjoy cooking like she used to, she is using prepared foods and supplements to maintain her nutrient intake.

Clinical Reasoning in Patient Care

1. What is the physiologic basis for Mrs. Morris's low albumin and cholesterol levels?
2. Mrs. Morris asks, "Can I get better by just taking more vitamins?" How will you respond?
3. Design a teaching plan for a Hispanic patient with protein-calorie malnutrition.

See Evaluating Your Response in Appendix B.

the cause likely is multifactorial, including cultural, psychosocial, and biologic factors. The patient with bulimia often restricts caloric intake, leading to increased hunger and overeating. Foods consumed during a binge often are high calorie, high fat, and sweet. After binge eating, the patient induces vomiting (usually by stimulating the gag reflex), or may take excessive quantities of laxatives or diuretics. Fluid and electrolyte balance may be severely disrupted by loss of fluid and gastrointestinal secretions. The complications of bulimia nervosa (see the Manifestations box) primarily result from the purging behavior.

Binge-Eating Disorder

Binge-eating disorder (BED) shares many of the characteristics of bulimia; however, patients with BED do not purge. BED commonly affects middle-aged adults who are obese. The cause of BED is unknown, although genetics may play a role in its development. Psychosocial factors contribute; people with BED often are depressed, anxious, or have a personality disorder. People with BED consume an excessive amount of food during binging episodes, eating even when not hungry and continuing to eat until uncomfortably full. Binging often occurs when the person is alone. After overeating, the patient may feel disgusted or guilty about the amount of food consumed, and depressed about the inability to control eating.

●○● INTERPROFESSIONAL CARE

Eating disorders, anorexia nervosa in particular, are difficult to treat effectively. Because of the intense fear of weight gain and the distorted body image of patients with anorexia, they strongly resist increasing food intake. While community-based care is appropriate for most patients with an eating disorder, complications of the disorder or resistance to treatment may necessitate hospitalization for some patients. In all cases, a comprehensive treatment plan for eating disorders includes medical care and monitoring, psychosocial interventions, and nutrition counseling.

DIAGNOSIS

There is no specific diagnostic test for anorexia, bulimia, or binge-eating disorder. Laboratory studies in patients with anorexia or bulimia may show anemia and leukopenia on CBC, abnormal serum electrolyte levels, and elevated BUN and serum creatinine. In patients with BED, the blood glucose and lipid levels may be elevated. The BMI usually is above the normal range, and may identify the patient as obese.

A mental health evaluation is indicated for patients with eating disorders to identify contributing factors and help direct treatment.

TREATMENT

Patients with anorexia nervosa may require hospitalization, particularly if their weight is less than 75% of normal. Refeeding is gradually introduced to avoid complications related to refeeding syndrome such as electrolyte and acid–base imbalance, respiratory distress, neurologic symptoms, cardiac dysrhythmia, hypotension, and congestive heart failure. Multivitamins are given along with calcium and vitamin D supplements to minimize bone loss. Meals must

MANIFESTATIONS AND COMPLICATIONS OF EATING DISORDERS

Disorder	Manifestations	Complications
Anorexia nervosa	• Weight < 85% of normal, muscle wasting • Fear of weight gain, refusal to eat • Disturbed body image, excessive exercise • Amenorrhea • Skin and hair changes • Hypotension, bradycardia • Hypothermia, cold intolerance • Constipation • Insomnia	• Electrolyte and acid–base disturbances • Reduced cardiac output, dysrhythmias • Elevated BUN, serum creatinine levels • Anemia • Hypoglycemia, elevated serum uric acid levels • Osteoporosis • Enlarged salivary glands • Delayed gastric emptying • Abnormal liver function
Bulimia nervosa	• Weight often normal; may be slightly overweight • Binge–purge behavior • Oligomenorrhea or amenorrhea • Lacerations of palate; callus on fingers or dorsum of hand	• Enlarged salivary glands • Stomatitis, loss of dental enamel • Fluid, electrolyte, and acid–base imbalances • Dysrhythmias • Esophageal tears, stomach rupture
Binge-eating disorder	• Usually overweight or obese • Recurrent episodes of binge eating (2 or more days a week for 6 months) • Episodes characterized by the following: • Eating more rapidly than usual • Eating until uncomfortably full • Eating large amounts of food when not physically hungry • Eating alone due to embarrassment over quantity • Disgust, depression, or guilt following a binge episode • Marked distress about binging behavior	• Type 2 diabetes • Hypertension, hyperlipidemia • Coronary heart disease, heart failure • Gallbladder disease • Depression, social isolation

be supervised and a firm but empathetic attitude conveyed about the importance of adequate food intake. Intravenous feeding may be required in some cases. Psychologic treatment focuses on providing emotional support during weight gain and helping patients base their self-esteem on factors other than weight (e.g., personal relationships, satisfaction with achieving occupational goals) (Longo et al., 2013). Cognitive-behavioral therapy (CBT) or psychotherapy may be used; families often are included in the treatment program. Antidepressants may be used, although randomized clinical trials are inclusive regarding the effectiveness of treatment with medication.

The goal of bulimia treatment is to reduce or eliminate binge eating and purging behavior. A combination of nutritional counseling and therapy, psychosocial interventions, and medications may be used. Nutritional counseling is directed at establishing a regular meal pattern and encouraging an appropriate amount of regular exercise. An antidepressant drug such as fluoxetine (Prozac) may benefit the patient with bulimia nervosa and help prevent relapse. CBT also is used to treat bulimia, focusing on excessive concerns about weight, persistent dieting, and binge–purge behaviors.

Treatment for patients with binge-eating disorder focuses on establishing healthy eating patterns, psychosocial therapy (including CBT and group counseling) to address underlying issues, and management of obesity and its complications. Patients with BED also may benefit from an SSRI or other antidepressant drug.

●○● NURSING CARE

Health Promotion

Nurses can be instrumental in identifying patients with eating disorders and referring them for treatment. It is particularly important to identify these disorders early to prevent adverse effects on growth and increase the success of treatment. Nutritional education, promoting a healthy body image, and identification of risk factors and early signs of each disorder will increase the likelihood of successful treatment.

Assessment

In addition to the components of a standard nutritional assessment, a careful history related to weight loss patterns and descriptions of psychologic symptoms commonly associated with eating disorders should be explored. These symptoms include overvalued ideas about the importance of body shape and weight. Assess the patient for distractibility, depression, anxiety, agitation, sleep disturbance, obsessionality, and compulsivity.

Priorities of Care

Nursing priorities of care include monitoring indicators of nutritional status, including fluid and electrolyte status, establishing a therapeutic relationship with the patient, and supporting a psychosocial and behavioral treatment plan.

SAFETY ALERT

Refeeding syndrome is an uncommon but serious adverse effect associated with aggressive refeeding in the context of semistarvation. The nurse should monitor for fluid and electrolyte imbalance, hypophosphatemia, hypomagnesemia, rapid and significant peripheral edema, and signs and symptoms associated with heart failure when refeeding involves aggressive treatment such an enteral or parental feedings.

Diagnosis, Outcomes, and Interventions

The nurse is an integral part of the eating disorders treatment team. *Imbalanced Nutrition: Less Than Body Requirements* is a primary nursing diagnosis for patients with anorexia or bulimia, and *Imbalanced Nutrition: More Than Body Requirements* is a priority nursing diagnosis for patients with binge-eating disorder. The following nursing diagnoses also should be considered:

- *Ineffective Therapeutic Regimen Management*
- *Chronic Low Self-Esteem*
- *Disturbed Body Image*
- *Dysfunctional Family Processes*
- *Powerlessness*

When planning and implementing care, consider the following nursing activities:

- Regularly monitor weight, using standard conditions. *Weight gain or loss provides information about the effectiveness of care, as well as the patient's risk for complications.*
- Monitor food intake during meals, recording percentage of meal and snack consumed. Maintain close observation for at least 1 hour following meals; do not allow patient alone in bathroom. *Observing the patient during and after meals helps prevent disposal of food and purging behavior after eating. Recording actual food intake allows accurate calculation of calorie intake.*
- Serve balanced meals, including all nutrient groups. Increase serving size gradually. *The patient may find normal food servings overwhelming, reducing the desire to eat. Calorie intake is initially limited to prevent complications associated with refeeding, then gradually increased.*
- Serve frequent, small feedings of cold or room temperature foods. *Cool foods reduce sensations of early satiety, promoting greater food intake at a meal or snack.*
- Administer a multivitamin and mineral supplement to replace losses.

Patients with eating disorders require extended treatment of the disorder. Involvement of the family and social support persons is vital to success. Encourage family members to participate in teaching and nutritional counseling sessions. Discuss the value of family therapy to address issues that have contributed to the disorder. Emphasize the need to provide consistent messages of support for healthy eating habits. Discuss using rewards for food and calorie intake rather than weight gain. Provide referrals to a dietitian, nutritional support team, counseling, and support groups for people with eating disorders.

CHAPTER HIGHLIGHTS

- Developmental, genetic, sociocultural, psychologic, and physiologic factors may play a role in nutritional disorders. Consequently, a holistic approach to nursing care is vital.
- The nursing role involves coordinated and interprofessional care emphasizing health screening and teaching.
- **Nutritional disorders are common, affecting people worldwide, and contributing significantly to mortality and morbidity. Malnutrition is a serious problem in underdeveloped nations, whereas obesity and its consequences are more prevalent in the United States and other industrialized societies. They often cause serious health problems, such as hypertension, heart disease, fluid and electrolyte imbalances, disability, and death.**
- **Treatment of nutritional disorders requires skilled and holistic nursing care provided within the context of an interprofessional team that often includes the physician, dietitian, pharmacist, and social worker.**
- Obesity, defined as excess adipose tissue and a BMI greater than 30 kg/m^2, is linked with many disorders, including type 2 diabetes, coronary heart disease, gallbladder disease, and osteoarthritis.
- Exercise and reduced kilocalorie intake are the mainstays of obesity treatment. Drugs that suppress the appetite or interfere with fat absorption in the gut may be used to facilitate weight loss in patients with multiple risk factors for obesity complications or people who have had difficulty achieving weight loss through diet and exercise.
- Bariatric surgery is a treatment option for patients who are morbidly obese. The primary types of bariatric surgery used in the United States are restrictive procedures that limit stomach capacity and food consumption, and combination restrictive/malabsorptive procedures that limit both capacity and nutrient absorption.
- **Effective treatment of nutritional disorders involves physical, social, cognitive, and behavioral nursing action over time and should include relapse prevention interventions.**
- Nursing care for patients with obesity focuses on health promotion, education, health coaching, and support of the prescribed treatment plan.
- In the United States, protein-calorie malnutrition is a common problem among hospitalized patients. Malnutrition increases the risk for complications and impairs healing. Early identification and prevention are the primary focuses of treatment; nurses can be instrumental in identifying at-risk patients (e.g., older adults, patients living alone, people on extended NPO status).

- Refeeding of malnourished patients is a gradual process. Enteral feedings (oral or by feeding tube) are preferred whenever possible. Parenteral nutrition may be required when enteral feeding is not possible or not tolerated by the patient.
- Eating disorders, including anorexia nervosa, bulimia nervosa, and binge-eating disorder, can be difficult to treat effectively and maintain in remission. While patients with anorexia typically are underweight and malnourished, resisting efforts to achieve a normal weight, patients with bulimia are more likely to be of normal weight and those with binge-eating disorder are more likely to be overweight or obese.
- Treatment for eating disorders is multifaceted, including physical care to restore electrolyte balance and treat complications, nutritional counseling and therapy, psychosocial therapy, family support, and possibly medications.

TEST YOURSELF NCLEX-RN® REVIEW

1. While reviewing the medical history, the nurse determines a patient is at risk for obesity. Which is the greatest risk factor for the development of obesity?
1. Was adopted at 2 months of age.
2. Does not engage in regular activity.
3. Is allergic to chocolate and strawberries.
4. Usual diet includes fast-food lunches twice a week.

2. A patient on a reduced-calorie diet asks the nurse what she can do to lose weight faster, because most weeks she loses no more than 0.5 lb. "At this rate, it will take me years to get to my goal!" What should the nurse respond to this patient?
1. "Let's reevaluate your long-term goal. Perhaps it was set too low for you."
2. "You sound frustrated. Would you like to take some time off from your diet and exercise plan?"
3. "Perhaps we should look into a diet supplement since you are unable to stick with your prescribed diet plan."
4. "A pound of body fat equals 3500 calories. Let's re-evaluate your diet and exercise plan for calorie intake and expenditure."

3. The nurse suspects a patient is experiencing protein-calorie malnutrition. What did the nurse assess to come to this conclusion? (Select all that apply.)
1. thin hair
2. dry flaking skin
3. anxiety and agitation
4. recent 5-lb weight loss
5. hyperactive bowel sounds

4. The nurse is planning care for a patient scheduled for bariatric surgery. Which interventions should the nurse include that support the diagnosis *Imbalanced Nutrition: More Than Body Requirements*? (Select all that apply.)
1. Establish realistic weight loss goals.
2. Determine realistic activity objectives.
3. Review behavior modification strategies.
4. Determine strategies to prevent stress eating.
5. Set small goals and offer positive encouragement.

5. The nurse is negotiating goals of care with a patient being treated for anorexia nervosa. Which would be a realistic goal for this patient?
1. Gain 2 pounds per week.
2. Participate in family counseling.
3. Rest alone in room following meals.
4. Consume 100% of a 2500-calorie diet every day.

6. The nurse is identifying a diagnosis appropriate for a patient with obesity. Which diagnosis is the priority for a patient with a BMI of 30.4 kg/m^2 and a waist-to-hip ratio of 1.1?
1. *Ineffective Coping*
2. *Deficient Knowledge: Diet*
3. *Health-Seeking Behaviors: Weight Loss*
4. *Risk for Impaired Tissue Perfusion: Cardiac*

7. The nurse is providing discharge instructions to a patient recovering from bariatric surgery. Which patient statement indicates diet teaching has been effective?
1. "I should drink fluids with meals to aid with digestion."
2. "I should drink caffeinated carbonated liquids to aid with weight loss."
3. "I can eat anything that I want because weight loss will occur regardless of food intake."
4. "I should eat four to six small meals each day that are low-fat, high in complex carbohydrates, and high in protein."

8. The home care nurse is planning care for a home-bound older adult who is losing an unplanned 1 to 2 pounds each month. What should this patient's plan of care include? (Select all that apply.)
1. Meals-on-Wheels deliveries
2. Referral for diagnostic studies
3. Use of nutritional supplements
4. Follow-up by primary care physician
5. Placement in a residential care facility
6. Transportation to congregate senior meals

9. The nurse is concerned that a postoperative patient is at risk for malnutrition. Which intervention would be a priority to prevent malnutrition in this patient?
1. daily weights
2. aggressive pain management
3. maintaining intravenous flow
4. requesting early restoration of oral intake

10. Three days after gastric bypass surgery, a patient complains of increasing abdominal pain. Bowel sounds are absent and the abdomen is firm and very tender. What should the nurse do first?
1. Report findings to the surgeon.
2. Evaluate the effectiveness of analgesia.
3. Ambulate the patient to promote peristalsis.
4. Chart assessment data and continue to monitor.

See Test Yourself answers in Appendix B.

23 Nursing Care of Patients with Upper Gastrointestinal Disorders

LEARNING OUTCOMES

1. Describe the pathophysiology of common disorders of the mouth, esophagus, and stomach.
2. Distinguish manifestations and diagnostic test results and correlate with pathophysiologic processes involved in upper gastrointestinal disorders.
3. Explain interprofessional care for patients with upper gastrointestinal disorders.
4. Describe the role of the nurse in interprofessional care of patients with upper gastrointestinal disorders.

CLINICAL COMPETENCIES

1. Assess the health status of patients with upper gastrointestinal disorders.
2. Monitor, identify, document, and report significant manifestations of upper gastrointestinal disorders and their complications.
3. Plan patient-centered nursing care using evidence-based practice guidelines, research, and, as appropriate, health information technology.
4. Determine priority nursing diagnoses, problems, and interventions based on assessed data.
5. Administer medications and prescribed care knowledgeably and safely.
6. Integrate and coordinate interprofessional care into plan of care.
7. Construct and revise individualized plans of care considering the culture and values of the patient.
8. Plan and provide patient and family teaching to promote, maintain, and restore health.

MAJOR CHAPTER CONCEPTS

- Health problems of the upper gastrointestinal (GI) tract are common. Many are self-limiting and involve nursing care focused on symptom management and patient education.
- Chronic conditions of the upper GI tract are common and nursing interventions include patient teaching focused on improving and maintaining adequate nutrition and preventing complications.
- Acute GI bleeding is a life-threatening condition requiring interprofessional care interventions aimed at immediate resolution of the source of bleeding and aggressive fluid resuscitation.
- Cancers of the upper GI tract are serious, often diagnosed in the late stages, and require multiple treatment and coordinated interprofessional care.

KEY TERMS

achalasia, *604*
anorexia, *617*
Curling's ulcers, *617*
Cushing's ulcers, *617*
dumping syndrome, *620*
dysphagia, *604*
erosive (stress-induced) gastritis, *617*
gastric mucosal barrier, *606*
gastritis, *616*
gastroesophageal reflux, *599*
hematemesis, *607*
hematochezia, *607*
melena, *607*
nausea, *589*
occult bleeding, *607*
partial gastrectomy, *620*
peptic ulcer disease (PUD), *609*
peptic ulcers, *609*
steatorrhea, *612*
stomatitis, *591*
total gastrectomy, *620*
ulcer, *609*
vomiting, *589*
Zollinger-Ellison syndrome, *612*

The upper gastrointestinal tract includes the mouth, esophagus, stomach, and proximal small intestine. Food and fluids, ingested through the mouth, move through the esophagus to the stomach. The stomach and upper intestinal tract (duodenum and jejunum) are responsible for the majority of food digestion. When an acute or chronic condition or disease process interferes with the function of this portion of the gastrointestinal (GI) tract, nutritional status can be affected and the patient may experience symptoms that interfere with functional status and lifestyle.

Nurses provide acute care for the hospitalized patient, coordinate care in ambulatory and long-term care settings, and teach the skills and knowledge needed to manage these conditions at home.

THE PATIENT WITH NAUSEA AND VOMITING

Nausea and vomiting are common gastrointestinal symptoms. **Nausea** is a vague but unpleasant sensation of sickness or queasiness. It may or may not be accompanied by (and possibly relieved by) vomiting. **Vomiting** is the forceful expulsion of the contents of the upper GI tract resulting from contraction of muscles in the gut and abdominal wall. Nausea and vomiting without abdominal pain are commonly associated with food poisoning, infectious gastroenteritis (discussed in Chapter 24), gallbladder disease, or ingestion of toxins (drugs or alcohol). When associated with severe abdominal pain, they may indicate a serious disorder such as peritonitis, acute gastrointestinal obstruction, or pancreatitis.

Pathophysiology

Nausea, an unpleasant subjective sensation, occurs when the vomiting center in the medulla of the brain is stimulated. Distention of the duodenum is a common stimulus for nausea. The vomiting center can be stimulated by input from several different sources:

- The GI tract, produced by distention, irritation, or infection
- The vestibular system of the ear
- Higher central nervous system (CNS) centers in response to certain sights, smells, or emotional experiences
- Chemoreceptors outside the blood–brain barrier that are stimulated by drugs, chemotherapeutic agents, toxins, systemic disorders, and pregnancy
- Disorders such as acute myocardial infarction and heart failure commonly produce nausea and vomiting, possibly due to direct stimulation of the vomiting center by hypoxia
- Increased intracranial pressure (e.g., due to intracranial bleeding or a tumor) produces vomiting that may or may not be accompanied by nausea.

Anorexia (loss of appetite) commonly precedes nausea, just as nausea frequently precedes vomiting. Vomiting, a response that requires coordinated movements of the thorax and abdominal wall, the gut, the pharynx, and muscles of the mouth and face, is coordinated by the brainstem. *Emesis* (or *vomitus*) is produced when inspiratory muscles of the thorax (including the diaphragm) and abdomen contract, increasing intrathoracic and intra-abdominal pressures. The gastroesophageal sphincter relaxes, and the larynx moves upward to facilitate oral expulsion of gastric contents.

In addition to the subjective sensation of queasiness, nausea frequently is accompanied by autonomic nervous system manifestations such as pallor, sweating, tachycardia, and increased salivation (a reflex protecting the teeth from stomach acid). Vomiting, which stimulates the vagus nerve and parasympathetic nervous system, may be accompanied by dizziness, light-headedness, hypotension, and bradycardia.

Potential complications of vomiting include dehydration, hypokalemia, metabolic alkalosis (from loss of hydrochloric acid from the stomach), aspiration with resulting pneumonia, and rupture or tears of the esophagus.

●○● INTERPROFESSIONAL CARE

In most cases, nausea and vomiting are self-limited and require no treatment. However, repeated studies show nausea is the most debilitating effect of chemotherapy for many patients (Papadakis & Tierney, 2013) and is still a major problem for many surgical patients (Hambridge, 2012). Moreover, evidence suggests healthcare professionals underestimate the occurrence of nausea in postoperative and chemotherapy patients and that it is often poorly assessed and underreported (Papadakis & Tierney, 2013). Identifying the etiology of nausea and vomiting will facilitate the development of an effective treatment plan.

Vomiting can have several potentially serious physical effects. Postoperative nausea and vomiting (PONV) can delay healing and postpone discharge. Strong contractions of the abdominal wall and thoracic skeletal muscles can increase postoperative pain. Pressure may burst wounds, increase stress on the eye following ophthalmic surgery, and can dangerously increase intracranial pressure in cases of intracerebral hemorrhage or injury. Chronic and prolonged vomiting may cause fluid and electrolyte imbalance, disrupt acid–base balance, and lead to nutritional deficits. Prolonged vomiting can cause pitting and erosion of tooth enamel, causing dental decay. If vomiting is severe or accompanied by other symptoms, acute care may be required to determine the underlying problem and prevent or treat complications.

Diagnostic tests may include serum electrolytes; pregnancy testing if indicated; liver, pancreatic, and renal function studies; and imaging studies (flat plate of the abdomen, abdominal CT scan) to detect gastrointestinal obstruction. An upper endoscopy may be performed (see Chapter 21 for nursing care of the patient undergoing an upper endoscopy). CT scan or MRI of the head may be ordered if an intracranial problem is suspected as the cause. Specialized testing such as gastrointestinal motility studies may be indicated when other diagnostic studies are negative for an anatomic cause of nausea and vomiting.

Food is initially withheld, although clear liquids in small quantities are encouraged to prevent dehydration. Dry foods such as soda crackers may reduce nausea and promote comfort.

MEDICATIONS

Unless vomiting is associated with pregnancy, antiemetic medications may be prescribed to prevent or control nausea and vomiting. These drugs fall into a number of different classes, and often are more effective when given in combination.

- Serotonin receptor antagonists are widely used drugs available for patients experiencing nausea and vomiting due to chemotherapy. They are effective when given only once or twice a day, an additional advantage. Palonosetron (Aloxi), with a half-life of 40 hours, is particularly effective for nausea and vomiting related to chemotherapy. Ondansetron (Zofran) is a commonly prescribed drug in this class.
- Dopamine antagonists include the phenothiazines (e.g., prochlorperazine [Compazine] and thiethylperazine [Torecan]), butyrophenones (haloperidol [Haldol] and droperidol [Inapsine]), and other drugs such as metoclopramide (Reglan). These drugs, although effective, can produce extrapyramidal symptoms, sedation, and hypotension.
- Antihistamines such as meclizine (Antivert), hydroxyzine (Vistaril, Atarax), and dimenhydrinate (Dramamine) are primarily used to treat nausea and vomiting arising from vestibular center stimuli (e.g., motion sickness).
- Two drugs classed as cannabinoids, related to marijuana, are approved to treat nausea and vomiting associated with chemotherapy. These drugs, dronabinol (Marinol) and nabilone (Cesamet),

may produce unpleasant psychiatric effects such as dissociation and dysphoria, and are contraindicated for patients with psychiatric disorders. Tachycardia and hypotension are additional possible side effects.

- While corticosteroids are not approved as a class for treating nausea and vomiting, methylprednisolone (Solu-Medrol) and dexamethasone (Decadron) may be used in combination to treat vomiting associated with cancer treatment.
- Lorazepam (Ativan) is a benzodiazepine drug approved for use as an antiemetic. It produces a degree of sedation, but can suppress anticipatory vomiting (e.g., before chemotherapy). It also helps control extrapyramidal symptoms associated with the phenothiazine antiemetics.
- A new class of antiemetics, neurokinin receptor antagonists, is primarily used to prevent nausea and vomiting associated with chemotherapy. Aprepitant (Emend) is a prototype of this class.

Nursing responsibilities and patient education for antiemetic drugs are outlined in the Medication Administration box on page 592.

COMPLEMENTARY AND ALTERNATIVE MEDICINE

Mind–body interventions such as biofeedback, guided imagery, music therapy, and hypnosis may be effective for some patients with nausea. Biofeedback uses machinery to translate physiologic processes into audible or visible signals to teach the patient to exert conscious control over those processes. In guided imagery, the patient uses imagination to invoke specific images to modify physiologic responses. Music therapy involves creating or listening to music to affect physiologic and psychologic responses. In hypnosis, an altered mind state is induced to make the patient receptive to suggestions. Several studies suggest that acupressure and acupuncture may help relieve chemotherapy-induced nausea and vomiting when combined with standard therapies (Enblom et al., 2011). A recent meta-analysis indicates more research is needed to clearly establish the efficacy of acupuncture for the treatment of nausea and vomiting (Enblom et al., 2011). See the Moving Evidence into Action box.

Ginger, an aromatic root frequently used in cooking, may be helpful in relieving nausea and vomiting (Lee & Oh, 2013; Marx et al., 2013). In limited clinical trials, it has been shown to be safe for reducing nausea associated with pregnancy. It may also help relieve nausea associated with cancer chemotherapy. Ginger can inhibit platelet aggregation, and may increase the risk of bleeding in patients taking antiplatelet or anticoagulant drugs (Marx et al., 2013).

●○● NURSING CARE

Health Promotion

Developing a patient-centered treatment plan in collaboration with the interprofessional team may prevent the nausea and vomiting associated with chemotherapy-induced nausea and vomiting (CINV) and postoperative nausea and vomiting (PONV).

Assessment

Assessment of the patient is vital to help determine the cause of nausea and vomiting, and to rule out underlying systemic disease or acute conditions that require immediate care (e.g., bowel obstruction). When the cause is known or no other acute symptoms are present, nursing interventions can promote comfort and prevent complications.

- *Health history:* Determine if the patient has a past history with nausea and vomiting. Personal or family history of PONV or motion sickness increases an individual's likelihood of experiencing both PONV and CINV. Establish onset and duration of nausea and frequency, quantity, and characteristics of emesis. Ask the

Moving Evidence into Action

Complementary Treatment for Nausea and Vomiting

Patients undergoing regimens for cancer treatment often experience treatment-related nausea and vomiting. While newer antiemetic drugs are increasingly effective in preventing and treating radiation and chemotherapy-induced nausea and vomiting (CINV), many patients still experience both acute and delayed nausea and vomiting. A study by Enblom and associates (2011) examined the effectiveness of acupuncture for cancer patients receiving radiotherapy over abdominal/pelvic regions.

Acupuncture is a Chinese medicine technique that uses sterile needles to restore energy (*Qi*) balance in the body. It is believed that acupuncture needles applied to PC6, the traditional antiemetic point located between the tendons of the palmaris longus and flexor carpi radials at 2 inches proximal to the wrist crease, will alleviate nausea and vomiting.

All patients in the study received standard therapy used to treat nausea and vomiting. One study group received acupuncture bilaterally at PC6; a second placebo group had "sham" acupuncture administered to points proximal to the PC6 site and the needles were devised to not actually penetrate the skin. The control group received standard therapy without acupuncture. The patients in the acupuncture cohort and the patients in the placebo group experienced significantly less nausea than those in the control group who received only standard care. The researchers concluded nonspecific factors such as extra care and high expectations of positive treatment effects reduced nausea and vomiting.

Implications for Nursing

Several studies have found acupuncture and acupressure to be an effective adjunct for relieving nausea and vomiting associated with treatment for cancer. Nurses working in oncology units or with patients undergoing radiation and chemotherapy must be familiar with these treatments and be prepared to support patients who choose these complementary options. Patients may be less reluctant to start and continue cancer treatment if they perceive the ability to help control at least some of its unpleasant adverse effects.

Moving Knowledge into Action

1. What are the mechanisms by which chemotherapy produces nausea and vomiting? Why are some regimens associated with more CINV than others?
2. Why is *preventing* nausea and vomiting from the onset of cancer treatment so important?
3. Do you think acupressure and acupuncture are likely to be effective in a patient who does not "believe in all that alternative medicine stuff?" Why or why not?
4. Develop a teaching plan for a patient who will be starting radiation therapy known to produce nausea and vomiting in most patients who receive it.

patient what treatments he or she has used to control nausea and vomiting. Determine if patient is experiencing signs and symptoms associated with dehydration or electrolyte balance.

- *Physical assessment:* Physical assessment should focus on signs and symptoms of dehydration and electrolyte imbalance and include vital signs, skin turgor, mucous membranes, and weight.

Priorities of Care

Prolonged nausea and vomiting can cause fluid, electrolyte, and nutritional deficits and can severely affect patients' health. Monitor carefully for these untoward effects.

Diagnosis, Outcomes, and Intervention

Nursing care for the patient experiencing nausea and vomiting is supportive and educational. Both CINV and PONV should be treated aggressively with an aim toward preventing nausea and vomiting. CINV can result in an anticipatory response, which is nausea and vomiting occurring before drug administration due to a conditioned response to previous negative experience.

Expected Outcome: Patient's nausea will be relieved as evidenced by ample appetite, adequate hydration, absence of vomiting, and patient's reported relief from nausea.

Nausea

The nursing diagnosis of nausea is defined as a subjective, unpleasant, wavelike sensation in the throat, epigastric region, or abdomen that may lead to vomiting (Wilkinson, 2014).

- Monitor subjective complaints of nausea. *Nausea is a subjective sensation best described by the patient.*
- Monitor vital signs, skin turgor and condition, and weight. Maintain accurate intake and output records. Monitor amount, color, and specific gravity of urine. *Nausea can cause aversion to food and fluids, leading to dehydration even when it is not accompanied by vomiting.*
- Administer antiemetic medication as ordered, prior to meals and before treatments or procedures known to stimulate nausea. *Preventing nausea is particularly important for patients receiving chemotherapy, to avoid the association between the treatment and nausea. Preventing PONV is also important to expedite recovery and avoid prolonged hospitalization.*
- Instruct to deep breathe to voluntarily suppress the vomiting reflex. *Controlling vomiting helps prevent dehydration and other complications associated with prolonged or severe vomiting.*
- Instruct to consume small quantities of clear fluids and dry foods at separate times. *Separating the intake of dry foods and fluids helps reduce the nausea stimulus.*

Continuity of Care

Studies indicate healthcare providers underestimate postdischarge nausea and vomiting and that up to one-third of ambulatory surgery patients experience PONV following discharge (Hambridge, 2012). Providing thorough discharge teaching and ensuring patients have access to appropriate follow-up care will prevent unneeded rehospitalization. Patients at risk for PONV or CINV should be contacted after discharge to determine if any nausea and vomiting was experienced and follow-up care should be initiated as needed.

Instruct the patient to restrict intake to small quantities of clear liquids (tea, apple juice, broth, Jell-O) and dry foods such as soda crackers to help reduce nausea and prevent vomiting. Teach to avoid food-preparation odors if they produce nausea. Advise to restrict fluid intake for 1 hour before and after meals. Stress the need to maintain fluid intake to prevent dehydration and the importance of seeking additional medical help if unable to take in fluids or keep food down. Provide information about electrolyte replacement solutions such as sports drinks and commercially available electrolyte replacement solutions.

Evidence for Nursing Care

The Patient with Nausea and Vomiting

Selected resources that nurses may find helpful when planning evidence-based nursing care follow.

- Buckley, L., & Caple, C. (2013). Evidence-based care sheet: Chemotherapy-related nausea and vomiting. Glendale, CA: Cinahl Information Systems.
- Hambridge, K. (2012). Assessing the risk of post-operative nausea and vomiting. *Nursing Standard, 27*(18), 35–43.
- Viale, P. M. (2012). Efficacy and cost: Avoiding undertreatment of chemotherapy-induced nausea and vomiting. *Clinical Journal of Oncology Nursing, 16* (Suppl.), E133–E141. doi:10.1188/12.CJON.E133-E141

Disorders of the Mouth

Inflammations, infections, and neoplastic lesions of the mouth affect food ingestion and nutrition. Oral lesions may have a variety of causes, including infection, trauma, irritants such as alcohol, and hypersensitivity. Appropriate treatment of the disorder, any underlying factors, and associated symptoms is essential.

THE PATIENT WITH STOMATITIS

Stomatitis, inflammation and ulcers of the oral mucosa, is a common disorder of the mouth. Viral infection is the most common cause. Other causes include bacterial or fungal infections, mechanical trauma (e.g., cheek biting), irritants (e.g., tobacco or ill-fitting dentures), nutritional deficiencies, and chemotherapeutic agents. Stomatitis often affects people who are immunocompromised (e.g., patients with HIV disease or who have cancer, and frail older adults). Box 23–1 lists common risk factors for stomatitis.

BOX 23–1 Risk Factors for Stomatitis

- Age > 65 years
- Impaired immune status (HIV disease, cancer, diabetes)
- Chronic renal failure or heart failure
- Chemotherapy, radiation therapy, stem cell transplant
- Oxygen therapy, mouth breathing
- Medications (antibiotics, phenytoin, anticholinergics, corticosteroids)
- Poor oral hygiene, ill-fitting dentures
- Tobacco or alcohol use

MEDICATION ADMINISTRATION

Drugs Used to Prevent and Treat Nausea and Vomiting

SEROTONIN RECEPTOR ANTAGONISTS

dolasetron (Anzemet)

granisetron (Kytril)

ondansetron (Zofran)

palonosetron (Aloxi)

The serotonin receptor antagonists suppress nausea and vomiting by blocking the effect of serotonin on vagal afferent nerves that stimulate the vomiting center. Their primary uses are to prevent and treat vomiting associated with chemotherapy, radiation therapy, and surgery.

Nursing Responsibilities

- Administer 30 to 60 minutes prior to chemotherapy or surgery as directed.
- May be given orally or intravenously (push or infusion; follow directions specific to the drug used).
- Monitor liver function and clotting studies; report abnormal levels to the physician.

Health Education for the Patient and Family

- Take this drug exactly as directed.
- This drug may be taken without regard to food intake.
- Headache is a common side effect of these drugs; use acetaminophen or another mild analgesic as directed by your physician.

DOPAMINE ANTAGONISTS

chlorpromazine (Thorazine)

prochlorperazine (Compazine)

promethazine (Phenergan)

thiethylperazine (Torecan)

haloperidol (Haldol)

droperidol (Inapsine)

metoclopramide (Reglan)

These drugs act by blocking dopamine receptors in the chemoreceptor trigger zone (CTZ). Their primary use is to suppress the nausea and vomiting associated with surgery, cancer chemotherapy, and toxins. The major adverse effects associated with these drugs are sedation, hypotension, and extrapyramidal reactions. Older adults are more sensitive to the effects of these drugs; a lower dose often is indicated.

Nursing Responsibilities

- Administer orally or parenterally as ordered before surgery or before meals and procedures known to produce nausea and vomiting.
- These drugs may interact with a number of other medications, often increasing their sedative and hypotensive effects.
- Administer with caution to older adults, closely monitoring for adverse effects such as confusion, agitation, or changes in vital signs.
- Monitor for evidence of extrapyramidal symptoms, including tremor, restlessness, hyperactivity, anxiety, impaired coordination; notify physician if symptoms develop.

Health Education for the Patient and Family

- Use the drug as ordered; do not increase your dose without consulting your primary care provider.
- These drugs may cause drowsiness. Avoid using other CNS depressants such as alcohol while taking these drugs.
- Change positions from lying to sitting and sitting to standing slowly because these drugs can cause light-headedness or dizziness.
- Promptly report changes in coordination, tremors, difficulty speaking or swallowing, or weakness to your physician.

SUBSTANCE P/NEUROKININ RECEPTOR ANTAGONIST

aprepitant (Emend)

Aprepitant is a new drug that can prevent both acute and delayed chemotherapy-induced nausea and vomiting when given in combination with other antiemetic drugs. It is well absorbed when given orally, and has a prolonged duration of action.

Nursing Responsibilities

- Administer daily for 3 days, giving the first dose 1 hour before chemotherapy.
- Can be given with food or on an empty stomach.
- Monitor for toxic and desired effects of other drugs, including chemotherapy drugs, corticosteroids, and warfarin (Coumadin), because aprepitant can affect metabolism and blood levels.

Health Education for the Patient and Family

- Use barrier contraception while taking this drug because oral contraceptives will be less effective.
- Promptly contact your physician if you develop skin rash, difficulty breathing, changes in heartbeat or blood pressure, dizziness or confusion, leg or abdominal pain, or rectal bleeding.
- Contact your physician before taking any new prescription, over-the-counter, or herbal preparations.

ANTIHISTAMINES

buclizine (Bucladin-S)

cyclizine (Marezine)

dimenhydrinate (Dramamine)

diphenhydramine (Benadryl)

hydroxyzine (Vistaril, Atarax)

meclizine (Antivert)

Antihistamines are primarily used to treat the nausea and vomiting associated with motion sickness. They act by blocking histamine and acetylcholine (muscarinic) receptors in the neural pathway from the inner ear to the vomiting center in the brainstem.

Nursing Responsibilities

- Do not administer these drugs to patients for whom anticholinergic drugs are contraindicated: people with narrow-angle glaucoma, urinary retention, or bowel obstruction.
- May be administered orally, parenterally, or rectally, depending on the preparation and the patient's ability to tolerate oral preparations.
- Use with caution in patients who are taking other CNS depressants or antihistamine preparations, tricyclic antidepressants, or monoamine oxidase inhibitors.

Health Education for the Patient and Family

- These drugs frequently cause drowsiness. Use caution when operating machinery or performing tasks requiring mental alertness.
- Avoid using alcohol or other substances that cause drowsiness or sedation while taking these drugs.
- The medication may cause dry mouth. Sips of water, ice chips, hard candies, and sugarless gum can be used for comfort.
- Use sunscreen and protective clothing to protect from sunburn while using these drugs.

CANNABINOIDS

dronabinol (Marinol)

nabilone (Cesamet)

Drugs in this class, which contain the same active ingredient as marijuana, are reserved for use to relieve nausea and vomiting associated with cancer chemotherapy in patients who have not responded to treatment with other antiemetics. Their action is thought to result from inhibition of the vomiting center in the medulla.

MEDICATION ADMINISTRATION (*continued*)

Nursing Responsibilities

- Use with caution in older adults and people with a history of cardiovascular disease or substance abuse. These drugs are contraindicated for patients with a history of psychiatric disorders.
- Monitor for adverse effects such as dizziness, tachycardia, hypotension, impaired thinking and judgment, incoordination, irritability, depersonalization, distorted vision, and hallucinations.

Health Education for the Patient and Family

- Take the drug 1 to 3 hours before chemotherapy.
- Change positions slowly after taking this drug to prevent dizziness.
- You may experience distorted thinking, visual disturbances, confusion, and other mental symptoms while taking this drug.
- Keep this and all drugs out of the reach of children. Do not share this drug with anyone else.

FAST FACTS

- Herpes simplex (cold sore) is the most frequent viral cause of stomatitis; others include primary varicella zoster (chickenpox), Epstein-Barr virus, influenza, cytomegalovirus, and HIV.
- Overgrowth of *Candida albicans* is the most frequent fungal cause of stomatitis, usually following antibiotic or corticosteroid therapy.
- About 40% of people undergoing chemotherapy to treat cancer experience *oral mucositis*, a type of stomatitis; 75% of those undergoing chemotherapy in preparation for bone marrow or stem cell transplant develop oral mucositis.
- Most patients undergoing radiation therapy of the head and neck develop oral mucositis.

Pathophysiology and Manifestations

The oral mucosa, which lines the oral cavity, is a relatively thin, fragile layer of stratified squamous epithelial cells that constantly is being replaced. The blood supply to the oral mucosa is rich. As epithelial cells slough, stem cells in the submucosa develop into epithelial cells to replace those that are lost.

Frequent exposure to the environment, a rich blood supply, and the oral mucosa's delicate nature increase the risk of infection or inflammation, reaction to toxins, and trauma. Stomatitis results from persistent damage to oral mucosal cells. Damage is initially superficial, progressing to ulceration and involvement of the entire epithelium. Finally, healing begins within 2 to 4 weeks.

Oral mucositis progresses through identifiable stages. Radiotherapy and chemotherapy damage the DNA of epithelial cells, resulting in necrosis and death of some cells. This stimulates the release of inflammatory mediators that further damage tissues, causing additional epithelial cells to die. As a result, the oral mucosa thins. Tumor necrosis factor alpha (TNF-α) is released, which activates additional inflammatory cytokines. Tissues below the mucosa are damaged as well. In the ulcerative stage of oral mucositis, irregular ulcers that extend from the epithelium into the submucosa develop. As nerve endings are exposed, this stage is accompanied by significant pain. During the final healing stage, cells in the epithelium proliferate, and the normal thickness of the oral mucosa is restored.

The clinical manifestations of stomatitis vary according to its cause. Table 23–1 outlines common causes of stomatitis with their manifestations and treatment. Chemotherapy or chemical irritation may result in initial generalized redness and swelling, followed by development of deep, irregular ulcerations. Ulcers may be covered with pseudomembranes. Oral pain associated with stomatitis can interfere with the ability to eat, drink, and swallow normally.

Potential complications of stomatitis include malnutrition, fluid and electrolyte imbalance, sepsis, and bacterial endocarditis.

●○● INTERPROFESSIONAL CARE

Stomatitis is diagnosed by direct physical examination and, if indicated, cultures, smears, and evaluation for systemic illness. Treatment addresses both the underlying cause and any coexisting illnesses. An undiagnosed oral lesion present for more than 1 week that does not respond to therapy must be evaluated for malignancy.

Direct smears and cultures of lesions may be obtained to identify causative organisms. If systemic illness is suspected, a variety of diagnostic tests may be ordered to identify the underlying cause.

General treatment measures include providing meticulous oral hygiene, with brushing using a soft brush and flossing (as tolerated). A solution of saline, sodium bicarbonate, or a combination of saline/bicarbonate promotes comfort and healing when used after and between meals.

MEDICATIONS

Using a topical anesthetic, such as a mouthwash of 2% viscous lidocaine diluted with water, diphenhydramine (Benadryl) solution, or benzocaine spray or gel can promote comfort and the ability to consume oral food and fluids.

SAFETY ALERT

Instruct patients to expectorate lidocaine solution, not swallow it, to avoid impairment of swallowing.

Amlexanox (Aphthasol, OraDisc A) or Orabase, a protective paste, may be applied to oral ulcers to promote comfort. Amlexanox also speeds healing of aphthous ulcers. Triamcinolone acetonide may be mixed in Orabase to reduce inflammation and promote healing. Other coating agents include Amphojel or Kaopectate. Sodium bicarbonate mouthwashes may provide relief and promote cleansing, whereas alcohol-based mouthwashes may cause pain and burning and should be avoided. Agents that form a film over exposed nerve endings and deep ulcerations (e.g., Zilactin, Gelclair) may be used in patients with oral mucositis.

Fungal infections often are treated with a nystatin oral suspension; patients are instructed to "swish and swallow" the solution. Clotrimazole lozenges also treat oral fungal infections. If the infection does not resolve, oral antifungal medications such as fluconazole or ketoconazole may be used. Antifungals are usually continued for at least 3 days after symptoms disappear.

Herpetic lesions may be treated with topical or oral acyclovir (Zovirax), famciclovir (Famvir), or valacyclovir (Valtrex). Acyclovir ointment provides comfort and lubrication while limiting the spread

TABLE 23–1 Manifestations and Treatment of Common Stomatitis Conditions

Type	Cause	Manifestations	Treatment
Cold sore, fever blister	Herpes simplex virus	• Initial burning at site • Clustered vesicular lesions on lip or oral mucosa	• Self-limiting • Acyclovir, famciclovir, valacyclovir to shorten course
Aphthous ulcer (canker sore, ulcerative stomatitis)	Unknown; may be type of herpes virus	• Well-circumscribed, shallow erosions with white or yellow center encircled by red ring • Less than 1 cm in diameter • Painful	• Topical steroid ointment • Amlexanox oral paste (Aphthasol) • *Oral prednisone*
Candidiasis (thrush)	*Candida albicans*	• Creamy white, curdlike patches • Red, erythematous mucosa	• Fluconazole (Diflucan) • Ketoconazole (Nizoral) • Clotrimazole troches • Nystatin vaginal troches (dissolved orally) or mouth rinse
Necrotizing ulcerative gingivitis (trench mouth, Vincent's infection)	Infection with spirochetes and bacilli or systemic infection	• Acute gingival inflammation and necrosis • Bleeding, halitosis • Fever • Cervical lymphadenopathy	• Correct any underlying disorders • Warm, half-strength peroxide mouthwashes • Oral penicillin
Oral mucositis	Damage to epithelial cells and stem cells in the submucosa caused by chemotherapy or radiation therapy	• Erythema and inflammation of oral mucosa • Painful, irregularly shaped ulcerations, initially superficial, progressing to deep ulcers that may be confluent (overlapping with one another) • Pseudomembranes covering ulcers • Tissue necrosis with spontaneous bleeding, potential sepsis	• Regular oral hygiene with brushing and flossing • Saline or sodium bicarbonate solution mouth rinses after and between meals • Gelclair mouth rinse before meals for analgesia • Palifermin, an epithelial cell growth factor per FDA, used preventively • Low-level laser therapy

of the virus. Oral preparations reduce the severity of symptoms and the duration of the lesions.

Bacterial infections are treated with antibiotics based on cultures and smears. Oral penicillin is the treatment of choice if the patient is not allergic and the cultured bacteria are sensitive. Nursing implications for selected drugs used to treat stomatitis are outlined in the accompanying Medication Administration box.

An epithelial cell growth-stimulating factor, palifermin (Kepivance), reduces the incidence and duration of oral mucositis in patients undergoing high-dose chemotherapy in preparation for bone marrow or stem cell transplant.

●○● NURSING CARE

Health Promotion

Nurses can help prevent stomatitis by identifying patients at risk and suggesting measures to reduce the likelihood that stomatitis will develop. Teach and encourage all patients to regularly perform mouth care, including teeth brushing and flossing. Provide frequent mouth care with nondrying agents for patients who are unable to provide self-care. Encourage patients with ill-fitting dentures or other dental prostheses (such as partial plates) to see a qualified dentist or denturist. Suggest patients taking an extended course of antibiotic therapy or who have impaired immune function consume 8 oz of yogurt containing live bacterial cultures or 8 oz of buttermilk daily unless contraindicated. Discuss dietary modifications, such as limiting consumption of highly spiced or acidic foods and avoiding very hot beverages. Patients undergoing chemotherapy or radiation therapy should avoid use of alcohol and tobacco because these substances further damage oral mucosa, increasing the risk for oral mucositis.

Assessment

Oral assessment is important not only for patients who have been diagnosed with stomatitis, but also for those with risk factors, manifestations, or evidence of possible complications (e.g., recent weight loss).

- *Health history:* Ask about mouth pain, altered taste, lack of appetite, malaise; presence of dentures, regularity of dental care; current health status including chronic diseases; current medications; use of alcohol or tobacco.
- *Physical assessment:* Inspect lips, gums, teeth, interior cheeks, tongue and base of tongue, soft and hard palate; tonsils; and oral pharynx. Observe and assess general health status including temperature, weight. For patients undergoing chemotherapy and radiation therapy, expert groups recommend consistent use of an oral grading system to assess the oral cavity at regular intervals (Caplinger et al., 2010; Dauncey et al., 2012).
- *Diagnostic tests:* Conduct WBC, sedimentation rate, and serum albumin tests.

Priorities of Care

Provide patient education focused on oral hygiene and frequently assess oral cavity of patients at risk for developing stomatitis and oral mucositis. Maintain adequate hydration and nutrition for patients experiencing stomatitis or oral mucositis.

Diagnoses, Outcomes, and Interventions

Nursing care for the patient with stomatitis or oral mucositis focuses not only on the oral inflammation, but also on any underlying systemic diseases and the effects of the condition on the patient's comfort and nutrition.

Impaired Oral Mucous Membrane

Stomatitis and oral mucositis disrupt the integrity of the oral mucous membrane. Regardless of cause, the pain and symptoms must be relieved to promote comfort as well as food and fluid intake.

Expected Outcome: Patient's mucous membranes will heal and be free from signs and symptoms of stomatitis or oral mucositis.

- Assess and document oral mucous membranes and the character of any lesions every 4 to 8 hours. *Baseline and ongoing assessment data provide the basis for evaluation.*
- Assist with thorough mouth care after meals, at bedtime, and every 2 to 4 hours while awake. If unable to tolerate a toothbrush, offer sponge or gauze toothettes. Avoid using alcohol-based mouthwashes or lemon-glycerin swabs. Provide saline or sodium bicarbonate rinse or a combined saline/sodium bicarbonate rinse after every meal and between meals. *Mouth care promotes hygiene, comfort, and healing. Alcohol-based mouthwashes and lemon-glycerin swabs may dry and irritate mucous membranes, causing pain and further tissue damage, whereas saline or bicarbonate rinses promote comfort and healing* (*Treister & Woo, 2013*).
- Assess knowledge and teach about condition, mouth care, and treatments. Instruct to avoid alcohol, tobacco, and spicy or irritating foods. *Knowledge promotes patient participation in the plan of care and compliance. Alcohol, tobacco, and hot, spicy, or rough foods may injure the inflamed mucous membranes.*

Imbalanced Nutrition: Less Than Body Requirements

Oral lesions and pain may limit oral intake, which may in turn lead to nutritional deficits. Anorexia and general malaise may also contribute to decreased intake.

Expected Outcome: Patient will maintain adequate oral intake, report adequate energy levels, and maintain body mass and weight and normal lab values (transferrin, albumin and electrolytes).

- Assess food intake as well as the patient's ability to chew and swallow. Weigh daily. Provide appropriate assistive devices such as straws or feeding syringes. *Adequate nutrition is essential for healing. Daily weights allow monitoring of the adequacy of food intake. Assistive devices may allow food intake while avoiding irritation of ulcerations or lesions.*
- Encourage a high-calorie, high-protein diet considerate of food preferences. Offer soft, lukewarm, or cool foods or liquids such as eggnogs, milk shakes, nutritional supplements, popsicles, and puddings frequently in small amounts. Obtain nutritional consultation. *Oral intake may be limited, and enriched foods and liquids enhance nutrition. A nutritional consultation can help ensure an adequate diet and assist in meeting nutritional needs.*
- Provide analgesics for pain relief as needed. *Significant pain associated with stomatitis or oral mucositis can interfere with effective mouth care and food and fluid intake. Pain management is a vital part of nursing care.*

Continuity of Care

Patients with mild stomatitis generally provide self-care. Although patients with cancer treatment–related oral mucositis may require more aggressive therapy, the patient and caregivers often are able to manage the regimen in home- or community-based settings. Include the following topics in teaching for home care:

- Management of any underlying health conditions and ongoing treatments such as chemotherapy

MEDICATION ADMINISTRATION

Drugs Used to Treat Stomatitis

TOPICAL ORAL ANESTHETICS

benzocaine (Anbesol, Orajel)

triamcinolone acetonide

These drugs reduce the pain associated with mucous membrane lesions or stomatitis. They provide temporary relief of pain. Triamcinolone acetonide also reduces inflammation. Any oral lesion that persists longer than 1 week should be evaluated by an oral surgeon.

Nursing Responsibilities

- Instruct the patient to seek medical attention for any oral lesion that does not heal within 1 week.
- Monitor for local hypersensitivity reactions, and discontinue use if they occur.

Health Education for the Patient and Family

- Apply every 1 to 2 hours as needed.
- Perform oral hygiene after meals and at bedtime.

TOPICAL ANTIFUNGAL AGENTS

clotrimazole

nystatin

These products help in the topical treatment of candidiasis. Their effects are primarily local rather than systemic.

Nursing Responsibilities

- Instruct the patient to dissolve lozenges in the mouth.
- Instruct the patient to rinse mouth with oral suspension for at least 2 minutes and expectorate or swallow as directed.
- These drugs are contraindicated in pregnancy.

Health Education for the Patient and Family

- Take medication as prescribed.
- Do not eat or drink 30 minutes after medication.
- Contact physician if symptoms worsen.
- Perform good oral hygiene after meals and at bedtime; remove dentures at bedtime.

ANTIVIRAL AGENTS

acyclovir (Zovirax)

famciclovir (Famvir)

valacyclovir (Valtrex)

Acyclovir, famciclovir, and valacyclovir are useful in the treatment of oral herpes simplex virus. They help reduce the severity and frequency of infections. These antiviral agents interfere with the DNA synthesis of herpes simplex virus.

Nursing Responsibilities

- Start therapy as soon as herpetic lesions are noted.
- Administer with food or on an empty stomach.

Health Education for the Patient and Family

- The virus remains latent and can recur during stressful events, fever, trauma, sunlight exposure, and treatment with immunosuppressive drugs.
- Take the medication as ordered, and contact the physician if symptoms worsen.

- Inspection of the oral cavity at regular intervals and reporting of early signs of oral mucositis
- The recommended diet and oral hygiene regime, including foods and substances (e.g., alcohol, tobacco products) to avoid
- Nutritional supplements to help meet nutritional requirements
- Prescribed medication, its route, side effects, frequency of administration, and signs and symptoms to report
- The importance of completing the full course of antibiotic, antiviral, or antifungal treatment
- Manifestations to report and the importance of follow-up care.

Delegating Nursing Care Activities

Nursing care activities such as providing or assisting the patient with oral care may be delegated to unlicensed assistive personnel. Instruct unlicensed assistive personnel in appropriate technique and use of preferred tool (toothbrush, sponge, gauze toothettes) for individual patient need and condition. The nurse may delegate nursing care activities such as measuring intake and output, obtaining daily weights, measuring intake and output, and assisting with meals. Ensure that unlicensed assistive personnel avoid feeding patient hot foods and provide oral hygiene after meals.

THE PATIENT WITH ORAL CANCER

Oral cancer (malignancy of the oral mucosa) may develop on the lips, tongue, floor of the mouth, or other oral tissues. Incidence rates are more than twice as high in men as in women. Recent studies have shown increases in cancers of the oropharynx associated with the human papillomavirus (HPV) infection among White men and women (National Cancer Institute, 2013). It is seen more often in people over age 40. Although a lesion can develop in any area of the mouth, the most common sites are the lower lip, tongue, and floor of the mouth. The stage of an oral cancer determines the prognosis, treatment, and degree of disability. The primary risk factors for oral cancer are smoking, drinking alcohol, and chewing tobacco. Marijuana use, occupational exposures to chemicals, and viruses such as HPV also may contribute to the risk for oral cancer.

Pathophysiology and Manifestations

More than 90% of oral and oropharyngeal tumors are squamous cell carcinomas. Most early cancers present as inflamed areas with irregular, ill-defined borders. These lesions typically are not painful. More advanced cancers appear as deep ulcers that are fixed to deeper tissues. Early lesions involve the mucosa or submucosa, whereas more advanced tumors may invade and destroy underlying tissues, including muscles and bones of the face. Tumors frequently metastasize to regional lymph nodes. Other cancerous lesions, including lymphoma, malignant melanoma, and Kaposi's sarcoma, may develop in the mouth, although less frequently than squamous cell carcinoma.

MANIFESTATIONS OF ORAL CANCER

- White patches (leukoplakia)
- Red patches (erythroplakia)
- Ulcers
- Neck mass
- Pigmented areas (brownish or black)
- Fissures
- Lump or thickening in the throat or mouth
- Difficulty chewing, swallowing, or moving the tongue or jaws

Figure 23–1 ■ Oral cancer.
Source: Biophoto Associates/Photo Researchers, Inc.

The earliest symptom of oral cancer is a painless oral ulceration or lesion (Figure 23–1 ■). Later symptoms vary and may include difficulty speaking, swallowing, or chewing; swollen lymph nodes; and blood-tinged sputum. See the accompanying box for other manifestations of oral cancer. Any oral lesion that does not heal or respond to treatment within 1 to 2 weeks should be evaluated for malignancy.

●○● INTERPROFESSIONAL CARE

The first component of treatment is eliminating any causative factors such as chewing tobacco, smoking, or drinking alcohol. Tumor staging then determines therapy. The TNM (tumor, nodes, metastasis) classification is used to stage oral cancer. See Box 23–2. A biopsy of the oral lesion allows direct visualization of cells to determine the presence or absence of cancerous cells. Staging may require additional diagnostic studies such as computed tomography (CT) scans or magnetic resonance imaging (MRI).

Early cancers (stages I and II) are highly curable using surgery or radiation therapy. The treatment choice is based on the expected functional and cosmetic results of treatment. More advanced tumors (stages III and IV) generally require a treatment combination of surgery, radiation, and possibly chemotherapy. See Chapter 14 for more information about radiation and chemotherapy to treat cancer.

BOX 23–2 Oral Cancer Staging

Stage 0	Carcinoma *in situ*
Stage I	Tumor ≤ 2 cm; no regional node involvement
Stage II	Tumor > 2 cm to ≤ 4 cm; no regional node involvement
Stage III	Tumor ≤ 2 cm to > 4 cm; one involved lymph node
Stages IVA and B	Tumor may invade adjacent structures; one or more nodes involved
Stage IVC	Distant metastasis present

Following biopsy and staging of the tumor, surgery is often indicated, although an advanced or extensive tumor may be considered unresectable. If the tumor involves surrounding tissues, the cosmetic effects of surgery are important considerations. The goal of surgery is removal of the lesion and potentially cancerous surrounding tissue or lymph nodes. Advanced carcinomas may require extensive excision or a *radical neck dissection*, a potentially disfiguring procedure in which the lymph nodes and muscles of the neck are removed. A tracheostomy is performed at the time of surgery. The tracheostomy may be temporary, but often is permanent. See Chapter 35 for more information about caring for a patient following radical neck dissection and a tracheostomy.

●○● NURSING CARE

Health Promotion

Reducing or eliminating tobacco use (smoking and smokeless tobacco) and excess alcohol consumption can significantly reduce the incidence of oral cancer. Teach children and adolescents about the dangers of using tobacco and alcohol. Emphasize the relationship between smokeless tobacco and oral cancer. Discuss strategies to deal with peer pressure to use tobacco and alcohol.

To promote early identification of and intervention for oral cancer, teach patients about the risk factors for and manifestations of the disease. This is a particularly important nursing strategy in older men who have the highest incidence, and in populations in whom the disease often is advanced when detected (people of lower socioeconomic status, people who rarely see a dentist, and African American men). Encouraging and facilitating annual and biannual preventive dental care is an important nursing responsibility. Due to the increase in HPV, health teaching should include informing patients about the risk of infection from oral sex and instruction on preventive measures and safe sex practices.

Assessment

Early precancerous oral lesions are very treatable. Unfortunately, these lesions usually are painless, so diagnosis and treatment often are delayed. Assess the oral cavity of all patients, particularly those with risk factors for oral cancer.

- *Health history:* Ask about oral lesions that fail to heal; use (current or past) of tobacco products or excess alcohol.
- *Physical assessment:* Inspect and palpate lips and oral mucosa (including tongue and floor of mouth under the tongue) for tumors or lesions. Lesions may appear as velvety red or white patches that do not scrape off, or as ulcers or areas of necrosis.

Priorities of Care

Monitoring airway clearance and maintaining adequate hydration and nutrition are key components of care.

Diagnoses, Outcomes, and Interventions

The mouth allows for food ingestion, and the lips are integral to verbal and nonverbal expression. The head, mouth, and lips are important to self-perception and body image. Nursing diagnoses discussed in this section consider such problems as airway clearance, nutrition, communication, and body image. Also see the accompanying Case Study & Nursing Care Plan.

Risk for Ineffective Airway Clearance

The location and the extent of an oral cancer and its excision may compromise the airway. Swelling of adjacent tissues, increased oral secretions, or difficulty swallowing may contribute to respiratory distress. If extensive surgery is performed, a tracheostomy usually is performed to maintain airway patency.

Expected Outcome: Patient's airway will remain patent as evidenced by ease of breathing, normal respiratory rate and rhythm, and $SpO_2 < 95$.

- In the initial postoperative period, assess airway patency and respiratory status at least hourly. A patent airway is vital to maintain respirations and oxygenation of tissues. *Frequent assessment allows early identification of possible airway compromise.*
- Unless contraindicated, place in Fowler's position, supporting arms. Assist the patient to turn, cough, and deep breathe at least every 2 to 4 hours. *Fowler's position promotes lung expansion. Turning, coughing, and deep breathing help maintain a patent airway by preventing pooling of secretions.*
- Maintain adequate hydration (2000 to 3000 mL per day unless contraindicated) and humidity of inspired air. *Adequate hydration helps thin and loosen secretions.*

Imbalanced Nutrition: Less Than Body Requirements

Surgery affects oral food and fluid intake. Enteral feedings or parenteral nutrition may be required. A gastrostomy tube usually is inserted during surgery to maintain nutrition. If an oral diet is permitted, anorexia or pain may affect intake.

Expected Outcome: Patient will maintain adequate hydration and stable weight.

- Weigh daily. Assess oral intake for adequacy of protein, calories, and nutrients. *Daily weights and nutritional assessments provide information about the adequacy of diet.*
- Offer soft, bland foods with supplements as indicated. Provide small, frequent feedings, making mealtimes pleasant. *Soft, bland foods may be better tolerated following oral surgery. Large meals may be overwhelming; small, frequent meals promote food and nutrient intake.*
- Provide enteral feedings per gastrostomy tube as ordered. Elevate the head of the bed 30 to 40 degrees. *Enteral feedings maintain nutritional status in the patient who is unable to consume foods orally. Elevating the head of the bed reduces the risk of regurgitation and aspiration of gastric contents.*
- Assess for gastric residual volume per facility protocol for the type of feeding (intermittent or continuous). Notify the physician of volumes greater than 200 mL or 50% of previous feeding if feeding is intermittent. *Excess residual volume may increase the risk for aspiration.*
- Consider a nutritional consultation to assess diet and plan appropriate supplements. *A registered dietitian can calculate energy requirements and develop an individualized diet plan to meet nutritional requirements.*

Impaired Verbal Communication

Oral surgery can interfere with communication. Effective communication is vital to postoperative recovery and prevention of complications.

CASE STUDY & NURSING CARE PLAN A Patient with Oral Cancer

Juan Chavez, a married 44-year-old farmer, has two adult children. He and his wife raise and sell fruits and vegetables. Two months ago, Mr. Chavez developed a sore on his tongue that would not heal. Mr. Chavez tells his admission nurse, Sara Bucklin, "The doctor says he will have to remove part of my tongue," and anxiously asks, "Will I ever look the same? How will I be able to talk?"

ASSESSMENT

Mr. Chavez's admission history reveals that he has been healthy, but has smoked two packs of cigarettes a day for more than 20 years, and usually drinks two to four beers per day. He admits to being anxious and fearful of surgery and its outcomes. He says he quit smoking and drinking 2 weeks ago. The biopsy report is positive for squamous cell carcinoma of the tongue. Mr. Chavez has no enlarged cervical nodes and says he has no bloody sputum or saliva, difficulty swallowing, chewing, or talking. His weight is in the normal range for his height. A wide excision of the oral lesion is planned.

DIAGNOSES

- *Risk for Ineffective Airway Clearance* related to oral surgery
- *Risk for Imbalanced Nutrition: Less Than Body Requirements* related to oral surgery
- *Impaired Verbal Communication* related to excision of a portion of the tongue
- *Disturbed Body Image* related to surgical excision of the tongue

EXPECTED OUTCOMES

- Patient will maintain a patent airway and remain free of respiratory distress.
- Patient will maintain a stable weight and level of hydration.
- Patient will effectively communicate with staff and family using a magic slate and flash cards.
- Patient will communicate an increased ability to accept changes in body image.

PLANNING AND IMPLEMENTATION

- Assess airway patency and respiratory status every hour until stable.
- Maintain semi-Fowler's position, supporting arms. Encourage to turn, cough, and deep breathe every 2 to 4 hours.
- Teach the importance of activity, turning, coughing, and deep breathing.
- Monitor daily weights.
- Consult with dietitian to assess calorie needs and plan appropriate enteral feeding. Assess response to enteral feedings.
- Demonstrate and allow to practice using magic slate and flash cards prior to surgery.
- Allow adequate time for communication efforts.
- Keep emergency call system in reach at all times and answer light promptly. Alert all staff of inability to respond verbally.
- Encourage expression of feelings regarding perceived and actual changes.
- Provide emotional support and encourage self-care and participation in decision making.

EVALUATION

At the time of discharge, Mr. Chavez has maintained his weight and has started on oral liquids, including supplements and enriched liquids. His airway has remained clear, and he is effectively coughing and deep breathing. He has used the magic slate to communicate throughout his hospital stay. He is regaining use of his tongue, and can speak a few words. Although initially distressed, he is communicating an increased ability to cope with loss of part of his tongue. He and his wife say they understand his discharge instructions, including diet, activity, follow-up care, and signs and symptoms to report.

Clinical Reasoning in Patient Care

1. What measures can you, as a nurse, implement to reduce the incidence of oral cancer?
2. Plan a health education program for young athletes who chew tobacco.
3. Mr. Chavez's wife calls you 2 weeks after discharge. She tells you that he refuses to try to talk and is relying on his magic slate to communicate. How will you respond?

See Evaluating Your Response in Appendix B.

Expected Outcome: Patient will accurately communicate status such as level of pain and comfort and respond to nurse's instructions. Patient will participate in speech therapy interventions.

- Before surgery, establish and practice a communication plan such as using a magic slate or flash cards. *Practicing communication techniques reduces fear and anxiety while promoting communication.*
- Provide ample time for communication efforts and do not answer for the patient. Be alert for nonverbal communications. Use yes/no questions and simple phrases. *Providing adequate time allows the patient opportunity to express ideas and thoughts. Nonverbal communication provides cues regarding comfort or other needs. Simple yes/no questions are easily answered nonverbally.*
- If indicated, refer to or consult with a speech therapist. *A speech therapist can help promote or restore effective communication.*

SAFETY ALERT

Provide an emergency call system and respond promptly. Make all staff aware that the patient cannot respond over an intercom system by posting an alert on the intercom. Nonverbal patients rely on an emergency call system to summon help. *Answering promptly reduces fear and anxiety and maintains safety.*

Disturbed Body Image

Radical surgery of the head or neck seriously affects body image. An altered speech pattern and any disfigurement affect the ability to feel attractive or effective in work or social roles. Patients may defer life-saving surgery to postpone disfiguring interventions or therapies.

Expected Outcome: Patient will identify personal strengths, acknowledge impact of situation on self-image, maintain close social interaction and personal interactions, and participate in self-care.

- Assess coping style, self-perception, and responses to altered appearance or function. *This information can be used to identify appropriate interventions and care.*
- Encourage verbalization of feelings regarding perceived and actual changes. *Nonjudgmental acceptance of feelings and fears helps establish trust.*
- Provide emotional support, encourage self-care, and provide decision-making opportunities. *Self-care promotes self-acceptance and independence. Giving choices empowers the patient to participate in care.*

Continuity of Care

Discharge planning for the patient with oral cancer depends on the type of treatment planned and surgery performed. Depending on the

patient's age, condition, and availability of support systems, referral to a rehabilitation center and community healthcare agencies may be an essential component of care. Visits from home care nurses can assist in meeting healthcare needs.

Discuss the following topics with the patient and family members or care providers:

- Diagnosis and prescribed care
- Monitoring for new lesions or recurrences
- Diet, nutrition, and activity
- Pain management
- Airway management, care of incision, and signs and symptoms to report.

Delegating Nursing Care Activities

As appropriate and allowed by the designated duties and responsibilities of unlicensed assistive personnel, the nurse may delegate nursing care activities such as measuring intake and output, obtaining daily weights, assisting with ADLs, and assisting with meals.

Ensuring that unlicensed assistive personnel are proficient in appropriate communication techniques and answer call lights promptly is important to promote patient-centered care.

Encourage unlicensed assistive personnel (UAP) to socialize and communicate frequently with the patient. Instruct UAP to encourage self-care while assisting patient with ADLs.

Disorders of the Esophagus

The esophagus plays an essential role in the ingestion of food and liquids. Disorders of the esophagus can be inflammatory, mechanical, or cancerous. Because of its location and neighboring organs, the symptoms of esophageal disorders may mimic those of a variety of other illnesses.

FAST FACTS

- GERD affects 15% to 20% of adults.
- Up to 7% of people experience daily symptoms such as heartburn, regurgitation, and indigestion, and as many as 15% to 20% have symptoms weekly (Papadakis & Tierney, 2013).

THE PATIENT WITH GASTROESOPHAGEAL REFLUX DISEASE

Gastroesophageal reflux is the backward flowing of gastric contents into the esophagus. When this occurs, the patient experiences heartburn. Many people with gastroesophageal reflux have few symptoms, while others develop inflammatory esophagitis as a result of exposure to gastric juices. *Gastroesophageal reflux disease (GERD)* is a common gastrointestinal disorder.

Pathophysiology

Normally, the lower esophageal sphincter remains closed except during swallowing. Reflux (backflow) of gastric contents into the esophagus is prevented by pressure differences between the stomach and the lower esophagus. The diaphragm, the lower esophageal sphincter, and the location of the gastroesophageal junction below the diaphragm help maintain this pressure difference (Figure 23–2 ■).

Gastroesophageal reflux may result from transient relaxation of the lower esophageal sphincter, an incompetent lower esophageal

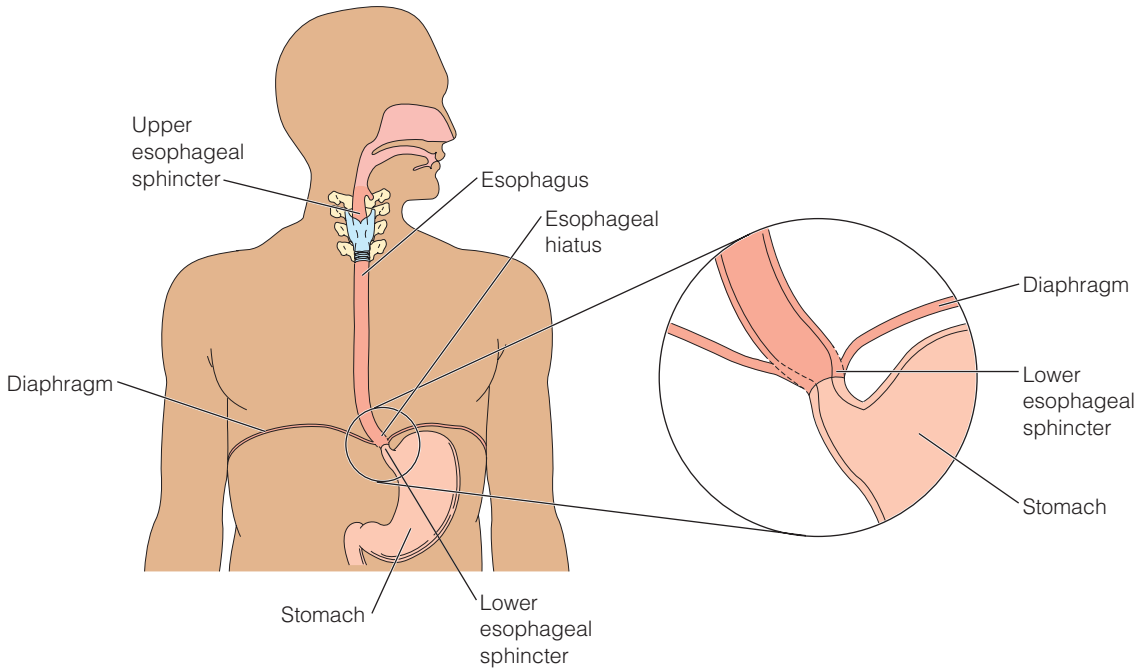

Figure 23–2 ■ The esophagus. The inset shows a closer view of the lower esophageal sphincter.

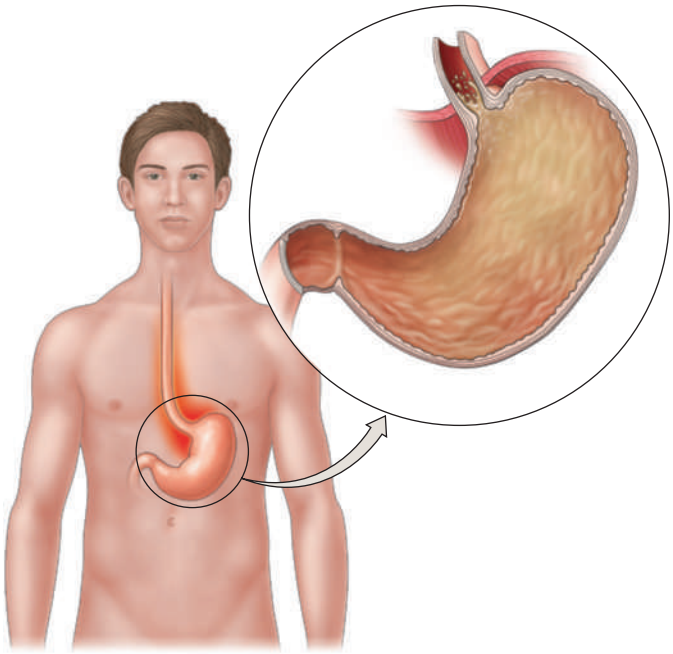

Figure 23–3 ■ In gastroesophageal reflux disease, reflux of corrosive gastric secretions into the lower esophagus causes inflammation of esophageal mucosa.

sphincter, and/or increased pressure within the stomach. Factors contributing to gastroesophageal reflux include increased gastric volume (e.g., after meals), positioning that allows gastric contents to remain close to the gastroesophageal junction (e.g., bending over, lying down), and increased gastric pressure (e.g., obesity or wearing tight clothing). A hiatal hernia may contribute to GERD.

Gastric juices contain acid, pepsin, and bile, which are corrosive substances. Esophageal peristalsis and bicarbonate in salivary secretions normally clear and neutralize gastric juices in the esophagus. During sleep and in patients with impaired esophageal peristalsis or decreased salivation, the esophageal mucosa is damaged by gastric juices, causing an inflammatory response (Figure 23–3 ■). With prolonged exposure, reflux esophagitis develops. In nonerosive reflux disease, the mucosa remains normal or mildly inflamed. Erosive esophagitis, however, is characterized by red, friable (easily torn) mucosa and superficial ulcers. If untreated, scarring occurs, and esophageal stricture may develop.

Manifestations

GERD causes heartburn, usually after meals, with bending over, or when reclining. Regurgitation of sour material into the mouth, or difficulty and pain with swallowing, may develop. Other manifestations may include atypical chest pain, sore throat, and hoarseness. See the accompanying box illustrating links between the pathophysiology of GERD and its symptoms. Aspiration of gastric contents can cause hoarseness or respiratory symptoms.

Complications include esophageal strictures and Barrett's esophagus. Strictures, caused by scar tissue, edema, and spasm, can lead to dysphagia. Barrett's esophagus is characterized by changes in the cells lining the esophagus and an increased risk of developing esophageal cancer (Longo et al., 2013).

●○● INTERPROFESSIONAL CARE

Often the diagnosis of GERD is made by the history of symptoms and predisposing factors. Interprofessional care focuses on lifestyle changes, diet modification, and, for more severe cases, drug therapy. Surgery is reserved for patients who develop serious complications.

DIAGNOSIS

Diagnostic tests that may be ordered for patients with manifestations of GERD include the following:

- *Barium swallow* to evaluate the esophagus, stomach, and upper small intestine.
- *Upper endoscopy* to permit direct visualization of the esophagus. Tissue may be obtained for biopsy to establish the diagnosis and rule out malignancy. See Chapter 21 for nursing care of the patient undergoing an upper endoscopy.
- In the *Bernstein test*, saline and dilute acid solutions are instilled into the esophagus. In patients with GERD, the acid solution produces symptoms of heartburn, whereas the saline solution does not; neither solution produces symptoms in patients who do not have GERD.
- *24-hour ambulatory pH monitoring* may be performed to establish the diagnosis of GERD. For this test, a small tube with a pH electrode is inserted through the nose into the esophagus. The electrode is attached to a small box worn on the belt that records the data. The data are later analyzed by computer.
- *Esophageal manometry* measures pressures of the esophageal sphincters and esophageal peristalsis.

MANIFESTATIONS AND PATHOPHYSIOLOGY OF GERD

Manifestation	Pathophysiology
Heartburn Chest pain Regurgitation Belching	Reflux of gastric juices through the lower esophageal (cardiac) sphincter into the lower esophagus exposes esophageal mucosa to corrosive pepsin, acid, and bile. Gastric juices normally are cleared by esophageal peristalsis or neutralized by saliva; when these mechanisms are impaired, esophageal mucosa becomes inflamed, and eventually may ulcerate. Further exposure of the inflamed and ulcerated mucosa to corrosive gastric juices leads to heartburn or angina-like or atypical chest pain.
Dysphagia	Untreated esophagitis leads to inflammatory cell infiltrates, fibrosis, and scarring of esophageal tissue, constricting its lumen and causing difficult, painful swallowing.
Pain after eating	Increased gastric volume increases pressure within the stomach relative to the ability of the lower esophageal sphincter to prevent reflux into the esophagus. Reflux irritates already inflamed tissue, causing pain.
Chronic cough Hoarseness Laryngitis, pharyngitis	Reflux of gastric contents into the pharynx and mouth allows aspiration of gastric contents into the tracheobronchial tree. This usually occurs during sleep, when a recumbent position increases gastroesophageal reflux, and relaxation of tissues and muscles in the oropharynx increases the risk of aspiration.

MEDICATIONS

Antacids, such as Mylanta or Maalox, relieve mild or moderate symptoms by neutralizing stomach acid. Gaviscon, which forms a floating barrier between the gastric contents and the esophageal mucosa when the patient is upright, may be used.

Proton-pump inhibitors (PPIs) such as omeprazole (Prilosec) and lansoprazole (Prevacid) reduce gastric secretions. PPIs promote healing of erosive esophagitis and relieve symptoms. An 8-week course of treatment is initially prescribed, although some patients may require 3 to 6 months of therapy. Relapse is common after PPI therapy is discontinued. Although these drugs have minimal side effects, they may interfere with absorption of calcium and vitamin B_{12}. A systematic review and meta-analysis completed by Ye and associates (2011) showed PPI therapy may increase the risk of hip fracture. Histamine$_2$-receptor (H_2-receptor) blockers reduce gastric acid production and are effective in treating GERD symptoms. When treating GERD, H_2-receptor blockers are usually given twice a day or more frequently for a prolonged period of time. Several H_2-receptor blockers approved by the FDA for the treatment of GERD are available over the counter. This class of drugs does not appear to increase hip-fracture risk (Al Talalwah & Woodward, 2013b). A promotility agent, such as metoclopramide (Reglan), may be ordered to enhance esophageal clearance and gastric emptying. Metoclopramide is used to treat patients with regurgitation, symptoms of indigestion, and nighttime symptoms. However, it is not recommended for long-time use. See the accompanying Medication Administration box for the nursing implications of drugs used to treat GERD.

NUTRITION AND LIFESTYLE MANAGEMENT

GERD is a chronic condition. Dietary and lifestyle changes are important to reduce symptoms and long-term effects of the disorder. Acidic foods such as tomato products, citrus fruits, spicy foods, and coffee are eliminated from the diet. Fatty foods, chocolate, peppermint, and alcohol relax the lower esophageal sphincter or delay gastric emptying, so they should be avoided. The patient is advised to maintain ideal body weight, eat smaller meals, refrain from eating for 3 hours before bedtime, and stay upright for 2 hours after meals. Elevating the head of the bed on 6- to 8-inch blocks often is beneficial. Stopping smoking and reducing alcohol consumption are necessary lifestyle changes. Avoiding tight clothing and avoiding bending may help to relieve symptoms.

SURGERY

Surgery may be used for patients who do not respond to pharmacologic and lifestyle management. Antireflux surgeries increase pressure in the lower esophagus, inhibiting gastric content reflux. Laparoscopic fundoplication, a procedure in which the gastric fundus is wrapped around the distal esophagus, is the treatment of choice for GERD. An open surgical procedure known as Nissen fundoplication also may be done (Figure 23–4 ■). Other laparoscopic procedures to tighten the lower esophageal sphincter may include use of an endoscopic suturing system or burning spots on the muscle surrounding the sphincter to create scar tissue. Surgery or ablation therapy also is recommended to reduce the risk of esophageal cancer in patients with persistent cell changes in the distal esophagus.

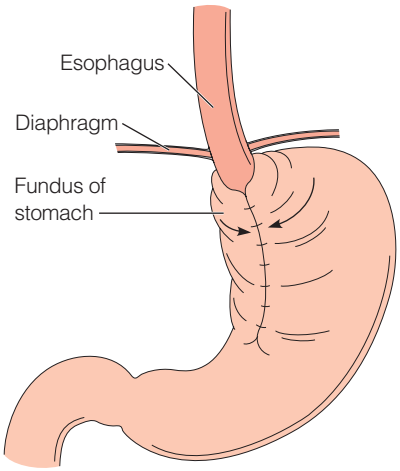

Figure 23–4 ■ Nissen fundoplication. The fundus of the stomach is wrapped around the lower esophagus and the edges are sutured together.

●○● NURSING CARE

Assessment

Assessment data related to GERD include the following:

- *Health history:* manifestations such as frequent heartburn or atypical chest pain; intolerance of foods that are acidic, spicy, or fatty; regurgitation of acidic gastric juice; increased symptoms when bending over, lying down, or wearing tight clothing; difficulty swallowing; possible hoarseness
- *Physical assessment:* epigastric tenderness.

Priorities of Care

Relieving the discomfort associated with GERD is the priority of nursing care. Teaching focuses on preventing symptoms and long-term consequences of the disorder.

Diagnoses, Outcomes, and Interventions

Nursing care for the patient with GERD focuses on symptom relief. Treatment involves medication management and nursing management that is supportive and educational. Left untreated, GERD can lead to serious complications so assisting the patient with needed lifestyle changes is important.

Acute Pain

The epigastric pain associated with GERD can be severe, interfering with rest and causing anxiety.

Expected Outcome: Patient will use preventive measures to control pain associated with GERD and will verbalize adequate pain control.

- Provide small, frequent meals. Restrict intake of fat, acidic foods, coffee, and alcohol. *Limiting the size of meals reduces pressure in the stomach, reducing esophageal reflux. Fatty, acidic foods, coffee, and alcohol increase gastric acidity and interfere with gastric emptying, increasing the incidence of gastroesophageal reflux.*
- Instruct to stop smoking. Refer to a smoking cessation clinic or program as needed. *Cigarette smoking increases gastric acidity and interferes with healing of damaged mucosa.*
- Administer antacids, H_2-receptor blockers, and PPIs as ordered. Instruct patient to continue therapy as prescribed, even after

MEDICATION ADMINISTRATION

Drugs Used to Treat GERD, Gastritis, and Peptic Ulcer Disease

PROTON-PUMP INHIBITORS

esomeprazole (Nexium)
lansoprazole (Prevacid)
omeprazole *(Prilosec)*
pantoprazole (Protonix)
rabeprazole (AcipHex)

Proton-pump inhibitors are the drugs of choice for severe GERD. PPIs inhibit the hydrogen-potassium-ATP pump, reducing gastric acid secretion. If the patient's symptoms do not improve with treatment, the dose may be increased.

Nursing Responsibilities

- Administer 30 minutes before breakfast (and at bedtime if ordered twice a day).
- Do not crush tablets.
- Monitor liver function tests for possible abnormal values, including increased AST, ALT, alkaline phosphatase, and bilirubin levels.

Health Education for the Patient and Family

- Take the drug as ordered for the full course of therapy, even if symptoms are relieved.
- Do not crush, break, or chew tablets.
- Increase your calcium intake or take a calcium supplement while using this drug because it can interfere with calcium absorption.
- Avoid cigarette smoking, alcohol, aspirin, and NSAIDs while taking this drug because these substances may interfere with healing.
- Report black tarry stools, diarrhea, or abdominal pain to your primary care provider.

H_2-RECEPTOR BLOCKERS

cimetidine (Tagamet)	ranitidine (Zantac)
famotidine (Pepcid)	nizatidine (Axid)

H_2-receptor blockers reduce acidity of gastric juices by blocking the ability of histamine to stimulate acid secretion by the gastric parietal cells. As a result, both the volume and concentration of hydrochloric acid in gastric juice are reduced. H_2-receptor blockers are given orally or intravenously. Both prescription and over-the-counter preparations are available.

Nursing Responsibilities

- To ensure absorption, do not give an antacid within 1 hour before or after giving an H_2-receptor blocker.
- When administered intravenously, do not mix with other drugs. Administer in 20 to 100 mL of solution over 15 to 30 minutes. Rapid intravenous injection as a bolus may cause dysrhythmias and hypotension.
- Monitor for interaction with such drugs as oral anticoagulants, beta-blockers, benzodiazepines, tricyclic antidepressants, and others. H_2-receptor blockers may inhibit the metabolism of other drugs, increasing the risk of toxicity.

Health Education for the Patient and Family

- Take the drug as directed, even if pain and gastric discomfort are relieved early in the course of therapy.
- Take at bedtime if once-a-day dosing is ordered. If spaced through the day, take before meals. Avoid taking antacids for 1 hour before and 1 hour after taking this drug.
- To promote healing, avoid cigarette smoking (which increases gastric acid secretion) and gastric mucosal irritants such as alcohol, aspirin, and NSAIDs.
- Long-term use of these drugs can lead to gynecomastia (breast enlargement) and impotence in men and breast tenderness in women. Discontinuing the drug will reverse these effects.
- Report possible adverse effects such as diarrhea, confusion, rash, fatigue, malaise, or bruising to your care provider.

ANTIULCER AGENT

sucralfate (Carafate)

Sucralfate reacts with gastric acid to form a thick paste that adheres to damaged gastric mucosal tissue. It protects gastric mucosa and promotes healing through this local action.

Nursing Responsibilities

- Administer on an empty stomach, 1 hour before meals and at bedtime.
- Do not crush tablets.
- Separate administration time from antacids by at least 30 minutes and other medications (1 hour or longer).

Health Education for the Patient and Family

- Take as directed, even after symptoms have been relieved.
- Do not crush or chew tablets; shake suspension well.
- Increase your intake of fluids and dietary fiber to prevent constipation.

ANTACIDS

Maalox	Gaviscon	Gelusil	Tums
Mylanta	Aludrox	Riopan	Amphojel

Antacids buffer or neutralize gastric acid, usually acting locally. Antacids are used in GERD, gastritis, and peptic ulcer disease to relieve pain and prevent further damage to esophageal and gastric mucosa.

Nursing Responsibilities

- Antacids interfere with the absorption of many drugs given orally; separate administration times by at least 2 hours.
- Monitor for constipation or diarrhea resulting from antacid therapy. Notify the physician should either develop; a different antacid may be ordered.
- Although most antacids have little systemic effect, electrolyte imbalances can develop. Monitor serum electrolytes, particularly sodium, calcium, and magnesium levels.

Health Education for the Patient and Family

- Take your antacid frequently as prescribed, 1 to 3 hours after meals and at bedtime. To be effective, the antacid must be in contact with the lining of your stomach, so should be ingested on an empty stomach.
- Avoid taking an antacid for approximately 2 hours before and 1 hour after taking another medication.
- Shake suspensions well prior to administration.
- Chew tablets thoroughly, and follow with 4 to 6 ounces of water.
- Report worsening symptoms, diarrhea, or constipation to your primary care provider.
- Continue taking the antacid for the duration prescribed. Although pain and discomfort often are relieved soon after treatment begins, healing takes 6 to 8 weeks.

PROMOTILITY AGENT

metoclopramide (Reglan)

By acting on the central nervous system, metoclopramide stimulates upper gastrointestinal motility and gastric emptying. As a result, nausea, vomiting, and symptoms of GERD are reduced.

MEDICATION ADMINISTRATION (*continued*)

Nursing Implications

- Do not administer this drug to patients with possible gastrointestinal obstruction or bleeding, or a history of seizure disorders, pheochromocytoma, or Parkinson's disease.
- Monitor for extrapyramidal side effects (e.g., difficulty speaking or swallowing, loss of balance, gait disruptions, twitching or twisting movements, weakness of arms or legs) or manifestations of tardive dyskinesia (uncontrolled rhythmic facial movement, lip-smacking, tongue rolling). Report immediately.
- Give oral doses 30 minutes before meals and at bedtime.
- May be given by direct intravenous push over 1 to 2 minutes, or diluted by slow infusion over 15 to 30 minutes.

Health Education for the Patient and Family

- Take this drug as directed. If you miss a dose, take as soon as you remember unless it is close to the time for the next dose.
- Do not drive or engage in other activities that require alertness if this drug makes you drowsy.
- Avoid using alcohol or other CNS depressants while you are taking this drug.
- Immediately contact your healthcare provider if you develop involuntary movements of your eyes, face, or limbs.

Note: Drugs identified in italics are among the 200 most commonly prescribed medications in the U.S.

Evidence for Nursing Care

The Patient with Gastroesophageal Reflux Disease

Selected resources that nurses may find helpful when planning evidence-based nursing care follow.

- Al Talalwah, N., & Woodward, S. (2013b). Gastro-oesophageal reflux. Part II: Medical treatment. *British Journal of Nursing, 22*(5), 277–284.
- Pinto, S. (2012). *Gastroesophageal reflux disease: Proton pump inhibitors.* Glendale, CA: Cinahl Information Systems.

symptoms have been relieved. *These drugs neutralize or reduce gastric acid secretion, relieving symptoms and promoting healing.*

- Discuss the long-term nature of GERD and its management. *Lifestyle changes need to be continued after healing and symptom relief to manage the long-term effects of GERD.*

Continuity of Care

GERD is a lifelong condition best managed by the patient. Teach the patient and family about continuing management strategies, including dietary changes, remaining upright after meals, and avoiding eating for at least 3 hours before bedtime. Suggest elevating the head of the bed on 6- to 8-inch wooden blocks placed under the legs. Discuss the need for continued gastric acid reduction using antacids, H_2-receptor blockers, or PPIs. All are effective to reduce the acidity of gastric juices. Antacids are the most cost-effective measure, requiring frequent doses to neutralize gastric acid. H_2-receptor blockers, also available over the counter, are a cost-effective management strategy that requires only twice-a-day dosing.

THE PATIENT WITH HIATAL HERNIA

A *hiatal hernia* occurs when part of the stomach protrudes through the esophageal hiatus of the diaphragm into the thoracic cavity. Although hiatal hernia is thought to be a common problem, most affected individuals are asymptomatic. The incidence of hiatal hernia increases with age.

In a *sliding hiatal hernia*, the gastroesophageal junction and the fundus of the stomach slide upward through the esophageal hiatus (Figure 23–5 ■). Several factors may contribute to a sliding hiatal hernia, including weakened anchors of the gastroesophageal junction to the diaphragm, shortening of the esophagus, or increased intra-abdominal pressure. Small sliding hiatal hernias produce few symptoms.

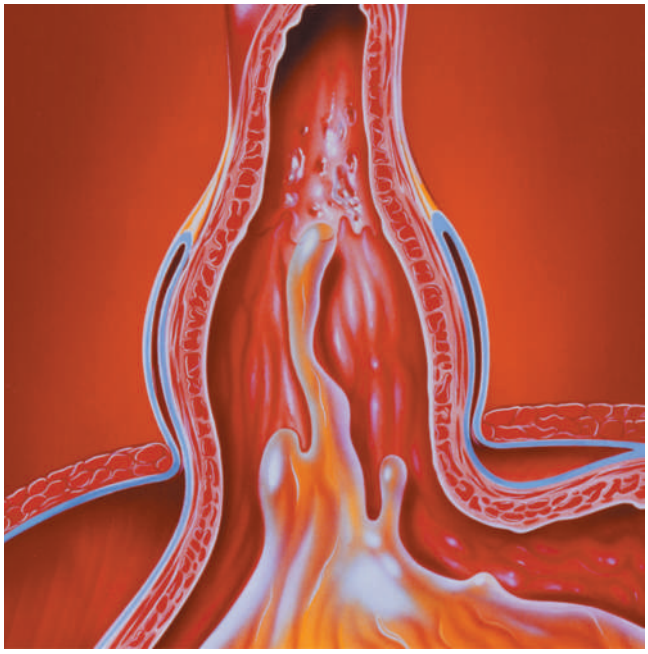

Figure 23–5 ■ Hiatal hernia. The gastroesophageal junction and fundus of the stomach slide upward through the diaphragm, allowing gastric juices to reflux into the lower esophagus.

In a *paraesophageal hiatal hernia*, the junction between the esophagus and stomach remains in its normal position below the diaphragm while a part of the stomach herniates through the esophageal hiatus. A paraesophageal hernia can become incarcerated (constricted) and strangulate, impairing blood flow to the herniated tissue. Patients with paraesophageal hernia may develop gastritis, or chronic or acute gastrointestinal bleeding. The manifestations of hiatal hernias are listed in an accompanying box.

A barium swallow or an upper endoscopy may be done to diagnose hiatal hernia. Many patients with hiatal hernia require no treatment. If symptoms are present, treatment measures such as those for patients with GERD may be ordered. If medical management is ineffective or the hernia becomes incarcerated, surgery may be required. The most common surgical procedure is the Nissen fundoplication (refer to Figure 23–4). This surgery, which may be done laparoscopically, prevents the gastroesophageal junction from slipping into the thoracic cavity.

Nursing care for the patient with a hiatal hernia is similar to that for the patient with GERD. If surgery is performed, nursing care is similar to that for patients undergoing gastric or thoracic surgery (see Chapter 4).

MANIFESTATIONS OF HIATAL HERNIA

- Reflux, heartburn
- Feeling of fullness
- Substernal chest pain
- Dysphagia
- Occult bleeding
- Belching, indigestion

THE PATIENT WITH IMPAIRED ESOPHAGEAL MOTILITY

Disorders of esophageal motility can cause **dysphagia** (difficult or painful swallowing) or chest pain. It is estimated that nearly 75% of patients hospitalized with stroke experience dysphagia. Other neurologic disorders such as Parkinson's disease, amyotrophic lateral sclerosis, and Alzheimer's disease also can cause dysphagia.

Primary disorders of swallowing are less common. **Achalasia**, a disorder of unknown etiology, is characterized by impaired peristalsis of the smooth muscle of the esophagus and impaired relaxation of the lower esophageal sphincter (LES). The patient experiences gradually increasing dysphagia with both solid foods and liquids. Fullness in the chest during meals, chest pain, and nighttime cough are additional manifestations. Other patients may experience *diffuse esophageal spasm* that causes nonperistaltic contraction of esophageal smooth muscle. This disorder causes chest pain and/or dysphagia. The chest pain can be severe, and usually occurs at rest.

Treatment of achalasia may include endoscopically guided injection of botulinum toxin into the lower esophageal sphincter or balloon dilation of the LES. Botulinum toxin injection lowers LES pressure, but may need to be repeated every 6 to 9 months. Balloon dilation tears muscle fibers in the LES, reducing its pressure (Figure 23–6 ■). A laparoscopic myotomy (incision into the circular muscle layer of the LES) also reduces pressure and relieves symptoms.

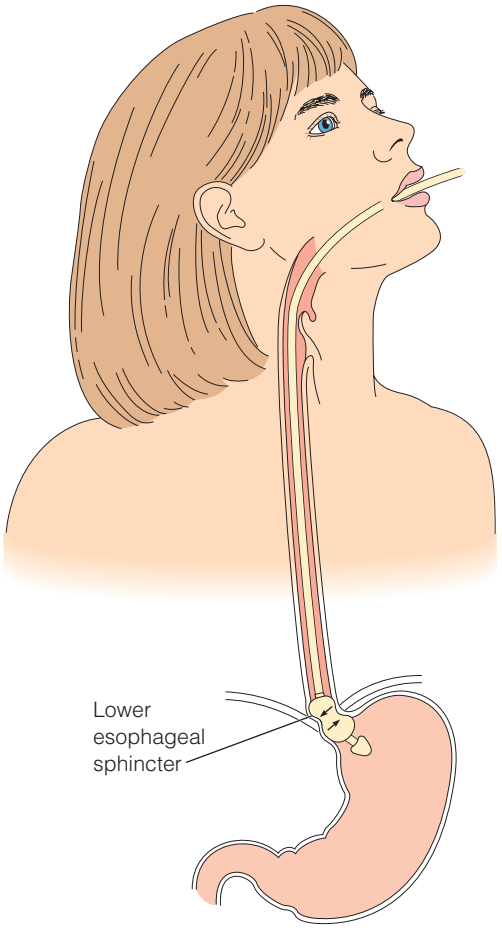

Figure 23–6 ■ Balloon dilation of the lower esophageal sphincter.

THE PATIENT WITH ESOPHAGEAL CANCER

Cancer of the esophagus is a relatively uncommon malignancy in the United States. It does, however, have a high mortality rate, primarily because symptoms often are not recognized until late in the course of the disease.

FAST FACTS

- Esophageal cancer is the seventh leading cause of cancer deaths in men.
- It accounted for an estimated 12,040 deaths in 2012 (American Cancer Society [ACS], 2012).
- Esophageal cancer usually occurs after age 50; it is more common in men than in women and in Blacks than in Whites.
- Most esophageal tumors develop in the lower third of the esophagus.

Pathophysiology

There are two types of esophageal tumors, adenocarcinoma and squamous cell carcinoma. During the past two decades, the incidence of squamous cell tumors of the esophagus has been decreasing, whereas the incidence of adenocarcinoma has increased dramatically, particularly among White males (Papadakis & Tierney, 2013). Cigarette smoking and chronic alcohol use are strong risk factors for squamous cell esophageal tumors, and also appear to contribute to the risk of developing adenocarcinoma. Box 23–3 lists major identified risk factors for esophageal cancer.

Only about 10% of esophageal tumors develop in the ~~upper portion~~ of the esophagus; about 35% develop in the midportion. The lower third of the esophagus is the most common site, accounting for about 55% of tumors. Adenocarcinomas tend to develop in dysplastic (abnormal) columnar epithelium in the distal esophagus. It is commonly associated with Barrett's esophagus, a possible complication of chronic GERD and achalasia.

BOX 23–3 Factors for Esophageal Cancer

- Excess alcohol consumption
- Cigarette smoking
- Ingested carcinogens such as nitrates and industrial chemicals
- Smoked opiates
- Physical mucosal damage (e.g., hot tea, lye ingestion, radiation damage, chronic achalasia)
- Congenital disorders
- Chronic gastric reflux

The disease usually spreads to adjacent and supraclavicular lymph nodes and the liver, lungs, and pleura.

Manifestations

The most common symptoms of esophageal carcinoma are progressive dysphagia and recent weight loss. Other manifestations are listed in an accompanying box. The cancer often is advanced and incurable by the time the disease is diagnosed because symptoms such as difficulty swallowing do not develop until more than 60% of the circumference of the esophagus is affected by tumor (Longo et al., 2013; Papadakis & Tierney, 2013).

Tracheoesophageal fistulas may develop as the disease progresses, leading to aspiration and pneumonia. Paraneoplastic symptoms such as hypercalcemia may accompany advanced esophageal cancer.

●○● INTERPROFESSIONAL CARE

Controlling dysphagia and maintaining nutritional status are essential goals of therapy for patients with esophageal cancer, regardless of the stage of the disease. Treatment may involve surgery, radiation therapy, and/or chemotherapy.

DIAGNOSIS

Diagnostic and staging procedures for esophageal cancer may include esophagography, bronchoscopy, and scans to detect metastasis. The following diagnostic tests may be performed (see Chapter 21):

- *Barium swallow* to identify irregular mucosal patterns or narrowing of the lumen, which suggests esophageal cancer
- *Esophagoscopy* to allow direct visualization of the tumor and obtain tissue for biopsy
- *Chest x-ray, CT scans*, or *MRI* to identify possible tumor metastases to other organs or tissues
- *Complete blood count (CBC),* which may indicate anemia due to chronic blood loss. *Serum albumin levels* may be low due to malnutrition, and *liver function tests (ALT, alkaline phosphatase, AST,* and *bilirubin)* are elevated if liver metastases are present.

TREATMENTS

The treatment of esophageal cancer is challenging; fewer than 5% of patients survive 5 years after it is diagnosed (Longo et al., 2013; Papadakis & Tierney, 2013). A combination of chemotherapy and radiation, followed by surgery to resect the tumor, appears to be more effective than any single form of therapy.

Surgery involves resection of the affected portion of the esophagus (*esophagectomy*) and possible anastomosis of the stomach to the remaining esophagus. Mediastinal lymph nodes may be resected at the time of surgery. Esophagectomy is not without risk; potential surgical complications include anastomosis leak, respiratory complications such as pneumonia or acute respiratory distress syndrome, gastric necrosis or bleeding, cardiac dysrhythmias, and infection and sepsis. Intensive nursing care is required postoperatively to prevent and rapidly identify and treat complications that do develop.

The effectiveness of primary radiation therapy is similar to that with radical surgery. Complications associated with radiation therapy to the esophagus include perforation, hemorrhage, and strictures. When used, combination chemotherapy regimens are more effective in reducing tumor mass than single-drug regimens. When the tumor has spread locally or to distant sites, palliative therapy relieves dysphagia and pain (Papadakis & Tierney, 2013). Palliative therapy may include local treatments such as endoscopic dilation, wire stents or laser therapy to keep the esophagus patent, and placement of a gastrostomy or jejunostomy for enteral feeding and fluids.

MANIFESTATIONS OF ESOPHAGEAL CANCER

- Dysphagia
- Anemia
- Weight loss
- GERD-like symptoms
- Regurgitation
- Anorexia
- Chest pain
- Persistent cough

●○● NURSING CARE

Health Promotion

Health promotion measures to reduce the risk for and incidence of esophageal cancer include educating people (especially young people) about the dangers of cigarette smoking and excess alcohol use. Refer to smoking cessation and alcohol treatment programs as indicated. Educate patients with GERD about the relationship between chronic damage to the esophagus due to reflux and esophageal cancer, and stress the importance of effective disease management.

Assessment

Early diagnosis and treatment of esophageal cancer can make a difference in the patient's prognosis. Collect the following assessment data related to esophageal cancer:

- *Health history:* current symptoms such as chest pain, dysphagia, odynophagia (pain with swallowing), coughing or hoarseness; duration of symptoms; recent weight loss; smoking history; current and past patterns of alcohol consumption
- *Physical assessment:* weight; general health status; skin color; supraclavicular and cervical lymph nodes for lymphadenopathy.

Priorities of Care

Maintaining a patent airway is the primary priority of care. Ensuring the patient is comfortable is important, and maintaining adequate hydration and supporting nutritional intake are key areas of focus.

Diagnoses, Outcomes, and Interventions

Disruption of the integrity and function of the esophagus and the discomfort associated with swallowing in patients with esophageal cancer affect the patient's ability to maintain adequate nutritional status, and, potentially, a patent airway.

Imbalanced Nutrition: Less Than Body Requirements

The patient diagnosed with esophageal cancer may already suffer from some degree of malnutrition because of difficulty and pain with swallowing. Enteral nutrition via nasogastric feeding tube or gastrostomy tube or parenteral nutrition maintains nutritional

status after surgery or if the tumor is inoperable and obstruction occurs. See Chapter 22 for nursing interventions related to enteral and parenteral feedings.

Expected Outcome: Patient will maintain body mass and weight within normal limits.

Risk for Ineffective Airway Clearance

After surgery for esophageal cancer, the patient is at high risk for aspiration and difficulty maintaining a patent airway due to disruption of the esophagus and incision into the thoracic cavity.

Expected Outcome: Patient will maintain airway patency as evidenced by ease of breathing, normal respiratory rate and rhythm, and stated absence of dyspnea.

- Assess mental and respiratory status (including rate, depth, breath sounds, and oxygen saturation levels) at least every hour during the initial postoperative period. *Altered mental status increases the risk for aspiration. An increased respiratory rate, dyspnea, diminished and/or abnormal breath sounds, or decreased oxygen saturation levels may indicate impaired airway clearance or possible aspiration pneumonia.*
- Provide aggressive pulmonary hygiene measures, including endotracheal suctioning and chest physiotherapy as indicated or ordered. Following extubation, encourage frequent coughing, deep breathing, and use of the incentive spirometer. *Respiratory complications are a frequent complication of esophagectomy. Aggressive nursing care helps mobilize secretions and prevent atelectasis and possible pneumonia.*
- If present, monitor chest tube function and drainage. Promptly report drainage that is bright red and excessive in amount (>70 mL/h) or purulent. Maintain patency of chest tubes per unit protocol or physician's order. *If a thoracic incision has been used, chest tubes are placed to promote lung reinflation. Proper chest tube function is necessary to prevent pneumothorax and impaired lung inflation.*
- Monitor cardiopulmonary status and hemodynamic pressures. Administer intravenous fluids and fluid boluses as ordered. *Fluid volume imbalances that compromise cardiopulmonary status may develop following esophagectomy. Maintaining adequate fluid intake and preventing fluid overload are important postoperatively. The patient also is at risk for acute respiratory distress syndrome, a critical complication that can further compromise ventilation, gas exchange, and circulation.*
- Do not move or manipulate the nasogastric tube. Maintain low gastric suction as ordered. *Manipulating or moving the nasogastric tube may disrupt suture lines, resulting in a leak into the mediastinum.*
- Verify enteral tube feeding placement by checking the pH of gastric aspirate. Stop enteral feedings if feelings of fullness or nausea occur. Suction gastrointestinal contents as needed, positioning the patient on the side. *Overdistention of the stomach or delayed gastric emptying may result in regurgitation of stomach contents. Nausea or a feeling of fullness may indicate stomach overdistention. Suctioning and positioning limit the risk of aspiration.*

Anticipatory Grieving

Upon a diagnosis of cancer, the patient and family may experience a grief reaction. The pessimistic prognosis associated with esophageal cancer and the disruptions in relationships may result in an intense sense of loss. Chapter 5 discusses care for the patient experiencing grief and loss.

Continuity of Care

Most care for patients with esophageal cancer is provided in community-based and home settings. Include the following topics in patient and family teaching for home care:

- Planned treatment options including the risks, benefits, and potential adverse effects of each option
- Wound and follow-up care following surgery
- Prevention and manifestations of complications such as wound or chest infection, anastomosis leak, deep venous thrombosis
- How to prepare, implement, and care for tube feedings or home parenteral nutrition.

Based on the patient's needs and prognosis, referral to a home health agency and/or hospice may be appropriate.

Delegating Nursing Care Activities

Nursing care activities such as providing or assisting the patient with oral care may be delegated to unlicensed assistive personnel. The nurse may delegate nursing care activities such as taking vital signs, measuring intake and output, and obtaining daily weights. Be sure to reinforce the need to be alert for signs and symptoms of respiratory distress.

Disorders of the Stomach and Duodenum

The stomach and upper small intestine (duodenum and jejunum) are responsible for the majority of food digestion. The major disorders that affect digestion are nausea and vomiting, gastritis, peptic ulcer disease, and cancer of the stomach. Nursing roles in managing these disorders include both acute care for the hospitalized patient and teaching to give the patient the skills and knowledge to manage these conditions at home.

OVERVIEW OF NORMAL PHYSIOLOGY

Normally, the stomach is protected from the digestive substances it secretes—namely, hydrochloric acid and pepsin—by the **gastric mucosal barrier**. The gastric mucosal barrier includes the following:

- An impermeable hydrophobic lipid layer that covers gastric epithelial cells. This lipid layer prevents diffusion of water-soluble molecules, but substances such as aspirin and alcohol can diffuse through it.
- Bicarbonate ions secreted in response to hydrochloric acid secretion by the parietal cells of the stomach. When bicarbonate (HCO_3^-) secretion is equal to hydrogen ion (H^+) secretion, the gastric mucosa remains intact. Prostaglandins, chemical messengers involved in the inflammatory response, support bicarbonate production and blood flow to the gastric mucosa.
- Mucous gel that protects the surface of the stomach lining from the damaging effects of pepsin and traps bicarbonate to neutralize hydrochloric acid. This gel also acts as a lubricant, preventing mechanical damage to the stomach lining from its contents.

When an acute or chronic irritant disrupts the mucosal barrier, or when disease alters the processes that maintain the barrier, the gastric mucosa becomes irritated and inflamed. Lipid-soluble substances such as aspirin and alcohol penetrate the gastric mucosal barrier, leading to irritation and possible inflammation. Bile acids also break down the lipids in the mucosal barrier, increasing the potential for irritation (Longo et al., 2013). In addition, aspirin and other nonsteroidal anti-inflammatory drugs (NSAIDs) inhibit prostaglandins. Aspirin and NSAIDs alter the nature of gastric mucus, affecting its protective function.

THE PATIENT WITH GASTROINTESTINAL BLEEDING

Because of its constant exposure to the environment, the gastrointestinal tract can be subjected to trauma, exposure to toxins, infection with pathogens such as *Helicobacter pylori*, inflammatory processes, and insults such as ischemia due to systemic diseases. While the mucosal lining of the GI tract is remarkably able to withstand these insults and heal rapidly, its rich supply of blood can result in significant bleeding when a vessel is eroded or abnormally distended (*varices*). Gastrointestinal hemorrhage is a relatively common admitting diagnosis and complication of critical illnesses. It is a medical emergency requiring aggressive medical and nursing care.

Although bleeding and hemorrhage can occur anywhere in the GI tract, the upper portion of the tract is more commonly affected. The three primary disorders leading to upper gastrointestinal (UGI) hemorrhage are erosive gastritis, peptic ulcer disease, and esophageal varices. Peptic ulcer disease and erosive gastritis are discussed in the following sections of this chapter; esophageal varices, usually seen as a complication of cirrhosis of the liver, are discussed in Chapter 25.

FAST FACTS

- About 50% of UGI bleeds are due to peptic ulcer disease.
- Erosive gastritis is the second leading cause of UGI hemorrhage, responsible for about 20% of bleeds.
- The third leading cause, esophageal varices, has the highest mortality rate, between 40% and 70%.

Pathophysiology

Blood in the GI tract has several effects. It is irritating to the stomach, and typically leads to nausea and vomiting (**hematemesis**, vomiting blood). If the blood has been present in the stomach for a period of time and is partially digested, it may have a "coffee-grounds" appearance, rather than presenting as bright red blood. The accumulation of blood in the GI tract stimulates peristalsis, leading to hyperactive bowel sounds and diarrhea. Stools may be black and tarry (**melena**) or frankly bloody (**hematochezia**), stool containing partially digested blood has a foul characteristic odor. With significant upper GI bleeding, digestion of blood proteins increases blood urea nitrogen (BUN) levels.

Physiologic responses to an upper GI bleed depend on the rapidity and magnitude of the blood loss. GI bleeding resulting from erosion of a small vessel typically is slow, and may not be identified until the patient presents with manifestations of blood loss anemia due to depletion of iron stores. Although no visible blood may be visible in the stool, **occult** (or hidden) **bleeding** may be detected by chemical means.

GI hemorrhage, a medical emergency with loss of a significant amount of blood within a few hours, rapidly depletes blood volume, producing manifestations of decreased cardiac output: tachycardia, hypotension, pallor, and decreased urine output. Peripheral blood vessels constrict to maintain perfusion of vital organs. Unless the blood volume is restored, hypovolemic shock progresses, leading to acidosis, renal failure, bowel infarction, acute coronary syndrome, coma, and death. See Chapter 11 for more information about shock and its management.

●○● INTERPROFESSIONAL CARE

The acuity of the bleed and the patient's condition dictate the timing and extent of diagnostic testing and interventions. A patient with a massive GI hemorrhage is admitted to the critical care unit and aggressively treated to stem bleeding, restore blood volume, and stabilize the cardiovascular system. Identifying the cause of the bleeding is postponed in many cases until the patient's condition has been stabilized.

When the bleeding is slow or chronic, diagnostic testing and treatment may be managed in an ambulatory care setting.

DIAGNOSIS

Diagnostic testing focuses on determining the extent and effects of the bleed, as well as its cause:

- A *complete blood count with hemoglobin and hematocrit* is obtained. In an acute bleed, the CBC, hemoglobin, and hematocrit may not initially indicate the extent of blood loss because plasma is lost along with blood cells.
- A *blood type and crossmatch* is performed to prepare for transfusion as necessary.
- *Serum electrolytes*, *osmolality*, and *BUN* are obtained to determine the effects of the blood loss and protein digestion on blood chemistries.
- *Liver function studies* and a *coagulation profile* may be obtained to help determine the cause of the bleeding.
- An *upper endoscopy* is performed as soon as possible to identify and, if possible, treat the source of bleeding. See Chapter 21 for nursing care of the patient undergoing an upper endoscopy.

TREATMENTS

In acute GI hemorrhage, initial treatment focuses on stemming the bleeding and restoring cardiovascular stability. Oxygen should be administered to support myocardial oxygen demand. Fluid resuscitation is initiated. Intravenous fluids such as normal saline or a balanced electrolyte solution are administered through a large-bore intravenous catheter. Fresh whole blood, which contains clotting factors, is administered to restore blood volume and components in an acute hemorrhage. In less acute situations, packed red cells may be administered to restore the oxygen-carrying capacity of the blood.

Hemostasis is achieved using upper endoscopy whenever possible. A sclerosing agent may be injected into the bleeding vessel, or the vessel may be sealed using a heated probe, electrocautery, or laser. Rarely, emergency surgery is required to stop hemorrhage.

GASTRIC LAVAGE Gastric lavage, washing out of stomach contents, may be done in patients with upper GI hemorrhage to remove blood from the GI tract, prevent vomiting, and prepare for upper endoscopy.

●○● NURSING CARE

Health Promotion

Preventing gastrointestinal bleeding is the most important step in reducing the mortality and morbidity associated with an acute GI hemorrhage. Identifying patients at risk and instituting regular gastric pH monitoring and maintenance of drug therapy to reduce gastric acidity are important preventive measures. All critically ill patients should be considered to be at risk for stress-related erosive gastritis.

Assessment

Assessment of the patient experiencing an acute GI hemorrhage is very focused on the immediate crisis. The ability to obtain subjective information may be limited; however, it is important to identify possible contributing factors such as use of aspirin, other platelet inhibitors, or anticoagulant medications and the presence of any acute or chronic conditions that may contribute to bleeding (e.g., hypertension, a clotting disorder, peptic ulcer disease, chronic hepatitis, or cirrhosis of the liver). If possible, identify all current medications and their purpose, as well as any allergies to medications or other substances.

Physical examination focuses on the effect of the bleeding on cardiovascular status. Obtain vital signs and orthostatic vital signs (an early sign of hypovolemia). Place the acutely ill patient on a cardiac monitor and obtain a rhythm strip. Obtain oxygen saturation level. Assess peripheral pulse strength, as well as color, temperature, and capillary refill of extremities. Evaluate mental status, including level of consciousness and orientation. An indwelling catheter may be inserted to evaluate urine output.

Priorities of Care

Nursing care priorities for the patient with an acute GI bleed focus on restoring and maintaining an effective cardiac output and tissue perfusion, and on stopping the hemorrhage and preventing further bleeding.

Diagnoses, Outcomes, and Interventions

Risk for Shock

Significant amounts of blood may be lost in a very short time with an acute GI hemorrhage. Because some of the blood enters the bowel, it may be difficult to accurately estimate the amount of blood lost by measuring emesis, gastric suction return, and blood expelled as feces. As blood volume drops, venous return decreases. The heart rate increases to maintain the cardiac output, and peripheral blood vessels constrict to improve venous return and cardiac output.

Expected Outcome: Patient's stable hemodynamic status will be restored (i.e., vital signs within normal range with no evidence of decreased tissue perfusion).

- Frequently assess and document vital signs, including blood pressure, pulse rate and cardiac rhythm, respiratory rate, and oxygen saturation levels. Obtain hemodynamic pressure measurements as ordered, reporting trends and changes. *The vital signs, oxygen saturation levels, and hemodynamic pressure values provide indicators of the effectiveness of peripheral tissue perfusion, oxygenation, and fluid replacement.*
- Monitor for and report changes in skin color, temperature, and moisture, or slow capillary refill. *Peripheral vasoconstriction and activation of the sympathetic nervous system typically cause pale, cool, and moist or diaphoretic skin. Development of cyanosis or mottling indicates a further decrease in tissue perfusion and oxygenation.*
- Insert an indwelling urinary catheter and measure urine output hourly. Report an output of less than 30 mL for two consecutive hours. *A fall in urine output may indicate further reduction in cardiac output. As cardiac output falls, the kidneys become ischemic and acute renal failure may develop.*
- Unless contraindicated, insert a nasogastric tube and connect to low suction. Measure gastric output hourly unless otherwise directed. *Measuring gastric output provides information about the amount of blood and fluid lost. This information helps determine fluid and blood replacement needs.*
- Maintain two peripheral intravenous lines with large-bore catheters or a central venous catheter for fluid and blood administration as ordered. Frequently monitor vital signs, respiratory status, and hemodynamic pressure measurements, reporting changes in status. *Rapid administration of isotonic intravenous fluids, blood, and blood products can lead to fluid overload and potential heart failure.*
- Replace gastric drainage with balanced electrolyte intravenous solutions as ordered. *GI losses are replaced in addition to fluids given to meet daily requirements to prevent fluid volume deficiency.*

Risk for Bleeding

Expected Outcome: Patient will not experience recurrent episodes of GI bleeding (evidenced by lack of visible bleeding and negative evidence of occult bleeding).

- Maintain gastric suction and drainage and patency of nasogastric tube. *Blood is irritating to the GI tract, precipitating vomiting and stimulating peristalsis, leading to diarrhea. In addition, digested blood can increase BUN levels, potentially leading to confusion and altered mental status.*
- Irrigate the nasogastric tube with room temperature saline or tap water as ordered. Calculate intake and output, subtracting the amount of irrigant from gastric output. *Irrigation of the nasogastric tube helps remove irritating blood from the gut and produces a degree of vasoconstriction in the stomach mucosa, slowing bleeding.*
- Prepare for upper endoscopy or surgery as planned. *Endoscopy or emergency surgery may be performed to repair the bleeding site or sclerose bleeding vessels.*
- Following an acute bleed and in patients at risk for GI bleeding, monitor gastric pH as ordered and check vomitus and feces for the presence of occult blood. Maintain infusions of drugs to reduce gastric acidity as ordered. *The patient remains at risk for GI bleeding. Monitoring for occult blood helps identify slow bleeding or recurrent hemorrhage. Reducing the acidity of gastric secretions reduces irritation of the gastric mucosa, reducing the risk of bleeding.*

Continuity of Care

Following an acute GI hemorrhage, continuing care focuses on resolving the underlying disease process if possible and preventing future episodes of GI bleeding. If a bleeding gastric ulcer was identified, testing for *H. pylori* infection will be done, and a treatment regimen prescribed to eradicate the infection (the section on peptic ulcer disease follows). The patient who experienced an episode of erosive stress gastritis will often be discharged with instructions to continue taking a gastric acid–reducing medication and avoid known gastric

irritants such as aspirin and alcohol. The patient with esophageal varices due to cirrhosis or chronic hepatitis needs additional instructions (see Chapter 25).

Patients with minor or slow GI bleeding often are managed in the community. Provide teaching about the cause of the bleeding and measures to prevent future episodes. Provide verbal and written instructions for prescribed medications such as acid reducers and oral iron supplements. Discuss appropriate nutrition; although a special diet to "soothe the stomach" rarely is indicated, foods rich in iron may be recommended to treat the resulting anemia.

Ensure the patient can identify indicators of GI bleeding to be reported to the physician. If the source of bleeding has not been identified, provide instructions about prescribed follow-up diagnostic testing.

THE PATIENT WITH PEPTIC ULCER DISEASE

Peptic ulcer disease (PUD), a break in the mucous lining of the gastrointestinal tract where it comes in contact with gastric juice, is a chronic health problem. PUD affects approximately 10% of the population or 4 million people in the United States every year, primarily those between ages 25 and 64 years. Furthermore, its complications account for an estimated 15,000 deaths annually (Kumar & Mills, 2011; Longo et al., 2013).

Peptic ulcers occur in any area of the gastrointestinal tract exposed to acid-pepsin secretions, including the esophagus, stomach, or duodenum. *Duodenal ulcers* are the most common. They usually develop between the ages of 30 and 55, and are more common in men than women. *Gastric ulcers* more often affect older patients, between the ages of 55 and 70. Ulcers are more common in people who smoke and who are chronic users of NSAIDs. Alcohol and dietary intake do not seem to cause PUD, and the role of stress is uncertain. Although the incidence of PUD has dramatically decreased, the incidence of gastric ulcers is increasing and is believed to be due to the widespread use of NSAIDs (Papadakis & Tierney, 2013).

Risk Factors

Chronic *H. pylori* infection and use of aspirin and NSAIDs are the major risk factors for PUD. Contributing risk factors are listed in Box 23–4. Overall, an estimated 10% to 15% of patients infected with *H. pylori* develop PUD. Of the NSAIDs, aspirin is the most ulcerogenic. A strong familial pattern suggests a genetic factor in the development of PUD. Cigarette smoking is a significant risk factor, doubling the risk of PUD. Cigarette smoking inhibits the secretion of bicarbonate by the pancreas and possibly causes more rapid transit of gastric acid into the duodenum.

BOX 23–4 Risk Factors for Peptic Ulcer Disease

- *H. pylori* infection
  - Older age
  - Low socioeconomic status
  - Birth in a developing country
  - Crowded, unsanitary living conditions
  - Unclean food or water
- Use of aspirin
- History of ulcer
- Concurrent use of drugs such as glucocorticoids or NSAIDs
- Cigarette smoking
- Family history of PUD

Pathophysiology

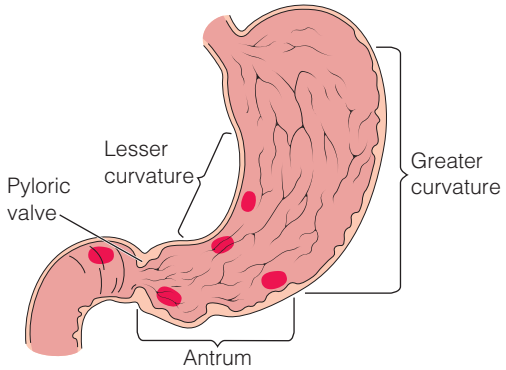
The innermost layer of the stomach wall, the gastric mucosa, consists of columnar epithelial cells, supported by a middle layer of blood vessels and glands, and a thin outer layer of smooth muscle. The mucosal barrier of the stomach, a thin coating of mucous gel and bicarbonate, protects the gastric mucosa. The mucosal barrier is maintained by bicarbonate secreted by the epithelial cells, by mucous gel production stimulated by prostaglandins, and by an adequate blood supply to the mucosa (see the overview of normal physiology earlier in this chapter).

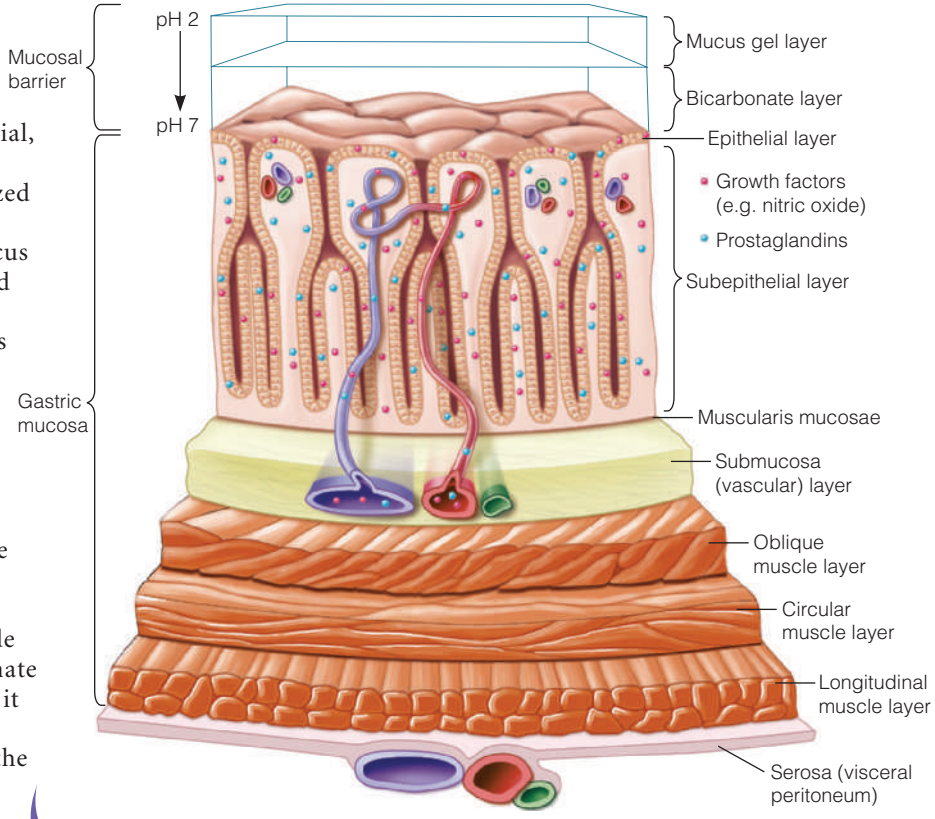
An **ulcer**, or break in the gastrointestinal mucosa, develops when the mucosal barrier is unable to protect the mucosa from damage by hydrochloric acid and pepsin, the gastric digestive juices. See the accompanying Pathophysiology Illustrated: Peptic Ulcer Disease feature on page 610.

H. pylori infection, found in about 50% of people who have PUD, is unique in colonizing the stomach. It is spread person to person (oral–oral or fecal–oral) and contributes to ulcer formation in several ways. The bacteria produce enzymes that reduce the efficacy of mucous gel in protecting the gastric mucosa. In addition, the host's inflammatory response to *H. pylori* contributes to gastric epithelial cell damage without producing immunity to the infection. Although the gastric mucosa is the usual site for *H. pylori* infection, this infection also contributes to duodenal ulcers. This is possibly related to an increase in gastric acid production associated with *H. pylori* infection.

NSAIDs contribute to PUD through both systemic and topical mechanisms. Prostaglandins are necessary for maintaining the gastric mucosal barrier. NSAIDs interrupt prostaglandin synthesis by disrupting the action of the enzyme cyclooxygenase (COX). The two forms of this enzyme are COX-1 and COX-2. The COX-1 enzyme is necessary to maintain the integrity of the gastric mucosa, but the anti-inflammatory effects of NSAIDs result from their ability to inhibit the COX-2 enzyme. The COX-2–selective NSAIDs may be less damaging to the gastric mucosa because they have less effect on the COX-1 enzyme. In addition to their systemic effect, aspirin and many NSAIDs cross the lipid membranes of gastric epithelial cells, damaging the cells themselves.

The ulcers of PUD may affect the esophagus, stomach, or duodenum. They may be superficial or deep, affecting all layers of the mucosa (see Pathophysiology Illustrated: Peptic Ulcer Disease). Duodenal ulcers, the most common, usually develop in the proximal portion of the duodenum, close to the pylorus (Figure 23–7 ■). They are sharply demarcated and usually less than 1 cm in diameter





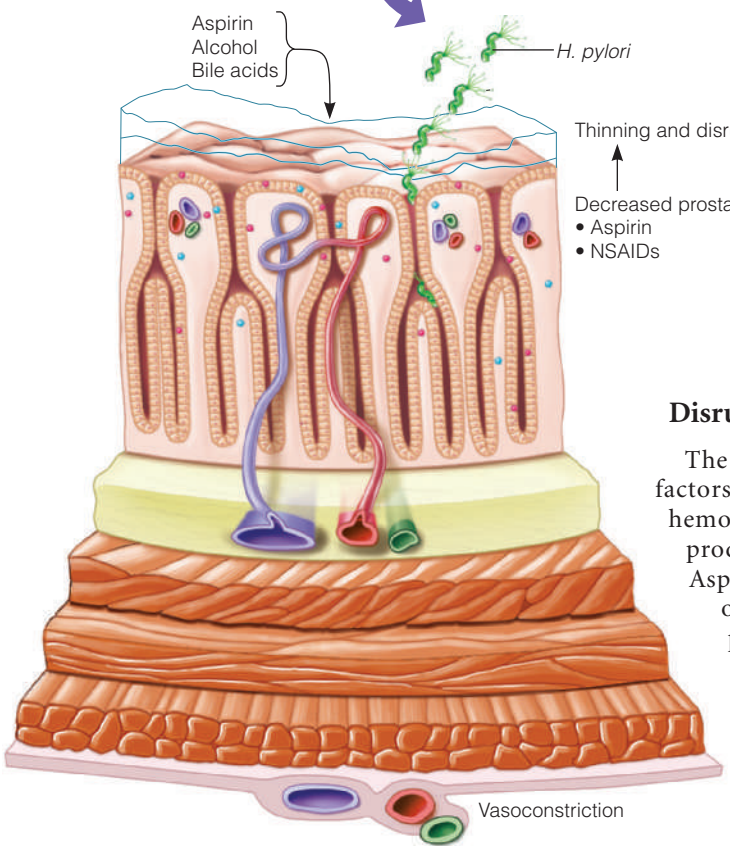


Figure 23–7 ■ Common sites affected by peptic ulcer disease.

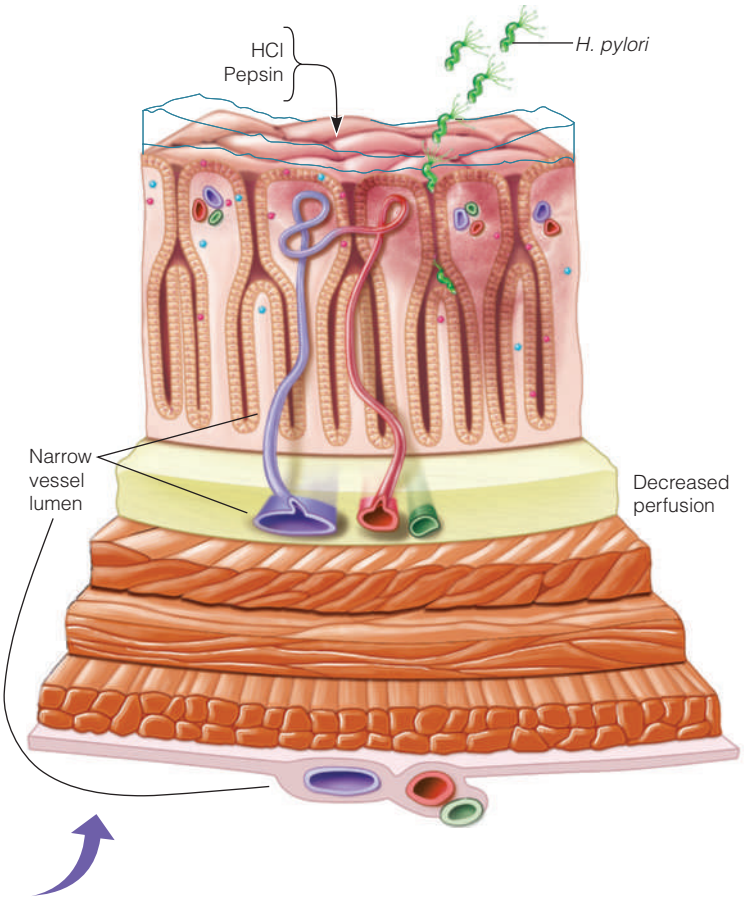
PATHOPHYSIOLOGY ILLUSTRATED
Peptic Ulcer Disease

Normal gastric mucosa

In the stomach and duodenum, the mucosal barrier protects the gastric mucosa (including the epithelial, vascular, and smooth muscle layers) from damage. Specialized mucous cells throughout the gastric mucosa produce a mucus (a mixture of water, lipids, and glycoproteins) that serves as a barrier to the diffusion of ions (such as hydrogen ion) and molecules (such as pepsin). A thin layer of bicarbonate, secreted by surface epithelial cells, forms between the mucus and cell membranes. Blood flow to the gastric mucosa is vital to maintain this barrier. Prostaglandins and nitric oxide stimulate mucus and bicarbonate production, helping maintain it as well. The mucosal barrier constantly bathes surfaces of the gastric epithelial lining.

Thinning and disruption of mucosal barrier



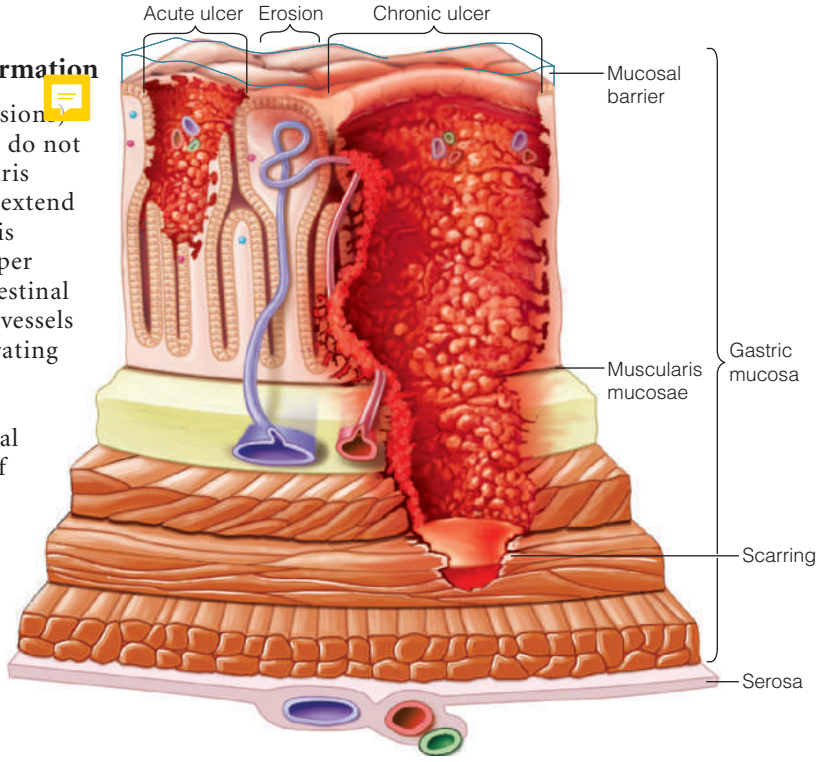
Decreased prostaglandins due to
- Aspirin
- NSAIDs

Ischemia due to
- Hemorrhage
- Hypotension
- Shock

Disruption of mucosal barrier

The mucosal barrier can be disrupted by a number of factors. Ischemia of the gastric mucosa (e.g., due to hemorrhage, hypotension, or shock) impairs mucous production, increasing the risk of damage to the mucosa. Aspirin disrupts the mucosal barrier, and, along with other nonsteroidal anti-inflammatory drugs, inhibits prostaglandins which are necessary to maintain mucous production. Alcohol and bile acids also damage the mucous barrier. *Helicobacter pylori*, a common pathogen to infect the gastric mucosa, disrupts the mucosal barrier.

PATHOPHYSIOLOGY ILLUSTRATED (*continued*)



Inflammatory process

When the mucosal barrier is damaged, gastric acid and digestive juices disrupt the epithelial cell membranes, allowing acid to diffuse into cell walls. An acute inflammatory process results. Gastric epithelial cells migrate to the damaged area, a process known as restitution. Adequate blood flow and an alkaline environment are necessary for this repair process. Prostaglandins play an important role in epithelial repair. In the presence of *H. pylori* infection, excess acid production, inadequate blood flow, inhibition of prostaglandins, and other factors that are less clear, the inflammatory process further damages gastric and duodenal epithelial cells, leading to ulceration of the mucosa.

Erosion and ulcer formation

Superficial ulcers (erosions) erode the mucosa, but do not penetrate the muscularis mucosae. True ulcers extend through the muscularis mucosae and into deeper layers of the gastrointestinal wall, damaging blood vessels and potentially penetrating the entire wall. Hemorrhage and peritonitis are potential acute complications of peptic ulcers.

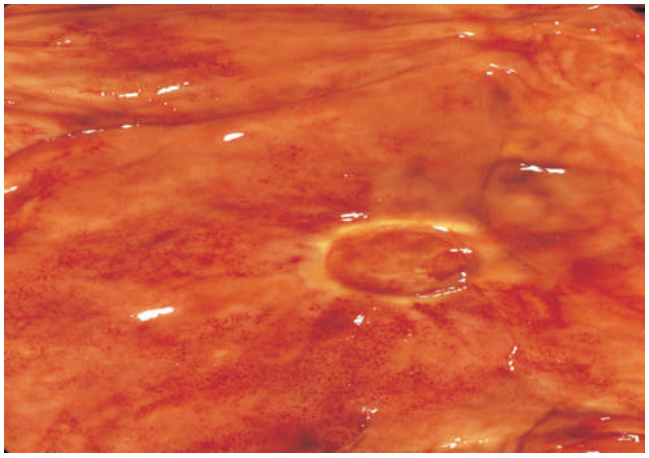


Figure 23–8 ■ A superficial peptic ulcer.
Source: SPL/Photo Researchers, Inc.

(Figure 23–8 ■). Gastric ulcers often are found on the lesser curvature and the area immediately proximal to the pylorus. Gastric ulcers are associated with an increased incidence of gastric cancer.

Peptic ulcer disease may be chronic, with spontaneous remissions and exacerbations. Exacerbations of the disease may be associated with trauma, infection, or other physical or psychologic stressors.

Manifestations

Pain is the classic symptom of peptic ulcer disease. The pain is typically described as gnawing, burning, aching, or hunger-like and is experienced in the epigastric region, sometimes radiating to the back. The pain occurs when the stomach is empty (2 to 3 hours after meals and in the middle of the night) and is relieved by eating with a classic "pain–food–relief" pattern. The patient may complain of heartburn or regurgitation and may vomit.

The presentation of peptic ulcer disease in the older adult is often less clear, with vague and poorly localized discomfort, perhaps chest pain or dysphagia, weight loss, or anemia. In the older adult, a complication of PUD such as upper GI hemorrhage or perforation of the stomach or duodenum may be the presenting symptom.

Complications

The complications associated with peptic ulcers include hemorrhage, obstruction, and perforation. See the accompanying box for the manifestations of these complications.

Among people with PUD, 10% to 20% experience hemorrhage as a result of ulceration and erosion into the blood vessels of the gastric mucosa. Bleeding is the most frequent complication in older adults. It is the presenting symptom in up to 20% of people with PUD (Longo et al., 2013). When small blood vessels erode, blood loss may be slow and insidious, with occult blood in the stool the only initial sign. If bleeding continues, the patient becomes anemic and experiences symptoms of weakness, fatigue, dizziness, and orthostatic hypotension. Erosion into a larger vessel can lead to sudden and severe bleeding with hematemesis, melena, or hematochezia (blood in the stool), and signs of hypovolemic shock.

Gastric outlet obstruction may result from edema surrounding the ulcer, smooth muscle spasm, or scar tissue. Generally, obstruction is a gradual rather than an acute process. Symptoms include a feeling of epigastric fullness, accentuated ulcer symptoms, and nausea. If the obstruction becomes complete, vomiting occurs. Hydrochloric acid, sodium, and potassium are lost in vomitus, potentially leading to fluid and electrolyte imbalance and metabolic alkalosis.

The most lethal complication of PUD is *perforation* of the ulcer through the mucosal wall. When perforation occurs, gastric or duodenal contents enter the peritoneum, causing an inflammatory process and peritonitis. Chemical peritonitis from the hydrochloric acid, pepsin, bile, and pancreatic fluid is immediate; bacterial peritonitis follows within 6 to 12 hours from gastric contaminants entering the normally sterile peritoneal cavity. When an ulcer perforates, the patient has immediate, severe upper abdominal pain, radiating throughout the abdomen and possibly to the shoulder. The abdomen becomes rigid and boardlike, with absent bowel sounds. Signs of shock may be present, including diaphoresis, tachycardia, and rapid, shallow respirations. Classic symptoms of perforation may not be present in an older adult. The older adult may instead present with mental confusion and other nonspecific symptoms. This atypical presentation can lead to delays in diagnosis and treatment, increasing the associated mortality rate.

Zollinger-Ellison Syndrome

Zollinger-Ellison syndrome is peptic ulcer disease caused by a gastrinoma, or gastrin-secreting tumor of the pancreas, stomach, or intestines. More than 60% of gastrinomas are malignant tumors. Gastrin is a hormone that stimulates the secretion of pepsin and hydrochloric acid. The increased gastrin levels associated with these tumors result in hypersecretion of gastric acid, which in turn causes mucosal ulceration.

The peptic ulcers of Zollinger-Ellison syndrome may affect any portion of the stomach or duodenum, as well as the esophagus or jejunum. Characteristic ulcer-like pain is common. The high levels of hydrochloric acid entering the duodenum may cause diarrhea and **steatorrhea** (excess fat in the feces) from impaired fat digestion and absorption. Complications of bleeding and perforation are often seen with Zollinger-Ellison syndrome. Fluid and electrolyte imbalances may result from persistent diarrhea with resultant losses of potassium and sodium in particular.

MANIFESTATIONS OF PUD COMPLICATIONS

HEMORRHAGE
- Occult or obvious blood in the stool
- Hematemesis
- Fatigue
- Weakness, dizziness
- Orthostatic hypotension
- Hypovolemic shock

OBSTRUCTION
- Sensations of epigastric fullness
- Nausea and vomiting
- Electrolyte imbalances
- Metabolic alkalosis

PERFORATION
- Severe upper abdominal pain, radiating to the shoulder
- Rigid, boardlike abdomen
- Absence of bowel sounds
- Diaphoresis
- Tachycardia
- Rapid, shallow respirations
- Fever

●○● INTERPROFESSIONAL CARE

Treatment for PUD focuses on eradicating *H. pylori* infection and treating or preventing ulcers related to use of NSAIDs.

DIAGNOSIS

- *Upper GI series* using barium as a contrast medium can detect 80% to 90% of peptic ulcers. It commonly is the diagnostic procedure chosen first; it is less costly and less invasive than endoscopy. Small or very superficial ulcers may be missed, however.
- *Endoscopy* allows visualization of the esophageal, gastric, and duodenal mucosa and direct inspection of ulcers. Tissue also can be obtained for biopsy.
- Biopsy specimens obtained during an endoscopy can be tested for the presence of *H. pylori* using a *biopsy urease test*, which is more than 90% accurate in diagnosing the infection. It is, however, invasive and costly.
- Noninvasive methods of detecting *H. pylori* infection include fecal *H. pylori* antigen tests (to detect antigens to *H. pylori* in the feces) and the *urea breath test*. In this test, radiolabeled urea is given orally. The urease produced by *H. pylori* bacteria converts the urea to ammonia and radiolabeled carbon dioxide, which can then be measured as the patient exhales. These tests also can be used to evaluate the effectiveness of treatment to eradicate *H. pylori*. Treatment with PPIs interferes with urea breath test and fecal antigen test results, so these drugs should be discontinued for 7 or more days prior to testing (Smith, 2012).
- If Zollinger-Ellison syndrome is suspected, *gastric analysis* may be performed to evaluate gastric acid secretion. Stomach contents are aspirated through a nasogastric tube and analyzed. In Zollinger-Ellison syndrome, gastric acid levels are very high.

MEDICATIONS

The medications used to treat PUD include agents to eradicate *H. pylori*, drugs to decrease gastric acid content, and agents that protect the mucosa. Nursing responsibilities related to selected drugs to treat GERD, gastritis, and PUD are found in the Medication Administration box on page 602.

Eradication of *H. pylori* generally requires 14 days of therapy using a combination of two antibiotics with a PPI or a bismuth compound (e.g., a PPI, clarithromycin, and amoxicillin, or a PPI, bismuth subsalicylate, tetracycline, and metronidazole). With complete eradication of *H. pylori*, reinfection rates are less than 0.5% per year.

In patients who have NSAID-induced ulcers, the NSAID in use should be discontinued if at all possible. If this is not possible, twice-daily PPIs enable ulcer healing.

Medications that decrease gastric acid content include PPIs and the H_2-receptor antagonists.

- Proton-pump inhibitors bind the acid-secreting enzyme (H^+, K^+ ATPase) that functions as the proton pump, disabling it for up to 24 hours. These drugs are very effective, resulting in more than 90% ulcer healing after 4 weeks. Compared to the H_2-receptor blockers, the PPIs provide faster pain relief and more rapid ulcer healing.
- H_2-receptor blockers inhibit histamine binding to the receptors on the gastric parietal cells to reduce acid secretion. These drugs are very well tolerated and have few serious side effects; however, drug interactions can occur. These drugs must be continued for 8 weeks or longer for ulcer healing.

Agents that protect the mucosa include sucralfate, bismuth, antacids, and prostaglandin analogs.

- Sucralfate binds to proteins in the ulcer base, forming a protective barrier against acid, bile, and pepsin. Sucralfate also stimulates the secretion of mucus, bicarbonate, and prostaglandin.
- Bismuth compounds (e.g., Pepto-Bismol, CBS, BBS) stimulate mucosal bicarbonate and prostaglandin production to promote ulcer healing, and likely provide a coating action that prevents further damage by HCl and pepsin. In addition, bismuth has an antibacterial action against *H. pylori*. There are very few side effects, other than constipation and a harmless darkening of stools and the tongue. When used in high doses for a prolonged period, bismuth compounds may be neurotoxic.
- Antacids stimulate gastric mucosal defenses, thereby aiding in ulcer healing. They provide rapid relief of ulcer symptoms, and are often used as needed to supplement other antiulcer medications. Antacids are inexpensive, but patients often have difficulty with a regular regimen because the drugs must be taken frequently and may cause either constipation (from the aluminum-type antacids) or diarrhea (from the magnesium-based antacids). Antacids also interfere with the absorption of iron, digoxin, some antibiotics, and other drugs.
- Prostaglandin analogs (misoprostol) promote ulcer healing by stimulating mucus and bicarbonate secretions and by inhibiting acid secretion. Although not as effective as the other drugs discussed, misoprostol is used to prevent NSAID-induced ulcers.

TREATMENTS

NUTRITION In addition to pharmacologic treatment, patients are encouraged to maintain good nutrition, consuming balanced meals at regular intervals. It is important to teach patients that bland or restrictive diets are unnecessary. Mild alcohol intake is not harmful. Smoking should be discouraged, because it slows the rate of healing and increases the frequency of relapses.

SURGERY The identification of *H. pylori* as a cause of PUD and the availability of drugs to treat the infection and heal peptic ulcers has all but eliminated surgery as a primary treatment option for peptic ulcer disease. Surgery may be required to treat a complication of PUD, such as hemorrhage, perforation, or gastric outlet obstruction. See the section on gastric cancer for more information about gastric surgery and related nursing care.

TREATMENT OF COMPLICATIONS

The patient hospitalized with a complication of PUD such as bleeding, gastrointestinal obstruction, or perforation and peritonitis requires additional interventions to restore homeostasis.

In hemorrhage associated with PUD, initial interventions focus on restoring and maintaining circulation. Normal saline, lactated Ringer's, or other balanced electrolyte solutions are administered intravenously to restore intravascular volume if signs of shock (tachycardia, hypotension, pallor, low urine output, and anxiety) are present. Whole blood or packed red blood cells may be administered to restore hemoglobin and hematocrit levels. A nasogastric tube is inserted to prevent aspiration of vomited gastric contents.

Endoscopy with direct injection of a clotting or sclerosing agent into the bleeding vessel may be performed. Laser photocoagulation, using light energy, or electrocoagulation, which uses electric current to generate heat, can also be done via endoscopy to seal bleeding vessels.

The patient is kept NPO until bleeding is controlled. PPIs are administered intravenously (e.g., 40 mg of pantoprazole [Protonix] per intravenous push or admixture daily) to reduce the risk of rebleeding. Surgery may be necessary if medical measures are ineffective in controlling bleeding. Older adults who experience bleeding as a complication of PUD are more likely to rebleed or require surgery to control the hemorrhage. Nursing care of the patient having gastric surgery is discussed later in this chapter.

Repeated inflammation, healing, scarring, edema, and muscle spasm can lead to gastric outlet (pyloric) obstruction. Initial treatment includes gastric decompression with nasogastric suction and administration of intravenous normal saline and potassium chloride to correct fluid and electrolyte imbalance. H_2-receptor blockers are given intravenously as well. Balloon dilation of the gastric outlet may be done via upper endoscopy. If these measures are unsuccessful in relieving obstruction, surgery may be required.

Gastric or duodenal perforation resulting in contamination of the peritoneum with gastrointestinal contents often requires immediate intervention to restore homeostasis and minimize peritonitis. Intravenous fluids maintain fluid and electrolyte balance. Nasogastric suction removes gastric contents and minimizes peritoneal contamination. Placing the patient in Fowler's or semi-Fowler's position allows peritoneal contaminants to pool in the pelvis. Intravenous antibiotics aggressively treat bacterial infection from intestinal flora. Laparoscopic surgery or an open laparotomy may be performed to close the perforation.

●○● NURSING CARE

Health Promotion

Although it is difficult to predict which patients will develop peptic ulcer disease, promote health by advising patients to avoid risk factors such as excessive aspirin or NSAID use and cigarette smoking. In addition, encourage patients to seek treatment for manifestations of GERD or chronic gastritis, both of which are associated with *H. pylori* infection.

Assessment

Collect the following subjective and objective data when assessing the patient with peptic ulcer disease:

- *Health history:* complaints of epigastric or left upper quadrant pain, heartburn, or discomfort; its character, severity, timing, and relationship to eating; measures used for relief; nausea or vomiting, presence of bright blood or "coffee-grounds" material in vomitus; current medications including use of aspirin or other NSAIDs; cigarette smoking and use of alcohol or other drugs
- *Physical assessment:* general appearance including height and weight relationship; vital signs including orthostatic measurements; abdominal examination including shape and contour, bowel sounds, and tenderness to palpation; presence of obvious or occult blood in vomitus and stool.

Priorities of Care

The priorities of nursing care for the patient with peptic ulcer disease are reducing discomfort, maintaining nutritional status, and preventing or rapidly identifying and intervening for potential complications. See the accompanying Case Study & Nursing Care Plan.

Diagnoses, Outcomes, and Interventions

Acute Pain

The pain of peptic ulcer disease is often predictable and preventable. Pain is typically experienced 2 to 4 hours after eating, as high levels of gastric acid and pepsin irritate the exposed mucosa. Measures to neutralize the acid, minimize its production, or protect the mucosa often relieve this pain, minimizing the need for analgesics.

Expected Outcome: Patient will identify pain triggers, use treatment plan (pharmacologic and nonpharmacologic) to prevent and alleviate discomfort, and report relief from pain.

- Assess pain, including location, type, severity, frequency, and duration, and its relationship to food intake or other contributing factors. *Thorough pain assessment will aide in identifying triggers causing pain and help to determine preventive measures and best treatment options.*

SAFETY ALERT

Avoid making assumptions about pain. Acute pain may indicate a complication, such as perforation (often heralded by sudden, severe epigastric pain and a rigid, boardlike abdomen), or it may be totally unrelated to PUD (e.g., angina, gallbladder disease, or pancreatitis).

- Administer PPIs, H_2-receptor antagonists, antacids, or mucosal protective agents as ordered. Monitor for effectiveness and side effects or adverse reactions. *The pain associated with PUD is generally caused by the effect of gastric juices on exposed mucosal tissue. These medications reduce pain and promote healing by reducing acid production, neutralizing acid, or providing a barrier for the damaged mucosa.*
- Teach relaxation, stress reduction, and lifestyle management techniques. Refer for stress management counseling or classes as indicated. *Although there is no clear relationship between stress and PUD, measures to relieve stress and promote physical and emotional rest help reduce the perception of pain and may reduce ulcer genesis.*

Disturbed Sleep Pattern

Nighttime ulcer pain, which typically occurs between 1:00 and 3:00 a.m., may disrupt the sleep cycle and result in inadequate rest. Anticipation of pain may lead to insomnia or other sleep disruptions.

Expected Outcome: Patient will report absence of symptoms of sleep disruption (anxiety, daytime drowsiness, tiredness).

- Stress the importance of taking medications as prescribed. *The bedtime dose of PPI or H_2-receptor blocker minimizes hydrochloric acid production during the night, reducing nighttime pain.*

Evidence for Nursing Care

The Patient with Peptic Ulcer Disease

Selected resources that nurses may find helpful when planning evidence-based nursing care follow.

CASE STUDY & NURSING CARE PLAN A Patient with Peptic Ulcer Disease

Sean O'Donnell is a 47-year-old police officer who lives and works in a metropolitan area. Mr. O'Donnell has had heartburn and abdominal discomfort for years, but thought it went along with his job. Last year, after becoming weak, light-headed, and short of breath, he was found to be anemic and was diagnosed as having a duodenal ulcer. He took omeprazole (Prilosec) and ferrous sulfate for 3 months before stopping both, saying he had "never felt better in his life." Mr. O'Donnell has now been admitted to the hospital with active upper GI bleeding.

ASSESSMENT

Rachel Clark is Mr. O'Donnell's admitting nurse and case manager. On initial assessment, Mr. O'Donnell is alert and oriented, though very apprehensive about his condition. Skin pale and cool; BP 136/78 mmHg, P 98/min; abdomen distended and tender with hyperactive bowel sounds; 200 mL bright red blood obtained on nasogastric tube insertion. Hemoglobin 8.2 g/dL and hematocrit 23% on admission. Mr. O'Donnell is taken to the endoscopy lab where his bleeding is controlled using laser photocoagulation. On his return to the nursing unit, he receives two units of packed RBCs and intravenous fluids to restore blood volume. A 5-day course of high-dose oral omeprazole (40 mg bid) is ordered to prevent rebleeding, and Mr. O'Donnell is allowed to begin a clear liquid diet 24 hours after his endoscopy. Tissue biopsy obtained during endoscopy confirms the presence of *H. pylori* infection.

DIAGNOSES

- *Deficient Fluid Volume* related to acutely bleeding duodenal ulcer
- *Risk for Injury* related to acute blood loss
- *Fear* related to threat to well-being
- *Ineffective Self-Health Management* related to lack of knowledge regarding PUD and its treatment

EXPECTED OUTCOMES

- Patient will maintain normal blood pressure, pulse, and urine output (>30 mL/h).
- Patient will remain free of injury.
- Patient will seek information to reduce fear.
- Patient will identify and use coping strategies to manage fear.
- Patient will describe prescribed therapeutic regimen.
- Patient will verbalize ability to manage prescribed regimen.

PLANNING AND IMPLEMENTATION

- Place call light within reach and encourage to ask for help when getting up or ambulating. Remind to rise slowly from lying to sitting and sitting to standing.
- Discuss situation and provide information about all procedures and treatments.
- Reassure about the effectiveness of treatment in reducing the risk for further bleeding.
- Discuss current and planned treatment measures; stress the importance of completing the prescribed treatment to reduce the risk of further ulcer development.
- Encourage to avoid using aspirin or NSAIDs in the future; suggest alternative medications such as acetaminophen.
- Discuss stress reduction techniques and refer for stress reduction counseling or workshops as indicated.

EVALUATION

Mr. O'Donnell is discharged 48 hours after admission. He has had no further evidence of bleeding, and has resumed a regular diet. His hemoglobin and hematocrit remain low, and he has a prescription for ferrous sulfate. He will complete the prescribed high-dose omeprazole regimen at home, then begin treatment with omeprazole, amoxicillin, and clarithromycin (Biaxin) to eradicate the *H. pylori* infection detected during endoscopy. After 2 weeks of this regimen, he will continue taking omeprazole at bedtime for 4 to 8 weeks. He verbalizes a good understanding of his treatment and the importance of completing the entire regimen. Mr. O'Donnell expresses concern about his ability to "keep his cool on the inside" when under stress. Ms. Clark, his case manager, gives him the names of several resources to help with stress management in case he wants help.

Clinical Reasoning in Patient Care

1. How does *H. pylori* infection contribute to the development of peptic ulcers?
2. Describe the physiologic responses to fear and anxiety. Why is it important to alleviate fear and its physical consequences in patients with PUD?
3. What suggestions can you make to help Mr. O'Donnell manage his complex treatment regimen during the next 3 months?
4. Develop a teaching plan that includes stress reduction techniques Mr. O'Donnell can use while performing his duties as a police officer.

See Evaluating Your Response in Appendix B.

- Instruct to limit food intake after the evening meal, eliminating any bedtime snack. *Eating before bed can stimulate the production of gastric acid and pepsin, increasing the likelihood of nighttime pain.*
- Encourage use of relaxation techniques and comfort measures such as soft music as needed to promote sleep. *Once the pain associated with PUD has been controlled, these measures help reduce anxiety and reestablish a normal sleep pattern.*

Imbalanced Nutrition: Less Than Body Requirements

In an attempt to avoid discomfort, the patient with peptic ulcer disease may gradually reduce food intake, sometimes jeopardizing nutritional status. Anorexia and early satiety are additional problems associated with PUD.

Expected Outcome: Patient's weight and body mass index will stabilize and be within normal limits. Patient will describe intake of a well-balanced diet and normal eating patterns.

- Assess current diet, including pattern of food intake, eating schedule, and foods that precipitate pain or are being avoided in anticipation of pain. *The patient may not realize the extent of self-imposed dietary limitations, especially if symptoms have persisted for an extended time. Assessment increases awareness and also helps identify the adequacy of nutrient intake.*
- Refer to a dietitian for meal planning to minimize PUD symptoms and meet nutritional needs. Consider normal eating patterns and preferences in meal planning. *Although no specific diet is recommended for PUD, patients should avoid foods that increase pain. Six small meals per day often help increase food tolerance and decrease postprandial discomfort.*
- Monitor for complaints of anorexia, fullness, nausea, and vomiting. Adjust dietary intake or medication schedule as indicated. *PUD and resultant scarring can lead to impaired gastric emptying, necessitating a treatment change.*
- Advise the patient to report increasing or persistent symptoms of anorexia, nausea, vomiting, or fullness to the healthcare provider.

These are symptoms of gastric outlet obstruction, which can lead to serious complications and nutritional deficiencies.

- Monitor laboratory values for indications of anemia or other nutritional deficits. Monitor for therapeutic and side effects of treatment measures such as oral iron replacement. Instruct the patient taking oral iron replacement to avoid using an antacid within 1 to 2 hours of taking the iron preparation. *Anemia can result from poor nutrient absorption or chronic blood loss in patients with PUD. Oral iron supplements may cause GI distress, nausea, and vomiting; if these side effects are intolerable, notify the physician for a possible change of therapy. Antacids bind with oral iron preparations, blocking absorption.*

Risk for Bleeding

Erosion of a blood vessel with resultant hemorrhage is a significant risk for the patient with peptic ulcer disease. Acute bleeding can lead to hypovolemia and fluid volume deficit, which can lead to a decrease in cardiac output and impaired tissue perfusion.

Expected Outcome: Patient will not exhibit signs of visible or occult blood. Hematocrit and hemoglobin will be maintained within normal limits. Vital signs will be maintained within normal limits and urine output will be >30 mL/h.

SAFETY ALERT

Monitor and record blood pressure and apical pulse every 15 to 30 minutes until stable; monitor central venous pressure or pulmonary artery pressure as indicated. Insert a Foley catheter and monitor urinary output hourly. Weigh daily. Continuous monitoring of cardiac output parameters is essential in patients with an acute hemorrhage to identify possible shock and assure interventions are initiated at an early stage.

- Monitor stools and gastric drainage for overt and occult blood. Assess gastric drainage (vomitus or from a nasogastric tube) to estimate the amount and rapidity of hemorrhage. *Drainage is bright red with possible clots in acute hemorrhage; dark red or the color of coffee grounds when blood has been in the stomach for a period of time.* Hematochezia *(stool containing red blood and clots) is present in acute hemorrhage;* melena *(black, tarry stool) is an indicator of less acute bleeding. When small vessels are disrupted, bleeding may be slow and not overtly evident. With chronic or slow gastrointestinal bleeding, the risk of a fluid volume deficit is minimal; anemia and activity intolerance are more likely.*
- Maintain intravenous therapy with fluid volume and electrolyte replacement solutions; administer whole blood or packed cells as ordered. *Both fluids and electrolytes are lost through vomiting, nasogastric drainage, and diarrhea in an episode of acute bleeding. To prevent shock, it is essential to maintain a blood volume and cardiac output sufficient to perfuse body tissues. Whole blood and packed cells replace both blood volume and red blood cells, providing additional oxygen-carrying capacity to meet cell needs.*
- Insert a nasogastric tube and maintain its position and patency according to agency policy and procedure. Initially, measure and record gastric output every hour, then every 4 to 8 hours. *Nasogastric suction removes blood from the gastrointestinal tract, preventing vomiting and possible aspiration. Gastric output is replaced milliliter for milliliter with a balanced electrolyte solution to maintain homeostasis.*
- Monitor hemoglobin and hematocrit, serum electrolytes, BUN, and creatinine values. Report abnormal findings. *Hemoglobin and hematocrit are lower than normal with acute or chronic GI bleeding. In acute hemorrhage, initial results may be within normal range because both cells and plasma are lost. Loss of fluids and electrolytes with gastric drainage and diarrhea will alter normal levels. Digestion and absorption of blood in the GI tract may result in elevated BUN and creatinine levels.*
- Assess abdomen, including bowel sounds, distention, girth, and tenderness, every 4 hours and record findings. *Borborygmi or hyperactive bowel sounds with abdominal tenderness are common with acute GI bleeding. Increased distention, increasing abdominal girth, absent bowel sounds, or extreme tenderness with a rigid, boardlike abdomen may indicate perforation.*
- Maintain bed rest with the head of the bed elevated. Ensure safety. *Loss of blood volume may cause orthostatic hypotension with resultant syncope or dizziness upon standing.*

Continuity of Care

Peptic ulcer disease is managed in home and community-based settings; only its complications typically require treatment in an acute care setting. Provide the following information when preparing the patient for home care:

- Prescribed medication regimen, including desired and potential adverse effects
- Importance of continuing therapy even when symptoms are relieved
- Relationship between peptic ulcers and factors such as NSAID use and smoking (If indicated, refer to a smoking cessation clinic or program.)
- Importance of avoiding use of aspirin and other NSAIDs; stress the necessity of reading the labels of over-the-counter medications for possible aspirin content
- Manifestations of complications that should be reported to the care provider, including increased abdominal pain or distention, vomiting, black or tarry stools, light-headedness, or fainting
- Stress and lifestyle management techniques that may help prevent exacerbation. Refer to resources for stress management, such as classes, counseling, and formal or informal groups.

THE PATIENT WITH GASTRITIS

Gastritis, inflammation of the stomach lining, results from irritation of the gastric mucosa. Gastritis is common, and may be caused by a variety of factors. The most common form of gastritis, *acute gastritis*, is generally a benign, self-limiting disorder associated with the ingestion of gastric irritants such as aspirin, alcohol, caffeine, or foods contaminated with certain bacteria. Manifestations of acute gastritis may range from asymptomatic to mild heartburn to severe gastric distress, vomiting, and bleeding with hematemesis (vomiting blood).

Chronic gastritis is a separate group of disorders characterized by progressive and irreversible changes in the gastric mucosa (Longo et al., 2013). Chronic gastritis is more common in older adults, individuals with alcoholism, and those who smoke cigarettes. When symptoms of chronic gastritis occur, they are often vague, ranging from a feeling of heaviness in the epigastric region after meals to gnawing, burning, ulcer-like epigastric pain unrelieved by antacids.

Pathophysiology

ACUTE GASTRITIS

Acute gastritis is characterized by disruption of the mucosal barrier by a local irritant. This disruption allows hydrochloric acid and pepsin to come into contact with the gastric tissue, resulting in irritation, inflammation, and superficial erosions. The gastric mucosa rapidly regenerates, generally making acute gastritis a self-limiting disorder, with resolution and healing occurring within several days.

The ingestion of aspirin or other NSAIDs, corticosteroids, alcohol, and caffeine is commonly associated with the development of acute gastritis. Accidental or purposeful ingestion of a corrosive alkali (such as ammonia, lye, Lysol, and other cleaning agents) or acid leads to severe inflammation and possible necrosis of the stomach. Gastric perforation, hemorrhage, and peritonitis are possible results. Iatrogenic causes of acute gastritis include radiation therapy and administration of certain chemotherapeutic agents.

EROSIVE GASTRITIS

A severe form of acute gastritis, **erosive (stress-induced) gastritis**, occurs as a complication of other life-threatening conditions such as shock, severe trauma, major surgery, sepsis, burns, or head injury. When these erosions follow a major burn, they are called **Curling's ulcers**, after Thomas Curling, a British physician, who first described them in 1842. When stress ulcers occur following head injury or CNS surgery, they are referred to as **Cushing's ulcers**, after Harvey Cushing, a U.S. surgeon.

The primary mechanisms leading to erosive gastritis appear to be ischemia of the gastric mucosa resulting from sympathetic vasoconstriction, and tissue injury due to gastric acid. As a result, multiple superficial erosions of the gastric mucosa develop. Maintaining the gastric pH at greater than 3.5 and inhibiting gastric acid secretion with medications help prevent erosive gastritis.

MANIFESTATIONS The patient with acute gastritis may have mild symptoms such as **anorexia** (loss of appetite) or mild epigastric discomfort relieved by belching or defecating. More severe manifestations include abdominal pain, nausea, and vomiting. Gastric bleeding may occur, with hematemesis or melena (black, tarry stool that contains blood). Erosive gastritis is not typically associated with pain. The initial symptom often is painless gastric bleeding occurring two or more days after the initial stressor. Bleeding typically is minimal, but can be massive. Corrosive gastritis can cause severe bleeding, signs of shock, and an *acute abdomen* (severely painful, rigid, boardlike abdomen) if perforation occurs. See the accompanying Manifestations box.

CHRONIC GASTRITIS

Unrelated to acute gastritis, chronic gastritis is a progressive disorder that begins with superficial inflammation and gradually leads to atrophy of gastric tissues. The initial stage is characterized by superficial changes in the gastric mucosa and a decrease in mucus. As the disease evolves, glands of the gastric mucosa are disrupted and destroyed. The inflammatory process involves deep portions of the mucosa, which thins and atrophies. There are several types of chronic gastritis; *H. pylori* gastritis and autoimmune gastritis are the most commonly seen.

H. pylori gastritis is the most common form of chronic gastritis. Its incidence increases with age, and is significantly higher in developing countries than in industrialized countries (Longo et al., 2013). It is caused by chronic infection of the gastric mucosa by *H. pylori*, a gram-negative spiral bacterium. *H. pylori* infection causes inflammation of the gastric mucosa, with infiltration by neutrophils and lymphocytes. The outermost layer of gastric mucosa thins and atrophies, providing a less effective barrier against the autodigestive properties of hydrochloric acid and pepsin.

Infection with *H. pylori* also is associated with peptic ulcer disease and an increased risk of developing gastric cancer.

Autoimmune gastritis is a less common form of chronic gastritis, accounting for about 10% of patients with chronic gastritis (Longo et al., 2013). In autoimmune gastritis, the body produces antibodies to parietal cells and intrinsic factor. These antibodies destroy gastric mucosal cells, resulting in tissue atrophy and the loss of hydrochloric acid and pepsin secretion. Production of intrinsic factor also is affected in most cases. Because intrinsic factor is required for the absorption of vitamin B_{12}, this immune response results in pernicious anemia.

MANIFESTATIONS Chronic gastritis is often asymptomatic until atrophy is sufficiently advanced to interfere with digestion and gastric emptying. The patient may complain of vague gastric distress, epigastric heaviness after meals, or ulcer-like symptoms. These symptoms are typically not relieved by antacids. In addition, the patient may experience fatigue and other symptoms of anemia. If intrinsic factor is lacking, paresthesias and other neurologic manifestations of vitamin B_{12} deficiency may be present. See the previous Manifestations box.

MANIFESTATIONS OF ACUTE AND CHRONIC GASTRITIS

ACUTE GASTRITIS

Gastrointestinal	Systemic
• Anorexia • Nausea and vomiting • Hematemesis • Melena • Abdominal pain	• Possible shock

CHRONIC GASTRITIS

Gastrointestinal	Systemic
• Vague discomfort after eating; may be asymptomatic	• Anemia • Fatigue

●○● INTERPROFESSIONAL CARE

Acute gastritis is usually diagnosed by the history and clinical presentation. In contrast, the vague symptoms of chronic gastritis may require more extensive diagnostic testing.

Patients with acute and chronic gastritis are generally managed in community settings. The patient requires acute care only when nausea and vomiting are severe enough to interfere with normal fluid and electrolyte balance and nutritional status. If hemorrhage results, surgical intervention may be required.

DIAGNOSIS

Diagnostic tests that may be ordered for the patient with gastritis include the following:

- *Testing* for *H. pylori* infection, including urea breath tests, serologic testing, and fecal antigen testing.
- *Gastric analysis* to assess hydrochloric acid secretion. Secretion may be decreased in patients with chronic gastritis.
- *Hemoglobin, hematocrit*, and *red blood cell (RBC) indices* are evaluated for evidence of anemia. The patient with gastritis may develop pernicious anemia because of parietal cell destruction, or iron-deficiency anemia because of chronic blood loss.
- *Serum vitamin B_{12} levels* are measured to evaluate for possible pernicious anemia. Normal values for vitamin B_{12} are 200 to 1000 pg/mL, with lower levels seen in older adults.
- *Upper endoscopy* may be done to inspect the gastric mucosa for changes, identify areas of bleeding, and obtain tissue for biopsy. Bleeding sites may be treated with electro- or laser coagulation or injected with a sclerosing agent during the procedure.

See Chapter 21 for patient preparation and teaching related to diagnostic tests for upper GI disorders.

MEDICATIONS

Drugs such as a PPI, H_2-receptor blocker, or sucralfate may be ordered to prevent or treat acute stress gastritis. PPIs and H_2-receptor blockers reduce the amount or effects of hydrochloric acid on the gastric mucosa. Lansoprazole (Prevacid), esomeprazole (Nexium), and omeprazole (Prilosec) are examples of PPIs. H_2-receptor blockers include cimetidine (Tagamet), ranitidine (Zantac), famotidine (Pepcid), and nizatidine (Axid). These drugs also are available in nonprescription strength. Sucralfate (Carafate) works locally to prevent the damaging effects of acid and pepsin on gastric tissue. It does not neutralize or reduce acid secretion. Nursing implications for drugs commonly used in managing gastritis are included in the Medication Administration box earlier in this chapter.

Chronic *H. pylori* infection may be treated using combination therapy that includes two antibiotics (such as metronidazole, amoxicillin, clarithromycin, or tetracycline), a bismuth compound, and possibly a PPI. In some cases, eradication of the infection is not warranted, and the patient is treated symptomatically.

TREATMENTS

In acute gastritis, gastrointestinal tract rest is provided by 6 to 12 hours of NPO status, then slow reintroduction of clear liquids (broth, tea, gelatin, carbonated beverages), followed by ingestion of heavier liquids (cream soups, puddings, milk), and finally a gradual reintroduction of solid food.

If nausea and vomiting threaten fluid and electrolyte balance, intravenous fluids and electrolytes are ordered.

GASTRIC LAVAGE Acute gastritis resulting from ingestion of a poisonous or corrosive substance (acid or strong alkali) is treated with immediate dilution and removal of the substance. Vomiting is not induced because it might further damage the esophagus and possibly the trachea; instead, gastric lavage (washing out of the stomach contents) is performed.

COMPLEMENTARY THERAPIES Complementary therapies such as herbal remedies or aromatherapy may be appropriate to recommend for patients with gastritis. Refer the patient to a healthcare provider trained in natural and herbal remedies or to an aromatherapist for an individualized treatment plan. Recommendations may include the following:

- Chamomile tea or the essential oil used in aromatherapy
- Garlic; one clove chopped fine and taken daily at bedtime
- Ginger, powdered or in capsules or made into a tea taken before or after meals
- Mint oil aromatherapy via a diffuser, in a bath, or diluted with a carrier oil and used for a soothing massage.

●○● NURSING CARE

Health Promotion

Teach all patients and community members about measures to prevent acute gastritis. Food contaminated with bacteria is a significant cause of acute gastritis. Discuss food safety measures such as fully cooking meats and egg products, and promptly refrigerating foods after cooking to avoid bacterial growth. Stress that food contaminated with potential pathogens often looks, smells, and tastes good, making it difficult to identify. Teach patients to abstain from eating or drinking anything during an acute episode of vomiting, then reintroduce clear liquids gradually once vomiting has stopped (2 to 4 hours after the last episode of vomiting). Suggest using liquids such as Pedialyte or a sport drink to replace lost electrolytes and fluid. Instruct patients to avoid milk and milk products until they easily tolerate clear liquids and solid foods such as dry toast or saltine crackers.

Assessment

Assessment data to collect for patients with acute or chronic gastritis include the following:

- *Health history:* current symptoms and their duration; relieving and aggravating factors; history of ingestion of toxins, contaminated food, alcohol, aspirin, or NSAIDs; other medications
- *Physical assessment:* vital signs including orthostatic vitals if indicated; peripheral pulses; general appearance; abdominal assessment including appearance, bowel sounds, and tenderness.

Priorities of Care

Managing pain and other symptoms associated with gastritis is the key to promoting healing of tissue damage related to gastritis. Ensuring the patient's nutritional status is adequate is also a priority.

Diagnoses, Outcomes, and Interventions

In planning and implementing nursing care for the patient with acute or chronic gastritis, consider both the direct effects of the disorder on the gastrointestinal system and nutritional status as well as its effects on lifestyle and psychosocial integrity. This section focuses on problems related to nausea and anorexia associated with gastritis.

Nausea

Nausea, vomiting, and abdominal distress are the primary manifestations of acute gastritis. Patients with chronic gastritis often experience anorexia and nausea that can interfere with food intake and nutritional status.

Expected Outcome: Patient will express relief from nausea and be free from emesis. Patient's fluid intake will be adequate to establish and maintain an adequate fluid balance as evidenced by stable vital signs and urine output >30 mL/h.

- Monitor subjective complaints of nausea. *Nausea is a subjective sensation best described by the patient.*
- For the patient with acute gastritis, monitor vital signs, skin turgor and condition, and weight. Maintain accurate intake and output records. Monitor amount, color, and specific gravity of urine. *Nausea and vomiting associated with acute gastritis can significantly affect food and fluid intake, leading to dehydration.*
- Administer antiemetic medication as ordered, prior to meals and before treatments or procedures known to stimulate nausea. *Preventing nausea is particularly important to ensure the patient can resume a nutritional diet that will facilitate healing of damaged tissue.*
- Instruct to consume small quantities of clear fluids and dry foods at separate times. *Separating the intake of dry foods and fluids helps reduce the nausea stimulus.*

Imbalanced Nutrition: Less Than Body Requirements

Manifestations of chronic gastritis may lead to reduced food intake and malnutrition. The patient often associates these unpleasant sensations with eating, and may gradually reduce food intake. Associated anorexia also contributes to poor food intake.

Expected Outcome: Patient's food intake will meet caloric and nutritional demand required to meet metabolic needs and promote healing of damaged tissue.

- Monitor and record food and fluid intake and any abnormal losses (such as vomiting). *Careful monitoring can help in developing a dietary plan to meet the caloric needs of the patient.*
- Monitor weight and laboratory studies such as serum albumin, hemoglobin, and RBC indices. *Weights and laboratory values provide data regarding nutritional status and the effectiveness of interventions.*
- Arrange for a dietary consultation to determine caloric and nutrient needs and develop a dietary plan. Consider food preferences and tolerances in menu planning. *A diet high in protein, vitamins, and minerals may be prescribed to meet nutritional needs of the patient with chronic gastritis. In addition, specific food intolerances may need to be considered. Planning to include preferred foods in the diet helps ensure consumption of the prescribed diet.*
- Provide nutritional supplements between meals or frequent small feedings as needed. *Many patients with chronic gastritis tolerate small, frequent feedings better than three large meals per day.*
- Maintain tube feedings or parenteral nutrition as ordered. Refer to Chapter 22 for further information on enteral and parenteral feedings.

Delegating Nursing Care Activities

As appropriate and allowed by the designated duties and responsibilities of unlicensed assistive personnel, the nurse may delegate nursing care activities such as measuring intake and output, obtaining daily weights, and assisting with meals.

Continuity of Care

Because acute or chronic gastritis is usually managed in community-based settings, teaching is vital. For the patient with acute gastritis, teaching focuses on managing acute symptoms, reintroducing fluids and solid foods, identifying indicators of possible complications (e.g., continued vomiting, signs of fluid and electrolyte imbalance), and preventing future episodes.

Provide the following information for patients with chronic gastritis:

- How to maintain optimal nutrition
- Helpful dietary modifications
- Use of prescribed medications
- How to avoid known gastric irritants, such as aspirin, alcohol, and cigarette smoking. Referral to smoking cessation classes or programs to treat alcohol abuse may be necessary.

THE PATIENT WITH CANCER OF THE STOMACH

Worldwide, cancer of the stomach is the most common cancer (after skin cancer), but it is less common in the United States.

FAST FACTS

- An estimated 21,320 new cases of stomach cancer are diagnosed annually in the United States (ACS, 2012).
- Its incidence is highest in Hispanics, African Americans, and Asian Americans.
- Men are affected nearly twice as often as women.

Older adults are more likely to develop gastric cancer. The mean age at time of diagnosis is 63. People in lower socioeconomic groups are more often affected by gastric cancer.

Risk Factors

H. pylori infection is a major risk factor for cancer of the distal portion of the stomach; 60% to 90% of cases can be attributed to this infection. Other risk factors are a genetic predisposition, chronic gastritis, pernicious anemia, gastric polyps, smoking, or carcinogenic factors in the diet (such as smoked foods and nitrates). Achlorhydria, a lack of hydrochloric acid in the stomach, is a known risk factor. The risk for gastric cancer also is increased in people who have had a partial gastric resection.

Pathophysiology

Adenocarcinoma, which involves the mucus-producing cells of the stomach, is the most common form of gastric cancer. These carcinomas may arise anywhere on the mucosal surface of the stomach but are most frequently found in the distal portion. More than half of all gastric cancers occur in the antrum or pyloric region (Papadakis & Tierney, 2013). Gastric cancer begins as a localized lesion (*in situ*), then progresses to involve the mucosa or submucosa (early gastric carcinoma). Lesions may spread by direct extension to tissues surrounding the stomach, the liver in particular. The lesion may ulcerate or appear as a polypoid (polyp-like) mass (Figure 23–9 ■). Lymph node involvement and metastasis occur early due to the rich blood and lymphatic supply to the stomach. Metastatic lesions are often found in the liver, lungs, ovaries, and peritoneum.

Manifestations

Gastric cancer has few manifestations. Unfortunately, the disease is often quite advanced and metastases are usually present at the time

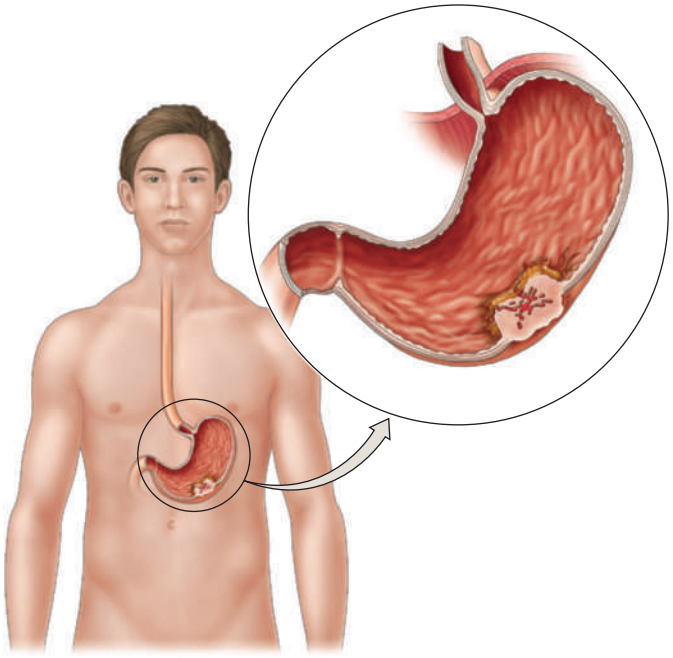

Figure 23–9 ■ Gastric cancer affecting the antrum of the stomach.

of diagnosis. Early symptoms are vague, including feelings of early satiety, anorexia, indigestion, and possibly vomiting. The patient may experience ulcer-like pain unrelieved by antacids, typically occurring after meals. As the disease progresses, weight loss occurs, and the patient may be *cachectic* (in very poor health and malnourished) at the time of diagnosis. An abdominal mass may be palpable, and occult blood may be present in the stool, indicating gastrointestinal bleeding.

●○● INTERPROFESSIONAL CARE

DIAGNOSIS

Anemia detected by a CBC often is the first indication of gastric cancer. Upper endoscopy should be performed on patients over age 55 with new onset of epigastric symptoms and in anyone with persistent dyspepsia (Papadakis & Tierney, 2013). An upper GI x-ray with barium swallow is an acceptable alternative to identify lesions, and ultrasound or other radiologic techniques may identify a mass. Upper endoscopy with visualization and biopsy of the lesion provides a definitive diagnosis of gastric cancer.

SURGERY

When gastric cancer is identified prior to the development of metastasis, surgical removal of part or all of the stomach and regional lymph nodes is the treatment of choice. **Partial gastrectomy** involves removal of a portion of the stomach, usually the distal half to two-thirds. In partial gastrectomy, the surgeon constructs an anastomosis from the remainder of the stomach directly to the duodenum or to the proximal jejunum. The *gastroduodenostomy* (Billroth I) and the *gastrojejunostomy* (Billroth II) are commonly used partial gastrectomy procedures.

A **total gastrectomy**, removal of the entire stomach, may be done for diffuse cancer that is spread throughout the gastric mucosa but limited to the stomach. In a total gastrectomy, the surgeon constructs an anastomosis from the esophagus to the duodenum or jejunum.

COMPLICATIONS Several long-term complications may develop following gastrectomy procedures. **Dumping syndrome** is the most common problem. It may follow a partial gastrectomy with duodenal or jejunal anastomosis. When the pylorus has been resected or bypassed, a hypertonic, undigested food bolus may rapidly enter the duodenum or jejunum. Water is pulled into the lumen of the intestine by the hyperosmolar character of the chyme, resulting in decreased blood volume and intestinal dilation. Peristalsis is stimulated, and intestinal motility is increased.

Early symptoms of dumping syndrome occur within 5 to 30 minutes after eating. These symptoms result from intestinal dilation, peristaltic stimulation, and hypovolemia caused by undigested food in the proximal small intestine. Manifestations include nausea with possible vomiting, epigastric pain with cramping and *borborygmi* (loud, hyperactive bowel sounds), and diarrhea. Systemic symptoms from the hypovolemia and reflex sympathetic stimulation include tachycardia, orthostatic hypotension, dizziness, flushing, and diaphoresis.

The entry of hyperosmolar chyme into the jejunum also causes a rapid rise in the blood glucose. This stimulates the release of an excessive amount of insulin, leading to hypoglycemic symptoms 2 to 3 hours after the meal. Dumping syndrome is typically self-limiting, lasting 6 to 12 months after surgery; however, a small percentage of people continue to experience long-term symptoms.

Dumping syndrome is managed primarily by a dietary pattern that delays gastric emptying and allows smaller boluses of undigested food to enter the intestine. Meals should be small and more frequent. Liquids and solids are taken at separate times instead of together during a meal. The amount of proteins and fats in the diet is increased, because they exit the stomach more slowly than carbohydrates. Carbohydrates, especially simple sugars, are reduced. The patient is instructed to rest in a recumbent or semirecumbent position for 30 to 60 minutes after meals. Anticholinergics, sedatives, and antispasmodics may be prescribed.

Anemia may be a chronic problem after a major gastric resection. Iron is absorbed primarily in the duodenum and proximal jejunum; rapid gastric emptying or a gastrojejunostomy may interfere with adequate absorption.

The cells of the stomach produce intrinsic factor, required for the absorption of vitamin B_{12}. Vitamin B_{12} deficiency leads to pernicious anemia. Because of hepatic stores of vitamin B_{12}, symptoms of anemia may not be seen for 1 to 2 years after surgery. Vitamin B_{12} levels are routinely monitored following extensive gastric resections.

Other nutritional problems seen following surgery include folic acid deficiency and decreased absorption of calcium and vitamin D. Poor absorption of nutrients, combined with the inability to eat large meals, puts the patient at risk for weight loss in addition to the more specific nutrient deficiencies. Nearly 50% of patients who have gastric surgery experience significant weight loss, primarily because of insufficient calorie intake. Factors contributing to insufficient intake of calories include early satiety (feeling of fullness), decreased stomach size, and altered emptying patterns.

OTHER THERAPIES

Combination chemotherapy administered before surgery and in combination with radiation therapy after surgery has been found to

reduce tumor recurrence and prolong survival (Longo et al., 2013). For the patient with more advanced disease, treatment is palliative and may include surgery, radiation therapy, and chemotherapy. These patients may require a gastrostomy or jejunostomy feeding tube.

Because gastric cancer is generally advanced by the time of diagnosis, the prognosis is poor. The 5-year survival rate of all patients treated for gastric carcinoma is 10%.

●○● NURSING CARE

Health Promotion

Although the exact causes of gastric cancer are unknown, contributing factors such as *H. pylori* infection and consumption of foods preserved with nitrates have been identified. To reduce their risk of developing gastric cancer, encourage patients with known *H. pylori* infection to complete the prescribed course of treatment and verify that it has eradicated the infection. With all patients, discuss the relationship between gastric cancer and consumption of foods preserved with nitrates (such as bacon and other processed meats), and encourage limited consumption of these products.

Assessment

Assessment data related to gastric cancer include the following:

- *Health history:* manifestations such as anorexia, early satiety, indigestion, or vomiting; epigastric pain after meals; recent unintentional weight loss
- *Physical assessment:* general appearance, weight for height; abdominal distention or a palpable upper abdominal mass; occult blood in stool or vomitus.

Priorities of Care

Priorities of nursing care for the patient with gastric cancer focus on effects of the disease and its treatment on nutritional status, and on the implications of a potentially fatal disease on the patient and family. See the accompanying Case Study & Nursing Care Plan.

CASE STUDY & NURSING CARE PLAN A Patient with Gastric Cancer

George Harvey is a 61-year-old estate attorney who lives with his wife, Harriet. For the last 3 months, Mr. Harvey has had increasing anorexia and difficulty eating. He has lost 10 pounds. His physician has diagnosed gastric cancer, and Mr. Harvey is admitted for a partial gastrectomy and gastrojejunostomy. The oncologist has recommended postoperative chemotherapy and radiation. Mr. Harvey reports that the physician told him "that will give me the best chance for cure."

ASSESSMENT

On admission before surgery, Mr. Harvey tells his nurse, Lauren Walsh, that he has eaten very little in the past few weeks. He asks, "What will happen to my wife if something happens to me? I'm afraid this cancer will get me." Mr. Harvey weighs 67 kg (147 lb) and is 183 cm (72 in.) tall. He is pale and thin; his vital signs are BP 148/86 mmHg, P 92 bpm, R 18/min, and T 36.6°C (97.8°F) PO. A firm mass is palpable in the left epigastric region. The rest of his physical assessment data is within normal limits. Mr. Harvey's hemoglobin is 12.8 g/dL, hematocrit is 39%, and serum albumin level is 3.2 g/dL, indicating that he is mildly malnourished. All other preoperative laboratory and diagnostic studies are within normal limits.

DIAGNOSES

- *Imbalanced Nutrition: Less Than Body Requirements* related to anorexia and difficulty eating
- *Risk for Acute Pain* related to surgical incision and manipulation of abdominal organs
- *Risk for Ineffective Airway Clearance* related to upper abdominal surgery
- *Grieving* related to recent diagnosis of cancer

EXPECTED OUTCOMES

- Patient will maintain present weight during hospitalization.
- Patient will resume a high-calorie, high-protein diet by time of discharge.
- Patient will verbalize effective pain management, maintaining a reported pain level of 3 or less on a scale of 1 to 10.
- Patient will maintain a patent airway and clear breath sounds.
- Patient will verbalize feelings regarding diagnosis and participate in decision making.

PLANNING AND IMPLEMENTATION

- Weigh daily.
- Maintain nasogastric tube placement, patency, and suction as ordered.
- Maintain intravenous fluids and parenteral nutrition as ordered until oral food intake is resumed.
- Arrange for diet teaching, including strategies to prevent dumping syndrome, before discharge.
- Maintain patient-controlled analgesia until able to take oral analgesics.
- Assess respiratory status including rate, depth, and breath sounds every hour initially, then every 4 hours.
- Assist to cough, deep breathe, and use inspirometer every 2 to 4 hours and as needed. Splint abdomen during coughing.
- Encourage verbalization of feelings about diagnosis and perceived losses.
- Encourage participation in decision making.

EVALUATION

Mr. Harvey's weight remained stable through his hospitalization. On discharge he is taking a high-protein, high-calorie diet in six small feedings per day. He and his wife have reviewed his diet with the dietitian and are planning on using some dietary supplements at home to meet protein needs. He verbalizes an understanding of measures to prevent dumping syndrome, including separating his intake of solid foods and liquids. Mr. Harvey is using oral analgesics in the morning and at bedtime to control his pain. He and his wife have begun to discuss the meaning of his diagnosis. Mrs. Harvey tells the discharge nurse, "We are going to go to a support group called 'Coping with Cancer' when George is stronger."

Clinical Reasoning in Patient Care

1. What is the rationale for maintaining nasogastric suction after gastrojejunostomy?
2. Develop a preoperative teaching plan for a patient undergoing a partial gastrectomy.
3. Mr. Harvey calls you just before the initial dose of chemotherapy and says, "Everyone tells me that chemotherapy will cause vomiting, and I don't think I can take being sick again." How would you respond?
4. Design interventions to ensure adequate nutrition for people with advanced gastric cancer.

See Evaluating Your Response in Appendix B.

Diagnoses, Outcomes, and Interventions

Imbalanced Nutrition: Less Than Body Requirements

The patient with gastric cancer may be malnourished because of anorexia, early satiety, and increased metabolic needs related to the tumor. Extensive gastric resection also makes it difficult to consume an adequate diet. Malnourishment, in turn, impairs healing and the patient's ability to tolerate cancer treatment.

Expected Outcome: Patient will maintain adequate oral intake; report adequate energy levels; maintain body mass and weight and normal lab values (transferrin, albumin, and electrolytes); and will describe intake of a well-balanced diet and normal eating patterns.

- Consult with dietitian for a complete nutrition assessment and diet planning. *The patient is at risk for protein-calorie malnutrition, which impairs the ability to heal and recover from extensive surgery.*
- Weigh daily. Monitor laboratory values such as hemoglobin, hematocrit, and serum albumin levels. *Daily weights are a valuable measurement of both fluid and nutritional status. Laboratory values provide further evidence of nutritional status.*
- Provide preferred foods; have family prepare meals when possible. Provide supplemental feedings between meals. *Small, frequent feedings and preferred foods encourage intake of nutrients.*
- Assess ability to consume adequate nutrients. *Nausea and feelings of early satiety may impair nutrient consumption, indicating a need to institute enteral or parenteral feedings.*
- Arrange for visitors to be present during meals. *Eating is a social function as well as a physiologic one. Companionship often improves food intake.*
- Administer pain and antiemetic medications as needed before meals. *Pain and nausea suppress the appetite; relief promotes food intake.*

Grieving

Expected Outcome: Patient and family will express thoughts, feelings and spiritual beliefs about loss and progress through the stages of grief.

- Encourage family members to spend as much time as possible with the patient. *The family may feel helpless and ineffectual. Supporting family members' presence can encourage this vital interaction.*
- Do not negate denial if present. *Denial is a coping mechanism that protects the patient from hopelessness.*
- Allow the patient to talk openly if desired about the condition and the prognosis. *Acceptance of the patient's fears helps reduce anxiety and promote coping behaviors.*
- Actively listen to the patient's and family's expressions of grieving. Avoid interrupting or offering meaningless words of consolation. *Being present and listening actively are often the most effective interventions for the grieving patient.*

Continuity of Care

Although the patient with gastric cancer may be hospitalized for surgery, most care is provided in the home and community-based settings such as hospice care. When preparing the patient and family for home care, discuss the following topics:

- Care of incision and feeding tube (if present) or central venous line
- Maintaining nutrition and preventing complications of surgery such as dumping syndrome
- Pain management
- Referrals to home care agencies, hospice, and cancer support groups as appropriate
- Information about services available through the local chapter of the American Cancer Society.

CHAPTER HIGHLIGHTS

- **Health problems of the upper gastrointestinal (GI) tract are common. Many are self-limiting and involve nursing care focused on symptom management and patient education.**
- **Chronic conditions of the upper GI tract are common and nursing interventions include patient teaching focused on improving and maintaining adequate nutrition and preventing complications.**
- **Acute GI bleeding is a life-threatening condition requiring interprofessional care interventions aimed at immediate resolution of the source of bleeding and aggressive fluid resuscitation.**
- Nausea and vomiting, common GI symptoms, may be indicative of disorders affecting many organ systems, including the GI tract, inner ear, CNS, or heart. Nausea and vomiting also are frequently related to medical interventions, such as drugs and cancer therapies. Complications such as dehydration, electrolyte imbalance, and aspiration of gastric contents are primary concerns when treating nausea and vomiting.
- Stomatitis and oral mucositis are common disorders of the mouth, potentially having a significant effect on comfort and nutrition. In most cases, management is symptomatic and supportive, directed toward promoting comfort and maintaining nutritional status.
- Tobacco and alcohol use contribute to a number of upper GI disorders, including gastroesophageal reflux disease (GERD), oral and esophageal cancers, and peptic ulcer disease. Encourage all patients to stop smoking or using smokeless tobacco and to consume alcohol in moderate amounts if at all to reduce their risk of these disorders.
- GERD is common. While it often is considered to be a benign condition, prolonged exposure of the lower esophagus to gastric juices can lead to esophagitis, hemorrhage, and scarring.

- **Both esophageal and gastric cancer often are diagnosed late in the disease because their symptoms may be vague. Cancers of the upper GI tract are serious and require multiple treatment and coordinated interprofessional care.** Encourage patients with complaints of dysphagia, a sensation of gastric fullness, or heartburn to seek medical evaluation. Surgical resection of the cancerous portion of the esophagus or stomach is the treatment of choice when the tumor is diagnosed early.
- Upper gastrointestinal bleeding can lead to significant blood loss and shock. Peptic ulcer disease accounts for the majority of UGI hemorrhage, although erosive gastritis and esophageal varices also are common causes. Nursing care focuses on monitoring and promoting cardiovascular stability and preventing further hemorrhage.
- Acute gastritis, often associated with aspirin or NSAID use, is generally benign and self-limited. Erosive gastritis, a complication of critical conditions such as shock, trauma, a major burn, or head injury, can lead to unexpected gastric hemorrhage. Prophylactic therapy with proton-pump inhibitors or H_2-receptor blockers is important to prevent erosive gastritis in at-risk patients. Chronic gastritis is an unrelated disorder usually associated with *H. pylori* infection.
- *H. pylori* infection also is a major risk factor for peptic ulcer disease and gastric cancer. Effectively treating the infection can reduce or eliminate the risk of future exacerbations of PUD.
- An acute change in the nature of abdominal pain in a patient with PUD, especially when accompanied by vomiting, guarding of the abdomen, or a change in bowel sounds, could indicate an obstruction or perforation and release of gastric contents into the peritoneal cavity.

TEST YOURSELF NCLEX-RN® REVIEW

1. The nurse is assessing a patient with a persistent sore on the tongue. For which oral cancer risk factors should the nurse assess this patient?
1. tobacco use in any form
2. regular use of dental floss
3. consumption of highly spiced foods
4. thumb sucking or pacifier use as a child

2. The nurse is preparing teaching for a patient with gastroesophageal reflux disease. What should this teaching include? (Select all that apply.)
1. There is no treatment for this disease.
2. Avoid lying down for several hours after eating.
3. Elevate the head of the bed on 6- to 8-inch blocks.
4. Peppermint and chocolate candies can help relieve symptoms.
5. Stop taking the prescribed proton-pump inhibitor once symptoms are relieved.

3. The nurse provides discharge teaching to a patient with acute gastritis. Which patient statement indicates that teaching has been effective?
1. "I will eat only bland foods."
2. "I will have yearly upper endoscopy exams."
3. "I will fully cook all meat, poultry, and egg products."
4. "I will avoid using aspirin or NSAIDs for routine pain relief."

4. The nurse is identifying diagnoses appropriate for a patient with a possible perforation from peptic ulcer disease. Which nursing diagnosis would be a priority for this patient?
1. *Nausea*
2. *Acute Pain*
3. *Risk for Bleeding*
4. *Ineffective Health Maintenance*

5. The nurse is concerned that a patient recovering from a partial gastrectomy for stomach cancer is at risk for nutritional deficiencies. For which nutritional deficiencies should the nurse focus care? (Select all that apply.)
1. anemia
2. calcium
3. folic acid
4. vitamin C
5. vitamin B_{12}

6. The nurse is caring for a patient receiving radiation therapy for esophageal cancer. Which manifestation should the nurse immediately report to the healthcare provider?
1. weight loss
2. bright bleeding from the mouth
3. difficulty swallowing solid foods
4. crackles in the base of the right lung

7. A patient is prescribed omeprazole 20 mg twice daily, clarithromycin 500 mg twice daily, and amoxicillin 1 g daily for treatment of peptic ulcer disease caused by *H. pylori*. What is the most important instruction for the nurse to give the patient about these medications?
1. Take the drugs with a full glass of water.
2. Complete the full course of all medications as prescribed.
3. Consume 8 oz of yogurt or buttermilk daily while taking these drugs.
4. Take the drugs on an empty stomach, 1 hour before breakfast and at least 2 hours after dinner.

8. A patient receiving chemotherapy is experiencing stomatitis. Which intervention should be a priority for this patient?
1. Refer the patient to a smoking cessation program.
2. Allow patient to select appealing foods from a menu.
3. Assist patient to cleanse mouth with mouthwash following meals.
4. Provide viscous lidocaine to relieve mouth pain before meals.

9. The evening following surgery for esophageal cancer, the nurse notes that there has been no drainage from the nasogastric tube for the past 3 hours. What should the nurse do first?
1. Chart the finding.
2. Notify the surgeon.
3. Reposition the nasogastric tube.
4. Gently irrigate the tube with normal saline.

10. A patient with a history of peptic ulcer disease suddenly begins to complain of severe abdominal pain. Which actions should the nurse take at this time? (Select all that apply.)
1. Notify the physician.
2. Withhold oral food and fluids.
3. Place the patient in Fowler's position.
4. Obtain an order for a narcotic analgesic.
5. Administer the prescribed proton-pump inhibitor.

See Test Yourself answers in Appendix B.

24 Nursing Care of Patients with Bowel Disorders

LEARNING OUTCOMES

1. Compare and contrast the causes, pathophysiology, manifestations, interprofessional care, and nursing care of patients with disorders of bowel motility.
2. Explain the pathophysiology, manifestations, complications, interprofessional care, and nursing care of patients with acute or chronic inflammatory bowel disorders, neoplastic disorders, and structural and obstructive bowel disorders.
3. Discuss the purposes, nursing implications, and health education for the patient and family related to medications used to treat bowel disorders.
4. Explain the rationale for using selected diets, including those for diarrhea and constipation and low-residue, gluten-free, and high-fiber diets.
5. Describe selected surgical procedures of the bowel, including colectomy, colostomy, ileostomy, and perianal surgery.

CLINICAL COMPETENCIES

1. Assess the functional status of patients with bowel disorders, and recognize, document, and report unexpected or abnormal findings.
2. Use assessment data to determine priority nursing diagnoses, identify and implement patient-centered evidence-based nursing interventions, and revise the plan of care for patients with bowel disorders.
3. Integrate interprofessional care and administer medications knowledgeably and safely for patients with bowel disorders.
4. Provide skilled care to patients having bowel surgery, an ostomy, or perianal surgery.
5. Provide culturally appropriate teaching to promote nutrition, prevent acute and chronic bowel disorders, encourage screening, and facilitate continuity of care related to bowel disorders.

MAJOR CHAPTER CONCEPTS

- Disorders of intestinal absorption and bowel elimination can affect functional elimination status.
- Bowel function can be affected by inflammations, infections, tumors, obstructions, or changes in structure.
- Patients with intestinal disorders often face extensive diagnostic testing, surgery, and permanent changes in physical appearance and lifestyle.
- Nursing care is directed toward meeting the patient's physiologic needs, providing emotional support, and educating the patient to adapt to changes in lifestyle.

borborygmi, *628*
colectomy, *657*
colostomy, *674*
constipation, *629*
diarrhea, *626*
hematochezia, *659*
ileostomy, *659*
inflammatory bowel disease (IBD), *652*
malabsorption, *666*
paralytic ileus, *642*
peritonitis, *640*
steatorrhea, *628*
stoma, *657*

Disorders of Intestinal Motility

Few body functions respond as readily to internal and external influences as the process of defecation. Factors affecting the gastrointestinal (GI) tract directly, such as food intake and bacterial population, affect the number and consistency of stools. Indirect factors, such as psychologic stress or voluntary postponement of defecation, also affect elimination.

In modern society, normal bowel elimination patterns vary widely. For some patients, two to three stools per day is the usual pattern. Others may normally have as few as three stools per week. It is important to evaluate each patient's bowel elimination against his or her own normal pattern.

THE PATIENT WITH DIARRHEA

Diarrhea is an increase in the frequency, volume, and fluid content of a stool. In diarrhea, the water content of feces is increased, usually due to either malabsorption or water secretion in the bowel. It is a manifestation rather than a primary disorder.

Diarrhea may be acute or chronic. Acute diarrhea, which lasts less than a week, is usually due to an infectious agent. Chronic diarrhea (diarrhea that persists longer than 3 to 4 weeks) may be caused by inflammatory bowel disorders, malabsorption, or endocrine disorders.

Pathophysiology

About 1500 mL of digested material enters the large intestine daily. Normally, most of the water and some of the solutes are reabsorbed in the bowel, leaving only about 200 mL of feces to be eliminated.

Large-volume diarrhea, characterized by both increased numbers and volume of stools, is caused by increased water content of the stool. This increased water content may result from either osmotic or secretory processes. Water may be pulled into the bowel lumen by osmosis when the feces contain osmotically active molecules. Some stool softeners and laxatives work on this principle. When the lactose in milk is not broken down and absorbed, the lactose molecules exert an osmotic pull, causing diarrhea. The diarrhea associated with cholera and *Escherichia coli* infection is caused by increased water secretion in the small and large intestines. Unabsorbed dietary fat, some cathartics and other drugs, and other factors can cause secretory diarrhea.

Small-volume diarrhea, characterized by frequent small stools, is usually caused by inflammation or disease of the colon. Diseases that affect the intestinal mucosa, such as inflammatory bowel disease, cause an exudative diarrhea. The mucosal inflammation causes plasma, serum proteins, blood, and mucus to accumulate in the bowel, increasing fecal bulk and fluidity. An increased rate of propulsion within the bowel can also decrease the amount of water normally absorbed from the chyme, leading to diarrhea. For this reason, laxatives that increase bowel motility and bowel resection or bypass can lead to diarrhea.

Antibiotic-associated diarrhea may occur as a result of disruption of normal intestinal flora by antibiotic therapy. Loss of normal flora can affect food digestion, leading to diarrhea, or can allow overgrowth of pathogens such as *Clostridium difficile* (see the section on gastroenteritis for more information about *C. difficile*). The Moving Evidence into Action box in the section on patients with gastroenteritis presents information about other possible causes of diarrhea in hospitalized patients.

Manifestations

The manifestations of diarrhea depend on its cause, duration, and severity, as well as the area of bowel affected and the patient's general health. Diarrhea can present as several large, watery stools daily, or very frequent small stools that contain blood, mucus, or exudate.

Complications

Diarrhea can have devastating effects. Water and electrolytes are lost in diarrheal stool. This can lead to dehydration, particularly in the very young, the older adult, or the debilitated patient unable to respond to thirst. With severe diarrhea, vascular collapse and hypovolemic shock may occur. Potassium and magnesium are lost, potentially leading to hypokalemia and hypomagnesemia. The loss of bicarbonate in the stool can lead to metabolic acidosis. See Chapter 10 for further discussion of the effects of these imbalances.

SAFETY ALERT

Monitor orthostatic vital signs, skin turgor, serum electrolytes and osmolality, and urinalysis to identify and respond to possible adverse effects of diarrhea.

●○● INTERPROFESSIONAL CARE

Management of diarrhea focuses on identifying and treating the underlying cause. In addition, the diarrhea itself may need to be treated to promote comfort and to prevent complications. The history (including the onset and associated circumstances of the diarrhea) and physical examination often provide enough information to identify its cause.

DIAGNOSIS

Diagnostic tests that may be ordered to help identify the cause of diarrhea include a stool specimen analysis and culture. A sigmoidoscopy may be conducted to directly visualize the bowel mucosa. (See Chapter 21 for further information on diagnostic tests.) Tissue biopsy may be performed to identify chronic inflammatory processes, infection, and other causes of diarrhea. In addition, laboratory tests of serum electrolytes, serum osmolality, and arterial blood gases (ABGs) may be ordered to assess for adverse effects of diarrhea. Increased serum osmolality indicates water loss and dehydration.

MEDICATIONS

Antidiarrheal medications are used sparingly or not at all until the cause of diarrhea has been identified. In diarrhea associated with botulism or bacillary dysentery, giving an antidiarrheal agent can worsen or prolong the disease by slowing elimination of the toxin from the bowel. Once the underlying cause for diarrhea has been established, specific medications may be ordered to treat the cause. Antibiotics are used with caution because they alter the normal bacterial population of the bowel and may actually worsen diarrhea. A balanced electrolyte solution may be required to replace fluid losses. Intravenous or oral potassium preparations may be prescribed.

Opium and some of its derivatives, anticholinergics, absorbents, and demulcents are commonly used as antidiarrheal preparations. Specific preparations, their method of action, and the nursing implications for these medications are outlined in the Medication Administration box on page 627.

NUTRITION

Fluid replacement is of primary importance in managing the patient with diarrhea. If the patient is able to tolerate oral fluids (i.e., if the patient is not experiencing nausea and vomiting), an oral glucose/balanced electrolyte solution provides the best fluid replacement. Commercial preparations such as Gatorade and other sports drinks are available, as are pediatric solutions (e.g., Pedialyte), which can be used for adults as well as children. Oral rehydration mixtures may be made at home. Several recipes are available; one example is mixing 1 teaspoon of salt and 8 teaspoons of sugar into 1 liter of water, along with 4 ounces of orange juice. Another common solution of 5 mL

MEDICATION ADMINISTRATION

Antidiarrheal Preparations

ABSORBENTS AND PROTECTANTS

kaolin and pectin (Kaopectate, Donnagel-MB)

polycarbophil (FiberNorm, Equalactin)

Absorbent preparations act locally in the intestines to bind substances that can cause diarrhea. Absorbents are safe and are generally available over the counter, although their efficacy has not been proved.

Nursing Responsibilities

- Assess for contraindications to antidiarrheal therapy, such as some infections or chronic inflammatory bowel disease, including ulcerative colitis.
- If fever is present, check with physician before giving the medication.
- Administer these medications at least 1 hour before or 2 hours after other oral medications; they may interfere with the absorption of other drugs.
- Observe the patient's response to the medication. Constipation is a potential problem.

Health Education for the Patient and Family

- Take the recommended dosage at the onset of diarrhea and after each loose stool.
- Do not take any of these preparations for more than 48 hours. If diarrhea persists, notify the physician.
- Do not give antidiarrheal medications to debilitated older patients without physician supervision.

ANTISECRETORY

bismuth subsalicylate (Pepto-Bismol)

Bismuth subsalicylate, available without a prescription, has antisecretory, anti-inflammatory, and antibacterial effects. It is widely used to control traveler's diarrhea. Although it is generally safe at recommended doses, bismuth subsalicylate has potential toxic effects and interacts with drugs such as aspirin and oral anticoagulants.

Nursing Responsibilities

- Administer as ordered.
- Do not administer within 1 hour of other drugs, because it may interfere with their absorption.
- Monitor for increased anticoagulant effect when given with warfarin (Coumadin) or aspirin.

Health Education for the Patient and Family

- Chew bismuth subsalicylate tablets, rather than swallowing them whole, for maximal effectiveness.
- This drug may cause harmless darkening of your tongue and stools.
- If you are allergic to aspirin, use bismuth subsalicylate with caution. Do not use aspirin while you are taking this drug unless directed to do so by your physician. Contact your physician if diarrhea persists for more than 2 days.

OPIUM AND OPIUM DERIVATIVES

camphorated tincture of opium (Paregoric)

tincture of opium (laudanum)

difenoxin (Motofen)

diphenoxylate (Lomotil, others)

loperamide hydrochloride (Imodium)

Opium and its derivatives act on the central nervous system (CNS) to decrease the motility of the ileum and colon, slowing transit time and promoting more water absorption. They also decrease the sensation of a full rectum and increase anal sphincter tone. Paregoric and tincture of opium have a greater potential for abuse and are prescription drugs subject to controls under the federal Controlled Substances Act of 1970. Difenoxin, diphenoxylate, and loperamide are derivatives of opium with few analgesic, euphoric, or abuse-promoting effects and are in more common use today.

Nursing Responsibilities

- Assess for contraindications to antidiarrheal or narcotic medications prior to giving these drugs.
- Administer paregoric undiluted with water.
- Do not administer difenoxin and diphenoxylate to patients receiving monoamine oxidase inhibitors (MAOIs); hypertensive crises may occur.
- Observe closely for increased effects of other CNS depressants, such as alcohol, narcotic analgesics, or barbiturate sedatives.
- Observe for abdominal distention; toxic megacolon may occur if these drugs are given to the patient with ulcerative colitis.

Health Education for the Patient and Family

- Take the medication as recommended at the onset of diarrhea and after each loose stool.
- These drugs may be habit forming; use for no more than 48 hours.
- Avoid using alcohol and OTC cold preparations while taking these drugs.
- These preparations may cause drowsiness; avoid driving or operating machinery while taking them.

(1 teaspoon) each of table salt and baking soda and 20 mL (4 teaspoons) of granulated sugar added with desired flavoring (such as lemon extract or juice) to 1 L (1 quart) of water can be made at home to replace water and electrolytes.

Solid food is withheld in the first 24 hours of acute diarrhea to rest the bowel. After that time, frequent, small, soft feedings can be added. The BRAT diet (bananas, rice, applesauce, and toast) is frequently recommended as a good start to beginning solid foods. Milk and milk products are added last, because the lactose they contain frequently aggravates the diarrhea. Raw fruits and vegetables, fried foods, bran, whole-grain cereals, condiments, spices, coffee, and alcoholic beverages are avoided during the recovery period.

Patients with chronic diarrhea may benefit by eliminating specific foods from the diet. Foods and nonfood substances that may aggravate diarrhea are outlined in Table 24–1. The diet should be high in calories and nutritional value. Vitamin supplements may be necessary, particularly the fat-soluble vitamins (A, D, E, and K). Patients with severe chronic diarrhea may require parenteral nutrition (see Chapter 22).

COMPLEMENTARY AND ALTERNATIVE THERAPIES

Herbal or homeopathic therapies may be used to help relieve diarrhea. Patients who are lactose intolerant may use lactase enzyme tablets or drops when consuming milk products. Herbal treatments may include a strong tea of black pepper, chamomile, coriander, rosemary, sandalwood, or thyme. Ginger in the form of tea or capsules can be helpful in reducing intestinal inflammation and lessening the effects

TABLE 24–1 Foods That May Aggravate Chronic Diarrhea

Foods	Reason
Milk, ice cream, yogurt, soft cheeses, cottage cheese	Contain lactose; not tolerated by patients with lactase deficiency who cannot digest lactose.
Apple juice, pear juice, grapes, honey, dates, nuts, figs, fruit-flavored soft drinks	Contain fructose; when consumed in large quantities, fructose may not be totally absorbed, causing an osmotic pull of fluid into the bowel.
Table sugar	Contains sucrose; not tolerated by patients with sucrase deficiency.
Apple juice, pear juice, sugarless gums, and mints	May contain sorbitol or mannitol, sugars that are not absorbed and can cause osmotic draw.
Antacids	Magnesium-containing antacids decrease bowel transit time and contain poorly absorbed salts that can exert an osmotic draw.
Coffee, tea, cola drinks, over-the-counter (OTC) analgesics	Contain caffeine, which can increase bowel transit time.

of food poisoning. Homeopathic practitioners may use podophyllum tablets to treat diarrhea. Probiotics, live microorganisms similar to those normally found in the gut, may be used to prevent or treat antibiotic-associated diarrhea (National Center for Complementary and Alternative Medicine, 2012). Probiotics are available as dietary supplements and foods (e.g., yogurt, yogurt drinks). Refer the patient to a qualified practitioner for more information about using complementary and alternative therapies to treat diarrhea.

FECAL BACTERIOTHERAPY

Fecal bacteriotherapy treatment is gaining acceptance for patients who experience chronic diarrhea related to various etiologies (e.g., Clostridium difficile infection (CDI), irritable bowel syndrome). Fecal bacteriotherapy is a process that restores the colon's homeostasis by instilling normal bacterial flora from a healthy person (donor) into the GI tract of the affected patient. The donor screening process usually begins with the patient's spouse/significant other or a household family member. Potential donors are screened for overall health, exposure to infectious disease, recent receipt of systemic antibiotics, CDI, ova, parasites, and enteric bacterial pathogens.

Once the donor has been selected and sufficiently screened, the instillation process can begin. The donor stool is broken down into a liquid suspension. Most patients receive their fecal bacteriotherapy through a retention enema or colonoscopy in an outpatient setting. The recipient of the fecal transplant is pretreated with oral antibiotics (vancomycin) for several days. Fecal bacteriotherapy is considered safe and effective with a success rate of treating CDI of 81% to 100%. This treatment is considered cost effective, breaks the cycle of repeated antibiotic use, prevents the emergence of antibiotic-resistant strains of bacteria, avoids the risk of allergic reactions, and is considered a low-tech treatment (Brandt, 2012; Mitchell et al., 2013).

●○● NURSING CARE

Diarrhea is a common problem that may complicate patient care.

Health Promotion

Teach all patients about the importance of proper hand hygiene as a measure to prevent the spread of infectious diseases, including those that cause diarrhea. Teach safe food-handling techniques to prevent bacterial contamination, and discuss measures to ensure safe drinking water. For patients planning to travel outside the United States or to wilderness areas, teach measures to purify water for drinking and cooking.

Assessment

The nursing assessment can help identify the cause of a patient's diarrhea, as well as early signs of complications. Collect the following assessment data:

- *Health history:* duration and extent of diarrhea; associated manifestations; dietary intake; recent travel out of the country or to wilderness areas; previous history of diarrhea; chronic diseases; prescription and nonprescription medications
- *Physical assessment:* vital signs (including orthostatic blood pressure); peripheral pulses; skin temperature, moisture, turgor; color and moisture of mucous membranes; abdominal contour and girth; bowel sounds; stool for obvious or occult blood, pus, mucus, or **steatorrhea** (bulky, foul-smelling stool containing fat/grease).

Priorities of Care

The primary priority of care is ensuring that the patient is monitoring and maintaining fluid and electrolyte balance. Managing nutritional intake is a key component of care for patients experiencing chronic diarrhea.

Diagnoses, Outcomes, and Interventions

Nursing care of the patient with diarrhea focuses on identifying the cause, relieving the manifestations, preventing complications, and preventing the potential spread of infection to others.

Diarrhea

Nursing interventions for diarrhea are provided to help the patient recover a normal elimination pattern without adverse consequences.

Expected Outcome: Patient's diarrhea will be controlled or eliminated as demonstrated by resumption of normal bowel elimination patterns.

- Monitor and record the frequency and characteristics of bowel movements *to provide a measure of the effectiveness of treatment.*
- Establish and document patient's normal bowel elimination pattern. *Individual bowel elimination patterns vary widely. Establishing the patient's baseline pattern is necessary to measure progress toward meeting desired outcome.*
- Measure abdominal girth and auscultate bowel sounds every 8 hours as indicated. Loud, rushing bowel sounds (**borborygmi**) indicate increased peristalsis, and may be heard in patients with acute diarrhea. *Diminished or absent bowel sounds may indicate a complication of treatment, such as constipation or toxic megacolon.*
- Use standard precautions and contact precautions as needed, including gloves and hand hygiene. *Standard precautions help prevent the spread of infection to others. Contact precautions in the acute and long-term care environments is recommended to prevent the spread of infectious diarrhea (Berman & Snyder, 2012).*
- Provide ready access to bathroom, commode, or bedpan. *The patient may have little warning of the need to defecate. Easily accessed toileting facilities reduce the risk for soiling or injury.*

- Administer antidiarrheal medications as prescribed *to promote comfort and prevent excess fluid loss.*
- Limit food intake if the diarrhea is acute, reintroducing solid foods slowly, in small amounts, *to allow the bowel to rest and mucosa to heal in acute diarrhea states.*

Risk for Deficient Fluid Volume

The increased water content of diarrheal stool places the patient at risk for fluid deficit.

Expected Outcome: Deficient fluid volume in the patient will be prevented as evidenced by normal vital signs, lab values, and absence of physical signs of dehydration (e.g., thirst, change in mental status, decreased urine output, dry skin and mucous membrane, weakness, sudden weight loss).

- Record intake and output; weigh daily; assess skin turgor, mucous membranes, and urine specific gravity every 8 hours. *These assessments are used to monitor fluid volume.*
- Assess skin turgor over the sternum in the older adult. Loss of subcutaneous fat associated with aging makes skin turgor assessment on the arms or hands less reliable.
- Monitor vital signs, including orthostatic blood pressures (BP). *Orthostatic hypotension is identified by a drop in BP of more than 10 mmHg and pulse increase of 10 bpm when changing from a lying to a sitting position or from a sitting to a standing position. It is an indicator of fluid volume deficit.*
- Institute safety precautions such as providing assistance when ambulating the patient with orthostatic hypotension. *The fall in blood pressure with position changes can cause light-headedness and syncope.*
- Provide fluid and electrolyte replacement solutions as indicated. Ensure ready access to fluids; assist the debilitated patient with fluid intake. Notify the care provider if the patient is unable to tolerate oral fluids. *Oral fluids are encouraged as tolerated to prevent dehydration. Intravenous fluids are necessary if oral fluids are not tolerated. An intake of 3000 mL/day or more is often needed to replace fluid losses.*

Risk for Impaired Skin Integrity

Decreased extracellular fluid volume and the irritating effects of diarrheal stool increase the risk for skin breakdown.

Expected Outcome: Patient's skin will remain intact and will not show redness or excoriation.

- Assist with cleaning the perianal area as needed. Use warm water, a gentle cleanser, and soft cloths. *Cleansing removes irritating substances in the stool. Gentle cleansing helps maintain the integrity of dehydrated skin.*
- Apply protective ointment to the perianal area. *Moisture-barrier ointments or creams protect the skin from excoriation and help prevent tissue breakdown.*

Continuity of Care

Acute and chronic diarrhea are generally managed by the patient in the home. Teach the patient and family members about the following subjects:

- Causes of diarrhea (as directed by the diagnosis)
- Importance of hand hygiene and other hygiene measures
- Importance of maintaining adequate fluid intake to replace lost water and electrolytes
- Use of a balanced electrolyte solution such as Gatorade or a similar product (purchased or home prepared) for fluid replacement
- Recommendations to limit food intake during acute diarrhea, and resume gradually with small feedings of foods that have a constipating effect: applesauce, bananas, crackers, rice, potatoes
- To avoid foods high in fiber, milk products, and caffeine
- Ways to maintain nutrition if chronic diarrhea is a problem: frequent small meals, nutritional supplements, vitamin supplements
- Precautions and limitations of antidiarrheal preparations
- Importance of seeking medical intervention if diarrhea continues or recurs.

THE PATIENT WITH CONSTIPATION

Constipation is defined as including two of the following symptoms for at least 12 weeks in the past 12 months: fewer than three bowel movements (BMs) per week, straining, hard stools, incomplete evacuation, or manual evacuation required for 25% of BMs (Seltzer, 2012). Constipation affects older adults more frequently than younger people and occurs 2.5 times more frequently in women than men. Although fecal transit in the large intestine slows with aging, the increased incidence of constipation is thought to relate more to impaired general health status, increased medication use, and decreased physical activity in the older adult.

Pathophysiology

Constipation may be a primary problem or a manifestation secondary to another disease or condition. Acute constipation, a definite change in the bowel elimination pattern, often is caused by an organic process. A change in bowel patterns that persists or becomes more frequent or severe may be due to a tumor or other partial bowel obstruction. With chronic constipation, functional causes that impair storage, transport, and evacuation mechanisms impede the normal passage of stools. Common causes of constipation are listed in Table 24–2.

TABLE 24–2 Selected Causes of Constipation

Factor	Related Cause
Activity	Lack of exercise: bed rest
Dietary	Highly refined, low-fiber foods; inadequate fluid intake
Drugs	Antacids containing aluminum or calcium salts; narcotic analgesics; anticholinergics; many antidepressants, tranquilizers, and sedatives; antihypertensives, such as ganglionic blockers, calcium-channel blockers, beta-adrenergic blockers, and diuretics; iron salts
Large bowel	Diverticular disease, inflammatory disease, tumor, obstruction; changes in rectal or anal structure or function
Psychogenic	Voluntary suppression of urge; perceived need to defecate on schedule; depression
Systemic	Advanced age; pregnancy; neurologic conditions (trauma, multiple sclerosis, tumors, cerebrovascular accident, parkinsonism); endocrine and metabolic disorders (hypothyroidism, hypercalcemia, uremia, porphyria)
Other	Chronic laxative or enema use

Psychogenic factors are frequently associated with causes of chronic constipation. These factors include postponing defecation when the urge is felt, and the perception of satisfaction with defecation. Patients often use laxatives and enemas to stimulate a bowel movement when constipation is perceived. Overuse of these measures can lead to real intestinal problems that worsen the condition. For example, *cathartic colon* (impaired colonic motility and changes in bowel structure) mimics ulcerative colitis in that the normal pouchlike or saccular appearance of the colon is lost. *Melanosis coli* is a brownish-black discoloration of the colon mucosa. Both conditions may be caused by long-term laxative use.

Manifestations and Complications

The manifestations of constipation include having bowel movements less often than the usual pattern, frequent flatus, abdominal discomfort, anorexia, straining to have a bowel movement, and the passage of hard, dry stools.

With significant constipation or long-term dependence on laxatives or enemas, fecal impaction may develop. Impaction may also occur following barium administration for radiologic exam. The impaction is felt as a rock-hard or putty-like mass of feces in the rectum. Abdominal cramping and a full sensation in the rectal area may be manifestations of impaction. Watery mucus or foul-smelling liquid stool may be passed around the impaction, causing the patient to complain of diarrhea.

●○● INTERPROFESSIONAL CARE

Initial evaluation of constipation is based on the history and physical examination. The abdomen may appear somewhat distended, and bowel sounds may be reduced. If an impaction is present, digital examination of the rectum reveals a palpable, hard or putty-like fecal mass.

Simple or chronic constipation is treated with education (a daily bowel movement is not necessary for health) and modification of diet and exercise routines. If the problem is acute or does not resolve, further diagnostic examination may be ordered.

DIAGNOSIS

A barium enema may be ordered to identify bowel structure, tumors, or diverticula. If the problem is acute, a sigmoidoscopy or colonoscopy may be used for evaluation and biopsy. Computed tomography colonography (CTC) may be ordered instead of barium enema. CTC may be preferred because of the increased sensitivity to detection of polyps and cancer. (See Chapter 21 for nursing implications of these tests.)

MEDICATIONS

Laxative and cathartic preparations are used to promote stool evacuation. Milder preparations are generally known as laxatives; cathartics have a stronger effect. Most laxatives are appropriate only for short-term use. Cathartics and enemas interfere with normal bowel reflexes and should not be used for simple constipation. Laxatives should not be given if a patient has an undiagnosed intestinal obstruction, abdominal pain, fecal impaction, rectal fissures, ulcerated hemorrhoids, Crohn's disease, ulcerative colitis, or chronic inflammatory bowel disease. When the bowel is obstructed, laxatives or cathartics may cause serious mechanical damage and perforate the bowel.

The only laxatives that are appropriate and safe for long-term use are bulking agents, such as psyllium seed, calcium polycarbophil, and methylcellulose. These agents act by increasing the bulk of the feces and drawing water into the bowel to soften it. Commonly prescribed laxatives and cathartics are discussed in the accompanying Medication Administration box.

NUTRITION

Foods that have high fiber content are recommended. Vegetable fiber is largely indigestible and unabsorbable, so it increases stool bulk. Fiber helps draw water into the fecal mass, softening the stool and making defecation easier. Raw fruits and vegetables are good sources of dietary fiber, as is cereal bran. Use 2 to 3 teaspoons of unprocessed bran with meals (sprinkled on fruit or cereal) or up to 1/4 cup daily to supply adequate fiber.

Fluids are important to maintain bowel motility and soft stools. The patient should drink 6 to 8 glasses of fluid per day. It is important to advise the patient to increase fluid intake when dietary fiber is initially increased to decrease flatus and help maintain softer stools.

In older adults, constipation may be due to inadequate food intake. Carefully evaluate diet history and usual daily intake.

MEDICATION ADMINISTRATION

Laxatives and Cathartics

BULK-FORMING AGENTS

calcium polycarbophil (Fibercon, others)

methylcellulose (Citrucel)

psyllium (Metamucil, others)

Bulk-forming agents contain vegetable fiber, which is not digested or absorbed in the gut. This natural fiber creates bulk and draws water into the intestine, softening the stool mass.

Nursing Responsibilities

- Mix the agent with a full glass of cool liquid just prior to administering.
- Do not administer to patients with possible stool impaction or bowel obstruction.

Health Education for the Patient and Family

- Drink at least 6 to 8 full glasses of nonalcoholic fluid per day. Adequate hydration is necessary to produce the medication's laxative effect.
- These agents may be mixed with water, milk, or fruit juice.
- Take the drug in the morning or with meals. To reduce the risk of impaction, do not take at bedtime.
- Because of the increased risk of impaction, check with the physician before increasing dietary fiber while you are taking these agents.

WETTING AGENTS

docusate (Colace, Surfak, Doxidan, others)

MEDICATION ADMINISTRATION (*continued*)

Wetting agents reduce stool surface tension and form an emulsion of fat and water, softening the stool. They are used primarily to prevent straining and reduce the discomfort of expelling hard stools.

Nursing Responsibilities

- Administer with ample fluids to promote softening effect.
- Wetting agents may alter the absorption of other drugs. Do not administer within 1 hour of other oral medications.
- Do not attempt to crush or open caplets; a liquid form is available for patients who cannot swallow pills or capsules.

Health Education for the Patient and Family

- Do not use for more than 1 week unless specifically recommended by the physician.
- Take the medication in the morning or evening, but avoid taking it with other medications.
- Adequate fluid is necessary to obtain the beneficial effect of the drug. Drink 6 to 8 glasses of nonalcoholic fluid per day.

OSMOTIC AND SALINE LAXATIVES/CATHARTICS

lactulose (Rhodialose)

sorbitol

magnesium citrate

magnesium hydroxide (Milk of Magnesia)

polyethylene glycol (Klean-Prep)

Laxatives in this group contain poorly absorbed salts or carbohydrates that remain in the bowel, increasing osmotic pressure and drawing water into the intestine. Stool volume increases, consistency decreases, and peristalsis is stimulated. Many of these agents also have an irritant effect on the bowel, further stimulating peristalsis. They are used to stimulate rapid or complete bowel evacuation to relieve constipation and to prepare the bowel for diagnostic and surgical procedures. They should be limited to acute, short-term use; chronic use may suppress normal bowel reflexes.

Nursing Responsibilities

- Assess for possible contraindications to osmotic or saline laxatives, including bowel ulceration or obstruction, dehydration, electrolyte imbalances, heart failure (which may be aggravated by the sodium content), or renal failure.
- Administer with a full glass of liquid, preferably in the morning to avoid sleep disturbance.
- Monitor fluid and electrolyte status: skin turgor, mucous membranes; intake and output; daily weight; and laboratory studies, such as hemoglobin and hematocrit levels, serum osmolality and electrolytes, and urine specific gravity.

Health Education for the Patient and Family

- Do not use these agents on a routine basis to treat or prevent constipation.
- Chill the solution to increase its palatability.
- Expect some abdominal cramping.
- Use only as directed. Increase fluid intake to at least 6 to 8 glasses of nonalcoholic fluid daily.
- Notify the physician if adverse effects occur, including abdominal pain, bloody stool, excessive skin or mucous membrane dryness, rapid weight loss, dizziness, or other unusual symptoms.
- These agents work in 3 to 6 hours; take them in the morning or early evening to avoid sleep disturbance.

IRRITANT OR STIMULANT LAXATIVES

bisacodyl (Dulcolax, Bisco-Lax, Carter's Liver Pills, Codylax, others)

phenolphthalein (Evac-U-Gen, Evac-U-Lax, Feen-A-Mint, Phenolax, others)

senna (Senna laxative, Fletcher's Castoria)

castor oil

Stimulant laxatives work by stimulating the motility and secretion of intestinal mucosa. Their use results in watery stool, often accompanied by abdominal cramping and pain. They are used to relieve constipation, although they should not be used as the initial treatment. Stimulant laxatives are also used for preparing the bowel for diagnostic testing.

Nursing Responsibilities

- Assess for potential contraindications to these laxatives, including abdominal pain and cramping, nausea and vomiting, and anal or rectal fissures.
- Administer on an empty stomach to minimize the effects of food on its dissolution and absorption.
- Do not crush enteric-coated bisacodyl tablets or administer with alkaline products. This may hasten their dissolution in the stomach, leading to gastric distress.

Health Education for the Patient and Family

- Discourage the use of this type of laxative, even in OTC preparations, for the initial or continuing relief of constipation.
- Do not use the laxative for more than 1 week; chronic use can be habit forming and may suppress normal bowel reflexes.
- These laxatives are excreted in breast milk and should not be used by lactating women.
- Phenolphthalein-containing products may discolor the urine pink or red. Report possible hypersensitivity manifestations, such as difficulty breathing, dizziness or light-headedness, or skin rashes, to the primary care provider, and stop taking the medication.

LUBRICANTS

mineral oil

Mineral oil acts by forming an oily coat on the fecal mass, preventing the reabsorption of water, and resulting in softer stool. Problems associated with the use of mineral oil as a laxative include reduced absorption of the fat-soluble vitamins A, D, E, and K; possible damage to the liver and spleen due to systemic absorption; and potential pneumonitis from aspiration of oil droplets into the lungs.

Nursing Responsibilities

- Assess for possible contraindications to use of mineral oil, including advanced age, preexisting lung disease, and hemorrhoids or other rectal lesions.
- Do not give mineral oil concurrently with wetting agents or stool softeners, because these increase the potential for systemic absorption and increase the effects of the mineral oil.
- Administer mineral oil in the evening before bedtime to reduce the effect on the absorption of fat-soluble vitamins and minimize the risk of aspiration.
- Assess for manifestations of vitamin deficiency. Monitor the patient taking oral anticoagulants for evidence of increased bleeding, such as bleeding gums, easy bruising, or melena.

Health Education for the Patient and Family

- Long-term use of mineral oil is not recommended because of its risks and adverse effects.
- Do not use mineral oil if hemorrhoids or rectal lesions are present; leakage of the oil through the anal sphincter may cause itching and interfere with healing.
- Suck on a lemon or orange slice after taking oral mineral oil to reduce the oily aftertaste.

ENEMAS

Significant or chronic constipation or a fecal impaction may require the administration of an enema. As a general rule, enemas are used only in acute situations and only on a short-term basis. They may be ordered to prepare the bowel for diagnostic testing or examination. The following types of enemas may be prescribed:

- A *saline enema* using 500 to 2000 mL of warmed physiologic saline solution is the least irritating to the bowel.
- *Tap-water enemas* use 500 to 1000 mL of water to soften feces and irritate the bowel mucosa, stimulating peristalsis and evacuation.
- *Soap-solution enemas* consist of a tap-water solution to which soap is added as a further irritant.
- *Phosphate enemas* (e.g., Fleet) use a hypertonic saline solution to draw fluid into the bowel and irritate the mucosa, leading to evacuation.
- *Oil retention enemas* instill mineral or vegetable oil into the bowel to soften the fecal mass. The instilled oil is retained overnight or for several hours before evacuation.

The repeated use of enemas can lead not only to impaired bowel function, but also to fluid and electrolyte imbalances. Tap-water and phosphate enemas are particularly likely to cause these problems. In acute conditions with risk of bowel obstruction, perforation, ulceration, or other problem, enemas should not be administered until their safe use can be established.

COMPLEMENTARY AND ALTERNATIVE THERAPIES

Herbal or homeopathic therapies may be used to help relieve constipation. Flaxseed oil lubricates the colon for easier passage of stool. Patients are instructed to take 1 to 2 tablespoons daily. Flax seeds are a lesser known but highly concentrated source of fiber, and 1 to 2 tablespoons of ground flaxseeds can be sprinkled on cereals or salads daily, followed by 10 ounces of water. Acupressure, massage, reflexology, aromatherapy, and stress management therapies can be beneficial in relieving constipation. Other recommendations include exercise to stimulate intestinal contractions.

●○● NURSING CARE

Health Promotion

Education can prevent constipation. Teach patients the importance of maintaining a diet high in natural fiber. Foods such as fresh fruits, vegetables, whole-grain products, and bran provide natural fiber. Encourage reducing consumption of meats and refined foods, which are low in fiber and can be constipating. Emphasize the need to maintain a high fluid intake every day, particularly during hot weather and exercise. Discuss the relationship between exercise and bowel regularity. Encourage patients to engage in some form of exercise, such as walking daily.

Discuss normal bowel habits, and explain that a daily bowel movement is not the norm for all people. Encourage patients to respond to the urge to defecate when it occurs. Suggest setting aside a time, usually following a meal, for elimination.

Assessment

To assess the patient with real or perceived constipation, collect the following data:

- *Health history:* usual and current pattern of defecation, including time of day, amount, and stool consistency; usual diet, fluid intake, and activity pattern; possible contributing factors such as opioid analgesics, activity limitations, painful hemorrhoids, perianal surgery; chronic diseases such as endocrine or neurologic disorders; prescribed and nonprescription medications. Determine patients' perspectives on their bowel function and establish toilet accessibility.
- *Physical assessment:* abdominal girth and shape, bowel sounds, tenderness, and percussion tone; digital exam of the rectum if impaction is suspected. An oral examination should be included to identify any difficulty with chewing or swallowing that can lead to a decrease in fiber intake. Assess musculoskeletal and functional level to determine patient's capacity for accessing toileting facilities.

For discussion of constipation in the older adult see the Meeting Individualized Needs box below.

Priorities of Care

Educate the patient and caregivers as appropriate to ensure that the patient establishes regular elimination habits, hydration, an exercise or mobility plan, and a high-fiber diet. Preventing constipation associated with other diagnoses, medical procedures, and medications is a key nursing responsibility.

Diagnoses, Outcomes, and Interventions

Nursing interventions for the patient with constipation focus chiefly on education.

Constipation

Whether real or perceived, constipation is disruptive to the patient's activities of daily living (ADLs) and life satisfaction.

Expected Outcome: Patient will report passage of stool with reduction of straining and pain and verbalize knowledge of bowel regimen necessary to avoid the constipating side effects of medication.

- Monitor pattern of defecation and stool consistency. *This information helps establish the patient's usual pattern of defecation and differentiate between actual and perceived constipation.*

Meeting Individualized Needs

Constipation and the Older Adult

Constipation and perceived constipation are common problems in older adults. Although constipation is not a normal consequence of aging, factors such as slowed peristalsis, lowered activity levels, reduced food and fluid intake, and decreased sensory perception contribute to the higher incidence of constipation seen in older adults. Chronic diseases such as diabetes, mobility problems, and medications also increase the risk of constipation in older adults.

Cultural influences and advertising lead many older adults to believe that a daily bowel movement is important for health. This belief contributes to an increased incidence of perceived constipation in older adults. Because of this perception, the older adult may come to rely on laxatives, suppositories, or enemas to facilitate regular bowel movements. These external aids to defecation can further impair the ability to maintain normal bowel habits.

- Provide additional fluids to maintain an intake of at least 2500 mL per day. *A generous fluid intake helps maintain soft stool consistency and promote intestinal motility.*
- Encourage drinking a glass of warm water before breakfast. Provide time and privacy following breakfast for bowel elimination. *This helps develop a pattern of natural elimination; the warm water provides mild stimulation of bowel peristalsis.*
- Consult with the dietitian to provide a diet high in natural fiber unless contraindicated. Provide foods such as natural bran, prunes, or prune juice. *Natural fiber adds bulk to the stool and has a mild stimulant effect.*
- Encourage activities such as ambulation or chair exercises (e.g., range of motion, stretching, wheelchair lifts) as tolerated. *Activity stimulates peristalsis and strengthens abdominal muscles, facilitating elimination.*
- If indicated, consult with primary care provider about the use of bulk laxatives, stool softeners, or other laxatives as needed. *Laxatives may be necessary to relieve acute constipation. Patients with long-term activity or diet restrictions or impaired abdominal muscle strength may need a bulk-forming laxative to maintain normal elimination patterns and prevent constipation.*

Continuity of Care

Include the following topics when teaching self-care measures to prevent and treat constipation:

- Increasing dietary fiber intake by including fresh fruits and vegetables, whole grains, high-fiber breakfast cereals, and unprocessed bran in the diet (Bran can be sprinkled on cereals, mixed into bread or muffin recipes, or mixed with fruit juice to increase its palatability.)
- Maintaining fluid intake of 6 to 8 glasses of water per day (unless contraindicated)
- Suggestions for remaining physically active to promote bowel function and maintain muscle tone
- Responding to the urge to defecate when perceived
- Appropriate use of laxatives:
  - Do not use laxatives, suppositories, or enemas on a regular basis.
  - Bulk-forming agents provide insoluble fiber, and are safe for long-term use; it is important to drink at least 6 to 8 glasses of water daily when using these (or any) laxatives.
  - Other laxatives such as milk of magnesia, docusate (Colace, DSS), bisacodyl (Dulcolax), cascara, or castor oil should be used only occasionally to relieve constipation.
- Reporting any change in bowel habits such as new or persistent constipation or diarrhea, abdominal pain, black or bloody stools, nausea or anorexia, weakness, or unexplained weight loss to the primary care provider.

THE PATIENT WITH IRRITABLE BOWEL SYNDROME

Irritable bowel syndrome (IBS), also known as *spastic bowel* or *mucous colitis*, is a motility disorder of the lower GI tract. It is a functional and chronic disorder with no identifiable organic causes characterized by abdominal pain and bloating with constipation, diarrhea, or both.

Irritable bowel syndrome is common, affecting 5% to 15% of the adult population of both developed and developing countries (Smith, 2012a). It usually affects young people, with about 50% of patients diagnosed before age 35. There is a higher prevalence of IBS in women than in men (Smith, 2012b).

Pathophysiology

In IBS, it appears that CNS regulation of the motor and sensory functions of the bowel is altered. Patients with IBS often experience increased motor reactivity of the small bowel and colon in response to stimuli such as food intake, hormonal influences, and physiologic or psychologic stress. IBS is characterized by visceral hypersensitivity and hyperactivity of the GI tract. Hypersecretion of colonic mucus is a common feature of the syndrome.

IBS may develop as a sequela of gastroenteritis, particularly when the infection is caused by *Campylobacter*, *Salmonella*, or *Shigella*.

A lower visceral pain threshold is often found in patients with IBS. Patients may complain of pain, bloating, and distention when intestinal gas levels are normal. Serotonin, a neurotransmitter involved in regulating GI motility, and visceral perception may play a role in IBS. Higher than expected postprandial plasma serotonin levels are noted in some patients with IBS (Longo et al., 2013; Smith, 2012b).

Psychologic factors such as depression or anxiety have been linked to IBS; however, they have not been identified as causes of the disorder (Dainty, 2012). Recent research does indicate a correlation between emotional, physical, and sexual abuse and IBS (Dainty, 2012; Smith, 2012b).

Manifestations

IBS is characterized by abdominal pain that often is relieved by defecation and a change in bowel habits (see the accompanying Manifestations box). The pain may either be colicky, occurring in spasms, or dull and continuous. Altered patterns of defecation may include the following:

- A change in frequency
- Abnormal stool form (hard or lumpy, loose or watery)
- Altered stool passage (straining, urgency, or a sensation of incomplete evacuation)
- Passage of mucus.

The patient may also complain of abdominal bloating and excess gas. Other manifestations include nausea, vomiting, anorexia, fatigue, headache, depression, or anxiety. The abdomen is often tender to palpation, particularly over the sigmoid colon.

●○● INTERPROFESSIONAL CARE

Irritable bowel syndrome is diagnosed based on the presence of abdominal pain or discomfort at least 3 days per month in the past 3 months that has at least two of the following characteristics: (1) improved with defecation, (2) associated with a change in frequency of elimination, or (3) associated with a change in stool form (Longo et al., 2013). Management is directed toward relieving manifestations and reducing or eliminating precipitating factors. Many patients benefit from cognitive behavioral therapy or psychotherapy (Dainty, 2012).

DIAGNOSIS

The primary purpose of diagnostic testing is to rule out other causes of abdominal pain and altered fecal elimination. The stools may be examined for occult blood, ova and parasites, and white blood cells (WBCs). A sigmoidoscopy, colonoscopy, and/or a small-bowel series (upper GI series with small-bowel follow-through) and barium enema may be performed to visually examine the bowel mucosa, measure intraluminal pressures, and biopsy suspicious lesions. Nursing care for these procedures is outlined in Chapter 21. Laboratory tests include a complete blood count (CBC) with differential and erythrocyte sedimentation rate to evaluate for anemia from bleeding or a possible tumor. An increased WBC count indicates a bacterial infection.

MEDICATIONS

Although not curative, medications may be prescribed to manage the manifestations of IBS. Bulk-forming laxatives (such as bran, methylcellulose, or psyllium) may help reduce bowel spasm and normalize the number and form of bowel movements. An anticholinergic drug such as dicyclomine (Antispas, Bentyl) or hyoscyamine (Anaspaz) may be ordered to inhibit bowel motility by interfering with parasympathetic stimulation of the gastrointestinal tract. It relieves postprandial abdominal pain when given 30 to 60 minutes before meals. Because of side effects such as dry mouth, blurred vision, and urinary hesitancy, these drugs are used with caution in older adults. In patients with diarrhea, loperamide (Imodium) or diphenoxylate (Lomotil) may be used prophylactically to prevent diarrhea in selected situations.

Antidepressant drugs, including tricyclics and selective serotonin reuptake inhibitors (SSRIs), may help relieve abdominal pain associated with IBS. Although the anticholinergic side effects of the tricyclics (such as desipramine [Norpramin] and imipramine [Tofranil]) may help decrease diarrhea, they have more adverse effects than SSRIs such as sertraline (Zoloft) and fluoxetine (Prozac). Alosetron (Lotronex) is a serotonin receptor antagonist that reduces abdominal pain and diarrhea in patients with IBS. Its use is limited, however, by its association with ischemic colitis.

NUTRITION

Many patients with IBS benefit from additional dietary fiber. Adding bran to meals provides added bulk and water content to the stool, reducing the incidence of both loose diarrheal stools and hard, constipated stools. Other dietary changes are specific to individual triggers for IBS manifestations. Some patients may benefit from limiting lactose, fructose, or sorbitol intake (refer to Table 24–1). When excess gas and flatulence are problems, reducing the intake of gas-forming foods, such as beans, cabbage, apple and grape juices, nuts, and raisins, may be helpful. Caffeinated drinks, such as coffee, tea, and soft drinks, act as gastrointestinal stimulants; limiting intake of these fluids may prove beneficial.

COMPLEMENTARY AND ALTERNATIVE THERAPIES

Herbal preparations may provide some benefit for patients with IBS. Herbs with an antispasmodic effect, such as anise, chamomile, peppermint, and sage, may be used to reduce the manifestations of IBS. Ginger root can be consumed as a tea or capsule to assist with reduction of gas, bloating, and diarrhea and to improve the functioning of the stomach. Probiotic therapies (such as yogurt with active bacterial cultures) have been shown to benefit patients with IBS, as has hypnosis (Dainty, 2012; Medlin, 2012a). Many patients use complementary and alternative medicine in addition to traditional medicine in the treatment of IBS. The accompanying Moving Evidence into Action box illustrates the importance of providing patient-centered care for patients experiencing chronic illness like IBS.

MANIFESTATIONS OF IRRITABLE BOWEL SYNDROME

- Abdominal pain
  - May be relieved by defecation
  - May be intermittent and colicky or dull and continuous
- Altered bowel elimination
  - Constipation
  - Diarrhea
  - Mucous stools
- Abdominal bloating and flatulence
- Abdominal tenderness, especially over sigmoid colon
- Possible nausea, vomiting

●○● NURSING CARE

Patients with IBS rarely require acute care for it as a primary problem. However, nurses frequently interact with these patients in clinics and other community settings.

Health Promotion

There is no cure for IBS and current treatment focuses on managing symptoms through lifestyle and dietary modifications. Patient education and exercise are important aspects of managing this chronic illness.

Assessment

Careful assessment is important to help identify the effects of IBS on the patient. Collect the following assessment data:

- *Health history:* current manifestations, their onset and duration; current treatment measures; effect of manifestations on lifestyle; careful exploration of history of emotional, physical, or sexual abuse
- *Physical assessment:* apparent general state of health; abdominal shape and contour, bowel sounds, tenderness.

Priorities of Care

Managing symptoms of IBS through dietary modification and stress reduction is the focus of nursing care. Monitoring the patient's nutritional status is a key component of ongoing care.

Diagnoses, Outcomes, and Intervention

The primary nursing responsibility to patients with IBS is education; providing referrals and counseling are additional nursing responsibilities. See the previous sections on diarrhea and constipation for selected nursing interventions.

Continuity of Care

Include the following topics in teaching for the patient with IBS:

- The nature of the disorder and the reality of the patient's manifestations

Moving Evidence into Action

Irritable Bowel Syndrome

Irritable bowel syndrome is a functional disorder; although the patient's symptoms are real, physical findings often are absent or limited. Nurse researchers Taylor, Cummings, and McGilly (2012) conducted a study to determine the extent of complementary and alternative medicine (CAM) use by patients treated in a gastroenterology clinic for chronic functional bowel disorders (e.g., constipation, diarrhea, IBS). Over a 6-month period, 93 surveys were completed in the office waiting room while patients waited to be seen. Sixty-three patients (68%) indicated they had either previously used or were currently using some kind of CAM to treat their functional bowel disorder. Twenty-one different CAM treatments were identified through the survey and the most common therapy (29%) was herbal medicine. Respondents identified a wide range of rationales for using CAM, from those who wholeheartedly espoused a philosophy for using complementary and alternative therapy to those who indicated they were desperate for symptom relief and were willing to try anything that might control the ailment. Other drivers for using CAM identified in this study included failure of orthodox medical treatments to cure, lack of service provision by traditional medicine personnel, and concern about the side effects of prescribed medication.

Implications for Nursing

Patients increasingly use CAM while receiving traditional medical care. As nurses, a patient-centered approach to care involves guiding and supporting patients' decisions regarding care. Patient teaching is a continuous intervention during treatment of chronic conditions such as functional bowel disorders. Patient teaching will require varied content and approaches throughout the trajectory of chronic illness. To develop an accurate diagnostic picture that is used to guide teaching and other nursing interventions, the nurse should obtain an up-to-date, complete history and maintain a nonjudgmental attitude regarding the patient's preferences.

Moving Knowledge into Action

1. In this study, researchers found that a significant number of patients were using herbal remedies in addition to traditional medical treatment. What questions could you ask to ensure that patients have reported all treatments they are using to treat functional bowel conditions?
2. You are talking with a patient who tells you she is considering using herbal medicine instead of her prescribed medications because she is concerned about the side effects. How will you respond?
3. As you are talking with your patient with IBS symptoms, she says, "I might as well just go home and learn to live with this, because nobody seems to believe me, and all of the tests come back normal. I guess I'm just crazy." How will you respond?

Taylor, C., Cummings, R., & McGilly, C. (2012). Holistic needs assessment following colorectal treatment. *Gastrointestinal Nursing, 10*(9), 42–49.

Evidence for Nursing Care

The Patient with Irritable Bowel Syndrome

Selected resources that nurses may find helpful when planning evidence-based nursing care follow.

- Anastasi, J. K., Capili, B., & Chang, M. (2013). Managing irritable bowel syndrome. *American Journal of Nursing, 113*(7), 42–52.
- Dainty, A. D. (2012). Irritable bowel syndrome: Psychological comorbidities and cognitive behavioural therapy. A review of literature. *Gastrointestinal Nursing, 10*(10), 44–50.

- Stress and anxiety reduction techniques, such as meditation, visualization, exercise, "time-out," and progressive relaxation
- Dietary influences that may contribute to IBS and suggested dietary changes, such as additional fiber and water intake
- The use and role of prescribed medications, their adverse effects, and when to contact the physician
- The importance of routine follow-up appointments and of notifying the primary care provider if manifestations change (such as blood in the stool, significant constipation or diarrhea, increasing abdominal pain, or weight loss).

If needed, refer the patient to a counselor or other mental health professional for assistance in dealing with psychologic factors.

THE PATIENT WITH FECAL INCONTINENCE

Fecal incontinence, the loss of voluntary control of defecation, occurs less frequently than urinary incontinence but is no less distressing to the patient. Multiple factors may contribute to fecal incontinence (see Box 24–1). Bowel incontinence is usually considered a symptom, not a disease or disorder. Patients often do not reveal fecal incontinence in discussing health concerns. Little information is available about its incidence and prevalence. Because many of the etiologic factors are more prevalent in the older adult, older patients are more often affected.

BOX 24–1 Selected Causes of Fecal Incontinence

NEUROLOGIC CAUSES
- Spinal cord injury or disease
- Head injury, stroke, or brain tumor
- Degenerative neurologic disease, such as multiple sclerosis, amyotrophic lateral sclerosis (ALS), dementia
- Diabetic neuropathy

LOCAL TRAUMA
- Obstetric tears
- Anorectal injury
- Anorectal surgery with sphincter damage

INFLAMMATORY PROCESSES
- Infection
- Radiation

OTHER CAUSES
- Diarrhea
- Stool impaction
- Pelvic floor relaxation or loss of sphincter tone
- Tumors

Pathophysiology

To understand the pathophysiology of fecal incontinence, it is necessary to understand the normal mechanisms of defecation. The rectum is normally empty. The defecation reflex is stimulated when the rectum is distended by feces entering from the sigmoid colon. This reflex causes involuntary relaxation of the internal sphincter and stimulates the urge to defecate. When the external sphincter, which is under both somatic (voluntary) and autonomic (involuntary)

control, relaxes, defecation occurs. Adults normally can override the defecation reflex by voluntary contraction of the external sphincter and pelvic floor muscles. The wall of the rectum gradually relaxes, and the urge to defecate subsides.

The most common causes of fecal incontinence are those that interfere with either sensory or motor control of the rectum and anal sphincters. If the external sphincter is paralyzed as a result of spinal cord injury or disease, defecation occurs automatically when the internal sphincter relaxes with the defecation reflex. If sphincter muscles have been damaged or excessive pelvic floor relaxation has occurred, it may not be possible to override the defecation reflex with voluntary control.

Age-related changes in anal sphincter tone and response to rectal distention increase the risk for fecal incontinence in older adults. Resting and maximal anal sphincter pressures are decreased, particularly in older women. In addition, less rectal distention is needed to produce sustained relaxation of the anal sphincter in older females.

●○● INTERPROFESSIONAL CARE

The diagnosis of fecal incontinence is based on the patient's history. Physical examination of the pelvic floor and anus is performed to evaluate muscle tone and rule out a fecal impaction. Impaired sphincter muscle may be palpable on digital exam. Anorectal manometry or a rectal motility test may be used to evaluate the functional ability of the sphincter muscles. In this test, a small, flexible balloon catheter is introduced into the rectum, and pressures are measured in the rectum and internal and external sphincters. Normally, rectal dilation causes the internal sphincter to relax and the external sphincter to contract. Sigmoidoscopy may be used to examine the rectum and anal canal.

Management of fecal incontinence is directed toward the identified cause. Medications to relieve diarrhea or constipation may be prescribed. A high-fiber diet, ample fluids, and regular exercise are helpful for many patients. Exercises to improve sphincter and pelvic floor muscle tone (Kegel exercises) may be of long-term benefit. Patients may benefit from using loperamide before meals and prophylactically before running errands or leaving the house. Research shows biofeedback therapy is helpful for mentally alert patients with intact sphincter muscles but low muscle tone (Collins & Norton, 2013). With motivation and reinforcement, patients achieve improved sphincter control in response to a stimulus. The goal of biofeedback is to improve sensation, coordination, and strength of the sphincter muscle.

When damage to the sphincter or rectal prolapse (protrusion of rectal mucous membrane through the anus) is the cause of fecal incontinence, surgical repair is the treatment of choice. Surgery may be indicated when conservative measures have not been effective. Permanent colostomy, the creation of an opening from the large bowel on the abdominal wall, is a last choice option for some patients, but it can control fecal output when other measures fail.

●○● NURSING CARE

Health Promotion

A bowel training program to establish a regular pattern of elimination often is effective in relieving fecal incontinence. Teach the patient to establish a regular time of day for elimination, usually 15 to 30 minutes after breakfast. A stimulant, such as a cup of coffee, a rectal suppository, or even a phosphate enema, may be given to prompt defecation. Patients with neurologic incontinence may learn to stimulate the anal canal digitally to initiate defecation.

Dietary changes may be useful in managing fecal incontinence. If incontinence occurs only with mild loose or liquid stools, increasing dietary fiber or using a bulking agent to increase stool bulk and solidity may be effective. The majority of the fiber should come from a fiber-rich diet because fiber supplements provide only a limited amount of additional fiber. When incontinence of solid stool occurs, a low-residue diet of foods that are easily digested and absorbed may be prescribed to reduce the frequency of defecation.

Assessment

- *Health history:* extent, onset, and duration of incontinence; identified contributing factors; history of spinal cord or anorectal injury or surgery; chronic diseases such as diabetes, multiple sclerosis, or other neurologic disorders
- *Physical assessment:* mental status; general health; examination of perianal tissues; digital rectal examination.

Priorities of Care

Studies reveal fecal incontinence has a significant impact on quality of life. Many patients experience anxiety about possible embarrassment from visible soiling or fecal odor. Assessing for depression, social isolation, and anxiety is important, as is assessing skin integrity.

Diagnoses, Outcomes, and Interventions

Bowel Incontinence

Nurses are often responsible for instituting bowel training programs and other measures to manage fecal incontinence.

Expected Outcome: Patient will control stool passage by establishing routine bowel habits, recognizing the urge to defecate, and responding to urge in a timely manner.

- Teach caregivers to place the patient on a toilet or commode and provide for privacy at a certain time of day. *Placing the patient in a normal position to defecate at a consistent time of day stimulates the defecation reflex and helps reestablish a pattern of stool evacuation.*
- If necessary, insert a glycerin or bisacodyl (Dulcolax) suppository 15 to 20 minutes before positioning on the toilet or commode. *This helps to stimulate evacuation. Once a regular elimination pattern has been established, it may be possible to discontinue suppository use.*
- Maintain a caring, nonjudgmental manner in providing care. *This promotes a feeling of acceptance when the patient may feel unacceptable.*

Risk for Low Self-Esteem

The patient may develop negative feelings about self or self-care capabilities due to long-standing and frequent inability to control bowel evacuation. This may lead to social isolation due to fear of soiling and foul odor.

Expected Outcome: Patient will demonstrate self-esteem as evidenced by maintaining grooming and hygiene and participation in social situations such as work, school, or social groups.

- Provide room odor control with deodorizer tablets, sprays, or other devices. *Controlling odor is important to preserve the patient's self-esteem.*
- Assist patient with hygiene and grooming quickly when fecal incontinence occurs. *Helping patient maintain personal hygiene and a pleasant environment will promote feelings of well-being and control.*

Risk for Impaired Skin Integrity

Good skin care is vital for the patient with fecal incontinence. Stool contains enzymes and other irritating substances that promote skin breakdown when they are not promptly removed. This can lead to pressure ulcers, particularly when a neurologic disorder (such as spinal cord injury, dementia, or stroke) impairs mobility.

Expected Outcome: Patient's skin will remain intact with no evidence of redness or breakdown.

- Clean the skin thoroughly with mild soap and water after each bowel movement. *Toilet tissue may be more irritating to the skin and less effective in removing fecal material.*
- Apply a skin barrier cream or ointment after each bowel movement. *These help protect the skin from irritating substances in the feces.*
- If incontinence pads or briefs are used, check frequently for soiling and change when feces are noted. *Although these help protect bedding and clothing from soiling, they can contribute to skin breakdown if they are not checked and changed frequently.*

Continuity of Care

Managing fecal incontinence is a challenging problem for the patient and family caregivers. For the patient with intact cognition, it can be psychologically devastating. The patient may become socially isolated from fear of odor or soiling clothing. Self-esteem may suffer from a sense of lost control over body functions and the inability to provide self-care. It is important to stress that incontinence is never normal (i.e., aging alone is not a cause of incontinence) and often is treatable. Encourage the patient to seek medical evaluation of the problem.

Topics of patient and family education include the following:

- Recommended dietary measures such as consuming a high-fiber diet and ample fluids to maintain soft, formed stool, or a low-residue diet to reduce the number of stools.
- Suggestions for regular exercise to stimulate bowel peristalsis and regular evacuation.
- Use of bulk-forming laxatives, such as psyllium seed (Metamucil), to provide stool bulk and reduce the number of small, liquid stools.
- Prescribed medications (such as loperamide to reduce the number of stools), their appropriate use, and management of adverse effects (such as constipation).
- Bowel training program instructions, including techniques for digital anal stimulation, inserting suppositories, or administering enemas as recommended. For digital anal simulation, teach to insert a lubricated gloved finger through the anal sphincter into the rectum 1.5 to 2 inches while seated on the toilet or commode, then use a circular side-to-side movement to gently stretch the rectal wall until the internal sphincter relaxes.
- The importance of good skin care, particularly if neurologic impairment is present.
- The potential benefits and associated risks of biofeedback and surgical treatment, if recommended.
- Provide referrals for home care or community health services as indicated.

Acute Inflammatory and Infectious Bowel Disorders

The GI tract is particularly vulnerable to inflammation and infection because of its continual exposure to the external environment. Although most pathogens affecting the GI tract are ingested in food or water, infection may be spread by direct contact, possibly by the respiratory route. Pathogens may also be transmitted sexually through anal intercourse.

Acute disease of the GI tract may be caused by the pathogen itself or by a bacterial or other toxin. Acute inflammatory disorders such as appendicitis and peritonitis result from contamination of damaged or normally sterile tissue by the patient's own endogenous or resident bacteria.

THE PATIENT WITH APPENDICITIS

Appendicitis, inflammation of the vermiform appendix, is a common cause of acute abdominal pain. It is the most common reason for emergency abdominal surgery, affecting 10% of the population (Papadakis & McPhee, 2013). Appendicitis can occur at any age, but is more common in adolescents and young adults and slightly more common in males than females.

Pathophysiology

The appendix is a tubelike pouch attached to the cecum just below the ileocecal valve. It is usually located in the right iliac region, at an area designated as McBurney's point (Figure 24–1 ■). The function of the appendix is not fully understood, although it may serve as a type of reservoir for beneficial intestinal bacteria.

Obstruction of the proximal lumen of the appendix is apparent in most acutely inflamed appendices. The obstruction is often caused by a *fecalith*, or a hard mass of feces. Other obstructive causes include a calculus or stone, a foreign body, inflammation, a tumor, parasites (e.g., pinworms), or edema of lymphoid tissue. Following obstruction, the appendix becomes distended with fluid secreted by its mucosa. Pressure within the lumen of the appendix increases, impairing its blood supply and leading to inflammation, edema, ulceration, and infection. Purulent exudate forms, further distending the appendix. Within 24 to 36 hours, tissue necrosis and gangrene result, leading to perforation if treatment is not initiated. Perforation results in bacterial peritonitis.

Appendicitis can be classified as simple, gangrenous, or perforated, depending on the stage of the process. In simple appendicitis, the appendix is inflamed but intact. When areas of tissue necrosis and microscopic perforations are present in the appendix, the disorder is called gangrenous appendicitis. A perforated appendix shows evidence of gross perforation and contamination of the peritoneal cavity.

Manifestations

Continuous mild generalized or upper abdominal pain is the initial characteristic manifestation of acute appendicitis. During the next 4 hours, the pain intensifies and localizes in the right lower quadrant of the abdomen, aggravated by moving, walking, or coughing. On palpation, localized and rebound tenderness are noted at McBurney's point. *Rebound tenderness* is demonstrated by relief of pain with

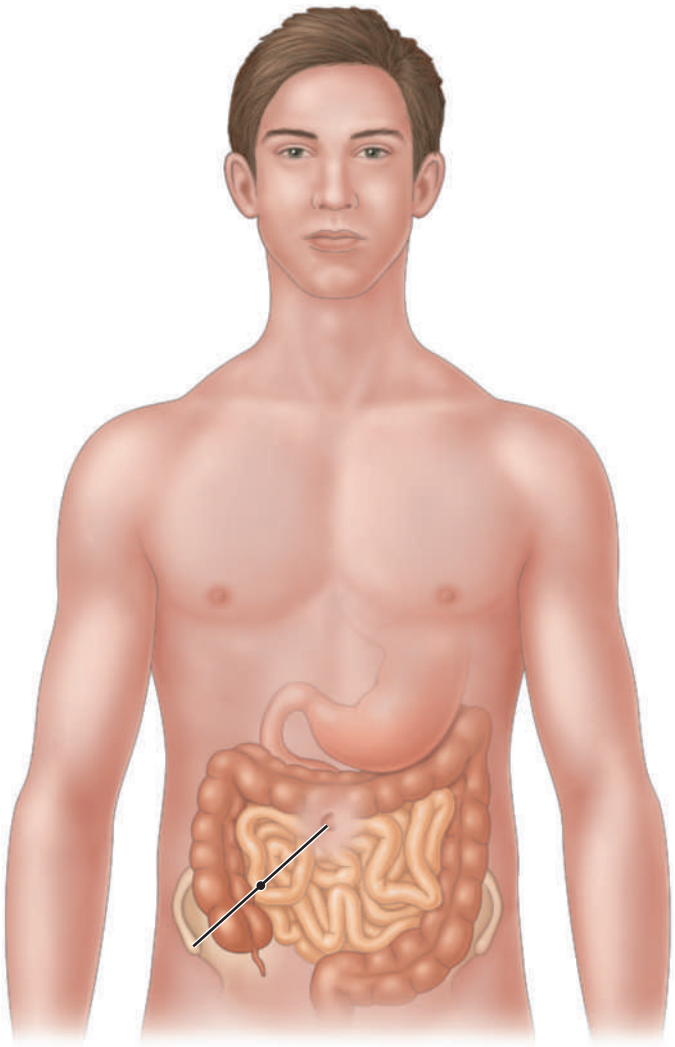

Figure 24–1 ■ McBurney's point, located midway between the umbilicus and the anterior iliac crest in the right lower quadrant. It is the usual site for localized pain and rebound tenderness due to appendicitis.

direct palpation of McBurney's point followed by pain on release of pressure. Extension or internal rotation of the right hip increases the pain. In addition to pain, a low-grade temperature, anorexia, nausea, and vomiting are often present.

Pain and local tenderness may be less acute in older adults, delaying the diagnosis, and leading to a 15% mortality from perforated appendicitis in the older adult (Papadakis & McPhee, 2013). This can present a significant problem; the course of acute appendicitis in older adults is more virulent and complications develop sooner. Pregnant women may develop right lower quadrant, periumbilical, or right subcostal (under the rib cage) pain due to possible displacement of the appendix by the distended uterus. Appendicitis can be difficult to diagnose. The classic history of pain beginning in the periumbilical region and migrating to the right lower quadrant occurs in about 50% of patients (Buckley & Schub, 2013a; 2013b).

Complications

Perforation, peritonitis, abscess are possible complications of acute appendicitis. Perforation is manifested by increased pain and a high fever. It can lead to a small, localized abscess, local peritonitis, or significant generalized peritonitis. (Peritonitis is discussed in the next section of this chapter.)

A less common disorder is chronic appendicitis, characterized by chronic abdominal pain and recurrent acute attacks at intervals of several months or more. Other conditions, such as inflammatory bowel disease and renal disorders, often cause manifestations attributed to chronic appendicitis.

●○● INTERPROFESSIONAL CARE

The acutely inflamed appendix can perforate within 24 hours, so rapid diagnosis and treatment are important. Because of this urgency and the low incidence of surgical complications, diagnostic testing and preoperative treatment may be limited. The patient is admitted to the hospital, and intravenous fluids and antibiotics are initiated. Oral food and fluids are withheld until a diagnosis is confirmed. Once the diagnosis is established, an appendectomy is performed.

DIAGNOSIS

Diagnostic and laboratory tests are used to help confirm the diagnosis and rule out other possible causes for the manifestations. Abdominal ultrasound is the most effective test for diagnosing acute appendicitis. Ultrasound examination has reduced the incidence of exploratory surgery and is particularly useful for patients with atypical symptoms, such as older adults. Other diagnostic tests used to accurately diagnose appendicitis include abdominal x-rays, an intravenous pyelogram, a urinalysis, and a pelvic examination. In addition, a WBC count with differential is obtained. With appendicitis, the total white count is elevated (10,000 to 20,000/mm^3), with an increased number of immature WBC (bands).

MEDICATIONS

Prior to surgery, intravenous fluids are given to restore or maintain vascular volume and prevent electrolyte imbalance. Antibiotic therapy with a third-generation cephalosporin effective against many gram-negative bacteria, such as cefoperazone (Cefobid), cefotaxime (Claforan), ceftazidime (Fortaz), or ceftriaxone (Rocephin), is initiated prior to surgery. The antibiotic is repeated during surgery and continued for at least 48 hours postoperatively. (The nursing implications for cephalosporin antibiotics are discussed in Chapter 12.) Pain medications are administered as prescribed.

SURGERY

The treatment of choice for acute appendicitis is an *appendectomy*, surgical removal of the appendix. Either a laparoscopic approach (insertion of a laparoscope to view abdominal contents) or laparotomy (surgical opening of the abdomen) may be used for appendectomy. A laparoscopic appendectomy is generally preferred because this procedure requires a very small incision through which the laparoscope is inserted. This procedure has several advantages: (1) Direct visualization of the appendix allows definitive diagnosis without laparotomy; (2) postoperative hospitalization is short; (3) postoperative complications are infrequent; and (4) recovery and resumption of normal activities is rapid. Disadvantages include increased cost and longer operating time (about 20 minutes longer than an open appendectomy).

A needle appendectomy is a newer type of laparoscopic procedure and is comparable to a traditional laparoscopic appendectomy in terms of complications and hospital length of stay (Buckley & Schub, 2013a).

A needle appendectomy is associated with a longer operative time and higher conversion rate to open appendectomy than a laparoscopic appendectomy.

An open appendectomy is performed by laparotomy. A small transverse incision is made at McBurney's point (refer to Figure 24–1); the appendix is isolated and ligated (tied off) to prevent contamination of the site with bowel contents, and then removed. Laparotomy generally is used when the appendix has ruptured. It allows removal of contaminants from the peritoneal cavity by irrigation with sterile normal saline. Occasionally the wound may be left unsutured for periodic irrigation. Recovery is generally uneventful. Refer to Chapter 4 for a discussion of preoperative and postoperative nursing care.

Surgery remains the common treatment for appendicitis and has long been considered the only treatment for appendicitis. However, a recent meta-analysis of randomized controlled trials found nonoperative treatment using antibiotic therapy to be a safe and effective alternative as surgery for patients with uncomplicated acute appendicitis (Varadhan et al., 2012). When compared with surgery, antibiotic therapy is associated with fewer complications, better pain control, and shorter recovery time but is correlated with a higher rate of reoccurring appendicitis (Mason et al., 2012).

●○● NURSING CARE

A Case Study & Nursing Care Plan for a patient with appendicitis is provided later in this chapter.

Health Promotion

The incidence of appendicitis is lower in cultures where higher fiber intake is common. Encouraging a diet high in fiber and low in animal fats may prevent the development of appendicitis.

Assessment

Because appendicitis can rapidly progress from inflammation to perforation, prompt assessment is vital. Obtain the following assessment data:

- *Health history:* current manifestations, including onset, duration, progression, and aggravating or relieving factors; most recent food or fluid intake; known medication or other allergies; current medications; history of chronic diseases
- *Physical assessment:* vital signs including temperature; apparent general health; abdominal shape and contour, bowel sounds, tenderness to light palpation.

Priorities of Care

Assessing patient for signs and symptoms of ruptured appendix is the priority focus of care. Prevention of dehydration and correction of fluid and electrolyte imbalance are also of key importance. Administration of prescribed antibiotics should be a priority nursing action. Managing the patient's pain pre- and postoperatively is an important component of care.

Diagnoses, Outcomes, and Interventions

Preoperative nursing care is directed toward preparing the patient physically and psychologically for emergency surgery. Limited time is available for preoperative teaching.

Risk for Infection

Preventing complications during the preoperative and postoperative periods is a primary nursing care goal. Perforation and peritonitis are the most likely preoperative complications; postoperative complications include wound infection, abscess, and possible peritonitis.

Expected Outcome: Patient will not exhibit signs and symptoms of perforation and peritonitis. Patient will remain afebrile, and WBC will decrease or remain at baseline. Patient will remain free of pain associated with perforation and peritonitis.

SAFETY ALERT

Assess abdominal status frequently, including distention, bowel sounds, and tenderness. Increasing generalized pain, a rigid, boardlike abdomen, and abdominal distention may indicate developing peritonitis.

- Monitor vital signs, including temperature. *Tachycardia and rapid shallow respirations may indicate perforation of the appendix with resulting peritonitis. Fever may develop as well, and the blood pressure may fall if sepsis is present.*
- Maintain intravenous infusion until oral intake is adequate. *Intravenous fluids are given to maintain vascular volume and to provide a route for antibiotic administration.*
- Assess wound, abdominal girth, and postoperative pain. *Swelling of the wound, increased abdominal girth, or an increase in pain may indicate infection or peritonitis.*
- Keep the patient with suspected appendicitis NPO, and do not administer laxatives or enemas. *Laxatives or enemas may cause perforation of the appendix.*
- No heat should be applied to the abdomen. *Heat may increase circulation to the appendix and also cause perforation.*

Acute Pain

The patient with appendicitis experiences pain before and after surgery. Analgesia is limited until the diagnosis is established. Postoperative pain is controlled by narcotic or nonnarcotic analgesics.

Expected Outcome: Patient will express tolerable preoperative pain using pain scale. Patient will report adequate pain control postoperatively.

- Assess pain, including its character, location, severity, and duration. Report any unexpected changes in the nature of pain. *Both preoperatively and postoperatively, the patient's pain provides important clues about the diagnosis and possible complications such as rupture of the appendix or peritonitis.*

SAFETY ALERT

Sudden relief of preoperative pain may signal rupture of the distended and edematous appendix.

- Administer analgesics as ordered. *Preoperatively, pain medication may be given cautiously until a diagnosis is established. Postoperatively, provide analgesics to maintain comfort and enhance mobility.*
- Assess effectiveness of medication 30 minutes after administration. Report unrelieved pain. *Pain unrelieved by prescribed analgesic may indicate a complication or the need for further assessment. For example, continued abdominal discomfort and distention may indicate excess intestinal gas that may be better relieved by ambulation.*

CASE STUDY & NURSING CARE PLAN A Patient with Acute Appendicitis

Jamie Lynn is a 19-year-old college student majoring in physical therapy. Ms. Lynn arrives at the emergency department at 1:00 a.m. complaining of general lower abdominal pain that had started the previous evening. By midnight, the pain was more localized over the right lower quadrant. She also reports nausea and vomiting.

ASSESSMENT

Sue Grady, RN, completes the admission assessment in the emergency department. Ms. Lynn is complaining of nausea and severe abdominal pain, stating, "Walking makes my stomach hurt worse." Physical assessment findings include T 37.8°C (100.2°F), P 84 bpm, R 16/min, and BP 110/70 mmHg; skin warm to touch; abdomen flat and guarded, with marked tenderness in right lower quadrant. Ms. Lynn's CBC shows WBC 14,000/mm^3; neutrophils 81.1%; lymphocytes 12.5%. The diagnosis of acute appendicitis is made, and Ms. Lynn is transferred to surgery for a laparoscopic appendectomy.

DIAGNOSES

- *Impaired Skin Integrity* related to surgical incision
- *Acute Pain* related to surgical intervention
- *Anxiety* related to situational crisis

EXPECTED OUTCOMES

- Patient's incision will heal without infection or complications.
- Patient will verbalize adequate pain relief.
- Patient will verbalize decreased anxiety.
- Patient will return to preoperative activities.

PLANNING AND IMPLEMENTATION

- Assess pain using a pain scale; provide analgesics as needed.
- Teach pain management following discharge.
- Teach abdominal splinting during coughing, turning, or ambulating as needed.
- Teach home care of incision.
- Discuss activity limitations as ordered.
- Instruct to report fever or warmth, redness, or drainage from the incision.

EVALUATION

On discharge the following evening, Ms. Lynn is fully ambulatory. Her appetite has returned, and she is tolerating food and fluids well. Her temperature is normal. The nurse provides Ms. Lynn with written and verbal information on postoperative care following an appendectomy.

Clinical Reasoning in Patient Care

1. What is the pathophysiologic basis for Ms. Lynn's elevated WBC on admission?
2. How would Ms. Lynn's postoperative care and teaching differ if she had undergone a laparotomy instead of a laparoscopic appendectomy?
3. Outline a teaching plan to give to patients for home care following an appendectomy.
4. Develop a care plan for Ms. Lynn for the nursing diagnosis of *Anxiety* related to a situational crisis.

See Evaluating Your Response in Appendix B.

Continuity of Care

Preoperative teaching may be limited by pain and the urgent nature of surgery. Explain why food and fluids are not permitted during this time. If time allows, teach postoperative turning, coughing, deep breathing, and pain management.

With uncomplicated appendectomy, the patient often is discharged either the day of surgery or the day following surgery. Postoperative teaching includes the following:

- Wound or incision care, including hand hygiene and dressing change procedures as indicated
- Instructions to report fever, increased abdominal pain, swelling, redness, drainage, bleeding, or warmth of the operative site to the physician
- Activity limitations (e.g., lifting, driving), if any
- Returning to work if appropriate.

THE PATIENT WITH PERITONITIS

Peritonitis, inflammation of the peritoneum, is a serious complication of many acute abdominal disorders. Peritonitis is usually caused by enteric bacteria entering the peritoneal cavity through a perforated ulcer, ruptured appendix, perforated diverticulum (discussed later in this chapter), necrotic bowel, or during abdominal surgery. Pelvic inflammatory disease, gallbladder rupture, abdominal trauma, or peritoneal dialysis can also lead to peritonitis.

Pathophysiology

The peritoneum is a double-layered serous membrane lining the walls (parietal peritoneum) and organs (visceral peritoneum) of the abdominal cavity. There is a potential space between the parietal and visceral layers of the peritoneum that contains a small amount of serous fluid.

Peritonitis results from contamination of the normally sterile peritoneal cavity by infection or a chemical irritant. Chemical peritonitis often precedes bacterial peritonitis. Perforation of a peptic ulcer or rupture of the gallbladder releases gastric juices (hydrochloric acid and pepsin) or bile into the peritoneal cavity, causing an acute inflammatory response.

Bacterial peritonitis usually is caused by infection by *Escherichia coli*, *Klebsiella*, *Proteus*, or *Pseudomonas* bacteria, which normally inhabit the bowel. Inflammatory and immune defense mechanisms are activated when bacteria enter the peritoneal space. These defenses can effectively eliminate small numbers of bacteria, but may be overwhelmed by massive or continued contamination. When this occurs, mast cells release histamine and other vasoactive substances, causing local vasodilation and increased capillary permeability. Polymorphonuclear leukocytes (a type of WBC) infiltrate the peritoneum to phagocytize bacteria and foreign matter. Fibrinogen-rich plasma exudate promotes bacterial destruction and forms fibrin clots to seal off and segregate the bacteria. This process helps limit and localize the infection, allowing host defenses to eradicate it. Continued contamination, however, leads to generalized inflammation of the peritoneal cavity. The inflammatory process causes fluid to shift into the peritoneal space (third spacing). Circulating blood volume is depleted, leading to hypovolemia. *Septicemia*, a systemic disease caused by pathogens or their toxins in the blood, may follow.

Manifestations

Manifestations of peritonitis depend on the severity and extent of the infection, as well as the age and general health of the patient. Both

local and systemic manifestations are present (see the accompanying box). The patient often presents with evidence of an *acute abdomen*, an abrupt onset of diffuse, severe abdominal pain. The pain may localize and intensify near the area of infection. Movement may intensify the pain. The entire abdomen is tender, with guarding or rigidity of abdominal muscles. The acute abdomen is often described as boardlike. Rebound tenderness may be present over the area of inflammation. Peritoneal inflammation inhibits peristalsis, resulting in a paralytic ileus. (Paralytic ileus is discussed in a later section of this chapter.) Bowel sounds are markedly diminished or absent, and progressive abdominal distention is noted. Pooling of GI secretions may cause nausea and vomiting. Systemic manifestations of peritonitis include fever, malaise, tachycardia and tachypnea, restlessness, and possible disorientation. The patient may be oliguric (having little urine output) and show signs of dehydration and shock.

Patients who are older, chronically debilitated, or immunosuppressed may present with few of the classic signs of peritonitis. Increased confusion and restlessness, decreased urinary output, and vague abdominal complaints may be the only manifestations present. These patients are at increased risk for delayed diagnosis, contributing to a higher mortality rate.

Complications

Complications of peritonitis may be life threatening. Abscess formation is common. The very defense mechanisms designed to isolate and localize the infection can protect it from immune responses and systemic antibiotics. Fibrous adhesions in the abdominal cavity are a late complication and may lead to subsequent obstruction.

Without prompt and effective treatment, septicemia and septic shock can develop. Fluid loss into the abdominal cavity may lead to hypovolemic shock. These potentially lethal complications require immediate, aggressive intervention to prevent multiple organ failure and death. Septicemia, shock, and its management are discussed in Chapter 11.

FAST FACTS

Mortality from Peritonitis

- The overall mortality rate associated with peritonitis is about 40%.
- Patients with other medical conditions, older patients, and those with greater bacterial contamination have a higher risk of dying.
- Young people with perforated ulcers or appendicitis, those with less extensive bacterial contamination, and those who receive early surgical intervention have mortality rates of less than 10%.

●○● INTERPROFESSIONAL CARE

Care of the patient with peritonitis focuses on establishing the diagnosis and identifying and treating its cause as well as the peritonitis. Preventing complications is an important aspect of care.

DIAGNOSIS

Diagnostic tests are performed to establish the diagnosis of peritonitis, rule out other disorders, and help identify the cause. The tests that may be ordered include a WBC (elevated to approximately 20,000/mm^3 in peritonitis), blood cultures, abdominal CT scan, liver and renal function studies, serum electrolytes, and a paracentesis (in peritonitis, peritoneal fluid will contain increased protein and WBCs). Increased numbers of immature blood cells are present as the bone marrow releases them in response to the infection.

MANIFESTATIONS OF PERITONITIS

ABDOMINAL/GASTROINTESTINAL MANIFESTATIONS

- Diffuse or localized pain
- Tenderness with rebound
- Boardlike rigidity
- Diminished or absent bowel sounds
- Distention
- Anorexia, nausea, and vomiting

SYSTEMIC MANIFESTATIONS

- Fever
- Malaise
- Tachycardia
- Tachypnea
- Restlessness
- Confusion or disorientation
- Oliguria

MEDICATIONS

Until the infecting organism has been identified, a broad-spectrum antibiotic effective against organisms commonly implicated in peritonitis is prescribed. A beta-lactam antibiotic such as imipenem (Primaxin) or meropenem (Merrem), which has a very broad spectrum of action, may be used. Once culture results have been obtained, antibiotic therapy is modified to the specific organism(s) responsible. Antibiotics that may be ordered include ampicillin (e.g., Omnipen, Polycillin), metronidazole (Flagyl), ciprofloxacin (Cipro), clindamycin (Cleocin), a cephalosporin such as ceftriaxone (Rocephin), or an aminoglycoside antibiotic such as gentamicin (Garamycin) or amikacin (Amikin). Nursing implications for antibiotic therapy are discussed in Chapter 12. Analgesics are prescribed to promote comfort.

SURGERY

If the cause of peritonitis is a perforation, gangrenous bowel, or inflamed appendix, a laparotomy is done to close the perforation or remove the damaged and inflamed tissue. If an abscess is present, it may be surgically drained or removed.

Peritoneal lavage, washing of the peritoneal cavity with copious amounts of warm isotonic fluid, may be done during surgery. This procedure dilutes residual bacteria and removes gross contaminants, blood, and fibrin clots. In rare instances, peritoneal lavage may be continued for several days following surgery. The solution is infused into the upper portion of the peritoneal cavity and removed via drains in the pelvic cul-de-sac. Careful attention to fluid and electrolyte status and strict aseptic technique are necessary.

Patients who have had a laparotomy for peritonitis often return from surgery with either a Penrose or closed drain system such as a Jackson-Pratt drain. In some cases, the incision may be left unsutured. With severe and long-standing peritonitis, the abdomen may be closed temporarily with polypropylene mesh containing a nylon zipper or Velcro to allow repeated exploration of the abdomen and drainage of infectious sites.

NUTRITION

Intravenous fluids and electrolyte replacements are administered to maintain vascular volume and fluid and electrolyte balance. Parenteral nutrition is given until adequate oral intake resumes.

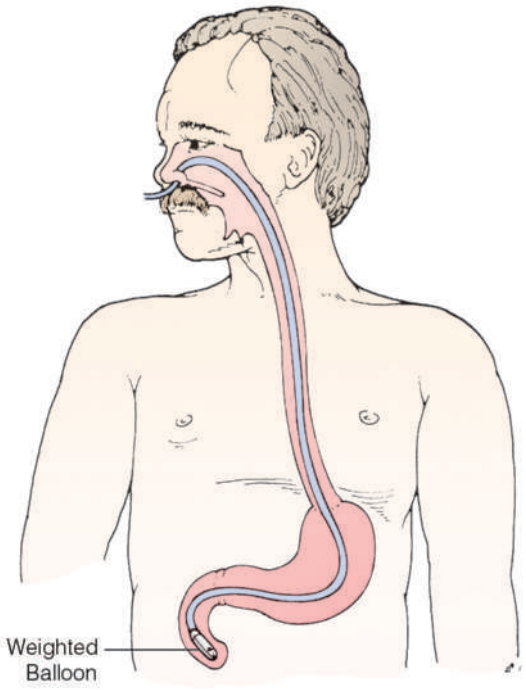

Figure 24–2 ■ The weighted tip or inflated balloon at the end of an intestinal tube is drawn into the intestine by gravity and peristalsis.

OTHER TREATMENTS

The patient is placed on bed rest in Fowler's position to help localize the infection and promote lung ventilation. Oxygen is often ordered to facilitate cellular metabolism and healing.

INTESTINAL DECOMPRESSION The inflammatory process of peritonitis often draws large amounts of fluid into the abdominal cavity and the bowel. In addition, peristaltic activity of the bowel is slowed or halted by the inflammation, causing **paralytic ileus** (or *ileus*), impaired propulsion or forward movement of bowel contents. Intestinal decompression is used to relieve abdominal distention, facilitate closure, and minimize postoperative respiratory problems. A nasogastric or long intestinal tube is inserted and connected to continuous drainage (Figure 24–2 ■). If prolonged intestinal decompression is anticipated, a jejunostomy may be performed for comfort. Suction is maintained until peristalsis resumes, bowel sounds are present, and the patient is passing flatus. Food and fluids are withheld until intestinal motility has returned and suction is discontinued.

●○● NURSING CARE

Health Promotion

Peritonitis is a serious illness. Early recognition and treatment are important to minimize the risk of complications.

Assessment

- *Health history:* pain, its onset, character, severity, location, aggravating and relieving factors; associated symptoms such as anorexia, nausea, vomiting; current and previous history of peptic ulcer disease, gallbladder disease, chronic diseases; current medications
- *Physical assessment:* vital signs including temperature; level of consciousness; skin color, temperature, warmth, capillary refill and turgor; abdominal shape, contour, bowel sounds, tenderness, tympany, and guarding.

Priorities of Care

Patients with peritonitis require intensive nursing and medical care to prevent complications and recover fully. Nursing care priorities include interventions to manage pain, altered fluid balance, infection, and anxiety.

Diagnoses, Outcomes, and Interventions

Acute Pain

Abdominal distention and acute inflammation contribute to the pain associated with peritonitis. Surgery further disrupts abdominal muscles and other tissues, causing pain. Effective pain management promotes immune function, healing, mobility, and recovery.

Expected Outcome: Patient will identify early escalation of pain, will use treatment plan (pharmacologic and nonpharmacologic) to prevent and alleviate discomfort, and will report relief from pain.

- Assess pain, including its location, severity (using a standard pain scale), and type. Monitor analgesic effectiveness. Report changes to the primary care provider. *A change in pain may indicate the patient's condition is worsening.*

SAFETY ALERT

Unrelieved pain or a change in the location, severity, or type of pain may indicate spread of infection, abscess formation, or other complications of peritonitis.

- Place in Fowler's or semi-Fowler's position with the knees and feet elevated. *This position reduces stress on abdominal structures and facilitates respirations, promoting comfort.*
- Administer analgesics as ordered on a routine basis or using patient-controlled analgesia (PCA). *Routine analgesic administration maintains a therapeutic blood level and helps maintain comfort, facilitating healing and movement.*
- Teach and assist with adjunctive pain management techniques such as meditation, visualization, massage, and progressive relaxation. *Adjunctive measures augment analgesics and help promote a sense of control over pain.*

Deficient Fluid Volume

In peritonitis, significant amounts of fluid are drawn into the abdominal cavity and bowel, reducing vascular volume and cardiac output. This fluid also may be lost from the body by intestinal suction or through drains placed in the abdomen during surgery. An unsutured incision causes additional significant fluid loss.

Expected Outcome: Deficient fluid volume in the patient will be prevented as evidenced by normal vital signs, lab values, and absence of physical signs of dehydration (e.g., thirst, change in mental status, decreased urine output, dry skin and mucous membrane, weakness, sudden weight loss).

- Maintain accurate intake and output records. Measure urine output every 1 to 2 hours; report output of less than 30 mL/h. Measure gastrointestinal output at least every 4 hours. *Intake and output records provide valuable information about fluid volume status.*

SAFETY ALERT

Urine output of less than 30 mL/h may indicate hypovolemia, decreased cardiac output, and impaired tissue perfusion.

- Monitor vital signs and hemodynamic parameters such as central venous pressure, cardiac output, and pulmonary artery pressures every hour or as indicated. *These measurements provide important information about fluid and vascular volumes as well as cardiovascular status.*
- Weigh daily. *Weight is an accurate indicator of fluid status. Rapid weight gains or losses reflect changes in fluid volume.*
- Assess skin turgor, color, temperature, and mucous membranes at least every 8 hours. *Warm, dry skin with poor turgor and dry, shiny mucous membranes indicate dehydration.*
- Measure or estimate fluid losses through abdominal drains and on dressings. *Significant amounts of exudative fluid may be lost.*
- Monitor laboratory values, including hemoglobin and hematocrit, urine specific gravity, serum osmolality and electrolytes, and ABGs. Report changes to the physician. *Laboratory results provide information about fluid and electrolyte status and acid–base balance.*
- Administer intravenous fluids and electrolytes as ordered. Gastrointestinal drainage may be replaced milliliter for milliliter with a balanced electrolyte solution. *Intravenous fluids are necessary to meet daily fluid intake needs, as well as replace continuing losses of water and electrolytes.*
- Provide good skin care and frequent oral hygiene. *Fluid deficit increases the risk of skin breakdown and ulceration of mucous membranes.*

Delayed Surgical Recovery

Repeated surgeries, an unsutured incision, and the presence of drains interrupt skin integrity and the body's first line of defense against microorganisms. In addition, immune defenses are stressed by the infection and potential malnutrition. An acute infection such as peritonitis causes a stress response with excess energy expenditure and loss of body proteins and cell mass. Glycogen stores are rapidly depleted, and body proteins are used to meet energy needs. Withholding food further complicates this process, leading to rapid development of protein-calorie malnutrition (PCM). PCM impairs the immune response and slows healing. As a result, the risk for impaired healing and further infection is increased.

Expected Outcome: Patient will experience regeneration of cells and tissue without signs of infection (e.g., redness, swelling, purulent drainage, fever).

- Monitor temperature, pulse rate, and for localized signs of infection such as redness and swelling around incisions and drain sites, increased or purulent drainage, and cloudy or malodorous urine. *Impaired defenses increase the risk for extension of the infection or unrelated infections.*
- Obtain cultures of purulent drainage from any site. *Early identification of any additional infection allows timely intervention.*
- Monitor WBC and differential, serum protein, and albumin. *An increased WBC with a higher percentage of immature cells present in the blood is an indicator of infection and normal immune response. Serum albumin and protein levels are indicators of nutritional status as well as immune function.*
- Practice meticulous hand hygiene and use standard precautions at all times. *Hand hygiene reduces transient bacteria on the skin and remains the most important method of controlling infection. Standard precautions reduce the risk of spreading infection to or from the patient.*
- Use strict aseptic technique for dressing changes, wound care, and irrigations. *Disruption of the protective barrier of the skin increases the risk of contamination and further infection.*
- Maintain fluid balance and nutritional status through enteral or parenteral feedings, as indicated. See the Moving Evidence into Action box for evidence-based recommendations for care of enterally fed patients. *Adequate nutrition and fluid balance are necessary for optimal immune system function.*

Continuity of Care

Teaching for home care includes the following topics:

- Wound care procedures, including dressing changes or irrigations. Provide verbal and written instructions on how to change dressings or do irrigations as well as where to obtain supplies, and allow opportunities to practice and demonstrate the procedure prior to discharge.
- Prescribed medications, including name and purpose of the drug, potential adverse effects, and their management.
- Manifestations of further infection (redness, heat, swelling, purulent drainage, chills, and fever) and potential complications to be reported to the care provider.
- Prescribed activity restrictions.
- Instructions for a high-calorie, high-protein diet for healing and optimal immune function.

Provide a referral to home health services for assessment, wound care, and further teaching, as needed.

THE PATIENT WITH GASTROENTERITIS

Gastroenteritis, or *enteritis*, is an inflammation of the stomach and small intestine. Enteritis may be caused by bacteria, viruses, parasites, or toxins. Upper GI manifestations such as anorexia, nausea, and vomiting are common. Diarrhea of varying intensity and abdominal discomfort are nearly universal features of gastroenteritis.

The infectious organism usually enters the body in contaminated water or food. For this reason, gastroenteritis often is called food poisoning. Viruses commonly cause acute diarrheal illness. Diarrhea due to rotaviruses or the Norwalk virus occurs year-round in both adults and children. These illnesses are generally mild and self-limited, and reinfections are progressively less severe. However, rotaviruses can have severe consequences in the very young, the very old, or in people with impaired immune function.

Pathophysiology

Bacterial or viral infection of the GI tract produces inflammation, tissue damage, and manifestations by two primary mechanisms:

- *Production of exotoxins:* A number of bacteria produce and excrete an exotoxin that enters the surrounding environment (intestinal lumen), causing damage and inflammation. Exotoxins in the GI tract are often referred to as *enterotoxins*. They impair intestinal

Moving Evidence into Action

Enterally Fed, Seriously Ill Patient

A vital component of the treatment and care of seriously ill patients (such as those with peritonitis) is providing nutritional support, primarily through enteral feedings. Although this remains the method of choice for the seriously ill population and has many advantages, enteral feeding also comes with the risk of malposition of the feeding tube, resulting in pulmonary injury associated with aspiration, pneumothorax, atelectasis, and pleural effusion. Not much information has been published about how to assess for misplacement and migration of the tube in enterally fed patients. Stepter (2012) conducted a study to review and synthesize current research in order to make recommendations to improve the quality and safety of administering enteral nutrition to seriously ill patients. This meta-analysis found that nurses frequently use methods to care for patients that are not supported by evidence. Recommended techniques to prevent complications associated with enteral tube feedings included the following:

- Prevent aspiration with feeding tube placement by verifying placement via radiologic confirmation. After verifying the placement, the tube should be securely taped and the external tube length should be measured, noted, and marked on the tube as a reference point for further tube placement checks. If the position of the tube is questioned, the x-ray should be repeated.
- Maintain the head of the bed at an angle of at least 30 degrees, with 45 degrees being ideal. Stop feedings 30 to 60 minutes before placing the patient in the supine position.
- Flush with water only (no juice, soda, or meat tenderizer).
- Eliminate the use of blue dye in feedings.
- Maintain cuff pressure in patients with artificial airways at 20 to 30 cm H_2O.
- Administer medications separately, flushing with water before and after each drug is administered.

Implications for Nursing

Based on this review of the relevant research, it is obvious that more research is needed in this area of care. However, daily assessments of the patient and the feeding tube using multiple methods (including x-ray, external length marking, pH testing, aspirate characteristics, or trypsin/pepsin levels) should be conducted by caregivers who have the knowledge to accurately interpret the results.

Moving Knowledge into Action

1. Aspiration is defined as the inhalation of oropharyngeal or gastric contents into the larynx and lower respiratory tract. The result is usually aspiration pneumonitis or aspiration pneumonia. What assessments would you conduct and monitor to identify these complications?
2. You are on a committee that is evaluating the practice of adding blue dye to feeding solutions in order to better detect aspiration. The literature does not support this method. How and what would you do to convince the committee that this practice should not be continued?
3. What principle supports elevating the head of the bed to prevent aspiration? (Consider gravity and the placement of internal organs with the patient in this position.)

absorption and can cause secretion of significant amounts of electrolytes and water into the bowel, resulting in diarrhea and fluid loss. Common bacterial enterotoxins include those produced by *Staphylococcus, Clostridium perfringens*, *Clostridium botulinum*, some strains of *Escherichia coli*, *Vibrio cholera*, and *C. difficile*.

- *Invasion and ulceration of the mucosa:* Other bacteria, including some *Shigella*, *Salmonella*, and *E. coli* species, damage tissue more directly. They invade the intestinal mucosa of the small bowel or colon, producing microscopic ulceration, bleeding, fluid exudate, and water and electrolyte secretion.

In some cases, the mechanism of injury is unclear. It may be a combination of direct and toxic damage. For example, the Norwalk virus damages the mucosa of the jejunum.

Manifestations

Although the manifestations of bacterial and viral enteritis vary according to the organism involved, several features are common. Anorexia, nausea, and vomiting are caused by distention of the upper GI tract by unabsorbed chyme and excess water. Bowel distention, along with irritation of the bowel mucosa and gas production due to fermentation of undigested food, leads to abdominal pain and cramping. Borborygmi, excessively loud and hyperactive bowel sounds, are another result. The abdomen is often distended and tender.

Diarrhea is usually predominant with enteritis. Fluid is secreted into the bowel lumen, and the unabsorbed chyme and electrolytes create an osmotic pull of fluid into the bowel. Motility is stimulated, and stools become watery and frequent. Loss of fluids and electrolytes through diarrhea can lead to the most serious manifestations of enteritis. Refer to Chapter 10 for manifestations related to fluid and electrolyte loss. Fluid volume can be rapidly depleted, leading to dehydration and hypovolemia. Orthostatic hypotension and fever may be noted initially. If fluid loss continues, hypovolemic shock may develop.

Complications

Electrolyte and acid–base imbalances may result from gastroenteritis. Extensive vomiting can lead to metabolic alkalosis due to the loss of hydrochloric acid from the stomach. When diarrhea dominates, metabolic acidosis is more likely. Potassium is lost in either case, leading to hypokalemia. Hyponatremia may develop if fluids are replaced with pure water. Headache, cardiac irregularities, changes in respiratory rate and pattern, malaise and weakness, muscle aching, and signs of neuromuscular irritability are the possible manifestations of these disturbances in homeostasis.

SPECIFIC TYPES OF GASTROINTESTINAL INFECTIONS

Several gastrointestinal infections produce specific effects that are discussed below and summarized in Table 24–3.

TRAVELER'S DIARRHEA People traveling to another country frequently develop diarrhea within 2 to 10 days, particularly when there is a significant difference in climate, sanitation standards, or food and drink. Strains of enterotoxin-producing *E. coli*, *Shigella* species, *Salmonella*, and *Campylobacter* are frequent causes of traveler's diarrhea (Longo et al., 2013). Other bacteria and viruses also may cause traveler's diarrhea.

TABLE 24–3 Selected Bacterial Infections of the Bowel

Disease and Organism	Incubation	Pathogenesis	Manifestations	Management
Traveler's diarrhea: *Escherichia coli*	24–72 hours	Enterotoxin causes hypersecretion of the small intestine.	Abrupt onset of diarrhea; vomiting rare	Prophylactic bismuth subsalicylate; antidiarrheal such as loperamide; 3-day course of norfloxacin, ciprofloxacin, or azithromycin
Hemorrhagic colitis: *E. coli* O157:H7	1–3 days	Enterotoxin causes direct mucosal damage in large intestine; also toxic to vascular endothelial cells.	Severe abdominal cramping, watery diarrhea that becomes grossly bloody; fever; possible complications: hemolytic uremic syndrome and thrombotic thrombocytopenic purpura	Supportive care with fluid replacement and bland diet; may require dialysis or plasmapheresis for complications
Staphylococcal food poisoning	2–8 hours	Enterotoxin impairs intestinal absorption and affects vomiting centers in the brain.	Severe nausea and vomiting; abdominal cramping and diarrhea; headache and fever	Fluid and electrolyte replacement as needed
Cholera: *Vibrio cholerae*	1–3 days	Enterotoxin affects entire small intestine, causing secretion of water and electrolytes into bowel lumen.	Severe diarrhea with "rice water stool," gray, cloudy, odorless, with no blood or pus; vomiting; thirst, oliguria, muscle cramps, weakness; dehydration and vascular collapse	Oral or intravenous rehydration; possible antimicrobial therapy with tetracycline, doxycycline, ciprofloxacin, others
Salmonellosis: *Salmonella*	8–48 hours	Superficial infection of the GI tract without invasion or production of toxins.	Diarrhea with abdominal cramping, nausea, and vomiting; low-grade fever, chills, weakness	Treatment of symptoms; a third-generation cephalosporin or a fluoroquinolone antibiotic for severe illness
Shigellosis (bacillary dysentery): *Shigella*	1–4 days	Local tissue invasion, primarily involving large intestine and distal ileum; endotoxin causes fluid and electrolyte secretion into bowel lumen.	Watery diarrhea with severe abdominal cramping and tenesmus; lethargy	Fluid and electrolyte replacement; correction of acidosis; antibiotic therapy with ciprofloxacin, ceftriaxone, others
Clostridium difficile colitis: *C. difficile*	1–2 weeks	Antibiotic therapy interferes with normal protective bacteria in the colon; *C. difficile* colonizes and releases toxins that cause mucosal inflammation and damage.	Diarrhea, abdominal cramps, malaise, fever, anorexia	Cessation of the causative antibiotic; antibiotic therapy with metronidazole (specific for *C. difficile*)—possibly vancomycin for resistant strains

Up to 10 or more loose stools per day and abdominal cramping are common manifestations. Nausea and vomiting are less frequent; fever is rare. Manifestations usually resolve within 2 to 5 days and complications are rare.

***ESCHERICHIA COLI* HEMORRHAGIC COLITIS** Most pathologic forms of *E. coli* bacteria cause little more than common traveler's diarrhea. However, some strains, such as serotype O157:H7, produce a potent enterotoxin in the large intestine after being ingested. This toxin damages bowel mucosa and the endothelial cells of blood vessels in the GI tract. If absorbed, the toxin can damage other blood vessels as well, such as those of the kidney.

Cattle provide the reservoir for *E. coli* O157:H7. It is usually spread through undercooked beef (hamburger in particular) and unpasteurized milk or apple juice. It may also be spread by direct contact via the fecal–oral route. The onset of hemorrhagic colitis is abrupt, with severe abdominal cramping and watery diarrhea that becomes grossly bloody within 24 hours. Fever may be present.

Hemolytic uremic syndrome and thrombotic thrombocytopenic purpura are significant complications of *E. coli* hemorrhagic colitis, affecting about 5% of people with the disease. Older adults have the highest risk for developing complications.

STAPHYLOCOCCAL FOOD POISONING Certain foods provide an excellent medium for staphylococcal growth when contaminated and left at room temperature. Examples include meats and fish, dairy products (e.g., custards), and bakery products (e.g., cream-filled pastries). The organism itself does not affect the bowel; the toxin it produces, however, impairs intestinal absorption and acts on receptors in the gut, stimulating the medullary center to produce vomiting.

The onset of staphylococcal food poisoning is abrupt, occurring within 2 to 8 hours after consuming the contaminated food. Nausea and vomiting are severe. Manifestations typically last 3 to 6 hours, and include abdominal cramping, diarrhea, headache, and fever. Complications such as fluid and electrolyte imbalances are rare, but may develop in older adults and people with underlying chronic disease processes.

CHOLERA *Cholera* is an acute diarrheal illness caused by strains of *Vibrio cholerae*. It is endemic in parts of Asia, the Middle East, and Africa and a potential epidemic following natural disaster. Cholera

is spread by the fecal–oral route through contaminated water or food. The organism produces an enterotoxin, enzymes, and other substances that affect the entire small intestine. Water and electrolytes are secreted into the bowel lumen in response to the toxin. The enzymes and other substances produced by the bacteria may affect mucous protection of bowel endothelium.

Cholera ranges in severity from very mild, with few or no manifestations, to acute and fulminant. Its onset is typically abrupt, with severe, frequent, watery diarrhea. Up to 1 L of stool may be passed in an hour, rapidly depleting fluid volume. This type of stool is often described as "rice water stool" and is characteristically gray and cloudy, with no fecal odor, blood, or pus. Vomiting may accompany the diarrhea. Other manifestations relate to the loss of fluid and electrolytes: thirst, oliguria, muscle cramps, weakness, and significant signs of dehydration. Metabolic acidosis and hypokalemia develop. If untreated, circulatory collapse and acute renal failure may occur.

Recovery from cholera usually occurs spontaneously within 3 to 6 days. With prompt and adequate fluid replacement, mortality is less than 1%.

***CLOSTRIDIUM DIFFICILE* COLITIS** *Clostridium difficile colitis* (*C. difficile* colitis) is associated with antibiotic therapy. Treatment with antibiotics (especially broad-spectrum antibiotics) predisposes to interference with the normal protective bacteria of the colon, leading to colonization by *C. difficile* by the oral–fecal route. Subsequent release of toxins by the bacteria causes mucous damage and inflammation. This is primarily a problem in hospitalized patients, causing diarrhea and abdominal cramping. These manifestations commonly begin within 1 to 2 weeks of antibiotic treatment. It is also being seen in the community in healthy adults. The bacteria can be identified in the stool. See the following Moving Evidence into Action box discussing diarrhea.

SALMONELLOSIS *Salmonellosis* is food poisoning caused by ingesting raw or improperly cooked foods contaminated with *Salmonella* bacteria. Meat, poultry, eggs, and dairy products commonly are implicated in salmonellosis; recent outbreaks have been linked to products such as peanuts and alfalfa sprouts. These bacteria cause superficial infection of the GI tract, rarely invading further. They do not produce a toxin.

Manifestations develop 8 to 48 hours after ingesting the bacteria. Diarrhea may be violent with abdominal cramping, nausea, and vomiting. A low-grade fever, chills, and weakness may accompany GI manifestations. The disease usually is self-limited, resolving within 3 to 5 days, although bacteremia may develop.

SHIGELLOSIS (BACILLARY DYSENTERY) *Shigellosis* (or bacillary dysentery) occurs worldwide, and may be endemic or occur in epidemics. Humans are the reservoir for *Shigella* organisms, which are spread directly via the fecal–oral route or indirectly through contaminated food, fomites (inanimate objects), and vectors (such as fleas). The incubation period for shigellosis is 1 to 4 days.

Shigella organisms infect the distal ilium and lower intestine. They invade the tissue, causing inflammation, and they produce an enterotoxin. The result is watery diarrhea containing blood, mucus, and inflammatory exudate. The onset of diarrhea is abrupt, with severe abdominal cramping, and *tenesmus*, a sensation of urgent and continuing need to defecate. Lethargy is common; rarely, neurologic manifestations occur.

Moving Evidence into Action

Diarrhea

Hospitalized patients often have a number of risk factors for diarrhea. *Clostridium difficile* is now recognized as the cause of a significant portion of treatment-related diarrhea. The incidence of *C. difficile* infection (CDI) is increasing in hospitals and is the most common cause of antibiotic-associated infection. CDI is listed as an epidemiologically significant organism in the Joint Commission's National Safety Goal and an estimated 7178 inpatients are infected with CDI in the U.S. hospitals in any one day. The estimated cost of CDI in the United States is approximately $32.1 million per year and this healthcare-associated infection is responsible for an average of 40,197 extra hospital days for patients (Link, 2011). Numerous studies have shown that hand hygiene using soap and water is significantly more effective at removing *C. difficile* spores than are alcohol-based hand rubs. Edmonds et al. (2013) compared use of soap and water with several hand hygiene preparations. Results showed commonly used alcohol-based hand hygiene preparations used in hospitals did not aid in spore removal. Preparations more effective than soap and water were too harsh for the skin given the frequency of hand washing required. The researchers confirmed the recommendation for hand hygiene practice with antimicrobial soap and water using friction for a minimum of 15 seconds. Ensuring that hospital staff and visitors comply with contact precautions was also confirmed as an important standard of care to implement for patients with CDI.

Implications for Nursing

Patients are getting sicker and pathogens continue to evolve as the prevalence of healthcare-associated infections increases. In addition to assuming responsibility for creating, implementing, and evaluating plans of care for individual patients with CDI, nurses must participate in developing a plan of care for the environment to prevent transmission to other patients and staff. In summary, hand hygiene using soap and water along with contact precautions is necessary to prevent the spread of CDI. Contaminated medical equipment such as stethoscopes, commodes, and bathtubs contribute to the transmission of CDI. Ensuring that the environmental services department uses appropriate disinfectants to eradicate CDI spores is essential. Educating unlicensed assistive personnel (UAP) on precautions to prevent transmission of CDI among patients should be included in planned nursing interventions.

Moving Knowledge into Action

1. Ensuring that all personnel perform adequate hand hygiene and use contact precautions is critical for preventing the spread of CDI among patients. What specific instruction and oversight will you provide for UAP involved in caring for a patient with CDI?
2. CDI is transmitted by the fecal–oral route. The acid-resistant spores linger and germinate in the colon after surviving the gastric acid barrier and bypassing the stomach. Thinking about the functions of the stomach, pyloric valve, duodenum, and jejunum, which type of tube (gastric, duodenal, or jejunal) might carry the highest risk for CDI? The lowest?
3. Prior antibiotic treatment disrupts the normal flora in the intestine, allowing proliferation of *C. difficile* bacteria. Your patient is being discharged home with a diagnosis of healthcare-associated CDI. What teaching will you provide to the patient and family regarding hand hygiene, diet, and signs and symptoms to monitor?

In adults, shigellosis is usually mild and self-limiting. Older adults and debilitated patients are at risk for volume depletion and electrolyte imbalances. Secondary infection is another potential complication, as is acute blood loss from mucosal ulcerations.

NOROVIRUS Norovirus-associated gastroenteritis is a highly contagious disease that often occurs in outbreaks within an institution or facility. Norovirus is characterized by acute vomiting; watery, nonbloody diarrhea; abdominal cramps; and nausea. Systemic manifestations such as myalgia, malaise, headache, and low-grade fever are common.

Noroviruses are transmitted primarily by the fecal–oral route, either through direct contact or via contaminated food or water. The average incubation period is 12 to 48 hours. The disease tends to be self-limiting, with dehydration its most common complication.

●○● INTERPROFESSIONAL CARE

The goals of care for gastroenteritis are to manage the manifestations, prevent complications, identify the cause of the infection, and prevent its spread. The history and manifestations provide valuable cues about the cause. Diagnostic testing is used to identify the pathogen and evaluate its effects. In most cases, treatment is supportive, directed toward relieving manifestations, restoring fluid and electrolyte balance, and maintaining function.

DIAGNOSIS

If manifestations are severe or do not resolve within about 48 hours, laboratory testing is used to identify the causative organism and to assess fluid, electrolyte, and acid–base balance. A stool specimen for culture, ova and parasites, and fecal leukocytes usually reveals the infective organism, but may require up to 6 weeks to identify some bacteria. In infections such as botulism, the toxin itself may be isolated in the stool. Contamination of the stool by urine or treatment with antibiotics, bismuth subsalicylate (Pepto-Bismol), or mineral oil may interfere with pathogen growth, altering stool culture results. Use a clean bedpan or collection device to obtain the stool specimen, and instruct the patient to avoid mixing the stool with urine or toilet tissue.

A sigmoidoscopy may be done to differentiate inflammatory bowel disease from infectious processes. It does not replace stool cultures, because the lesions associated with some infectious processes are indistinguishable from those of ulcerative colitis. (Nursing care of the patient having a sigmoidoscopy is discussed in Chapter 21.)

Serum osmolality and electrolytes and ABGs are done to assess and monitor fluid, electrolyte, and acid–base balance. Common imbalances associated with enteritis and diarrhea are outlined in Table 24–4.

MEDICATIONS

Acute enteritis usually resolves spontaneously, and no drug treatment is required. If the patient is severely ill and manifestations are prolonged, medications may be prescribed.

Antibiotic therapy specific to the organism may be used to treat bacterial colitis, cholera, salmonellosis, or shigellosis. Ciprofloxacin (Cipro), clarithromycin (Biaxin), erythromycin, amoxicillin–clavulanate (Augmentin), or another antibiotic may be prescribed. Stool culture is obtained prior to starting antibiotics, but treatment may begin before culture results are available. A presumptive diagnosis based on history and presenting manifestations guides the choice of antibiotic.

An antidiarrheal drug may be prescribed to promote comfort and reduce fluid loss. Nursing measures related to antidiarrheal medications are outlined in the accompanying Medication Administration box.

Use of antidiarrheal preparations prolongs the course and increases risk for complications in some types of gastroenteritis, and therefore is contraindicated. Obtain a careful history before recommending these agents to the patient.

TABLE 24–4 Laboratory Values Associated with Enteritis and Diarrhea

Test	Normal Value	Change with Significant Diarrhea
Serum osmolality	280–300 mOsm/kg	Increased; levels above 320 mOsm/kg indicate significant dehydration.
Serum potassium	3.5–5.3 mEq/L	Decreased due to loss through stool and vomitus; levels below 2.5 mEq/L are critical.
Serum sodium	135–145 mEq/L	Decreased due to loss through stool and vomitus; may be significant when fluid losses are replaced with pure water; levels below 120 mEq/L may be critical.
Serum chloride	95–105 mEq/L	Increased when sodium loss is greater than chloride loss; decreased with severe diarrhea and with vomiting; possible critical values are below 80 mEq/L or above 115 mEq/L.
Blood gases		
• pH	Arterial: 7.35–7.45	Decreased in metabolic acidosis, a possible result of severe diarrhea; increased in metabolic alkalosis, a possible result of severe vomiting and chloride loss; values below 7.25 or above 7.55 are critical.
• PCO_2	Arterial: 35–45 mmHg	Typically decreased in metabolic acidosis as the body attempts to eliminate excess acid by "blowing off" CO_2; increased with metabolic alkalosis as the body retains CO_2 in an attempt to normalize pH.
• Bicarbonate	24–28 mEq/L	Decreased in metabolic acidosis; increased in metabolic alkalosis.
Hematocrit	Males: 40%–54% Females: 36%–46%	Increased with dehydration and hypovolemia as a result of concentration of blood cells.
Urine specific gravity	1.005–1.030	Increased with dehydration and hypovolemia as kidneys attempt to conserve fluid.

NUTRITION AND FLUIDS

Replacing lost fluids and electrolytes is vital when vomiting and/or diarrhea are severe or prolonged. In many cases of enteritis, fluid and electrolyte replacement are all that is required until the infection resolves.

Oral rehydration is preferred for replacing physiologic fluids. An oral glucose-electrolyte solution is often well tolerated in sips, even when vomiting is present. Intravenous rehydration may be necessary with severe diarrhea and fluid loss. In some cases, a combination of oral and intravenous fluids may be used to replace lost fluids and maintain vascular volume. Balanced electrolyte solutions, such as glucose in normal saline and Ringer's solution, are used. Lactated Ringer's solution or another alkalinizing solution may be ordered if metabolic acidosis is present.

GASTRIC LAVAGE

Gastric lavage and catharsis—in effect, "washing out" the stomach and intestines—may be performed to remove unabsorbed toxin from the GI tract if botulism is suspected.

PLASMAPHERESIS

Plasmapheresis (plasma exchange therapy) may be performed to remove circulating toxins for hemorrhagic colitis caused by *E. coli*. See Chapter 44 for the nursing care of a patient having this procedure. Potential complications include those associated with intravenous catheters, shifts in fluid balance, and altered blood clotting.

DIALYSIS

Acute tubular necrosis and renal failure associated with hemorrhagic colitis may necessitate dialysis to remove wastes and prevent severe fluid and electrolyte imbalances and metabolic acidosis. Although acute renal failure often resolves spontaneously and renal function resumes, dialysis can be lifesaving. Either hemodialysis or peritoneal dialysis may be used, generally as a temporary measure. Nursing care related to acute renal failure and dialysis is discussed in Chapter 28.

●○● NURSING CARE

Most patients are treated in community settings. Assessment, education, and support of self-care measures are major nursing responsibilities.

Health Promotion

Nurses play significant roles in preventing enteritis as educators, community health providers, and advocates for environmental safety.

Teach the importance of proper food handling and maintaining appropriate temperatures. Raw fruits and vegetables should be thoroughly washed before consuming. Adequate cooking of meat products is vital to prevent disorders such as staphylococcal food poisoning, *E. coli* hemorrhagic colitis, and salmonellosis. Emphasize the importance of not consuming raw meat products, and cooking hamburger, in particular, to the point that no redness is noted in the meat. The highly pathogenic *E. coli* serotype O157:H7 is present in the gut of infected animals. Meats from the animal may be contaminated with bowel contents. The organism is readily destroyed by heat, so cuts of meat such as steaks or roasts are less likely to cause infection, since the organism is on the outside of the meat. However, the process of grinding hamburger allows *E. coli* to be mixed throughout the meat. Thorough cooking destroys the organism. This pathogen (and others) may be spread through unpasteurized milk. Discuss the dangers of consuming milk that has not been pasteurized and encourage patients to avoid it.

Dairy products, eggs, and egg products left at room temperature provide a good growth medium for bacteria. Discuss the importance of prompt refrigeration of meats and these products to minimize this risk. Many gastrointestinal infections are spread through contaminated water. Encourage travelers to consume only bottled water unless local water supplies are clearly safe. Water purification tablets are available for hikers and campers, and may be used when traveling abroad.

Assessment

- *Health history:* onset, duration, and severity of manifestations; recent activities such as attending a picnic or potluck, international travel, or camping; other affected members of the household; measures taken to relieve manifestations or replace fluids
- *Physical assessment:* vital signs including temperature and orthostatic blood pressure; skin color, temperature, moisture, and turgor; peripheral pulses and capillary refill; abdominal shape, contour, bowel sounds, tenderness.

Priorities of Care

Diarrhea and fluid volume deficit are priority nursing diagnoses. See the earlier section of this chapter on diarrhea for specific nursing interventions related to these diagnoses. Nausea and vomiting frequently accompany the diarrhea associated with gastroenteritis. Nursing care of the patient experiencing nausea and vomiting is detailed in Chapter 23.

Diagnoses, Outcomes, and Interventions

Nursing care for the patient with diarrhea is supportive and educational. Manifestations of diarrhea can interfere with the patient's ability to maintain normal roles and responsibilities.

Continuity of Care

Discuss the following self-care topics with the patient:

- The importance of good hand hygiene, particularly before handling food and after each bowel movement
- The need to wash clothing and linens contaminated with feces separately in hot water and detergent
- Oral solutions to replace lost fluids and electrolytes
- Appropriate use of antidiarrheal medications if recommended
- Manifestations of complications to report to the healthcare provider

THE PATIENT WITH A PROTOZOAL BOWEL INFECTION

Parasites live within, on, or at the expense of other organisms. Parasitic intestinal infections are common in developing countries. They include both protozoal and helminthic (parasitic worms) infections. Parasites that infect the bowel usually enter the GI tract through the mouth by the fecal–oral route; some are spread by direct contact or through sexual activity.

Of the protozoal bowel infections, only giardiasis is common in the United States. Amebiasis is found chiefly in the tropics and where sanitation is poor. Cryptosporidiosis, a form of coccidiosis, is an important worldwide cause of sporadic mild diarrhea, traveler's diarrhea, and severe diarrhea in people who are immunocompromised.

Pathophysiology and Manifestations

The most common protozoal infections of the bowel are discussed next and summarized in Table 24–5.

GIARDIASIS

Giardiasis is a protozoal infection of the upper small intestine caused by *Giardia lamblia*. It is the most common intestinal protozoal pathogen in the United States. Humans and other mammals are the reservoir for *Giardia*, which is spread by the fecal–oral route, usually in contaminated food or water. It is also spread by direct contact. When the cyst form of the organism is ingested, trophozoites emerge in the duodenum and jejunum, attaching itself to the intestinal mucosa. This leads to superficial invasion, inflammation, and destruction of the mucosa of the small intestine.

Giardiasis may be asymptomatic, or manifestations may develop suddenly or insidiously. Diarrhea is common. It is usually mild, with one or more large, loose stools per day. Diarrhea may be severe, however, with frequent, copious, frothy, malodorous, and greasy stools. Other manifestations include weight loss and weakness; anorexia, nausea, and vomiting; epigastric pain; abdominal cramping and distention; and flatulence and belching. Malabsorption may develop.

AMEBIASIS

Amebiasis (amebic dysentery) is caused by the protozoon *Entamoeba histolytica*. Several strains of the protozoon have been identified. Humans are the host for this parasite. It usually is transmitted through food or water contaminated by feces and by person-to-person contact. The parasite enters the intestines, where it may live without causing disease, or it may invade the intestinal wall to cause ulceration and inflammation. The cecum, appendix, ascending colon, sigmoid colon, and rectum are most often affected. Ulcers may spread to cause hemorrhage, edema, and mucosal sloughing. The infection may spread via the blood to the liver, lungs, or brain.

Amebiasis is usually asymptomatic. Mild manifestations include abdominal cramps, flatulence, and intermittent diarrhea containing blood and mucus. Severe manifestations of amebic dysentery include frequent watery stools containing blood, mucus, and necrotic tissue; colic, tenesmus, and abdominal tenderness; nausea and vomiting; and fever. The liver may be enlarged and tender to palpation.

Complications are rare, but may include appendicitis, bowel perforation with peritonitis, and fulminating colitis.

CRYPTOSPORIDIOSIS (COCCIDIOSIS)

Cryptosporidiosis causes sporadic mild diarrhea and traveler's diarrhea in all age groups. In people with impaired immune function, such as those with human immunodeficiency virus (HIV) disease, it causes severe diarrhea, malabsorption, and significant weight loss.

This organism is transmitted by the fecal–oral route. Contaminated water is a frequent source of infection. The organism attaches to epithelium of the small bowel, causing surface damage and inflammation and characteristic watery diarrhea. The disease is self-limited in people with competent immune systems. Watery diarrhea may be accompanied by low-grade fever, nausea, vomiting, abdominal cramps, and general malaise.

Immunocompromised patients develop profuse watery diarrhea with significant fluid and electrolyte losses and severe malabsorption. The organism may be found in the respiratory tract, large intestines, and biliary tract of immunocompromised people. Lymphadenopathy (enlarged lymph nodes) may develop.

TABLE 24–5 Common Protozoal Infections of the Bowel

Disease and Organism	Incubation	Pathogenesis	Manifestations	Management
Giardiasis: *Giardia lamblia*	1–3 weeks or more	Trophozoite attaches to mucosa in duodenum and jejunum, causing superficial invasion, inflammation, and tissue destruction.	Diarrhea, mild or severe, daily or intermittent; anorexia, nausea, vomiting; epigastric pain, cramping, distention; flatulence and belching; may be asymptomatic	Metronidazole (Flagyl, others), tinidazole (Tindamax), nitazoxanide (Alinia)
Amebiasis: *Entamoeba histolytica*	2–4 weeks	Organisms may reside in large intestine without causing disease or can invade colon wall, causing ulceration; may be carried via blood to liver to produce abscess.	Usually asymptomatic; diarrhea may be mild, with few semiformed mucus-containing stools per day, or severe, with 10–20 blood-streaked liquid stools per day; abdominal cramps and flatulence; colic, tenesmus, vomiting, tenderness; fatigue, weight loss; prostration and toxicity	Metronidazole and paromomycin (Humatin) or iodoquinol (Diiodohydroxyquin, Yodoxin); metronidazole or tinidazole for hepatic abscess
Cryptosporidiosis: *Cryptosporidium*	2–10 days	Organisms attach to epithelial surface of small bowel (jejunum), causing villous atrophy and mild inflammatory changes; may secrete enterotoxin.	In immunocompetent patients: asymptomatic to profuse, watery diarrhea of sudden onset, abdominal cramping; malaise, fever; anorexia, nausea, vomiting. In immunodeficient patients: profuse watery diarrhea with loss of up to 15–20 L/day; severe malabsorption, electrolyte imbalance; weight loss; lymphadenopathy	Self-limiting in immunocompetent patients. For immunodeficient patients: spiramycin, zidovudine (AZT), paromomycin (Humatin), octreotide, eflornithine; fluid and electrolyte replacement; parenteral nutrition as needed

●○● INTERPROFESSIONAL CARE

Management of protozoal bowel infections includes identifying the causative organism and administering medications.

DIAGNOSIS

Diagnostic testing includes a stool examination for ova and parasites, and possibly for their antigens. Many protozoa are shed intermittently rather than continuously; stools are collected sequentially (e.g., every other day for a total of three specimens). These organisms often are fragile, requiring a fresh stool specimen. Serology testing for an immune response to the suspected parasite may be performed. A sigmoidoscopy may be done to examine the bowel mucosa and collect a stool specimen for examination (in this case, no bowel prep is done prior to the test). When giardiasis is suspected, duodenal aspirate may be stained and examined microscopically for the protozoa. Small-bowel biopsy can identify giardiasis or *Cryptosporidium* infection.

MEDICATIONS

Pharmacologic treatment includes both local and systemic antiparasitic drugs, such as iodoquinol (Amebaquin), paromomycin (Humatin), metronidazole (Flagyl), tinidazole (Tindamax), or nitazoxanide (Alinia). Treatment is usually provided on an outpatient basis. Severe amebic dysentery may require hospitalization for intravenous fluid and electrolyte replacements. Nursing care related to common antiprotozoal drugs is outlined in the accompanying Medication Administration box.

●○● NURSING CARE

Nursing assessment, diagnoses, and interventions for the patient with a protozoal GI infection are similar to those indicated for patients with bacterial or viral infections. *Diarrhea* and *Risk for Deficient Fluid Volume* are priority nursing diagnoses. See previous sections of this chapter for specific nursing interventions related to these diagnoses.

MEDICATION ADMINISTRATION

Antiprotozoal Agents

LOCAL (GASTROINTESTINAL) AGENTS

iodoquinol (Yodoxin, Amebaquin)

paromomycin (Humatin)

These drugs exert a local amebicidal effect in the intestines and are poorly absorbed when administered orally. Local agents have the advantage of provoking fewer side effects than systemically active agents.

Nursing Responsibilities

- Assess for potential contraindications:
  a. Hypersensitivity to the drug or drug class
  b. Iodoquinol: malnutrition, thyroid disorders; hepatic or renal impairment, optic neuropathy, or hypersensitivity to iodine
  c. Paromomycin: ulcerative bowel lesions; hypersensitivity to aminoglycoside antibiotics; impaired renal function, intestinal obstruction.
- Observe for adverse effects: anorexia, nausea, vomiting, abdominal cramping, diarrhea, and increased flatulence; report skin rash, visual disturbances, or changes in blood work to primary care provider.

Health Education for the Patient and Family

- Take as prescribed for the full course of therapy.
- Take with food to reduce gastrointestinal effects.
- Keep follow-up appointments as recommended to evaluate the effects of treatment.
- Report adverse effects to the physician:
  a. Any change in vision
  b. Numbness, tingling, or pain in extremities
  c. Chills, fever, skin rash or boils
  d. A change in urination or character of urine
  e. Diminished hearing or tinnitus
  f. Weight loss, diarrhea, fatty stools
  g. Candidiasis of the mouth or vagina.
- Practice good hand hygiene, particularly after using the toilet, to prevent spreading the disease to others.

SYSTEMIC AGENTS

metronidazole (Flagyl, Metazol, others)

furazolidone (Furoxone), albendazole (Albenza)

Patients with symptomatic protozoal infections are generally treated with a systemic antiprotozoal agent. Metronidazole is the most widely used of these antiprotozoal agents and is the drug of choice for treating amebiasis.

Nursing Responsibilities

- Assess for possible contraindications to therapy:
  a. Hypersensitivity to the prescribed agent or related drugs
  b. Liver dysfunction or blood dyscrasias
  c. Concurrent use of alcohol or an MAOI
  d. Pregnancy.
- Administer as ordered:
  a. Metronidazole may be given orally after meals or as a continuous or intermittent intravenous infusion.
  b. Administer furazolidone and albendazole orally with meals to minimize gastric distress.
- Observe for possible adverse effects; notify the physician if significant. Gastrointestinal effects are common.
  a. Peripheral neuropathy and CNS effects may occur with metronidazole.
  b. Blood dyscrasias may develop with furazolidone or albendazole; monitor CBC and report abnormal results.
  c. Furazolidone can cause hypoglycemia; carefully monitor blood glucose in patients with diabetes.
  d. Report abnormal liver function test results.
- Monitor the character and number of stools; obtain specimens as ordered to evaluate the effectiveness of therapy.

Health Education for the Patient and Family

- Take the drug as prescribed for the full duration of the prescription.
- Taking oral preparations after meals helps minimize gastrointestinal side effects. Notify the physician if nausea and vomiting continue.
- Do not use alcohol while taking these drugs. An Antabuse-type response with severe headache, flushing, and vomiting may occur.
- Report adverse effects to the physician, including dizziness and other nervous system changes, sore throats, fatigue, bruising, or infection.
- Candidiasis of the mouth or vagina may occur with metronidazole therapy. Report symptoms to the physician.
- A harmless change in urine color to deep yellow (quinacrine) or rust or brown (metronidazole or chloroquine) may occur while taking these drugs.
- If you have diabetes and are taking furazolidone, carefully monitor blood glucose levels because hypoglycemia may develop.
- Practice good hand hygiene, particularly after using the toilet, to prevent transmitting the protozoa to others.

Nurses need to teach the public how parasitic diseases are transmitted and how to avoid spreading the infection. Prevention of amebiasis and giardiasis involves the following:

- Provision of safe water supplies
- Appropriate disposal of human feces
- Safe food storage, handling, and preparation
- Adequate hand hygiene after defecating and before handling food.

Instruct people living in high-risk areas (e.g., tropical climates, areas with untreated water supplies) to boil, filter, or treat water supplies with iodine to eliminate protozoal contamination. Instruct them to avoid foods that cannot be peeled or cooked. Teach the manifestations of protozoal infections and where to obtain treatment.

Emphasize the importance of keeping toilet areas clean and maintaining good personal hygiene. Advise the patient to avoid rectal contact during sexual activity. Other household members should have stool specimens examined for parasites. Contaminated recreational water (swimming pools, water slides) is increasingly recognized as a potential source of cryptosporidiosis; advise immunocompromised individuals to avoid this exposure.

THE PATIENT WITH A HELMINTHIC DISORDER

Helminths are parasitic worms, capable of causing infectious diseases in humans. Helminths are subclassified as round worms (nematodes), flukes (trematodes), or tapeworms (cestodes).

Pathophysiology

Although all helminths can infect humans, the definitive host and intermediate hosts vary with each organism. In nearly all instances of helminthic disorders, the organism enters the body through the GI tract in contaminated and inadequately cooked foods. Some of these organisms remain in the intestinal tract; others migrate to infect the liver, lungs, or other structures. Table 24–6 summarizes the most common helminths and their effects.

●○● INTERPROFESSIONAL CARE

The management of helminthic disorders includes diagnostic testing and medications.

TABLE 24–6 Selected Helminthic Diseases

	Infection	Host	Area	Pathogenesis	Manifestations
Nematode infections	Ascariasis	Humans	Worldwide, cosmopolitan; warm, moist climates	Eggs are ingested in fecally contaminated food and drink; motile larvae migrate to lungs and back to small intestine, where they mature to produce more eggs.	Pulmonary: low-grade fever, cough, blood-tinged sputum, wheezing, dyspnea, substernal chest pain GI: ulcer-like epigastric pain, vomiting, abdominal distention
	Enterobiasis (pinworm infection)	Humans	Worldwide, cosmopolitan	Infect cecum; eggs deposit on perianal skin, organisms may be transmitted to others or reinfect host by oral ingestion.	Nocturnal perianal and perineal pruritus; insomnia, irritability, restlessness
	Hookworm disease	Humans	Tropics and subtropics	Larvae enter through skin or by ingestion and migrate to lungs, up bronchial tree, and down esophagus to mature in upper small bowel, where they attach and suck blood.	Skin: pruritic dermatitis at site of entry Pulmonary: dry cough, wheezing, blood-tinged sputum GI: anorexia, diarrhea, abdominal pain Systemic: anemia, pallor, cardiac insufficiency
	Trichinosis	Pigs, dogs, cats, rats, many wild animals	Temperate areas where pork is consumed	Larvae are ingested in undercooked meat; adult female burrows into mucosa of small intestine to produce larvae that disseminate via blood and lymphatic system to body tissues and become encysted in striated muscle.	GI: diarrhea, abdominal cramps, malaise Muscle: fever; muscle pain, tenderness, edema, and spasm Systemic: periorbital and facial edema, sweating; photophobia and conjunctivitis; manifestations of inflammation in tissues invaded by larvae
Cestode infections	Fasciolopsiasis (intestinal fluke) Tapeworm	Humans; other mammals and fish	Worldwide	Organism is ingested by eating uncooked fish or meat containing embryo cysts, by fecal contamination, or by swallowing infected intermediate hosts, such as arthropods, fleas, or lice; head (scolex) of adult worm attaches in upper small intestine, and eggs form in individual segments.	Large tapeworms: often asymptomatic; infection may cause mild nausea, diarrhea, abdominal pain; anemia, thrombocytopenia, and mild leukopenia Small tapeworms: may be asymptomatic; diarrhea, abdominal pain, anorexia, vomiting, weight loss, and irritability

DIAGNOSIS

The primary means of diagnosing helminthic disorders is examination of the stool for ova and parasites. Enterobiasis is diagnosed by the presence of the parasite's eggs on the perianal skin or on cellulose tape placed over the anus. A CBC may also be ordered. Anemia may be present, particularly with hookworm disease. *Eosinophilia* (an increased percentage of eosinophils in the blood) is common in helminthic disorders. With trichinosis, serum muscle enzymes such as creatinine kinase (CK) and aspartate aminotransferase (AST) are typically elevated. Serologic testing for antibodies to the worm may be performed. Blood, duodenal washings, and cerebrospinal fluid (CSF) may be examined for the presence of the trichinosis larvae. Inflamed muscle may be biopsied.

MEDICATIONS

Helminthic infections often are treated with a single oral dose or 3-day course of pyrantel pamoate (Antiminth), albendazole (Albenza), or mebendazole (Vermox). Doses may need to be repeated every 2 weeks for patients with heavy infections. These drugs are generally safe, requiring few precautions. Giving the drug after meals minimizes GI side effects. Treatment is followed by a stool culture at 2 weeks to evaluate effectiveness. If necessary, an additional course of the drug is prescribed. Other members of the household are generally also treated.

●○● NURSING CARE

Because many patients with these disorders are asymptomatic, nurses need to be alert for histories that indicate risk and subtle manifestations of the disorder. Use standard precautions to minimize the risk of spreading these infections to other patients. Wear gloves and gowns as necessary to prevent fecal contamination of hands and clothing. On rare occasions, parasites may be present in the sputum or vomitus, so handle these secretions with care. Disinfect toilets, toilet seats, and commodes after use. Teach the patient the importance of hand hygiene after using the toilet and before handling food to prevent reinfection.

Discuss measures to prevent spread of the disease in the household. Emphasize the importance of hygiene measures including changing bedding, daily cleaning of toilets with disinfectant, and hand hygiene.

Many helminthic disorders are acquired by consuming food that has been fecally contaminated or contains larvae of the organism. Explain the importance of not fertilizing food or grain crops with fecal material, particularly human feces. Teach patients to cook all meats and fish adequately to destroy possible larvae. In general, pickled or salt-preserved meats and fish are no safer than raw. Smoking, another means of preserving fish and meat, may not achieve temperatures high enough to destroy the organisms. Vegetables grown in soil that may be contaminated with eggs or larvae should be peeled or cooked prior to eating.

Emphasize the importance of safe water supplies. Encourage people traveling to areas in which water supplies are questionable to drink only bottled water or carry purification tablets. Work with patients who have private water systems to protect water from fecal contamination by either humans or animals.

The patient with a helminthic disorder may feel dirty or be ashamed of the disease. Emphasize the prevalence of these disorders, and assure the patient that infection can occur despite good health practices when the eggs or larva of the organism are prevalent.

Chronic Inflammatory Bowel Disorders

THE PATIENT WITH INFLAMMATORY BOWEL DISEASE

Chronic **inflammatory bowel disease (IBD)** includes two separate but closely related conditions: ulcerative colitis and Crohn's disease. These conditions have a number of similarities. The etiology of both illnesses is unknown, although current evidence implicates both genetic and environmental factors. IBD occurs more frequently in the United States and northern European nations than it does in southern Europe and countries in the Southern Hemisphere. IBD affects certain ethnic groups more than others, as outlined in the Focus on Cultural Diversity box. As many as 1.5 million Americans have IBD (Pullen & Julian, 2012); that number is divided about equally between ulcerative colitis and Crohn's disease (Crohn's & Colitis Foundation of America [CCFA], 2013). It tends to run in families, with 15% to 25% of patients having a close relative with one of the types of IBD (CCFA, 2013). Factors such as an abnormal immune response to microorganisms normally found in the gut are thought to play a role in the development of IBD. Factors such as smoking and oral contraceptive use also affect the risk for IBD.

The peak incidence of IBD is in adolescents and young adults between the ages of 15 and 30 years, but it also affects older adults (Pullen & Julian, 2012). IBD is a chronic and recurrent disease process. Responses to physiologic or psychologic stresses do not cause IBD, but often play a role in exacerbations of the disease.

Despite the similarities, ulcerative colitis and Crohn's disease have distinct differences. Ulcerative colitis primarily affects the large bowel in a continuous pattern, progressing distally to proximally. In Crohn's disease, a patchy pattern of involvement is seen, affecting primarily the small intestine. Ulcerative colitis shows mainly mucosal involvement; in Crohn's disease, the submucosal layers of the bowel are affected. A comparison of ulcerative colitis and Crohn's disease is given in Table 24–7. See the Multisystem Effects of Inflammatory Bowel Disease feature on page 656.

FOCUS ON CULTURAL DIVERSITY

Incidence and Prevalence of IBD

- American Jews of European descent are four to five times more likely to develop IBD than the general population.
- There has been a steady increase of IBD in African Americans.
- The prevalence rates of IBD for Asians and Hispanics are lower than those for Whites and African Americans.

TABLE 24–7 Characteristics of Ulcerative Colitis and Crohn's Disease

	Characteristic	Ulcerative Colitis	Crohn's Disease
Clinical	Gender	Equal	Equal
	Age at onset	15–30 years; secondary peak 60–80 years	15–30 years; secondary peak 60–80 years
	Course of disease	Typically chronic and intermittent	Slowly progressive, relapsing
	Diarrhea	5–30 stools per day with blood and mucus	Common, usually less severe than colitis, with no obvious blood or mucus in stool
	Abdominal pain	Cramping in left lower quadrant; relieved by defecation	Cramping or steady right lower quadrant or periumbilical pain; tenderness and mass noted in right lower quadrant
	Nutritional deficit	Common; involves anemia, hypoalbuminemia, and weight loss	Common and significant: involves anemia, weight loss, and multiple vitamin and mineral deficits
	Constitutional manifestations	Fever rare; may have associated arthritic, skin, or other organ involvement, such as erythema nodosum or uveitis	Fever, malaise, fatigue; may have some associated conditions plus urinary complications
Pathologic	Depth of involvement	Mucosa and submucosa	Transmural (entire bowel wall)
	Portion of bowel involved	Typically rectum and sigmoid colon; may extend to involve entire large bowel	Any portion of GI tract; terminal ileum and ascending colon involvement predominates
	Distribution	Continuous from rectum	Patchy; skip lesions
	Appearance of mucosa	Granular, dull, hyperemic, friable; disease uniform in affected bowel; pseudopolyps may be seen	Cobblestone appearance, with areas of normal tissue surrounded by ulceration and fissures
Complications	Acute	Toxic megacolon, perforation, massive hemorrhage	Obstruction, fistulization, abscess formation, malabsorption
	Long term	Colorectal cancer	Colon cancer

Ulcerative Colitis

Ulcerative colitis is a chronic inflammatory bowel disorder that affects the mucosa and submucosa of the colon and rectum. Most people with ulcerative colitis have mild or moderate disease, with six or fewer stools per day. Its onset usually is insidious, with attacks that last 1 to 3 months occurring at intervals of months to years. Typically, only the distal colon is affected, with few systemic manifestations of the disease. Approximately 15% of people with ulcerative colitis develop *fulminant colitis*, with involvement of the entire colon, severe bloody diarrhea, acute abdominal pain, and fever. Patients with fulminant disease are at high risk for complications.

PATHOPHYSIOLOGY

The inflammatory process of ulcerative colitis begins at the rectosigmoid area of the anal canal and progresses proximally. In most patients, the disease is confined to the rectum and sigmoid colon. It may progress to involve the entire colon, stopping at the ileocecal junction.

Ulcerative colitis begins with inflammation at the base of the crypts of Lieberkühn in the distal large intestine and rectum. Microscopic, pinpoint mucosal hemorrhages occur, and crypt abscesses develop (Figure 24–3 ■). These abscesses penetrate the superficial submucosa and spread laterally, leading to necrosis and sloughing of bowel mucosa. Further tissue damage is caused by inflammatory exudates and the release of inflammatory mediators, such as prostaglandins and other cytokines (see Chapter 12 for further discussion of the inflammatory process). The mucosa is red and edematous due to vascular congestion, friable (easily broken), and ulcerated. It bleeds easily, and hemorrhage is common. Edema creates a granular appearance. Pseudopolyps, tonguelike projections of bowel mucosa into the lumen, may develop as the epithelial lining of the bowel regenerates. Chronic inflammation leads to atrophy, narrowing, and shortening of the colon, with loss of its normal haustra (series of pouches producing a series of internal folds).

MANIFESTATIONS

Diarrhea is the predominant manifestation of ulcerative colitis. Stools contain both blood and mucus. Nocturnal diarrhea may occur. Mild ulcerative colitis is characterized by fewer than 4 stools per day, intermittent rectal bleeding and mucus, and few systemic manifestations. Severe ulcerative colitis can lead to more than 5 to 30 bloody stools per day, extensive colon involvement, anemia, hypovolemia, and malnutrition. Rectal inflammation causes fecal urgency and tenesmus. Left lower quadrant cramping relieved by defecation is common. Other manifestations include fatigue, anorexia, and weakness.

Patients with severe disease may also have systemic manifestations such as arthritis involving one or several joints, skin and mucous membrane lesions, or *uveitis* (inflammation of the uvea, the vascular layer of the eye, which may also involve the sclera and cornea). Some patients develop thromboemboli, with blood vessel obstruction due to clots carried from the site of their formation. The liver and biliary system may be affected by the disease, as may the kidneys, with an increased risk for gallstones, cirrhosis, kidney stones, and ureteral obstruction (Longo et al., 2013).

COMPLICATIONS

Acute complications of ulcerative colitis include hemorrhage, toxic megacolon, and colon perforation. Massive hemorrhage may occur with severe attacks of the disease. *Toxic megacolon*, a condition characterized by acute motor paralysis and dilation of the colon to greater than 6 cm (2.4 in.), may affect part or all of the colon. The transverse segment of the bowel is most often affected. Toxic megacolon may be triggered by the use of laxatives or narcotics and by electrolyte

Figure 24–3 ■ A, Photomicrograph of the mucosa of the large intestine showing the entrances to the crypts of Lieberkühn. The crypts are the focal points for B, ulcerative colitis, and C, Crohn's disease.
Source: B, Dr. E. Walker/Photo Researchers, Inc.; *C*, Javier Domingo/Photo Researchers, Inc.

imbalances (Longo et al., 2013). Manifestations of toxic megacolon include fever, tachycardia, hypotension, dehydration, abdominal tenderness and cramping, and a change in the number of stools per day. Perforation is rare, but the risk of this dangerous complication is increased with toxic megacolon. Perforation leads to peritonitis.

The risk for colorectal cancer is increased in patients with ulcerative colitis. Beginning 8 to 15 years after the diagnosis, annual or biennial colonoscopies with biopsy to detect masses or cell dysplasia are recommended for patients who have extensive ulcerative colitis (Longo et al., 2013).

Crohn's Disease

Like ulcerative colitis, Crohn's disease, also known as regional enteritis, is a chronic, relapsing inflammatory disorder affecting the gastrointestinal tract. Crohn's disease can affect any portion of the GI tract from the mouth to the anus, but usually affects the terminal ileum and ascending colon. Only the small bowel is involved in nearly 40% of patients with Crohn's disease. The disease is limited to the colon only in 30% of those affected. Both the small and large intestine are involved in the remaining 30% of patients (Grossman & Porth, 2014).

PATHOPHYSIOLOGY

Crohn's disease typically begins as a small inflammatory *aphthoid lesion* (shallow ulcers with a white base and elevated margin, similar to a canker sore) of the mucosa and submucosa of the bowel. These initial lesions may regress, or the inflammatory process can progress to involve all layers of the intestinal wall. Deeper ulcerations, granulomatous lesions, and fissures (knifelike clefts that extend deeply into the bowel wall) develop. The inflammatory process involves the entire bowel wall (transmural).

The lumen of the affected bowel assumes a cobblestone appearance as fissures and ulcers surround islands of intact mucosa over edematous submucosa. The inflammatory lesions of Crohn's disease are not continuous; rather, they often occur as skip lesions with intervening areas of normal-appearing bowel. Some evidence suggests that despite its normal appearance, the entire bowel is affected by this disorder.

As the disease progresses, fibrotic changes in the bowel wall cause thickening and loss of flexibility; the bowel wall takes on an appearance that has been likened to rubber hosing. The inflammation, edema, and fibrosis can lead to local obstruction, abscess development, and the formation of fistulas between loops of bowel or bowel and other organs (Figure 24–4 ■). Fistulas between loops of bowel are known as enteroenteric fistulas; those that occur between bowel and bladder are known as enterovesical fistulas; and fistulas that occur between bowel and skin are known as enterocutaneous fistulas. Perineal fistulas are relatively common, originating in the ileum.

Depending on the severity and extent of the disease, malabsorption and malnutrition may develop as the ulcers prevent absorption of nutrients. When the jejunum and ileum are affected, the absorption of multiple nutrients may be impaired, including carbohydrates, proteins, fats, vitamins, and folate. Disease in the terminal ileum can lead to vitamin B_{12} malabsorption and bile salt reabsorption. The ulcerations can also lead to protein loss and chronic, slow blood loss with consequent anemia.

MANIFESTATIONS

Because the GI system involvement in Crohn's disease can be so diverse, manifestations vary among patients. The majority of people with Crohn's disease experience persistent diarrhea. Stools are liquid or semiformed and typically do not contain blood, although blood may be passed if the colon is involved. Abdominal pain and tenderness are also common. The pain may be located in the right lower quadrant and relieved by defecation. A palpable right lower quadrant mass is often present. Systemic manifestations such as fever, fatigue,

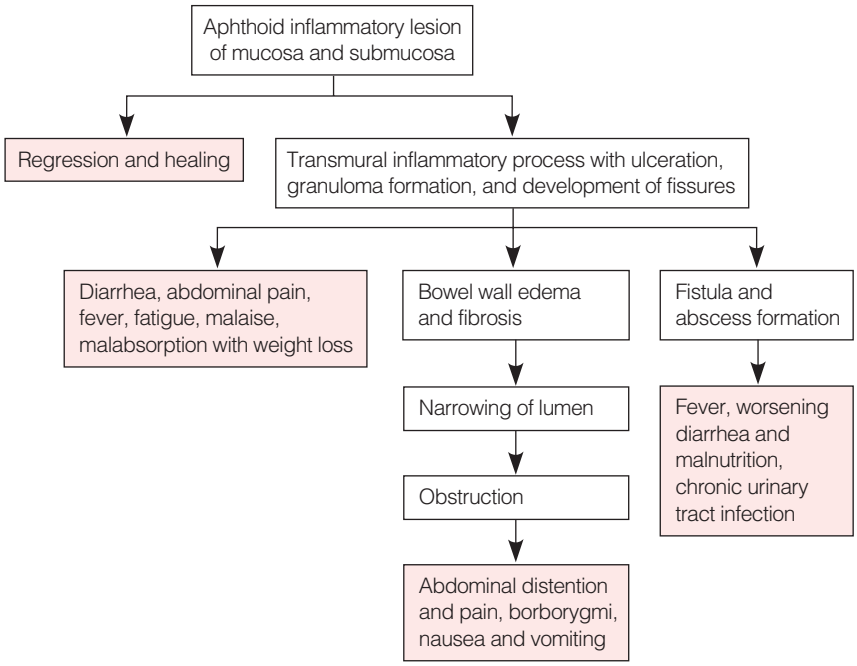

Figure 24–4 ■ The progression of Crohn's disease.

malaise, weight loss, and anemia are common. Anorectal lesions such as fissures, ulcers, fistulas, and abscesses also are common and may occur years before intestinal disease is apparent. If the stomach and duodenum are involved, nausea, vomiting, and epigastric pain may occur.

COMPLICATIONS

Certain complications of Crohn's disease (e.g., intestinal obstruction, abscess, and fistula) are so common that they are considered part of the disease process. For many patients, the disease initially presents with one of these complications. Intestinal obstruction is a common complication caused by repeated inflammation and scarring of the bowel that leads to fibrosis and stricture. Obstruction of the bowel lumen causes abdominal distention, cramping pain, and borborygmi. Nausea and vomiting may occur.

Fistulas may be asymptomatic, particularly if they occur between loops of small bowel. When fistulization causes an abscess, chills and fever, a tender abdominal mass, and leukocytosis develop. A fistula between the small bowel and colon may exacerbate diarrhea, weight loss, and malnutrition. When the bladder is involved, recurrent urinary tract infections occur.

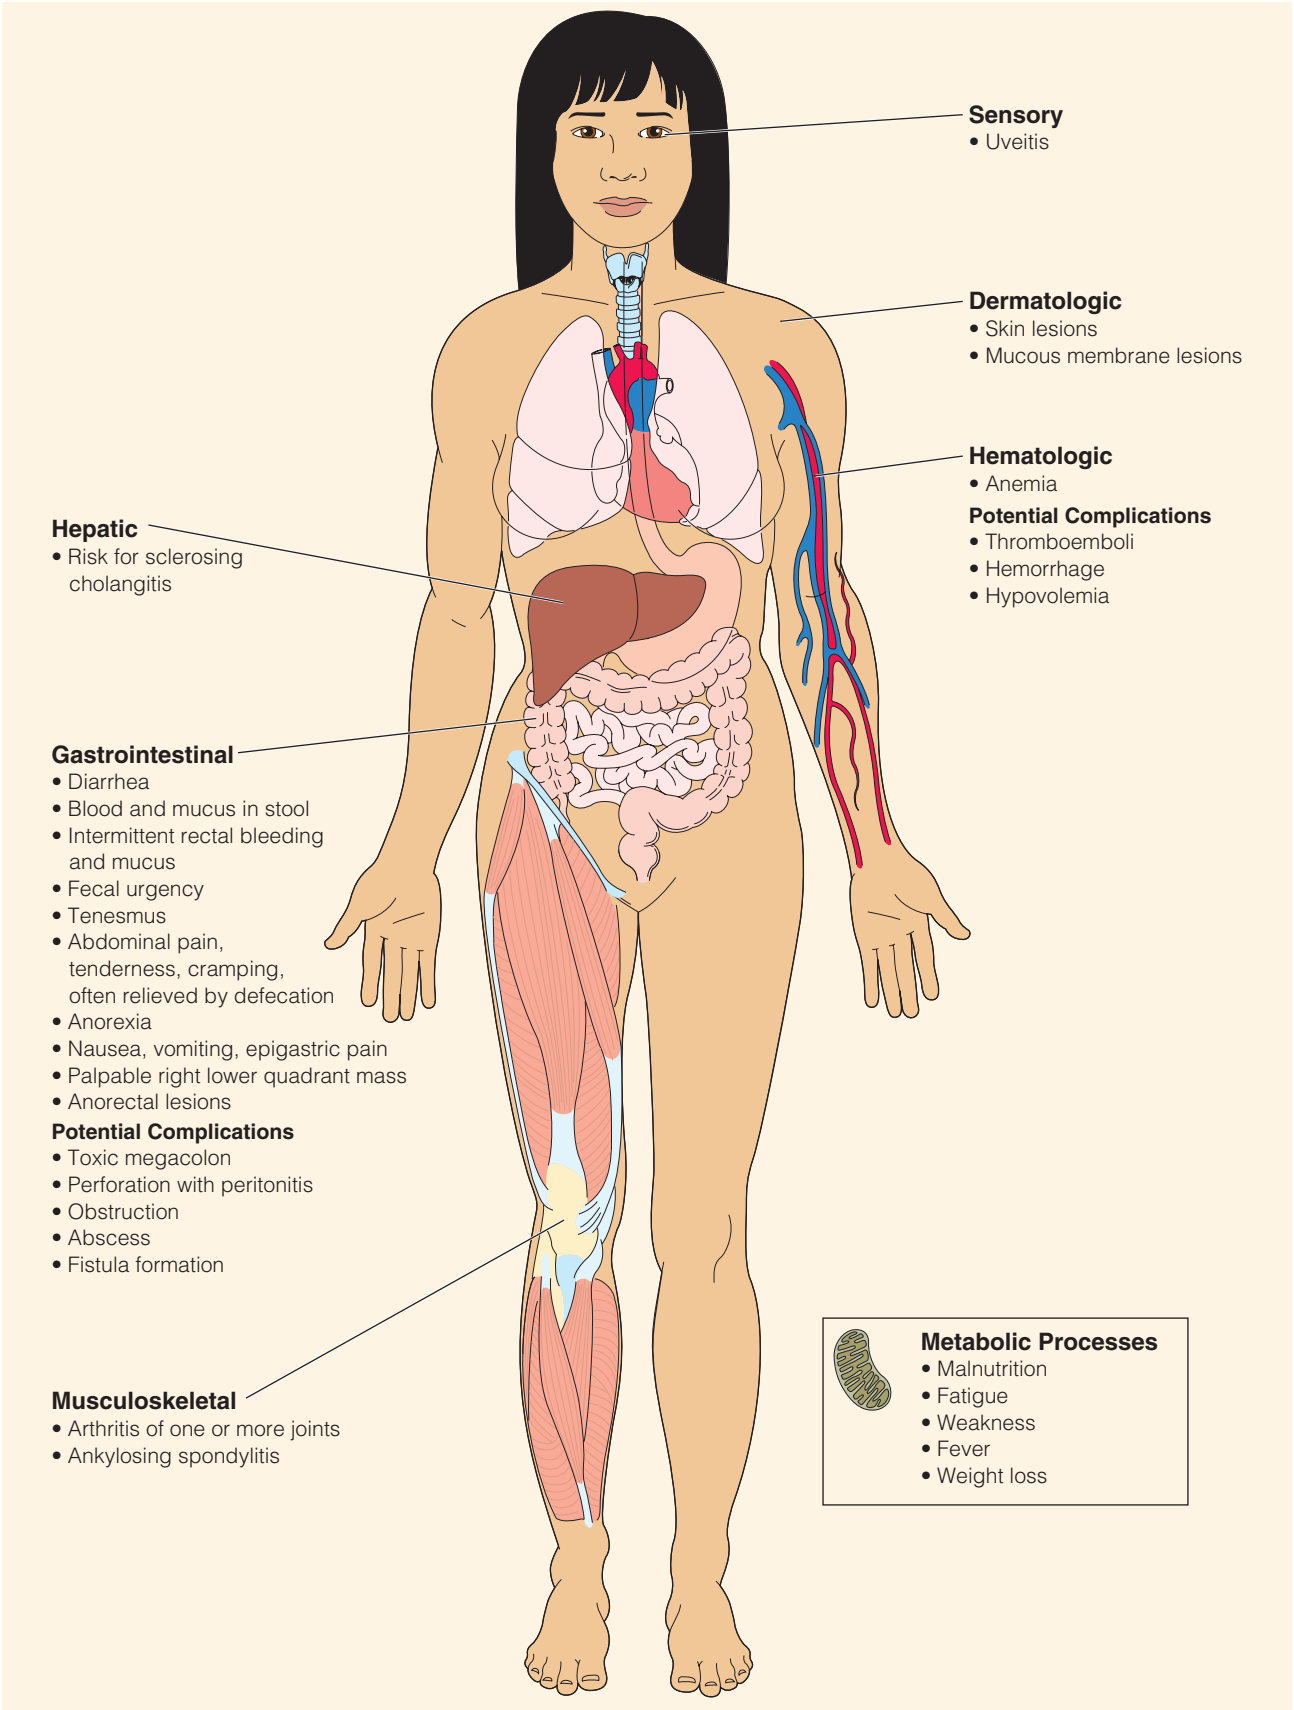
Perforation of the bowel is uncommon, but can lead to generalized peritonitis. Massive hemorrhage also is an uncommon complication of Crohn's disease. Long-standing Crohn's disease increases the risk of cancer of the small intestine or colon by five to six times. This cancer risk, however, is significantly lower than the risk associated with ulcerative colitis.

●○● INTERPROFESSIONAL CARE

Interprofessional care for inflammatory bowel disease begins by establishing the diagnosis and the extent and severity of the disease. Treatment is supportive, including medications and dietary measures to decrease inflammation, promote intestinal rest and healing, and reduce intestinal motility. Many patients with IBD require surgery at some point to manage the disease or its complications.

DIAGNOSIS

Diagnostic testing is used to establish the diagnosis of IBD, assess the extent of the disease, and evaluate the effects of the disorder. A sigmoidoscopy, colonoscopy, or a barium upper and lower x-ray series is performed to inspect the bowel mucosa for the characteristic changes of IBD. (Nursing implications for these tests are outlined in Chapter 21.)



Laboratory tests to differentiate IBD and to identify effects and complications of the disease include a stool examination for blood and mucus, and stool cultures to rule out infectious causes of bowel inflammation and diarrhea. CBC with hemoglobin and hematocrit shows anemia from chronic inflammation, blood loss, and malnutrition, and leukocytosis due to inflammation and possible abscess formation. The sedimentation rate and levels of C-reactive protein are typically elevated during periods of acute inflammation. Serum albumin may be decreased because of malabsorption, malnutrition, protein loss through intestinal lesions, and chronic inflammation. Folic acid and serum levels of most vitamins, including A, B complex, C, and the fat-soluble vitamins, often are decreased due to malabsorption. Additional tests for renal and hepatic function may be done if the patient has significant systemic manifestations of the disease.

MEDICATIONS

The ultimate goal of care is to achieve and maintain remission of the disease and its symptoms. Drug therapy plays a key role in achieving this goal. Locally acting and systemic anti-inflammatory drugs are the primary medications used to manage mild to moderate IBD. Drugs to suppress the immune response may be used to treat patients with severe disease.

Sulfasalazine (Azulfidine) is a sulfonamide antibiotic and anti-inflammatory that is poorly absorbed from the gastrointestinal tract and acts topically on the colonic mucosa to inhibit the inflammatory process. The active anti-inflammatory ingredient in sulfasalazine, 5-aminosalicylic acid (5-ASA), also is available in preparations that do not contain sulfa, such as olsalazine and mesalamine. They

MULTISYSTEM EFFECTS OF
Inflammatory Bowel Disease

have the advantage of causing fewer adverse effects than sulfasalazine. Azo compounds, such as balsalazide and olsalazine, are 5-ASA compounds that are released in the colon and are especially useful for treating ulcerative colitis. Mesalamine (Asacol, Canasa, Rowasa) is an orally or rectally administered 5-ASA compound that provides topical anti-inflammatory action in the colon of patients with ulcerative colitis. Specific preparations, their method of action, and nursing implications for these medications are outlined in the Medication Administration box on page 658.

For acute exacerbations of IBD, corticosteroids are given to reduce inflammation and induce remission. For ulcerative colitis, the drug may be administered rectally for its local effect and to minimize systemic effects. Hydrocortisone can be administered rectally. Intravenous corticosteroids may be required to treat severe disease; oral preparations are used for less severe manifestations and long-term therapy. Corticosteroids are tapered off once remission has been achieved.

Mercaptopurine (6-MP, Purinethol) and other immunosuppressive agents such as azathioprine (Imuran), methotrexate, and cyclosporine (Sandimmune) can be used to treat patients who have not responded to other treatments or who require chronic steroid therapy. These drugs may allow withdrawal from corticosteroids, maintain remission, and facilitate healing. Long-term therapy may be required to produce a beneficial effect. For more information about immunosuppressive drugs, see Chapter 13.

Newer treatments for IBD employ other immune response modifiers, such as the monoclonal antibodies infliximab (Remicade) and adalimumab (Humira), to suppress tumor necrosis factor (TNF, an inflammatory mediator substance) in patients who have not responded to standard therapies. Although antibiotic therapy generally is not indicated in IBD, metronidazole (Flagyl) has active anti-inflammatory effects. It may be prescribed to help prevent remission after ileal resection in Crohn's disease. Ciprofloxacin (Cipro) is an alternative to metronidazole.

Antidiarrheal agents, such as loperamide and diphenoxylate, may be given to slow gastrointestinal motility and reduce diarrhea. These drugs are safe for patients with mild, chronic manifestations, but they are not given during acute attacks because they may precipitate toxic dilation of the colon.

NUTRITION

Antigens in the diet may stimulate the immune response in the bowel, exacerbating IBD. As a result, dietary management for inflammatory bowel disease is individualized. Some patients benefit from eliminating all milk and milk products from the diet. Increased dietary fiber may help reduce diarrhea and relieve rectal manifestations, but is contraindicated for patients with intestinal strictures caused by repeated inflammation and scarring.

All food may be withheld to promote bowel rest during an acute exacerbation of Crohn's disease. Nutritional status is maintained using enteral nutrition or TPN. An elemental diet such as Ensure, which contains all essential nutrients in a residue-free formula, may be prescribed. Elemental diets provide essential nutrients to the small intestine to support cell growth, but are not always palatable. TPN carries a higher risk of complications than does enteral nutrition.

SURGERY

Surgical interventions for IBD differ, depending on the primary disease process and the portion of the bowel affected. Generally, surgery is performed only when necessitated by complications of the disease or failure of conservative treatment measures.

Bowel obstruction is the leading indication for surgery in Crohn's disease. Other complications that may require surgical intervention include perforation, internal or external fistula, abscess, and perianal complications. Resection of the affected portion of bowel with an end-to-end anastomosis to preserve as much bowel as possible is the usual treatment. The disease process tends to recur in other areas following removal of affected bowel segments. There is an increased risk of fistula formation following surgery. Bowel strictures may be treated with a strictureplasty. In this procedure, longitudinal incisions are made in the narrowed segment to relieve the stricture while preserving bowel.

COLECTOMY Patients with extensive chronic ulcerative colitis may require a total **colectomy** (surgical resection and removal of the colon) to treat the disease itself; for complications such as toxic megacolon, perforation, or hemorrhage; or as a prophylactic measure due to the high colon cancer risk associated with extensive ulcerative colitis.

The surgical procedure of choice for extensive ulcerative colitis is a *total colectomy with an ileal pouch-anal anastomosis (IPAA)*. In this procedure, the entire colon and rectum are removed; a pouch is formed from the terminal ileum; and the pouch is brought into the pelvis and anastomosed to the anal canal (Figure 24–5 ■). A temporary or loop ileostomy (described in the next section) is generally performed at the same time and is maintained for 2 to 3 months to allow the anal anastomosis to heal. When the healing is complete, the ileostomy is closed and the patient evacuates through the anus. Six to eight daily bowel movements through the anus may occur due to the liquid nature of the ileal contents. Advanced age, obesity, or other factors may preclude an IPAA. For these patients, a permanent ileostomy or continent ileostomy may be created.

OSTOMY An intestinal ostomy is a surgically created opening between the intestine and the abdominal wall that allows the passage of fecal material. The surface opening is called a **stoma**

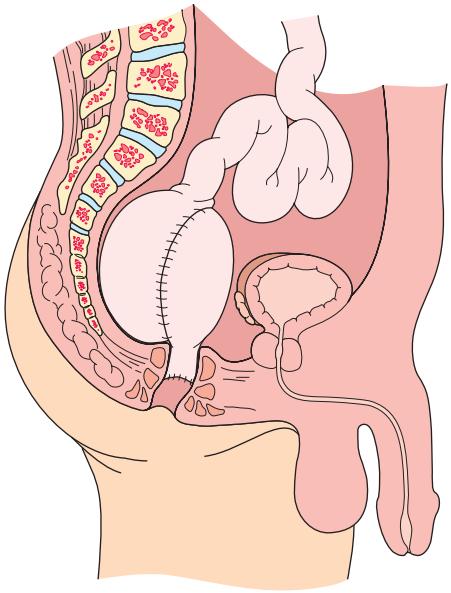


Figure 24–5 ■ Ileal pouch-anal anastomosis (IPAA).

MEDICATION ADMINISTRATION

Inflammatory Bowel Disease

SULFASALAZINE (AZULFIDINE)

Sulfasalazine is an anti-inflammatory drug used for its local effect on the intestinal mucosa in inflammatory bowel disease. The active part of the drug is 5-ASA, which inhibits prostaglandin production in the bowel. Prostaglandin is an important mediator of the inflammatory process; blocking its production reduces inflammation.

Nursing Responsibilities

- Assess for contraindications, including pregnancy or a history of hypersensitivity to sulfonamides or salicylates.
- Assess baseline values for renal function tests (serum creatinine, BUN, urinalysis), liver function tests, and CBC.
- Administer as ordered. Suppositories or retention enemas may be administered at bedtime. Administer oral forms with a full glass of water.
- Have resuscitation equipment available; anaphylactic responses may occur.
- Evaluate for therapeutic response, including reduced number of stools, reduced mucus and blood, and improved stool consistency.
- Monitor for possible adverse responses:
  a. Headache, anorexia, nausea, or vomiting
  b. Skin rash, dermatitis, urticaria, or pruritus
  c. Evidence of blood dyscrasias, such as bleeding, easy bruising, fever
  d. Leukopenia, thrombocytopenia, hemolytic anemia, or agranulocytosis
  e. Changes in urinary output or renal function studies
  f. Evidence of hepatitis or myocarditis.

Health Education for the Patient and Family

- Take oral preparations after meals to decrease gastric distress.
- Drink at least 2 quarts of fluid per day to reduce the risk of kidney damage.
- Use sunscreen to prevent burns; this drug increases sensitivity to sun.
- Do not take aspirin, vitamin C, or any other OTC medications containing aspirin or vitamin C without consulting your doctor.
- This medication may interfere with the effectiveness of oral contraceptives; use alternative methods of contraception.
- Notify your doctor if you develop headache, anorexia, nausea, vomiting, skin rash or hives, sore throat or mouth, bleeding gums, joint pain, easy bruising, or fever.

MESALAMINE (ASACOL, CANASA, ROWASA) AND OLSALAZINE (DIPENTUM)

Mesalamine and olsalazine contain the same active ingredient, 5-ASA, as sulfasalazine, but cause fewer adverse effects. Their mechanism of action is the same as that of sulfasalazine. These drugs are available as suppositories, suspension for enema, or oral tablets.

Nursing Responsibilities

- Assess for possible contraindications such as pregnancy, lactation, or hypersensitivity to these drugs or aspirin.
- Administer as ordered. If more than one dose per day is ordered, space doses evenly over the 24-hour period.
- Evaluate for desired effects (as for sulfasalazine) and potential adverse effects:
  a. Nausea, diarrhea, abdominal cramps, or flatulence
  b. CNS effects including headache, dizziness, insomnia, weakness, or fatigue
  c. Rash or itching
  d. Flulike symptoms, general malaise.

Health Education for the Patient and Family

- Teach the recommended method of administration, including how to insert rectal suppositories or administer a retention enema.
- Shake suspension forms well prior to using.
- Diarrhea is the most common side effect of these drugs. Notify your doctor if adverse effects occur.

CORTICOSTEROIDS

methylprednisolone (Medrol, Solu-Medrol)

prednisolone (Delta-Cortel)

prednisone

Glucocorticoids are hormones produced by the adrenal cortex. These hormones are necessary for the stress response. Cortisol, the main glucocorticoid, has potent anti-inflammatory effects. Corticosteroids are used to treat acute episodes of IBD. Because of their multiple and significant side effects, they are not used to maintain remission.

Nursing Responsibilities

- Assess for conditions that may be adversely affected by corticosteroid drugs: peptic ulcer disease, glaucoma or cataracts, diabetes, or psychiatric disorders.
- Obtain baseline vital signs and weight; monitor both routinely during therapy. Hypertension and weight gain may result from salt and water retention.
- Monitor for edema.
- Administer as ordered. For daily or alternate-day dosing, administer in the morning, when physiologic glucocorticoid levels are highest, to reduce adrenal cortisone suppression.
- Administer oral preparations with food to decrease gastrointestinal side effects. Antacids or histamine H_2-receptor blocking agents, such as cimetidine (Tagamet), may be prescribed during corticosteroid therapy.
- Monitor for desired effects: reduced diarrhea, less blood and mucus in the stool, and less abdominal cramping.
- Monitor for adverse effects:
  a. Increased susceptibility to infection and masking of early signs of infection
  b. Hyperglycemia
  c. Hypokalemia, as manifested by muscle weakness, nausea, vomiting, and cardiac rhythm disturbances
  d. Edema, hypertension, and signs of heart failure
  e. Peptic ulcer formation and possible gastrointestinal hemorrhage (abdominal pain, black or tarry stools, and signs of bleeding)
  f. Changes in mental status, including depression, euphoria, aggression, and behavioral changes
  g. With long-term use, cushingoid effects, such as abnormal fat deposits in the face (moon faces) and trunk (buffalo hump), muscle wasting and thin extremities, thinning of the skin, and osteoporosis.

Health Education for the Patient and Family

- Take as prescribed; do not change the dose or time of day. Do not stop the medication abruptly. The dose will be tapered down gradually when the drug is discontinued.
- Notify the physician if adverse or cushingoid effects occur.
- Take with food or at mealtimes to decrease the gastrointestinal effects.
- Monitor weight. If a gain of more than 5 pounds is noted, notify the physician.
- Moderate salt intake and avoid foods and snacks high in sodium, such as processed meats and potato chips. Increase intake of foods high in potassium, such as fruits, vegetables, and lean meats.
- Carry a card or wear a bracelet or tag at all times identifying corticosteroid use.

Note: Drugs identified in *italics* are among the 200 most commonly prescribed medications in the U.S.

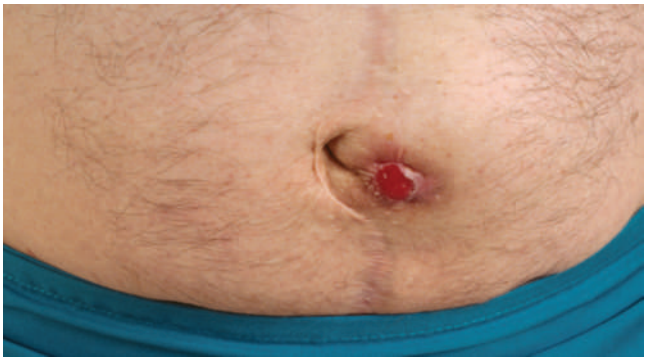

Figure 24–6 ■ A healthy-appearing stoma.
Source: CMSP/Custom Medical Stock Photo.

(Figure 24–6 ■). The preferred name of the ostomy depends on the location of the stoma. An **ileostomy** is an ostomy made in the ileum of the small intestine. In an ileostomy, the colon, rectum, and anus are usually completely removed (*total proctocolectomy with permanent ileostomy*). The anal canal is closed, and the end of the terminal ileum is brought to the body surface through the right abdominal wall to form the stoma and allow stool drainage into an external pouch. A temporary or *loop ileostomy* may be formed to eliminate feces and allow tissue healing for 2 to 3 months following an IPAA. When the ileostomy is no longer necessary, a second surgery is performed to close the stoma and repair the bowel, restoring fecal elimination through the anus.

In a *continent ileostomy* an intra-abdominal reservoir is constructed and a nipple valve formed (the ileum folded back on itself) from the terminal ileum before it is brought to the surface of the abdominal wall. Stool collects in the internal pouch; the nipple valve prevents it from leaking through the stoma. A catheter is inserted into the pouch to drain the stool.

Nursing care of the patient with an ileostomy is outlined in the following box.

COMPLEMENTARY AND ALTERNATIVE THERAPIES

The chronic nature of IBD and adverse effects of many prescribed treatments lead up to 50% of patients with IBD to seek or use complementary and alternative therapies. Peppermint tea is an excellent tonic for reducing nausea, relieving abdominal pain, and providing a calming effect. Many complementary and alternative therapies for IBD may interact with prescribed medications; instruct the patient to discuss all potential therapies with the primary care provider. Acupressure, body massage, reflexology, aromatherapy, and stress reduction therapies can also aid in reducing manifestations of IBD.

●○● NURSING CARE

Health Promotion

Although IBD cannot be predicted or prevented, effective management may help the patient avoid complications of the disease. Stress the importance of complying with the prescribed treatment regimen and promptly reporting manifestations of exacerbations to the physician.

Assessment

Assessment data related to IBD includes the following subjective and objective data:

- *Health history:* current manifestations, including onset, duration, severity (number of stools per day, presence of blood or mucus in stool, abdominal pain or cramping, tenesmus); usual diet, ability to maintain weight and nutrition, food intolerances; associated manifestations such as arthralgias, fatigue, malaise; current medications; previous treatment and diagnostic tests
- *Physical assessment:* general appearance; weight; vital signs including orthostatic vitals and temperature; abdominal assessment including shape, contour, bowel sounds, palpation for tenderness and masses, presence of stoma or scars.

Priorities of Care

Teaching is a major aspect of care. Diarrhea and disturbed body image are significant nursing care problems for the patient with IBD. With severe disease, impaired nutrition must be considered a priority problem as well. See the accompanying Case Study & Nursing Care Plan for a patient with ulcerative colitis.

Diagnoses, Outcomes, and Interventions

When planning nursing care for the patient with IBD, it is vital to consider the chronic, recurrent nature of the disorder. Living with a chronic disease such as IBD requires nursing care to help the patient adapt and effectively cope with symptoms of the disease such as pain, fatigue, diarrhea, anxiety, and depression.

Diarrhea

During an acute exacerbation of IBD, diarrhea can be frequent and painful. The frequency of defecation and associated abdominal pain and cramping may interfere with ADLs and increase the risk for fluid volume deficit and impaired skin integrity.

Expected Outcome: Patient's diarrhea will be controlled as demonstrated by stable fluid and electrolyte balance, successful self-care of ostomy, and reduction in symptom severity.

- Record the frequency, amount, and color of stools using a stool chart. Measure and record liquid stool as output. *The severity of diarrhea is an indicator of the severity of the disease and helps determine the need for fluid replacement.*
- Observe stools for obvious blood and test for occult blood as indicated. Report grossly bloody stools (**hematochezia**), which may indicate hemorrhage and necessitate emergency surgery.
- Monitor vital signs every 4 hours. *Tachycardia, tachypnea, and fever may be indicators of fluid volume deficit.*

Evidence for Nursing Care

The Patient with Inflammatory Bowel Disease

Selected resources that nurses may find helpful when planning evidence-based nursing care follow.

- Bettany, J., & Gardiner, A. (2013). Inflammatory bowel disease: An overview on assessment. *Nursing and Residential Care, 15*(9), 607–610.
- Brotherton, C. S., & Taylor, A. G. (2013). Dietary fiber information for individuals with Crohn's disease. *Gastroenterology Nursing, 36*(5), 320–327.
- Dudley-Brown, S., & Baker, K. (2012). Ulcerative colitis from patients' viewpoint. *Gastroenterology Nursing, 35*(1), 54–63.

NURSING CARE OF THE PATIENT

Having an Ileostomy

PREOPERATIVE CARE

- Provide routine preoperative care and teaching, as outlined in Chapter 4.
- Refer to an enterostomal therapist for marking and teaching about the stoma location, ostomy care, and options for ostomy appliances. *It is important to begin teaching prior to surgery to facilitate learning and acceptance of the ostomy postoperatively.*
- Discuss the availability of a local United Ostomy Association chapter, and provide a referral as necessary or desired. *Local chapters often have members with ostomies who are willing to provide both preoperative and postoperative teaching, listening, and support.*
- Provide preoperative bowel preparation as ordered. *Cathartics, enemas, and preoperative antibiotics are often ordered to reduce the risk of abdominal contamination and infection after surgery.*

POSTOPERATIVE CARE

- Provide routine postoperative care and teaching, as outlined in Chapter 4.
- Apply an ostomy pouch over the stoma. *Stool from an ileostomy is expressed continuously or irregularly, and it is liquid in nature; continuous use of a pouch to collect the drainage is necessary.*
- Assess frequently for bleeding, stoma viability, and function. In the early postoperative period, small amounts of blood in the pouch are expected. A healthy stoma appears pink or red and moist as a result of mucous production (refer to Figure 24–6). It should protrude approximately 2 cm from the abdominal wall. *Frequent assessment is particularly important in the initial postoperative period to ensure stoma health and monitor for possible complications. A dusky, brown, black, or white stoma indicates circulatory compromise. Other possible stoma complications include retraction (indentation or loss of the external portion of the stoma) or prolapse (outward telescoping of the stoma, that is, an abnormally long stoma).*
- As the stoma starts to function, empty the pouch, explaining the procedure to the patient. Initial drainage is dark green, viscid, and usually odorless. Drainage gradually thickens and becomes yellow-brown. Empty the pouch when it is one-third full. Measure drainage, and include it as output on intake and output records. Rinse the pouch and reapply the clamp. *Emptying the pouch when it is no more than one-third full helps prevent the skin seal from breaking as a result of the weight of the pouch. Because of the potential for excess fluid loss through ileostomy drainage, it is important to include it as fluid output.*
- Assess the peristomal skin. Skin around the stoma should remain clean and pink and free of irritation, rashes, inflammation, or excoriation. *Skin complications may arise from appliance irritation or hypersensitivity, excoriation from a leaking appliance, or* Candida albicans, *a yeast infection.*
- Protect peristomal skin from enzymes and bile salts in the ileostomy effluent. Using a skin barrier on the pouch is essential. Change the pouch if leakage occurs or if the patient complains of burning or itching skin. *Enzymes and bile salts normally reabsorbed in the large intestine are irritating to the skin. Excoriation of skin surrounding the stoma impairs the first line of defense against microorganisms and can interfere with the ability to achieve a tight skin seal and prevent pouch leakage.*
- Report the following abnormal assessment findings to the physician:
  a. Allergic or contact dermatitis. *A rash may result from contact with fecal drainage or indicate sensitivity to pouch, paste, tape, or sealant.*
  b. Purulent ulcerated areas surrounding the stoma. *Disruption of the protective barrier of the skin allows bacterial entry.*
  c. A red, bumpy, itchy rash or white-coated area. *This is a manifestation of* Candida albicans, *a yeast infection.*
  d. Bulging around the stoma. *This finding may indicate herniation, caused by loops of intestine protruding through the abdominal wall.*
- Apply protective ointments to the perirectal area of patients with newly functioning ileoanal reservoirs and anastomoses. *This helps protect the skin from the initial stools. As stools thicken and become fewer per day, the patient experiences less perirectal irritation.*

Health Education for the Patient and Family

- While caring for the ostomy, explain procedures to the patient. *Teaching is immediate and ongoing to facilitate acceptance of the ostomy and self-care.*
- Teach to manage the pouch clamp, and to empty, rinse, and perform pouch changes. *Self-care is vital to independence and self-esteem.*
- Instruct how to use an electric razor to shave the peristomal hair if necessary. *An electric razor prevents accidental cutting of the stoma with a razor blade.*
- Teach to check the stoma and peristomal skin with each pouch change. *Ongoing assessment is important for optimal health and function of the stoma and surrounding skin. Stripping of tape or excessively frequent pouch removal may cause mechanical trauma to peristomal skin. Chronic skin irritation by ileostomy effluent may lead to pseudoverrucous lesions, or wartlike nodules.*
- Instruct to report abnormal appearance of the stoma or surrounding skin to the physician:
  a. Narrowing of the stoma lumen. *This indicates stenosis and may interfere with fecal elimination.*
  b. Lacerations or cuts in the stoma. *The stoma contains no nerves, so trauma may occur without pain.*
  c. Separation of the stoma from the abdominal surface. *This potential complication may require surgical repair.*
- Emphasize the importance of adequate fluid and salt intake; the risk for dehydration and hyponatremia is increased particularly during hot weather, when fluid is lost through perspiration as well as ileostomy drainage. Water intake should be sufficient to maintain pale urine and an output of at least 1 quart per day. When exercising in hot weather, the patient should consume extra water and salt. High-potassium foods, such as bananas and oranges, may be recommended. *Loss of the reabsorptive surface of the large bowel increases the amount of water and sodium loss in the stool. If the ileostomy is high (more proximal in the ileum), additional potassium losses may also occur.*
- Discuss dietary concerns. A low-residue diet is recommended initially (see Table 24–8). Foods that may cause excessive odor or gas are typically avoided as well. *Because food blockage is a potential problem, high-fiber foods are limited, and foods that may cause blockage, such as popcorn, corn, nuts, cucumbers, celery, fresh tomatoes, figs, strawberries, blackberries, and caraway seeds, are avoided. Symptoms of food blockage include abdominal cramping, swelling of the stoma, and absence of ileostomy output for over 4 to 6 hours.*
- Teach self-care measures to relieve food blockage:
  a. Take a warm shower or tub bath. *This can help relax the abdominal muscles.*
  b. Assume a knee–chest position. *The knee–chest position reduces intra-abdominal pressure.*
  c. Drink warm fluids or grape juice if not vomiting. *This provides a mild cathartic effect.*

NURSING CARE OF THE PATIENT (*continued*)

d. Massage peristomal area. *Massage may stimulate peristalsis and fecal elimination.*
e. Remove pouch if the stoma is swollen, and apply a pouch with a larger opening. *If the stoma swells, the pouch may create a mechanical obstruction to output.*

- Notify the physician or enterostomal therapy nurse if:
  a. The measures listed above fail to relieve the obstruction.
  b. Signs of a partial obstruction persist, including high-volume odorous fluid output, abdominal cramps, nausea, and vomiting.
  c. There is no ileostomy output for 4 to 6 hours.
  d. Signs of fluid and electrolyte imbalance occur, such as weakness, dizziness, light-headedness, or headache.

Should self-care measures not succeed in breaking up a blockage, ileostomy lavage may be required.

- Weigh daily and record. *Rapid weight loss (over days to a week) usually indicates fluid loss, whereas weight loss over weeks to months may indicate malnutrition.*
- Assess for other indications of fluid deficit: warm, dry skin, poor skin turgor, dry shiny mucous membranes, weakness, lethargy, complaints of thirst. *The extent of fluid loss may not be readily evident with diarrhea, particularly if the patient uses the bathroom without assistance. Systemic manifestations of fluid volume deficit may be the first indicators of the problem.*
- Maintain bowel rest by keeping NPO or limiting oral intake to elemental feedings as indicated. *Bowel rest during an acute exacerbation of IBD promotes healing and reduces diarrhea and other manifestations.*
- Administer prescribed anti-inflammatory and antidiarrheal medications as indicated. *Anti-inflammatory medications reduce the extent of bowel inflammation and diarrhea. Unless contraindicated, antidiarrheal medications help reduce fluid loss and increase comfort.*

SAFETY ALERT

When giving antidiarrheal medications to a patient with ulcerative colitis, closely observe for manifestations of toxic megacolon: fever, tachycardia, hypotension, dehydration, abdominal pain and cramping, and an abrupt relief of diarrhea.

- Maintain fluid intake by mouth or intravenously as indicated. *The patient with IBD requires fluid to replace ongoing losses, as well as fluid to meet the usual daily needs of the body. If an elemental diet or TPN is prescribed, additional fluids may be required to meet fluid intake needs.*
- Provide good skin care. *Fluid deficit and tissue dehydration increase the risk for skin excoriations or breakdown.*
- Assess perianal area for irritation or denuded skin from the diarrhea. Use gentle cleansing agents, such as a peri-wash or Tucks, diaper wipes, or cotton balls saturated with witch hazel. Apply a protective cream, such as zinc oxide–based preparations, to protect skin from the irritating effects of diarrheal stool. *Digestive enzymes in the stool are very corrosive, increasing the risk of skin breakdown where exposed to diarrheal stool.*

Disturbed Body Image

The patient with IBD may experience frustration at not being able to control, or even predict, fecal elimination, particularly when the disease is severe. Diarrhea can interfere with the ability to complete tasks, maintain employment or engage in social activities, and even meet basic needs such as eating, sleeping, and sexual activity. Body image can suffer as a result. Treatment of IBD, be it total colectomy with IPAA, ileostomy, or chronic corticosteroid therapy, can affect the view of self.

TABLE 24–8 Low-Residue Diet

Food Group	Allowed	Avoid
Beverages	Coffee, teas, juices, carbonated beverages; milk limited to 2 cups per day	Alcohol, prune juice
Breads and cereals	Products made from refined flours (white bread, crackers) or finely milled grains (e.g., corn flakes, crisp rice cereal, puffed wheat)	Whole-grain breads, rolls, or cereal; breads or rolls with seeds, nuts, or bran
Desserts	Gelatins, tapioca, plain custards, or puddings; angel food or sponge cake; ice cream or frozen desserts without fruit or nuts	Any desserts containing dried fruits, nuts, seeds, or coconut; rich pastries, pies
Fruits	Fruit juices and strained fruits; cooked or canned apples, apricots, cherries, peaches, pears; bananas	All other raw or cooked fruits
Meats and other protein sources	Roasted, baked, or broiled tender or ground beef, veal, pork, lamb, poultry, or fish; smooth peanut butter; cottage, cream, American, or mild cheddar cheeses in small amounts	Tough or spiced meats and those prepared by frying; highly flavored cheeses; nuts
Potatoes, rice, and pasta	Peeled potatoes; white rice; most pasta products	Potato skins, potato chips, or fried potatoes; brown rice; whole-grain pasta products
Sweets	Sugar, honey, jelly, hard candy and gumdrops, plain chocolates	Jam, marmalade; candy made with seeds, nuts, coconut
Vegetables	Vegetable juices and strained vegetables; cooked or canned vegetables	Raw or whole cooked vegetables
Other	Salt, ground seasonings; cream sauce and plain gravy	Chili sauce, horseradish; popcorn, seeds of any kind; whole spices, olives, vinegar

CASE STUDY & NURSING CARE PLAN A Patient with Ulcerative Colitis

Cortez Lewis is a 42-year-old real estate agent and mother of three school-age children. She has had ulcerative colitis for 18 years and has been treated with prednisone and sulfasalazine. During the past 4 months she has been having abdominal pain and cramping and frequent bloody, diarrheal stools. During the same period, she has lost 9 kg (20 lb) and has had difficulty maintaining her career. She recently developed several lesions of the lower leg identified as erythema nodosum. A recent colonoscopy revealed extensive involvement of the entire colon. On admission, Mrs. Lewis states, "I'm tired of fighting this disease. I am a prisoner in my home because of the diarrhea." She is admitted for a total proctocolectomy and ileal pouch-anal anastomosis.

ASSESSMENT

Janet Wheeler, RN, completes the admission assessment. Mrs. Lewis now weighs 52.2 kg (115 lb). She complains of abdominal cramping, pain, and frequent bloody, diarrheal stools. Several reddened lesions are noted on her lower legs. Physical assessment findings include T 36.6°C (98°F), P 72 bpm, R 20/min, and BP 104/72 mmHg. Skin cool and pale. Abnormal laboratory findings include hemoglobin 7.3 g/dL (normal 11.7 to 15.7 g/dL); hematocrit 23.3% (normal 35% to 47%); WBC 15,580/mm^3 (normal 3500 to 11,000/mm^3); platelet count 995,000/mm^3 (normal 150,000 to 450,000/mm^3); serum protein 4.6 g/dL (normal 6 to 8 g/dL); serum albumin 2.4 g/dL (normal 3.5 to 5 g/dL). Preparation for surgery is begun.

DIAGNOSES

- *Imbalanced Nutrition: Less Than Body Requirements* related to impaired absorption
- *Diarrhea* related to inflammation of bowel
- *Risk for Deficient Fluid Volume* related to abnormal fluid loss
- *Risk for Ineffective Tissue Perfusion* related to low hemoglobin
- *Risk for Impaired Tissue Integrity* related to drainage from temporary ileostomy
- *Acute Pain* related to surgical intervention
- *Risk for Sexual Dysfunction* related to temporary ileostomy

EXPECTED OUTCOMES

- Patient will resume prescribed diet within 5 days after surgery.
- Patient will demonstrate normal fecal elimination through the temporary ileostomy.
- Patient will maintain adequate tissue perfusion
- Patient will maintain adequate fluid balance.
- Patient will demonstrate appropriate ostomy care prior to discharge.
- Patient will report a tolerable level of discomfort.
- Patient will verbalize feelings about sexuality and acknowledge importance of discussing sexual issues with husband.

PLANNING AND IMPLEMENTATION

- Discuss dietary modifications related to nutritional status and presence of ileostomy. Provide referral to dietitian for diet planning and teaching.
- Teach importance of maintaining a high fluid intake and manifestations of dehydration.
- Teach activity conservation and importance of maintaining balance of rest with progressive activity.
- Teach to empty and change ostomy pouch of choice.
- Teach stoma and peristomal skin assessment with each pouch change.
- Teach food blockage management.
- Refer to local United Ostomy Association.
- Provide list of local medical suppliers for ostomy appliances.

EVALUATION

On discharge, Mrs. Lewis is caring for her ileostomy by demonstrating her ability to empty, rinse, and change the pouch. The enterostomal therapy (ET) nurse has provided written and verbal instructions on ileostomy care. Mrs. Lewis verbalizes her understanding of the recommended diet and the need to limit high-fiber food intake and avoid enteric-coated and timed-release medications. The ET nurse has discussed sexual aspects of having an ileostomy and has given Mrs. Lewis a booklet, "Sex and the Female Ostomate," available through the United Ostomy Association. Mrs. Lewis is looking forward to the planned surgery to close the temporary ileostomy.

Clinical Reasoning in Patient Care

1. Why is the patient with an ileostomy at risk for dehydration? How can Mrs. Lewis monitor her fluid status at home?
2. Why were Mrs. Lewis's hemoglobin and hematocrit values low on admission? If her hemoglobin had been low but her hematocrit normal on admission, what might be the explanation?
3. Outline a teaching plan that could be given to patients for home care of an ileostomy.
4. Develop a care plan for Mrs. Lewis for the nursing diagnosis *Risk for Impaired Skin Integrity.*

See Evaluating Your Response in Appendix B.

Expected Outcome: Patient will consistently demonstrate satisfaction with body appearance and function, and willingly manage required self-care activities.

- Accept feelings and perception of self. *Negating or denying the reality of the patient's perception impairs trust.*
- Encourage discussion of physical changes and their consequences as they relate to self-concept. *This demonstrates acceptance and provides an opportunity to express the impact of the disease and its treatment on the patient's life.*
- Encourage discussion about concerns regarding the effect of the disease or treatment on close personal relationships. *This demonstrates understanding and provides an opportunity for the patient to express feelings about the impact of the disease on relationships and significant others.*
- Encourage the patient to make choices and decisions regarding care. *This increases the patient's sense of control over the disease and his or her future.*
- Discuss possible treatment options and their effects openly and honestly. *Open discussion allows more informed decisions.*
- Involve the patient in care, teaching and demonstrating as needed. *This encourages and facilitates independence and decision making.*
- Provide care in an accepting, nonjudgmental manner. *Acceptance of the patient despite potential embarrassment about odors or diarrhea enhances self-esteem.*
- Arrange for interaction with other patients or groups of people with IBD or ostomies. *The patient may feel that only someone who has experienced a similar problem can understand his or her feelings.*
- Teach coping strategies (odor control, dietary modifications, and so on), and support their use. *This facilitates healthy adaptation to the disease.*

Imbalanced Nutrition: Less Than Body Requirements

Crohn's disease can significantly alter the bowel's ability to absorb nutrients. In both forms of IBD, blood and protein-rich fluid may

be lost in diarrheal stools. With malabsorption and continuing nutrient losses, multiple nutrient deficits can develop, affecting growth and development, healing, muscle mass, bone density, and electrolyte balances.

Expected Outcome: Patient will maintain adequate oral intake, report adequate energy levels, and maintain body mass and weight and normal lab values (hemoglobin and hematocrit, albumin, and electrolytes).

- Monitor laboratory results, including hemoglobin and hematocrit, serum electrolytes, and total serum protein and albumin levels. *These studies provide an indicator of nutritional status.*
- Provide the prescribed diet: high-kilocalorie, high-protein, low-fat diet with restricted milk and milk products if lactose intolerance is present. *Calories and protein are important to replace lost nutrients. Fat restriction helps reduce diarrhea and nutrient loss, particularly when significant portions of the terminal ileum have been resected.*
- Provide parenteral nutrition as necessary if the patient is unable to absorb enteral nutrients. *Parenteral nutrition can help reverse nutritional deficits and promote weight gain and healing in the patient with acute manifestations.*
- Arrange for dietary consultation. Consider food preferences as allowed. *Providing preferred foods in the prescribed diet increases intake and supports nutritional status.*
- Provide or administer elemental enteral nutrition and supplements as ordered. *Elemental enteral nutritional supplements support healing while providing for bowel rest. They can replace losses and improve nutritional status more rapidly than diet alone.*
- Include family members, the primary food preparer in particular, in teaching and dietary discussions. *Families can reinforce teaching and help the patient maintain required restrictions or kilocalorie intake.*

Continuity of Care

IBD is a chronic condition for which the patient provides daily self-management. For this reason, teaching is a vital component of care. Teach the patient and family about the following topics:

- The type of IBD affecting the patient, including the disease process, short- and long-term effects, the relationship of stress to disease exacerbations, and the manifestations of complications
- Prescribed medications, including drug names, desired effects, schedules for tapering the doses if ordered (as with corticosteroids), and possible side effects or adverse reactions and their management
- The recommended diet and the rationale for any specific restrictions
- Use of nutritional supplements such as Ensure to maintain weight and nutritional status
- Indicators of malabsorption and impaired nutrition; recommendations for self-care and when to seek medical intervention
- If discharged with a central catheter and home parenteral nutrition, written and verbal instructions on catheter care, troubleshooting, and parenteral nutrition administration (Have the patient and a family member demonstrate catheter care and parenteral nutrition maintenance.)
- The importance of maintaining a fluid intake of at least 2 to 3 quarts per day, increasing fluid intake during warm weather, exercise, or strenuous work, and when fever is present
- The increased risk for colorectal cancer and importance of regular bowel exams
- Risks and benefits of various treatment options
- Importance of informing interprofessional care team of complementary and alternative therapy use.

If surgery is planned or has been done, include the following topics in home care instructions:

- Ileal pouch-anal anastomosis or ileostomy care as indicated
- Where to obtain ostomy supplies
- Use of nonprescription drugs, such as enteric-coated and timed-release capsules, that may not be adequately absorbed before elimination through the ileostomy
- Community and national ostomy support groups.

Provide referrals to a dietary consultant or nutritionist, a community healthcare agency, home care services, and home intravenous care services as indicated. In addition, suggest the following resources:

- Crohn's and Colitis Foundation of America, Inc.
- The Israel Foundation for Crohn's Disease and Ulcerative Colitis
- United Ostomy Association, Inc.

THE PATIENT WITH DIVERTICULAR DISEASE

Diverticula are small (0.5- to 1.0-cm) outpouchings of the colon that occur in rows (Figure 24–7 ■). Diverticula may occur anywhere in the intestinal tract, excluding the rectum. The vast majority affect the large intestine, with 85% to 95% occurring in the sigmoid colon (Longo et al., 2013; Papadakis & McPhee, 2013).

FAST FACTS

Diverticular Disease

- People in the United States, Australia, the United Kingdom, and France have high and increasing incidence rates of diverticular disease.
- The incidence of diverticula increases with age, with 5% to 10% of the population older than 45 years of age and almost 80% of those older than 85 years of age experiencing it.
- Most of the people diagnosed with diverticular disease remain asymptomatic.
- Men and women are equally affected.

Cultural factors, particularly diet, are thought to play an important role in the development of diverticula. A diet consisting of highly refined and fiber-deficient foods is believed to be the major factor contributing to the disease. Decreased activity levels and delaying defecation have been suggested as contributing factors. The increasing incidence of diverticula with aging suggests that dietary factors (lack of fiber), a decrease in physical activity, poor bowel habits (neglecting the urge to defecate), and the effects of aging contribute to development of the disease (Grossman & Porth, 2014).

Pathophysiology

Diverticula form when increased pressure within the bowel lumen causes bowel mucosa to herniate through defects in the colon wall. The circular and longitudinal muscles often thicken or hypertrophy in the area affected by diverticula. This narrows the bowel lumen,

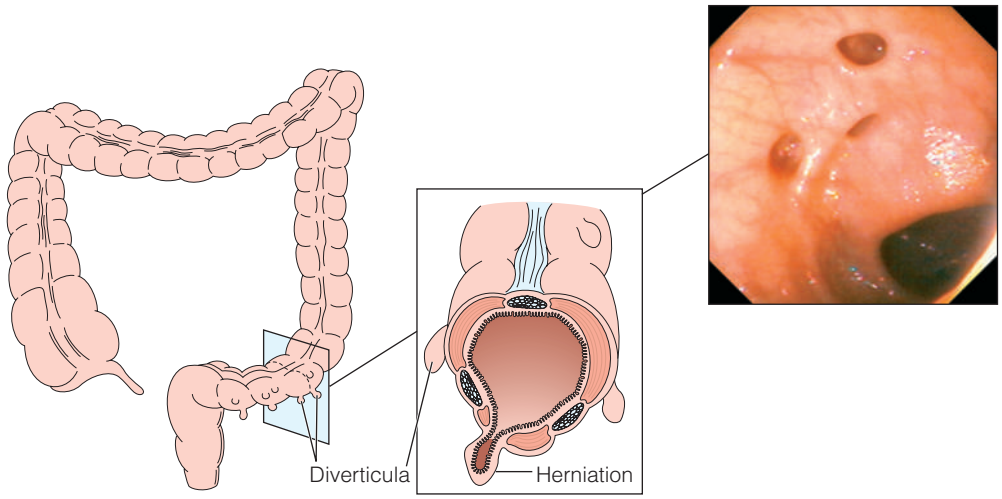

Figure 24–7 ■ Diverticula of the colon.

increasing intraluminal pressure. Deficient dietary fiber and a lack of fecal bulk contribute to muscle hypertrophy and narrowing of the bowel. Contraction of the muscles in response to normal stimuli such as meals may occlude the narrowed lumen, further increasing intraluminal pressure. The high pressure causes mucosa to herniate through the muscle wall, forming a diverticulum. Areas where nutrient blood vessels penetrate the circular muscle layer are the most common sites for diverticula formation.

DIVERTICULOSIS

Diverticulosis indicates the presence of diverticula. More than two-thirds of patients with diverticulosis are asymptomatic. When manifestations such as episodic pain (usually left-sided), constipation, and diarrhea occur, they often can be attributed to irritable bowel syndrome (IBS), which commonly accompanies diverticular disease. As the disease progresses, abdominal cramping, narrow stools (decrease in caliber), increased constipation, bleeding in the stools, weakness, and fatigue may develop.

Complications of diverticulosis include hemorrhage and diverticulitis. A diverticulum may bleed, whether it is inflamed or not, possibly due to erosion of an adjacent blood vessel by a fecalith (hard mass) in the diverticulum.

DIVERTICULITIS

Diverticulitis is inflammation in and around the diverticular sac. It typically affects only one diverticulum, usually in the sigmoid colon. Undigested food and bacteria collect in the diverticula, forming a hard mass that impairs the mucosal blood supply, allowing bacterial invasion. Mucosal ischemia leads to perforation. With microscopic perforation, inflammation is localized. Gross perforation of a diverticulum results in more extensive bacterial contamination and can lead to abscess formation or peritonitis.

MANIFESTATIONS Pain is a common manifestation of diverticulitis. It is usually left-sided and may be mild to severe and either steady or cramping. The patient may also experience either constipation or increased frequency of defecation. Depending on the location and severity of the inflammation, nausea, vomiting, and a low-grade fever may occur. On examination, the abdomen may be distended, with tenderness and a palpable mass in the left lower quadrant resulting from the inflammatory response.

The older adult may have less specific manifestations, complaining of vague abdominal pain. A palpable mass and signs of a large bowel obstruction may be present.

COMPLICATIONS Complications associated with diverticulitis (in addition to peritonitis and abscess formation) include bowel obstruction, fistula formation, and hemorrhage. Severe or repeated episodes of diverticulitis may lead to scarring and fibrosis of the bowel wall, further narrowing the bowel lumen. This increases the risk for obstruction of the large bowel. Acutely inflamed tissue may adhere to the small bowel, increasing the potential for small-bowel obstruction as well. Fistulas may form, usually between the sigmoid colon and the bladder. Urinary tract infection is the usual sign of a colovesical fistula. Fistulas may also perforate into the small intestine, ureter, vagina, perineum, or abdominal wall. Bleeding from perforation of a vessel wall can occur with diverticulitis. Although it may be significant, bleeding usually stops spontaneously.

●○● INTERPROFESSIONAL CARE

Management of diverticular disease varies from no prescribed treatment to surgical resection of affected colon, depending on the severity of the disease and its complications.

DIAGNOSIS

Diagnostic testing is used to identify diverticular disease when the disease is symptomatic or complications develop. In addition to illustrating diverticula, a barium enema and x-rays can reveal segmental spasm and muscular thickening with a narrowed bowel lumen. Flexible sigmoidoscopy or colonoscopy may be done to detect diverticulosis, assess for strictures or bleeding, and rule out tumor as the cause of the patient's manifestations. Abdominal x-ray films may show free abdominal air associated with diverticulitis and perforation. CT scan may be done with or without contrast media to assess inflammation and detect an abscess or fistula.

Laboratory tests include Hemoccult or guaiac testing of stool to identify the presence of occult blood, and a WBC count, which may show leukocytosis with a left shift (an increased number of immature WBCs) due to inflammation in diverticulitis.

MEDICATIONS

Systemic broad-spectrum antibiotics effective against usual bowel flora are prescribed to treat acute diverticulitis. Oral antibiotics such as metronidazole (Flagyl) and ciprofloxacin (Cipro) or trimethoprim-sulfamethoxazole (Septra, Bactrim) may be prescribed if manifestations are mild. Rifaximin (Xifaxan) is a poorly absorbed antibiotic that may be used together with fiber to treat uncomplicated diverticular disease. Severe, acute attacks often necessitate hospitalization and treatment with intravenous fluids and antibiotics effective against anaerobic and gram-negative bacteria. Therapy may include a second-generation cephalosporin such as cefoxitin (Mefoxin), or another antibiotic such as piperacillin-tazobactam (Zosyn) or ticarcillin-clavulanate (Timentin). Antibiotics and their nursing implications are discussed in Chapter 12.

Although a stool softener such as docusate sodium (Colace) may be prescribed, it is important to note that laxatives (which can further increase intraluminal pressure in the colon) are avoided for the patient with diverticular disease.

NUTRITION

Dietary modification is central to the management of diverticular disease. It appears that dietary changes can reduce the risk of complications of diverticulosis. A high-fiber diet is recommended; it increases stool bulk, decreases intraluminal pressures, and may reduce spasm (Table 24–9). Bran is a low-cost fiber supplement that can be added to cereal, soups, salads, or other foods. Commercial bulk-forming products, such as psyllium seed (Metamucil) or methylcellulose, also may be recommended. These products are discussed in the Medication Administration box on page 630. The patient often is advised to avoid foods with small seeds (such as popcorn, caraway seeds, figs, or berries), which could obstruct diverticula.

Bowel rest is prescribed during an acute episode of diverticulitis. The patient initially may be NPO with intravenous fluids and possibly parenteral nutrition. Feeding is resumed gradually. Initially, a clear liquid diet is prescribed with gradual advancement to a soft, low-roughage diet (i.e., a diet low in insoluble fiber) with daily added psyllium seed to soften stool and increase its bulk. Among the foods the patient should avoid are wheat and corn bran, vegetable and fruit skins, nuts, and dry beans. The high-fiber diet is resumed following full recovery.

TABLE 24–9 Foods Recommended in a High-Fiber, High-Residue Diet

Food Group	Recommended Foods
Cereals and grains	Wheat or oat bran; cooked cereals, such as oatmeal; dry cereals, such as bran buds or flakes, corn flakes, shredded wheat; whole-grain breads or crackers; brown rice
Fruits	Unpeeled raw apples, peaches, and pears; oranges; blackberries, raspberries, strawberries (may be restricted for the patient with diverticulosis)
Vegetables	Dried beans (navy, kidney, pinto), lima beans; broccoli; peas; corn; squash; raw vegetables, such as carrots, celery, and tomatoes; potatoes (with skins)

SURGERY

Patients with acute diverticulitis may require surgery, usually to treat generalized peritonitis or an abscess that fails to respond to medical treatment. Hemorrhage that recurs or cannot be controlled may also necessitate surgery. Elective surgery may be performed for recurrent episodes of diverticulitis or persistent diverticulitis with continuing pain, tenderness, and a palpable mass.

The affected bowel segment is resected, and if possible an anastomosis of the proximal and distal portions is performed. When an acute infection and diverticulitis are present, a two-stage Hartmann procedure is required. A temporary colostomy is created and anastomosis delayed until the inflammation has subsided. A second surgery is performed 2 to 3 months later to reconnect the bowel and close the temporary colostomy.

●○● NURSING CARE

Health Promotion

Teaching patients about the benefits of a high-fiber diet is important primary prevention for diverticular disease. Nurses working with groups and individuals in the community should emphasize the importance of a high-fiber diet and its benefits in preventing diverticular disease and other disorders. In facilities such as residential settings, the nurse can work with dietary staff and care providers to increase the amount of fiber in residents' diets, unless this is contraindicated by a preexisting condition.

Assessment

Because most patients with diverticular disease have few or no manifestations, nursing assessment focuses on manifestations of complications.

- *Health history:* abdominal pain or cramping, chronic constipation or irregular bowel habits; nausea and vomiting; history of diverticular disease or irritable bowel syndrome
- *Physical assessment:* bowel sounds, presence of abdominal tenderness of masses and location; stool for occult blood.

Priorities of Care

Priority care focuses on preventing complications of diverticulitis and managing pain and anxiety related to the possibility of a significant complication or possible surgery. Refer to Chapter 4 and Chapter 9 for nursing care related to acute pain and anxiety.

Diagnoses, Outcomes, and Interventions

Patients with acute diverticulitis are acutely ill and have multiple nursing care needs. The risk of perforation and resulting peritonitis or abscess formation is high.

Potential Complication: Perforation

During an acute attack of diverticulitis, inflammation and mucosal ischemia place the patient at risk for perforation and peritonitis. In addition to maintaining bowel rest to reduce the risk of perforation, the nurse monitors for manifestations of perforation and possible sepsis.

Expected Outcome: Patient will remain free from exhibiting signs and symptoms of complications related to diverticulitis. Patient will

remain afebrile, maintain heart and respiratory rate within normal limits, maintain normal abdominal girth, have normal bowel patterns, and test negative for occult blood on a guaiac test.

- Monitor vital signs including temperature at least every 4 hours. *Tachycardia and tachypnea may be early indications of increased inflammation and resulting fluid shift. Fever greater than 38.3°C (101°F) may indicate increased inflammation or spread of inflammation. Note, however, that little temperature elevation may occur in the older patient. A change in behavior or increasing lethargy may be subtle indications of infection in the older adult.*
- Assess abdomen every 4 to 8 hours or more often as indicated, including observing for distention, auscultating bowel sounds, and palpating for tenderness. Promptly report significant changes to the physician. *Increasing abdominal distention, a decrease or change in the quality of bowel sounds, and/or increasing tenderness or guarding may indicate spread of the infectious process or peritonitis.*
- Assess for evidence of lower intestinal bleeding by visual examination and guaiac testing of stools for occult blood. *Perforation of a diverticulum may produce either intestinal or intra-abdominal bleeding and require immediate treatment such as surgery.*
- Maintain intravenous fluids, TPN, and accurate intake and output records. *During acute diverticulitis, oral intake is usually prohibited or restricted. Intravenous fluids are given to maintain fluid and electrolyte balance; TPN is used to maintain nutritional status, facilitating healing and recovery.*

Continuity of Care

The patient with diverticular disease is responsible for self-care. Discuss the following topics for home care:

- Prescribed high-fiber diet and the need to maintain the diet for life to reduce the incidence of complications, including ways to increase dietary fiber
- Complications of diverticular disease and its manifestations

Provide a referral to a dietitian for teaching as indicated. Prior to discharge of the patient with acute diverticulitis, discuss the following:

- Food and fluid limitations, including recommendations for a low-residue diet during the initial period of healing
- Colostomy management (if a temporary colostomy has been created), including where to obtain supplies and dietary management
- Planned procedure to reanastomose the colon and revise the colostomy. Refer to community healthcare agencies as indicated.

Malabsorption Syndromes

Malabsorption is a condition in which the intestinal mucosa ineffectively absorbs nutrients—including carbohydrates, proteins, fats, water, electrolytes, minerals, and vitamins—resulting in their excretion in the stool. Many bowel disorders can lead to malabsorption.

Diseases of the small intestine often cause malabsorption. Other medical and/or surgical conditions can result in malabsorption if they affect digestion or the intestinal mucosa. Primary diseases of the small-bowel mucosa, such as sprue, Crohn's disease, and acute infections, can lead to malabsorption. It can also result from *maldigestion*, inadequate preparation of chyme for absorption. For example, major gastric resections, pancreatic disorders with impaired pancreatic enzyme secretion, and biliary disorders that affect bile secretion can impair digestion and absorption of chyme. Selected causes of impaired absorption and digestion are listed in Table 24–10.

Regardless of the cause, malabsorption causes common manifestations resulting from impaired absorption of chyme and the nutrients it contains. Predominant GI manifestations include anorexia; abdominal bloating; diarrhea with loose, bulky, foul-smelling stools; and steatorrhea (fatty stools). Weight loss, weakness, general malaise, muscle cramps, bone pain, abnormal bleeding, and anemia are common systemic manifestations of malabsorption. These manifestations result from malnutrition and fluid loss due to poor absorption.

Three common malabsorption disorders in adults are celiac disease, lactose intolerance, and short bowel syndrome.

THE PATIENT WITH CELIAC DISEASE

Celiac disease (known as *celiac sprue* or *nontropical sprue*) is a chronic T-cell–mediated autoimmune genetic disorder of the small intestine in which the absorption of nutrients, particularly fats, is impaired. It is characterized by sensitivity to the gliadin fraction of gluten, a cereal protein. Gluten is found in wheat, rye, barley, oats and as a filler in many prepared foods and medications.

The cause of celiac disease is a genetic illness that affects the small intestine; in most people the duodenum is affected first, and the jejunum may also be involved. Caucasians of European descent are most commonly affected (Papadakis & McPhee, 2013). Having a first-degree relative with celiac disease significantly increases the

TABLE 24–10 Selected Causes of Malabsorption

Cause	Related Factors or Conditions
Impaired absorption	Celiac disease
	Short bowel syndrome
	Gastric bypass surgeries
	Acute enteritis and other bowel infections or infestations
	AIDS-related opportunistic infections and Kaposi's sarcoma
	Celiac disease
	Crohn's disease
	Intestinal ischemia or infarction
	Scleroderma
Impaired digestion	Lactose intolerance
	Gastrectomy
	Chronic pancreatitis, cancer of the pancreas
	Cystic fibrosis
	Biliary obstruction
	Cirrhosis, hepatitis, or liver failure
	Zollinger-Ellison syndrome

risk. Nearly all people with celiac disease share the HAL-DQ2 allele, although only a small percentage of people with this allele actually have celiac disease (Longo et al., 2013). Celiac disease affects 0.5% to 1% of the U.S. population, and according to a consensus statement by the National Institutes of Health is a disease that is widely underrecognized (McCabe et al., 2012).

Manifestations of celiac disease often develop in childhood, but may develop at any age. The average time from onset of symptoms to diagnosis of celiac disease in adults in the United States is 10 years (McCabe et al., 2012). Celiac disease is one of the most commonly diagnosed genetic diseases in Europe. The severity of the disease depends on the extent of mucosal involvement in the intestine and the duration of the disease. Three factors—immunology, genetics, and environment—contribute to the pathogenesis of celiac disease (McCabe et al., 2012).

Pathophysiology

Most absorption of nutrients occurs in the small intestine. The mucosa of the small intestine is arranged in microscopic folds, which in turn contain even smaller finger-like projections called villi. The cells of the villi are covered with microscopic hairs, microvilli, projecting from the cell membrane. The folds, villi, and microvilli of the intestinal mucosa provide a huge surface area for nutrient absorption. Cells of the intestines are specialized to absorb different nutrients. Readily digested nutrients are absorbed in the proximal intestine; others are absorbed more distally in the intestines. Nutrients are absorbed by the processes of simple diffusion (water and small lipids), facilitated diffusion (water-soluble vitamins), and active transport (glucose and amino acids). Once absorbed into the cells of the villi, nutrients enter the blood or lymph for systemic distribution.

Celiac disease is provoked by the ingestion of gluten and affects an individual who has a genetic predisposition for the disease. The intestinal mucosa is damaged by an immunologic response. Gliadin acts as an antigen (a substance that induces the formation of antibodies that interact specifically with it), prompting an inappropriate T-cell–mediated immune response. People with celiac disease have increased antibodies to other antigens as well. The immune response prompts an inflammatory response in the small bowel, resulting in loss of villi and microvilli. The villi shorten and atrophy, resulting in loss of intestinal folds and absorptive surface. Digestive enzyme production, including disaccharidase and particularly lactase, is reduced as well. The proximal small bowel is affected to the greatest extent, likely due to its greater exposure to dietary gluten.

Manifestations

Manifestations of celiac disease may develop at any age and recent studies show increased incidence after age 55. Researchers are unsure whether this reflects diagnosis or late emergence of the condition (McCabe et al., 2012). Local manifestations include abdominal bloating and cramps, diarrhea, and steatorrhea. Systemic manifestations result from the effects of malabsorption and resulting deficiencies. Anemia is common. Patients are often small in stature, and may have delayed maturity. Other signs of nutrient deficiencies include tetany, vitamin deficiencies, muscle wasting, and rickets (impaired bone development). When gluten is removed from the diet, the manifestations resolve.

The 2004 National Institutes of Health consensus statement indicated that celiac disease can be classified as classical, atypical, silent, or latent (NIH, 2004). *Classical celiac disease* is referred to as *severe* and involves villous atrophy of a large portion of the small intestine. The symptoms are severe and include the typical sequelae of GI malabsorption syndromes. Patients with classical or severe celiac disease experience diarrhea, abdominal pain, bloating and distention, constipation, and reflux. *Atypical celiac disease* involves only the duodenum and is characterized by minimal or mild GI symptoms. *Silent celiac disease* refers to patients who are asymptomatic. Patients learn they have the disease when it is discovered through serologic screening or when villous atrophy is found during endoscopy or biopsy performed for other reasons. Patients with *latent celiac disease* have a positive serology but no villous atrophy on biopsy, or develop a positive serology after previous negative serology results.

Some experts purport there is a spectrum of gluten disorders that distinguishes between celiac disease, wheat allergy, and gluten sensitivity. Wheat allergy is defined as an adverse immunologic response to wheat proteins, and IGE antibodies play a central role in the body's response to exposure to gluten. Gluten sensitivity applies

PATHOPHYSIOLOGY LINKAGE

Local and Systemic Manifestations of Malabsorption

Category	Manifestation	Cause
Local (GI)	Diarrhea	Disruption of bowel mucosa impairs absorption of fluid and electrolytes, leading to excess water in the stool
	Abdominal distention	Gas formation from fermentation of undigested carbohydrates
	Steatorrhea	Impaired fat absorption leading to excess fat in feces
Systemic	Weight loss	Carbohydrate, protein, and fat deficit
	Weakness and malaise	Kilocalorie deficit; impaired absorption of micronutrients (vitamins and minerals) leading to nutrient deficiencies, anemia; fluid and electrolyte losses
	Anemia	Vitamin B_{12}, folic acid, and iron deficits impair erythropoiesis
	Bone pain	Calcium and vitamin D deficits lead to bone demineralization
	Muscle cramps, paresthesias	Protein wasting, vitamin B_{12} and electrolyte deficits impair neuromuscular function
	Easy bruising and bleeding	Vitamin K deficit
	Glossitis, cheilosis	Iron, folic acid, and vitamin B_{12} deficits

to cases when there is a gluten reaction and both allergic and autoimmune mechanisms have been ruled out (Sapone et al., 2012).

Gastrointestinal malignancies and intestinal lymphoma are potential complications of celiac disease. Other complications include intestinal ulceration and development of refractory disease, or disease that no longer responds to a gluten-free diet.

●○● INTERPROFESSIONAL CARE

With any malabsorptive disorder, the initial focus of management is to identify the cause. Once this has been determined, specific therapy can be prescribed.

DIAGNOSIS

Laboratory and diagnostic testing are used to make the differential diagnosis for various causes of malabsorption syndromes and to determine the severity of nutrient deficiencies.

An enteroscopy permits direct examination of intestinal mucosa and collection of a tissue specimen for biopsy. Tissue biopsy is necessary to establish the diagnosis of celiac disease. Upper GI series with small-bowel follow-through may be done to evaluate the structures of the upper GI tract. With celiac disease, the typical "feathery" pattern of barium in the small bowel is lost, and the barium may precipitate and clump. Nursing implications of diagnostic tests are included in Chapter 21.

Genetic testing for the presence of HLA genes is available and testing is recommended for patients who are symptomatic and have a first- or second-degree relative with celiac disease (McCabe et al., 2012). Serologic testing for IgA endomysial antibodies and IgG and IgA antigliadin antibodies is used to diagnose celiac disease and evaluate compliance with the prescribed gluten-free diet. Biopsy of the jejunum is the gold standard for diagnosis (McCabe et al., 2012). Laboratory tests are used to identify pathophysiologic effects of the disease. Fecal fat is measured to document the presence of steatorrhea. The fat content of stool is increased in many malabsorptive disorders, including celiac disease. Serum levels of protein, albumin, cholesterol, electrolytes, and iron may be ordered to evaluate for nutrient deficiencies. The hemoglobin, hematocrit, and RBC indices are used to evaluate anemia. Prothrombin time is increased in vitamin K deficiency.

MEDICATIONS

Patients with severe nutritional deficits may require vitamin and mineral supplements, as well as iron and folic acid to correct anemia. Vitamin K may be administered parenterally if the prothrombin time is prolonged. In patients whose disease fails to respond to dietary management, corticosteroids may be ordered to suppress the inflammatory response.

NUTRITION

The patient with celiac disease is placed on a gluten-free diet. This treatment is generally successful, as long as the patient avoids gluten totally. Gluten is so widely used in prepared foods that this may be no easy task. Consultation with a dietitian and detailed dietary instructions are necessary. Patients need to become aware of hidden sources of gluten and to analyze dietary labels. Common sources of gluten and foods to be avoided are indicated in Table 24–11.

The prescribed diet is high in calories and protein to correct nutrient deficits. Fat content is restricted to minimize steatorrhea. The diet usually is restricted in lactose as well to compensate for the loss of lactase-containing microvilli. Foods containing lactose may be reintroduced once remission has occurred. Patients with refractory disease may benefit from restriction of other dietary proteins such as soy (Longo et al., 2013).

●○● NURSING CARE

Nursing care for the patient with celiac disease focuses on the effects of the disorder on health and nutrition, as well as the patient's ability to manage the disease.

Assessment

- *Health history:* onset, duration, and severity of manifestations; number and character of stools; previous teaching related to disorder; current treatment and diet
- *Physical assessment:* vital signs; abdominal shape, contour, bowel sounds; manifestations of malnutrition (e.g., anemia, small stature, muscle wasting, signs of other nutrient deficiencies).

Priorities of Care

Diarrhea and malnutrition are significant problems for the patient with celiac disease and are priorities for nursing intervention.

TABLE 24–11 Dietary Sources of Gluten

Food Group	Contains Gluten	May Contain Gluten
Cereals, grains, and grain products	Bread, crackers, cereal, and pasta containing wheat, rye, or barley grain or flour	Seasoned rice and potato mixes
Beverages	Malt, Postum, Ovaltine, beers, and ales	Commercial chocolate milk, cocoa, and other beverage mixes, such as instant tea mix, dietary supplements
Desserts	Cakes, cookies, and pastries made with wheat, rye, or barley flour	Commercial ice cream and sherbet
Meats and other protein sources		Meat loaf, cold cuts and prepared meats, breaded meats; cheese products; soy protein meat substitutes; commercial egg products
Fruits and vegetables		Commercial seasoned vegetable mixes or vegetables with sauce; canned baked beans; commercial pie fillings
Miscellaneous		Commercial salad dressings and mayonnaise; ketchup and prepared mustard; gravy, white sauce; nondairy creamer; syrups; commercial pickles; fillers used in prescription and OTC medications

Diagnoses, Outcomes, and Interventions

Diarrhea

Steatorrhea and diarrhea typically occur with celiac disease because fat, water, and other nutrients are poorly absorbed, remaining in the bowel to be eliminated in the stool. Diarrhea can interfere with lifestyle, ADLs, skin integrity, and fluid and electrolyte balance.

Expected Outcome: Patient's diarrhea will be controlled or eliminated as demonstrated by resumption of normal bowel elimination patterns.

- Assess and document the frequency and nature of stools. *Bowel elimination reflects the severity of the disease and efficacy of treatment. With effective treatment, stools become less frequent and more normal in color and appearance.*
- Weigh daily, monitor intake and output, and assess skin turgor and mucous membranes for indications of fluid balance. *Diarrhea increases the risk for hypovolemia and dehydration resulting from excess fluid loss in the stool.*
- Assess and document perianal skin condition. *Frequent defecation can irritate skin and mucous membranes, increasing the risk of breakdown.*
- Encourage a liberal fluid intake. *Oral fluids help replace fluid lost through diarrheal stool.*

Imbalanced Nutrition: Less Than Body Requirements

Celiac disease is a chronic condition. With continuing malabsorption, multiple nutrient deficits may occur, resulting in impaired growth and development, impaired healing, muscle wasting, bone disease, and electrolyte imbalances.

Expected Outcome: Patient will maintain adequate oral intake, report adequate energy levels, and maintain body mass, weight, and normal lab values (hemoglobin and hematocrit, albumin, and electrolytes).

- Maintain accurate dietary intake records. *Assessment of dietary intake provides information about compliance with the prescribed diet as well as the adequacy of nutrient intake.*
- Monitor laboratory results, including hemoglobin and hematocrit, serum electrolytes, total serum protein, and albumin levels. *These studies provide information about nutritional status.*
- Arrange for dietary consultation. Provide for food preferences as allowed. *An individualized diet developed to address the patient's food preferences as well as nutrient needs will promote appetite and food intake.*
- Provide the prescribed high-kilocalorie, high-protein, low-fat, gluten-free diet for the patient with celiac sprue. Restrict lactose (dairy product) intake as indicated. *Calories and protein are important to replace lost nutrients. Fat restriction helps reduce diarrhea and nutrient loss. Lactose may be restricted during initial treatment, then slowly reintroduced into the diet as the gut heals and its normal structure is restored.*
- Provide parenteral nutrition as ordered if the patient is unable to absorb enteral nutrients. *Parenteral nutrition can help reverse nutritional deficits and promote weight gain when manifestations are acute.*
- Encourage nutritional supplements. *Nutritional supplements often are necessary to replace losses and restore nutrient levels to normal more rapidly than diet alone can achieve.*
- Include family members, the primary food preparer in particular, in teaching and dietary discussions. *Families can reinforce teaching and help the patient maintain required restrictions or kilocalorie intake.*

Continuity of Care

The patient with celiac disease has a chronic condition that requires continuing dietary management.

Provide a detailed list of foods containing gluten. Identity foods that need to be eliminated from the diet, as well as foods that are allowed. Teach the patient and family how to identify gluten-containing commercial products by reading labels and lists of ingredients. Encourage the purchase and use of a gluten-free cookbook. Discuss potential long-term complications of the disorder and manifestations to be reported to the primary care provider.

If corticosteroids have been prescribed, stress the importance of taking the medication as ordered. Emphasize the need to avoid stopping the medication abruptly and to notify all caregivers that a corticosteroid is part of the patient's medication regimen. Instruct patient to frequently monitor weight. A weight gain of 2.3 kg (5 lb) or more in less than a week usually reflects fluid gain, a possible adverse effect of corticosteroids. Other potential effects include decreased resistance to infection, an impaired inflammatory response, and changes in the metabolism of carbohydrates, proteins, and fats.

THE PATIENT WITH LACTASE DEFICIENCY

For carbohydrates to be absorbed from the small intestine, they first must be broken down into simple sugars, or monosaccharides. Lactose is the primary carbohydrate in milk and milk products. Lactose is a disaccharide, requiring the enzyme lactase for digestion and absorption. Lactase deficiency can lead to *lactose intolerance* and manifestations of malabsorption. Lactase deficiency usually is genetic in origin, but also occurs secondarily to celiac disease, Crohn's disease, and other disorders affecting the mucosa of the small intestine. There is a racial/ethnic component to the disorder, described in the Focus on Cultural Diversity box.

Manifestations

Many people with lactase deficiency are asymptomatic. Small to moderate amounts of milk (one to two 8-ounce glasses) may be well tolerated. Manifestations of lactose intolerance include lower abdominal cramping, pain, and diarrhea following milk ingestion. Undigested lactose ferments in the intestine, forming gases that contribute to bloating and flatus. Lactic and fatty acids produced by this fermentation irritate the bowel, leading to increased motility and abdominal cramping. The undigested lactose draws water into the intestine, which contributes to increased motility and diarrhea. The diarrhea associated with lactose intolerance may be explosive.

FOCUS ON CULTURAL DIVERSITY

Lactase Deficiency

- Lactase deficiency affects up to 100% of Asians and 95% of Native Americans.
- Lactase deficiency affects approximately 70% of African Americans.
- Lactase deficiency is common among Jewish Americans and Hispanics.
- Fewer than 25% of Caucasians are affected.

●○● INTERPROFESSIONAL CARE

The diagnosis of lactase deficiency usually is based on a history of intolerance to milk and milk products, and a trial of a lactose-free diet. If manifestations resolve when lactose intake is eliminated, the diagnosis of lactase deficiency is confirmed.

DIAGNOSIS

The lactose breath test is a noninvasive test that may be used to diagnose lactase deficiency. Expired hydrogen gas (H_2) is measured following oral administration of 50 g of lactose. If lactose is digested and absorbed normally, then little change occurs in the amount of exhaled H_2 from fasting to postlactose administration. With lactose intolerance, exhaled H_2 increases following lactose administration as the sugar ferments in the bowel.

For the lactose tolerance test, 50 to 100 g of lactose solution is orally administered, followed by measurement of blood glucose levels at intervals of 30 minutes and 1, 2, and 3 hours. If lactose is digested and absorbed normally, the blood glucose rises more than 20 mg/dL. The expected blood glucose elevation does not occur in lactase deficiency.

NUTRITION

A lactose-free or reduced-lactose diet relieves the manifestations of the disorder. Some patients require total elimination of milk and milk products from the diet. Many can tolerate limited amounts of lactose. Milk pretreated with lactase is readily available. Nonprescription lactase enzyme preparations are available to improve milk tolerance. Yogurt containing bacterial lactases may be well tolerated. Calcium supplements are often recommended, particularly for women on a reduced-lactose or lactose-free diet.

●○● NURSING CARE

Nursing care for the patient with lactose intolerance focuses on providing education and support. Discuss sources of lactose: Milk, ice cream, and cottage cheese are high in lactose; aged cheese and yogurt contain much smaller amounts. Potential hidden sources of lactose include sherbets, desserts made from milk and milk chocolate, sauces and gravies, and cream soups. Suggest a trial of lactase-treated milk or lactase enzyme supplements. Emphasize the importance of obtaining nutrients contained in dairy products from other sources. Proteins may be obtained from meats, eggs, legumes, and grains. Other sources of calcium include sardines, oysters, and salmon, as well as plant sources such as beans, cauliflower, rhubarb, and green leafy vegetables.

THE PATIENT WITH SHORT BOWEL SYNDROME

The small bowel may be resected due to tumors, infarction of bowel mucosa, incarcerated hernias, Crohn's disease, bariatric surgery, trauma, and enteropathy resulting from radiation therapy. Resection of significant portions of the small intestine may result in a condition known as *short bowel syndrome*. The severity of the disorder depends on the total amount of bowel resected, as well as the portions of bowel removed. Removal of the proximal portions, including the duodenum, jejunum, proximal ileum, and the distal portion of the ileum, is associated with more severe malabsorption and manifestations than is resection of midportions of the ileum.

Resection of the small intestine affects the absorption of water, nutrients, vitamins, and minerals. Transit time of ingested foods and fluids is reduced, and digestive processes are impaired. The bowel undergoes an adaptive process in which the remaining villi enlarge and lengthen to increase absorptive surface following resection. For many patients, absorption and bowel function return to preoperative or near-normal levels. Others have continued significant impairment of digestion and absorption, leading to nutrient deficiencies, weight loss, and diarrhea. Short bowel syndrome is associated with an increased risk for kidney stones and gallstones.

●○● INTERPROFESSIONAL CARE

Management of short bowel syndrome focuses on alleviating manifestations. Patients often simply require frequent, small, high-kilocalorie, high-protein feedings.

DIAGNOSIS

Laboratory and diagnostic studies are used to evaluate nutrient deficiencies. Total serum proteins and albumin are reduced, as are serum levels of folate, iron, vitamins, minerals, and electrolytes. Anemia and a prolonged prothrombin time (indicative of vitamin K deficiency) may develop.

MEDICATIONS

Multivitamin and mineral supplementation is frequently necessary. Antidiarrheal medications are used to reduce bowel motility, allowing a greater amount of time for nutrient absorption. Some patients are affected by gastric hypersecretion following bowel resection. For these patients, a proton-pump inhibitor such as omeprazole (Prilosec) may be ordered. Patients with severe manifestations of short bowel syndrome may require parenteral nutrition (PN).

●○● NURSING CARE

Nursing care for the patient with short bowel syndrome focuses on the problems of potential fluid volume deficit, malnutrition, and diarrhea.

Fluid losses are generally greatest in the initial periods following surgery, warranting the closest attention at that time. Close monitoring of vital signs, intake and output, daily weights, skin turgor, and condition of mucous membranes is vital. It is important to remember that the risk also is high when other abnormal fluid losses occur through, for example, fever, draining wounds, or excess perspiration.

Document nutritional status, including weight, anthropometric measurements, laboratory values, and kilocalorie intake. Provide nutritional supplementation with enteral feedings as needed. Maintain central lines and PN, using aseptic technique.

For diarrhea, document the number and character of stools. Administer antidiarrheal medications as ordered. If the patient is lactose intolerant, limit intake of milk and milk products. Provide good skin care of the perianal region to prevent breakdown from frequent bowel movements. Refer to the discussion of nursing care for the patient with celiac disease for other measures for altered nutrition and diarrhea.

The patient and family affected by this condition require extensive education. Because there is no way to cure or replace the lost bowel at this time, the patient must manage the disorder on a

day-to-day basis. Provide instructions about the recommended diet and medication regimen. Emphasize the importance of maintaining an adequate fluid intake, particularly in hot weather or during strenuous exercise. Teach the patient to monitor his or her weight frequently and report changes. Include teaching about possible manifestations of dehydration and nutrient deficiencies that should be reported to the physician. Referring the patient to a dietitian or counselor can help the person cope with what may be a lifelong problem. See Chapter 23 for discussion and treatment of dumping syndrome, which is a possible complication of bowel surgery.

Neoplastic Disorders

Cancer remains the second leading cause of death in the United States, preceded only by heart disease. Although cancer may affect any portion of the digestive tract, the large intestine and rectum are the most common sites. Malignant neoplasms of the lower bowel are the second leading cause of death from cancer (after lung cancer), making this a significant healthcare concern.

THE PATIENT WITH POLYPS

A *polyp* is a mass of tissue that arises from the bowel wall and protrudes into the lumen. Polyps may develop in any portion of the bowel, but they occur most often in the sigmoid colon and rectum. They vary considerably in size and may be single or multiple. It is estimated that approximately 30% of people over the age of 50 have polyps. Although most polyps are benign, some have the potential to become malignant. Familial adenomatous polyposis (FAP) is a syndrome with a dominant inheritance pattern that leads to the development of hundreds to thousands of adenomatous polyps. Some of these polyps will inevitably become malignant (Longo et al., 2013).

Pathophysiology

Polyps are identified by their structure and tissue type. Most polyps are adenomas, benign epithelial tumors that are considered premalignant lesions. More than 95% of adenocarcinomas arise from adenomas (Longo et al., 2013). Of polyps that are removed during colonoscopy, more than 70% are adenomatous (Papadakis & McPhee, 2013).

Adenomatous polyps represent disruption of the normal process of cell proliferation to replace epithelial cells lining the intestine. Cells are constantly being reproduced to replace those shed as feces move through the colon. Disruption of the normal process of cell division and maturation can lead to formation of a polyp composed of tightly packed epithelial cells. The cells may appear grossly normal or show signs of dysplasia. Polyps may develop as tubular, villous, or tubulovillous adenomas. Polyps may be named by the way they are attached to the bowel wall as either sessile (raised nodules) or pedunculated (attached by a stalk).

Tubular adenomas (also called pedunculated polyps) are more common than sessile polyps and account for about 65% of benign polyps of the large intestine (Figure 24–8A ■) (Grossman & Porth, 2014). A tubular adenoma is a globelike structure attached to the intestinal wall by a thin, stalk-like stem. The incidence of this type of polyp increases with age, although it occurs in all age groups and in both genders. Most are small, 1 cm or less in diameter, although they may be as large as 4 to 5 cm. The malignant potential of these polyps seems to be related to their size. Small adenomas less than 1 cm have a low risk of being malignant, but larger adenomas (>1 cm) have a much higher risk of harboring malignancy or a high-grade dysplasia.

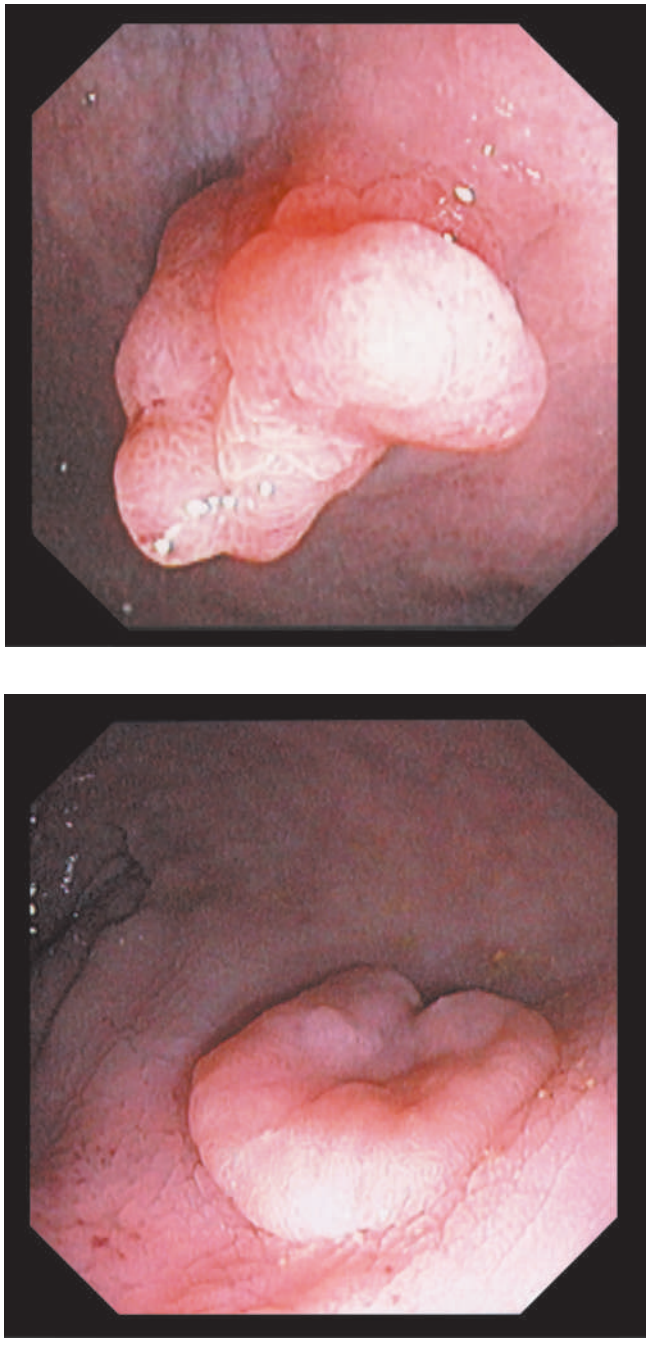

Figure 24–8 ■ A, Tubular (or pedunculated) and B, villous (or sessile) polyps.

Villous adenomas (also called *sessile polyps*) have a broad base and an elevated, cauliflower-like surface (Figure 24–8B). They typically develop in the rectosigmoid colon. This type of polyp is often larger than a tubular adenoma, usually more than 5 cm. Villous

adenomas are not common, accounting for about 10% of colon polyps. They have a higher malignant potential than tubular adenomas. Some adenomatous polyps contain both tubular epithelium and villi and are known as *tubulovillous adenomas*.

Manifestations

Most polyps are asymptomatic, found coincidentally during routine examination or diagnostic testing. Intermittent painless rectal bleeding, bright or dark red, is the most common presenting complaint. A large polyp may cause abdominal cramping, pain, or manifestations of obstruction. Diarrhea and mucous discharge may be associated with a large villous adenoma.

●○● INTERPROFESSIONAL CARE

The diagnosis of intestinal polyps is generally based on diagnostic studies such as sigmoidoscopy or colonoscopy. A rectal polyp may be palpable on digital examination, but further studies are necessary to determine its size and type and the extent of colon involvement, and to assess for malignancy. Genetic testing and counseling are offered to patients with a family history of FAP. First degree relatives of a patient with FAP undergo annual sigmoidoscopy beginning at age 10 years.

Once identified, polyps are removed because of the risk of malignancy. Pedunculated polyps and small villous lesions may be removed during colonoscopy using an electrocautery snare or hot biopsy forceps passed through the scope. This relatively safe procedure has less than a 2% risk of complications such as perforation or hemorrhage. Large villous adenomas are completely excised and examined histologically for evidence of malignancy. In some cases, the colon segment containing the polyp is resected. Patients with FAP usually undergo a total colectomy with ileorectal anastomosis before age 30 years to significantly reduce their risk for developing colon cancer.

Treatment following polypectomy depends on histologic examination of the excised tissue. Because polyps tend to recur, follow-up colonoscopy is recommended in 3 years and then every 5 years if no further polyps are detected. When the polyp is found to be malignant, follow-up care is determined by the tissue type and degree of invasion.

●○● NURSING CARE

Health Promotion

The incidence of intestinal polyps increases with age. They affect men and women equally. It is believed that an adenomatous polyp requires more than 5 years of growth to become significant in size and malignant potential. Advise all patients to have a screening for colorectal cancer at age 50 and as recommended thereafter for early detection of polyps (American Cancer Society [ACS], 2013a; 2013b).

Assessment

Polyps are a silent disease, with few or no manifestations.

- *Health history:* rectal bleeding; personal or family history of intestinal polyps or colorectal cancer.

Diagnoses, Outcomes, and Interventions

Nursing care for the patient with polyps focuses on education and assisting the patient through diagnostic testing and polyp removal. Before and after colonoscopy and polypectomy, provide direct care and teaching about the procedure, expected sensations during the procedure, and anticipated postoperative care. Cathartics are prescribed prior to colonoscopy; cleansing enemas may be ordered. Observe for evidence of fluid and electrolyte imbalance during preoperative preparation. If enemas are ordered, use normal saline (not tap water) to reduce the risk of electrolyte imbalances. Following polypectomy, observe closely for possible complications such as hemorrhage.

Continuity of Care

Include the following topics when teaching for home care:

- The significance of polyps and their relationship to colorectal cancer
- The importance of keeping follow-up appointments and undergoing repeat colonoscopy as recommended: at 3 years following polypectomy, then every 5 to 10 years unless additional polyps are found
- Manifestations to report to the physician include diarrhea, pain, rectal bleeding, light-headedness, or other indications of possible blood loss.

THE PATIENT WITH COLORECTAL CANCER

Colorectal cancer (cancer of the colon or rectum) is the third most common cancer diagnosed in the United States. In the United States about 142,820 new cases of colorectal cancer were diagnosed in 2013, and it was expected to cause about 50,830 deaths during that year (ACS, 2013a; 2013b). Earlier diagnosis and improved treatment have improved the survival rate for colorectal cancer. Its incidence, which is nearly equal among men and women, has been declining in the United States for the past two decades primarily due to improved screening. The incidence of colorectal cancer varies among ethnic groups; see the Focus on Cultural Diversity box. Colorectal cancer occurs most frequently after age 50. The incidence continues to rise with increasing age. With early diagnosis and treatment, the 5-year survival rate for colorectal cancer is 90%; however, only 39% of colorectal cancers are diagnosed at this early stage.

Although the specific cause of colorectal cancer is unknown, a number of risk factors have been identified (Box 24–2). Genetic factors are linked to the risk for colorectal cancer. Up to 25% of people who develop colorectal cancer have a family history of the disease (Longo et al., 2013). Individuals with familial adenomatous polyposis inevitably will develop colon cancer unless the colon is removed. Hereditary nonpolyposis colorectal cancer (also known as Lynch

FOCUS ON CULTURAL DIVERSITY

Colorectal Cancer Risk

- The incidence of colorectal cancer is higher among African Americans than among Whites.
- Ashkenazi Jews (of Eastern European descent) have a higher rate of colorectal cancer than Whites.
- Hispanic men and women have a lower rate of colorectal cancer than non-Hispanic Whites.

BOX 24–2 Risk Factors for Colorectal Cancer

- Age over 50 years
- Polyps of the colon and/or rectum
- Family history of colorectal cancer
- Personal history of colorectal, ovarian, endometrial, or breast cancer
- Inflammatory bowel disease
- Exposure to radiation
- Diet: high animal fat and kilocalorie intake
- Obesity, smoking, and alcohol use

syndrome) is an autosomal dominant disorder that significantly increases the risk for developing colorectal and other cancers. Tumors associated with Lynch syndrome often affect the ascending colon, and tend to occur at an earlier age. Inflammatory bowel diseases increase the risk of colorectal cancer. Studies indicate individuals with type 2 diabetes are at higher risk for developing cancer (ACS, 2013b).

Diet plays a role in the development of colorectal cancer. The disease is prevalent in economically prosperous countries where people consume diets high in calories, meat proteins, and fats. This dietary pattern, common in the United States, is thought to increase the population of anaerobic bacteria in the gut. These anaerobes convert bile acids into carcinogens. Diets high in fruits and vegetables, folic acid, and calcium appear to reduce the risk of colorectal cancer. Other factors that may reduce the risk of colorectal cancer include regular exercise, taking a daily multivitamin, and the use of aspirin and other NSAIDs.

Pathophysiology

Nearly all colorectal cancers that begin as adenomatous polyps are adenocarcinomas. Most tumors develop in the rectum and sigmoid colon, although any portion of the colon may be affected (Figure 24–9 ■). The tumor typically grows undetected, producing few manifestations. By the time manifestations occur, the disease may have spread into deeper layers of the bowel tissue and adjacent organs. Colorectal cancer spreads by direct extension to involve the entire bowel circumference, the submucosa, and outer bowel wall layers. Neighboring structures such as the liver, greater curvature of the stomach, duodenum, small intestine, pancreas, spleen, genitourinary tract, and abdominal wall also may be involved by direct extension. Metastasis to regional lymph nodes is the most common form of tumor spread. This is not always an orderly process; distal nodes may contain cancer cells while regional nodes remain normal. Cancerous cells from the primary tumor may spread by way of the lymphatic system or circulatory system to secondary sites such as the liver, lungs, brain, bones, and kidneys. "Seeding" of the tumor to other areas of the peritoneal cavity can occur when the tumor extends through the serosa or during surgical resection.

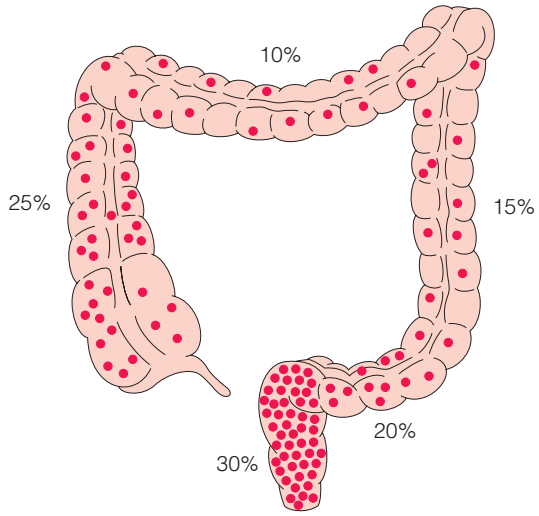

Figure 24–9 ■ The distribution and frequency of cancer of the colon and rectum.

Manifestations

Bowel cancer often produces no manifestations until it is advanced. Because it grows slowly, 5 to 15 years of growth may occur before manifestations develop. The manifestations depend on its location, type and extent, and complications. Rectal bleeding is often the initial manifestation that prompts patients to seek medical care. Other common early manifestations include a change in bowel habits, either diarrhea or constipation. Pain, anorexia, and weight loss are characteristic in advanced disease. A palpable abdominal or rectal mass may be present. Occasionally the patient presents with anemia from occult bleeding.

Complications

The primary complications associated with colorectal cancer are (1) bowel obstruction due to narrowing of the bowel lumen by the lesion; (2) perforation of the bowel wall by the tumor, allowing contamination of the peritoneal cavity by bowel contents; and (3) direct extension of the tumor to involve adjacent organs.

Most recurrences of colorectal cancer after tumor removal occur within the first 4 years. The size of the primary tumor does not necessarily relate to long-term survival. The number of involved lymph nodes, penetration of the tumor through the bowel wall, and tumor adherence to adjacent organs are better predictors of the prognosis for the disease.

●○● INTERPROFESSIONAL CARE

The focus of interprofessional care for colorectal cancer is prevention, early detection, and intervention. Colorectal cancer is always treated by surgical resection, with chemotherapy and radiation therapy used as adjuncts.

PREVENTION

Measures to prevent colon cancer that are considered to be effective and safe include consuming a diet high in fruits and vegetables and low in saturated fat and red meat, regular exercise, maintaining a healthy weight, limiting alcohol consumption, and quitting smoking. Consuming fiber supplements, minerals such as calcium, vitamins, and NSAIDs may help prevent colorectal cancer (ACS, 2013b). Although considered safe, these measures are the subject of further research to demonstrate conclusive proof of effectiveness.

SCREENING

The ACS (2013b) recommends one of the following testing schedules for the early detection of colorectal cancer, beginning at age 50. These options are acceptable choices for average-risk adults.

- Yearly fecal occult blood test (FOBT) or fecal immunochemical test (FIT) or stool DNA test (sDNA).
- Flexible sigmoidoscopy every 5 years, *or*
- Double-contrast barium enema every 5 years, *or*
- CT colonography (virtual colonoscopy) every 5 years, *or*
- Colonoscopy every 10 years.

DIAGNOSIS

Diagnostic and laboratory tests are used for screening, diagnosis, and monitoring purposes. Diagnostic tests include a sigmoidoscopy or colonoscopy as the primary diagnostic test used to detect and visualize tumors. While flexible sigmoidoscopy can detect 50% to 65% of colorectal cancers, many clinicians recommend colonoscopy. Tissue for biopsy is obtained at the time of endoscopy to confirm cancerous tissue and evaluate cell differentiation. Current staging methods primarily use the TNM system, as outlined in Table 24–12. Radiologic examinations may include a chest x-ray to detect tumor metastasis to the lung. Computed tomography (CT) scan, magnetic resonance imaging (MRI), or ultrasonic examination may be used to assess tumor depth and involvement of other organs by direct extension or metastasis.

Laboratory tests used are a fecal occult blood (by guaiac or Hemoccult testing) to detect blood in the feces and a CBC to detect anemia resulting from chronic blood loss and tumor growth. Carcinoembryonic antigen (CEA) is a tumor marker that can be detected in the blood of patients with colorectal cancer. CEA levels are used to estimate prognosis, monitor treatment, and detect cancer recurrence.

SURGERY

Surgical resection of the tumor, adjacent colon, and regional lymph nodes is the treatment of choice for colorectal cancer. Options for surgical treatment vary from destruction of the tumor by laser photocoagulation performed during endoscopy to abdominoperineal resection with permanent colostomy. When possible, the anal sphincter is preserved and colostomy avoided.

Laser photocoagulation uses a very small, intense beam of light to generate heat in tissues toward which it is directed. The heat generated by the laser beam can be used to destroy small tumors. It is also used for palliative surgery of advanced tumors to remove obstruction. Laser photocoagulation can be performed endoscopically and is useful for patients who cannot tolerate major surgery.

Other surgical treatment options for small, localized tumors include local excision and fulguration. These procedures may be performed during endoscopy, eliminating the need for abdominal surgery. Local excision may be used to remove a disk of rectum containing a tumor in patients with a small, well-differentiated, mobile polypoid lesion. *Fulguration* or electrocoagulation is used to reduce the size of some large tumors for patients who are poor surgical risks. This procedure requires general anesthesia and may need to be repeated at intervals.

Most patients with colorectal cancer undergo surgical resection of the colon with anastomosis of remaining bowel as a curative procedure. The distribution of regional lymph nodes determines the extent of resection because these may contain metastatic lesions. Most tumors of the ascending, transverse, descending, and sigmoid colon can be resected.

Tumors of the rectum usually are treated with an abdominoperineal resection in which the sigmoid colon, rectum, and anus are removed through both abdominal and perineal incisions. A permanent sigmoid colostomy is performed to provide for elimination of feces. Nursing care of the patient having bowel surgery is outlined in the accompanying box.

COLOSTOMY Surgical resection of the bowel may be accompanied by a colostomy for diversion of fecal contents. A **colostomy** is an ostomy made in the colon. It may be created if the bowel is obstructed by the tumor, as a temporary measure to promote healing of anastomoses, or as a permanent means of fecal evacuation when the distal colon and rectum are removed. Colostomies take the name of the portion of the colon from which they are formed: ascending colostomy, transverse colostomy, descending colostomy, and sigmoid colostomy (Figure 24–10 ■).

A *sigmoid colostomy* is the most common permanent colostomy performed, particularly for cancer of the rectum. It is usually created during an abdominoperineal resection. This procedure involves the

TABLE 24–12 The TNM Classification for Colorectal Cancer

Stage	Primary Tumor (T)	Regional Lymph Nodes (N)	Distant Metastasis (M)
	TX—Primary tumor cannot be assessed TO—No evidence of primary tumor	NX—Regional lymph nodes cannot be assessed	MX—Presence of distant metastasis cannot be assessed
Stage 0	Tis—Carcinoma *in situ*	NO—No regional lymph node metastasis	MO—No distant metastasis
Stage I	T1—Tumor invades submucosa		
	T2—Tumor invades muscularis propria		
Stage II	T3—Tumor invades through muscularis propria into subserosa or into nonperitonealized pericolic or perirectal tissues		
	T4—Tumor perforates visceral peritoneum or directly invades other organs or structures		
Stage III	Any T	N1—Metastasis in one to three pericolic or perirectal lymph nodes	
		N2—Metastasis in four or more pericolic or perirectal lymph nodes	
Stage IV	Any T	Any N	M1—Distant metastasis

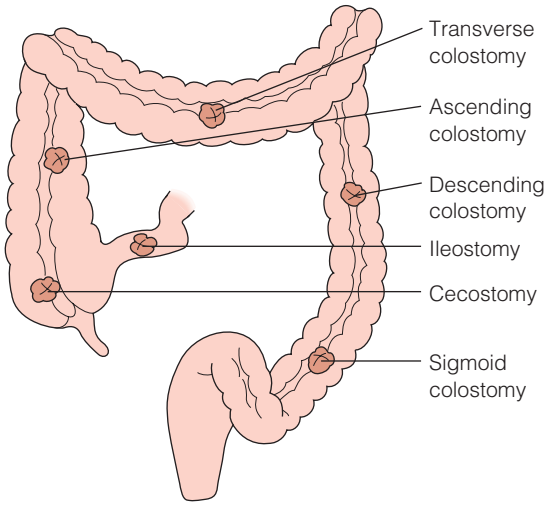

Figure 24–10 ■ Various ostomy levels and sites.

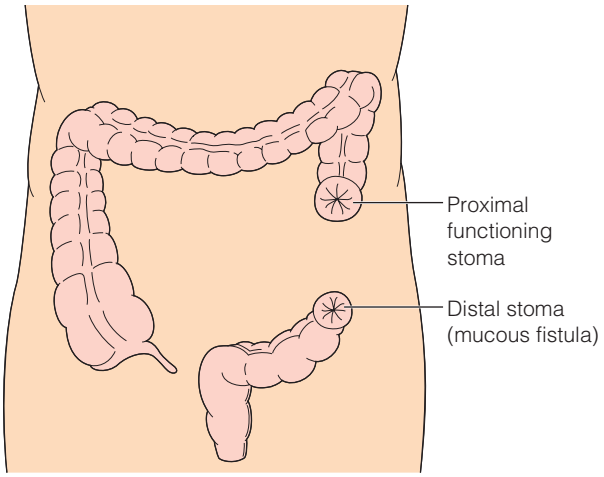

Figure 24–11 ■ A double-barrel colostomy. The proximal stoma is the functioning stoma; the distal stoma expels mucus from the distal colon.

removal of the sigmoid colon, rectum, and anus through abdominal and perineal incisions. The anal canal is closed, and a stoma formed from the proximal sigmoid colon. The stoma usually is located on the lower left quadrant of the abdomen.

When a *double-barrel colostomy* is performed, two separate stomas are created (Figure 24–11 ■). The distal colon is not removed, but bypassed. The proximal stoma, which is functional, diverts feces to the abdominal wall. The distal stoma, also called the mucous fistula, expels mucus from the distal colon. It may be pouched or dressed with a 4 × 4 gauge dressing. A double-barrel colostomy may be created for cases of trauma, tumor, or inflammation, and it may be temporary or permanent.

NURSING CARE OF THE PATIENT

Having Bowel Surgery

PREOPERATIVE NURSING CARE

- Provide routine preoperative care for the surgical patient, as outlined in Chapter 4.
- Arrange for consultation with ET specialist if appropriate. *The ET nurse is trained to identify and mark an appropriate stoma location, taking into consideration the level of ostomy, skinfolds, and the patient's clothing preferences. Initial ostomy care teaching also is provided by the ET nurse during the preoperative visit.*
- Insert a nasogastric tube if ordered. *Although it is often inserted in the surgical suite just prior to surgery, the nasogastric tube may be placed preoperatively to remove secretions and empty stomach contents.*
- Perform bowel preparation procedures as ordered. *Oral and parenteral antibiotics as well as cathartics and enemas may be prescribed preoperatively to clean the bowel and reduce the risk of peritoneal contamination by bowel contents during surgery.*

POSTOPERATIVE NURSING CARE

- Provide routine care for the surgical patient, as outlined in Chapter 4.
- Monitor bowel sounds and degree of abdominal distention. *Surgical manipulation of the bowel disrupts peristalsis, resulting in an initial ileus. Bowel sounds and the passage of flatus indicate a return of peristalsis.*
- Assess the position and patency of the nasogastric tube, connecting it to low suction. If the tube becomes clogged, gently irrigate with sterile normal saline. *A nasogastric or gastrostomy tube is used postoperatively to provide gastrointestinal decompression and facilitate healing of the anastomosis. Ensuring its patency is important for comfort and healing.*
- Assess color, amount, and odor of drainage from surgical drains and the colostomy (if present), noting any changes or the presence of clots or bright bleeding. *Initial drainage may be bright red and then become dark and finally clear or greenish yellow over the first 2 to 3 days. A change in the color, amount, or odor of the drainage may indicate a complication such as hemorrhage, intestinal obstruction, or infection.*
- Alert all personnel caring for the patient with an abdominoperineal resection to avoid rectal temperatures, suppositories, or other rectal procedures. *These procedures could disrupt the anal suture line, causing bleeding, infection, or impaired healing.*
- Maintain intravenous fluids while nasogastric suction is in place. *The patient on nasogastric suction is unable to take oral food and fluids and, moreover, is losing electrolyte-rich fluid through the nasogastric tube. If replacement fluid and electrolytes are not maintained, the patient is at risk for dehydration; sodium, potassium, and chloride imbalance; and metabolic alkalosis.*
- Provide antacids, H_2-receptor antagonists, proton-pump inhibitors, and antibiotic therapy as ordered. *These medications may be ordered for the postoperative patient, depending on the procedure performed. Antibiotic therapy is a common measure to prevent infection resulting from contamination of the abdominal cavity with gastric contents.*
- Resume oral food and fluids as ordered. Initial feedings may be clear liquids, progressing to full liquids, and then frequent small feedings of regular foods. Monitor bowel sounds and monitor for abdominal distention frequently during this period. *Oral feedings are reintroduced slowly to minimize abdominal distention and trauma to the suture lines.*
- Begin discharge planning and teaching. Consult with a dietitian for instructions and menu planning; reinforce teaching. Teach about potential postoperative complications such as abdominal abscess, or bowel obstruction, their signs and symptoms, and preventive measures.

An emergency procedure used to relieve an intestinal obstruction or perforation is called a *transverse loop colostomy*. During this procedure, a loop of the transverse colon is brought out from the abdominal wall and suspended over a plastic rod or bridge, which prevents the loop from slipping back into the abdominal cavity. The loop stoma may be opened at the time of surgery or a few days later at the patient's bedside. The bridge may be removed in 1 to 2 weeks. Transverse loop colostomies are typically temporary.

In a *Hartmann procedure*, a common temporary colostomy procedure, the distal portion of the colon is left in place and is oversewn for closure. A temporary colostomy may be done to allow bowel rest or healing, such as following tumor resection or inflammation of the bowel. It also may be created following traumatic injury to the colon, such as a gunshot wound. Anastomosis of the severed portions of the colon is delayed because bacterial colonization of the colon would prevent proper healing of the anastomosis. About 3 to 6 months following a temporary colostomy, the colostomy is closed and the colon is reconnected. Patients with temporary colostomies require the same care as patients with permanent colostomies. See Nursing Care of a Patient with a colostomy on page 677.

RADIATION THERAPY

Although radiation therapy is not used as a primary treatment for colon cancer, it is used with surgical resection for treating rectal tumors. Small rectal cancers may be treated with intracavitary, external, or implantation radiation. Rectal cancer has a high rate of regional recurrence following complete surgical resection, particularly when the tumor has invaded tissues outside the bowel wall or regional lymph nodes. Pre- or postoperative radiation therapy reduces the recurrence of pelvic tumors, although the effect of radiation therapy on long-term survival is less clear. Radiation therapy is used preoperatively to shrink large rectal tumors enough to permit surgical removal of the tumor.

CHEMOTHERAPY

Chemotherapeutic agents, such as intravenous fluorouracil (5-FU) and folinic acid (leucovorin), are used postoperatively as adjunctive therapy for colorectal cancer. When combined with radiation therapy, chemotherapy reduces the rate of tumor recurrence and prolongs survival for patients with stage II and stage III rectal tumors. The benefit for colon cancers is less clear, but chemotherapy may be used to reduce its spread to the liver and prevent recurrence. Irinotecan (CPT-11) or oxaliplatin may be used in chemotherapy regimens for colorectal cancer. Further discussion about chemotherapy and nursing implications is included in Chapter 14.

●○● NURSING CARE

Health Promotion

Primary prevention of colorectal cancer is a significant nursing care issue. Teach patients the importance of maintaining an optimal weight and staying physically active. Discuss dietary recommendations provided by the ACS for the prevention of colorectal cancer. These recommendations include decreasing the amount of fat, refined sugar, and red meats in the diet while increasing intake of dietary fiber. Foods that contain high amounts of fiber include raw fruits and vegetables, legumes, and whole-grain products.

Stress the importance of regular health examinations, including digital rectal exams. Discuss recommendations for regular Hemoccult testing of stool after age 40. Include the importance of seeking medical treatment if blood is noted in or on the stool. Teach patients the warning signs for cancer, including those specific to bowel cancer, such as a change in bowel habits.

Assessment

- *Health history:* usual bowel patterns and any recent changes; weight loss, fatigue, decreased activity tolerance; presence of blood in the stool; pain with defecation, abdominal discomfort, perineal pain; usual diet; family history of colon cancer; other specific risk factors such as inflammatory bowel disease or colon polyps
- *Physical assessment:* general appearance; weight; abdominal shape, contour; bowel sounds, abdominal tenderness; stool Hemoccult or guaiac.

Priorities of Care

Nursing care includes providing emotional support, teaching, and direct care before and after diagnostic procedures and surgery and during adjunctive treatments. Priority nursing diagnoses include *Acute Pain, Imbalanced Nutrition: Less Than Body Requirements* and *Anticipatory Grieving. Risk for Sexual Dysfunction* should be considered as a priority diagnosis if a colostomy has been created.

Diagnoses, Outcomes, and Interventions

In planning and implementing care, consider both physical care needs and emotional response to the diagnosis. Because colorectal cancer is often advanced at the time of diagnosis, the prognosis, even with treatment, may be poor. Denial and anger are common. Extensive abdominal surgery and potentially a colostomy may be necessary, and the effects of chemotherapy and radiation therapy can leave the patient fatigued and discouraged. A Case Study & Nursing Care Plan for a patient with colorectal cancer is provided on page 678.

SAFETY ALERT

If an abdominoperineal resection has been performed, alert all care personnel to avoid rectal temperatures, suppository use, or other procedures that could damage sutures.

Acute Pain

Surgery for colorectal cancer is a major procedure and will require aggressive postoperative pain management.

Expected Outcome: Patient will use treatment plan (pharmacologic and nonpharmacologic) to prevent and alleviate discomfort. Patient will consistently verbalize a pain level of 3 or less on a pain scale of 1 to 10 and will not exhibit nonverbal signs associated with uncontrolled pain. Patient will participate in postoperative care such as ambulation, coughing, deep breathing, and use of an incentive spirometer.

- Monitor for adequate pain relief. Use subjective and objective information, including the location, intensity, and character of pain, as well as nonverbal signs, such as grimacing; muscle tension; apparent dozing; changes in pulse or blood pressure; or rapid, shallow respirations. *The patient may assume that pain is to be expected*

NURSING CARE OF THE PATIENT

With a Colostomy

- Assess the location of the stoma and the type of colostomy performed. *Stoma location is an indicator of the section of bowel in which it is located and a predictor of the type of fecal drainage to expect.*
- Assess stoma appearance and surrounding skin condition frequently (see earlier Nursing Care box on page 660). *Assessment of stoma and skin condition is particularly important in the early postoperative period, when complications are most likely to occur and are most treatable.*
- Position a collection bag or drainable pouch over the stoma. *Initial drainage may contain more mucus and serosanguineous fluid than fecal material. As the bowel starts to resume function, drainage becomes fecal in nature. The consistency of drainage depends on the stoma location in the bowel.*
- If ordered, irrigate the colostomy, instilling water into the colon similar to an enema procedure. *The water stimulates the colon to empty.*
- When a colostomy irrigation is ordered for a patient with a double-barrel or loop colostomy, irrigate the proximal stoma. Digital assessment of the bowel direction from the stoma can assist in determining which is the proximal stoma. *The distal bowel carries no fecal contents and does not need irrigation. It may be irrigated for cleansing just prior to reanastomosis.*
- Empty a drainable pouch or replace the colostomy bag as needed or when it is no more than one-third full. *If the pouch is allowed to overfill, its weight may impair the seal and cause leakage.*
- Provide stomal and skin care for the patient with a colostomy as for the patient with an ileostomy (see earlier Nursing Care box on page 660). *Good skin and stoma care is important to maintain skin integrity and function as the first line of defense against infection.*
- Use caulking agents, such as Stomahesive or karaya paste, and a skin barrier wafer as needed to maintain a secure ostomy pouch. This may be particularly important for the patient with a loop colostomy. *The main challenge for a patient with a transverse loop colostomy is to maintain a secure ostomy pouch over the plastic bridge.*
- A small needle hole high on the colostomy pouch will allow flatus to escape. This hole may be closed with a Band-Aid and opened only while the patient is in the bathroom for odor control. *If gas collects, ostomy bags may "balloon" out, disrupting the skin seal.*

Health Education for the Patient and Family

- Prior to discharge, provide written, verbal, and psychomotor instruction on colostomy care, pouch management, skin care, and irrigation for the patient. *Whether the colostomy is temporary or permanent, the patient will be responsible for its management. Good understanding of procedures and care enhances the ability to provide self-care, as well as self-esteem and control.*
- Allow ample time for the patient (and family, if necessary) to practice changing the pouch, either on the patient or a model. *Practice of psychomotor skills improves learning and confidence.*
- If an abdominoperineal resection has been performed, emphasize the importance of using no rectal suppositories, rectal temperatures, or enemas. Suggest that the patient carry medical identification or wear a medical alert tag or bracelet. *These measures are important to prevent trauma to the tissues when the rectum has been removed.*
- The diet for a patient with a colostomy is individualized and may require no alteration from that consumed preoperatively. Dietary teaching should, however, include information on foods that cause stool odor and gas and foods that thicken and loosen stools. Foods that cause these effects on ostomy output are listed next.

Foods That Increase Stool Odor

- Asparagus
- Beans
- Cabbage
- Eggs
- Fish
- Garlic
- Onions
- Some spices

Foods That Increase Intestinal Gas

- Beer
- Broccoli
- Brussels sprouts
- Cabbage
- Carbonated drinks
- Cauliflower
- Corn
- Cucumbers
- Dairy products
- Dried beans
- Peas
- Radishes
- Spinach

Foods That Thicken Stools

- Applesauce
- Bananas
- Bread
- Cheese
- Creamy peanut butter
- Pasta
- Pretzels
- Rice
- Tapioca
- Yogurt

Foods That Loosen Stools

- Chocolate
- Dried beans
- Fried foods
- Greasy foods
- Highly spiced foods
- Leafy green vegetables
- Raw fruits and juices
- Raw vegetables

Foods That Color Stools

- Beets
- Red gelatin

or tolerated or may fear becoming addicted to analgesic medications. Careful questioning and assessment can provide accurate information about pain status, allowing better control of discomfort.

- Ask patient to rate pain using a 0 to 10 pain scale. Document the level of pain. *Pain is a subjective experience. Patients perceive and respond to pain differently. Religion and ethnic background may affect the response to pain.*
- Monitor analgesic effectiveness 30 minutes after administration. Monitor for pain relief and adverse effects. *The method of delivery, dosage, or medication itself may need to be adjusted to provide adequate pain relief.*
- Assess the incision for inflammation or swelling; assess drainage catheters and tubes for patency. *Poorly controlled pain or pain that changes may be related to organ distention from an obstructed nasogastric tube, urinary catheter, or wound drain, or may indicate an infection.*
- Assess the abdomen for distention, tenderness, and bowel sounds. *Intra-abdominal bleeding, peritonitis, or paralytic ileus can cause pain that may be confused with incisional pain.*
- Administer analgesia prior to an activity or procedure. *Adequate pain relief reduces muscle tension, allowing for more comfortable participation in activities.*

Evidence for Nursing Care

The Patient with Colorectal Cancer

Selected resources that nurses may find helpful when planning evidence-based nursing care follow.

- National Cancer Institute. (2013). *Colon cancer treatment (PDQ®). Health professional version.* Retrieved from www.cancer.gov/cancertopics/pdq/treatment/colon/healthprofessional/
- Taylor, C., McGilly, C., & Cummings, R. (2012). Holistic needs assessment following colorectal cancer treatment. *Gastrointestinal Nursing, 10*(9), 42–46.

- Assist with adjunctive comfort measures, such as positioning, diversional activities, management of environmental stimuli, guided imagery, and relaxation techniques. *These measures enhance the effects of analgesia by reducing muscle tension.*
- Splint incision with a pillow, and teach the patient how to self-splint when coughing and deep breathing *to prevent respiratory complications related to fear of pain.*

Imbalanced Nutrition: Less Than Body Requirements

Bowel preparation for diagnostic procedures, surgery, radiation therapy, and chemotherapy place the patient with colorectal cancer at risk for nutritional deficiencies. Fluid and electrolyte replacement is provided following surgery, along with possible parental nutrition (PN) (see Chapter 22). Adequate kilocalorie and nutrient intake are necessary for healing after surgery. Additionally, if the tumor is advanced, metabolic needs may be increased and the appetite decreased.

Expected Outcomes: Patient will maintain fluid and electrolyte balance, avoid complications associated with parenteral nutrition, maintain body mass and weight and normal lab values (transferrin, albumin and electrolytes), and resume a healthy diet.

- Assess nutritional status, using data such as height and weight, skinfold measurements, a body mass index (BMI) calculation (see Chapter 21), and laboratory data including serum albumin level. Refer to a dietitian or nutritionist for dietary management. *The patient who is malnourished before beginning aggressive cancer treatment requires vigorous nutrition management to promote healing.*
- Assess readiness for resumption of oral intake after surgery or procedures using data such as statements of hunger, presence of bowel sounds, passage of flatus, and minimal abdominal distention. *Manipulation of the bowel interrupts peristalsis of the GI tract. It is important to ensure that peristalsis has resumed prior to resumption of oral intake.*
- Monitor and document food and fluid intake. *Documentation helps identify the adequacy of kilocalories and other nutrient intake.*
- Weigh daily. *Weight fluctuation may indicate adequate or inadequate dietary intake.*
- Maintain PN and central intravenous lines as ordered. *Parenteral nutrition prevents tissue catabolism and promotes healing when food intake is disrupted for more than 2 to 3 days.*

CASE STUDY & NURSING CARE PLAN A Patient with Colorectal Cancer

William Cunningham is a 65-year-old retired railroad employee, husband, and father of three grown children. For the past 3 months, Mr. Cunningham has noticed small amounts of blood and occasional mucus in his stools. He has a sensation of pressure in the rectum, and notices that his stools are smaller in diameter, about the size of pencil. After palpating a mass on digital examination of the rectum, the physician orders a colonoscopy. A large sessile lesion is found in the rectum and biopsied. The pathology report shows the lesion to be adenocarcinoma. Mr. Cunningham is scheduled for an abdominoperineal resection and sigmoid colostomy.

ASSESSMENT

Madonna Hart, RN, completes the admission assessment. Mr. Cunningham states that his bowel habits have recently changed, but denies pain or other symptoms. Physical assessment findings include T 36.9°C (98.4°F), P 82 bpm, R 18/min, and BP 118/78 mmHg. He is 178 cm (70 in.) tall and weighs 84 kg (185 lb). Laboratory findings are normal except for the previous pathology report of adenocarcinoma of rectal lesion.

Mr. Cunningham states, "I really don't want a colostomy, but if that is what it takes to get rid of this, I'm ready to get it over with."

DIAGNOSES

- *Acute Pain* related to surgical intervention
- *Risk for Impaired Skin Integrity (Peristomal)* related to fecal drainage and pouch adhesive
- *Risk for Constipation/Diarrhea* related to effects of surgery on bowel function
- *Disturbed Body Image* related to colostomy
- *Risk for Sexual Dysfunction* related to wide rectal incision, radiation therapy, and colostomy

EXPECTED OUTCOMES

- Patient will report pain is within an acceptable range that allows ease of movement and ambulation.
- Patient will perform colostomy care using correct technique.
- Patient will demonstrate willingness to discuss changes in sexual function.
- Patient will wear clothing to enhance physical and emotional self-esteem.

PLANNING AND IMPLEMENTATION

- Provide analgesia as ordered, evaluating its effectiveness.
- Discuss foods that cause odor and gas.
- Teach colostomy care.
- Maintain consistent nursing personnel assignment to facilitate trust.
- Refer to the local United Ostomy Association.
- Provide a list of local medical supply companies for ostomy supplies.
- Provide for privacy when teaching and discussing concerns about ostomy.

EVALUATION

On discharge, Mr. Cunningham is able to empty and rinse out his colostomy pouch. He is changing the pouch and caring for surrounding skin appropriately. Ms. Hart has given him verbal and written instructions on colostomy care. He verbalizes understanding of phantom rectal pain, and the importance of avoiding rectal suppositories. He expresses an understanding of the need to avoid heavy lifting, and the importance of follow-up care. Ms. Hart has referred Mr. Cunningham to a home health agency in his community for further questions and follow-up care.

Clinical Reasoning in Patient Care

1. What is the cause of phantom rectal pain?
2. Why is it important to discuss dietary concerns with a patient with a colostomy, especially odor- and gas-forming foods?
3. Outline a plan to teach Mr. Cunningham how to irrigate a colostomy.
4. Develop a care plan for Mr. Cunningham for the nursing diagnosis *Disturbed Body Image*.

See Evaluating Your Response in Appendix B.

- When oral intake resumes, help the patient develop a meal plan that incorporates food preferences and considers the patient's schedule and environment. *Consideration of likes, dislikes, and circumstances in meal planning promotes adequate intake.*

Grieving

When a bowel resection is performed for colorectal cancer, the patient needs to adjust to the loss of a major body part as well as to the diagnosis of cancer. Even when the prognosis for recovery is good, many people perceive cancer as fatal. Supporting the patient and family during the initial stages of grieving can improve physical recovery as well as psychologic coping and eventual adaptation.

Expected Outcome: Patient and family will express thoughts and feelings about fears and perceived losses related to diagnosis and treatments (colostomy) and progress through the stages of grief to acceptance.

- Work to develop a trusting relationship with the patient and family. *This increases the nurse's effectiveness in helping them work through the grieving process.*
- Listen actively, encouraging the patient and family to express their fears and concerns. Assist to identify strengths, past experiences, and support systems:
  - Demonstrate respect for cultural, spiritual, and religious values and beliefs; encourage use of these resources to cope with losses.
  - Encourage discussion of the potential impact of loss on individual family members, family structure, and family function. Assist family members to share concerns with one another.
  - Refer to cancer support groups, social services, or counseling as appropriate.
  These resources can be used throughout the grieving process.

Risk for Sexual Dysfunction

Colorectal cancer and ostomy surgery increase the risk for sexual dysfunction, defined as a change in sexual function so that it becomes unsatisfying, unrewarding, or inadequate. Physical factors that can lead to sexual dysfunction include disruption of nerves and blood vessels that supply the genitals, radiation therapy, chemotherapy, and other medications prescribed after surgery.

Psychologically, an *ostomate* (patient with an ostomy) experiences an altered body image and may develop low self-esteem. The patient may feel undesirable and fear rejection. He or she may be concerned about odors or pouch leakage during sexual activity. This emotional stress can contribute to sexual dysfunction.

Expected Outcome: Patient and family will express thoughts, feelings, and concerns regarding actual and perceived changes in sexual function. Patient will identify resources available for ongoing support and information related to changes in sexual function.

- Provide opportunities for the patient and family to express feelings about the cancer diagnosis, ostomy, and effects of other treatments. *Encouraging verbalization of feelings about the diagnosis, ostomy, and treatments provides an opportunity to validate that feelings of anger and depression are normal responses to the diagnosis and change in body function.*
- Provide consistent colostomy care. *An accepting attitude and consistent care that provides a secure appliance and controls odor and leakage instill a sense of confidence in the patient.*
- Encourage expression of sexual concerns. Provide privacy and caregivers who have established trust with the patient and family and are comfortable with discussions about sexual concerns. *Sexuality is a very private concern to most people. The patient and family are not likely to express their concerns openly unless trust has been established.*
- Reassure the patient and significant other that the effect of physical illness and prescribed interventions on sexuality usually is temporary. *The patient and partner may misinterpret an initial decrease in libido as evidence that sexual activity will not be possible or resume following recovery.*
- Refer the patient and partner to social services or a family counselor for further interventions. *Patients are often discharged from acute care settings well before concerns about sexual activity surface. Ongoing counseling provides a continuing resource.*
- Arrange for a visit from a member of the United Ostomy Association. *People who are living and coping with an ostomy can provide information and support, helping the new ostomate overcome feelings of isolation and rejection.*

Continuity of Care

During the diagnostic and preoperative periods, provide instruction about the following topics:

- Tests to be performed and preparatory procedures, including dietary restrictions, laxatives, enemas, and food and fluid restrictions just prior to the procedure
- Recommended postprocedure care and potential adverse effects to report
- Preoperative care, such as intestinal preparation and food and fluid restrictions.

If a colostomy is planned, refer the patient to an enterostomal therapist for stoma placement and initial teaching.

Once treatment has been initiated, include the following topics (as appropriate) in teaching for home care:

- Pain management
- Skin care and management of potential adverse effects of radiation therapy and/or chemotherapy. (Refer to Chapter 14 for further discussion of teaching needs related to these therapies.)
- Incision and ostomy care
- Recommended diet
- Follow-up appointments and care.

If the tumor is inoperable or a cure is not anticipated, provide information about pain and symptom management. Discuss the hospice philosophy and available services. Provide a referral to a local hospice or home health department.

Structural and Obstructive Bowel Disorders

Any portion of the intestines may be affected by a structural or obstructive disorder. Defects in the abdominal wall may allow intra-abdominal contents (such as loops of bowel) to protrude, indirectly affecting bowel function. Likewise, obstructions may result from disease of the bowel itself or from obstruction of the bowel lumen by an external force.

THE PATIENT WITH A HERNIA

A *hernia* is a defect in the abdominal wall that allows abdominal contents to protrude out of the abdominal cavity. Trauma, surgery, and increased intra-abdominal pressure caused by such conditions as pregnancy, obesity, weight lifting, or tumors are risk factors for hernia formation.

Pathophysiology

Hernias are classified by location (Figure 24–12 ■), and may be congenital or acquired. Most hernias occur in the groin (inguinal or femoral hernias). Inguinal hernias often are congenital, caused by improper closure of the tract that develops as the testes descend into the scrotum during fetal development. Groin hernias may be acquired, resulting from weakness of fascia in a region called *Hesselbach's area* or from dilation of the femoral ring (e.g., during pregnancy and childbirth). Ventral or incisional hernias of the abdominal wall generally are acquired, caused by weakening of normal abdominal wall musculature. Umbilical hernias also are congenital, and usually are detected in infancy. Hiatal hernias develop in the diaphragm (see Chapter 23).

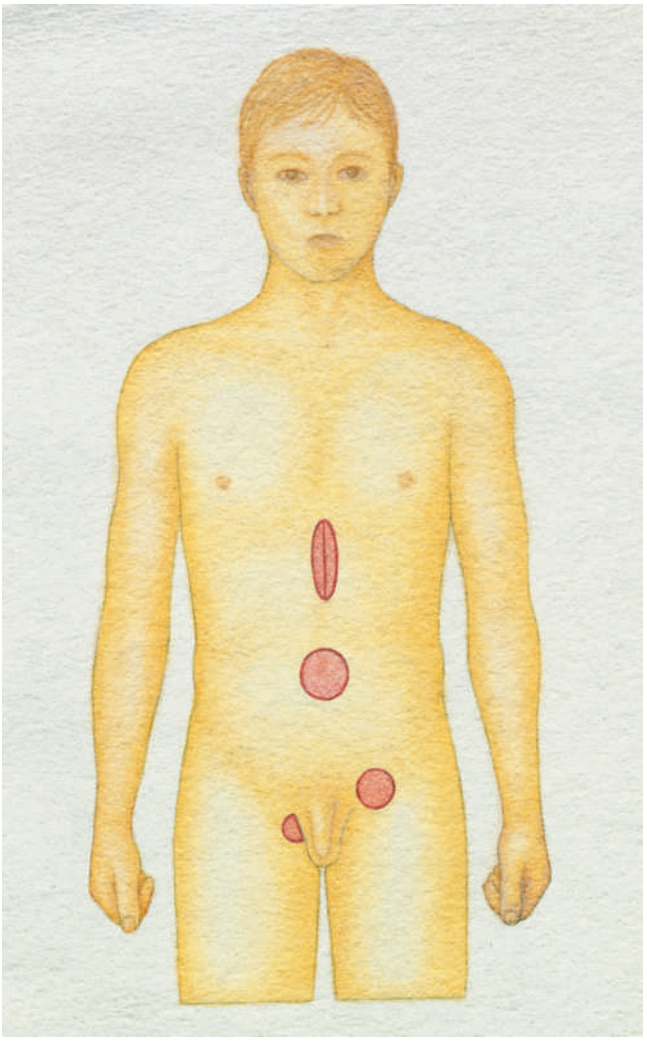

Figure 24–12 ■ An abdominal wall (ventral or incisional) hernia and an inguinal hernia.

INGUINAL HERNIA

Inguinal hernias usually affect males, and may be classified as indirect or direct inguinal hernias. *Indirect inguinal hernias* are caused by improper closure of the tract that develops as the testes descend into the scrotum before birth. A sac of abdominal contents protrudes through the internal inguinal ring into the inguinal canal. It often descends into the scrotum. Although indirect inguinal hernias are congenital defects, they often are not evident until adulthood, when increased intra-abdominal pressure and dilation of the inguinal ring allow abdominal contents to enter the channel.

Direct inguinal hernias are acquired defects that result from weakness of the posterior inguinal wall. Direct inguinal hernias usually affect older adults. *Femoral hernias* are acquired defects in which a peritoneal sac protrudes through the femoral ring. These hernias usually affect women who are pregnant or obese.

Inguinal hernias may produce no symptoms and are discovered during routine physical examination. They may cause a lump, swelling, or bulge in the groin, particularly with lifting or straining. An inguinal hernia may cause sharp pain or a dull ache that radiates into the scrotum. A palpable mass may be present in the groin, although it may be felt only with increased intra-abdominal pressure (as occurs during coughing) and invagination of the scrotum toward the inguinal ring.

UMBILICAL HERNIA

Pregnancy and obesity contribute to the development of umbilical hernias in adults. *Umbilical hernias* may be congenital and evident during infancy, or acquired as the tissue closing the umbilical ring weakens, allowing protrusion of abdominal contents. These hernias are more common in women. Other predisposing factors include multiple pregnancies with prolonged labor, ascites, and large intra-abdominal tumors.

Umbilical hernias tend to enlarge steadily and contain omentum, although they may also contain small or large bowel. The hernia may cause sharp pain on coughing or straining or a dull, aching sensation. Strangulation is a common complication of umbilical hernias.

INCISIONAL OR VENTRAL HERNIA

Incisional or *ventral hernias* occur at a previous surgical incision or following abdominal muscle tears. Inadequate healing of the incision or tear can lead to hernia development. Contributing factors include poor wound closure, postoperative infection, age or debility, obesity, inadequate nutrition, and excess incisional stress caused by vigorous coughing.

Ventral hernias are characterized by a bulge at the incisional site, often noted when the patient pulls to a sitting position from a lying position. Ventral hernias often are asymptomatic, and the risk of incarceration is low because of the size of the defect (see the following section on complications).

Manifestations

Abdominal contents (peritoneum, bowel, and other abdominal organs) can protrude through the abdominal wall to form a sac covered by skin and subcutaneous tissues. In most cases, abdominal contents move into the sac when intra-abdominal pressure increases, then return to the abdominal cavity when pressure returns to normal or when manual pressure is placed on the bulging sac. This is known as a *reducible hernia*.

Complications

The risk for complications is low with a reducible hernia. If the contents of a hernia cannot be returned to the abdominal cavity, it is said to be *incarcerated*. Contents of an incarcerated hernia are trapped, usually by a narrow neck or opening to the hernia. Incarceration increases the risk of complications, including obstruction and strangulation. Obstruction occurs when the lumen of the bowel contained within the hernia becomes occluded, much like the crimping of a hose. A *strangulated hernia* develops when blood supply to bowel and other tissues in the hernia sac is compromised, leading to necrosis. The affected bowel can infarct, leading to perforation with contamination of the peritoneal cavity. Manifestations of a strangulated hernia include severe abdominal pain and distention, nausea, vomiting, tachycardia, and fever.

●○● INTERPROFESSIONAL CARE

The diagnosis of a hernia is made by a physical examination. The patient is examined in a supine or standing position. A bulge may be seen or felt when the patient coughs or bears down. No laboratory or diagnostic testing is usually required, unless bowel obstruction or strangulation is suspected.

Surgical repair, or *herniorrhaphy*, is the usual treatment of hernia. Surgery is generally well tolerated by people of all ages and carries a much lower risk than the complications of incarceration, obstruction, and strangulation. Emergency surgery is indicated for a hernia that is incarcerated, painful, or tender. In a herniorrhaphy, the abdominal wall defect is closed by suturing or with wire or mesh over the defect. If incarceration has occurred or strangulation is suspected, the abdomen is explored at the time of surgery and any infarcted bowel resected. Heavy lifting and heavy manual labor are restricted for approximately 3 weeks after surgery.

When surgery is contraindicated, the patient may be taught to reduce the hernia by lying down and gently pushing against the mass. A binder or truss may be worn to prevent or control the protrusion. An incarcerated hernia should not be reduced by the patient.

●○● NURSING CARE

Assessment

- *Health history:* Ask about manifestations of hernia, such as bulging in the groin or of the abdominal wall when coughing, straining, or moving from lying to standing; pain (abdominal, groin, or scrotal); history of hernia or abdominal surgery.
- *Physical assessment:* Observe for bulging of the abdominal wall or around the umbilicus when raising head and shoulders from supine position; wearing gloves, palpate inguinal region for bulges when the patient coughs or bears down (Valsalva maneuver) while standing.

Priorities of Care

Preoperative assessment and teaching and immediate postoperative care are the primary nursing care needs.

Diagnoses, Outcomes, and Interventions

Herniorrhaphy is generally an uncomplicated procedure, usually performed as same-day surgery. Care is similar to that provided for a patient with an appendectomy.

Risk for Ineffective Gastrointestinal Perfusion

When providing care for a patient with a known hernia, the possibility of obstruction and strangulation must be considered throughout nursing assessments. Although nursing interventions may not be able to prevent these complications, rapid identification of the problem allows timely surgical treatment. Prompt treatment may prevent major complications related to infection and peritoneal contamination by bowel contents.

Expected Outcome: Patient will resume normal bowel sounds within 8 hours after surgery and be free from unusual pain and abdominal distention.

- Assess bowel sounds and abdominal distention at least every 8 hours. *A change in bowel sounds—either cessation of sounds or an onset of hyperactive, high-pitched sounds—may indicate obstruction. With obstruction, abdominal girth may increase.*

SAFETY ALERT

Promptly report any acute increase in abdominal, groin, perineal, or scrotal pain. An abrupt increase in the intensity of pain may indicate bowel ischemia due to strangulation.

- Notify primary care provider if the hernia becomes painful or tender. *Pain and tenderness may indicate incarceration and increased risk for strangulation.*
- If signs of possible obstruction or strangulation occur, notify the physician. Place patient in supine position with the hips elevated and knees slightly bent. Withhold all food and fluids (NPO), and begin preparations for surgery. *This position helps relax abdominal muscles and may facilitate reduction of the hernia. Strangulation or obstruction require immediate surgical intervention.*

Continuity of Care

Include the following topics when teaching patients about hernias and home care:

- Rationale for examining the groin and abdomen for bulges
- The nature of hernias, risk factors, and manifestations
- Surgical intervention for hernias
- How to reduce a hernia if necessary
- The importance of seeking immediate medical intervention for signs of strangulation or obstruction
- The need to notify the physician if upper respiratory infection and cough develop preoperatively (forceful coughing is not recommended postoperatively)
- Postoperative pain management and activity restrictions.

THE PATIENT WITH INTESTINAL OBSTRUCTION

Intestinal obstruction is failure of intestinal contents to move through the bowel lumen. Intestinal obstructions may affect either the large or small bowel. The small intestine is more commonly affected; however, bowel obstructions may also occur in the large intestine. Obstruction is the most common reason for small-bowel surgery.

Pathophysiology

Intestinal obstructions may be either mechanical or functional in nature. *Mechanical* obstructions may be caused by (1) problems

outside the intestine, such as bands of scar tissue (adhesions) or hernias; (2) problems within the intestine, such as tumors or inflammatory bowel disease; or (3) obstruction of the intestinal lumen. The obstruction may be partial or complete. In some mechanical obstructions, such as a strangulated hernia, blood supply to the affected portion of bowel also is impaired, resulting in necrosis of the affected segment. *Functional* obstruction occurs when peristalsis fails to propel intestinal contents although there is no mechanical obstruction. *Adynamic ileus* (also known as *paralytic ileus* or simply *ileus*) is the most common functional obstruction after abdominal surgery. Obstructions are further classified by the portion of intestine affected.

When the intestine is obstructed, gas and fluid accumulate proximal to and within the obstructed segment, distending the bowel. Swallowed air accounts for most of the gas. Ingested fluid, saliva, gastric juice, and pancreatic secretions contribute to accumulated fluid. Water and sodium are drawn into the bowel lumen, contributing to fluid accumulation, distention, and vascular fluid losses. Distention of the bowel lumen interferes with peristaltic movement, leading to atony and further distention. Significant distention of the bowel lumen compromises blood flow to mucosa, eventually leading to necrosis. Gangrenous bowel may perforate with resulting peritonitis. Rapid bacterial growth in the obstructed bowel can lead to sepsis and death.

Significant bowel distention, vomiting, and third spacing of fluids in the bowel and peritoneal cavity can lead to massive loss of fluids and electrolytes with resulting hypovolemia, hypokalemia, renal insufficiency, and shock.

SMALL-BOWEL OBSTRUCTION

Adhesions, or bands of scar tissue, and hernias account for most mechanical small bowel obstructions. In adults, adhesions develop following abdominal surgery or inflammatory processes. Adhesions usually produce a *simple obstruction*, or single blockage in one portion of the intestine (Figure 24–13A ■). The obstruction produced by an incarcerated hernia is a *closed-loop obstruction*, with two different portions of the bowel lumen obstructed (Figure 24–13B).

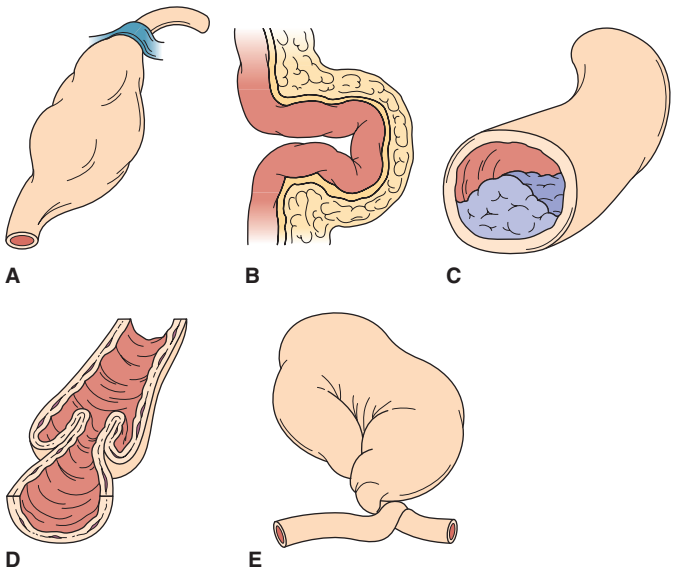

Figure 24–13 ■ Selected causes of mechanical obstruction. A, Adhesions; B, Incarcerated hernia; C, Tumor; D, Intussusception; and E, Volvulus.

Tumors, either intrinsic (of the bowel itself) or extrinsic (of another organ but affecting the bowel because of their size), can progressively occlude the bowel lumen and eventually obstruct it (Figure 24–13C). Other, less common causes of bowel obstruction include intussusception (rare in adults) (Figure 24–13D); volvulus, which is the rotation of loops of bowel about a fixed point (Figure 24–13E); foreign bodies; stricture; and inflammatory bowel disease.

Both volvulus and an incarcerated hernia can cause a *strangulated obstruction*. In a strangulated obstruction, not only is the lumen of the bowel obstructed, but the blood supply to the affected portion is also compromised.

In a functional obstruction or adynamic ileus, peristalsis stops due to either neurogenic or muscular impairment. The bowel lumen remains patent, but contents are not propelled forward. Temporary ileus commonly follows gastrointestinal surgery. It may result from tissue anoxia or peritoneal irritation due to hemorrhage, peritonitis, or perforation of an organ. Other conditions that can precipitate paralytic ileus include renal colic, spinal cord injuries, uremia, and electrolyte imbalances, hypokalemia in particular. In addition, the effects of some narcotics, anticholinergic drugs, and antidiarrheal medications such as diphenoxylate can produce a functional obstruction.

MANIFESTATIONS The manifestations of a small-bowel obstruction vary, depending on the type and level of obstruction and how rapidly it develops. Cramping or colicky abdominal pain that may be intermittent or increasing in intensity is common. Vomiting is common, particularly in high or proximal obstructions, because distention of the lumen stimulates the vomiting center. In a high obstruction, vomitus contains bile and mucus. As bacterial fermentation occurs, vomitus often contains fecal matter, particularly with a low or distal obstruction. Flatus and feces already present in the lower bowel may be expelled early in the obstructive process, but this expulsion ceases as the obstruction continues.

Early in the course of a mechanical obstruction, borborygmi and high-pitched tinkling bowel sounds often are present. Borborygmi may coincide with waves of colicky abdominal pain as the intestine attempts to propel contents past the obstruction. Visible peristaltic waves may be noted in the distended loops of bowel in thin patients. In the later stages, the bowel becomes silent. With a paralytic ileus, bowel sounds are greatly diminished or absent throughout the process. Abdominal distention is minimal with proximal obstructions, but may be pronounced with distal obstruction and paralytic ileus. The abdomen may be tender to palpation as well.

In addition to abdominal and gastrointestinal manifestations, signs of fluid and electrolyte imbalance develop. Hypovolemia can develop rapidly as extracellular fluid is sequestered in the bowel and vomiting occurs. Although early vital signs may be normal, changes are noted as dehydration and hypovolemia develop. The patient becomes tachycardic and tachypneic, and blood pressure falls. Temperature may be elevated. Urine output drops, and signs of hypovolemic shock may be seen. The manifestations of mechanical small-bowel obstruction are outlined with their accompanying pathophysiologic processes in the Pathophysiology Linkage box.

COMPLICATIONS Hypovolemia and hypovolemic shock with multiple organ dysfunction are significant complications of bowel obstruction and can lead to death. Renal insufficiency from hypovolemia can lead to acute renal failure. Pulmonary ventilation

PATHOPHYSIOLOGY LINKAGE

Small-Bowel Obstruction

Manifestation	Pathophysiology
Abdominal pain: intermittent midabdominal, colicky; intensity may initially decrease, then become severe and steady	Peristaltic waves attempt to propel bowel contents past the obstruction. As the bowel becomes increasingly distended, peristalsis is inhibited and pain may decrease in intensity. If unrelieved, distention of bowel lumen impairs mucosal blood supply, leading to ischemia and necrosis. Bowel infarction or perforation may occur, leading to chemical and bacterial peritonitis.
Bowel sounds: initially loud, possibly high pitched; may correspond with waves of abdominal pain; later infrequent or absent	Initial distention of the bowel proximal to the obstruction stimulates peristalsis as the bowel attempts to propel contents past the obstruction. With further distention and resulting electrolyte imbalances, peristalsis is inhibited and bowel sounds become less frequent to inaudible.
Vomiting	Distention of the bowel stimulates the vomiting center of the brain, which, in turn, stimulates the vomiting reflex.
Abdominal distention	Fluid (saliva, gastric juice, bile, pancreatic secretions) and air are trapped in the bowel proximal to the obstruction.
Hypovolemia, electrolyte imbalance	Normal movement of water and sodium from the bowel lumen to the interstitial and intravascular spaces is initially inhibited. Fluids and electrolytes are lost through vomiting. With continued obstruction and bowel distention, sodium and water move from the vascular system into the bowel lumen, further distending it. Intestinal venous return is inhibited, leading to tissue edema and accumulation of fluid and electrolytes within the peritoneal cavity.

may be impaired because abdominal distention elevates the diaphragm and interferes with respiratory processes.

Strangulation associated with incarcerated hernia or volvulus impairs the blood supply to the bowel. Gangrene may rapidly result, causing bleeding into the bowel lumen and peritoneal cavity and eventual perforation. With perforation, bacteria and toxins from the strangulated intestine enter the peritoneum and, potentially, the circulation, resulting in peritonitis and possible septic shock. Strangulation greatly increases the risk of mortality.

LARGE-BOWEL OBSTRUCTION

Obstruction of the large intestine occurs much less frequently than small-bowel obstruction. Although any portion of the colon may be affected, obstruction usually occurs in the sigmoid segment. Cancer of the bowel is the most common cause; other causes include volvulus, diverticular disease, inflammatory disorders, and fecal impaction.

MANIFESTATIONS Constipation and colicky abdominal pain are usual manifestations of large-bowel obstruction. The pain is often deep and cramping; severe, continuous pain may signal bowel ischemia and possible perforation. Vomiting is a late sign, if it occurs at all. The abdomen is distended, with high-pitched, tinkling bowel sounds with rushes and gurgles. On palpation, localized tenderness or a mass may be noted.

COMPLICATIONS If the ileocecal valve between the small and large intestines is competent, distention proximal to the obstruction is limited to the colon itself. This is known as a *closed-loop obstruction*. It can lead to massive colon dilation as the ileum continues to empty gas and fluid into the colon. Increasing pressure within the obstructed colon impairs circulation to the bowel wall. Gangrene, perforation, and peritonitis are potential complications. Massive distention can impair function of the diaphragm, leading to atelectasis. Pressure on the inferior vena cava may impair venous return.

●○● INTERPROFESSIONAL CARE

The management of a bowel obstruction focuses on relieving the pressure and obstruction, and providing supportive care. The intestine is decompressed, and fluid and electrolyte balance is restored. Surgery may be necessary to relieve a mechanical obstruction or if strangulation is suspected.

DIAGNOSIS

Radiologic studies (x-rays and CT scan) are used to confirm the diagnosis of bowel obstruction. Laboratory testing is used to evaluate for the presence of infection and fluid and electrolyte imbalances.

An abdominal x-ray often shows distended loops of intestine with fluid and gas in a small-bowel obstruction. Free air under the diaphragm indicates a perforation. X-ray or CT scan with contrast media may be required to confirm a mechanical obstruction and assess the completeness of the obstruction. Gastrografin is often used to provide contrast rather than barium when a bowel obstruction is suspected.

Laboratory tests used are WBC, serum amylase, serum osmolality, electrolytes, and arterial blood gases. These tests will show the following results with a bowel obstruction:

- *WBC* often shows mild leukocytosis due to an inflammatory response to changes within the obstructed bowel lumen. With strangulation, leukocytosis is marked.
- *Serum amylase levels* may be elevated, particularly when strangulation is present.
- *Serum osmolality* and *electrolyte levels* are affected by fluid and electrolyte losses from vomiting and fluid sequestering in the bowel lumen. With hypovolemia, the serum osmolality and urine specific gravity increase. Potassium and chloride are lost through vomiting, leading to hypokalemia and hypochloremia.
- ABGs may reveal metabolic alkalosis (pH $>$ 7.45, bicarbonate $>$ 24 mEq/L, PCO_2 $>$ 45 mmHg) with small-bowel obstruction due to loss of hydrochloric acid from the stomach.

GASTROINTESTINAL DECOMPRESSION

Most partial small-bowel obstructions are successfully treated with gastrointestinal decompression using a nasogastric tube. Functional obstructions respond to treatment with bowel rest and intestinal decompression as well. Current evidence indicates that a standard nasogastric tube is as effective for gastrointestinal decompression as a longer intestinal tube. Collected fluid and gas are removed using low suction until peristalsis resumes or the obstruction is relieved.

SURGERY

Surgical intervention is required for complete mechanical obstructions as well as for strangulated or incarcerated obstructions of the small intestine. Patients with incomplete mechanical obstruction may also require surgery if the obstruction persists.

Prior to surgery, a nasogastric tube is inserted to relieve vomiting and abdominal distention and to prevent aspiration of intestinal contents. Fluid and electrolyte balance must be restored before surgery. Isotonic intravenous fluids, such as normal (physiologic) saline, Ringer's solution, or other balanced electrolyte solutions, are used. Additional electrolytes may be added to the solution to correct low levels. It is particularly important to correct hypokalemia prior to surgery. Acid–base imbalances are also addressed, often using intravenous acidifiers or alkalinizing agents. If strangulation has occurred, the patient may require plasma or blood replacement. Intravenous broad-spectrum antibiotics are administered prophylactically (see the section on peritonitis).

Simple mechanical obstruction due to adhesions may be relieved using laparoscopic surgery to remove or lyse the scar tissue. A laparotomy may be performed to allow inspection of the small intestine and removal of infarcted or gangrenous tissue. Obstructing tumors are resected, and foreign bodies are removed. Any bowel that appears to be gangrenous is resected, usually followed by an end-to-end anastomosis of remaining intestine. If a large tumor mass or dense adhesions are found, the area of obstruction may be bypassed by anastomosis of proximal small bowel to small or large intestine distal to the obstruction. Nursing care of the patient having bowel surgery is provided in an earlier Nursing Care box on page 675.

Obstructions of the large intestine usually necessitate surgery. The primary goal is to relieve colonic distention and prevent perforation; the secondary goal is to remove the obstructing lesion. In some cases, colonoscopy may be used to relieve the distention. If the patient's condition prohibits major surgery or the obstructing tumor is advanced, laser photocoagulation may be used to enlarge the bowel lumen and a stent inserted to reduce the risk of reobstruction. Removal of the obstructing lesion is the preferred treatment. The proximal and distal bowel segments may be anastomosed, or a permanent colostomy or ileostomy may be required.

●○● NURSING CARE

Health Promotion

Teach health promotion activities, such as increasing dietary fiber intake, maintaining a generous fluid intake, and exercising daily to help prevent constipation and possible large-bowel obstruction, particularly in the older adult. Stress the importance of complying with dietary restrictions (such as avoiding popcorn) for patients who experience repeated small-bowel obstructions.

Assessment

Nurses may be instrumental in the early identification of intestinal obstructions in older adults, the homebound patient, or the institutionalized patient. Early identification and intervention significantly reduce morbidity from bowel obstruction.

- *Health history:* complaints of abdominal pain and bloating, constipation; previous history of bowel obstruction or risk factors such as hernia, inflammatory bowel disease, diverticulosis, or previous abdominal surgery; current medications
- *Physical assessment:* vital signs including orthostatic blood pressure, temperature; skin color, temperature, texture, and turgor; color and moisture of mucous membranes; abdominal shape, contour, bowel sounds, presence of tenderness or masses on palpation.

Priorities of Care

Monitoring for fluid and electrolyte imbalance, acid–base imbalances, hypovolemic shock, perforation, and peritonitis is the focus of care. Managing pain and discomfort before and after surgery for bowel obstruction is a priority.

Diagnoses, Outcomes, and Interventions

In patients with a suspected or confirmed bowel obstruction, frequent assessment for complications is necessary.

Deficient Fluid Volume

Because of the large collection of fluid in the bowel proximal to an obstruction, the accompanying vomiting, and nasogastric suction, the patient with an intestinal obstruction often has a fluid volume deficit. If not corrected promptly, hypovolemic shock, acute renal failure, and multiple organ system dysfunction from poor tissue perfusion may result.

Expected Outcome: Deficient fluid volume in the patient will be prevented as evidenced by normal vital signs, lab values, and absence of physical signs of dehydration (e.g., thirst, change in mental status, decreased urine output, dry skin and mucous membranes, low pulmonary artery pressures, cardiac output, and central venous pressure).

- Monitor vital signs, pulmonary artery pressures, cardiac output (CO), and central venous pressure (CVP) hourly. *A decrease in blood pressure, tachycardia, and tachypnea may indicate hypovolemia. Although invasive, hemodynamic parameters such as pulmonary artery pressures, CO, and CVP allow accurate assessment of fluid volume status.*
- Measure urinary output hourly and nasogastric drainage every 2 to 4 hours. *A urinary output of 30 mL/h or more usually indicates an adequate glomerular filtration rate (GFR), another indicator of fluid volume. Nasogastric output provides a tool for evaluating fluid replacement needs.*

SAFETY ALERT

Promptly report urine output of less than 30 mL/h. This often indicates hypovolemia and an increased risk for shock and acute renal failure.

- Maintain intravenous fluids and blood volume expanders as ordered. The amount of fluid administered is calculated to meet ongoing fluid needs and replace previous and current losses. *Restoration and maintenance of blood volume are necessary to maintain cardiac output and tissue and organ perfusion.*

- Evaluate for distention every 4 to 8 hours. Mark the level of measurement on the abdomen. *An increase in abdominal girth indicates increasing intestinal distention.*
- Notify the physician of changes in status. *Changes in vital signs, pain, and signs of increasing distention can indicate the need for immediate surgical intervention.*

Ineffective Gastrointestinal Perfusion

Perfusion of the intestinal wall and mucosa may be impaired by the obstructive process itself (e.g., strangulation or volvulus) or by significant intestinal distention. The goal is to maintain tissue perfusion and promote normal peristalsis and bowel elimination.

Expected Outcome: Stable perfusion of the patient's intestinal wall will be restored and demonstrated by vital signs within normal range, hourly urine output of 30 mL or greater, resumption of bowel sounds, and a soft, nontender abdomen without distention.

- Monitor vital signs hourly. Assess peripheral pulses, skin color, temperature, and capillary refill. *Cardiovascular assessment is vital to detect early signs of hypovolemic shock resulting from sequestering large volumes of fluid in the intestines. Hypovolemia and shock can convert mild bowel ischemia to infarction as the blood supply to the tissue falls.*
- Monitor urine output hourly. Report output of less than 30 mL/h. *Urine output is a good indicator of the GFR and tissue perfusion. The urine output often falls before vital sign changes are apparent in hypovolemia.*
- Monitor temperature at least every 4 hours. *An elevated temperature may be an early indication of sepsis from bowel perforation as a result of gangrene.*
- Frequently assess pain. *A change in the character of pain or a rapid increase in its intensity may signal bowel infarction or perforation.*
- Maintain NPO status until peristalsis resumes. *Enteral food or fluids may increase distention and bowel ischemia. They also are restricted until the possibility of perforation is eliminated.*

Ineffective Breathing Pattern

Significant abdominal distention from a bowel obstruction can cause the diaphragm to flatten, impairing pulmonary ventilation. Following surgery, splinting of abdominal muscles to avoid pain can lead to shallow respirations. These factors, plus the risk of aspiration of gastrointestinal contents during vomiting, place the patient at high risk for respiratory complications, particularly with a small-bowel obstruction.

Expected Outcome: Patient will maintain airway patency and adequate gas exchange as evidenced by ease of breathing, normal respiratory rate and rhythm, normal lung sounds on auscultation, pulse oximetry at patient's baseline, arterial blood gases within normal limits, and stated absence of dyspnea.

- Assess respiratory rate, pattern, and lung sounds at least every 2 to 4 hours. *Tachypnea, shortness of breath, or apparent dyspnea may be early signs of respiratory compromise. Diminished breath sounds, particularly in the bases of the lungs, or crackles indicate poor lung expansion and possible impaired ventilation.*
- Monitor ABG results for possible effects of altered respiratory status. *Tachypnea may lead to respiratory alkalosis as excess carbon dioxide is eliminated. Conversely, impaired chest expansion can lead to respiratory acidosis because of alveolar hypoventilation.*
- Elevate the head of the bed. *Elevating the head of the bed reduces the work of breathing and improves alveolar ventilation by reducing the pressure of abdominal distention on the diaphragm.*
- Provide a pillow or folded bath blanket to use in splinting the abdomen while coughing postoperatively. *Splinting abdominal muscles and incisions improves the ease and effectiveness of coughing postoperatively.*
- Maintain nasogastric or intestinal tube patency. *Maintaining gastrointestinal suction helps reduce abdominal distention and prevent aspiration associated with vomiting.*
- Encourage use of incentive spirometer or other assistive device hourly. *These devices encourage deep breathing, opening distal airways and preventing atelectasis.*
- Contact respiratory therapy as indicated. *The respiratory therapist may suggest or perform additional measures to maintain effective pulmonary ventilation.*
- Provide good oral care at least every 4 hours. *Dehydration and nasogastric suction dry the mucous membranes of the mouth and throat, increasing the risk of bacterial growth. Many respiratory infections result from aspirated organisms.*

Continuity of Care

Include the following topics when teaching the patient with intestinal obstruction in preparation for home care:

- Wound care
- Activity level, return to work, and any other recommended restrictions
- Recommended follow-up care
- Care of temporary colostomy (if appropriate) and planned reanastomosis
- For recurrent obstructions, their cause, early identification of manifestations, and possible preventive measures.

Anorectal Disorders

Anorectal lesions include hemorrhoids, a normal condition common to many adults, that may become enlarged and painful; anal fissure; anorectal abscess; anorectal fistulas; and pilonidal disease.

THE PATIENT WITH HEMORRHOIDS

Rectal bleeding is a common symptom for referral to colorectal clinics and in all cases requires examination, diagnosis, and treatment but is most commonly associated with anorectal conditions such as hemorrhoids. The anus and anal canal contain two superficial venous plexuses with the hemorrhoidal veins. When pressure on these veins is increased or venous return impeded, they can develop *varices*, or varicosities, becoming weak and distended. This condition is commonly known as *hemorrhoids*, or *piles.* When asymptomatic, hemorrhoids are considered to be a normal condition found in all adults.

Pathophysiology and Manifestations

Hemorrhoids develop when venous return from the anal canal is impaired. Straining to defecate increases venous pressure and is the

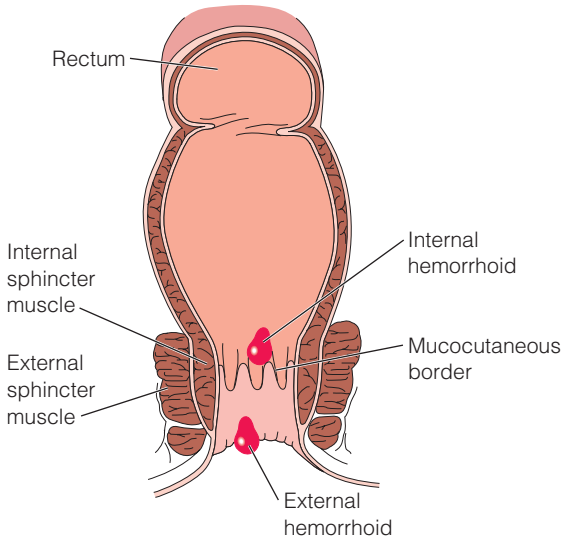

Figure 24–14 ■ The location of internal and external hemorrhoids.

most common cause of distended hemorrhoids. Pregnancy increases intra-abdominal pressure, raising venous pressure, and is another cause of hemorrhoids. Other factors that may contribute to symptomatic hemorrhoids include prolonged sitting, obesity, chronic constipation, and a low-fiber diet.

Hemorrhoids are classed as either internal or external. *Internal* hemorrhoids affect the venous plexus above the mucocutaneous junction of the anus (Figure 24–14 ■). Internal hemorrhoids rarely cause pain, usually presenting with bleeding. Bleeding from internal hemorrhoids is bright red and unmixed with the stool. It can vary in quantity from streaks on toilet tissue to enough to color the water in the toilet. Recurrent bleeding of internal hemorrhoids may be sufficient to cause anemia. Mucous discharge and a feeling of incomplete evacuation of stool also may be manifestations of internal hemorrhoids.

External hemorrhoids affect the inferior hemorrhoidal plexus below the mucocutaneous junction. Bleeding is rare with external hemorrhoids. Anal irritation, a feeling of pressure, and difficulty cleaning the anal region may be manifestations of external hemorrhoids.

As they enlarge, hemorrhoids may prolapse or protrude through the anus. Initially, prolapse occurs only with defecation and the hemorrhoids spontaneously regress back into the anal canal. Eventually, the patient may need to manually replace internal hemorrhoids after defecation, or they may become permanently prolapsed, in which case replacement is not possible. Manifestations of permanently prolapsed hemorrhoids include mucous discharge and clothing soilage.

Normal hemorrhoids are not painful. Prolapsed hemorrhoids may become strangulated as a result of congestion and edema, leading to thrombosis. Hemorrhoidal thrombosis causes extreme pain and may lead to infarction of skin and mucosa overlying the hemorrhoid. Internal hemorrhoids associated with portal hypertension in liver disease may bleed profusely if ruptured.

A *thrombosed external hemorrhoid* is a thrombosis of the subcutaneous external hemorrhoidal veins of the anal canal, rather than a true hemorrhoid. It appears as a painful bluish hematoma beneath the skin and typically occurs following a sudden increase in venous pressure, for example, heavy lifting, coughing, or straining. Pain is significant at onset but gradually subsides. Spontaneous rupture with bleeding may occur. Thrombosed external hemorrhoids resolve without intervention.

●○● INTERPROFESSIONAL CARE

Because hemorrhoids are a normal condition, management is conservative unless complications such as permanent prolapse or thrombosis occur.

DIAGNOSIS

Hemorrhoids are diagnosed by the patient's history and by examination of the anorectal area. External hemorrhoids can be seen on visual inspection, especially if thrombosed. The patient is asked to strain (Valsalva's maneuver) during the examination to detect prolapse. Internal hemorrhoids are usually not palpable or tender on digital examination of the rectum. Anoscopic examination is used to detect and evaluate internal hemorrhoids. For this exam, a speculum or endoscope is introduced into the anus to provide visual inspection of the tissues. Additional diagnostic examinations include testing of stool for occult blood and sigmoidoscopy, performed to rule out cancer of the colon or rectum, which may aggravate hemorrhoidal manifestations or produce similar manifestations. If liver disease with portal hypertension is suspected, liver function studies are ordered.

MEDICATIONS

Bulk-forming laxatives such as psyllium seed (Metamucil) or stool softeners such as docusate sodium (Colace) may be prescribed to improve constipation and reduce straining as well. Suppositories and local ointments such as Preparation H or Nupercaine have an anesthetic and astringent effect, reducing discomfort and irritation of surrounding tissues. They have little or no effect on the hemorrhoid itself. Warm sitz baths, bed rest, and local astringent compresses may be recommended to reduce the swelling of edematous prolapsed hemorrhoids after digital reduction.

NUTRITION

Hemorrhoids that are not permanently prolapsed or acutely thrombosed generally are treated conservatively. A high-fiber diet and increased water intake to increase stool bulk, improve its softness, and reduce straining are effective for most patients with internal or external hemorrhoids.

SCLEROTHERAPY

Hemorrhoids that are permanently prolapsed, are thrombosed, or produce significant manifestations may be treated more aggressively. *Sclerotherapy* involves injecting a chemical irritant into tissues surrounding the hemorrhoid to induce inflammation and eventual fibrosis and scarring. It is used to treat recurrent bleeding and early prolapse of internal hemorrhoids. The treatment produces minimal pain. Enlarged or prolapsing hemorrhoids also may be treated with rubber band ligation. A rubber band is placed snugly around the hemorrhoidal plexus and surrounding mucosa, causing the tissue to necrose and slough within 7 to 10 days. Treatment is limited to one hemorrhoidal complex at a time, so repeat treatments may be necessary. Pain should be minimal if the band is placed appropriately; persistent pain following band ligation may signal an infection. Bleeding can occur as the hemorrhoid sloughs. Other procedures used to treat hemorrhoids include cryosurgery, in which hemorrhoids are necrosed by freezing with a cryoprobe; infrared photocoagulation; or electrocoagulation.

HEMORRHOIDECTOMY

Patients with chronic manifestations, permanent prolapse, chronic bleeding and anemia, or painful thrombosed hemorrhoids may be

treated surgically with a *hemorrhoidectomy*. In this procedure, hemorrhoids are surgically excised, leaving normal skin and surrounding tissues. This procedure may use conventional techniques or a laser to remove both internal and external hemorrhoids. Few complications are associated with hemorrhoidectomy.

●○● NURSING CARE

Primary prevention of symptomatic hemorrhoids involves education of patients of all ages. Stress the importance of maintaining an adequate intake of dietary fiber, a liberal fluid intake, and regular exercise to maintain stool bulk, softness, and regularity. Discuss the need to respond to the urge to defecate rather than postponing defecation. Teach appropriate constipation management, including the use of bulk-forming laxatives.

Most patients with hemorrhoids are treated in community settings where the primary nursing focus is educational. Discuss the appropriate use of OTC preparations and sitz baths for the relief of minor hemorrhoidal manifestations. If necessary, teach patients how to reduce prolapsed hemorrhoids digitally.

Teach manifestations of possible hemorrhoidal complications, such as chronic bleeding, prolapse, and thrombosis. Stress the need to seek medical evaluation if manifestations persist. Discuss the link between manifestations of hemorrhoids and colorectal cancer, and urge the patient to seek medical intervention for persistent, unresolved, or progressive manifestations.

When a hemorrhoidectomy is performed, the patient requires more direct nursing intervention. Postoperative care of the patient with perianal surgery is outlined in Box 24–3. Anal packing may be in place for the first 24 hours following the procedure. When removed, observe the patient closely for bleeding. Pain is a common postoperative problem. Although the operative procedure is minor, postoperative discomfort can be significant because the anal region is richly innervated and muscle spasms may occur. In addition to systemic analgesics, sitz baths usually are ordered. These not only help promote relaxation and reduce discomfort but also clean the anal area. Use of a rubber ring or donut device minimizes pressure on the surgical site while the patient sits in the bath.

Stool softeners, adequate fluids, and analgesia before defecation can reduce anxiety and discomfort. Adequate cleaning following defecation, usually with a sitz bath, is vital.

Whether caring for a patient with hemorrhoids or a hemorrhoidectomy, consider the following nursing diagnoses:

- *Acute* or *Chronic Pain* related to inflamed anal tissues
- *Constipation* related to dietary habits and/or delay of defecation
- *Risk for Infection* related to disruption of anal tissue.

BOX 24–3 Perianal Postoperative Care

ASSESSMENT
- Monitor vital signs every 4 hours for 24 hours.
- Inspect rectal dressing every 2 to 3 hours for 24 hours.
- Monitor urinary output.

PAIN CONTROL
- Assist to position of comfort, usually side-lying.
- Provide analgesics as prescribed.
- Keep fresh ice packs over the rectal dressing as ordered.
- Assist with sitz bath three to four times per day.
- Provide a flotation pad for use when sitting.

ELIMINATION
- Give stool softeners as prescribed.
- Give an analgesic before the first postoperative bowel movement if possible.
- When tolerated, encourage fluid intake of at least 2000 mL/day.

PATIENT AND FAMILY TEACHING
- Take sitz bath after each bowel movement for 1 to 2 weeks after surgery.
- Drink at least 2 quarts of fluid per day.
- Eat adequate dietary fiber, and exercise moderately.
- Take stool softeners as prescribed.
- Report to the physician the following symptoms: rectal bleeding, continued pain on defecation, fever greater than 38.3°C (101°F), purulent rectal drainage.

THE PATIENT WITH AN ANORECTAL LESION

Unlike the rectum, which is relatively insensitive to pain, the anal canal is richly supplied with sensory nerves and highly sensitive to painful stimuli. Lesions of the anorectal area may cause significant pain, particularly with defecation. Infection is a potential complication of anorectal lesions because of contamination by fecal bacteria. The superior boundary of the anal canal (the anorectal juncture or pectinate line) contains 8 to 12 anal crypts where anorectal abscesses or fistulas can form. Lesions of the anorectal area include fissures, abscesses, fistulas, and pilonidal disease.

Anal Fissure

Anal fissures or ulcers occur when the epithelium of the anal canal over the internal sphincter becomes denuded or abraded. Irritating diarrheal stools and tightening of the anal canal with increased sphincter tension are frequent causes of anal fissures. Other factors that may contribute to their development include childbirth trauma, habitual cathartic use, laceration by a foreign body, and anal intercourse. Chronic inflammation and infection of surrounding tissues accompanies an anal fissure.

Patients with anal fissures typically have periods of exacerbation and remission. Because they occur below the mucocutaneous line, anal fissures are painful. The pain occurs with defecation and may be described as tearing, burning, or cutting. Bright red bleeding is noted with a bowel movement. Bleeding is typically minor and noted on toilet tissue. Because of fear of defecation, the patient may develop constipation, which further disrupts normal bowel habits and aggravates manifestations.

The diagnosis of anal fissure is made on gentle digital examination of the anal canal and anoscopy using a small anoscope. Treatment is usually conservative, involving dietary changes to increase fiber intake and stool bulk, increased fluid intake, and use of bulk-forming laxatives. A topical agent such as hydrocortisone cream may be prescribed. Surgical intervention with an internal sphincterotomy, an incision into the internal sphincter to increase its diameter, is considered when the fissure does not heal with medical intervention.

Anorectal Abscess

Invasion of the pararectal spaces by pathogenic bacteria can lead to an *anorectal abscess*. Commonly caused by infection that extends

from the anal crypt into a pararectal space, the abscess may appear small but often contains a large amount of pus. Multiple pathogens may be present, including *Escherichia coli*, *Proteus*, streptococci, and staphylococci. Other factors that may contribute to the development of an anorectal abscess include infection of a hair follicle, sebaceous gland, or sweat gland, and abrasions, fissures, or anal trauma. The incidence of anorectal abscess is higher in men.

Pain is the primary manifestation of an anorectal abscess. Sitting or walking may aggravate the pain, but it is unrelated to defecation. External swelling, redness, heat, and tenderness are apparent on examination. With a deeper abscess, swelling may not be visible, but the abscess is palpable on digital examination.

If the abscess either does not drain spontaneously or is not drained surgically, adjacent anatomic spaces will be affected. Systemic sepsis is also a potential complication.

Incision and drainage is the treatment of choice for an anorectal abscess because it rarely resolves with antibiotic therapy alone. This treatment often leads to a persistent fistula, which is surgically closed after the infection has cleared.

Anorectal Fistula

A fistula is a tunnel or tubelike tract with openings at each end. *Anorectal fistulas* have one opening in the anal canal with the other usually found in perianal skin. Most occur spontaneously or as a result of anorectal abscess drainage. Crohn's disease is a predisposing factor to fistula development.

The primary manifestation of an anorectal fistula is intermittent or constant drainage or discharge, which may be purulent. This may be accompanied by local itching, tenderness, and pain associated with defecation.

Digital and anoscopic examination with gentle probing of the fistula tract are used to establish the diagnosis. Although some fistulas may heal spontaneously, the treatment of choice is a fistulotomy. The primary opening of the fistula is removed, and the tract is opened to allow it to heal by secondary intention, from the inside outward. If the sphincter is involved, a two-stage operation may be done to preserve the muscle and prevent fecal incontinence.

Pilonidal Disease

The patient with *pilonidal disease* has an acute abscess or chronic draining sinus in the sacrococcygeal area. Underlying the abscess or sinus is a cyst with granulation tissue, fibrosis, and, often, hair tufts. This disease usually affects young hirsute (hairy) males and is probably due to hair entrapment in deep tissues of the sacrococcygeal area. Some researchers believe that it is a congenital disorder.

The lesion of pilonidal disease is generally asymptomatic unless it becomes acutely infected. Manifestations of acute inflammation accompany infection, including pain, tenderness, redness, heat, and swelling of the affected area. Purulent discharge may be noted from one or more sinuses or openings in the midline.

The preferred treatment option for pilonidal disease is incision and drainage. The sinus tract and underlying cyst are excised and closed by either primary- or secondary-intention healing. The patient may be instructed to remove hair from the area routinely by shaving or using a depilatory to prevent further hair entrapment and recurrence of the problem.

●○● NURSING CARE

Patients with anorectal disorders are often treated in the community, and the primary nursing responsibility is education. Teach the importance of maintaining a high-fiber diet and liberal fluid intake to increase stool bulk and softness and thereby decrease discomfort with defecation. Stress the importance of responding to the urge to defecate to prevent constipation.

Following surgical treatment of any of these disorders, teach the patient to keep the perianal region clean and dry. If a dressing is in place, instruct to avoid soiling it with urine or feces during elimination. Following removal of the dressing, teach to clean the area gently with soap and water following a bowel movement. Discuss the use of sitz baths for cleaning and comfort. Suggest taking an analgesic if necessary prior to defecation, but caution that some analgesics may promote constipation. Teach manifestations of infection or other possible complications to report to the physician. If an antibiotic has been prescribed, provide written and verbal instructions about its use, its desired and possible adverse effects, and their management.

CHAPTER HIGHLIGHTS

- **Disorders of intestinal absorption and bowel elimination can affect functional elimination status.**
- **Bowel function can be affected by inflammations, infections, tumors, obstructions, or changes in structure.**
- **Patients with intestinal disorders often face extensive diagnostic testing, surgery, and permanent changes in physical appearance and lifestyle.**
- **Nursing care is directed toward meeting the patient's physiologic needs, providing emotional support, and educating the patient to adapt to changes in lifestyle.**
- Disorders of intestinal motility include diarrhea, constipation, irritable bowel syndrome, and fecal incontinence. Diarrhea is a manifestation of many other bowel disorders, including lactose intolerance, infections, and inflammatory diseases of the bowel. Constipation may be a primary problem (especially for the older adult) or a manifestation of another disorder. Irritable bowel syndrome (IBS) is a functional disorder without any identifiable organic cause. Fecal incontinence is usually considered to be the manifestation of a disorder rather than a disorder itself.

- Appendicitis is an acute inflammation of the vermiform appendix, manifested by abdominal pain that localizes in the right lower quadrant of the abdomen. On palpation, localized and rebound tenderness is present at McBurney's point. It is treated most often with an appendectomy.
- Peritonitis (inflammation of the peritoneum from infection or chemical irritant) is a serious complication of a wide variety of acute abdominal disorders, including perforated ulcer, ruptured appendix, abdominal trauma or surgery, or necrotic bowel. Complications may be life threatening; without prompt and effective treatment, septicemia and septic shock may occur.
- Gastroenteritis, which may result from bacterial or viral infections, parasites, or toxins, is often the result of consuming contaminated water or food. Manifestations include nausea and vomiting, diarrhea, and abdominal discomfort.
- Nurses provide education to help prevent protozoal infections (such as giardiasis, amebiasis, and coccidiosis) and helminthic infestations (roundworms, flukes, or tapeworms). Both types of bowel disorders are treated with medications.
- Chronic inflammatory bowel disease (IBD) includes two separate but closely related conditions: ulcerative colitis and Crohn's disease. Ulcerative colitis affects the mucosa and submucosa of the colon and rectum. Crohn's disease can affect any part of the GI tract, but usually involves the terminal ilium and ascending colon. Diarrhea is common to both disorders. A colectomy (removal of the large colon) may be performed to treat ulcerative colitis; an ileostomy (artificial opening from the abdomen to the ileum) may be performed to treat Crohn's disease.
- Diverticula are saclike projections of mucosa through the muscular layer of the colon. When these sacs become inflamed, the condition is labeled diverticulitis. A diet high in fiber is recommended for self-care.
- Malabsorption syndromes, in which the intestinal mucosa ineffectively absorbs nutrients, may be caused by a wide variety of diseases. However, three common malabsorption disorders in adults are celiac disease, lactase deficiency with resulting lactose intolerance of milk and milk products, and short bowel syndrome (a condition that can develop following resection of the small bowel).
- Malignant tumors of the lower bowel are the second leading cause of death from cancer. The risk of colon cancer may be reduced through health-related screenings and a diet high in fruits, vegetables, folic acid, and calcium. Rectal bleeding is the most common initial manifestation but may not occur until the cancer is well advanced. Surgical treatment is through resection of the bowel, accompanied by a colostomy for diversion of fecal contents.
- A hernia is a defect in the abdominal wall that allows intra-abdominal contents to protrude out of the abdominal cavity. Hernias may follow trauma, surgery, and increased intra-abdominal pressure (e.g., from pregnancy or obesity). Hernias may be congenital or acquired, and may be inguinal, umbilical, incisional, or ventral.
- Intestinal obstructions occur when intestinal contents cannot move through the lumen of the bowel. They may occur in either the large or small intestine, may be partial or complete, and are caused by many factors, ranging from surgical ileus following abdominal surgery to adhesions or tumors.
- Anorectal disorders include hemorrhoids, anorectal lesions (fissures, abscess, and fistula), and pilonidal disease. These disorders are painful and pose a risk for bleeding and infection.

TEST YOURSELF NCLEX-RN® REVIEW

1. A patient has been experiencing diarrhea for the past week. What should the nurse do first when caring for this patient?
   1. Ask the patient to describe the number and character of daily stools.
   2. Advise the patient to abstain from all oral intake until the diarrhea subsides.
   3. Recommend an over-the-counter antidiarrheal preparation such as Pepto-Bismol.
   4. Question the patient about possible exposure to an enterotoxin or protozoal infection.

2. A patient comes into the emergency department with manifestations of appendicitis. What is the highest priority when caring for this patient?
   1. Withhold all food and fluids.
   2. Perform preoperative skin preparation.
   3. Insert saline lock for intravenous pain medication.
   4. Teach postoperative deep breathing, coughing, and leg exercises.

3. A patient with inflammatory bowel disease is prescribed sulfasalazine (Azulfidine). What should the nurse teach the patient about taking this medication?
   1. Take vitamin C while on the drug.
   2. Take the drug on an empty stomach.
   3. Use a sunscreen while taking the drug.
   4. Limit fluid intake to 1500 mL per day or less.

4. A patient is experiencing frequent large, fatty, foul-smelling stools. What additional information should the nurse obtain from the patient?
   1. known family history of colorectal cancer
   2. the relationship of episodes to particular foods
   3. history of alternating diarrhea and constipation
   4. possible exposure to enterotoxins in food or water

5. A patient has heard of several friends being diagnosed with colon cancer and does not want to develop the same health problem. What should the nurse recommend to this patient? (Select all that apply.)
   1. Obtain regular exercise.
   2. Maintain a healthy weight.
   3. Ingest two servings of red wine every day.
   4. Obtain recommended screening after age 50.
   5. Consume a diet high in fruit and vegetables and low in saturated fat and red meat.

6. The nurse identifies the diagnosis *Deficient Fluid Volume* as appropriate for a patient with a nasogastric tube for gastric decompression. Which actions should the nurse perform to support this diagnosis? (Select all that apply.)
   1. Measure abdominal girth every 4 to 8 hours.
   2. Provide the patient with generous amounts of oral fluids.
   3. Keep an accurate record of intake and output every 2 to 4 hours.
   4. Document the amount and color of nasogastric tube drainage every shift.
   5. Listen to bowel sounds prior to checking the placement of the nasogastric tube.

7. A patient has developed a paralytic ileus following a recent abdominal surgery. What is the most important nursing action when caring for this patient?
   1. Monitor bowel sounds every hour.
   2. Maintain the patient on strict bed rest.
   3. Ensure nasogastric tube is functioning.
   4. Ensure that the patient is given a clear liquid diet.
8. The nurse is preparing discharge diet teaching for a patient with diverticulosis. Which foods should the nurse teach the patient to refrain from eating?
   1. soup
   2. apples
   3. raspberries
   4. whole-wheat bread
9. An older patient is experiencing constipation. What should the nurse teach this patient to help with this health problem? (Select all that apply.)
   1. Eat a bran cereal for breakfast.
   2. Take bisacodyl (Dulcolax) daily.
   3. Eat plenty of fresh fruits and vegetables daily.
   4. Eat whole-wheat bread instead of white bread.
   5. Drink six to eight glasses of nonalcoholic fluid daily.
10. The nurse is caring for a patient with a small-bowel obstruction. Which action is the highest priority for this patient?
    1. Maintain nasogastric suction.
    2. Administer prescribed analgesics.
    3. Keep strict intake and output records.
    4. Place the patient in semi-Fowler's position.

25 Nursing Care of Patients with Gallbladder, Liver, and Pancreatic Disorders

LEARNING OUTCOMES

1. Describe the pathophysiology of commonly occurring disorders of the gallbladder, liver, and exocrine pancreas.
2. Use knowledge of normal anatomy and physiology to understand the manifestations and effects of biliary, hepatic, and pancreatic disorders.
3. Relate changes in normal assessment data to the pathophysiology and manifestations of gallbladder, liver, and exocrine pancreatic disorders.

CLINICAL COMPETENCIES

1. Assess health status of patients with gallbladder, liver, or pancreatic disease, eliciting patient values, preferences, and expressed needs when assessing, planning, and implementing care.
2. Monitor for, recognize, document, and report expected and unexpected manifestations in patients with gallbladder, liver, or pancreatic disease.
3. Integrate interprofessional measures into nursing care and teaching of the patient with a gallbladder, liver, or pancreatic disorder.
4. Provide safe, patient-centered nursing care for the patient who has surgery of the gallbladder, liver, or pancreas.
5. Integrate psychosocial, cultural, and spiritual considerations into the plan of care for a patient with a gallbladder, liver, or pancreatic disorder.
6. Use evidence-based practice, technology, and information management tools to develop, implement, evaluate, and, as needed, revise the plan of care for patients with disorders of the gallbladder, liver, or pancreas.
7. Provide appropriate evidence-based patient and family teaching to promote, maintain, and restore functional health status for patients with gallbladder, liver, and pancreatic disorders.

KEY CONCEPTS

- Gallbladder, liver, and exocrine pancreatic disorders may occur as primary disorders, or develop secondarily to other disease processes.
- The functioning of one organ frequently affects that of another. Duct inflammation or obstruction, and changes in the multiple functions of these organs, can cause significant health effects.
- Patients with a gallbladder, liver, or pancreatic disorder may experience pain, metabolic and nutritional disturbances, and altered body image. Nursing care addresses physiologic, emotional, and psychosocial needs of the patient and family.

Gallbladder Disorders

Altered bile flow through the hepatic, cystic, or common bile duct is a common problem and a frequent cause of hospitalization. It often leads to inflammation and other complications. Gallstones are the most common cause of obstructed flow. Tumors and abscesses also can obstruct bile flow.

THE PATIENT WITH GALLSTONES

Cholelithiasis is the formation of stones (*calculi* or *gallstones*) within the gallbladder or biliary duct system. Cholelithiasis is a common problem in the United States, affecting more than 10% of men and 20% of women by age 65 (Papadakis & McPhee, 2013). Box 25–1 lists risk factors for gallstones. The incidence of gallstones varies among people of different ethnic backgrounds; see the accompanying Focus on Cultural Diversity box.

Physiology Review

Normally, bile is formed by the liver and stored in the gallbladder. Bile contains bile salts, bilirubin, water, electrolytes, cholesterol, fatty acids, and lecithin. In the gallbladder, some of the water and electrolytes are absorbed, further concentrating the bile. Food entering the intestine stimulates the gallbladder to contract and release bile through the common bile duct and sphincter of Oddi into the intestine. The bile salts in bile increase the solubility and absorption of dietary fats.

Pathophysiology and Manifestations

CHOLELITHIASIS

Gallstones form when several factors interact: abnormal bile composition, biliary stasis, and inflammation of the gallbladder. Most gallstones (80%) consist primarily of cholesterol; the rest contain a mixture of bile components. Excess cholesterol in bile is associated with obesity, a high-calorie and high-cholesterol diet, and drugs that lower serum cholesterol levels. When bile is supersaturated with cholesterol, it can precipitate out to form stones. Biliary stasis, or slowed emptying of the gallbladder, contributes to cholelithiasis. Stones do not form when the gallbladder empties completely in response to hormonal stimulation. Slowed or incomplete emptying allows cholesterol to concentrate and increases the risk of stone formation. Finally, inflammation of the gallbladder allows excess water and bile salt reabsorption, increasing the risk for lithiasis. Certain very-low-calorie diets are associated with a high risk of cholelithiasis. Increased cholesterol concentration in the bile and decreased gallbladder contractions associated with fasting increase the risk of gallstone formation.

Most gallstones are formed in the gallbladder. They then may migrate into the ducts (Figure 25–1 ■), leading to *cholangitis* (duct inflammation). Although some people with cholelithiasis are asymptomatic, many develop manifestations. Early manifestations of gallstones may be vague: epigastric fullness or mild gastric distress after eating a large or fatty meal. Stones that obstruct the cystic duct or common bile duct lead to distention and increased pressure behind the stone. This causes **biliary colic**, severe, steady pain in the epigastric region or right upper quadrant of the abdomen. The pain may radiate to the back, right scapula, or shoulder. The pain often begins suddenly following a meal, and may last as long as 5 hours. It often is accompanied by nausea and vomiting.

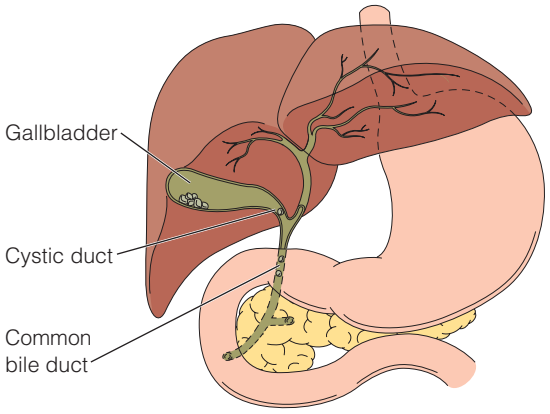

Figure 25–1 ■ Common locations of gallstones.

Obstruction of the common bile duct may cause bile reflux into the liver, leading to jaundice, pain, and possible liver damage. If the common duct is obstructed, pancreatic enzymes will be unable to enter the small intestine, and pancreatitis (discussed later in this chapter) becomes a potential complication.

CHOLECYSTITIS

Cholecystitis is inflammation of the gallbladder. *Acute cholecystitis* usually follows obstruction of the cystic duct by a stone. The obstruction increases pressure within the gallbladder, leading to ischemia of the gallbladder wall and mucosa. Retained bile causes chemical irritation, and bacterial inflammation often follows. The ischemia can lead to necrosis and perforation of the gallbladder wall.

Acute cholecystitis usually begins with an attack of biliary colic. The pain involves the entire right upper quadrant (RUQ), and may radiate to the back, right scapula, or shoulder. Movement or deep breathing may aggravate the pain. The pain usually lasts longer than biliary colic, continuing for 12 to 18 hours. Anorexia, nausea, and vomiting are common. Fever often is present, and may be accompanied by chills. The RUQ is tender to palpation.

Chronic cholecystitis may result from repeated bouts of acute cholecystitis or from persistent irritation of the gallbladder wall by stones. Bacteria may be present in the bile as well. Chronic cholecystitis often is asymptomatic.

Complications of cholecystitis include *empyema*, a collection of infected fluid within the gallbladder; gangrene and perforation with resulting peritonitis or abscess formation; formation of a fistula into

BOX 25–1 Risk Factors for Gallstones

- Age
- Family history of gallstones
- Race or ethnicity: Native American (either Northern or Southern Hemisphere); Northern European heritage
- Obesity, hyperlipidemia
- Rapid weight loss (e.g., following bariatric surgery)
- Female gender; use of oral contraceptives
- Biliary stasis: pregnancy, fasting, prolonged parenteral nutrition
- Diseases or conditions: diabetes mellitus; cirrhosis; ileal disease or resection; sickle cell disease

FOCUS ON CULTURAL DIVERSITY

Gallstones

Native Americans in both the Northern and Southern Hemispheres, and those of Arizona's Pima tribe in particular, have a higher incidence of gallstones than do Caucasians of American or European heritage. This is thought to result from genes that promote efficient calorie use and fat storage—a beneficial trait when the availability of adequate food varies over time. Gallstones composed of cholesterol are less common in African Americans, and Asians have a low incidence of the disease (Papadakis & McPhee, 2013).

TABLE 25–1 Manifestations and Complications of Cholelithiasis and Cholecystitis

Manifestations	Cholelithiasis	Cholecystitis
Pain	• Abrupt onset • Severe, steady • Localized to epigastrium and RUQ of abdomen • May radiate to back, right scapula, and shoulder • Lasts 30 minutes to 5 hours	• Abrupt onset • Severe, steady • Generalized in RUQ of abdomen • May radiate to back, right scapula, and shoulder • Lasts 12 to 18 hours • Aggravated by movement, breathing
Associated symptoms	• Nausea, vomiting	• Anorexia, nausea, vomiting • RUQ tenderness and guarding • Chills and fever
Complications	• Cholecystitis • Common bile duct obstruction with possible jaundice and liver damage • Common duct obstruction with pancreatitis	• Gangrene and perforation with peritonitis • Chronic cholecystitis • Empyema • Fistula formation • Gallstone ileus

an adjacent organ (such as the duodenum, colon, or stomach); or obstruction of the small intestine by a large gallstone (*gallstone ileus*). Table 25–1 compares the manifestations and complications of acute cholelithiasis with those of cholecystitis.

●○● INTERPROFESSIONAL CARE

Treatment of the patient with gallstones depends of the acuity of the condition and the patient's overall health status. When gallstones are present but asymptomatic and the patient has a low risk for complications, conservative treatment is indicated. However, when the patient experiences frequent symptoms, has acute cholecystitis, or has very large stones, the gallbladder and stones are usually surgically removed.

DIAGNOSIS

Diagnostic tests are ordered to identify the presence and location of stones, identify possible complications, and help differentiate gallbladder disease from other disorders.

- *Serum bilirubin* is measured. Elevated direct (conjugated) bilirubin may indicate obstructed bile flow in the biliary duct system (Box 25–2).
- *Complete blood count (CBC)* may show an elevated WBC count in the presence of inflammation and infection.
- *Serum amylase* and *lipase* are measured to identify possible pancreatitis related to common duct obstruction.
- *Ultrasonography of the gallbladder* is a noninvasive exam that can accurately diagnose cholelithiasis with more than 95% accuracy. It also can be used to assess emptying of the gallbladder.
- *Abdominal x-ray* (flat plate of the abdomen) may show gallstones that have a high calcium content.
- *Gallbladder scans* (e.g., HIDA, DIDA, or DISIDA scans) use an intravenous radioactive solution that is rapidly extracted from the blood and excreted into the biliary tree to diagnose cystic duct obstruction and acute or chronic cholecystitis.

See Chapter 21 for more information about and the nursing implications of these diagnostic tests.

BOX 25–2 Sorting Out Total, Direct, and Indirect Bilirubin Levels

When serum bilirubin levels are drawn, the results usually are reported as the total bilirubin, direct bilirubin, and indirect bilirubin levels. Most bilirubin is formed from hemoglobin, as aging or abnormal RBCs are removed from circulation and destroyed. It is then bound to protein and transported to the liver. This protein-bound bilirubin is called *indirect* or *unconjugated* bilirubin. Once in the liver, bilirubin is separated from the protein and converted to a soluble form, *direct* or *conjugated* bilirubin. Conjugated bilirubin is then excreted in the bile.

- Total (serum) bilirubin includes both indirect and direct forms. In adults, the normal total bilirubin is 0.1 to 1.2 mg/dL. Total bilirubin levels increase when more is being produced (e.g., RBC hemolysis), or when its metabolism or excretion is impaired (e.g., liver disease or biliary obstruction).
- Direct (conjugated) bilirubin levels, normally 0.1 to 0.3 mg/dL in adults, rise when its excretion is impaired by obstruction within the liver (e.g., in cirrhosis, hepatitis, exposure to hepatotoxins) or in the biliary system.
- Indirect (unconjugated) bilirubin levels, normally <1.0 mg/dL in adults, rise in RBC hemolysis (e.g., sickle cell disease or transfusion reaction).

MEDICATIONS

Patients who refuse surgery or for whom surgery is inappropriate may be treated with a drug to dissolve the gallstones. Ursodiol (Actigall) and chenodiol (Chenix) reduce the cholesterol content of gallstones, leading to their gradual dissolution. These drugs act by reducing cholesterol production in the liver, thus reducing the cholesterol content of bile. Consequently, these drugs are most effective in treating stones with high cholesterol content. They are less effective in treating radiopaque stones with high calcium salt content. Ursodiol is generally well tolerated with few side effects, whereas chenodiol has a high incidence of diarrhea at therapeutic doses. It also is hepatotoxic, so periodic liver function studies are required during therapy.

The primary disadvantages of pharmacologic treatment for gallstones include its cost, long duration (2 years or more), and the high incidence of recurrent stone formation when treatment is discontinued. If infection is suspected, antibiotics may be ordered to cure the

infection and reduce associated inflammation and edema. Patients with pruritus (itching) due to severe obstructive jaundice and an accumulation of bile salts on the skin may be given cholestyramine (Questran). This drug binds with bile salts to promote their excretion in the feces. An opioid analgesic such as morphine may be required for pain relief during an acute attack of cholecystitis.

TREATMENTS

SURGERY *Laparoscopic cholecystectomy* (removal of the gallbladder) is the treatment of choice for symptomatic cholelithiasis or cholecystitis. This minimally invasive procedure has a low risk of complications and generally requires a hospital stay of less than 24 hours. Not all patients are candidates for laparoscopic cholecystectomy, and there is a risk that a laparoscopic cholecystectomy may be converted to a *laparotomy* (surgical opening into the abdomen) during the procedure. See the accompanying box for nursing care of a patient having a laparoscopic cholecystectomy.

When stones are lodged within the ducts, a cholecystectomy with common bile duct exploration may be done. A T-tube (Figure 25–2 ■) is inserted to maintain patency of the duct and promote bile passage while the edema decreases. Excess bile is collected in a drainage bag secured below the surgical site. If it is suspected that a stone has been retained following surgery, a postoperative cholangiogram via the T-tube or direct visualization of the duct with an endoscope may be performed. Some patients who are poor surgical risks and for whom laparoscopic cholecystectomy is inappropriate may have either a *cholecystostomy* to drain the gallbladder, or a *choledochostomy* to remove stones and position a T-tube in the common bile duct.

NUTRITION Food intake may be eliminated during an acute attack of cholecystitis, and a nasogastric tube inserted to relieve nausea and vomiting. Dietary fat intake may be limited, especially if the patient is obese. If bile flow is obstructed, fat-soluble vitamins (A, D, E, and K) and bile salts may need to be administered.

OTHER THERAPIES In some cases, shock wave lithotripsy may be used with drug therapy to dissolve large gallstones. In *extracorporeal shock wave lithotripsy*, ultrasound is used to align the stones with the source of shock waves and the computerized lithotripter. Positioning is of prime importance throughout the procedure, which usually takes an hour. Mild sedation may be given during the procedure. Nursing care after the procedure includes monitoring for biliary colic, which can result from the gallbladder contracting to remove stone fragments; nausea; and transient hematuria. *Percutaneous cholecystostomy*, ultrasound-guided drainage of the gallbladder, may be done in high-risk patients to postpone or even eliminate the need for surgery.

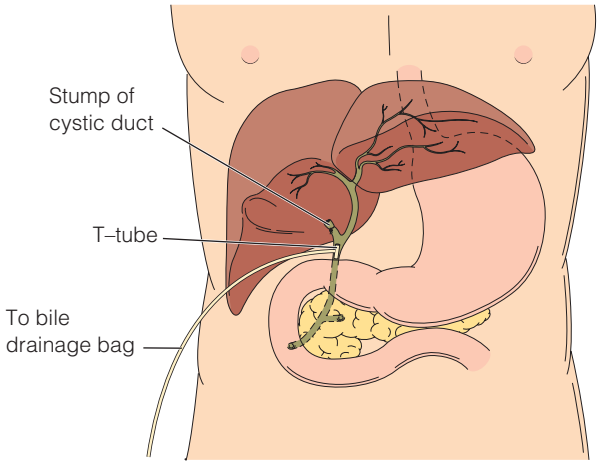

Figure 25–2 ■ T-tube placement in the common bile duct. Bile fluid flows with gravity into a drainage collection device below the level of the common bile duct.

NURSING CARE OF THE PATIENT

Having a Laparoscopic Cholecystectomy

PREOPERATIVE CARE

- Provide routine preoperative care as ordered (see Chapter 4).
- Assess for manifestations of cholecystitis and other complications of gallstones. *An acutely inflamed gallbladder and ductal system increase surgical complexity and may necessitate open cholecystectomy.*
- Reinforce teaching about the procedure and postoperative expectations, including pain management, deep breathing, and mobilization. *Preoperative teaching reduces anxiety and promotes rapid postoperative recovery*.

POSTOPERATIVE CARE

- Provide routine postoperative recovery care as ordered (see Chapter 4).
- Treat postoperative pain and nausea and vomiting prophylactically and as needed to relieve symptoms. *Postoperative pain is common during the first 24 to 48 hours after surgery. Manipulation of the bowel and insufflation of the abdomen with gas commonly lead to postoperative nausea.*
- Assist to chair at bedside as allowed. *Early mobilization promotes lung ventilation and circulation, reducing the potential for postoperative complications.*
- Advance oral intake from ice chips to regular diet as tolerated. *Oral intake can be rapidly resumed due to minimal disruption of the gastrointestinal tract during surgery.*
- Provide and reinforce teaching: pain management, incision care, activity level, postoperative follow-up appointments. *With early discharge, the patient and family assume responsibility for the majority of postoperative care. A clear understanding of this care and expected needs reduces anxiety and the risk of postoperative complications.*
- Initiate follow-up contact 24 to 48 hours after discharge to evaluate adequacy of pain control, incision management, and discharge understanding. *Contact following discharge provides an opportunity to evaluate care and reinforce teaching*.

●○● NURSING CARE

In addition to the nursing care discussed in this section, see the Case Study & Nursing Care Plan for a patient with cholelithiasis on page 697.

Health Promotion

Although most risk factors for cholelithiasis cannot be controlled or modified, several can. Modifiable risk factors include obesity, hyperlipidemia, extremely low-calorie diets, and diets high in cholesterol.

By contrast, physical activity, a high-fiber and low-carbohydrate diet, and consumption of unsaturated fats all appear to have a protective effect, reducing the incidence of gallstones and cholecystitis. Discuss the dangers of "yo-yo" dieting, with cycles of weight loss followed by weight gain, and of extremely low-calorie diets. Encourage patients with high serum cholesterol levels to discuss using cholesterol-lowering drugs with their primary care provider.

Assessment

Assessment data related to cholelithiasis and cholecystitis include the following:

- *Health history:* current manifestations, including RUQ pain, its character and relationship to meals, duration, and radiation, nausea and vomiting, or other symptoms; duration of symptoms; risk factors or previous history of symptoms; chronic diseases such as diabetes, cirrhosis, or inflammatory bowel disease; current diet; use of oral contraceptives or possibility of pregnancy
- *Physical assessment:* current weight; color of skin and sclera; abdominal assessment including light palpation for tenderness; color of urine and stool
- *Diagnostic tests:* WBC, serum bilirubin, liver enzymes, and pancreatic enzyme (amylase and lipase) results.

Priorities of Care

Priority nursing care for the patient with cholelithiasis or cholecystitis often includes managing pain related to biliary colic or surgery, addressing the nutritional imbalance related to the effects of altered bile flow, nausea and anorexia, and treating infection related to potential rupture of an acutely inflamed gallbladder. Nursing interventions for the patient who has undergone a laparoscopic or open cholecystectomy are similar to those for other patients having abdominal surgery.

Diagnoses, Outcomes, and Interventions

Pain

The pain associated with cholelithiasis can be severe. Sometimes a combination of interventions is indicated.

Expected Outcome: Patient will identify pain triggers, use treatment plan (pharmacologic and nonpharmacologic) to prevent and alleviate discomfort, and report relief from pain.

- Discuss the relationship between fat intake and the pain. Teach ways to reduce fat intake (Box 25–3). *Fat entering the duodenum initiates gallbladder contractions, causing pain when gallstones are present in the ducts.*

BOX 25–3 Examples of High-Fat Foods

- Whole-milk products (e.g., cream, ice cream, cheese)
- Doughnuts, deep-fried
- Avocados
- Sausage, bacon, hot dogs
- Gravies with fat, cream
- Most nuts (e.g., pecans, cashews)
- Corn chips and potato chips
- Butter and cooking oils
- Fried foods (e.g., cheeseburgers, hamburgers, french fries)
- Peanut butter
- Chocolate candies

- Withhold oral food and fluids during episodes of acute pain. Insert nasogastric tube and connect to low suction if ordered. *Emptying the stomach reduces the amount of chyme entering the duodenum and the stimulus for gallbladder contractions, thus reducing pain.*
- For severe pain, administer morphine, fentanyl, or other narcotic analgesia as ordered. *Controlling pain prevents pain related complications such as atelectisis and thrombosis.*
- Place in Fowler's position. *Fowler's position decreases pressure on the inflamed gallbladder.*

Imbalanced Nutrition: Less Than Body Requirements

The patient with severe gallbladder disease may develop nutritional imbalances related to anorexia, pain, and nausea following meals and to impaired bile flow that alters absorption of fat and fat-soluble vitamins (A, D, E, and K) from the gut.

Expected Outcome: Patient will maintain adequate oral intake, report adequate energy levels, and maintain body mass and weight and normal lab values (transferrin, albumin, and electrolytes).

- Assess nutritional status, including diet history, height and weight, and skinfold measurements. *Even though often obese, patients with gallbladder disease may have an imbalanced diet or may have specific vitamin deficiencies, particularly of the fat-soluble vitamins.*
- Evaluate laboratory results, including serum bilirubin, serum transferrin, serum albumin, glucose, electrolytes, and cholesterol levels. Report abnormal results to the primary care provider. *Elevated serum bilirubin may indicate impaired bilirubin excretion due to obstructed bile flow. A low serum albumin may indicate poor nutritional status. Glucose intolerance and hypercholesterolemia are risk factors for cholelithiasis.*
- Refer to a dietitian or nutritionist for diet counseling to promote healthy weight loss and reduce pain episodes. *A low-carbohydrate, low-fat, higher-protein diet reduces symptoms of cholecystitis. Although fasting and very-low-calorie diets are contraindicated, a moderate reduction in calorie intake and increased activity levels promote weight loss.*
- Administer vitamin supplements as ordered. *Patients who do not absorb fat well due to obstructed bile flow may require supplements of the fat-soluble vitamins.*

Risk for Infection

An acutely inflamed gallbladder may become necrotic and rupture, releasing its contents into the abdominal cavity. While the resulting infection often remains localized, peritonitis can result from chemical irritation and bacterial contamination of the peritoneal cavity.

SAFETY ALERT

Rupture of an acutely inflamed gallbladder may be heralded by abrupt but transient pain relief as contents are released from the distended gallbladder into the abdomen. Promptly report this change to the physician.

Following open cholecystectomy (*laparotomy*), the risk for pulmonary infection is significant due to the high abdominal incision.

Expected Outcome: Patient will be free from signs and symptoms of infection including vital signs within normal limits, clear lung sounds, and incision without redness, tenderness, drainage, or swelling.

CASE STUDY & NURSING CARE PLAN A Patient with Cholelithiasis

Joyce Red Wing is a 44-year-old married mother of three children. A member of the Chickasaw tribe, she is active in tribal activities and works part time as a cook at a community kitchen. Recently Mrs. Red Wing has noticed a dull pain in her upper abdomen that gets worse after eating fatty foods; nausea and sometimes vomiting accompany the pain. She had a similar pain after the birth of her last child. She is diagnosed with cholelithiasis, and is admitted for a laparoscopic cholecystectomy.

ASSESSMENT

David Corbin, RN, takes Mrs. Red Wing's admission history. It includes intolerance to fatty foods and intermittent "stabbing" abdominal pain that radiates to her back. Her usual diet includes tacos or fried bread and biscuits with gravy for breakfast. She reports "not wanting to eat much of anything lately." She states she has never had surgery before and hopes "everything goes well." Physical assessment includes T 37.7°C (100°F), P 88 bpm, R 20/min, and BP 130/84 mmHg. She has had a recent 2.3-kg (5–lb) weight loss, currently weighing 59 kg (130 lb). She is 160 cm (63 in.) tall. Abdominal examination elicits tenderness in the right upper abdominal quadrant. She has no jaundice, chills, or evidence of complications.

DIAGNOSES

- *Imbalanced Nutrition: Less Than Body Requirements* related to anorexia and recent weight loss
- *Acute Pain* related to inflamed gallbladder and surgical incisions
- *Risk for Infection* related to potential bacterial contamination of abdominal cavity
- *Anxiety* related to lack of information about perioperative experience

EXPECTED OUTCOMES

- Patient will maintain present weight within 2.3 kg (5 lb) during the next 3 weeks.
- Patient will resume regular diet, decreasing intake of foods high in fat.
- Patient will verbalize adequate pain control after surgery and with activity resumption.
- Patient will remain free of infection.
- Patient will verbalize a decrease in anxiety before surgery.

PLANNING AND IMPLEMENTATION

- Teach about the gallbladder and the function of bile.
- Discuss pre- and postoperative care, including self-care following discharge.
- Promote mobility as soon as allowed after surgery.
- Teach home care of incisions and recognition of signs of infection.
- Review specific high-fat foods to avoid and ways to maintain her weight.
- Provide analgesia as needed postoperatively. Teach appropriate analgesic use after discharge.

EVALUATION

Mrs. Red Wing is discharged the morning after her surgery. She is afebrile, has no signs of infection, and is able to appropriately care for her incisions. She identifies signs of infection and talks about ways to reduce her fat intake while keeping her weight stable. She verbalizes understanding of initial activity restrictions and resumption of normal activities. Mrs. Red Wing states, "It wasn't as bad as I thought it would be at first." She has an appointment to see her surgeon in 1 week.

Clinical Reasoning in Patient Care

1. What is the rationale for a low-fat diet with cholelithiasis? Discuss nutritional practices as they relate to the medical problem and Mrs. Red Wing's culture.
2. How would your discharge teaching for Mrs. Red Wing differ if she had had an open cholecystectomy instead of a laparoscopic cholecystectomy?
3. Design a nursing care plan for Mrs. Red Wing for the nursing diagnosis *Fatigue*.

See Evaluating Your Response in Appendix B.

- Monitor vital signs including temperature every 4 hours. Promptly report vital sign changes or temperature elevation. *Tachycardia, increased respiratory rate, or an elevated temperature may indicate an infectious process.*
- Assess abdomen every 4 hours and as indicated (e.g., when pain level changes abruptly). *Increasing abdominal tenderness or a rigid, boardlike abdomen may indicate rupture of the gallbladder with peritonitis.*
- Assist to cough and deep breathe or use incentive spirometer every 1 to 2 hours while awake. Splint abdominal incision with a blanket or pillow during coughing. *The high abdominal incision of an open cholecystectomy interferes with effective coughing and deep breathing, increasing the risk of atelectasis and respiratory infections such as pneumonia.*
- Place in Fowler's position and encourage ambulation as allowed. *Fowler's position and ambulating promote lung expansion and airway clearance, reducing the risk of respiratory infections.*
- Administer antibiotics as ordered. *Antibiotics may be given preoperatively to reduce the risk of infection from infected gallbladder contents, and may be continued postoperatively to prevent infection.*

Continuity of Care

Teaching varies, depending on the choice of treatment options for cholelithiasis and cholecystitis. If surgery is not an option, teach about medications that dissolve stones, their use and adverse effects (diarrhea is a common side effect), and the importance of maintaining a low-fat and low-carbohydrate diet if indicated. Include an explanation about the role of bile and the function of the gallbladder in terms that the patient and family can understand.

Provide appropriate preoperative teaching for the planned procedure. Discuss the possibility of open cholecystectomy even when a laparoscopic procedure is planned. Teach postoperative self-care measures to manage pain and prevent complications. If the patient will be discharged with a T-tube, provide instructions about its care. Discuss manifestations of complications to report to the physician. Stress the importance of follow-up appointments.

Following cholecystectomy, a low-fat diet may be initially recommended. Refer the patient and food preparer to a dietitian to review low-fat foods. (Refer to Box 25–3 for examples of high-fat foods to avoid.) Higher-fat foods may be gradually added to the diet as tolerated.

THE PATIENT WITH CANCER OF THE GALLBLADDER

Gallbladder cancer is rare, primarily affecting people over age 65. Women are more likely to develop the disorder. Manifestations of gallbladder cancer include intense pain and a palpable mass in the

RUQ of the abdomen. Jaundice and weight loss are common. Gallbladder cancers spread by direct extension to the liver, and metastasize via the blood and lymph system.

At the time of diagnosis, the cancer usually is too advanced to treat surgically. Ninety-five percent of patients with primary cancer of the gallbladder die within 1 year. Radical and extensive surgical interventions may be performed, but the prognosis is poor regardless of treatment. Nursing care is palliative, focusing on maintaining comfort and independence to the extent possible.

Liver Disorders

The liver is a complex organ with multiple metabolic and regulatory functions. Optimal liver function is essential to health. Because of the significant amount of blood in the liver at all times, it is exposed to the effects of pathogens, drugs, toxins, and possibly malignant cells. As a result, liver cells may become inflamed or damaged, or cancerous tumors may develop.

Physiology Review

The essential functions of the liver include the metabolism of proteins, carbohydrates, and fats. It also is responsible for the metabolism of steroid hormones and most drugs. It synthesizes essential blood proteins, including albumin and clotting factors in particular. The liver detoxifies alcohol and other toxic substances. Ammonia, a toxic by-product of protein metabolism, is converted to urea in the liver for elimination by the kidneys. The liver produces bile, an essential substance for absorbing fats and eliminating bilirubin from the body. Minerals and fat-soluble vitamins are stored in the liver, as is glycogen (stored carbohydrate for energy reserves). The Kupffer cells that line the sinusoids phagocytize foreign cells and damaged blood cells. See Chapter 21 for more information about the liver.

Common Manifestations of Liver Disorders

Although many different disorders can disrupt liver function, their manifestations relate to three primary effects: disrupted liver cell function, impaired bilirubin conversion and excretion leading to jaundice, and disrupted blood flow through the liver, with resulting portal hypertension.

HEPATOCELLULAR FAILURE

The liver is vital to digestion and metabolism of nutrients; the production of plasma proteins, including those involved in clotting; and the metabolism and excretion of compounds such as bilirubin, steroid hormones, and ammonia, as well as toxins (such as alcohol) and drugs. Impaired function of liver cells has multiple effects, including the following:

- Impaired protein metabolism with decreased production of albumin and clotting factors. Low albumin levels contribute to edema in peripheral tissues and **ascites**, accumulation of fluid in the abdomen (Figure 25–3 ■), as plasma oncotic pressure is reduced. Impaired clotting factor production increases the risk for bleeding.
- Disrupted glucose metabolism and storage with resulting alterations in blood glucose levels (either hyperglycemia or hypoglycemia).
- Reduced bile production that impairs the absorption of lipids and fat-soluble vitamins. Inadequate vitamin K, a fat-soluble vitamin, affects the production of clotting factors, leading to a bleeding tendency.
- Impaired metabolism of steroid hormones (including estrogen and testosterone) leads to feminization in men and irregular menses in women.

Figure 25–3 ■ In ascites, serous fluid collects in the abdominal cavity, causing uniform distention.

JAUNDICE

Disrupted metabolism and excretion of bilirubin allows it to accumulate in tissues, leading to **jaundice**, yellow staining of tissues (Figure 25–4 ■). Jaundice (*icterus*) often is first noticeable in the sclera of the eyes, then the skin.

When RBCs are destroyed (due to cell aging or disease), hemoglobin is released. The hemoglobin molecule breaks up into globin,

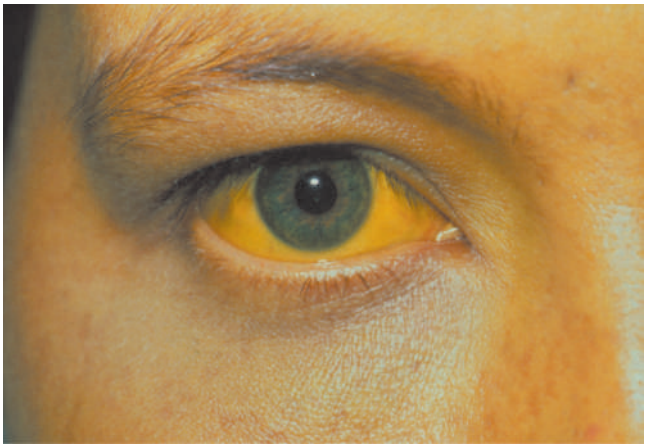

Figure 25–4 ■ Jaundice. Note the yellowing of the white (sclera) of the eye and of the surrounding facial skin.

a protein, and heme, the iron-containing portion of the molecule. In this process, biliverdin, later converted to fat-soluble bilirubin (*unconjugated bilirubin*), is released. The bilirubin binds with albumin to be transported to the liver. In the liver, it is converted to a water-soluble form (*conjugated bilirubin*) to be excreted in the bile. Refer to Box 25–2 for more information about bilirubin metabolism.

Jaundice can result from disruptions at any point in the production and metabolism of bilirubin:

- *Prehepatic/Hemolytic jaundice* develops when excess RBC destruction (hemolysis) releases more bilirubin into circulation than the liver is able to process. High blood levels of unconjugated bilirubin are seen.
- *Intrahepatic/Hepatic jaundice* occurs when impaired liver cell (*hepatocyte*) function disrupts the conversion and excretion of bilirubin. Blood levels of both conjugated and unconjugated bilirubin may be elevated. Stools may appear normal or clay colored, and urine is dark because the conjugated bilirubin is excreted by the kidneys.
- Obstruction of bile flow within the biliary system (the gallbladder and bile ducts) impairs bilirubin excretion, leading to *Posthepatic/Obstructive jaundice*. Levels of conjugated bilirubin are elevated. Stools are light or clay colored due to lack of bile pigment; and urine is dark because the kidneys excrete bilirubin.

PORTAL HYPERTENSION

Impaired blood flow through the liver increases pressure in the portal venous system that drains the gastrointestinal tract, the spleen, and surface veins of the abdomen. **Portal hypertension**, increased pressure in the portal system, has several effects when it is prolonged:

- Veins in the gastrointestinal tract and the abdominal wall dilate. This congestion tends to suppress the appetite and lead to formation of collateral vessels in the distal esophagus, stomach, and rectum. The dilated, congested vessels in the esophagus are known as **esophageal varices**; in the rectum, they lead to the development of hemorrhoids. In advanced liver failure, superficial varices may develop around the umbilicus, a feature known as *caput medusae*.
- The spleen enlarges (*splenomegaly*).
- Fluid accumulates in the peritoneal cavity, a condition known as *ascites*. Increased hydrostatic pressure in abdominal vessels forces fluid out of the vessels and into the peritoneal cavity. Low serum albumin levels (*hypoalbuminemia*) contribute to fluid accumulation by reducing the osmotic draw of fluid back into vessels.
- **Portal systemic encephalopathy** (or *hepatic encephalopathy*), impaired consciousness and mental status, results from the accumulation of toxic waste products in the blood (ammonia in particular) as blood bypasses the congested liver. It appears that factors other than elevated ammonia levels contribute, including the presence of toxic fatty acids and altered neurotransmitters and an imbalance of plasma amino acid ratios. Cerebral edema develops late in the course of liver failure, resulting from both the accumulation of toxins and vascular mechanisms. As cerebral edema progresses, intracranial pressure increases, cerebral perfusion decreases, and brain cells become hypoxic.
- *Hepatorenal syndrome* is acute kidney failure due to disrupted blood flow to the kidneys. See Chapter 28 for more information about kidney failure.

THE PATIENT WITH HEPATITIS

Hepatitis is inflammation of the liver. It is usually caused by a virus, although it may result from exposure to alcohol, drugs, toxins, or other pathogens and sometimes develops secondary to other viral infections such as those caused by Epstein-Barr, herpes simplex, varicella-zoster, and cytomegalovirus. Hepatitis may be acute or chronic in nature. Cirrhosis, discussed in the next section, is a potential consequence of severe hepatocellular damage. Chronic hepatitis also increases the risk for developing liver cancer.

Pathophysiology and Manifestations

The inflammatory process of hepatitis, whether caused by a virus, toxin, or other mechanism, damages hepatic cells and disrupts liver function. Cell-mediated immune responses damage hepatocytes and Kupffer cells, leading to hyperplasia, necrosis, and cellular regeneration. The flow of bile through bile canaliculi and into the biliary system can be impaired by the inflammatory process, leading to jaundice. When the inflammatory process is mild (e.g., hepatitis A), the liver parenchyma is not significantly damaged. The inflammatory processes associated with hepatitis B and hepatitis C, however, can lead to severe liver damage. The metabolism of nutrients, drugs, alcohol, and toxins and the process of bile elimination are disrupted by the inflammation of hepatitis. See Chapter 21 for more information about the liver, and the preceding section for more information about the effects of disrupted liver function.

VIRAL HEPATITIS

Viral hepatitis is nearly always caused by one of five viruses: hepatitis A virus (HAV), hepatitis B virus (HBV), hepatitis C virus (HCV), the hepatitis B–associated delta virus (HDV), and hepatitis E virus (HEV). With the exception of HBV, all of the hepatitis viruses are RNA viruses; HBV is a DNA virus. The viruses differ from one another in mode of transmission, incubation period, the severity and type of liver damage they cause, and their ability to become chronic or develop a carrier (asymptomatic) state. The illnesses they cause, however, are clinically very similar. Table 25–2 identifies unique features of the primary hepatitis viruses.

FAST FACTS

In the United States, hepatitis A, hepatitis B, and hepatitis C dominate.

- Hepatitis A is less common than hepatitis B and the incidence continues to decline, with a reported 1670 acute cases reported in 2010. The rate of hepatitis A infections per 100,000 population has fallen steadily since the introduction of hepatitis A vaccine, to the lowest ever reported rate of 0.5 in 2010.
- Reported cases of hepatitis B in 2010 numbered 3350. The rate of reported hepatitis B infections peaked at 11.5 per 100,000 population in 1985, since then falling to 1.1 in 2010.
- In 2010, 850 cases of hepatitis C were reported, for a national rate of 0.3 per 100,000 population.
- The estimated number of actual new cases of viral hepatitis is higher than the number of reported cases: An estimated 17,000 new cases of hepatitis A, 18,000 new cases of hepatitis B, and 16,500 new cases of hepatitis C are believed to have developed in 2010 (Centers for Disease Control and Prevention [CDC], 2012).

Hepatitis viruses replicate in the liver, indirectly damaging liver cells (hepatocytes). The viruses provoke an immune response that causes inflammation and necrosis of hepatocytes, leading to the

TABLE 25–2 Comparison of Types of Viral Hepatitis

Virus	Hepatitis A (HAV)	Hepatitis B (HBV)	Hepatitis C (HCV)	Hepatitis D (HDV)	Hepatitis E (HEV)
Mode of transmission	Fecal–oral	Blood and body fluids; perinatal	Blood and body fluids	Blood and body fluids; perinatal	Fecal–oral
Incubation (in weeks)	2–6	6–24	5–12	3–13	3–6
Onset	Abrupt	Slow	Slow	Abrupt	Abrupt
Carrier state	No	Yes	Yes	Yes	Yes
Possible complications	Rare	Chronic hepatitis	Cirrhosis	Liver cancer	Chronic hepatitis
Cirrhosis	Liver cancer	Chronic hepatitis	Cirrhosis	Fulminant hepatitis	May be severe in pregnant women
Laboratory findings	Anti-HAV antibodies present	Positive HBsAg (HBV surface antigen); anti-HBV antibodies present	Anti-HCV antibodies present	Positive HDVAg (delta antigen) early; anti-HDV antibodies later	Anti-HEV antibodies present

clinical presentation of acute disease. Although the extent of damage and the immune response vary among the different hepatitis viruses, the disease itself usually follows a predictable pattern.

No manifestations are present during the incubation period after exposure to the virus. The *prodromal* or *preicteric* (before jaundice) *phase* may begin abruptly or insidiously, with general malaise, anorexia, fatigue, and muscle and body aches. These manifestations often are mistaken for the flu. Nausea, vomiting, diarrhea, or constipation may develop, as well as mild RUQ abdominal pain. Chills and fever may be present.

The *icteric* (jaundiced) *phase* usually begins 5 to 10 days after the onset of symptoms. It is heralded by jaundice of the sclera, skin, and mucous membranes. Inflammation of the liver and bile ducts prevents bilirubin from being excreted into the small intestine. As a result, the serum bilirubin levels are elevated, causing yellowing of the skin and mucous membranes. Pruritus may develop due to deposition of bile salts on the skin. The stools are light brown or clay colored because bile pigment is not excreted through the normal fecal pathway. Instead, the pigment is excreted by the kidneys, causing the urine to turn brown. Whereas patients with acute hepatitis A or B are likely to develop jaundice, many people with hepatitis C do not develop jaundice. As a result, the infection may go undiagnosed for an extended period of time.

During the icteric phase, the initial prodromal manifestations usually diminish even though the serum bilirubin increases. The appetite increases, and the temperature returns to normal. When uncomplicated, spontaneous recovery usually begins within 2 weeks of the onset of jaundice.

The *convalescent phase* follows jaundice and lasts several weeks. During this time, manifestations gradually improve: Serum enzymes decrease, liver pain decreases, and gastrointestinal symptoms and weakness subside. See the accompanying box for the manifestations of each phase of hepatitis.

HEPATITIS A Hepatitis A, or *infectious hepatitis,* is transmitted by the fecal–oral route via contaminated food, water, shellfish, or direct contact with an infected person. International travel is the primary risk factor for developing hepatitis A; others include close household or sexual contact with an infected partner (CDC, 2012). The virus is in the stool of infected individuals up to 2 weeks before symptoms develop. Once jaundice develops, the amount of virus in the stool and the risk of spreading the disease decrease significantly. Although hepatitis A usually has an abrupt onset, it is typically a benign and self-limited disease with few long-term consequences. Symptoms last up to 2 months.

HEPATITIS B Hepatitis B can cause acute hepatitis, chronic hepatitis, *fulminant* (rapidly progressive) hepatitis, or a carrier state. In a *carrier state*, the individual harbors the active virus and is capable of spreading it to others, even though there are no discernible manifestations of the disease. It is more likely to develop when the virus is acquired at birth from an infected mother (Longo et al., 2013). This virus is spread through contact with infected blood and body fluids. High-risk groups for hepatitis B include injection drug users, people with multiple sex partners, men who have sex with other men, and people frequently exposed to blood products (such as people on hemodialysis). Healthcare workers are at risk through exposure to blood and needlestick injuries. Hepatitis B is a risk factor for primary liver cancer, particularly in people who are infected perinatally (Longo et al., 2013).

In hepatitis B, liver cells are damaged by the immune response to this antigen. Damage may affect only portions or the majority of the liver. The liver shows evidence of injury and scarring, regeneration, and proliferation of inflammatory cells. During the prodromal period, patients with HBV may experience such immune-mediated manifestations as urticaria and other rashes, arthralgias, serum sickness, or glomerulonephritis (Jack et al., 2013a). The disease itself may be asymptomatic.

HEPATITIS C Hepatitis C, formerly known as non-A, non-B hepatitis, is the primary worldwide cause of chronic hepatitis, cirrhosis, and liver cancer (Grossman & Porth, 2014). It is transmitted through infected blood and body fluids. Injection drug use is the primary risk factor for HCV infection, accounting for nearly half of all new infections (CDC, 2012). Acute hepatitis C usually is asymptomatic; if symptoms do develop, they often are mild and nonspecific. The disease often is recognized long after exposure occurred, when secondary effects of the disease (such as chronic hepatitis or cirrhosis) develop. Very few acute infections completely resolve; most progress to chronic active hepatitis (Jack et al., 2013a).

Nurses frequently care for patients whose hepatitis antigen status is unknown or who have a secondary diagnosis of chronic

hepatitis B or C. Exercise standard precautions including hand hygiene and personal protective equipment use with all patients to reduce the risk of exposure to these bloodborne pathogens.

HEPATITIS DELTA Hepatitis delta only causes infection in people who also are infected with hepatitis B. It can cause acute or chronic infection, and can increase the severity of HBV infection (Grossman & Porth, 2014). It is transmitted in the same manner as HBV; as the number of people with immunity to HBV has increased, the incidence of hepatitis delta has decreased (Longo et al., 2013).

HEPATITIS E Hepatitis E is rare in the United States. It is transmitted by fecal contamination of water supplies in developing areas such as southeast Asia, parts of Africa, and Central America. Person-to-person transmission is rare. It primarily affects young adults. It can cause fulminant, fatal hepatitis in pregnant women.

CHRONIC HEPATITIS

Chronic hepatitis is chronic infection of the liver. Although it may cause few symptoms, it is the primary cause of liver damage leading to cirrhosis, liver cancer, and liver transplantation. Three of the known hepatitis viruses cause chronic hepatitis: HBV, HCV, and HDV. Patients with chronic hepatitis may have periods of active liver disease interspersed with periods of inactivity. Liver damage and fibrosis variably progress during periods of disease activity (Fowler, 2013). Manifestations of chronic hepatitis include malaise, fatigue, and hepatomegaly. Occasional icteric (jaundiced) periods may occur. Liver enzymes, particularly serum aminotransferase levels, typically are elevated.

In chronic active hepatitis, inflammation extends to involve entire hepatic lobules. Chronic active hepatitis usually leads to cirrhosis and end-stage liver failure.

FULMINANT HEPATITIS

Fulminant hepatitis is a rapidly progressive disease, with liver failure developing within 2 to 3 weeks after the onset of symptoms. Although uncommon, it is usually related to HBV with concurrent HDV infection.

MANIFESTATIONS OF ACUTE HEPATITIS

PREICTERIC PHASE
- "Flulike" symptoms: malaise, fatigue, fever
- Gastrointestinal: anorexia, nausea, vomiting, diarrhea, constipation
- Muscle aches, polyarthritis
- Mild right upper abdominal pain and tenderness

ICTERIC PHASE
- Jaundice
- Pruritus
- Clay-colored stools
- Brown urine
- Decrease in preicteric phase symptoms (e.g., appetite improves; no fever)

POSTICTERIC/CONVALESCENT PHASE
- Serum bilirubin and enzymes return to normal levels
- Energy level increases
- Pain subsides
- Gastrointestinal: minimal to absent

TOXIC HEPATITIS

Many substances, including alcohol, certain drugs, and other toxins, can directly damage liver cells. Alcoholic hepatitis can result from chronic alcohol abuse or from an acute toxic reaction to alcohol. Alcoholic hepatitis causes necrosis of hepatocytes and inflammation of the liver parenchyma (functional tissue). Unless alcohol intake is avoided, progression to cirrhosis is common.

Other potential hepatotoxins include acetaminophen, benzene, carbon tetrachloride, halothane, chloroform, and poisonous mushrooms. These substances directly damage liver cells, leading to necrosis. The degree of damage often depends on age and the extent of exposure (dose) to the hepatotoxin. Acetaminophen overdose is the leading cause of acute liver failure.

AUTOIMMUNE HEPATITIS

Autoimmune hepatitis is a chronic disorder in which a cell-mediated immune response directed against liver cells causes persistent inflammation and necrosis with fibrosis and scarring. Circulating autoantibodies such as antinuclear antibody (ANA) usually are present. Many affected individuals have a personal or family history of other autoimmune disorders, such as rheumatoid arthritis or thyroiditis, suggesting a genetic link to the disorder. Chronic autoimmune hepatitis can ultimately lead to cirrhosis and liver failure.

●○● INTERPROFESSIONAL CARE

Management of hepatitis focuses on determining its cause, providing appropriate treatment and support, and teaching strategies to prevent further liver damage. Effective management begins with thorough assessment of diagnostic and laboratory data.

DIAGNOSIS

Liver function tests, such as blood levels of bilirubin and enzymes commonly released when liver cells are damaged, are obtained. These include the following:

- *Alanine aminotransferase (ALT)* is an enzyme contained within each liver cell. When liver cells are damaged, ALT is released into the blood. Levels may exceed 1000 units/L or more in acute hepatitis.
- *Aspartate aminotransferase (AST)* is an enzyme found predominantly in heart and liver cells. AST levels rise when liver cells are damaged; with severe damage, blood levels may be 20 to 100 times normal values.
- *Alkaline phosphatase (ALP)* is an enzyme present in liver cells and bone. Serum ALP levels often are elevated in hepatitis, and may remain elevated after ALT and AST levels have returned to normal ranges.
- *Serum bilirubin* levels, including *conjugated* and *unconjugated*, are elevated in viral hepatitis due to impaired bilirubin metabolism and obstruction of the hepatobiliary ducts by inflammation and edema. The bilirubin level decreases as inflammation and edema subside.
- Laboratory tests for viral antigens and their specific antibodies may be done to identify the infecting virus and its state of activity. These tests are summarized in Table 25–2.
- A *liver biopsy* may be done to detect and evaluate chronic hepatitis. (Nursing implications for this test are outlined in Chapter 21.)

TABLE 25–3 CDC Recommendations for Hepatitis Prevention in Adults

Disease/Strategy	Immunization	Adverse Reactions	Population Recommendations
HEPATITIS A			
Prevention	Hepatitis A vaccine (Havrix; VAQTA), 2 doses with at least 6 months between doses Injected IM into deltoid muscle Combined hepatitis A and hepatitis B vaccine (Twinrix), 3 doses (initial dose followed by doses 4 weeks and 6 months later) given IM into deltoid muscle	Pain at injection site	• Everyone who desires protection from HAV infection • International travelers • Men who have sex with men • Injection drug users • Individuals with clotting-factor disorders, chronic liver disease • Individuals with occupational risk • Close contacts of newly adopted non-U.S. children
Postexposure prophylaxis	Standard immune globulin IM into large muscle mass within 2 weeks of exposure Hepatitis A vaccine may be used in healthy people 40 years old and younger	Rare; risk of anaphylaxis in people with IgA deficiency	• Close contacts of people with known hepatitis A • People potentially exposed to hepatitis A at child care center or restaurant with infected food handler
HEPATITIS B			
Prevention	Recombinant hepatitis B vaccine (Recombivax HB; Engerix-B), 3 doses (minimum of 16 weeks between dose #1 and #3) given IM into deltoid muscle Combined hepatitis A and hepatitis B vaccine (Twinrix), 3 doses (initial dose followed by doses 4 weeks and 6 months later) given IM into deltoid muscle	Pain at injection site; fatigue, headache	• Infants and adolescents • Adults seeking protection from HBV infection • People with chronic liver disease • Men who have sex with men • Prostitutes; heterosexuals with multiple sexual partners • People with an STI • Injection drug users • Long-term male prisoners • People on hemodialysis • Healthcare workers
Postexposure prophylaxis	Hepatitis B immune globulin (HBIG) given IM into large muscle mass within 24 hours of exposure; concurrent initiation of hepatitis B vaccine series	Infrequent; muscle stiffness, pain	• Infants born to women with HBV infection • Percutaneous or permucosal exposure to HBV when unvaccinated or antibody response is negative or unknown

Source: Centers for Disease Control and Prevention (CDC). (2012). *Epidemiology and prevention of vaccine-preventable diseases* (12th ed., 2nd printing). Washington, DC: Public Health Foundation.

MEDICATIONS

PREVENTION Hepatitis A and hepatitis B are preventable diseases. Vaccines are available, as are preparations to prevent the disease following known or suspected exposure.

VACCINES Hepatitis A vaccine provides long-term protection against HAV infection. It is an inactivated whole-virus vaccine available in pediatric and adult formulations. Although more than 95% of adults achieve immunity after one dose of the vaccine, two doses are recommended for full protection. See Table 25–3.

Three doses of hepatitis B vaccine provide immunity to HBV infection in 90% of healthy adults. Because the hepatitis delta virus requires the presence of the hepatitis B virus, hepatitis B vaccine also protects against HDV. Hepatitis B vaccine is a recombinant vaccine. Vaccines produced by different manufacturers may be used interchangeably, although their dosages differ. Older adults are less likely to achieve immunity than younger adults. Patients on hemodialysis and people who are immunocompromised may need larger or more doses of the vaccine to achieve adequate protection. Serologic testing for immunity is recommended on completion of the series for people in these high-risk groups.

A combined hepatitis A and hepatitis B vaccine is available for use. It is recommended for the same high-risk populations as the single vaccines. Three doses are given: the initial dose, followed by doses no sooner than 4 weeks and 6 months later.

POSTEXPOSURE PROPHYLAXIS Postexposure prophylaxis may be recommended for household or sexual contacts of people with HAV or HBV and other people who are known to have been exposed to these viruses. It is not necessary if the exposed individual has been vaccinated and is known to be immune.

Hepatitis A prophylaxis is provided by a single dose of immune globulin (IG) given within 2 weeks after exposure. IG is recommended for all people with household or sexual contact with an individual known to be infected with hepatitis A. See Table 25–3 for further recommendations.

Hepatitis B postexposure prophylaxis is indicated for people exposed to the hepatitis B virus. Hepatitis B immune globulin (HBIG) is given to provide for short-term immunity. HBV vaccine may be given concurrently. Candidates for postexposure prophylaxis include those with known or suspected percutaneous or permucosal contact with infected blood, sexual partners of patients with acute HBV or

who are HBV carriers, and household contacts of patients with acute HBV infection (CDC, 2012).

DISEASE TREATMENT Nearly all people with acute viral hepatitis recover fully without pharmacologic treatment. Severe cases of acute hepatitis B may be treated with an antiretroviral drug such as lamivudine (Epivir, Heptovir), adefovir (Hepsera), entecavir (Baraclude), tenofovir (Viread), or telbivudine (Tyzeka). Treatment is not indicated for mild to moderate cases (Longo et al., 2013). Acute hepatitis C generally is treated with interferon alpha, an antiviral agent, to reduce the risk of chronic hepatitis C. Although single drug treatment with interferon-α (IFN-α) is common, a long-acting interferon (peginterferon [Pegasys]) may be combined with the antiviral drug ribavirin (Rebetol, Virazole). Combination therapy with peginterferon and ribavirin is the treatment of choice for chronic hepatitis C. A new investigational oral regimen involving a combination of an experimental medication called *sofosbuvir* with ribavirin shows promise for patients with liver damage caused by HCV (Harris & Crawford, 2013). See the accompanying Medication Administration feature for nursing responsibilities related to interferons and antiviral drugs.

IFN-α interferes with viral replication, reducing the viral load. It is given by intramuscular or subcutaneous injection. Virtually all patients treated with interferon develop a flulike syndrome with fever, fatigue, muscle aches, headache, and chills. Acetaminophen helps alleviate some of these adverse effects, which tend to decrease over time. Depression is a common adverse effect of this drug. Instruct patients to contact their physician if suicidal thoughts or manifestations of depression develop. Ribavirin has two major adverse effects: hemolytic anemia and birth defects. Blood counts are obtained before and during treatment to detect early signs of hemolytic anemia. Because of the risk for birth defects, this drug is contraindicated for use during pregnancy, and two reliable methods of birth control must be used by women taking the drug and female sexual partners of men taking the drug.

In addition to IFN-α or peginterferon, options for treating chronic hepatitis B include antiviral drugs such as lamivudine or adefovir. Using an antiviral drug in combination with an interferon reduces liver inflammation and fibrosis. Although side effects are minimal, patients may become resistant to the beneficial effects of these drugs. Entecavir is the most potent of the HBV antivirals and

MEDICATION ADMINISTRATION

Drugs to Treat Chronic Hepatitis

INTERFERON ALPHA

Conventional interferons

interferon alfa-2a (Roferon-A)

interferon alfa-2b (Intron A)

interferon alfacon-1 (Infergen)

Long-acting interferons:

peginterferon alfa-2a (Pegasys)

peginterferon alfa-2b (PEG-Intron)

Human interferons have antiviral, immunosuppressive, and antineoplastic activity. IFN-α interferes with viral replication by blocking the virus from entering host cells, inhibiting syntheses of viral RNA and proteins, and viral release from host cells. Conventional interferons have a short half-life and must be administered several times weekly; long-acting preparations can be given once weekly. Long-acting preparations have a higher incidence of adverse effects, however.

Nursing Responsibilities

- Administer by subcutaneous injection. Do not use if solution is discolored or contains visible particulates.
- Monitor for manifestations of hypersensitivity (e.g., angioedema or bronchoconstriction); immediately notify physician and administer emergency treatment as needed to maintain cardiorespiratory status.
- Monitor CBC, platelet count, and renal and liver function studies. Frequently assess mental status. Withhold the drug and notify the physician of significant changes in lab values, manifestations of neuropsychiatric effects, severe abdominal pain, or changes in vision.

Patient Education

- This drug may cause flulike symptoms with fever, fatigue, body aches, headache, and chills. These symptoms tend to diminish over time with continued use of the drug. If approved by your physician, acetaminophen may be used to promote comfort.
- Notify your physician immediately if you become severely depressed or develop thoughts of suicide, have severe chest pain or difficulty breathing, notice unusual bleeding or bruising or have bloody diarrhea, notice a change in your vision, develop severe stomach or lower back pain, or notice a new or worsening skin condition.
- Keep all appointments for lab tests and follow-up visits to your physician.
- Women: Use a reliable means of birth control and notify your physician immediately if you become pregnant.

ANTIRETROVIRAL DRUGS (NUCLEOSIDE/NUCLEOTIDE ANALOGS)

lamivudine (Epivir-HBV)

adefovir (Hepsera)

entecavir (Baraclude)

tenofovir (Viread)

telbivudine (Tyzeka)

The nucleoside/nucleotide analog antiretroviral drugs were originally developed for treating HIV infection and now also are approved for HBV treatment, although the recommended doses differ for these two uses. These drugs inhibit synthesis of viral DNA. Therapy with antiretroviral drugs may be prolonged as relapse is common when the drug is stopped. Viral resistance to the drug also is a concern.

Nursing Responsibilities

- Administer PO as ordered.
- Monitor baseline and periodic renal and liver function tests, CBC with differential, blood chemistries, and serum electrolytes. Notify the physician of significant changes.
- Lactic acidosis is a risk with these drugs; monitor for manifestations such as hyperventilation, lethargy, and ABG values indicative of metabolic acidosis. Withhold the drug and notify the physician if manifestations of lactic acidosis develop.

Patient Teaching

- Take the drug as prescribed.
- Notify your physician if you develop severe abdominal pain, nausea, vomiting, or anorexia or if you become jaundiced.
- Symptoms of recurrent hepatitis B may develop after you stop taking this drug; notify your physician if this occurs.

may be used as an alternate to lamivudine or adefovir. Treatment of acute hepatitis also includes as-needed bed rest, adequate nutrition as tolerated, and avoidance of strenuous activity, alcohol, and agents that are toxic to the liver. In most cases, clinical recovery takes 3 to 16 weeks.

COMPLEMENTARY THERAPIES

Milk thistle, with its active ingredient silymarin, has been used by herbalists to treat liver disease for over 2000 years. Clinical studies have demonstrated that treatment with silymarin promotes quality of life and reduces symptoms in patients with hepatitis C. It also is beneficial for patients who have liver damage due to toxins, cirrhosis, and alcoholic liver disease. Silymarin is a powerful antioxidant that also promotes liver cell growth; it has not been shown, however, to decrease viral activity or reduce liver inflammation (Smith, 2013).

Herbalists may use licorice root to treat hepatitis. It has both antiviral and anti-inflammatory effects. Long-term use of licorice root, however, can lead to hypertension and affect fluid and electrolyte balance.

Herbal preparations may be used to relieve the adverse effects of IFN-α. Ginger can help relieve nausea, and St. John's wort is used for the depression associated with IFN-α use.

●○● NURSING CARE

Health Promotion

Nurses play an instrumental role in preventing the spread of hepatitis. Stress the importance of hygiene measures such as hand hygiene after toileting and before all food handling. Discuss the dangers of injection drug use and, with drug users, of sharing needles or other equipment. Encourage all sexually active patients to use safer sexual practices such as abstinence, mutual monogamy, and barrier protection (such as male or female condoms).

Discuss recommendations for hepatitis A and hepatitis B vaccine with people in high or moderate risk groups for these infections. Ensure that nurses and other healthcare workers at risk for exposure to blood and body fluids are effectively vaccinated against hepatitis A and B. Encourage all people with known or probable exposure to HAV or HBV to obtain postexposure prophylaxis. See the accompanying Moving Evidence into Action feature for a study of healthcare workers' attitudes toward infected peers.

Assessment

Collect assessment data related to hepatitis, such as the following:

- *Health history:* current manifestations, including anorexia, nausea, vomiting, abdominal discomfort, changes in bowel elimination or color of stools; muscle or joint pain, fatigue; changes in color of skin or sclera; duration of symptoms; known exposure to hepatitis; high-risk behaviors such as injection drug use or multiple sexual partners; previous history of liver disorders; current medications, prescription and over the counter
- *Physical assessment:* vital signs including temperature; color of sclera and mucous membranes; skin color and condition; abdominal contour and tenderness; color of stool and urine.
- *Diagnostic tests:* serum bilirubin, liver function tests, serologic antibody–antigen levels.

Priorities of Care

Nursing care focuses on preventing spread of the infection to others, promoting the patient's comfort, helping with energy conservation, and supporting the ability to provide self-care.

Diagnoses, Outcomes, and Interventions

Patients with acute or chronic hepatitis usually are treated in community settings; hospitalization is rarely required.

Risk for Infection (Transmission)

An important goal when caring for patients with acute viral hepatitis is preventing spread of the infection.

Moving Evidence into Action

Applying Evidence to Practice

Many patients with hepatitis-related cirrhosis experience mood disorders, which may be related to the neuropsychologic syndrome associated with hepatitis infection or to hepatitis treatment. Cytokine (interferon) used to treat chronic viral hepatitis can cause serious psychiatric disorders such as severe depression, manic attack, psychotic excitation, and suicidal thoughts (Keskin et al., 2013).

The Keskin et al. (2013) study investigated the relationship between quality of life, the severity of physical signs and symptoms of the disease, and anxiety and depression. Keskin and colleagues found that a significant number of patients with chronic hepatitis B experience anxiety and depression and that their quality of life was low. A decrease in quality of life can lead to problems with adherence to the treatment plan, which in turn causes an increase in adverse physical symptoms and complications related to the disease.

Implications for Nursing

The researchers concluded that nurses must use an integrative approach to assess their patients with chronic hepatitis. This approach should include ongoing evaluation for depression, anxiety, and other adverse psychologic manifestations. They stress chronic hepatitis is a complex disease that often requires expertise from an interprofessional team. Providing holistic care requires nurses to assess and treat the physiologic, emotional, and social factors related to hepatic failure. When caring for patients with chronic hepatitis, medical-surgical nurses should be prepared to advocate for consultation with a psychiatric-mental health nurse or other disciplines with expertise in the psychologic and social domains.

Moving Knowledge into Action

1. In this study, the researchers found a relationship between anxiety, depression, and perceived quality of life for patients with chronic hepatitis. What other factors do you think may impact such a patient's quality of life?
2. Adherence to the treatment plan is a challenge for many patients with chronic hepatitis. How would you assess such a patient's adherence to the treatment plan?
3. Mr. Owens is a 62-year-old patient being treated in your clinical for chronic hepatitis B. His wife tells you her husband seems depressed and is sometime nervous. How will you respond to her concerns? What additional knowledge or information do you need to obtain to address this problem?

Expected Outcome: Eliminate or reduce the spread of hepatitis viruses in the patient's home, community, and in the healthcare setting where patient is seeking treatment and care.

- Use standard precautions. Practice meticulous hand hygiene. *The hepatitis viruses are spread by direct contact with feces or blood and body fluids. The use of standard precautions and good hand hygiene protect both healthcare workers and other patients from exposure to the virus.*
- For patients with HAV or HEV, use standard precautions and contact isolation if fecal incontinence is present. *The fecal–oral route is the primary mode of transmission of these viruses. Other hepatitis viruses are transmitted through blood and other body fluids.*
- Encourage prophylactic treatment of all members of household and intimate sexual contacts. *Prophylactic treatment of people in close contact with the patient decreases their risk of contacting the disease or, if already infected, the severity of the disease.*
- If the patient diagnosed with hepatitis A is employed as a food handler or child care worker, contact the local health department to report possible exposure of patrons. Maintain confidentiality. *Prophylactic treatment of people who have possibly been exposed to the virus can prevent a local epidemic of the disease.*

Fatigue

Fatigue and possible weakness are common in acute hepatitis. Although bed rest is rarely indicated, adequate rest periods and limitation of activities may be necessary. Many patients with acute hepatitis may be unable to resume normal activity levels for 4 or more weeks.

Expected Outcome: Patient will use energy conservation strategies to adapt to fatigue as evidenced by balancing rest and activity, maintaining adequate nutrition intake, and maintaining social interactions.

- Encourage planned rest periods throughout the day. *Adequate rest is necessary for optimal immune function.*
- Assist to identify essential activities and those that can be deferred or delegated to others. *Identifying essential and nonessential activities promotes the patient's sense of control.*
- Suggest using level of fatigue to determine activity level, with gradual resumption of activities as fatigue is reduced and a sense of well-being improves. *Fatigue associated with activity is an indicator of appropriate and inappropriate activity levels. As recovery progresses, increasing activity levels are tolerated with less fatigue.*

Imbalanced Nutrition: Less Than Body Requirements

Adequate nutrition is important for immune function and healing in patients with acute or chronic hepatitis.

Expected Outcome: Patient's food intake will meet caloric and nutritional demand required to meet metabolic needs and promote healing of damaged tissue.

- Help plan a diet of appealing foods that provides a high-kilocalorie intake of approximately 16 carbohydrate kilocalories per kilogram of ideal body weight. *Sufficient energy is required for healing; adequate carbohydrate intake can spare protein.*
- Encourage planning food intake according to symptoms of the disease. Discuss eating smaller meals and using between-meal snacks to maintain nutrient and calorie intake. *Patients with acute hepatitis often are more anorexic and nauseated in the afternoon and evening; planning the majority of calorie intake in the morning helps maintain adequate intake. Limiting fat intake and the size of meals may reduce the incidence of nausea.*
- Instruct to avoid alcohol intake and diet drinks. *Alcohol avoidance is vital to prevent further liver damage and promote healing. Diet drinks (e.g., diet sodas or juice drinks) provide few calories when an increased calorie intake is needed for healing.*
- Encourage use of nutritional supplements such as Ensure or instant breakfast drinks to maintain calorie and nutrient intake. *Nutritional supplement drinks are an additional source of concentrated calories and nutrients.*

Evidence for Nursing Care

The Patient with Hepatitis

Selected resources that nurses may find helpful when planning evidence-based nursing care follow.

- Harris, H., & Crawford, A. (2013). Hepatitis goes viral. *Nursing 2013, 43*(11), 38–43. doi:10.1097/01.NURSE.0000435198.73152.01.
- Redulla, R., & Dudley-Brown, S. (2013). Adherence and completion in hepatitis C management. *Gastroenterology Nursing, 36*(1), 53–58. doi:10.1097/SGA.0b013e318281634e.

Disturbed Body Image

Jaundice and associated rashes and itching can affect a patient's body image. Nursing measures to prevent skin breakdown and address body image are discussed in the following section on cirrhosis.

Continuity of Care

Provide discharge teaching to patients and their families for home care. Include the following topics:

- Recommended prophylactic treatment
- Infection control measures such as frequent hand hygiene; not sharing eating utensils; avoiding food handling or preparation activities by the patient with hepatitis A; abstaining from sexual relations during acute infection; and using barrier protection if a carrier or for chronic infection
- Managing fatigue and limited activity
- Managing pruritus and maintaining skin integrity: use warm, not hot water when bathing; use mild or no soap; limit duration of baths and showers; pat dry, do not rub, apply an alcohol-free lotion soon after bathing to retain skin moisture; wear loose cotton garments that allow moisture to evaporate from skin; reduce room temperature, especially at night, to prevent overheating; keep fingernails short, and wear cotton mittens or gloves as needed to prevent scratching during sleep
- Promoting nutrient intake
- Avoiding hepatic toxins such as alcohol, acetaminophen, and selected other drugs; encourage to alert all care providers to presence of infection
- Recommended follow-up.

If chronic hepatitis B or C is being treated with medications, teach how to administer the drug, its dosing schedule, precautions, and management of adverse effects. Stress the importance of keeping follow-up appointments, including recommended laboratory testing.

THE PATIENT WITH CIRRHOSIS

Cirrhosis is characterized by fibrosis of liver tissue leading to decreased mass, impaired liver function, and altered blood flow. Cirrhosis was previously thought to be an irreversible condition; now, however, it is recognized that fibrosis may be reversed when the underlying cause is eliminated (Longo et al., 2013).

FAST FACTS

- Cirrhosis is the 12th leading cause of death in the United States overall.
- In adults ages 25 to 64 years, however, cirrhosis/chronic liver disease is the 7th leading cause of death.
- Overall, the death rate due to cirrhosis and chronic liver disease in men is more than twice that of women (Murphy et al., 2013).

Alcoholic cirrhosis is the most common type of cirrhosis in the United States. Chronic hepatitis B or C are leading causes of cirrhosis, particularly in people who consume alcohol excessively. Other causes include prolonged obstruction of the biliary (bile drainage) system; long-term, severe right heart failure; and uncommon liver disorders. The incidence and mortality attributable to cirrhosis and chronic liver disease vary significantly among populations. See the accompanying Focus on Cultural Diversity box.

Pathophysiology

In cirrhosis, functional liver tissue is gradually destroyed and replaced by fibrous scar tissue. As hepatocytes and liver lobules are destroyed, the metabolic functions of the liver are lost. Structurally abnormal nodules encircled by connective tissue develop. This fibrous connective tissue forms constrictive bands that disrupt blood and bile flow within liver lobules. Blood no longer flows freely through the liver to the inferior vena cava. This restricted blood flow leads to portal hypertension, increased pressure in the portal venous system.

ALCOHOLIC CIRRHOSIS

Alcoholic or Laënnec's cirrhosis is the end result of alcoholic liver disease. Its development is directly related to alcohol consumption: total amount of alcohol consumed, number of years of excessive alcohol consumption, and blood alcohol levels. Women develop cirrhosis at lower overall levels of alcohol use than men. This may relate to the effects of estrogen and less effective metabolism of alcohol in women, resulting in higher blood alcohol levels.

Alcohol causes metabolic changes in the liver: Triglyceride and fatty acid synthesis increases, and the formation and release of lipoproteins decrease, leading to fatty infiltration of hepatocytes (fatty liver). At this stage, abstinence from alcohol can allow the liver to heal, however, with continued alcohol abuse, the disease progresses. Inflammatory cells infiltrate the liver (alcoholic hepatitis), causing necrosis, fibrosis, and destruction of functional liver tissue. In the final stage of alcoholic cirrhosis, regenerative nodules form, and the liver shrinks and develops a nodular appearance. Malnutrition commonly accompanies alcoholic cirrhosis. See the Pathophysiology Linkage and Pathophysiology Illustrated features on the following pages.

POSTHEPATIC CIRRHOSIS

Advanced progressive liver disease resulting from chronic hepatitis B or C, autoimmune hepatitis, or nonalcoholic fatty liver disease is known as *posthepatic* or *postnecrotic* cirrhosis. Chronic viral hepatitis is the leading cause of posthepatic cirrhosis in the United States. About 25% of persons with chronic hepatitis B or C will eventually develop cirrhosis. The immune response is responsible for producing liver damage and fibrosis in chronic and autoimmune hepatitis. The liver is shrunken and nodular, with extensive liver cell loss and fibrosis. The obesity epidemic is seen as a major factor contributing to an increased incidence of cirrhosis due to nonalcoholic fatty liver disease.

BILIARY CIRRHOSIS

When bile flow is obstructed within the liver or in the biliary system, retained bile damages and destroys liver cells close to the interlobular bile ducts. This leads to inflammation, fibrosis, and formation of regenerative nodules. Within the liver, bile ducts are narrowed or obstructed, leading to elevated bilirubin levels and progressive liver failure.

Manifestations and Complications

Early in the course of cirrhosis, few manifestations may be present. The liver usually is enlarged and may be tender. A dull, aching pain in the epigastric area or RUQ may be present. Other early signs include weight loss, weakness, and anorexia. Bowel function is disrupted with diarrhea or constipation.

As the disease progresses, manifestations related to liver cell failure and portal hypertension develop. Impaired metabolism causes such manifestations as bleeding, ascites, gynecomastia (breast enlargement) in men and infertility in women, jaundice, and neurologic changes. Portal hypertension accounts for such manifestations as ascites, peripheral edema, anemia, and low WBC and platelet counts. See the Multisystem Effects feature on page 710.

PORTAL HYPERTENSION

Increased pressure in the portal system causes blood to be rerouted to adjoining lower pressure vessels. This *shunting* of blood involves collateral vessels. Affected veins, which become engorged and congested, are located in the esophagus, rectum, and abdomen. Portal hypertension increases the hydrostatic pressure in vessels of the portal system. Increased hydrostatic pressure in the capillaries pushes fluid out, contributing to ascites formation.

FOCUS ON CULTURAL DIVERSITY

Cirrhosis

- Although cirrhosis/chronic liver disease is the 12th leading cause of death overall in the United States, it is the 6th leading cause of death for people of Native American (including Alaska Natives) and Hispanic (or Latino) origin.
- Native American men have the highest incidence and mortality rate from cirrhosis and chronic liver disease, followed by Native American women, Hispanic men, and women of Hispanic or Latino origin (Murphy et al., 2013).
- At this time, there is no clear explanation for these differences. Contributory factors may include the following:
  - Socioeconomic factors that lead to greater stress and alcohol consumption among certain populations
  - Patterns of alcohol consumption (e.g., consuming alcohol without food calories)
  - Variations in alcohol metabolism among populations
  - As-yet unidentified immunologic or genetic factors.

PATHOPHYSIOLOGY LINKAGE

Cirrhosis

Manifestations	Underlying Pathophysiology
Edema, ascites	• Impaired hepatocyte function impairs plasma protein synthesis (hypoalbuminemia) • Disrupted hormone balance due to loss of metabolic and detoxification functions • Impaired metabolism of aldosterone, leading to salt and water retention; disrupted renal blood flow contributes to fluid retention • Increased hydrostatic pressure in portal venous system
Bleeding, bruising	• Decreased clotting factor synthesis related to impaired hepatocyte function • Increased platelet destruction by enlarged spleen • Impaired vitamin K absorption and storage
Esophageal varices, hemorrhoids	• Increased pressure in portal venous system with development of weak, thin-walled vessels, particularly in the lower esophagus, rectum, and abdominal wall
Gastritis, anorexia, diarrhea	• Engorged veins in gastrointestinal system disrupt normal appetite mechanisms • Alcohol ingestion • Impaired bile synthesis and fat absorption
Abdominal wall vein distention (caput medusae)	• Portal hypertension
Jaundice	• Impaired bilirubin metabolism due to disrupted hepatocyte function • Bile excretion is impaired by fibrosis and obstruction of biliary channels
Malnutrition, muscle wasting	• Impaired nutrient metabolism • Impaired fat absorption • Impaired hormone metabolism
Anemia, leukopenia, increased risk for infection	• Bleeding • Increased blood cell destruction by spleen
Asterixis, encephalopathy	• Accumulated metabolic toxins • Impaired ammonia metabolism and excretion
Gynecomastia, infertility, impotence	• Altered sex hormone metabolism

SPLENOMEGALY

The spleen enlarges (splenomegaly) because portal hypertension causes blood to be shunted into the splenic vein. Splenomegaly increases the rate at which red and white blood cells and platelets are removed from circulation and destroyed. This increased blood cell destruction leads to anemia, leukopenia, and thrombocytopenia.

ASCITES

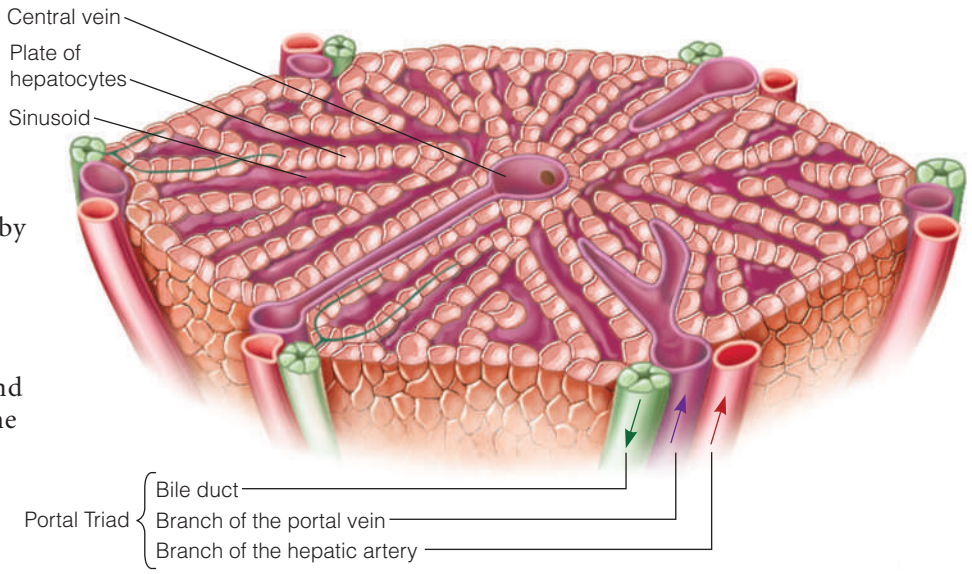
Ascites is the accumulation of plasma-rich fluid in the abdominal cavity. Although portal hypertension is the primary cause of ascites, decreased serum proteins and increased aldosterone also contribute to the fluid accumulation. *Hypoalbuminemia*, low serum albumin, decreases the colloidal osmotic pressure of plasma. This pressure normally holds fluid in the intravascular compartment; when plasma colloidal osmotic pressure decreases, fluid escapes into extravascular compartments. *Hyperaldosteronism*, an increase in aldosterone levels, causes sodium and water retention, contributing to ascites and generalized edema.

ESOPHAGEAL VARICES

Esophageal varices are enlarged, thin-walled veins that form in the submucosa of the esophagus. These collateral vessels form when blood is shunted from the portal system due to portal hypertension. The thin-walled varices may rupture, causing massive hemorrhage; even eating high-roughage foods can precipitate bleeding. Thrombocytopenia, platelet deficiency, and impaired production of clotting factors by the liver contribute to the risk for hemorrhage.

PORTAL SYSTEMIC ENCEPHALOPATHY

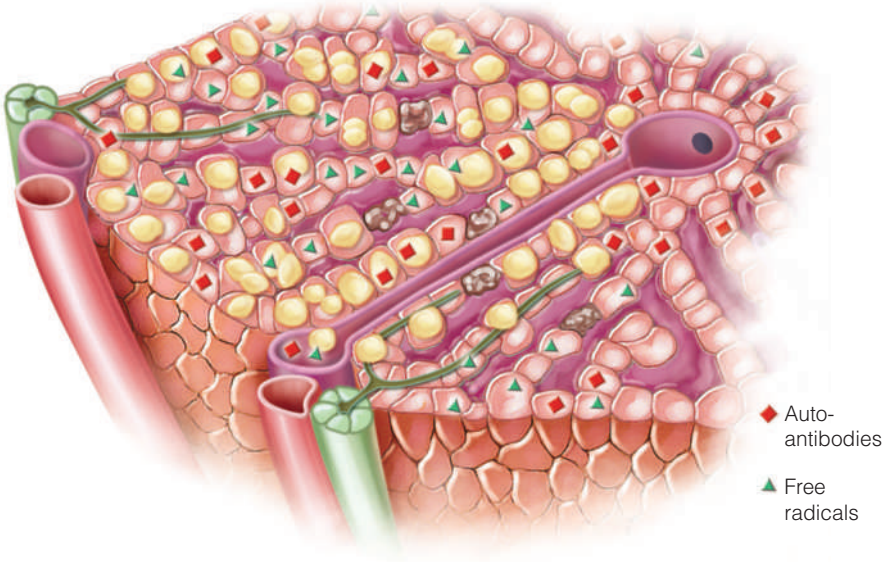
Portal systemic encephalopathy (*hepatic encephalopathy*) results from accumulation of neurotoxins in the blood and cerebral edema. Ammonia, a by-product of protein metabolism, contributes to hepatic encephalopathy. Ammonium ion is produced as proteins and amino acids are broken down by bacteria in the intestinal tract. Normally, the ammonia produced is then converted by the liver to urea before entering the general circulation. As functional liver tissue is destroyed, ammonia can no longer be converted to urea, and it accumulates in the blood. Other nervous system depressants, such as narcotics and tranquilizers, also can contribute to hepatic encephalopathy. Box 25–4 lists selected precipitating factors for hepatic encephalopathy. Accumulation of other metabolic toxins is thought to contribute as well.



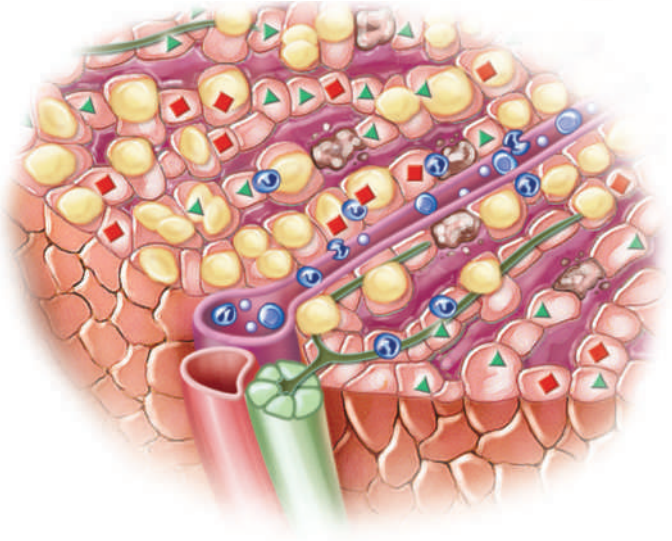
Asterixis (liver flap), a muscle tremor that interferes with the ability to maintain a fixed position of the extremities and causes involuntary jerking movements, is an early sign of portal systemic encephalopathy. Asterixis primarily affects the upper extremities, but also may affect the tongue and feet. Asterixis is elicited by instructing the patient to extend the arms and dorsiflex the wrists.

PATHOPHYSIOLOGY ILLUSTRATED

Cirrhosis and Portal Hypertension



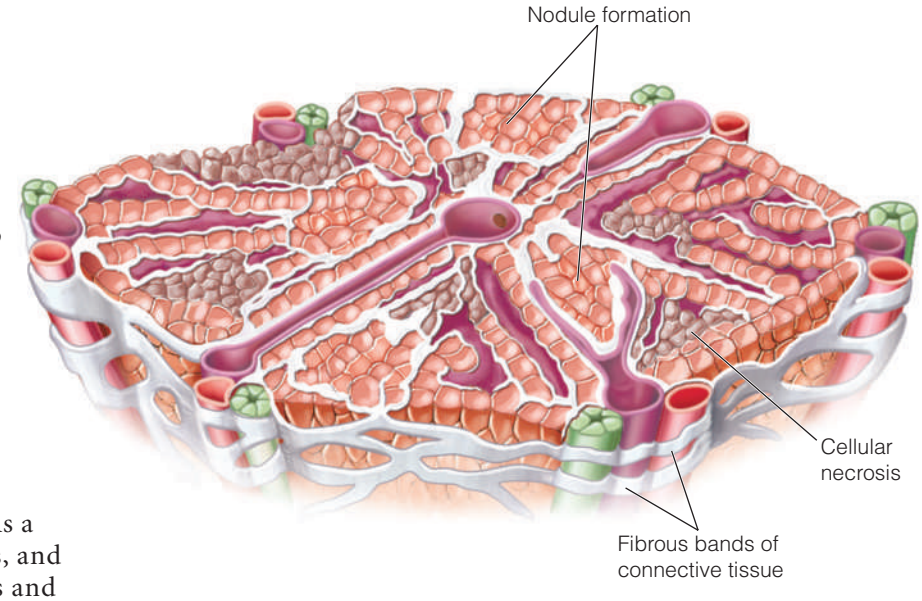
Normal liver



The liver contains multiple lobules made up of plates of hepatocytes, the functional cells of the liver, surrounded by small capillaries called sinusoids. These sinusoids receive a mixture of venous and arterial blood from branches of the portal vein and hepatic artery. Blood from the sinusoids drains into the central vein of the lobule. Hepatocytes produce bile, which drains outward to bile ducts.

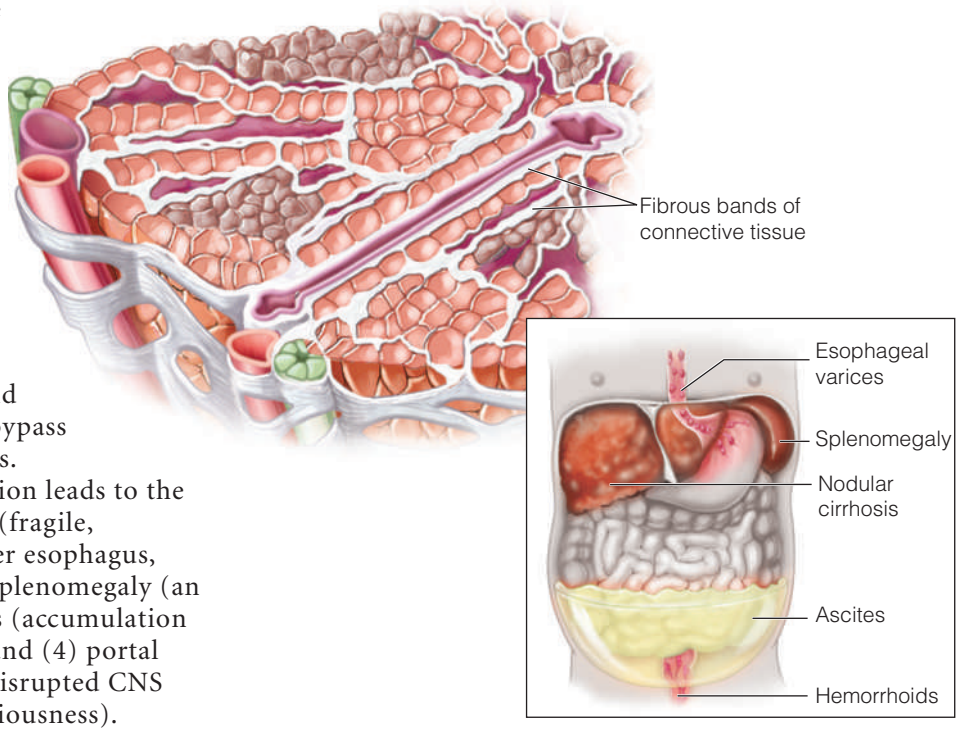
Fatty liver

Ingested alcohol is primarily metabolized in the liver. Acetaldehyde, formed when alcohol is metabolized, damages hepatocytes and impairs the oxidation of fatty acids. As a result, fat accumulates within hepatocytes and liver lobules. Other alcohol metabolism by-products, including oxygen free radicals, promote inflammation and may stimulate autoantibody production.



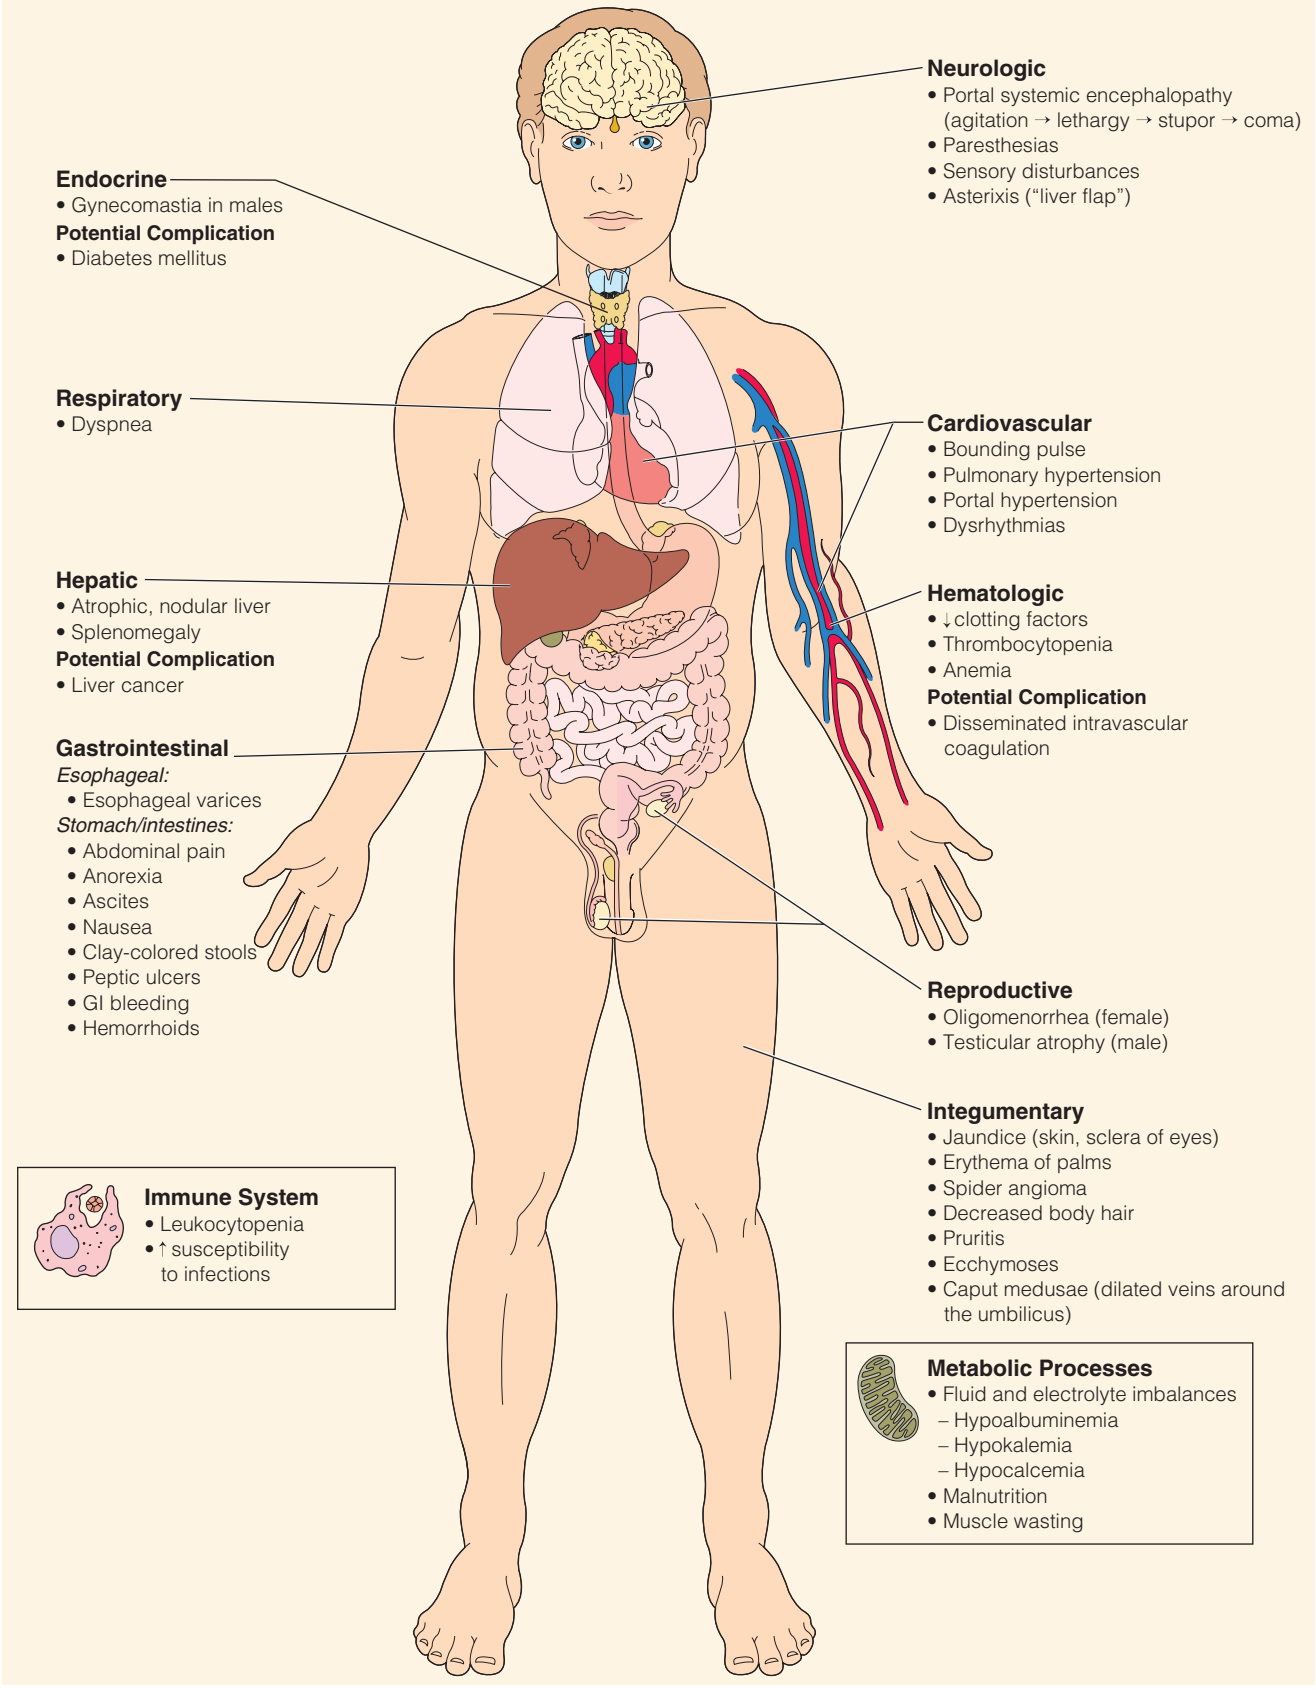
Alcoholic hepatitis

With continued alcohol intake, liver cells degenerate and spotty cellular necrosis occurs. Inflammatory cells such as polymorphonuclear leukocytes and lymphocytes infiltrate the lobule.



Alcoholic cirrhosis

Cellular necrosis and inflammation transform some liver cells into fibroblasts that produce and deposit collagen. Weblike bands of connective tissue develop around the portal triads and central vein, eventually connecting with one another. Small islands of liver cells continue to regenerate, forming nodules. Hepatocyte destruction outpaces regeneration. As a result of cell loss, fibrosis, and scarring, the liver shrinks and becomes hard and nodular.



Portal hypertension

Bands of fibrotic scar tissue obstruct the sinusoids and blood flow from the portal vein to the hepatic vein. Pressure in the portal venous system, which drains the gastrointestinal tract, pancreas, and spleen, increases. This increased pressure opens collateral vessels in the esophagus, anterior abdominal wall, and rectum, allowing blood to bypass the obstructed portal vessels. Prolonged portal hypertension leads to the development of (1) varices (fragile, distended veins) in the lower esophagus, stomach, and rectum; (2) splenomegaly (an enlarged spleen); (3) ascites (accumulation of fluid in the abdomen); and (4) portal systemic encephalopathy (disrupted CNS function with altered consciousness).

MULTISYSTEM EFFECTS OF Cirrhosis

BOX 25–4 Factors Precipitating Portal Systemic Encephalopathy

- High serum ammonia level
- Constipation
- Blood transfusions
- Gastrointestinal bleeding
- Medications: sedatives, tranquilizers, narcotic analgesics, anesthetics
- Hypoxia
- Severe infection
- Surgery

If present, asterixis causes a downward flapping of the hands (Figure 25–5 ■). Changes in personality and mentation develop; agitation, restlessness, impaired judgment, and slurred speech also are early manifestations of hepatic encephalopathy. As it progresses, confusion, disorientation, and incoherence develop. Cerebral edema that leads to increased intracranial pressure and cerebral hypoxia is the leading cause of death in people with portal systemic encephalopathy and liver failure.

HEPATORENAL SYNDROME

Although the cause is unclear, renal failure with azotemia (excess nitrogenous waste products in the blood), sodium retention, oliguria, and hypotension may develop in patients with advanced cirrhosis and ascites. Hepatorenal syndrome appears to be the result of imbalanced blood flow, leading to constriction of vessels leading to and within the kidneys. The syndrome may be precipitated by gastrointestinal bleeding, by aggressive diuretic therapy, or by an unknown cause.

SPONTANEOUS BACTERIAL PERITONITIS

Patients with cirrhosis and ascites may develop bacterial peritonitis, even in the absence of known contamination of the peritoneal cavity or other specific risk factors (e.g., paracentesis). The inflammatory response to peritonitis worsens ascites by increasing the permeability of capillaries in the mesentery. The manifestations of spontaneous bacterial peritonitis may be subtle, with increased abdominal discomfort or pain, fever, increasing ascites, worsening encephalopathy, and an overall decline in condition.

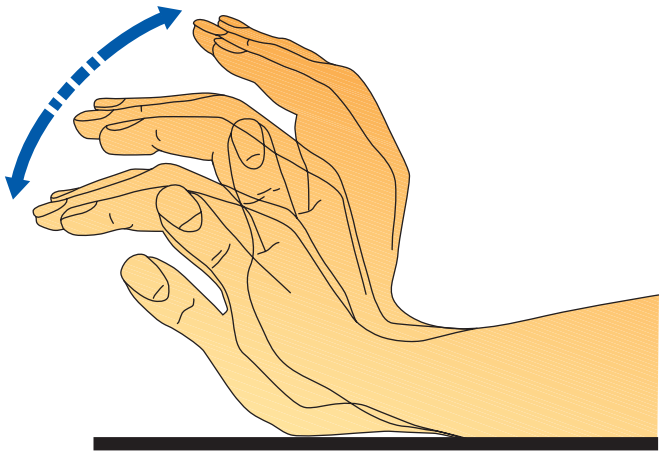


Figure 25–5 ■ Asterixis. Note the downward tremor of the hand on dorsiflexion of the wrist.

●○● INTERPROFESSIONAL CARE

Care for the patient with cirrhosis is holistic, addressing physiologic, psychosocial, and spiritual needs. The importance of including the family in the plan of care cannot be overemphasized, particularly if alcohol abuse is identified as the cause. Alcohol abstinence is critical: Fewer than 50% of patients who have experienced complications of cirrhosis and who continue to drink will survive for 5 years. The prognosis improves with abstinence, and liver transplant may be a treatment option in abstinent patients (Longo et al., 2013).

Treatment of cirrhosis is supportive, directed at slowing the progression to liver failure and reducing complications. Treatment includes medications to help regulate protein metabolism, maintenance of fluid and electrolyte balance, and supportive therapies, including treatment of underlying problems, such as malnutrition, anemia, bleeding, encephalopathy, renal failure, and infections.

DIAGNOSIS

Studies to confirm the diagnosis of cirrhosis and identify its cause and effects are performed. Diagnostic tests may include the following:

- *Liver function studies* include *ALT*, *AST*, and *ALP*. All may be elevated in cirrhosis, but usually not as severely as in acute hepatitis. Elevations in these enzymes may not correlate well with the extent of liver damage in cirrhosis.
- *CBC with platelets* is done. A low RBC count, hemoglobin, and hematocrit demonstrate anemia related to bone marrow suppression, increased RBC destruction, bleeding, and deficiencies of folic acid and vitamin B_{12}. Platelets are low, related to increased destruction by the spleen. Leukopenia (low WBC count) also relates to splenomegaly.
- *Coagulation studies* show a prolonged prothrombin time due to impaired production of coagulation proteins and lack of vitamin K.
- *Serum electrolytes* are measured. Hyponatremia is common, due to hemodilution. Hypokalemia, hypophosphatemia, and hypomagnesemia also are frequently seen, related to malnutrition and altered renal excretion of these electrolytes.
- *Bilirubin* levels are usually elevated in severe cirrhosis, including both direct (conjugated) and indirect (unconjugated) bilirubin.
- *Serum albumin* levels show hypoalbuminemia due to impaired liver production.
- *Serum ammonia* levels are elevated because the liver fails to effectively convert ammonia to urea for renal excretion.
- *Serum glucose* and *cholesterol* levels frequently are abnormal in patients with cirrhosis.
- *Abdominal ultrasound* is performed to evaluate liver size, detect ascites, and identify liver nodules. Ultrasound may be used in conjunction with *Doppler studies* to evaluate blood flow through the liver and spleen.
- *Esophagoscopy* (upper endoscopy) may be done to determine the presence of esophageal varices.
- *Liver biopsy* is not always necessary to diagnose cirrhosis, but may be done to distinguish cirrhosis from other forms of liver disease. Biopsy may be deferred if the bleeding time is prolonged (such as a prothrombin time [PT] greater than 3 seconds over the control).

See Chapter 21 for more information about the nursing implications of the aforementioned diagnostic tests.

MEDICATIONS

Medications are used to treat the complications and effects of cirrhosis; they do not reverse or slow the process of cirrhosis itself. Known hepatotoxic drugs and alcohol are avoided, as are drugs metabolized by the liver (e.g., barbiturates, sedatives, hypnotics, and acetaminophen). Several groups of drugs are commonly prescribed. See the Medication Administration box for nursing responsibilities and patient teaching for commonly used drugs in patients with cirrhosis.

- Diuretics reduce fluid retention and ascites. Spironolactone (Aldactone) is frequently the drug of first choice because it addresses one of the causes of ascites—increased aldosterone levels. If additional diuresis is necessary, a loop diuretic such as furosemide (Lasix) may be added to the regimen.
- Medications to reduce the nitrogenous load and lower serum ammonia levels are added when manifestations of hepatic encephalopathy develop. Commonly administered medications are lactulose and antibiotics such as neomycin, metronidazole, or rifaximin. Lactulose reduces the number of ammonia-forming organisms in the bowel and increases the acidity of colon contents, converting ammonia into ammonium ion. Ammonium ion is not absorbable, and is excreted in the feces. Neomycin sulfate is a locally acting antibiotic that also reduces the number of ammonia-forming bacteria in the bowel. Because it is toxic to the kidneys and auditory system, it is alternated with metronidazole. Metronidazole is a systemic antibiotic effective against common gram-negative bacteria that inhabit the bowel. Peripheral neuropathy is a potential toxic effect of metronidazole. Rifaximin, a poorly absorbed antibiotic, acts locally within the bowel and has few adverse or toxic effects.
- A beta-blocker such as nadolol (Corgard) or propranolol (Inderal) may be given to reduce portal hypertension and prevent bleeding of esophageal varices.
- Ferrous sulfate and folic acid are given as indicated to treat anemia. Vitamin K may be ordered to reduce the risk of bleeding. When bleeding is acute, packed RBCs, fresh frozen plasma, or platelets may be administered to restore blood components and promote hemostasis.
- Antacids are prescribed as indicated. A drug regimen to treat *Helicobacter pylori* infection may also be effective (see Chapter 23).
- Oxazepam (Serax), a benzodiazepine antianxiety/sedative drug, is not metabolized by the liver, and may be used to treat acute agitation.

MEDICATION ADMINISTRATION

The Patient with Cirrhosis

DIURETICS

spironolactone (Aldactone)

furosemide (Lasix)

Spironolactone is a potassium-sparing diuretic that competes with aldosterone. It reduces ascites by increasing renal excretion of fluid and decreasing aldosterone levels. Furosemide is a loop diuretic that promotes the excretion of potassium. Drugs may be given in combination if serum potassium level permits.

Nursing Responsibilities

- Monitor ECG, serum potassium, BUN, creatinine levels, and hydration status.
- Weigh daily.
- Carefully monitor intake and output.
- Monitor for signs of hyperkalemia if taking spironolactone alone: bradycardia; widening QRS, spiking T waves, or ST segment depression on ECG; diarrhea; and muscle twitching.
- Assess for hyponatremia: confusion, lethargy, apprehension.

Health Education for the Patient and Family

- Maintain diet and fluid restrictions as prescribed.
- Report increases in weight or edema.
- Immediately report signs of hyponatremia, hyperkalemia, or hypokalemia.
- Expect increased urinary output; take medications in morning hours to avoid nocturia.

LAXATIVES

lactulose (Cephulac, Chronulac)

Lactulose is a disaccharide laxative that is not absorbed by the gastrointestinal tract. It reduces the number of ammonia-producing bacteria and lowers the pH in the colon. The lower pH (increased acidity) converts ammonia to ammonium ion, a nonabsorbable form that is excreted in the feces. Lactulose also pulls water into the bowel lumen, increasing the number of daily stools.

Nursing Responsibilities

- Assess bowel sounds and abdominal girth.
- Maintain accurate stool chart.
- Adjust dose to achieve two to four soft stools per day.
- Monitor electrolytes and hydration.

Health Education for the Patient and Family

- Drink adequate fluids.
- Report diarrhea; if present, decrease dose. You should have an average of two to four stools per day.
- This drug may cause nausea. Continue taking the drug; taking it with crackers or a soft drink may reduce nausea.

ANTI-INFECTIVE AGENTS

neomycin sulfate (Neo Tabs)

metronidazole (Flagyl)

rifaximin (Xifaxan)

These antibiotics act in the gut to reduce intestinal bacteria and decrease ammonia production in the bowel lumen. Neomycin may be administered as an oral or rectal preparation; metronidazole and rifaximin are administered orally.

Nursing Responsibilities

- Monitor hearing, renal, and neurologic functions. Neomycin is ototoxic, nephrotoxic, and neurotoxic. Metronidazole is neurotoxic.
- Prior to administration, check for previous hypersensitivity reaction.
- Monitor intake and output.
- Monitor BUN and creatinine levels.

Health Education for the Patient and Family

- Report dizziness, tinnitus (ringing in ears), hearing loss, headaches, tremors, vision changes, or extremity numbness and tingling immediately.
- Keep follow-up appointments.
- Maintain fluids; avoid dehydration. (Teach signs of dehydration.)

Note: Drugs identified in *italics* are among the 200 most commonly prescribed medications in the U.S.

NUTRITION AND FLUID MANAGEMENT

Dietary support is an essential part of care for the patient with cirrhosis. Dietary needs change as hepatic function fluctuates.

- Sodium intake is restricted to less than 2 g/day, and fluids are restricted as necessary to reduce ascites and generalized edema. Fluids are often limited to 1500 mL/day. Fluid needs are calculated based on response to diuretic therapy, urine output, and serum electrolyte values.
- Unless serum ammonia levels are high, a palatable diet with adequate calories and protein is recommended. Although dietary protein restriction has previously been recommended for patients with cirrhosis and hepatic encephalopathy, it is now recognized that the effects of protein-calorie malnutrition are more damaging than protein consumption (Longo et al., 2013). Vegetable proteins may be recommended along with restricted red meat consumption. Parenteral nutrition is used as needed to maintain nutritional status when food intake is limited.
- Vitamin and mineral supplements are ordered based on laboratory values. Deficiencies in the B-complex vitamins, particularly thiamin, folate, and B_{12}, and the fat-soluble vitamins A, D, and E are common. These vitamins may need to be administered in a water-soluble form. Patients with alcohol-induced cirrhosis are at high risk for magnesium deficiency, which needs to be replaced.

COMPLICATION MANAGEMENT

ASCITES **Paracentesis**, aspiration of fluid from the peritoneal cavity, may be a diagnostic or a therapeutic procedure. It may be done therapeutically to relieve severe ascites that does not respond to diuretic therapy. The goal of paracentesis is to relieve respiratory distress caused by excess fluid in the abdomen. Ascites fluid may be withdrawn in moderate amounts of 500 mL to 1 L daily to reduce the risk of fluid and electrolyte imbalances. Large-volume paracentesis, withdrawal of 4 to 6 L of fluid at one time, may be used. Albumin is often administered intravenously during large-volume paracentesis to maintain intravascular volume as the pressure of the ascites fluid in the abdomen is relieved. Nursing care of the patient undergoing paracentesis is outlined in the accompanying box.

ESOPHAGEAL VARICES Primary care for esophageal varices involves screening with endoscopy. When varices are identified, beta-blocker therapy may be initiated to lower portal venous pressure, or endoscopic variceal ligation or sclerotherapy may be performed. In *variceal ligation* or *banding*, small rubber bands are placed on varices to occlude blood flow. *Endoscopic sclerosis* involves injecting a sclerosing agent directly into the varices to induce inflammation and clotting. See Chapter 21 for the nursing implications of endoscopy.

Bleeding esophageal varices are life threatening and require intensive care management. Restoration of hemodynamic stability is the first priority. A central line is inserted and central venous and pulmonary artery pressures are monitored. Blood is given to restore blood volume, and fresh frozen plasma may be administered to restore clotting factors. Somatostatin or octreotide, drugs that constrict blood vessels in the gut, are given intravenously to reduce blood flow in the portal venous system.

When the blood pressure and cardiac output have stabilized, upper endoscopy is performed to evaluate and treat the varices. A large nasogastric tube is inserted prior to endoscopy, and gastric lavage (irrigation of the stomach with large quantities of normal saline) is performed to improve visualization. During endoscopy, the varices may be banded or sclerosed to reduce the risk of recurrent bleeding. *Balloon tamponade* of bleeding varices may be used if bleeding cannot be controlled through vasoconstriction or if endoscopy is unavailable or contraindicated by the patient's condition. A multiple-lumen nasogastric (NG) tube (such as a Sengstaken-Blakemore tube or a Minnesota tube) is inserted, and the gastric and esophageal balloons are inflated to apply direct pressure on the bleeding varices (Figure 25–6 ■). Tension is applied to the tube to further compress the varices. Balloon tamponade carries a number of risks, including aspiration, airway

NURSING CARE OF THE PATIENT

Undergoing Paracentesis

PREPARATION

- Verify presence of an informed consent. *Paracentesis is an invasive procedure requiring informed consent.*
- Describe what to expect during paracentesis: Following cleansing and local anesthesia, a small incision may be made and a needle or trocar inserted to withdraw fluid. The trocar is connected to tubing and a collection bottle; specimens may be sent to laboratory. Blood pressure is monitored during the procedure. *A clear understanding of the procedure and its purpose reduces anxiety and facilitates cooperation during the procedure.*
- Weigh prior to paracentesis. Measure abdominal girth at the level of the umbilicus. *Weight is an accurate means of determining fluid balance, particularly in patients with edema. Abdominal girth provides an additional measure of the effectiveness of paracentesis.*
- Assess vital signs for baseline. *Fluid shifts during and after paracentesis can affect cardiovascular stability. Baseline vital signs provide a reference for subsequent measurements.*
- Have patient void immediately prior to the test. *The bladder must be empty prior to paracentesis to reduce the risk for bladder puncture.*
- Position seated, either on the side of the bed or in a chair, with feet supported. *The sitting position allows ascites fluid to collect in the lower abdomen, facilitating its removal.*

AFTER THE PROCEDURE

- A small dressing is placed over the puncture site after the needle is withdrawn. There may be some fluid leakage from the site. *Depending on the size of the trocar inserted and the amount of remaining ascites fluid, the insertion puncture may not immediately seal, allowing fluid to escape.*
- Monitor vital signs every 15 minutes for 1 hour, every 30 minutes for 1 hour, then every 4 hours. Measure abdominal girth and obtain weight. *Removal of large amounts of fluid from the abdominal cavity can cause significant fluid shifts with resulting vascular instability. Weight and abdominal girth measurements provide information about fluid balance.*
- Salt-poor albumin may be given after the procedure to replace lost protein. *Removing ascites fluid reduces pressure within the peritoneal cavity. In the patient with hypoalbuminemia and portal hypertension, a significant amount of vascular fluid can escape as a result, leading to hypovolemia. Albumin is given to increase plasma oncotic pressure, helping retain fluid within the vascular system.*

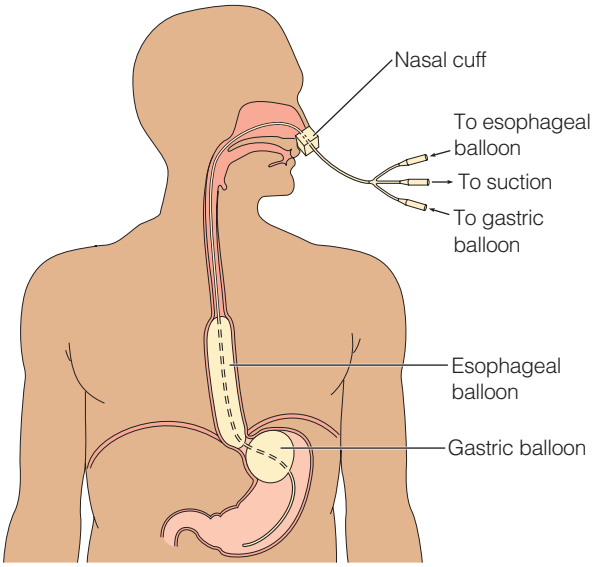

Figure 25–6 ■ Triple-lumen nasogastric tube (Sengstaken-Blakemore) used to control bleeding esophageal varices.

obstruction, and tissue ischemia and necrosis. An endotracheal tube is inserted prior to nasogastric intubation to support the airway and reduce the risk of aspiration. This short-term measure is used only until more definitive treatment can be done. Without definitive treatment, rebleeding is common when balloon tamponade is discontinued.

SAFETY ALERT

When caring for a patient with a multiple-lumen NG tube, always deflate the esophageal balloon before the gastric balloon. This practice prevents the balloon from becoming misplaced and occluding the airway. Always keep an appropriate syringe at the bedside to deflate the esophageal balloon should the patient develop respiratory distress.

PORTAL HYPERTENSION *Transjugular intrahepatic portosystemic shunt (TIPS)* may be used as an emergency measure to relieve portal hypertension and its complications of esophageal varices and ascites. A channel is created through the liver tissue using a needle inserted transcutaneously (Figure 25–7 ■). An expandable metal stent is inserted into this channel to allow blood to flow directly from the portal vein into the hepatic vein, bypassing the cirrhotic liver. The shunt relieves pressure in esophageal varices and allows better control of fluid retention with diuretic therapy. Stenosis and occlusion of the shunt are frequent complications. TIPS increases the risk of developing hepatic encephalopathy (due to decreased perfusion of the liver and impaired ammonia metabolism) and may reduce long-term survival. It generally is used as a short-term measure until liver transplant is performed.

SURGERY

Liver transplantation is indicated for some patients with irreversible, progressive cirrhosis. A decline in functional status, increasing bilirubin levels, falling albumin levels, and increasing problems with complications that respond poorly to treatment are indications for liver transplantation. Malignancy, active alcohol or drug abuse, and poor surgical risk are contraindications for the surgery. See the box for nursing care of the patient undergoing a liver transplant.

●○● NURSING CARE

In addition to the nursing care discussed in this section, see the Case Study & Nursing Care Plan for a patient with alcoholic cirrhosis on page 717.

Health Promotion

For most patients, high-risk behaviors are the risk factors for cirrhosis. With all patients (including children and young adults), stress the relationship between alcohol and drug abuse and liver disorders. Although many patients tolerate alcohol use in moderation with no adverse effects on the liver, excess alcohol use is the leading cause of cirrhosis. Injection drug use also is a significant risk factor, increasing the risk for contracting bloodborne hepatitis (B, C, or D). These types of viral hepatitis can lead to chronic hepatitis and, ultimately, to cirrhosis. Provide information and referral as appropriate for hepatitis B immunization. Discuss abstinence or safer sex practices as another measure to prevent viral hepatitis and potential liver damage.

Assessment

Assessment data related to cirrhosis include the following:

- *Health history:* current manifestations, including abdominal pain or discomfort, recent weight loss, weakness, and anorexia; altered

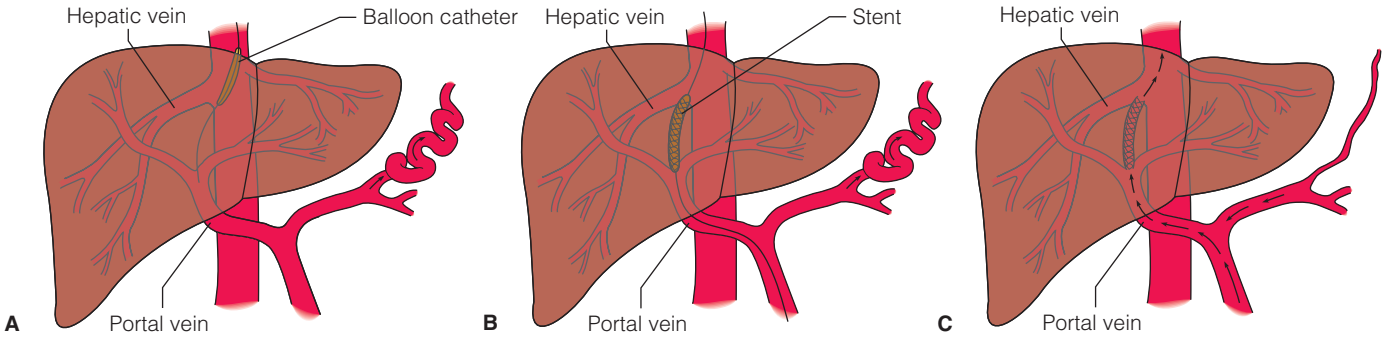

Figure 25–7 ■ Transjugular intrahepatic portosystemic shunt (TIPS). A, Guided by angiography, a balloon catheter inserted via the jugular vein is advanced to the hepatic veins and through the substance of the liver to create a portacaval (portal vein-to-vena cava) channel. B, A metal stent is positioned into the channel, and expanded by inflating the balloon. C, The stent remains in place after the catheter is removed, creating a shunt for blood to flow directly from the portal vein into the hepatic vein.

bowel elimination; excess bleeding or bruising; abdominal distention; jaundice, pruritus; altered libido or impotence; duration of symptoms; history of liver or gallbladder disease; pattern and extent of alcohol or injection drug use; use of other prescription and nonprescription drugs

- *Physical assessment:* vital signs; mental status; color and condition of skin and mucous membranes; peripheral pulses and presence of peripheral edema; abdominal assessment including appearance, shape and contour, bowel sounds, abdominal girth, percussion for liver borders, and palpation for tenderness and liver size.

Priorities of Care

Nursing care for the patient with cirrhosis focuses on problems with fluid and electrolyte balance, disturbed thought processes, risk for bleeding, skin integrity, and nutrition.

Diagnoses, Outcomes, and Interventions

Nursing care of the patient with cirrhosis presents many challenges because liver function affects all body systems. The nurse is responsible for coordinating care among healthcare providers. Many nursing diagnoses may apply.

Excess Fluid Volume

Cirrhosis affects water and salt regulation due to portal hypertension, hypoalbuminemia, and hyperaldosteronism. Signs of fluid volume overload and portal hypertension may develop: ascites, peripheral edema, internal hemorrhoids and varices, and prominent abdominal wall veins. Careful monitoring is necessary, because treatment measures can lead to further fluid and electrolyte imbalances.

Expected Outcome: Patient's fluid balance will not be compromised as evidenced by 24-hour intake and output balance, stable body weight, and absence of worsening ascites and peripheral edema.

- Weigh daily. Assess for jugular vein distention, measure abdominal girth daily, and check for peripheral edema. Monitor intake and output. *Careful assessment is important to detect fluid shifts.*
- Assess urine specific gravity. *Specific gravity measures the concentration of urine, an indicator of hydration.*
- Monitor the patient with cirrhosis for signs of impaired renal function, such as oliguria, a fixed specific gravity of about 1.012, central edema (around the eyes and of the face), and increasing serum creatinine and BUN levels. *Such signs may indicate hepatorenal syndrome or acute renal failure from another cause.*
- Provide a low-sodium diet (500 to 2000 mg/day) and restrict fluids as ordered. *Excess sodium leads to water retention, and can increase fluid volume, ascites, and portal hypertension.*

Evidence for Nursing Care

The Patient with Cirrhosis

Selected resources that nurses may find helpful when planning evidence-based nursing care follow.

- Felicilda-Reynaldo, R. F. (2012). Ammonia abolishers: antibiotics for hepatic encephalopathy. *MEDSURG Nursing, 21*(3), 173–175.
- Fowler, C. (2013). Management of patients with complications of cirrhosis. *The Nurse Practitioner, 38*(4), 14–22.
- Tarallo, P. A., & Smolowitz, J. (2013). Preparing for your patient's liver resection. *OR Nurse 2013, 7*(2), 28–34.

Risk for Acute Confusion

Accumulated nitrogenous waste products and other metabolites affect mental status and thought processes. Effects of portal systemic encephalopathy can range from mild confusion to agitation to coma.

Expected Outcome: Patient will demonstrate cognitive orientation as demonstrated by accurate identification of self, significant other, current location, current date and time, recollection of recent significant events, and appropriate behavioral response to situation.

- Assess neurologic status, including level of consciousness and mental status. Observe for signs of early encephalopathy: changes in handwriting, speech, and asterixis. *Early identification of evidence of encephalopathy allows prompt intervention—subtle changes in neurologic functioning are important!*
- Closely monitor patients who have experienced gastrointestinal bleeding for signs of portal systemic encephalopathy. *Blood in the intestinal tract is digested as a protein, increasing serum ammonia levels and the risk for portal systemic encephalopathy.*
- Avoid factors that may precipitate portal systemic encephalopathy. Avoid hepatotoxic medications and CNS depressant drugs. *Cautious use of medications and close monitoring can eliminate iatrogenic causes of encephalopathy.*
- If possible, plan for consistent nursing care assignments. *Consistent care providers facilitate early identification of subtle neurologic changes indicative of portal systemic encephalopathy.*
- Administer medications or enemas as ordered to reduce nitrogenous products. Monitor bowel function and provide measures to promote regular elimination and prevent constipation. *Oral or rectally administered (per enema) medications are ordered to reduce intestinal bacteria and the ammonia they produce. Regular bowel elimination promotes protein and ammonia elimination in the feces.*
- Orient to surroundings, person, and place; provide simple explanations and reassurance. *Modification of verbal interactions to level of understanding and mental status may reduce anxiety and agitation.*

Risk for Bleeding

Impaired coagulation, esophageal varices, and possible acute gastritis place the patient with cirrhosis at significant risk for hemorrhage. Clotting is altered by vitamin K deficiency; impaired manufacture of coagulation Factors II, VII, IX, and X; and increased platelet destruction due to splenomegaly.

Expected Outcome: Patient will not exhibit signs of visible or occult blood, and hematocrit and hemoglobin will be maintained within normal limits. Vital signs will be maintained within normal limits and urine output will be >30 mL/hr.

- Monitor vital signs; report tachycardia or hypotension. *Increased pulse and decreasing blood pressure may indicate hypovolemia due to hemorrhage.*
- Institute bleeding precautions (Box 25–5). *Preventive measures can decrease the risk for active bleeding.*
- Monitor coagulation studies and platelet count. Report abnormal results. *Coagulation studies help determine the risk for bleeding and the need for treatment.*
- Carefully monitor the patient who has had bleeding esophageal varices for evidence of rebleeding: hematemesis, hematochezia (bright blood in the stool) or tarry stools, signs of hypovolemia or shock. *Rebleeding is common following variceal hemorrhage, especially within the first week.*

NURSING CARE OF THE PATIENT

Undergoing Liver Transplantation

PREOPERATIVE CARE

- Obtain a complete nursing history and physical examination. *A complete preoperative nursing assessment provides baseline data for comparison after surgery.*
- Provide routine preoperative care as ordered. *Preoperative care is similar to that provided for other patients undergoing major surgery.*
- Discuss preoperative and postoperative expectations with the patient and family. Introduce to the intensive care unit, and discuss anticipated drainage tubes and supportive measures in the immediate postoperative period. Provide information about visiting policies and family accommodations (if available). *Preoperative teaching helps relieve anxiety in the patient and family members. Patients return from surgery to an intensive care or specialized care unit. Restrictions on the number of visitors and the time they may spend with the patient are common.*
- Once a donor liver is located, check for evidence of infection; if no infection is present, begin preoperative antibiotics as ordered. *An acute or chronic infection may contraindicate liver transplantation as drugs given postoperatively to suppress rejection of the transplanted organ also impair the ability to fight infection*.

POSTOPERATIVE CARE

- Provide routine postoperative care as ordered (see Chapter 4).
- Maintain airway and ventilatory support until awake and alert. *Until the new liver clears the anesthesia, the patient requires measures to support respirations and ventilation.*
- Monitor temperature and implement rewarming measures (such as warming blankets, heating lamps, and head covers) as indicated. *The patient often is hypothermic after liver transplant, necessitating careful rewarming while maintaining hemodynamic stability.*
- Frequently monitor hemodynamic pressures, including arterial blood pressure, central venous pressure, and pulmonary artery pressures. *Postoperative fluid volume status may be difficult to determine without careful pressure measurements. The rate and type of fluids administered are determined by hemodynamic status.*
- Monitor urine output hourly; maintain careful intake and output records. Weigh daily. *Urine output and weight provide additional information about fluid volume status. In addition, renal function may be altered after liver transplant; acute renal failure is a significant risk. See Chapter 28 for more information about acute renal failure and its management.*
- Monitor for signs of active bleeding, including excess drainage, increasing abdominal girth, bloody nasogastric drainage, black tarry stools, tachypnea, tachycardia, diminished peripheral pulses, or pallor. Report immediately. *Altered coagulation in the early postoperative period increases the risk for bleeding. Blood products to replace volume and clotting factors may be necessary.*
- Monitor serum electrolytes and laboratory values related to blood coagulation, liver function, and renal function. Report abnormal results or significant changes immediately. *Electrolyte imbalances are common postoperatively. Altered liver or renal function tests may indicate rejection of the transplanted liver or acute renal failure. Other early signs of transplant rejection include fever, a drop in bile output, or a change in bile color and viscosity.*
- Monitor neurologic status. *With good function of the transplanted organ, mental status should clear within days of the transplant.*
- Provide discharge teaching:
  a. Teach how to reduce risk of infection, and signs of infection to report.
  b. Instruct how to recognize and report signs of organ rejection.
  c. Discuss all medications, including their purpose, schedule, adverse effects, and potential long-term effects. Stress the importance of complying with all prescribed medications and postoperative precautions for the remainder of the patient's life.
  d. Discuss possible changes in body image and psychologic responses to receiving a transplanted organ. Refer to a counselor or support group as indicated.
  e. Refer to home health services for continued assessment and teaching.
  f. Stress importance of continued follow-up with transplant team and primary care provider.

SAFETY ALERT

Carefully monitor the respiratory status of the patient with a Sengstaken-Blakemore or Minnesota tube. Displacement of the tube can obstruct the airway unless an endotracheal tube is in place. The esophageal balloon prevents the patient from swallowing oral secretions, increasing the risk for aspiration. Keep the head of the bed elevated to 45 degrees to reduce the risk of aspiration and promote gas exchange.

Impaired Skin Integrity

Severe jaundice with bile salt deposits on the skin may cause pruritus. Scratching related to the pruritus damages the skin and impairs its integrity. Malnutrition, particularly protein deficiency, and edema also increase the risk for tissue breakdown and impaired skin integrity.

Expected Outcome: Patient's skin will remain intact, and will not show redness or excoriation. Patient will not scratch skin or complain of itching.

- Use warm water rather than hot water when bathing. *Hot water increases pruritus.*
- Use measures to prevent dry skin: Apply an emollient or lubricant as needed to keep skin moist, avoid soap or preparations with alcohol, and do not rub the skin. *Dry skin contributes to pruritus.*
- If indicated, apply mittens to the hands to prevent scratching. *Patients with encephalopathy may not understand the need to refrain from scratching.*
- Institute measures to prevent skin and tissue breakdown: Turn at least every 2 hours, use an alternating pressure mattress, and frequently assess skin condition. *Frequent position changes relieve pressure and promote circulation and tissue oxygenation.*
- Administer prescribed antihistamine (to relieve pruritus) cautiously. *Decreased liver function increases the risk for altered drug responses.*

Imbalanced Nutrition: Less Than Body Requirements

The patient with cirrhosis is at risk for malnutrition for a number of reasons: possible chronic alcohol use, anorexia, impaired vitamin and mineral absorption, and impaired protein metabolism. In addition,

CASE STUDY & NURSING CARE PLAN A Patient with Alcoholic Cirrhosis

Richard Wright is a 48-year-old divorced father of two teenagers. Mr. Wright has been admitted to the community hospital with ascites and malnutrition. He has had three previous hospital stays for cirrhosis, the most recent being 6 months ago.

ASSESSMENT

Mr. Wright is lethargic but responds appropriately to verbal stimuli. He complains of "spitting up blood the past week or so" and says, "I'm just not hungry." He has lost 9 kg (20 lb) since his previous admission. He is jaundiced and has petechiae and ecchymoses on his arms and legs. Liz Mowdi, Mr. Wright's nurse, notes pitting pretibial edema. Abdominal assessment reveals a tight, protuberant abdomen with caput medusae. The liver margin is not palpable; the spleen is enlarged. Vital signs are T 37.7°C (100°F), P 110 bpm, R 25/min, and BP 110/70 mmHg.

Abnormal laboratory results include WBC 3700/mm^3 (normal 4300 to 10,800/mm^3); RBC 4.0 million/mm^3 (normal 4.6 to 5.9 million/mm^3); platelets 75,000/mm^3 (normal 150,000 to 350,000/mm^3); serum ammonia 105 µm/dL (normal 35 to 65 µm/dL); total bilirubin 4.9 mcg/dL (normal 0.1 to 1.0 mcg/dL); and serum sodium 150 mEq/L (normal 135 to 145 mEq/L). Potassium, hemoglobin, hematocrit, total protein, and albumin levels are markedly decreased. Hepatic enzymes are elevated. Blood urea nitrogen and creatinine levels are marginally elevated. Oxygen saturation (O_2 sat) is 88% (normal range: 96% to 100%) per pulse oximetry.

Endoscopy shows bleeding from gastric ulcer, and the diagnosis of alcoholic cirrhosis with gastritis is made. Mr. Wright is started on Aldactone, 25 mg PO q8h; Riopan, 30 mL 2 h p.c. and at bedtime; lactulose, 30 mL every hour until onset of diarrhea, then 15 mL tid; and 800 mg sodium diet; fluid restriction of 1500 mL/day.

DIAGNOSES

- *Impaired Gas Exchange* related to pressure of ascites fluid on the diaphragm as manifested by tachypnea and decreased oxygen saturation
- *Excess Fluid Volume* related to electrolyte imbalance and hypoalbuminemia as manifested by ascites and peripheral edema
- *Imbalanced Nutrition: Less Than Body Requirements* related to anorexia and possible alcohol abuse as manifested by weight loss and low serum protein levels
- *Risk for Acute Confusion* related to effects of high ammonia levels as manifested by lethargy
- *Risk for Bleeding* related to impaired platelet formation and portal hypertension

EXPECTED OUTCOMES

- Patient's respiratory rate and O_2 saturation will be within normal limits.
- Patient's abdominal girth will decrease by 1 to 2 cm per day; peripheral edema will decrease.
- Patient will gain 0.45 kg (1 lb) per week without evidence of increased fluid retention. Serum albumin levels will return to normal range.
- Patient will be alert and oriented; serum ammonia levels will be within normal range.
- Patient will demonstrate no further evidence of active bleeding.
- Patient will verbalize willingness to join a community support group.

PLANNING AND IMPLEMENTATION

- Weigh daily.
- Provide high-calorie, low-salt, low-protein diet with between-meal snacks.
- Maintain stool chart.
- Assign same nurses to care as much as possible to facilitate evaluation of mental status. Promptly report changes in status or laboratory values.
- Measure abdominal girth every 8 hours, marking level of measurement.
- Institute bleeding precautions.
- Elevate head of bed; assist to chair with legs elevated tid as tolerated.
- Include significant others in care and teaching; refer to community agencies for discharge follow-up.

EVALUATION

A week after admission, Mr. Wright's ascites has decreased and no further active bleeding is noted. His serum protein levels have increased, and his laboratory values are improving. No further bruising is noted during hospitalization. Although he shows a 2.3-kg (5-lb) weight loss as excess water is eliminated, he is consuming 100% of his diet. His serum ammonia levels have returned to normal. On discharge, O_2 sat is 96%; respirations are 18. Lactulose will be continued on discharge.

Ms. Mowdi provides both written and verbal information about the medication and cirrhosis, including measures to prevent complications. Mr. Wright and his children express interest in Alcoholics Anonymous and Al-Anon and are referred to those agencies. Prior to discharge, follow-up appointments are made with a psychiatric social worker and a primary caregiver.

Clinical Reasoning in Patient Care

1. Describe the relationship between portal hypertension, liver dysfunction, and ascites.
2. Outline a 1-day menu for a low-protein, low-sodium, high-calorie diet.
3. What is the pathophysiologic basis for portal systemic encephalopathy? What are the nursing responsibilities related to lactulose and neomycin?
4. Design a nursing care plan for Mr. Wright for the nursing diagnosis of *Ineffective Coping*.

See Evaluating Your Response in Appendix B.

salt restrictions may make the diet less palatable and appealing to the patient.

Expected Outcome: Patient will maintain adequate oral intake, report adequate energy levels, and maintain body mass and weight and normal lab values (transferrin, albumin, and electrolytes).

- Weigh daily. Instruct to weigh at least weekly at home. *Weight is a good indicator of both nutritional status and fluid balance. Short-term weight fluctuations tend to reflect fluid balance, whereas longer term changes in weight are more reflective of nutritional status.*
- Provide small meals with between-meal snacks. *A small meal is more appealing for an anorexic patient. Between-meal snacks help maintain adequate calorie and nutrient intake.*
- Unless protein is restricted due to impending portal systemic encephalopathy, promote protein and nutrient intake by providing nutritional supplements such as Ensure or instant breakfasts. *The sodium and protein content of all meals and snacks must be calculated when maintaining restrictions of these nutrients.*
- Arrange for consultation with a dietitian for diet planning while hospitalized and at home. *The dietitian can provide detailed*

BOX 25–5 Bleeding Precautions

- Prevent constipation.
- Avoid rectal temperatures or enemas.
- Avoid injections; if needed, use small-gauge needle and apply gentle pressure.
- Monitor platelet count, PT, and aPPT.
- Assess for ecchymotic areas and areas of purpura.
- Apply pressure to bleeding sites. After venipuncture, apply direct pressure for at least 5 minutes.
- Use only a soft toothbrush.
- Avoid blowing nose.
- Assess oral cavity for bleeding gums.

instructions, sample menus, and suggestions for improving the palatability of the diet and promoting intake.

Continuity of Care

Cirrhosis is a chronic, progressive disease. As such, the patient and family assume major roles in managing the disease and its manifestations and in preventing complications. Teaching topics for home care include the following:

- The absolute necessity of avoiding alcohol and other hepatotoxic drugs. Suggest inpatient or community-based alcohol treatment programs and Alcoholics Anonymous as indicated.
- Diet and fluid intake restrictions and recommendations. Include suggestions to promote nutritional intake and increase the flavor of food when sodium is restricted.
- Prescribed medications, their timing, intended and adverse effects, and manifestations to report to the primary care provider.
- Bleeding precautions (refer to Box 25–5).
- Manifestations of potential complications to be reported to the primary care provider. Stress the importance of promptly reporting evidence of gastrointestinal bleeding for prompt intervention for potential hemorrhage.
- Skin care techniques to reduce pruritus and the risk of damage.
- Ways to manage fatigue and conserve energy.

Provide referrals for home health services, dietary consultation, social services, and counseling as needed by the patient and family. Suggest local support groups where available. If appropriate, suggest hospice services for the patient with end-stage liver disease.

THE PATIENT WITH CANCER OF THE LIVER

Primary liver cancer is uncommon in the United States, accounting for only 0.5% to 2% of all cancers (American Cancer Society [ACS], 2013a). It is, however, a common malignancy worldwide. Hepatocellular carcinoma is common in parts of Asia and Africa, where the incidence is as high as 500 cases per 100,000 people. This higher incidence is linked to chronic hepatitis B or C infection. The incidence of primary liver cancer in men is three times higher than in women. The incidence of liver cancer is higher in Hispanics than it is in Black and non-Hispanic Whites; Blacks have a higher incidence than Whites (ACS, 2013b; 2013c). The prognosis for primary liver cancer is poor, in part because the disease often is advanced at the time of diagnosis. Metastasis to the liver from primary tumors of the lung, breast, and gastrointestinal tract are relatively common.

BOX 25–6 Suspected Causes of Primary Liver Cancer

- Chronic hepatitis C infection
- Chronic hepatitis B infection
- Cirrhosis, regardless of type
- Aflatoxin (a toxin produced by *Aspergillus* molds) exposure
- Chronic ethanol consumption
- Nonalcoholic fatty liver (steatohepatitis or NASH)

Pathophysiology

More than 80% of primary hepatic cancers arise from the liver's parenchymal cells (hepatocellular carcinoma); the remainder form in the bile ducts (cholangiocarcinoma). Regardless of the origin, the progress of the disease is similar. Several etiologic factors have been identified (Box 25–6). Most primary liver cancer in the United States is related to alcoholic cirrhosis, HBV, or HCV.

The underlying pathophysiology of primary liver cancer is damage to hepatocellular DNA. This damage may be caused by integration of HBV or HCV into the DNA or by repeated cycles of cell necrosis and regeneration that facilitate DNA mutations. HBV and aflatoxins damage a specific tumor suppressor gene, p53. Tumors may be limited to one specific area, may occur as nodules throughout the liver, or may develop as surface infiltrates. The tumor interferes with normal hepatic function, leading to biliary obstruction and jaundice, portal hypertension, and metabolic disruptions (hypoalbuminemia, hypoglycemia, and bleeding disorders). It also may secrete bile products and produce hormones (paraneoplastic syndrome) that may lead to polycythemia, hypoglycemia, and hypercalcemia. Tumors usually grow rapidly and metastasize early.

Manifestations

Initial manifestations of liver cancer develop insidiously and often are masked by the presence of cirrhosis or chronic hepatitis. Weakness, anorexia, weight loss, fatigue, and malaise are common early manifestations. Abdominal pain and a palpable mass in the right upper quadrant are common presenting symptoms. See the accompanying box for manifestations of primary liver cancer. Ascites and jaundice may be present at diagnosis. Signs of liver failure with portal hypertension, splenomegaly, and altered metabolism develop as the tumor progresses.

●○● INTERPROFESSIONAL CARE

Ultrasound of the liver is used as a screening tool for liver cancer. CT scan with contrast and MRI are used to determine tumor size and extent. A liver biopsy is done to confirm the diagnosis and identify the tumor type or origin. See the accompanying box for the nursing

MANIFESTATIONS OF PRIMARY LIVER CANCER

- Malaise
- Anorexia
- Lethargy
- Weight loss
- Fever of unknown origin
- Jaundice
- Feeling of abdominal fullness
- Painful right upper quadrant mass
- Manifestations of liver failure

implications of liver biopsy. Serum alpha-fetoprotein (AFP) levels, normally low in nonpregnant adults, rise in most patients with hepatocellular cancer.

Small, localized tumors may be surgically resected, or destroyed using radio-frequency ablation or injection of an agent such as ethanol directly into the tumor. Most tumors, however, have spread extensively or have distant metastasis at the time of diagnosis, so this is frequently not an option. Additionally, patients with underlying liver disease such as cirrhosis may not tolerate loss of additional functional liver tissue. Liver transplantation may be done for stage I or II tumors (no apparent lymph node involvement or distant metastasis). Liver transplantation is limited as a treatment option by the availability of donor organs.

Radiation therapy may be used to shrink the tumor, decreasing pressure on surrounding organs and reducing pain. Chemotherapy may be used as primary treatment for advanced tumors. Direct continuous hepatic arterial infusion with an implanted pump has shown promise in prolonging survival rates. See Chapter 14 for nursing care of patients receiving radiation therapy or chemotherapy.

●○● NURSING CARE

Encourage patients with risk factors for primary liver cancer to avoid alcohol and other substances that may further damage the liver. Urge them to discuss regular screening for liver tumors (such as serum AFP levels) with their primary care physician.

Both the patient and the family need extensive nursing support. Controlling pain is a priority. Because of the poor prognosis, early referral for hospice services may be appropriate.

Nursing diagnoses, interventions, and teaching for the patient with liver cancer are similar to those for patients with cirrhosis (see pages 715–718).

THE PATIENT WITH LIVER TRAUMA

Blunt or penetrating trauma to the abdomen can damage the liver. Liver trauma is frequently seen in combination with injuries to other abdominal organs. Motor vehicle crashes, stab or gunshot wounds, and iatrogenic sources such as liver biopsy are among the causes of these injuries.

Pathophysiology and Manifestations

Liver trauma generally causes bleeding due to the vascularity of the organ. Liver injury may cause a surface hematoma, hematoma within the liver parenchyma, laceration of liver tissue, or disruption of vessels leading to or from the liver. Severe bleeding can rapidly disrupt hemodynamic stability and lead to shock.

SAFETY ALERT

Bleeding due to liver trauma may not be immediately apparent. Instruct the patient with apparent or potential liver trauma to immediately report light-headedness, rapid heart rate, shortness of breath, thirst, or increasing abdominal pain.

●○● INTERPROFESSIONAL CARE

Diagnostic peritoneal lavage is often used along with CT scan to diagnose liver trauma. The procedure is performed by making a small abdominal incision into the peritoneum (after the bladder has been emptied), and inserting a small catheter into the peritoneal cavity. If blood is immediately detected, the patient is taken directly to surgery for abdominal exploration. If frank bleeding is not apparent, a liter of isotonic fluid is instilled into the abdomen, then drained and sent for laboratory analysis.

Intravenous fluids, fresh frozen plasma, platelets, and other clotting factors are administered to restore blood volume and promote hemostasis. Hemodynamic status is closely monitored; continued instability may indicate a need for surgical intervention to control hemorrhage. Postoperative nursing care focuses on preventing pulmonary complications, such as atelectasis, and detecting and preventing infection.

●○● NURSING CARE

Nursing care of the patient with liver trauma focuses on fluid management and other supportive care related to shock. Keeping family members informed is an important aspect of care, especially during the period of patient instability. Diagnoses include the following:

- *Deficient Fluid Volume* related to hemorrhage
- *Risk for Infection* related to wound or abdominal contamination
- *Risk for Bleeding* related to impaired coagulation.

THE PATIENT WITH LIVER ABSCESS

Liver abscesses usually are bacterial or amoebic (protozoal) in origin. Bacterial abscesses may follow trauma or surgical procedures, including biopsy. Multiple or single abscesses occur most commonly in the right lobe. Amoebic abscesses most frequently occur following infestation of the liver by *Entamoeba histolytica*. Amoebic infestation is associated with poor hygiene, unsafe sexual practices, or travel in areas where drinking water is contaminated.

Pathophysiology and Manifestations

Following bacterial or amoebic invasion of the liver, healthy tissue is destroyed, leaving an area of necrosis, inflammatory exudate, and blood. This damaged region becomes walled off from the healthy liver tissue. Pyogenic (bacterial) liver abscess may be caused by cholangitis, or distant or intra-abdominal infections, such as peritonitis or diverticulitis. *Escherichia coli* is the most frequently identified causative organism. The onset of pyogenic abscess is usually sudden, causing acute symptoms such as fever, malaise, vomiting, hyperbilirubinemia, and pain in the right upper abdomen.

The infection pathway for amoebic hepatic abscesses usually is the portal venous circulation from the right colon. Generally, the onset of amoebic abscess is insidious.

●○● INTERPROFESSIONAL CARE

Hepatic abscess is diagnosed through biopsy, hepatic aspirate, blood and fecal cultures, and CT scan and ultrasound studies. Therapy is based on identifying the causative organism through laboratory cultures. Pyogenic abscesses are treated with antibiotics to which the causative organism is sensitive.

Pharmacologic agents used for amebic hepatic abscess are the same as those used for intestinal amebic infestation (see Chapter 24); combination therapy is commonly used. Two commonly used drugs for treating amebic liver abscesses are metronidazole (Flagyl) and

iodoquinol (Diquinol). Both medications can cause gastrointestinal symptoms. Bone marrow suppression is a risk with metronidazole.

If the abscess does not respond to antibiotic therapy, percutaneous aspiration or surgical drainage may be done. In these procedures, a *percutaneous closed-catheter drain* is placed in the abscess to promote drainage of purulent material.

●○● NURSING CARE

A major aspect of nursing care is prevention; teaching patients to avoid contaminated water and foods is especially important. Nursing interventions include teaching hikers to treat water and food handlers to wash hands thoroughly.

Patients who have a liver abscess require supportive care to prevent dehydration from the accompanying fever, nausea, vomiting, and anorexia. Careful monitoring of fluid and electrolyte status is indicated, as are comfort measures for abdominal pain. Possible nursing diagnoses include the following:

- *Risk for Deficient Fluid Volume* related to effects of prolonged fever and vomiting
- *Readiness for Enhanced Knowledge* related to transmission of amebic abscess
- *Activity Intolerance* related to pain and weakness

Exocrine Pancreas Disorders

The pancreas is both an exocrine and an endocrine gland. It is made up of two basic cell types, each having different functions. The exocrine cells produce enzymes that empty through ducts into the small intestine, whereas the endocrine cells produce hormones that enter the bloodstream directly. Disorders of the exocrine pancreas affect the secretion and glandular control of digestive enzymes, whereas disorders of the endocrine pancreas affect the production of hormones necessary for normal carbohydrate, protein, and fat metabolism. Disorders of the exocrine pancreas are discussed in this section of the chapter; diabetes mellitus, a disorder of the endocrine pancreas, is discussed in Chapter 20.

THE PATIENT WITH PANCREATITIS

Pancreatitis, or inflammation of the pancreas, is characterized by the release of pancreatic enzymes into the tissue of the pancreas itself, leading to hemorrhage and necrosis. Pancreatitis may be either acute or chronic. About 5000 new cases of acute pancreatitis are diagnosed every year in the United States. It is a serious disease, with a mortality rate of approximately 10% (Longo et al., 2013). Hospitalizations for acute pancreatitis have increased during the past 15 years. Alcoholism and gallstones are the primary risk factors for acute pancreatitis, however, the etiology of about 30% of cases is unclear.

The incidence of chronic pancreatitis is less clear because many people with chronic pancreatitis do not have classic manifestations of the disease. Patients with chronic pancreatitis may have long-term effects of the disease, with chronic changes in enzyme and hormone production.

Physiology Review

Knowledge of the normal structure and functions of the exocrine pancreas is important to understand how inflammation affects it and the patient. The exocrine pancreas consists of lobules of acinar cells. The acinar cells secrete digestive enzymes and fluids (pancreatic juices) into ducts that empty into the main pancreatic duct (the duct of Wirsung). The pancreatic duct joins the common bile duct and empties into the duodenum through the ampulla of Vater (in some people the main pancreatic duct empties directly into the duodenum). The epithelial lining of the pancreatic ducts secretes water and bicarbonate to modify the composition of the pancreatic secretions. Pancreatic enzymes are secreted primarily in an inactive form and are activated in the intestine, a modification that prevents digestion of pancreatic tissue by its own enzymes (Grossman & Porth, 2014). The pancreatic enzymes, with related functions, are as follows:

- Proteolytic enzymes, including trypsin, chymotrypsin, carboxypolypeptidase, ribonuclease, and deoxyribonuclease, which break down dietary proteins
- Pancreatic amylase, which breaks down starch
- Lipase, which breaks down fats into glycerol and fatty acids.

Pathophysiology

ACUTE PANCREATITIS

Acute pancreatitis is an inflammatory disorder that involves self-destruction of the pancreas by its own enzymes through autodigestion. The milder form of acute pancreatitis, *interstitial edematous pancreatitis*, leads to inflammation and edema of pancreatic tissue. It often is self-limiting. The more severe form, *necrotizing pancreatitis*, is characterized by inflammation, hemorrhage, and ultimately necrosis of pancreatic tissue.

Acute pancreatitis is more common in middle adults; its incidence is higher in men than in women. Gallstones are the leading cause of acute pancreatitis, with alcohol being the second leading cause (Longo et al., 2013). Some patients recover completely, others experience recurring attacks, and still others develop chronic pancreatitis. The mortality and symptoms depend on the severity and type of pancreatitis, as well as the patient's age and general health. Organ failure (respiratory failure in particular) is the leading cause of death in acute pancreatitis (Longo et al., 2013).

Although the exact cause of pancreatitis is not known, the following factors may activate pancreatic enzymes within the pancreas, leading to autodigestion, inflammation, edema, and/or necrosis:

- Gallstones may obstruct the pancreatic duct or cause bile reflux, activating pancreatic enzymes in the pancreatic duct system.
- Alcohol causes duodenal edema, and may increase pressure and spasm in the sphincter of Oddi, obstructing pancreatic outflow. It also stimulates pancreatic enzyme production, thus raising pressure within the pancreas.

Other factors associated with acute pancreatitis include tissue ischemia or anoxia, trauma or surgery, pancreatic tumors, third-trimester pregnancy, infectious agents (viral, bacterial, or parasitic),

elevated calcium levels, and hyperlipidemia. Some medications have been linked with this disorder, including thiazide diuretics, estrogen, steroids, salicylates, and NSAIDs.

Regardless of the precipitating factor, the pathophysiologic process begins with the release of activated pancreatic enzymes into pancreatic tissue. Activated proteolytic enzymes, trypsin in particular, digest pancreatic tissue and activate other enzymes such as phospholipase A, which digests cell membrane phospholipids, and elastase, which digests the elastic tissue of blood vessel walls. This leads to proteolysis, edema, vascular damage and hemorrhage, and necrosis of parenchymal cells. Cellular damage and necrosis release activated enzymes and vasoactive substances that produce vasodilation, increase vascular permeability, and cause edema. A large volume of fluid may shift from circulating blood into the retroperitoneal space, the peripancreatic spaces, and the abdominal cavity.

MANIFESTATIONS Acute pancreatitis develops suddenly, typically with an abrupt onset of continuous severe epigastric and abdominal pain. This pain commonly radiates to the back and is relieved somewhat by sitting up and leaning forward. The pain often is initiated by a fatty meal or excessive alcohol intake.

Other manifestations include nausea and vomiting; abdominal distention and rigidity; decreased bowel sounds; tachycardia; hypotension; elevated temperature; and cold, clammy skin. Within 24 hours, mild jaundice may appear. Retroperitoneal bleeding may occur 3 to 6 days after the onset of acute pancreatitis; signs of bleeding include bruising in the flanks (Turner's sign) or around the umbilicus (Cullen's sign). See the accompanying Manifestations box.

COMPLICATIONS Systemic complications of acute pancreatitis include intravascular volume depletion with shock, acute tubular necrosis and renal failure (see Chapter 28 for more information about acute kidney injury), and acute respiratory distress syndrome (ARDS). Hypovolemic shock and acute renal failure usually develop within 24 hours after the onset of acute pancreatitis. Manifestations of ARDS may be seen 3 to 7 days after its onset, particularly in patients who have experienced severe volume depletion.

Localized complications include pancreatic necrosis, abscess, pseudocysts, and pancreatic ascites. Pancreatic necrosis causes an inflammatory mass that may be infected. It may lead to shock and multiple organ failure. A pancreatic abscess may form late in the course of the disease (6 or more weeks after its onset), causing an epigastric mass and tenderness (Papadakis & McPhee, 2013). Pancreatic pseudocysts, encapsulated collections of fluid, may develop both within the pancreas itself and in the abdominal cavity (Figure 25–8 ■). They may impinge on other structures, or may rupture, causing generalized peritonitis. Rupture of a pseudocyst or of the pancreatic duct can lead to pancreatic ascites. Pancreatic ascites is recognized by gradually increasing abdominal girth and persistent elevation of the serum amylase level without abdominal pain.

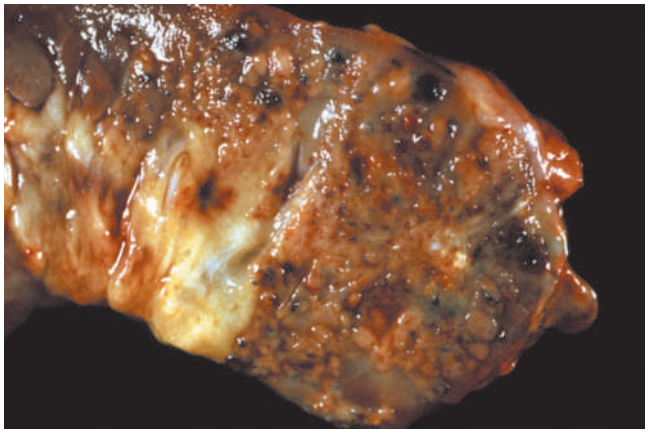

Figure 25–8 ■ Acute pancreatitis. Gross clinical specimen of a pancreas affected by acute pancreatitis. Pseudocyst, a pus-filled bleb seen as the yellow area (lower left center), is a potential complication of acute pancreatitis.

CHRONIC PANCREATITIS

Chronic pancreatitis is characterized by chronic inflammation, fibrosis, and gradual destruction of functional pancreatic tissue. In contrast to acute pancreatitis, which is reversible, chronic pancreatitis is an irreversible process that eventually leads to pancreatic insufficiency. Alcoholism is the primary risk factor for chronic pancreatitis in the United States. Malnutrition is a major worldwide risk factor. About 10% to 20% of chronic pancreatitis is idiopathic, with no identified cause. A genetic mutation on a gene associated with cystic fibrosis may play a role in these cases. Children or young adults with cystic fibrosis may develop chronic pancreatitis as well.

In chronic pancreatitis related to alcoholism, pancreatic secretions have an increased concentration of insoluble proteins. These proteins calcify, forming plugs that block pancreatic ducts and the flow of pancreatic juices. This blockage leads to inflammation and fibrosis of pancreatic tissue. In other cases, a stricture or stone may block pancreatic outflow, causing chronic obstructive pancreatitis. In chronic pancreatitis, recurrent episodes of inflammation eventually lead to fibrotic changes in the parenchyma of the pancreas, with loss of exocrine function. This leads to malabsorption from pancreatic insufficiency. If endocrine function is disrupted as well, clinical diabetes mellitus may develop.

MANIFESTATIONS OF ACUTE AND CHRONIC PANCREATITIS

ACUTE PANCREATITIS

- Abrupt onset of severe epigastric and left upper quadrant pain, may radiate to back
- Nausea, vomiting; fever
- Decreased bowel sounds; abdominal distention and rigidity
- Tachycardia, hypotension; cold, clammy skin
- Possible jaundice
- Positive Turner's sign (flank ecchymosis) or Cullen's sign (periumbilical ecchymosis)

CHRONIC PANCREATITIS

- Recurrent epigastric and LUQ pain, radiates to back
- Anorexia, nausea and vomiting, weight loss
- Flatulence, constipation
- Steatorrhea

MANIFESTATIONS Chronic pancreatitis typically causes recurrent episodes of epigastric and left upper abdominal pain that radiates to the back. This pain may last for days to weeks. As the disease progresses, the interval between episodes of pain becomes shorter. Other manifestations include anorexia, nausea and vomiting, weight loss, flatulence, constipation, and **steatorrhea** (fatty, frothy, foul-smelling stools caused by a decrease in pancreatic enzyme secretion).

COMPLICATIONS Complications of chronic pancreatitis include malabsorption, malnutrition, and possible peptic ulcer disease. Pancreatic pseudocyst or abscess may form, or stricture of the common bile duct may develop. Diabetes mellitus may develop, and there is an increased risk for pancreatic cancer. Opioid addiction related to frequent, severe pain episodes is common.

●○● INTERPROFESSIONAL CARE

Acute pancreatitis often is a mild, self-limiting disease. Treatment focuses on reducing pancreatic secretions and providing supportive care. Treatment to eliminate the causative factor is begun after the acute inflammatory process resolves. Severe necrotizing pancreatitis may require intensive care management. Treatment for chronic pancreatitis often focuses on managing pain and treating malabsorption and malnutrition.

DIAGNOSIS

The laboratory tests that may be ordered when pancreatitis is suspected are summarized in Table 25–4. Diagnostic studies include the following:

- *Ultrasonography* can identify gallstones, a pancreatic mass, or pseudocyst.
- *Endoscopic ultrasonography* can detect changes indicative of chronic pancreatitis in the pancreatic duct and parenchyma.
- *Contrast-enhanced CT scan* may be ordered to identify pancreatic enlargement, ductal calcifications, fluid collections in or around the pancreas, and perfusion deficits in areas of necrosis.
- *Magnetic resonance cholangiopancreatography (MRCP)* is a noninvasive test that allows visualization of the bile and pancreatic ducts.
- *Endoscopic retrograde cholangiopancreatography (ERCP)* may be performed to diagnose chronic pancreatitis and to differentiate inflammation and fibrosis from carcinoma.
- *Percutaneous fine-needle aspiration biopsy* may be performed to differentiate chronic pancreatitis from cancer of the pancreas; the cells that are aspirated are examined for malignancy.

More information about these tests and their nursing implications can be found in Chapter 21.

MEDICATIONS

The treatment of acute pancreatitis is largely supportive. Opioid analgesics such as morphine sulfate or hydromorphone (Dilaudid) are used as needed to control pain. Prophylactic antibiotics are prescribed for patients with severe or necrotizing pancreatitis to prevent infection.

Patients with chronic pancreatitis may also require analgesics, but are closely monitored to prevent drug dependence. Pancreatic enzyme supplements are given to manage abdominal pain and reduce steatorrhea (see the Medication Administration box on page 723). Patients with chronic pancreatitis may need to remain on pancreatic enzyme supplements for life. H_2-blockers, such as cimetidine (Tagamet) and ranitidine (Zantac), and proton-pump inhibitors such as omeprazole (Prilosec) may be given to neutralize or decrease gastric secretions. Octreotide (Sandostatin), a synthetic hormone, suppresses pancreatic enzyme secretion and may also be used to relieve pain in chronic pancreatitis.

TREATMENTS

NUTRITION Oral food and fluids generally are withheld during acute episodes of pancreatitis to reduce pancreatic secretions and promote rest of the organ. A nasogastric tube may be inserted and connected to suction. Intravenous fluids are administered to maintain vascular volume, and total parenteral nutrition (TPN) is initiated. Oral food and fluids are begun once the serum amylase levels have returned to normal, bowel sounds are present, and pain disappears. A low-fat diet is ordered, and alcohol intake is strictly prohibited.

SURGERY If the pancreatitis is the result of a gallstone lodged in the sphincter of Oddi, an *endoscopic transduodenal sphincterotomy* may be performed to remove the stone. When cholelithiasis is identified as a causative factor, a cholecystectomy is performed once the acute pancreatitis has resolved. Surgical procedures to promote drainage of pancreatic enzymes into the duodenum or resection of all or part of the pancreas may be done to provide pain relief in patients with chronic pancreatitis. Large pancreatic pseudocysts may be drained endoscopically or surgically.

TABLE 25–4 Laboratory Tests in Exocrine Pancreatic Disorders

Test	Normal Value	Significance
Serum amylase	30–170 units/L	Rises within 2–12 hours of onset of acute pancreatitis to two to three times normal. Returns to normal in 3–4 days.
Serum lipase	14–280 units/L	Levels rise in acute pancreatitis; remain elevated for 7–14 days.
Urine amylase	4–37 units/L/2h	Urine amylase levels rise in acute pancreatitis.
Serum glucose	70–110 mg/dL	May be transient elevation in acute pancreatitis.
Serum bilirubin	0.1–1.2 mg/dL	Compression of the common duct may increase bilirubin levels in acute pancreatitis.
Serum alkaline phosphatase (ALP)	42–136 units/L	Compression of the common duct may increase levels in acute pancreatitis.
Serum calcium	9–11 mg/dL or 4.5–5.5 mEq/L	Hypocalcemia develops in up to 25% of patients with acute pancreatitis.
White blood cells	4500–10,000/mm^3	Leukocytosis indicates inflammation and is usually present in acute pancreatitis.

MEDICATION ADMINISTRATION

The Patient with Chronic Pancreatitis

PANCREATIC ENZYME REPLACEMENT
pancrelipase (Lipancreatin)

Pancrelipase enhances the digestion of starches and fats in the gastrointestinal tract by supplying an exogenous source of the enzymes protease, amylase, and lipase. The drug promotes nutrition and decreases the number of bowel movements.

Nursing Responsibilities
- Assess for allergy to pork protein.
- Monitor frequency and consistency of stools.
- Weigh every other day. Record weights.
- Give with meals; if not enteric coated, H_2 antagonists or antacids may be given concurrently to prevent destruction of the enzymes by hydrochloric acid.
- Monitor for side effects: rash, hives, respiratory difficulty, hematuria, hyperuricemia, or joint pain.

Health Education for the Patient and Family
- Take with meals or snacks.
- If medicine is enteric coated, do not crush, chew, or mix with alkaline foods (e.g., milk, ice cream).
- Be sure to follow prescribed diet.
- Continue taking this drug until or unless advised by physician that it is no longer necessary.

COMPLEMENTARY THERAPIES Several complementary therapies may be used in conjunction with traditional treatments for patients with acute or chronic pancreatitis. Fasting or use of low-salt, low-fat vegetarian diets may reduce episodes of recurrent pain. Qigong, a system of gentle exercise, meditation, and controlled breathing, is believed to balance the flow of qi (a vital life force) through the body. Qigong lowers the metabolic rate, and may reduce the stimulation of pancreatic enzyme secretion. Magnetic field therapy also may be employed for patients with pancreatitis. All complementary therapies should be prescribed by a trained and competent practitioner.

●○● NURSING CARE

In addition to the nursing care discussed in this section, see the Case Study & Nursing Care Plan for a patient with acute pancreatitis on page 724.

Health Promotion

Teach patients who abuse alcohol about the risk for developing pancreatitis. Advise abstinence to reduce this risk, and refer to an alcohol treatment program or Alcoholics Anonymous.

Assessment

Assessment data related to acute or chronic pancreatitis include the following:

- *Health history:* current manifestations; abdominal pain (location, nature, onset and duration, identified precipitating factors); anorexia, nausea, or vomiting; flatulence, diarrhea, constipation, or stool changes; recent weight loss; history of previous episodes or gallstones; alcohol use (extent and duration); current medications
- *Physical assessment:* vital signs including orthostatic vitals and peripheral pulses; temperature; skin temperature and color, presence of any flank or periumbilical ecchymoses; abdominal assessment including bowel sounds, presence of distention, tenderness, or guarding.

Priorities of Care

Nursing care for the patient with acute pancreatitis focuses on managing pain, promoting nutrition, and maintaining fluid balance.

Diagnoses, Outcomes, and Interventions

Acute Pain

Obstruction of pancreatic ducts and inflammation, edema, and swelling of the pancreas caused by pancreatic autodigestion cause severe epigastric, left upper abdominal, or midscapular back pain. The pain often is accompanied by nausea and vomiting, abdominal tenderness, and muscle guarding.

Expected Outcome: Patient will identify pain triggers, use treatment plan (pharmacologic and nonpharmacologic) to prevent and alleviate discomfort, and report relief from pain.

- Using a standard pain scale (see Chapter 9), assess pain, including location, radiation, duration, and character. Note nonverbal cues of pain: restlessness or remaining rigidly still; tense facial features; clenched fists; rapid, shallow respirations; tachycardia; and diaphoresis. Administer analgesics on a regular schedule. *Pain assessment before and after analgesic administration measures its effectiveness. Administering analgesics on a regular schedule prevents pain from becoming established, severe, and difficult to control. Unrelieved pain has negative consequences; for example, pain, anxiety, and restlessness may increase pancreatic enzyme secretion.*
- Regularly assess respiratory status (at least every 4 to 8 hours), including respiratory rate, depth, and pattern; breath sounds; oxygen saturation; and arterial blood gas results. Report tachypnea, adventitious or absent breath sounds, oxygen saturation levels below 92%, $PaO_2 < 70$ mmHg or $PaCO_2 > 45$ mmHg. *Severe abdominal pain causes shallow respirations and hypoventilation, and suppresses cough effectiveness, which can lead to pooling of secretions, atelectasis, and pneumonia.*
- Maintain NPO status and nasogastric tube patency as ordered. *Gastric secretions stimulate hormones that stimulate pancreatic secretion, aggravating pain. Eliminating oral intake and maintaining gastric suction reduce gastric secretions. Nasogastric suction also decreases nausea, vomiting, and intestinal distention.*
- Maintain bed rest in a calm, quiet environment. Encourage use of nonpharmacologic pain management techniques such as meditation and guided imagery. *Decreasing physical movement and mental stimulation decreases the metabolic rate, gastrointestinal secretion, pancreatic secretions, and resulting pain. Adjunctive pain relief measures enhance the effectiveness of analgesics (see Chapter 9).*
- Assist to a comfortable position, such as a side-lying position with knees flexed and head elevated 45 degrees. *Sitting up, leaning*

CASE STUDY & NURSING CARE PLAN A Patient with Acute Pancreatitis

Rose Schliefer is a 59-year-old wife, mother of three, and grandmother of four. She has been hospitalized for the past 6 weeks for acute hemorrhagic pancreatitis and pseudocyst. The pancreatitis was caused by gallstones. Mrs. Schliefer spent 3 weeks in intensive care, and then underwent surgery to remove the gallstones and to insert drains into the pseudocyst. Prior to discharge, she had progressed to a soft, high-carbohydrate, low-fat diet; had all drains removed; and was able to walk in the hall. Mrs. Schliefer was referred to a community health agency in her home town for continued follow-up.

ASSESSMENT

Lee Quinn, the community health nurse, assesses Mrs. Schliefer at home after discharge. Mrs. Schliefer is thin and appears anxious and tired. She states that she lost 13.6 kg (30 lb) in the hospital and now weighs only 46 kg (102 lb). She is 168 cm (66 in.) tall. Her vital signs are within normal limits. Mrs. Schliefer has a well-healed upper abdominal scar and two small wounds (from drains) on each side of her abdomen. The wounds are closed but still have scabs. Her skin is cool and dry, and turgor is poor. She is alert and oriented and responds appropriately to questions. Blood glucose levels are normal. Mrs. Schliefer states that her main problems are lack of energy and lack of appetite for the low-fat diet that has been ordered. Mrs. Schliefer's husband and daughters express concern about their ability to provide care. Although they have been taught all about the disease and how to provide care, they still are not sure they know exactly what should be done now that Mrs. Schliefer is at home.

DIAGNOSES

- *Fatigue* related to decreased metabolic energy production
- *Imbalanced Nutrition: Less Than Body Requirements* related to prolonged hospitalization, dietary restrictions, and impaired digestion
- *Bathing Self-Care Deficit* (Level II: requires help of another person, supervision, and teaching) related to decreased strength and endurance
- *Risk for Caregiver Role Strain* related to inexperience with caregiving tasks

EXPECTED OUTCOMES

- Patient will set priorities for daily and weekly activities, and incorporate a rest period into daily activity.
- Patient will gain 0.5 to 1 kg (1 to 2 lb) per week.
- Patient will bathe and maintain personal hygiene without assistance.
- Family members will verbalize comfort with providing necessary care.

PLANNING AND IMPLEMENTATION

- Explain causes of fatigue. Review effects of pancreatitis, surgery, and acute illness on energy levels.
- Develop activity goals, incorporating small, incremental steps toward achieving goals. Mrs. Schliefer indicates that she wants to cook a meal for the whole family. To reach this goal, she will do the following:
  a. Schedule the meal when her energy level is highest.
  b. List actions necessary to prepare the meal and delegate difficult tasks to family members.
  c. Ask daughters to reorganize the kitchen to avoid unnecessary steps.
  d. Plan the meal no sooner than the third week after being home.
- Instruct her to do the following:
  a. Rest in bed each day from 1:00 p.m. to 3:00 p.m.
  b. Eat six small meals a day with family members or friends.
  c. Sit and rest quietly for 15 minutes before eating.
- Discuss dietary restrictions and how to adapt them to usual diet.
- Advise to use shower chair and develop self-care goals for bathing and hygiene in small steps. Add self-care tasks gradually as tolerated.
- Discuss division of responsibilities for physical care, home maintenance, and medical care with family members.
- Encourage family discussion of concerns about future; acknowledge family strengths.

EVALUATION

One month after discharge, Mrs. Schliefer and her family have established new routines based on her energy levels. Mrs. Schliefer now fixes lunch because she feels best during midday. She and her husband share this time together without interruption. Mrs. Schliefer still rests during the day but can now provide self-care. She has gained only 1 kg (2 lb), but states that she is getting used to the new diet and that "things are even starting to taste good without butter." She says that sitting quietly before meals is helpful and that she prefers eating six small meals a day. Mr. and Mrs. Schliefer and their daughters agree that their initial worries about Mrs. Schliefer's care have been resolved; now they all know what they must do, and the future looks much brighter.

Clinical Reasoning in Patient Care

1. Your patient with acute pancreatitis also abuses alcohol. Describe assessments that indicate the beginnings of withdrawal.
2. Discuss the pathophysiologic basis of hypovolemic shock in acute necrotic pancreatitis.
3. Outline a teaching plan that includes specific foods to omit and to include in a high-carbohydrate, low-protein, low-fat diet.
4. Develop a plan of care for the nursing diagnosis *Impaired Home Maintenance*.

See Evaluating Your Response in Appendix B.

forward, or lying in a fetal position tends to decrease pain caused by stretching of the peritoneum by edema and swelling.

- Remind family and visitors to avoid bringing food into the patient's room. *The sight or smell of food may stimulate secretory activity of the pancreas through the cephalic phase of digestion.*

Imbalanced Nutrition: Less Than Body Requirements

The effects of pancreatitis and its treatment may result in malnutrition. Inflammation increases metabolic demand and frequently causes nausea, vomiting, and diarrhea. At a time of increased metabolic demand, NPO status and gastric suction further decrease available nutrients. In the patient with chronic pancreatitis, loss of digestive enzymes affects the digestion and use of nutrients.

Expected Outcome: Patient's weight and body mass index and lab values (transferrin, albumin, hemoglobin, hematocrit, and electrolytes) will stabilize and be within normal limits. Patient will describe intake of a low-fat, well-balanced diet and will report normal eating patterns.

- Monitor laboratory values: serum transferrin, serum albumin, electrolytes, hemoglobin, and hematocrit. *Serum albumin, serum transferrin (which transports iron in the blood), hemoglobin, and hematocrit levels are decreased in malnutrition. Decreased pancreatic enzymes affect protein catabolism and absorption; decreased transferrin affects iron absorption and transport, thereby decreasing hematocrit and hemoglobin levels. Prolonged poor nutrition may cause electrolyte imbalance.*
- Weigh daily or every other day. *Short-term weight changes (over hours to days) accurately reflect fluid balance, whereas weight changes over days to weeks reflect nutritional status.*

- Maintain stool chart; note frequency, color, odor, and consistency of stools. *Protein and fat metabolism are impaired in pancreatitis; undigested fats are excreted in the stool. Steatorrhea indicates impaired digestion and, possibly, an increase in the severity of pancreatitis.*
- Monitor bowel sounds. *The return of bowel sounds indicates return of peristalsis; nasogastric suction usually is discontinued within 24 to 48 hours thereafter.*
- Administer prescribed intravenous fluids and/or TPN. *Intravenous fluids are given to maintain hydration. TPN is used to provide fluids, electrolytes, and kilocalories when fasting is prolonged (more than 2 to 3 days).*
- Provide oral and nasal care every 1 to 2 hours. *Fasting and nasogastric suction increase the risk for mucous membrane irritation and breakdown.*
- When oral intake resumes, offer small, frequent feedings. Provide oral hygiene before and after meals. *Small, frequent feedings reduce pancreatic enzyme secretion and are more easily digested and absorbed. Oral hygiene decreases oral microorganisms that can cause foul odor and taste, decreasing appetite.*

Risk for Deficient Fluid Volume

Acute pancreatitis can lead to a fluid shift from the intravascular space into the abdominal cavity (third spacing). Third spacing of fluid may cause hypovolemic shock, affecting cardiovascular function, respiratory function, renal function, and mental status.

Expected Outcome: Deficient fluid volume will be prevented as evidenced by normal vital signs, normal hemodynamic parameters, normal lab values, and absence of physical signs of dehydration (e.g., thirst, change in mental status, decreased urine output, dry skin and mucous membranes, weakness).

- Assess cardiovascular status every 4 hours or as indicated, including vital signs, cardiac rhythm, hemodynamic parameters (central venous and pulmonary artery pressures); peripheral pulses and capillary refill; and skin color, temperature, moisture, and turgor. *These measurements are indicative of fluid volume status and are used to monitor response to treatment. Stable values are as follows: heart rate less than 100 bpm; blood pressure within 10 mmHg of baseline; central venous pressure 0 to 8 mmHg; pulmonary wedge pressure 8 to 12 mmHg; cardiac output approximately 5 L/min; and skin warm, dry, with good turgor and color.*
- Monitor renal function. Obtain hourly urine output; report if less than 30 mL/hr. Weigh daily. *Urine output of less than 30 mL/hr indicates decreased renal perfusion or acute renal failure, a major complication of acute pancreatitis. Weight changes are an effective indicator of fluid volume status.*
- Monitor neurologic function, including mental status, level of consciousness, and behavior. *Hypotension and hypoxemia may decrease cerebral perfusion, causing changes in mental status, decreased level of consciousness, and changes in behavior. In addition, alcohol withdrawal is a risk in the patient with acute pancreatitis.*

Continuity of Care

The patient is often acutely ill. The patient and family member need information about hospital procedures and probable self-care requirements to be implemented following discharge. During the acute stage, keep explanations brief and simple.

Prior to discharge, teach the patient and family about the disease and how to prevent further attacks of inflammation. Include the following topics as appropriate:

- Alcohol can cause stones to form, blocking pancreatic ducts and the outflow of pancreatic juice. Continued alcohol intake is likely to cause further inflammation and destruction of the pancreas. Avoid alcohol entirely.
- Smoking and stress stimulate the pancreas and should be avoided.
- If pancreatic function has been severely impaired, discuss appropriate use of pancreatic enzymes, including timing, dose, potential side effects, and monitoring of effectiveness.
- A low-fat diet is recommended. Provide a list of high-fat foods to avoid. Crash dieting and binge eating also should be avoided as they may sometimes precipitate attacks. Spicy foods, coffee, tea, or colas, and gas-forming foods stimulate gastric and pancreatic secretions and may precipitate pain. Avoid them if this occurs.
- Report symptoms of infection (fever of 38.8°C [102°F] or more, pain, rapid pulse, malaise) because a pancreatic abscess can develop after initial recovery.

Refer to a dietitian or nutritionist for diet teaching as needed. If appropriate, refer to community agencies, such as Alcoholics Anonymous, or to an alcohol treatment program. Provide referrals to community or home health agencies as needed for continued monitoring and teaching at home.

THE PATIENT WITH PANCREATIC CANCER

Cancer of the pancreas accounts for approximately 3% of all cancers. It is, however, one of the most lethal cancers: The 5-year survival rate is only about 6%. An estimated 45,220 new cases occurred in the United States in 2013, with approximately 38,460 deaths from cancer of the pancreas occurring the same year (ACS, 2013a). The incidence of pancreatic cancer increases after age 50. The incidence is higher in Blacks than in Whites.

FAST FACTS

Identified risk factors for pancreatic cancer include:

- Cigarette smoking—the incidence is twice as high in smokers as in nonsmokers
- Chronic pancreatitis
- Diabetes mellitus
- Cirrhosis
- Obesity, high-fat diet; possibly red meat consumption
- Genetic predisposition.

In contrast to acute and chronic pancreatitis, alcohol abuse and gallstones are not identified risk factors for pancreatic cancer.

Pathophysiology and Manifestations

Most cancers of the pancreas occur in the exocrine pancreas, are adenocarcinomas, and are fatal within 1 to 3 years after diagnosis.

Cancer of the pancreas often causes few symptoms until advanced. Early manifestations are nonspecific, including anorexia, nausea, weight loss, flatulence, and dull epigastric pain. The pain increases in severity as the tumor grows. Other manifestations depend on the location of the tumor. Cancer of the head of the pancreas,

NURSING CARE OF THE PATIENT

Undergoing Whipple's Procedure

PREOPERATIVE CARE

- Provide routine preoperative nursing care as ordered (see Chapter 4).
- Clarify teaching and learning as needed. Provide psychologic support for patient and family. *The patient and family faced with a diagnosis of pancreatic cancer may require reinforcement of teaching because anxiety, fear, and possible denial can interfere with learning.*

POSTOPERATIVE CARE

- Provide postoperative care as ordered (see Chapter 4).
- Maintain in semi-Fowler's position. *Semi-Fowler's position facilitates lung expansion and reduces stress on the anastomosis and suture line.*
- Maintain low gastrointestinal suction. If drainage is not adequate, obtain an order to irrigate, using minimal pressure. Do not reposition nasogastric tube. *Pressure within the operative area from retained secretions increases intraluminal pressure and places stress on the suture line. Forceful irrigations and repositioning of the nasogastric tube may disrupt the suture line.*
- Maintain pain control using analgesics as prescribed (PCA, infusion, or given on a regular basis). Assess effectiveness of pain management. *Doses higher than normal may be required if narcotic analgesics have been used prior to surgery to manage pain. Increased pain may indicate complications such as disruption of suture line, leakage from anastomosis, or peritonitis. Adequate pain management increases resistance to stress, facilitates healing, and increases the ability to cough, deep breathe, and change position.*
- Assist with coughing, deep breathing, and changing position every 1 to 2 hours. Splint incision during coughing and deep breathing. *The location of the incision makes coughing and deep breathing more painful. The prolonged surgical procedure, anesthesia, location of incision, and immobility increase the risk of retained secretions, atelectasis, and pneumonia. Changing position facilitates drainage of secretions; effective coughing and deep breathing remove secretions and open distal alveoli.*
- Monitor for complications:
  a. Take vital signs every 2 to 4 hours or as indicated; immediately report changes (such as elevated temperature; hypotension; weak, thready pulse; increased or difficult respirations).
  b. Assess skin color, temperature, moisture, and turgor.
  c. Measure urinary output, gastrointestinal output, and drainage from any other tubes; monitor amount and type of wound drainage.
  d. Assess level of consciousness.
  e. Assess abdomen, including contour, bowel sounds, tenderness. Report increasing abdominal pain or signs of acute abdomen (rigid, boardlike abdomen).
  f. Monitor results of laboratory tests, especially arterial blood gases, hemoglobin, and hematocrit.

  The major complications following Whipple's procedure are hemorrhage, bile leak, hypovolemic shock, and hepatorenal failure. The assessments listed provide information about the patient's status and alert the nurse to abnormal findings that signal the onset of these complications.

which is the most common site, often obstructs bile flow through the common bile duct and the ampulla of Vater, resulting in jaundice, clay-colored stools, dark urine, and pruritus. Cancer of the body of the pancreas presses on the celiac ganglion, causing pain that increases when the person eats or lies supine. Cancer of the tail of the pancreas often causes no symptoms until it has metastasized. Other late manifestations include a palpable abdominal mass and ascites. Because the manifestations are nonspecific, up to 85% of patients with cancer of the pancreas do not seek healthcare until the cancer becomes too far advanced for a cure.

●○● INTERPROFESSIONAL CARE

Early cancers of the head of the pancreas may be resectable. A pancreatoduodenectomy (commonly called Whipple's procedure) is performed to remove the head of the pancreas, the entire duodenum, the distal third of the stomach, a portion of the jejunum, and the lower half of the common bile duct. The common bile duct is then sutured to the end of the jejunum, and the remaining pancreas and stomach are sutured to the side of the jejunum (Figure 25–9 ■). Radiation and chemotherapy are often used in addition to surgery.

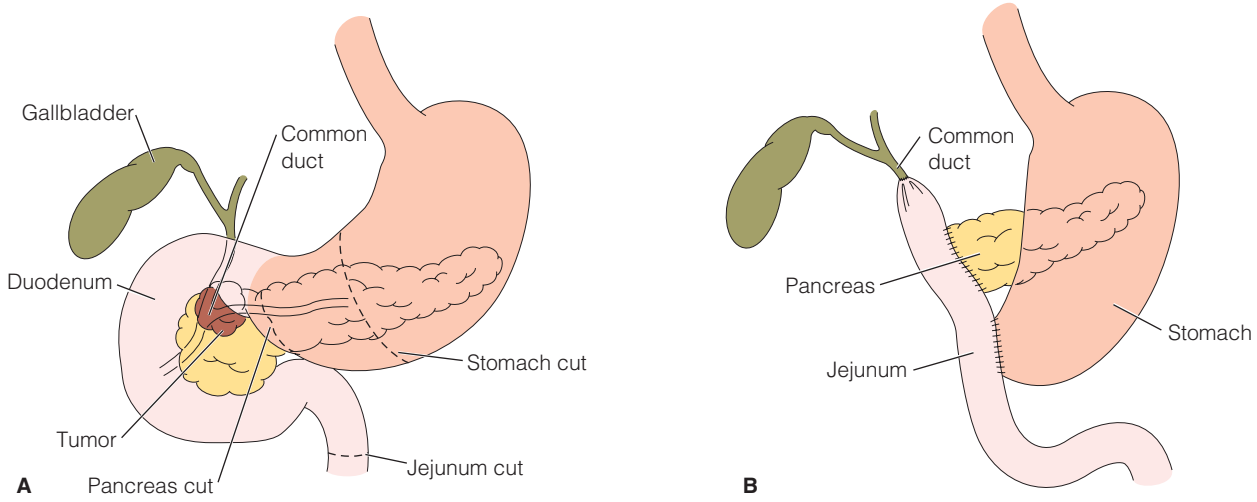

Figure 25–9 ■ Pancreatoduodenectomy (Whipple's procedure): A, areas of resection; B, appearance following resection.

Postoperative nursing care of the patient undergoing Whipple's procedure is outlined on page 726. Immediate postoperative care is often provided in the intensive care unit.

The patient with pancreatic cancer has multiple problems requiring nursing care. Chapter 14 provides a discussion of care of the patient with cancer; the nursing diagnoses and interventions discussed for the patient with pancreatitis are also appropriate for the patient with pancreatic cancer.

CHAPTER HIGHLIGHTS

- **Gallbladder, liver, and exocrine pancreatic disorders may occur as primary disorders, or develop secondarily to other disease processes.**
- **The functioning of one organ frequently affects that of another. Duct inflammation or obstruction, and changes in the multiple functions of these organs, can cause significant health effects.**
- **Patients with a gallbladder, liver, or pancreatic disorder may experience pain, metabolic and nutritional disturbances, and altered body image. Nursing care addresses the physiologic, emotional, and psychosocial needs of the patient and family.**
- Gallstones (cholelithiasis) are common and often unrecognized until the patient develops manifestations of biliary colic or acute cholecystitis. Laparoscopic cholecystectomy is the treatment of choice for symptomatic gallbladder disease.
- Hepatitis, inflammation of functional liver tissue, usually is a viral disease and therefore cannot be cured at this time. Preventing the spread of hepatitis through use of standard and body substance precautions is an important nursing responsibility.
- Hepatitis A, commonly transmitted via the fecal–oral route, generally is a self-limiting disease with few long-term sequelae. Some types of viral hepatitis, most notably hepatitis B and C, can become chronic and ultimately lead to liver failure and an increased risk for liver cancer. Hepatitis B and C can result in a carrier state in which the infected patient has no symptoms of the disease, but can spread it to others.
- Alcohol abuse is a significant risk factor for liver and pancreatic disorders. Prevention, early identification, and treatment of alcohol abuse reduce the risk of these disorders. Absolute abstinence from alcohol is an important part of the treatment plan for patients with liver and pancreatic disorders.
- Cirrhosis leads to portal hypertension and liver failure, which, in turn, account for most of the manifestations and complications of the disorder. Complications such as ascites, splenomegaly, esophageal varices, and portal systemic encephalopathy affect multiple body systems and significantly contribute to the mortality and morbidity associated with cirrhosis.
- Bleeding from esophageal varices may be massive, resulting in a medical emergency and requiring prompt control to maintain cardiac output.
- Acute pancreatitis often develops as a complication of gallstones. Acute pancreatitis often resolves with no long-term consequences. Chronic pancreatitis is more frequently related to alcohol abuse and can lead to continuing pain and digestive disruptions.
- All of the accessory organs of digestion (the gallbladder, liver, and pancreas) can be primary sites of malignancy. Cancer of the gallbladder is uncommon; hepatocellular and pancreatic cancers are more common and their incidence is increasing. These cancers often are advanced when diagnosed, reducing treatment options and the chance for cure.

TEST YOURSELF NCLEX-RN® REVIEW

1. A patient is scheduled for a laparoscopic cholecystectomy. What should the nurse expect to assess in this patient?
   1. a history of right upper quadrant pain
   2. obvious jaundice of the sclera and skin
   3. complaints of chills, fever, nausea, and vomiting
   4. complaints of recurrent heartburn and acid reflux

2. The nurse is planning instruction for a patient with acute cholecystitis. What should this teaching include? (Select all that apply.)
   1. Surgery for gallstones is optional.
   2. Follow a low-carbohydrate diet for weight loss.
   3. Call the physician if severe abdominal pain and a temperature occur.
   4. Avoid consumption of foods high in fat such as gravies and peanut butter.
   5. Limit intake to dry crackers and clear liquids during episodes of acute pain.

3. The community health nurse has been asked to provide teaching to employees of a local restaurant about ways to reduce the incidence of hepatitis A after an outbreak of the disease was traced back to the restaurant. What should the nurse teach these employees to eliminate future outbreaks of the disease?
   1. Test all new employees for hepatitis A antigen.
   2. Use gloves for handling food if any cuts or scrapes are on hands.
   3. Wash hands thoroughly before handling food and after using the bathroom.
   4. Emphasize the need for all food handlers to be immunized against hepatitis A.

4. The nurse instructs a patient with chronic hepatitis C about the disease process. Which patient statement indicates that teaching has been effective?
   1. "I will avoid donating blood and will use barrier protection during sex."
   2. "I will reduce my alcohol intake and use only acetaminophen for pain relief."
   3. "Even though no treatment is available for this disease, I plan to live a long life."
   4. "I understand that I must return to the doctor every year for a follow-up liver biopsy."
5. The nurse is interviewing a patient with hepatitis A. For which individuals or situations should the nurse ask the patient about possible exposure to the virus?
   1. immunization status of the patient
   2. sexual partners within the past 6 months
   3. close household contacts within the past 4 weeks
   4. food preparation activities since the development of jaundice
6. A patient with cirrhosis and esophageal varices vomits 200 mL of bright red blood. What should the nurse do first?
   1. Insert a nasogastric tube.
   2. Lower the head of the bed.
   3. Check stool for occult blood.
   4. Prepare for central line insertion.
7. A patient is having an abdominal paracentesis as an outpatient procedure. What should the nurse instruct the patient to do before this procedure?
   1. Empty the bladder before the procedure.
   2. Report excess flatus after the procedure to the physician.
   3. Scrub the abdomen with antiseptic soap before the procedure.
   4. Avoid eating or drinking fluid for 6 hours prior to the procedure.
8. A patient with cirrhosis and severe ascites develops a fever and confusion. What should the nurse do to help this patient?
   1. Inquire about headache and check for nuchal rigidity.
   2. Measure abdominal girth and percuss for shifting dullness.
   3. Observe for neck vein distention and auscultate lung sounds.
   4. Auscultate bowel sounds and palpate for abdominal tenderness.
9. A patient is surprised to be diagnosed with acute pancreatitis because the patient reports no history of alcohol intake. What should the nurse respond to the patient?
   1. "Was there a time in your life that you did drink heavily?"
   2. "It also is prevalent in smokers; do you smoke cigarettes?"
   3. "Gallstones also are a risk factor. We'll evaluate for them."
   4. "Intravenous drug use is a risk factor. Do you use drugs by injection?"
10. The nurse is caring for a patient recovering from the Whipple's procedure. What is the highest priority for this patient's care? (Select all that apply.)
    1. Provide pain control.
    2. Stabilize the nasogastric tube.
    3. Ambulate early as tolerated.
    4. Maintain in semi-Fowler's position.
    5. Turn frequently, encourage deep breathing and coughing exercises.

See Test Yourself answers in Appendix B.

UNIT

6 Building Clinical Competence

Responses to Altered Gastrointestinal Function

CLINICAL SCENARIO

Directions: *Read the following clinical scenario and answer the questions that follow. To complete this exercise successfully you will not only use knowledge of the content in this unit, but also principles related to setting priorities and maintaining patient safety.*

You have been assigned to work with the following four patients for the 0700 shift on a medical-surgical unit. Significant data obtained during report is as follows:

- Thomas Jones, age 56, was admitted with cirrhosis of the liver. He transferred to your unit yesterday after a 3-day stay in ICU for treatment of bleeding esophageal varices with a Sengstaken-Blakemore tube. Significant history includes daily alcohol consumption (6- to 12-pack of beer or a pint of liquor daily for several years) and history of smoking (2 packs per day for the past 30 years). Current vital signs are T 37.8°C (100°F), P 96 bpm, R 28/min, BP 150/90 mmHg. He complains of abdominal tenderness and dyspnea. Treatment for the bleeding problems has been successful but he appears anxious and irritable.
- Tonya Cooper, age 21, was admitted yesterday with dehydration, weakness, and fainting. Upon assessment her weight is 40.9 kg (90 lb) and height is 5′5′. Her vital signs are T 36.1°C (97°F), P 70 bpm, R 26/min, BP 90/56 mmHg with orthostatic BP of 70/48 mmHg. She has a history of bouts of anorexia nervosa and laxative use for 3 years. She has an IV infusing with 0.9% NaCl with 20 mEq of KCl. She is to be monitored for food intake and watched for 1 hour after meals. She is ringing her call light to get up to the bathroom.
- Paul Bruner, age 86, was admitted 5 days ago with abdominal pain and blood in the stool. His vital signs on admission were temperature 38°C (100.4°F), pulse 88 bpm, respirations 26/min, and blood pressure 150/86 mmHg. The patient has been prepped for a colonoscopy. He is scheduled for the procedure at 10:30 this a.m.
- Grace Freeman is a 36-year-old who had a temporary colostomy placed 5 days ago due to a motor vehicle crash. She has a history of hepatitis B. Vital signs at 0400 were temperature 37°C (98.6°F), pulse 78 bpm, respirations 14/min, and blood pressure 112/78 mmHg. She has put on her call light for assistance because her colostomy bag is full and she needs help emptying it.

CLINICAL REASONING

1. Mr. Jones is demonstrating anxiety and irritability. Why should this raise cause for concern to the nurse?

Priority Setting

2. In what order would you visit these patients after report? What is the rationale for your choice?
   A. _____
   B. _____
   C. _____
   D. _____

Health Promotion

3. When teaching the importance of early detection of malignant tumors, the nurse should include which of the following as the most common initial clinical manifestation of malignant tumors of the lower bowel?
   A. rectal bleeding
   B. diarrhea
   C. rectal pain
   D. constipation

Nursing Process

4. To prepare Mr. Bruner for the colonoscopy, the nurse implements which of the following?
   A. Keeps him NPO for 4 hours prior to the procedure.
   B. Maintains him on a liquid diet for 3 days prior to the procedure.
   C. Administers a bowel preparation the evening before the procedure.
   D. Administers a cleansing enema the evening before the procedure.
5. When Mr. Jones was admitted to the emergency department, which laboratory studies would you expect to draw? (Select all that apply.)
   A. AST
   B. troponins
   C. ALK
   D. complete blood cell count
   E. serum bilirubin
   F. ADH

6. Write a discharge teaching plan for Mrs. Freeman regarding how to take care of the colostomy at home.

Communication

7. Mr. Bruner states, "I am so afraid of having cancer in my bowel and I will need surgery. I would just rather die!" How should the nurse correctly respond?

Delegation

8. What instruction will you give the unlicensed assistive personnel (UAP) assisting Ms. Cooper with her meals?

Interprofessional Care

9. Why should the nurse collaborate with the healthcare provider regarding Ms. Cooper's blood pressure readings?

Continuity of Care

10. In planning discharge for Ms. Cooper, the family and patient participate in teaching and diet counseling sessions. Which is the priority item for the family and Ms. Cooper to follow after discharge?
    A. Monitor weight regularly to determine further weight loss.
    B. Use rewards for food and caloric intake rather than for weight gain.
    C. Gradually increase the amount of food taken at meals.
    D. Attend support groups for people with eating disorders.

Safety

11. Which of the following measures is consistent with safe patient care while a Sengstaken-Blakemore tube is in place?
    A. Avoid tension on the tubing.
    B. Maintain suctioning of the oral cavity to remove excess secretions.
    C. Maintain head-of-bed elevation at 15 to 30 degrees.
    D. When removing the tube, deflate the gastric balloon before the esophageal balloon.
12. While performing a venipuncture on Ms. Freeman, the nurse receives a needlestick. What steps should be taken to provide safety for the nurse?

Quality Improvement

13. The nurse manager has noticed an increase in the number of reported needlesticks received by nurses on the unit, putting them at risk for hepatitis transmission. Identify measures that can assist with reducing injury/harm to the nursing staff.

Informatics

14. When caring for a patient in pain, documentation in the electronic medical record regarding pain management should include: (Select all that apply.)
    A. pain assessment (0–10 scale).
    B. family member's perception of patient's pain.
    C. administration of prescribed pain medication.
    D. reassessment of effectiveness of pain medication.

UNIT

7

Responses to Altered Urinary Elimination

26 Assessing the Renal System 732

27 Nursing Care of Patients with Urinary Tract Disorders 746

28 Nursing Care of Patients with Kidney Disorders 779

Elimination Pattern

The body requires functional kidneys and the urinary tract to effectively eliminate metabolic wastes and regulate fluid balance.

26 Assessing the Renal System

LEARNING OUTCOMES

1. Describe the anatomy, physiology, and functions of the renal system.
2. Identify specific topics for consideration during a health history interview of the patient with health problems involving the renal system.
3. Describe techniques used to assess the integrity and function of the renal system.
4. Give examples of genetic disorders of the renal system.
5. Describe normal variations in assessment findings for the older adult.
6. Identify abnormal findings that may indicate alterations in urinary elimination.

CLINICAL COMPETENCIES

1. Conduct and document a health history for patients who have or are at risk for alterations in renal system function, eliciting patient values, preferences, and expressed needs as part of the interview.
2. Conduct and document a physical assessment of the renal system, demonstrating sensitivity and respect for the diversity of human experience.
3. Monitor the results of diagnostic tests and communicate abnormal findings within the interprofessional team.

MAJOR CHAPTER CONCEPTS

- The renal system, including the kidneys, ureters, urinary bladder, and urethra, plays a critical role in maintaining homeostasis of the body.
- Manifestations of dysfunction and disorders affecting the renal system may be detected during a general health assessment as well as during a focused assessment of renal system organs.

KEY TERMS

dysuria, *738*
hematuria, *735*
micturition, *738*
nocturia, *742*
urea, *736*

EQUIPMENT NEEDED

- Urine specimen container
- Disposable gloves
- Stethoscope

The functions of the renal system (the urinary system) are to regulate body fluids, to filter metabolic wastes from the bloodstream, to reabsorb needed substances and water into the bloodstream, and to eliminate metabolic wastes and water as urine. Disorders of the renal system affect the whole body, and may result in alterations in fluid and electrolyte balance, cardiovascular function, and nutritional status. In turn, healthy renal system function depends on the health of other body systems, especially the circulatory, endocrine, and nervous systems.

Anatomy, Physiology, and Functions of the Renal System

The organs of the renal system are the paired kidneys, the paired ureters, the urinary bladder, and the urethra (Figure 26–1 ■). Each structure is essential to the total functioning of the renal system.

The Kidneys

The two kidneys are located outside the peritoneal cavity and on either side of the vertebral column at the levels of T_{12} through L_3. These

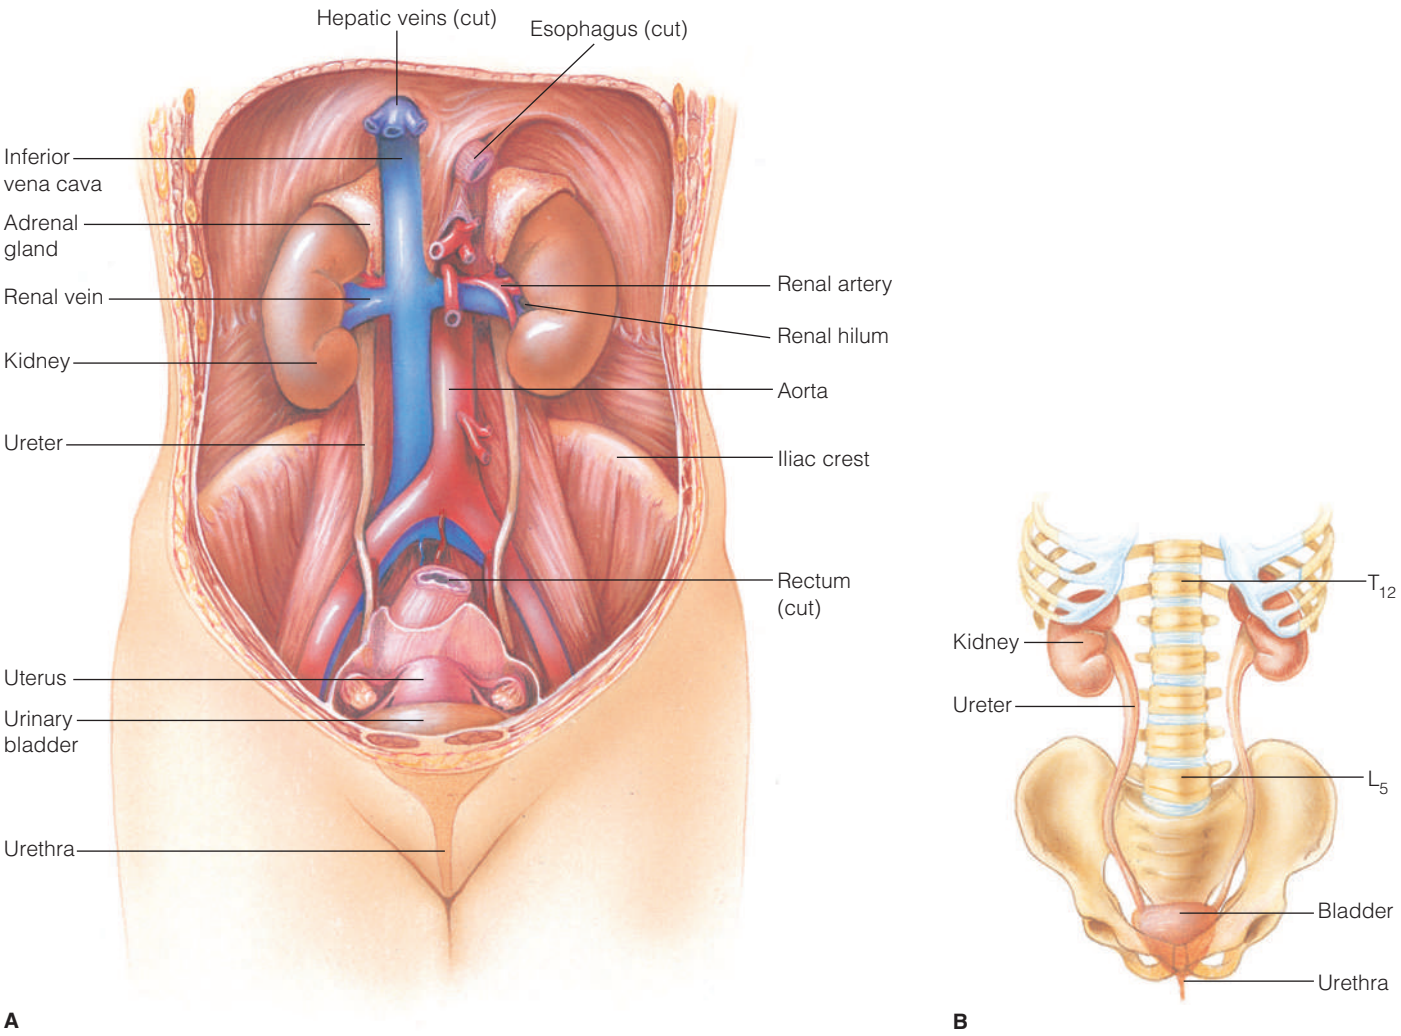

Figure 26–1 ■ The renal system. A, Anterior view of the renal system in a female. B, The kidneys are shown in relation to the vertebrae and ribs.

highly vascular, bean-shaped organs are approximately 11.4 cm (4.5 in.) long and 6.4 cm (2.5 in.) wide. The lateral surface of the kidney is convex; the medial surface is concave and forms a vertical cleft, the hilum. The ureter, renal artery, renal vein, lymphatic vessels, and nerves enter or exit the kidney at the level of the hilum.

Internally, each kidney has three distinct regions: the cortex, medulla, and pelvis. The outer region, or renal cortex, is light in color and has a granular appearance (Figure 26–2 ■). This region of the kidney contains the nephrons, the functional units of the kidney.

The renal medulla, just below the cortex, contains cone-shaped tissue masses called renal pyramids, formed almost entirely of bundles of collecting tubules. The collecting tubules that make up the pyramids channel urine into the calyces and the innermost region, the renal pelvis. The renal pelvis is continuous with the ureter as it leaves the hilum. The calyces serve to collect urine and empty it into the pelvis. From the pelvis, urine is channeled through the ureter and into the bladder for storage. The walls of the calyces, the renal pelvis, and the ureter contain smooth muscle that moves urine along by peristalsis.

FORMATION OF URINE

Each kidney contains approximately 1 million nephrons, which process the blood to make urine (Figure 26–3 ■). Each nephron consists of a glomerulus, a tuft of capillaries, and a renal tubule. The glomerulus is completely surrounded by the glomerular capsule (or Bowman's space), the cup-shaped end of the renal tubule. These complex structures process about 180 L (47 gal) of filtrate each day. Of this amount, only 1% is excreted as urine; the rest is returned to the circulation. (Normal and abnormal findings of urine on laboratory analysis are listed in Table 26–1.) Urine is formed by the nephron through three processes: glomerular filtration, tubular reabsorption, and tubular secretion (Figure 26–4 ■).

GLOMERULAR FILTRATION Glomerular filtration is a passive process in which hydrostatic pressure forces fluid and solutes out of glomerular capillaries and into the surrounding capsule. The amount of filtrate produced by the kidneys per minute is called the **glomerular filtration rate (GFR)**. Three factors influence this rate: the number of functional nephrons, the permeability of the filtration membrane (composed of capillary endothelium, basement membrane, and capsular epithelium), and the net filtration pressure.

Two forces determine net filtration pressure: hydrostatic pressure (push) and osmotic pressure (pull). Glomerular hydrostatic pressure pushes water and solutes across the filtration membrane. This pressure is opposed by the osmotic pressure in the glomerulus (primarily

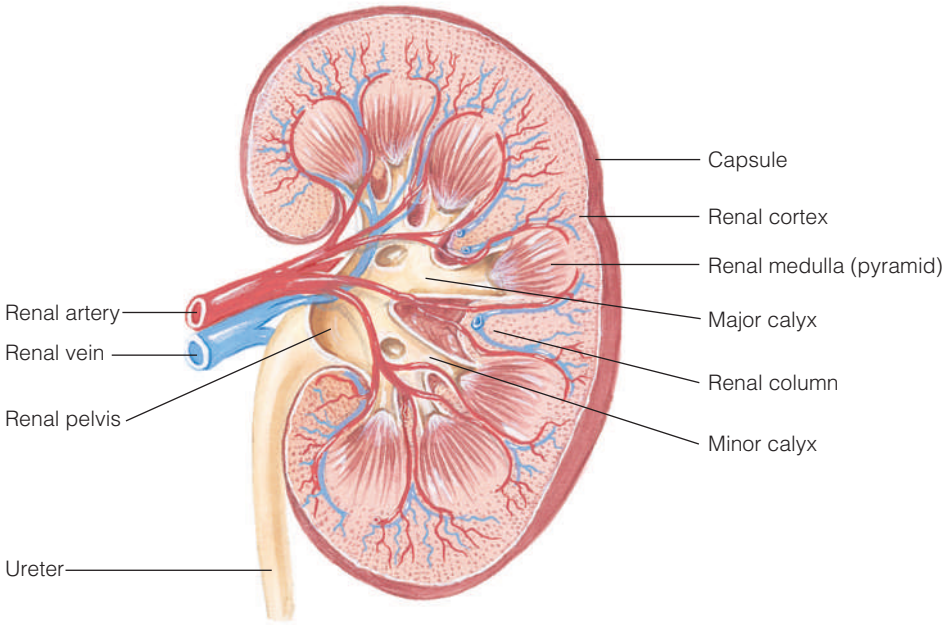

Figure 26–2 ■ Internal anatomy of the kidney.

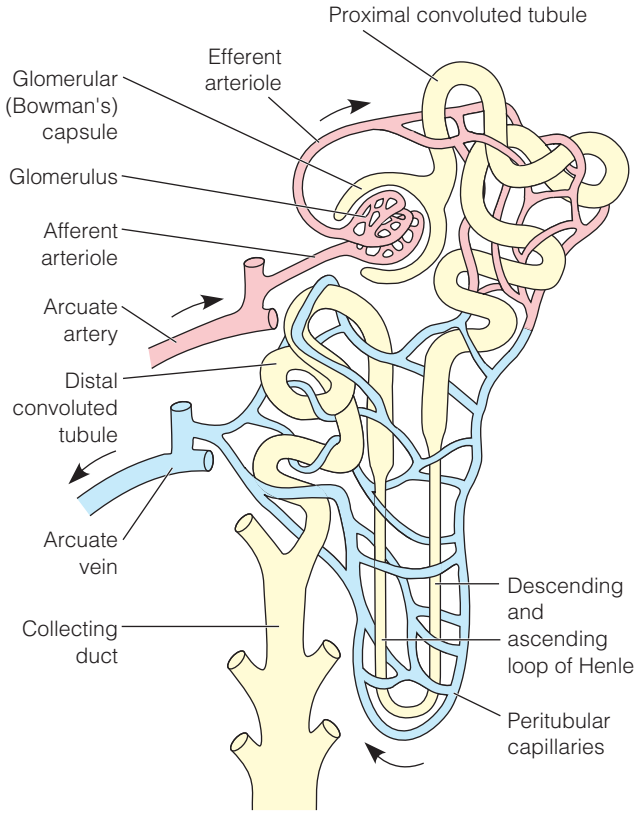

Figure 26–3 ■ The structure of a nephron, showing the glomerulus within the glomerular capsule.

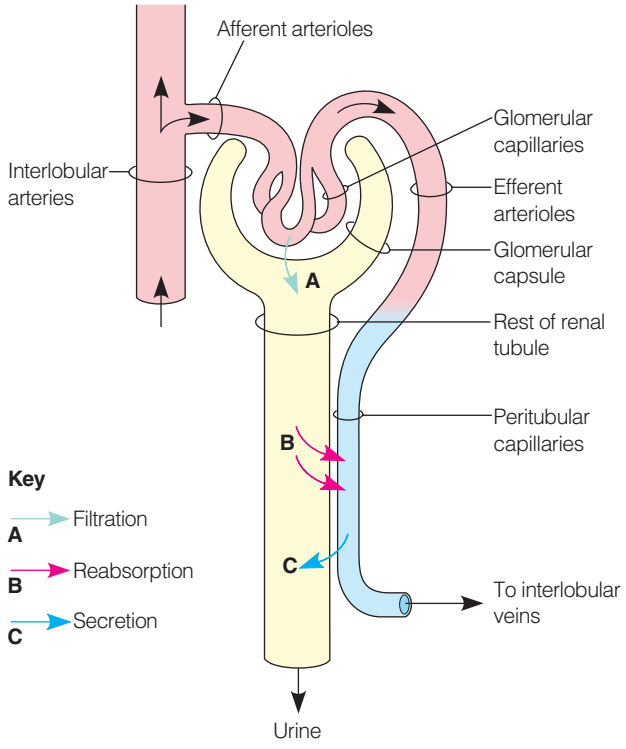

Figure 26–4 ■ Schematic view of the three major mechanisms by which the kidneys adjust to the composition of plasma: A, glomerular filtration; B, tubular reabsorption; and C, tubular secretion.

the colloid osmotic pressure of plasma proteins in the blood) and the capsular hydrostatic pressure exerted by fluids within the glomerular capsule. The difference between these forces determines the net filtration pressure, which is directly proportional to the GFR.

The normal GFR in adults is 120 to 125 mL/min. This rate is held constant under normal conditions by renal autoregulation. The myogenic mechanism, one factor in renal autoregulation, responds to pressure changes in the renal blood vessels, controlling the diameter of afferent arterioles. An increase in systemic blood pressure causes the renal vessels to constrict, whereas a decrease in blood pressure causes the afferent arterioles to dilate. These changes adjust glomerular hydrostatic pressure and, indirectly, maintain the GFR.

TABLE 26–1 Normal Results and Abnormal Findings: Urinalysis

Characteristic or Component	Normal Results	Abnormal Findings with Possible Cause
Color	Light straw to amber yellow	• Red, dark, smoky color may be the result of blood in the urine (**hematuria** or menstrual blood). • Cloudy urine occurs from infection (pyuria). • Colorless indicates very dilute urine, such as in overhydration, kidney disease, alcohol ingestion, or diabetes insipidus. • Very dark yellow urine indicates dehydration and/or fever. • Red or red brown urine may be caused by sulfisoxazole-phenazopyridine (Azo Gantrisin), phenytoin (Dilantin), cascara, chlorpromazine (Thorazine), docusate calcium, and phenolphthalein (Doxidan); and by carrots, rhubarb, and food coloring. • Orange urine is caused by fever, urobilin, phenazopyridine (Pyridium), amidopyrine, nitrofurantoin, sulfonamides, carrots, beets, and food coloring. • Blue or green urine is caused by *Pseudomonas*, amitriptyline (Elavil), methylene blue, methocarbamol (Robaxin), and yeast concentrate. • Brown or black urine is caused by Lysol poisoning, melanin, bilirubin, methemoglobin, porphyrin, cascara, and injectable iron.
Appearance	Clear	• Hazy or cloudy urine indicates bacteria, pus, RBCs, WBCs, phosphates, prostatic fluid spermatozoa, or urates. • Milky urine is the result of fats or pyuria. • Yellow foam results from bilirubin, bile, or severe cirrhosis of the liver. • A dark yellow to brownish color is seen with deficient fluid volume.
Odor	Aromatic	• Ammonia smell increases as urine stands outside the body. • Urinary tract infection (UTI) causes a foul or unpleasant odor, depending on the causative organism. • Asparagus causes a distinctive odor. • Mousy odors result from phenylketonuria. • Sweet or fruity odors occur in starvation and diabetic ketoacidosis.
pH	4.5–8.0	• <4.5: metabolic acidosis, respiratory acidosis, diet high in meat protein, ammonium chloride, and mandelic acid. • >8.0: bacteriuria, UTI, antibiotics (neomycin, kanamycin), sulfonamides, sodium bicarbonate, acetazolamide (Diamox), potassium citrate.
Specific gravity	1.005–1.030	• <1.005: diabetes insipidus, overhydration, renal disease, severe potassium deficit. • >1.030: dehydration, fever, diabetes mellitus, vomiting, diarrhea, contrast media.
Protein	0–5 mg/dL	• >5 mg/dL: proteinuria, exercise, fever, stress, acute infection, kidney disease, lupus erythematosus, leukemia, multiple myeloma, cardiac disease, toxemia of pregnancy, septicemia, lead, mercury, neomycin, barbiturates, sulfonamides.
Glucose	Negative	• >15 mg/dL or +4: diabetes mellitus, stroke, Cushing's syndrome, anesthesia, glucose infusions, severe stress, infections, ascorbic acid, aspirin, cephalosporins, and epinephrine.
Ketones	Negative	• +1 to 3: ketoacidosis, starvation, high-protein diet.
RBCs	Rare	• >2 per low-power field: kidney trauma, kidney diseases, renal calculi, cystitis, excess aspirin, anticoagulants, sulfonamides, menstrual contamination.
WBCs	3–4	• >4 per low-power field: UTI, fever, strenuous exercise, kidney diseases.
Casts	Occasional hyaline	• Fever, kidney diseases, heart failure.

Hormones of the renin–angiotensin system also regulate the GFR. The juxtaglomerular apparatus, located in the distal tubules, responds to stimuli such as the systemic blood pressure and the flow and NaCl concentration of filtrate. A sustained drop in systemic blood pressure triggers the juxtaglomerular cells to release renin. Renin acts on a plasma globulin, angiotensinogen, to release angiotensin I, which is in turn converted to angiotensin II. As a vasoconstrictor, angiotensin II activates vascular smooth muscle throughout the body, causing systemic blood pressure to rise.

Glomerular filtration is also controlled by the sympathetic nervous system (SNS). During periods of stress or emergency, SNS stimulation constricts the afferent arterioles and inhibits filtrate formation. The SNS also stimulates the juxtaglomerular cells to release renin, increasing systemic blood pressure.

TUBULAR REABSORPTION Tubular reabsorption occurs as the filtrate moves through the tubules and into the collecting ducts. In healthy kidneys, almost all organic nutrients such as glucose and amino acids are reabsorbed. However, the tubules constantly regulate and adjust the rate and degree of water and ion reabsorption in response to hormonal signals. Reabsorption may be active or passive. Substances reclaimed through active tubular reabsorption are usually moving against electrical and/or chemical gradients. These substances, including glucose, amino acids, lactate, vitamins, and most ions, require

an ATP-dependent carrier to be transported into the interstitial space. In passive tubular reabsorption, which includes diffusion and osmosis, substances move along their gradient without expenditure of energy.

TUBULAR SECRETION The final process in urine formation is tubular secretion, which is essentially reabsorption in reverse. Substances such as hydrogen and potassium ions, creatinine, ammonia, and organic acids move from the blood of the peritubular capillaries into the tubules themselves. Thus, urine consists of both filtered and secreted substances. Tubular secretion is important for disposing of substances not already in the filtrate, such as medications. This process eliminates undesirable substances that have been reabsorbed by passive processes and rids the body of excessive potassium ions. It is also a vital force in the regulation of blood pH.

MAINTAINING NORMAL COMPOSITION AND VOLUME OF URINE

Urine is composed, by volume, of about 95% water and 5% solutes. The largest component of urine by weight is **urea** (a nitrogenous waste product formed in the liver from the breakdown of amino acids). Other solutes normally excreted in the urine include sodium, potassium, phosphate, sulfate, creatinine, uric acid, calcium, magnesium, and bicarbonate.

Maintaining the normal composition and volume of urine involves a countercurrent exchange system. In this system, fluid flows in opposite directions through the parallel tubes of the loop of Henle and the vasa recta, tiny capillaries that run along the loop of Henle. Fluid and solutes are exchanged across these parallel membranes in response to a concentration gradient (Figure 26–5 ■). As the filtrate then flows through the collecting ducts and deep medullary regions of the kidney, water and urea are reabsorbed. The dilution or concentration of urine is largely determined by antidiuretic hormone (ADH), secreted by the posterior pituitary gland in response to blood volume and serum osmolality. When serum osmolality increases or blood volume falls, ADH is secreted. Pores of the collecting tubules enlarge in response, and more water is reabsorbed. When serum osmolality falls, ADH is not secreted and the filtrate passes through the system without further water reabsorption, and urine is more dilute.

RENAL CLEARANCE

The kidneys excrete water-soluble waste products and other chemicals or substances from the body. This process is called renal clearance, which refers to the volume of plasma that is cleared (or cleansed) of a particular substance in a given time (usually 1 minute). The kidneys clear 25 to 30 g of urea each day. They also clear creatinine (an end product of creatine phosphate, found in skeletal muscle), uric acid (a metabolite of nucleic acid metabolism), and ammonia as well as bacterial toxins and water-soluble drugs. Tests of renal clearance are done to determine the GFR and kidney function.

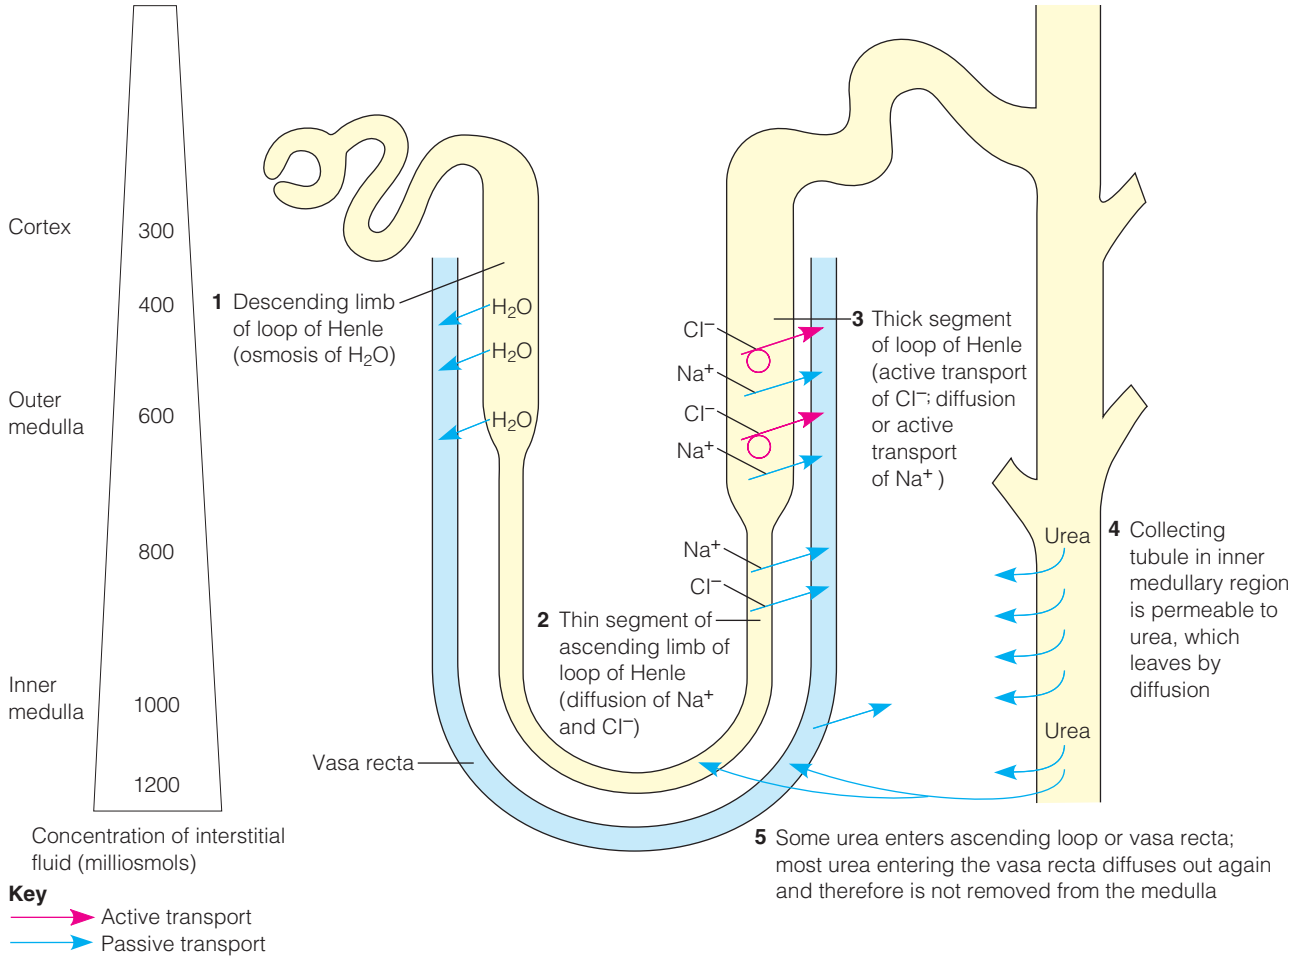

Figure 26–5 ■ The countercurrent exchange system is responsible for establishing and maintaining the osmotic gradient necessary for the composition, volume, and pH of urine.

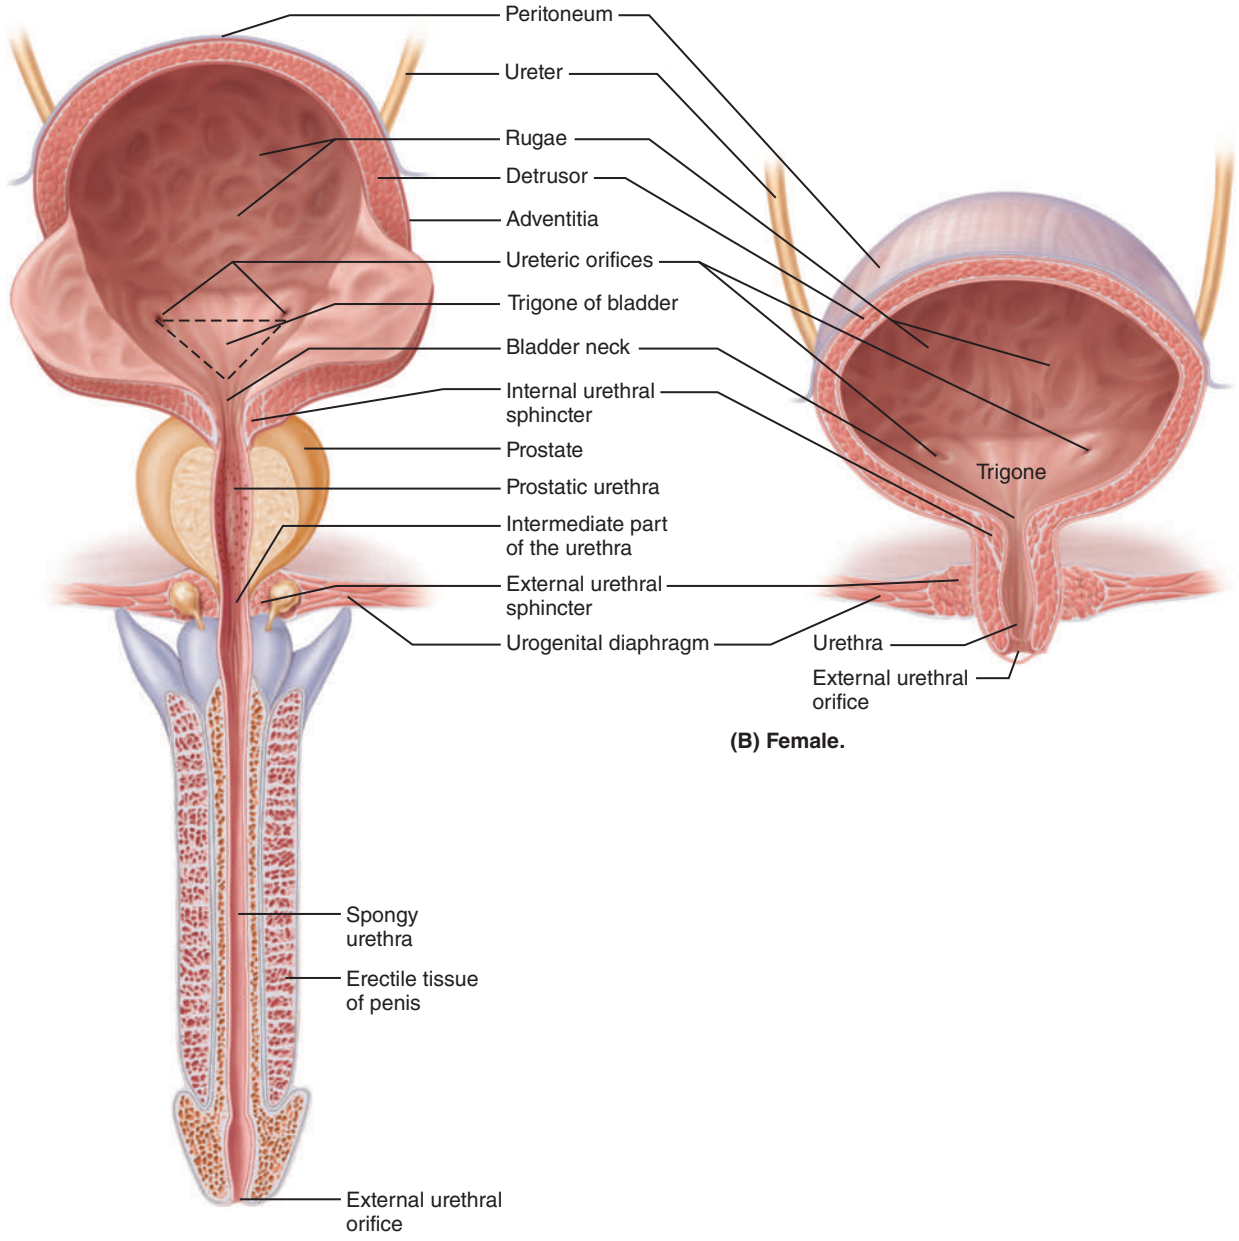
RENAL HORMONES



Hormones either activated or synthesized by the kidneys include the active form of vitamin D, erythropoietin, and natriuretic hormone.

Vitamin D is necessary for the absorption of calcium and phosphate by the small intestine. In an inactive form, vitamin D enters the body either by dietary intake or through the action of ultraviolet rays on cholesterol in the skin. Activation occurs in two steps, the first in the liver and the second in the kidneys. The renal step is stimulated by parathyroid hormone, which in turn responds to a decreased plasma calcium level. Erythropoietin stimulates the bone marrow to produce red blood cells in response to tissue hypoxia. The stimulus for the production of erythropoietin by the kidneys is decreased oxygen delivery to kidney cells. The right atria of the heart releases natriuretic hormone in response to increased volume and stretch, as occurs in increased extracellular volume. This hormone inhibits ADH secretion, so that the collecting tubules are less porous and a large amount of dilute urine is produced.

The Ureters, Urinary Bladder, and Urethra

The ureters are bilateral tubes approximately 26 to 30 cm (10 to 12 in.) long. They transport urine from the kidney to the bladder through peristaltic waves originating in the renal pelvis. The wall of the ureter has three layers: an inner epithelial mucosa, a middle layer of smooth muscle, and an outer layer of fibrous connective tissue. The urinary bladder is posterior to the symphysis pubis and serves as a storage site for urine. In males, the bladder lies immediately in front of the rectum; in females, the bladder lies in front of the vagina and the uterus. Openings for the ureters and the urethra are inside the bladder: The trigone is the smooth triangular portion of the base of the bladder outlined by the openings for the ureters and urethra (Figure 26–6 ■).

The size of the bladder varies with the amount of urine it contains. In healthy adults, the bladder holds about 300 to 500 mL of

(A) Male. The long male urethra has three regions: prostatic, intermediate, and spongy.

(B) Female.

Figure 26–6 ■ The urinary bladder, trigone, urethra, and surrounding structures: A, male; and B, female.

urine before internal pressure rises and signals the need to empty the bladder through **micturition** (urination or voiding). However, the bladder can hold more than twice that amount if necessary. The bladder has an internal urethral sphincter that relaxes in response to a full bladder and signals the need to urinate. A second external urethral sphincter is formed by skeletal muscle and is under voluntary control.

The urethra is a thin-walled muscular tube that channels urine to the outside of the body. It extends from the base of the bladder to the external urinary meatus. In males, the urethra is approximately 20 cm (8 in.) long and serves as a channel for semen as well as urine (refer to Figure 26–6A). The prostate gland encircles the urethra at the base of the bladder in males. The male urinary meatus is located at the end of the glans penis. In females, the urethra is approximately 3 to 5 cm (1.5 in.) long, and the urinary meatus is anterior to the vaginal orifice (refer to Figure 26–6B).

GENETIC CONSIDERATIONS

Examples of Renal System Disorders

- Adult polycystic kidney disease (APKD) is linked to a familial chromosome 16 disorder. The disease is characterized by large cysts in one or both kidneys and a gradual loss of kidney tissue with resultant chronic kidney disease.
- Chronic kidney disease may be a complication of type 1 and type 2 diabetes mellitus (DM), but is seen more often in patients with type 1 DM. Type 1 and type 2 DM are classified as multifactorial inheritance disorders because both genetic and environmental factors are necessary for onset of the disorder.
- Bladder cancer is the fourth most common type of cancer in men. Genetic factors related to chromosome 9 are interrelated with risk factors such as smoking and exposure to industrial chemicals to cause bladder cancer.

ASSESSING RENAL SYSTEM FUNCTION

Renal system function is assessed by findings from diagnostic tests, genetic considerations, a health assessment interview to collect subjective data, and a physical assessment to collect objective data.

Diagnostic Tests

The results of diagnostic tests of renal system function are used to support the diagnosis of a specific disease or condition, to provide information to identify or modify appropriate treatment, and to help monitor the patient's responses to treatment and nursing care interventions. Diagnostic tests to assess the structures and functions of the renal system are described in the accompanying box.

Regardless of the type of diagnostic test, the nurse is responsible for explaining the procedure and any special preparation needed, assessing for medication use that may affect the outcome of the tests, ensuring the consent form is signed (if necessary), supporting the patient during the examination as necessary, documenting procedures as appropriate, and monitoring the results of tests. The nurse is responsible for postprocedure care and patient teaching for self-care at home.

Genetic Considerations

When conducting a health assessment interview and physical assessment, it is important to consider genetic influences on adult health. During the health assessment interview, ask about family members with health problems affecting kidney function or those diagnosed with polycystic disease or diabetes mellitus. During the physical assessment, assess for manifestations that might indicate a genetic disorder (see the Genetic Considerations box). If data indicate the presence of genetic risk factors or alterations, ask about genetic testing and refer for appropriate genetic counseling and evaluation.

Health Assessment Interview

A health assessment interview to determine problems with renal system structure and function may be conducted during a health screening, may focus on a chief complaint (such as burning on urination or difficulty starting the stream when urinating), or may be part of a total health assessment. Patients with problems affecting renal system function may be embarrassed to talk about urinary elimination patterns. It is often helpful to discuss less personal information first.

Assess the patient's current urinary elimination status. Focus questions on changes in patterns of urination, changes in the urine, and pain. Assess changes in patterns of urination by asking the patient the following questions: How many times a day do you urinate? Do you feel that you empty your bladder each time? How many times do you get up at night to urinate? Do you experience a very strong desire to urinate and feel that you just cannot wait? Have you noticed that you urinate small amounts of dark, strong-smelling urine?

Changes in the urine that should be explored include the presence of blood or a cloudy appearance. If the patient has noticed blood, explore the use of medications (such as anticoagulants or dye-containing drugs) or bleeding problems. Cloudy, foul-smelling urine often indicates infection (pyuria); ask the patient about temperature elevations, chills, and general malaise. Cloudy urine in men may result from retrograde ejaculation (when semen is discharged into the bladder instead of from the penis) during intercourse.

If the patient reports pain, explore its location, duration, and intensity. Kidney pain is experienced in the back and the costovertebral angle (the angle between the lower ribs and adjacent vertebrae) and may spread toward the umbilicus. Renal colic (pain in response to renal calculi moving through the ureter) is severe, sharp, stabbing, and excruciating; often it is felt in the flank, bladder, urethra, testes, or ovaries. Bladder and urethral pain is usually dull and continuous but may be experienced as spasms. The patient with a distended bladder experiences constant pain increased by any pressure over the bladder. Pain experienced during voiding (**dysuria**) often is associated with urinary tract infection

Information about surgeries or other treatment of previous renal problems is essential to the health history, as is a family history of altered structure or function. Explore information regarding family occurrence of chronic kidney disease, renal calculi, and frequent infections as well as related problems such as hypertension and diabetes mellitus.

Questions about lifestyle, diet, and work history should explore cigarette smoking and/or exposure to toxic industrial or environmental chemicals (to identify risks for cancer), usual amount and type of fluid intake, and self-care measures to replace fluids lost during work or physical activity.

DIAGNOSTIC TESTS of the Renal System

Name of Test	Purpose and Description	Related Nursing Interventions
Blood urea nitrogen (BUN)	This blood test measures urea, a by-product of protein metabolism. It is used to determine renal function and the elimination of nitrogenous waste products. Urea levels rise in acute kidney injury and chronic kidney disease. **Normal values:** 5–25 mg/dL	Assess hydration status, medications, and for other factors (such as critical illness, trauma, gastrointestinal bleeding, sepsis, or liver disease) that may affect results (Dirkes, 2011). If BUN is mildly elevated, encourage increased fluid intake as allowed.
Creatinine (serum)	This blood test is used to evaluate kidney function. Creatinine is a by-product of the breakdown of muscle and is excreted by the kidneys. Serum creatinine levels rise as the GFR decreases. Normal BUN/creatine ratio is 10:1. **Normal value:** Serum: 0.5–1.5 mg/dL. (Older adults and women may have decreased values due to decreased muscle mass.)	Assess hydration; fluid overload can result in falsely low serum creatinine levels, delaying diagnosis of acute kidney injury (Bagshaw & Wald, 2011). Assess medications; values may be affected by some antibiotics (cephalosporins, aminoglycosides, kanamycin), ascorbic acid, cimetidine, L-dopa, methyldopa (Aldomet), and lithium carbonate. Suggest not eating red meat the evening before the test (red meats can increase the value).
Creatinine clearance	A blood sample and 24-hour urine test to evaluate GFR and renal function. **Normal value:** 85–135/min Women and older adults may have slightly lower values.	Assess medications: Phenacetin, steroids, and thiazides may decrease creatinine clearance; ascorbic acid, cimetidine, steroids, L-dopa, methyldopa (Aldomet), and cefoxitin may increase creatinine clearance. Ask the patient to void and discard first voiding. Instruct patient, family, and staff (if hospitalized) to save all urine for a clearly designated 24-hour period, maintaining the specimen in the container on ice or in the refrigerator.
CT scan of kidneys	The CT scan allows evaluation of kidney size, tumors, abscesses, suprarenal masses, and obstructions. A contrast dye may be administered orally or injected IV, allowing improved visualization of the density of renal tissue and masses in comparison to an ultrasound.	Assess the patient for allergies to iodine, x-ray contrast dye, and seafood. Assess medications: Oral hypoglycemic agents are contraindicated for use with iodinated contrast. Ensure that serum creatinine and BUN levels are available. Tell the patient to remain NPO for 4 hours prior to the test, and that laxatives or enemas may be ordered to remove gas or fecal material from the bowel. Post-test, monitor for and tell the patient to report allergic reactions to the dye (rash, itching, headache, vomiting), and to increase fluid intake to help excrete the dye.
Cystatin C	This blood test may be used to evaluate kidney function. Cystatin C is a protein that is produced at a constant rate and filtered by the kidneys; increased concentrations in the blood indicate a decrease in GFR and kidney dysfunction. **Normal value:** <0.70 mg/mL	No special preparation is required. Results of the test are not significantly affected by muscle mass, gender, age, or race.
Cystometrogram (CMG) (voiding cystogram)	This test is conducted to evaluate bladder capacity and neuromuscular functions of the bladder, urethral pressures, and causes of bladder dysfunction. A measured quantity of fluid is instilled into the bladder, and the filling capacity and voiding pressures are measured. **Normal value:** Urine stream strong and uninterrupted, normal filling pattern and sensation of fullness; bladder capacity: 300–600 mL; urge to void: >150 mL; fullness felt: 300 mL.	Tell patient that the bladder will be filled and during filling he or she will be asked to describe the first urge to void, and the sensation of being unable to delay urination any longer.
Cystoscopy, cystography	Direct visualization of the bladder wall and urethra is accomplished by using a cystoscope. During the procedure small calculi can be removed from the ureter, bladder, or urethra, and tissue biopsy can be done. It also permits determination of the cause of hematuria or UTI. A stent may be inserted during the procedure to facilitate urinary drainage past an obstruction. A retrograde pyelogram may be done during the cystoscopy. By instilling a contrast dye into the bladder (cystography), neurogenic bladder, fistulas, tumors, or ruptures can be identified. The test may be done with either local or general anesthesia.	Assess history of cystitis or prostatitis (these disorders could result in sepsis after the procedure), hypersensitivity to anesthetics, and urinary patterns (amount, color, odor). Take and record vital signs. Following the procedure, assess for complications (hemorrhage, bladder perforation, urinary retention) and report gross hematuria (blood in the urine). Apply heat to the lower abdomen or assist with sitz bath if ordered to relieve pain and muscle spasms. Tell the patient to avoid alcoholic drinks for 2 days, to increase fluid intake, and that a slight burning sensation with voiding may occur for a day or two. Instruct the patient to immediately notify the physician if the urine remains bloody for more than three voidings after the procedure, or if bright bleeding, low urine output, abdominal or flank pain, chills, or fever develops.

(*continued*)

DIAGNOSTIC TESTS of the Renal System (*continued*)

Name of Test	Purpose and Description	Related Nursing Interventions
Estimated GFR (eGFR)	The eGFR is calculated based on the serum creatinine, age, gender, and (in some instances) racial origin. It is widely used in lieu of the measured GFR, a complicated and expensive diagnostic test. Normal value: 90–120 mL/min	No special preparation is necessary.
Intravenous pyelogram (IVP), retrograde pyelogram	An IVP is a radiologic examination to visualize the entire urinary tract to diagnose kidney disorders or to detect calculi (stones), tumors, or cysts. A radiopaque substance is injected IV and a series of x-rays taken. If the patient is allergic to iodine or radiologic dyes or has kidney disease, a retrograde pyelogram, in which radiopaque dye is instilled directly into the ureter, may be done. It may be performed alone or in conjunction with a cystoscopy.	Schedule IVP prior to any ordered barium or gallbladder studies using contrast material. Ask about allergy to seafood, iodine, or radiologic contrast dye. Notify physician or radiologist if allergies are known. Assess medications: Oral hypoglycemic agents are contraindicated for use with iodinated contrast. Assess renal and fluid status, including serum osmolality, creatinine, and BUN levels. Notify the physician of any abnormal values. Instruct the patient to complete ordered pretest bowel preparation, including prescribed laxative or cathartic the evening before the test, and an enema or suppository the morning of the test. Tell the patient not to eat food for 8–12 hr prior to the test; clear liquids are allowed. Take and record vital signs. Instruct the patient to contact the healthcare provider for any delayed reactions to the dye (breathing difficulty, rash, itching, rapid heart beat).
MRI of the kidneys	An MRI is used to visualize the kidneys by assessing computer-generated films of radio-frequency waves and changes in magnetic fields.	Inform patient of need to lie still during the examination. Assess for any metallic implants (such as pacemakers, clips on brain aneurysms, body piercings, tattoos, shrapnel). If present, notify imaging physician. Remove transdermal medication patches (both OTC and prescribed) unless otherwise ordered. Replace the patch following the procedure. Tell the patient to inform the staff about the patch when making the appointment and when completing the admission information. Ask if patient is pregnant; if so, the test is not performed. Ask about claustrophobia; if this is a problem, ask the patient to request a relaxing medication to take prior to the MRI.
Portable ultrasonic bladder scan	This test is used to obtain information about residual urine. Warmed ultrasound gel is applied over the lower abdomen, and the ultrasound probe is placed just above the pubic bone. The scanner shows an outline of the bladder and displays the amount of urine in the bladder in milliliters.	No special preparation is needed, but the test is usually not used for pregnant women. Report a residual amount of more than 100 mL.
Renal arteriogram or angiogram	This radiologic test is done to visualize renal blood vessels to detect renal artery stenosis, renal thrombosis or embolism, tumors, cysts, or aneurysm; to evaluate a possible causative factor for hypertension; and to evaluate renal circulation. A contrast medium is injected into the femoral artery.	Assess for allergy to iodine, seafood, or other contrast dye from other x-ray procedures. Assess medications: Oral hypoglycemic agents are contraindicated for use with iodinated contrast; anticoagulants should be discontinued. Instruct the patient to take a laxative or cleansing enema the night before the test (if ordered) and to remain NPO for 8–12 hr prior to the test. Take and record vital signs. Ask the patient to void and remove dentures and jewelry before the test. After the test, monitor for bleeding from the femoral artery, restrict activity for a day, assess peripheral pulses, and monitor urine output. Instruct the patient to contact the healthcare provider for any delayed reactions to the dye (such as breathing difficulty, rash, itching, rapid heartbeat, decreased urine output).
Renal biopsy	A renal biopsy is performed to determine the cause of renal disease, to rule out cancer metastasis to the kidney, or if rejection is occurring with a kidney transplant. It is performed by using a cystoscope, excising a wedge of kidney tissue, or through the skin with a biopsy needle (percutaneous route).	If a general anesthetic is used, ask the patient not to eat or drink fluids for 8–12 hr before the biopsy. Take and record vital signs. Note hemoglobin and hematocrit values and report abnormal findings. After the biopsy, if the percutaneous route was used, apply pressure to the site for about 20 min to prevent bleeding. Assess bowel sounds if surgical interventions were used. Tell the patient to increase oral fluid intake and to report decreased urination or burning on urination.

DIAGNOSTIC TESTS of the Renal System (*continued*)

Name of Test	Purpose and Description	Related Nursing Interventions
Renal scan	This test is done to evaluate kidney blood flow, location, size, and shape; and to assess kidney perfusion and urine production. Radioactive isotopes are injected IV and radiation detector probes are placed over the kidneys to monitor activity in the kidneys. Radioisotope distribution in the kidneys is scanned and graphed. Nonfunctioning tissue, such as in tumors and cysts, appears as cold spots.	Ask patient to drink several glasses of water prior to the test. Obtain weight and have patient void. After the procedure, increase fluid intake.
Renal ultrasound	This noninvasive test is conducted to detect renal or perirenal masses, identify obstructions, and diagnose renal cysts and solid masses. It is done by applying a conductive gel to the skin and placing a small external ultrasound probe on the patient's skin. Sound waves are recorded on a computer as they are reflected off tissues.	No special preparation is needed.
Residual urine (postvoiding residual urine)	Residual urine is measured to determine the amount of urine left in the bladder after voiding. **Normal value:** <50 mL	Ask the patient to void in a collection device and measure the amount. Immediately after voiding, catheterize using sterile technique and a straight catheter. Drain bladder completely. Document time, amount voided, amount obtained on catheterization, color, clarity, odor, and any other significant data. Report amount of residual urine if it is more than 100 mL.
Urinalysis (UA)	This test examines the constituents of a urine sample to establish a baseline, provide data for diagnosis, or monitor treatment results. Expected findings and abnormal findings with causes are outlined in Table 26–1.	Provide a clean specimen cup for a urine sample. An early morning specimen is preferred. Note on the laboratory slip if the patient is menstruating (some menstrual blood may be present in the urine sample if so). Assess medications, fluid status, and foods that might affect urinalysis results. Tell the patient to refrigerate the specimen until it can be taken for analysis.
Urine culture (midstream, clean-catch)	A urine culture is conducted to identify the causative organism of a UTI. **Normal value:** <10,000 organisms/mL (urine is sterile but urethra contains bacteria and a few WBCs); values of >100,000 organisms/mL indicate UTI	Provide a sterile container for the urine sample. Instruct the patient to wash and dry the genitals and perineal area with soap and water. Ask women to separate labia with one hand and clean labia with other hand, using two or three disposable antiseptic towelettes, wiping once front to back with each towelette. Ask men to retract the foreskin and cleanse glans with antiseptic towelettes, using a circular motion. After cleaning, tell patient to begin voiding and then collect specimen in the container (initial voiding will contain urethral contaminants). If patient is unable to void, it may be necessary to obtain a specimen by urinary catheterization. Instruct the patient to avoid taking antibiotics or sulfonamides until after the specimen is collected and to refrigerate the specimen until it can be taken for testing. If the patient is taking antibiotics, it should be noted on the laboratory slip.
Uroflowmetry	This test measures the volume of urine voided per second.	Ask the patient to increase fluid intake and refrain from voiding for several hours before the test to ensure a full bladder and a strong urge to void during testing. Tell the patient he or she will be asked to urinate into a funnel.

Physical Assessment

The renal system is assessed by examining the skin, abdomen, kidneys, bladder, and urinary meatus. Guidelines for abdominal assessment are outlined in Chapter 21. Normal age-related findings for the older adult are summarized in the Nursing Care of the Older Adult box on page 742.

Physical assessment of the renal system may be performed as part of a total health assessment, as part of an abdominal assessment, or as part of the back examination (for the kidneys). The techniques of inspection, auscultation, palpation, and percussion are used.

Before beginning the assessment, ask the patient to provide a clean-catch urine specimen (if ordered) and give the patient a specimen cup. Assess the specimen for color, odor, and clarity before you send it to the laboratory.

At the beginning of the assessment, the patient may be sitting or lying supine. Prior to the examination, collect all necessary equipment and explain the techniques to the patient to decrease anxiety. Because the examination involves exposure of the genital area, give the patient a gown and drape the patient appropriately to minimize exposure.

PRACTICE ALERT!

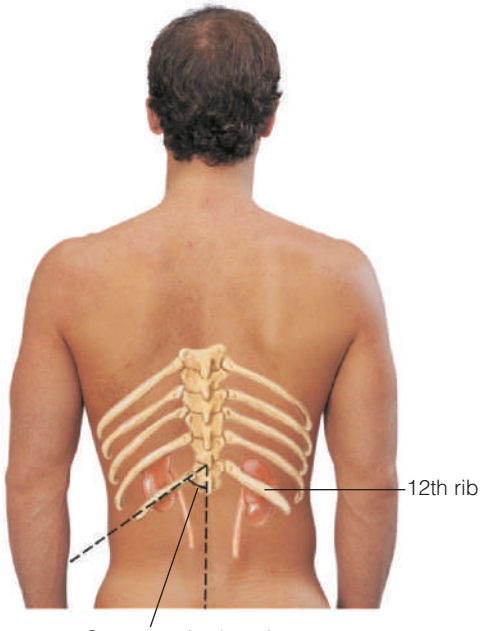
Auscultate immediately after inspection to avoid interference by bowel sounds stimulated by palpation and percussion.

Guidelines for percussion and palpation of the kidneys are outlined in Box 26–1.

NURSING CARE OF THE OLDER ADULT

Age-Related Renal System Changes

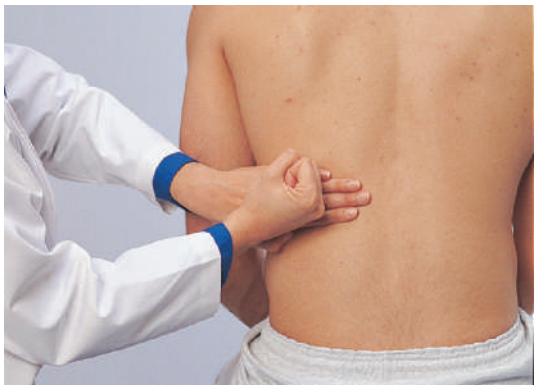
Age-Related Change	Significance
Kidneys: ↓ size of renal cortex and number of nephrons, ↓ growth of renal tissue, ↑ risk of atherosclerosis, all of which may result in atrophy of the kidneys.	• Decreased renal blood flow. • GFR decreases by about 50% between ages 20 and 90.
Renal tubules: ↓ function, with less effective exchange of substances, water and sodium conservation, and suppression of ADH secretion in presence of hypo-osmolality.	• Risk of hyponatremia and **nocturia** (voiding more often at night). • Effects of medications may be altered (with decreased filtration). • Decreased reabsorption of glucose may result in 1+ proteinuria and glycosuria, which are not of major clinical significance.
Bladder: • Muscles weaken and bladder capacity decreases. • More difficult to empty bladder. • Delayed micturition reflex.	• Urinary retention is more common. • Urinary frequency, urgency, and nocturia are more common with aging. • Larger amounts of residual urine present after voiding. • Some stress incontinence may occur, especially in multiparous women. • Urinary incontinence is *not* a normal outcome of aging.



BOX 26–1 Guidelines for Physical Assessment of the Kidneys

PERCUSSION OF THE KIDNEYS

Percussion helps assess pain or tenderness. Assist the patient to a sitting position, and stand behind the patient. Use the ulnar surface of your dominant hand, curled into a fist, for percussing the kidneys. For direct percussion, strike the area over the costovertebral angle with only enough force so the patient feels a gentle thud. For indirect percussion, place the palm of your nondominant hand over the costovertebral angle (see figure A). Strike the back of your hand with your dominant hand (see figure B). Repeat the technique for the other kidney. Percussion is usually done at the end of the assessment.



PALPATION OF THE KIDNEYS

Although the technique of palpation of the kidneys is outlined here, this technique is best performed by an advanced practitioner because it involves deep palpation and can cause tissue trauma.

A

Assist the patient to the supine position and stand at the right side of the patient. To palpate the left kidney, reach across the patient and place your left hand under the patient's left flank with your palm upward. Elevate the left flank with your fingers, displacing the kidney upward. Ask the patient to take a deep breath and use the palmer surface of your right hand to palpate the kidney (figure C). Repeat the technique for the right kidney.

B

C

Urinary System Assessments

Technique/Normal Findings	Abnormal Findings
Skin Assessment	
Inspect the skin and mucous membranes, noting color, turgor, edema, and excretions. *The color of skin and mucous membranes should be even and appropriate to the age and race of the patient; skin should be dry with no visible excretions.*	• Pallor may indicate anemia secondary to kidney disease. • Decreased skin turgor may indicate dehydration. • Edema (generalized or in the lower extremities) may indicate fluid volume excess. (Changes in skin turgor may indicate renal insufficiency with either excess fluid loss or retention.) • An accumulation of uric acid crystals, called uremic frost, may be seen on the skin of the patient with end-stage renal disease.
Abdominal Assessment	
Inspect the abdomen, noting size, symmetry, masses or lumps, swelling, distention, glistening, or skin tightness. *The abdomen should be slightly concave, symmetric, and without distention or masses.*	• Swellings or asymmetry may indicate a hernia or superficial mass. • If the urinary bladder is distended, it rises above the symphysis pubis as a rounded mass. • Distention, glistening, or skin tightness may be associated with fluid retention. • Ascites is an accumulation of fluid in the peritoneal cavity.
Urinary Meatus Assessment	
This technique is not part of a routine assessment, but it is an important component in patients with health problems of the renal system. *For the male patient:* With the patient in a sitting or standing position, compress the tip of the glans penis with the gloved hand to open the urinary meatus (Figure 26–7 ■). *For the female patient:* With the patient in the dorsal lithotomy position, spread the labia with your gloved hand to expose the urinary meatus. *The urinary meatus should be midline and free of redness, lesions, or discharge.*	• Increased redness, swelling, or discharge from the urinary meatus may indicate UTI or sexually transmitted infection. • Ulceration of the urinary meatus may indicate a sexually transmitted infection. • Hypospadias is displacement of the urinary meatus to the ventral surface of the penis. • Epispadias is displacement of the urinary meatus to the dorsal surface of the penis.
Kidney Assessment	
Refer to Box 26–1 for guidelines for percussion and palpation of the kidneys. Auscultate the renal arteries by placing the bell of the stethoscope lightly in the areas of the renal arteries, located in the left and right upper abdominal quadrants. *Bruits are not normally heard over the renal arteries.*	• Systolic bruits ("whooshing" sounds) may indicate renal artery stenosis.

Figure 26–7 ■ Inspecting the urinary meatus of the male.

(*continued*)

Urinary System Assessments (*continued*)

Technique/Normal Findings	Abnormal Findings
Percuss the kidneys for tenderness or pain. *No tenderness or pain should be elicited.*	• Tenderness and pain on percussion of the costovertebral angle suggests kidney disease.
Palpate the kidneys. The lower pole of the right kidney may be palpable with deep palpation; the remaining right kidney and the left kidney are normally not palpable. *If palpable, they should be nontender, bilaterally of appropriate size and density, and without palpable masses.*	• A painful or enlarged palpable kidney may suggest a tumor, cyst, or hydronephrosis.
Bladder Assessment	
Percuss the bladder for tone and position. *The bladder should be midline without dullness.*	• A dull percussion tone over the bladder of a patient who has just urinated may indicate urinary retention. • A distended bladder may be palpated at any point from the symphysis pubis to the umbilicus and is felt as a firm, rounded organ. It indicates urinary retention.

SAMPLE DOCUMENTATION

Assessment of Renal System Function

Home visit made to 66-year-old woman with end-stage renal disease. Skin pale and oral mucous membranes dry. Generalized edema noted, including face and extremities. 4+ edema bilateral lower extremities to knees. Skin tight and shiny over abdomen. Abdomen distended and tender on light palpation; further palpation deferred. Urinary bladder not palpable. Urine output for past 24 hours is 15 mL.

CHAPTER HIGHLIGHTS

- **The renal system, including the kidneys, ureters, urinary bladder, and urethra, plays a critical role in maintaining homeostasis of the body.**
- **Manifestations of dysfunction and disorders affecting the renal system may be detected during a general health assessment as well as during focused assessment of renal system organs.**

TEST YOURSELF NCLEX-RN® REVIEW

1. The nurse suspects that an older female patient has a health problem affecting the renal system. Which statement did the patient make that caused the nurse to come to this conclusion?
1. "I leak urine all the time."
2. "I sometimes have to get up at night to urinate."
3. "When I have to urinate, I really feel an urge to go."
4. "My doctor told me I have a slight amount of protein in my urine."

2. A patient has been vomiting for 4 hours. Which hormone will increase secretion in response to the physiologic changes caused by the vomiting?
1. ADH
2. renin
3. thyroxin
4. aldosterone

3. A patient is experiencing changes in the renal system. What diagnostic test should the nurse expect to be prescribed to determine this patient's glomerular filtration rate and glomerular damage?
1. renal scan
2. renal biopsy
3. routine urinalysis
4. creatinine clearance

4. During the health history of an older male patient, the nurse focuses on the gland that encircles the male urethra at the base of the bladder. On which organ is the nurse focusing?
1. spleen
2. prostate
3. adrenal
4. pancreas

5. During a health history interview, a patient reports having to get up to void several times during the night and there is burning when passing urine. Which terms should the nurse use when documenting this patient's manifestations? (Select all that apply.)
   1. pyuria
   2. dysuria
   3. polyuria
   4. nocturia
   5. hematuria
6. The nurse is preparing a patient for an intravenous pyelogram. What should be a part of the patient's care at this time? (Select all that apply.)
   1. Assess for allergies to seafood or iodine.
   2. Instruct on preprocedure bowel preparation.
   3. Teach to eat a soft diet the morning of the test.
   4. Remind to withhold taking diuretics the day of the test.
   5. Check prescribed medications for oral hypoglycemic agents.
7. The nurse is beginning to assess a patient's renal system. What should the nurse ask the patient to do before this examination?
   1. Empty the bladder.
   2. Provide a urine specimen.
   3. Take several deep breaths.
   4. Drink several glasses of water.
8. Following surgery, a patient has not voided for 12 hours. What assessment should the nurse make?
   1. Percuss for gastric tympany.
   2. Auscultate for bowel sounds.
   3. Palpate for bladder distention.
   4. Inspect for edema of the urethra.
9. A patient is diagnosed with a renal system disorder that is believed to be the result of genetic and environmental factors. Which health problem is the patient most likely experiencing?
   1. hematuria
   2. incontinence
   3. bladder cancer
   4. kidney infection
10. The nurse is conducting a physical examination of a patient's renal system. What assessment would the nurse use to assess the hydration status of a patient?
    1. palpation for skin turgor
    2. palpation of both kidneys
    3. auscultation of renal arteries
    4. percussion for dullness over bladder

27 Nursing Care of Patients with Urinary Tract Disorders

LEARNING OUTCOMES

1. Identify populations at risk for common urinary tract disorders and behaviors that increase the risk.
2. Explain the pathophysiology of common urinary tract disorders.
3. Describe the manifestations of urinary tract disorders, relating manifestations to the pathophysiology of the disorder.
4. Discuss the nursing implications of medications and treatments prescribed for patients with urinary tract disorders.
5. Describe invasive and surgical procedures used in treating urinary tract disorders.

CLINICAL COMPETENCIES

1. Assess the functional health status of patients with urinary tract disorders, using data and expressed needs, values, and preferences to determine priority nursing diagnoses and select individualized nursing interventions.
2. Identify, document, and monitor abnormal or unexpected changes in patient status, communicating information within the interprofessional team as appropriate.
3. Use evidence-based research to plan and implement nursing care for patients with urinary tract disorders.
4. Integrate the interprofessional plan of care into care for patients with urinary tract disorders.
5. Knowledgeably and safely administer prescribed medications and treatments for patients with urinary tract disorders.
6. Provide safe and effective nursing care for patients undergoing invasive procedures or surgery of the urinary tract.
7. Plan and provide appropriate teaching for prevention of and self-care of urinary tract disorders.
8. Use evidence-based care guidelines to reduce the incidence of healthcare-associated urinary tract infections.
9. Participate in studies and projects to improve the quality and safety of care for patients with urinary tract disorders.
10. Document care in the electronic medical record and use information management tools to monitor outcomes of care.

MAJOR CHAPTER CONCEPTS

- Urinary tract infections (UTIs) are common among adult women and patients in hospitals and long-term care facilities. In the untreated or immunocompromised patient, UTI can lead to sepsis or chronic kidney disease. Preventing UTI through patient and caregiver teaching and use of evidence-based guidelines is a major nursing responsibility.
- Obstructive processes such as stones and tumors can affect the urinary tract. Early recognition of obstructive processes and maintaining unobstructed urinary output are critical to maintain kidney function.
- Bladder cancer is the most commonly occurring malignancy of the urinary tract. When identified and treated early, bladder function can be preserved and the prognosis is good. Invasive bladder cancer may necessitate removal of the bladder and urinary diversion, altering patterns of urinary elimination and body image.
- Changes in muscle tone can affect the ability to effectively empty the urinary bladder and/or maintain urinary continence. Urinary incontinence, while treatable and rarely life threatening, can lead to embarrassment, social isolation, and institutionalization.

ureteral stent, *750*
ureteroplasty, *750*
urgency, *748*
urinary calculi, *754*
urinary diversion, *763*
urinary incontinence (UI), *771*

The urinary system includes the kidneys, ureters, urinary bladder, and urethra. This organ system can be affected by a variety of disorders, including congenital malformations, infections, obstructions, trauma, tumors, and neurologic conditions. Any portion of the system—from the kidney through the urethra—can be affected with serious or even life-threatening consequences unless the problem is appropriately diagnosed and treated. Kidney disorders can affect urine production and waste elimination directly, and are discussed

in Chapter 28. Disorders of the urinary drainage system (the kidney pelvis, ureters, bladder, and urethra) may obstruct urine flow or spread to the kidneys, affecting urine production and elimination.

When caring for patients with urinary tract disorders, it is important to consider the patient's modesty in voiding, possible difficulty in discussing the genitals, embarrassment about being exposed for examination and testing, and fear of changes in body image or function. These psychosocial issues may interfere with the patient's willingness to seek help, discuss treatment, and learn about preventive measures.

Nursing interventions for patients with urinary tract disorders are directed toward primary prevention, early detection, and management of the disorder through health teaching and nursing care.

THE PATIENT WITH A URINARY TRACT INFECTION

Bacterial infections of the urinary tract are a common reason for seeking health services, second only to upper respiratory infections. Community-acquired urinary tract infections (UTIs) are common in young women, and unusual in men under the age of 50.

FAST FACTS

- UTIs affect approximately 12.8 million women (13.3%) in the United States annually.
- The incidence of UTI in men is significantly lower than in women, affecting about 2 million men (2.3%) annually.
- Annually, UTIs result in more than 8 million office visits.
- Healthcare costs of an estimated $3.5 billion for evaluation and treatment are associated with UTIs every year (National Kidney and Urologic Diseases Information Clearinghouse [NKUDIC], 2012).
- Most (75% to 90%) community-acquired UTIs are caused by *Escherichia coli*, a common gram-negative enteral bacteria. About 5% to 15% of symptomatic UTIs are caused by *Staphylococcus saprophyticus*, a gram-positive organism. Catheter-associated UTIs often involve other gram-negative bacteria such as *Proteus*, *Klebsiella*, *Serratia*, and *Pseudomonas* (Gupta & Trautner, 2012).

Risk Factors for UTI

Patients can be predisposed to UTI by a variety of factors (Box 27–1). Some risk factors cannot be changed (e.g., aging and the female anatomy). In women, sexual activity increases the risk for UTI, thought to result from bacteria introduced into the bladder via the urethra during sexual intercourse. Use of spermicidal compounds with a diaphragm, cervical cap, or condom alters the normal bacterial flora of the vagina and perineal tissues and further increases the risk for UTI. Some females lack a normally protective mucosal enzyme and have decreased levels of cervicovaginal antibodies to enterobacteria, further increasing their risk. Prostatic hypertrophy and bacterial prostatitis are risk factors among males. Circumcision appears to have a protective effect. Unprotected anal intercourse also is a risk factor. Congenital or acquired factors contributing to the risk of infection include urinary tract obstruction by tumors or calculi, structural abnormalities such as strictures, impaired bladder innervation, bowel incontinence, and chronic diseases such as diabetes mellitus. Pregnancy increases the risk of UTI and asymptomatic bacteriuria due to hormonal effects, physical compression by the expanding uterus, and pregnancy-related changes in the bladder mucosa.

BOX 27–1 Risk Factors for UTI

FEMALE
- Short, straight urethra
- Proximity of urinary meatus to vagina and anus
- Sexual intercourse
- Use of diaphragm and spermicidal compounds for birth control
- Pregnancy

MALE
- Being uncircumcised
- Prostatic hypertrophy

BOTH
- Aging
- Urinary tract obstruction
- Neurogenic bladder dysfunction
- Vesicoureteral reflux
- Genetic factors
- Catheterization
- Anal intercourse

Instrumentation of the urinary tract (e.g., catheterization or cystoscopy) is a major risk factor for UTI. Even when performed under strict aseptic conditions, catheterization can result in bladder infection. The placement of the catheter prevents the flushing action of voiding, and bacteria may ascend to the bladder either through the catheter lumen or via exudate between the urethral mucosa and the catheter.

Older patients have an increased incidence of UTI. The greatest degree of increase is seen in men, as the ratio of female-to-male UTI in older adults changes from 50:1 to less than 5:1. An increased risk of urinary stasis, chronic disease states (such as diabetes mellitus), and an impaired immune response contribute to the higher incidence of UTI in the older adult. In men, the prostate typically enlarges with aging, potentially resulting in urinary retention as the urethra narrows. Prostatic secretions are lessened, diminishing their protective, antibacterial effect. In older women, loss of tissue elasticity and weakening of perineal muscles often contribute to the development of a cystocele or rectocele. Resulting changes in bladder and urethral position increase the risk of incomplete bladder emptying.

Physiology Review

The urinary tract is normally sterile above the urethra. Adequate urine volume, a free flow from the kidneys through the urinary meatus, and complete bladder emptying are the most important mechanisms maintaining sterility. Pathogens that enter and contaminate the distal urethra are washed out during voiding. Other defenses for maintaining sterile urine include its normal acidity and bacteriostatic properties of the bladder and urethral cells. The peristaltic activity of the ureters and a competent vesicoureteral junction help maintain sterility of the upper urinary tract. As the ureter enters the bladder, its distal portion tunnels between the mucosa and muscle layers of the bladder wall (Figure 27–1 ■). During voiding, increased intravesicular pressure compresses the ureter, preventing reflux (backflow of urine) toward the kidneys. In males, a long urethra and the antibacterial effect of zinc in prostatic fluid also help prevent contamination of this normally sterile environment.

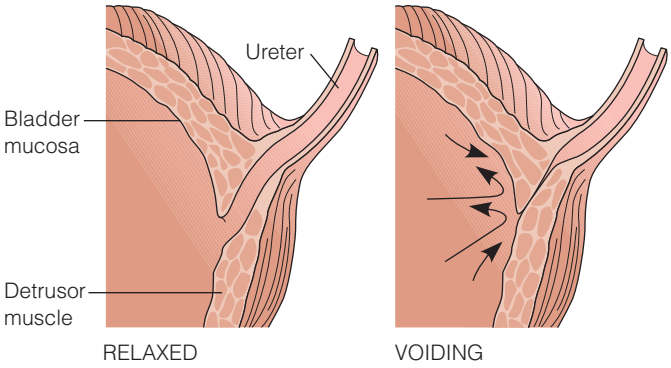

Figure 27–1 ■ A competent vesicoureteral junction. Note how increased intravesicular pressure during voiding occludes the distal portion of the ureter, preventing reflux.

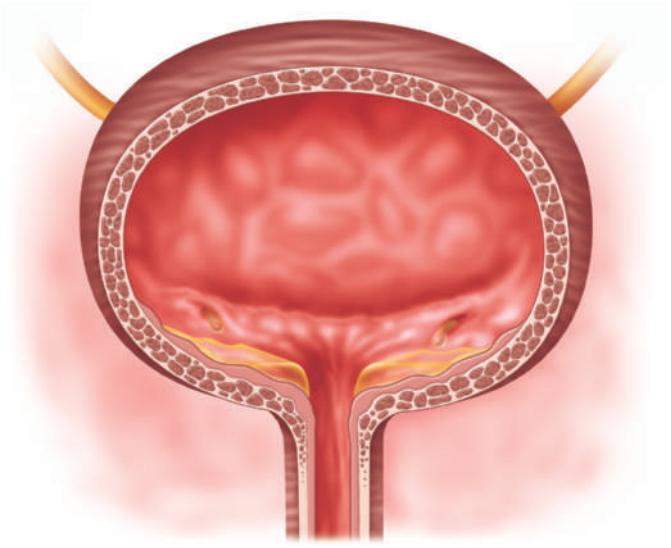

Figure 27–2 ■ Appearance of the bladder wall affected by cystitis.

Moving Knowledge into Action

Teaching to Reduce Risk of UTI

In young and middle adulthood, women have a significantly higher risk of developing a UTI. Frequent sexual activity or a new partner further increases this risk.

1. Diagram links between *E. coli*, the most frequent infecting organism in UTI, and the anatomy and physiology of the genitourinary and gastrointestinal systems to explain the frequency of UTI in adult women.
2. Using this information, identify specific points the nurse should include when teaching ways to reduce the risk for UTI.
3. How might the nurse's instructions be affected by the woman's age, cultural identity, or religious preference?

Pathophysiology and Manifestations
