The tuberculosis bacillus mutates readily to drug-resistant forms when only one anti-infective agent is used. Active disease is always treated with concurrent use of at least two antibacterial medications to which the organism is sensitive. The primary antituberculosis drugs can prevent development of resistance because all act by different mechanisms. However, the organism is protected within the tubercle, and 6 or more months of treatment is necessary to eradicate it.

Newly diagnosed TB is typically treated with an initial regimen of four oral antitubercular drugs, isoniazid (INH), rifampin, pyrazinamide, and ethambutol daily (or several times per week on a decreasing schedule of frequency) for the first 2 months of treatment. This initial regimen is followed by at least 4 additional months of therapy with INH and rifampin, given daily, twice per week, or weekly. In the presence of HIV infection, treatment is continued for at least 9 months. The most common antituberculosis drugs are outlined in Table 36–6; their nursing implications are outlined in the following Medication Administration box.

If a drug-resistant strain is suspected, therapy is tailored to the resistance. In some cases, four or more anti-infective drugs may be used.

Antitubercular medications have many adverse and toxic effects. Close monitoring during therapy is necessary. Most have some degree of, or risk for, hepatotoxicity. For this reason, patients should avoid using alcohol and other drugs (such as acetaminophen) or chemicals that can damage the liver. Baseline liver and renal function studies are done prior to initiating therapy. Audiometric testing also may be done before treatment is started, because several commonly used medications can affect hearing. Regular visits to a healthcare provider are necessary to evaluate regularly for adverse effects. Although none of these drugs have been proved to be teratogenic, potential adverse effects on the fetus are weighed against the benefit to the mother before they are prescribed during pregnancy.

Compliance with the prescribed regimen also is evaluated during follow-up visits. The urine can be examined for color changes characteristic of rifampin and tested for metabolites of INH. When compliance is a problem, medications are administered under direct supervision. Twice-weekly therapy is more cost effective in this instance, with a public health nurse watching the patient take and swallow the prescribed medication.

Repeat sputum specimens and chest x-rays are used to evaluate the effectiveness of therapy. In most cases, sputum cultures for *M. tuberculosis* are negative within 2 months of therapy; virtually all patients have negative sputum cultures within 3 months. If cultures remain positive at 3 months and beyond, treatment failure and drug resistance are suspected. In this case, cultures of the organism are tested for susceptibility to antitubercular agents, and two or three previously unused drugs are added to the treatment regimen.

With adherence to prescribed treatment, virtually all patients should have negative sputum cultures for *M. tuberculosis* within 3 months. The relapse rate for current treatment regimens is less than 5%. The principal cause of treatment failure is noncompliance.

●○● NURSING CARE

Health Promotion

TB today presents a greater threat to public health than it does to individuals. Nurses play a key role in maintaining public health. Education and TB screening are major nursing strategies to prevent TB. See the accompanying Moving Evidence into Action box regarding culturally competent interventions to promote TB therapy. Public health teaching includes increasing awareness of TB as a reemerging threat. Teach patients in all settings how to reduce the spread of TB by covering their mouths when coughing or sneezing and disposing of sputum appropriately. The benefit of screening programs to identify infected (though not necessarily infective) people also needs to be included in public health education.

The best TB prevention is early diagnosis of infections and appropriate treatment to achieve cure. BCG vaccine is recommended for infants born in countries where TB is prevalent, but is not widely used in the United States. It may be administered to healthcare

TABLE 36–6 Antituberculosis Medications

Drug and Dosage	Adverse Effects	Nursing Implications
Isoniazid (INH), oral: 300 mg daily or 900 mg one, two, or three times weekly	Peripheral neuropathy Hepatitis	Administer pyridoxine (vitamin B_6) concurrently. Monitor liver function studies (AST and ALT); avoid other hepatotoxins.
Rifampin (RMP), oral: 600 mg daily or two or three times weekly	Hepatitis Flu-like syndrome; fever Colors body fluids—including sweat, urine, saliva, tears, and cerebrospinal fluid (CSF)—orange-red	As for INH. Do not miss or skip doses; flu-like syndrome and fever occur when drug is resumed. Contact lenses may become discolored and should not be worn.
Pyrazinamide (PZA), oral: 1–2 g daily; or 2–4 g twice weekly	Hyperuricemia Hepatotoxicity	Monitor uric acid levels. Monitor AST and ALT; avoid other hepatotoxins.
Ethambutol (EMB), oral: 800–1600 mg daily; or 2–4 g twice weekly	Optic neuritis	Monitor red-green color discrimination and visual acuity.
Streptomycin (SM), intramuscular: 15 mg/kg, up to 1 g daily; or 25–30 mg/kg twice weekly	Ototoxicity, vertigo Nephrotoxicity	Conduct periodic audiometric examinations. Monitor renal function studies, including BUN and serum creatinine.

workers in settings where the risk of infection with MDR strains of *M. tuberculosis* is high despite rigorous infection control measures.

The primary preventive strategy used in the United States is treating people with latent TB infection demonstrated by a positive tuberculin test. A 9- to 10-month course of treatment with isoniazid reduces the risk of active TB by 90% or more. Isoniazid also is prescribed prophylactically for people with HIV infection who have been exposed to TB.

Assessment

See the Manifestations and Interprofessional Care sections for the assessment of the patient with tuberculosis.

Focused assessment for the patient with suspected TB includes the following:

- *Health history:* complaints of fatigue, weight loss, night sweats, difficulty breathing, cough (productive or nonproductive), bloody sputum, or chest pain; known exposure to TB; most recent tuberculin test and results; living circumstances; alcohol and other recreational drug use
- *Physical assessment:* vital signs including temperature; general appearance; respiratory rate and lung sounds
- *Laboratory data:* tuberculin test results, presence of acid-fast bacilli in sputum, chest x-ray.

Priorities of Care

Collaborating with the interprofessional team to ensure adequate treatment and surveillance of tuberculosis while providing care that supports the physical and psychologic recovery from the infection is a priority of nursing care.

Diagnoses, Outcomes, and Interventions

Nursing care related to TB focuses primarily on infection control and compliance with prescribed treatment. See the accompanying Case Study & Nursing Care Plan on page 1139.

Deficient Knowledge

Adequate knowledge and information are necessary to manage the disease and prevent its transmission to others. The patient needs to understand reasons for prolonged drug therapy and the importance of complying with treatment and follow-up. Antituberculosis drugs are relatively toxic. The patient needs to know how to minimize toxicity.

Expected Outcome: Patient will describe appropriate drug regimen and side effects for which they will monitor.

- Assess knowledge about the disease process; identify misperceptions and emotional reactions. *Teaching based on previous learning enhances understanding and retention of information.*
- Assess ability and interest in learning, developmental level, and obstacles to learning. *Assessment allows presentation of information in a manner tailored to the learning needs and style of the patient, promoting learning.*
- Identify support systems, and include significant others in teaching. *A knowledgeable significant other provides reinforcement of learning, confirmation of understanding, and encouragement for the patient. Including significant others also reduces the risk of inadvertent sabotage of the treatment plan.*
- Establish a relationship of mutual trust with the patient and significant others. *An atmosphere of trust increases receptiveness to teaching and learning.*
- Develop mutually acceptable learning goals with the patient and significant other. *Working together to identify learning needs and establish goals increases the patient's "ownership" and interest in the process.*
- Select appropriate teaching strategies, using learning aids such as literature and visual materials that are appropriate for age, level of education, and intellect. *Teaching tailored to the patient is more effective and results in better learning.*
- Teach about TB and the prescribed treatment, including the following:
  a. Nature of the disease and its spread
  b. Purpose of treatment and follow-up procedures
  c. Measures to prevent spreading the disease to others
  d. Importance of maintaining good general health by eating a well-balanced, high-protein, high-carbohydrate diet; balancing exercise with rest; and avoiding crowds and people with upper respiratory infections
  e. Names, doses, purposes, and adverse effects of prescribed medications
  f. Importance of avoiding alcohol and other substances that may damage the liver while taking chemotherapeutic drugs
  g. Fluid intake needs of 2.5 to 3.0 quarts of fluid per day
  h. Manifestations to report to the healthcare provider: chest pain, hemoptysis, difficulty breathing; anorexia, nausea, or vomiting; yellow tint to skin or sclera; sudden weight gain, swollen feet, ankles, legs, or hands; hearing loss, tinnitus, or vertigo; change in vision or difficulty discriminating colors.
  TB is a chronic disease requiring lengthy treatment with antitubercular medications. A good understanding of the disease, its treatment, and potential adverse effects of therapy prepares the patient to manage care.
- Document teaching and level of understanding. Reinforce teaching and learning as needed. *Teaching is not complete until the patient can demonstrate learning of the information.*

Ineffective Therapeutic Regimen Management

The populations at highest risk for developing active TB—the homeless and members of lower socioeconomic groups—are also at high risk for being unable to manage its complex treatment regimen. Three or more costly medications that may have unpleasant or even dangerous side effects are prescribed. Frequent medical follow-up is required. Infectious diseases such as TB carry a stigma that may lead to denial of the disease or its seriousness. Patients with alcoholism and those who use IV drugs need to withdraw from their addiction to

Evidence for Nursing Care

The Patient with Tuberculosis

Selected resource that nurses may find helpful when planning evidence-based nursing care follows.

- M'Imunya, J. M., Kredo, T., & Volmink, J. (2012). Patient education and counseling for promoting adherence to treatment for tuberculosis. *Cochrane Database of Systematic Reviews,* Issue 5, ISSN: 1469-493X.

MEDICATION ADMINISTRATION

Antituberculosis Drugs

ISONIAZID (INH, LANIAZID, NYDRAZID)

Isoniazid is the drug of choice for TB prophylaxis and a first-line drug for treating active disease. It is effective against both intracellular and extracellular organisms. Isoniazid is used alone as a prophylactic medication and in combination with rifampin, ethambutol, or both. A fixed-dose combination form with 150 mg of INH and 300 mg of rifampin (Rifamate) is available as well.

Nursing Responsibilities

- Administer on an empty stomach 1 hour before or 2 hours after meals for maximal effect if tolerated; may be given with meals to reduce gastrointestinal effects.
- Monitor for adverse effects:
  a. Numbness and tingling of the extremities (most likely to occur in patients who are malnourished, diabetic, or abusers of alcohol)
  b. Hepatotoxicity, as evidenced by abnormal liver function studies and scleral jaundice
  c. Hypersensitivity reactions, such as rash, drug fever, or evidence of anemia, bruising, bleeding, or infection related to agranulocytosis.
- Isoniazid interferes with the metabolism of diazepam (Valium), phenytoin (Dilantin), and carbamazepine. Doses of these drugs may need to be reduced to prevent toxicity.

Health Education for the Patient and Family

- Take the medication as prescribed for the entire treatment period to prevent incomplete eradication of the bacteria and development of resistant strains.
- Take the medication on an empty stomach. If nausea and vomiting occur, take with meals.
- If anorexia, nausea, vomiting, and jaundice (yellowing of the skin and the whites of the eyes) develop, notify your doctor immediately.
- Take pyridoxine as prescribed to prevent peripheral neuropathy.
- Avoid alcohol and other agents that may be harmful to the liver.
- Notify your doctor if you develop signs of an allergic reaction, such as rash, fever, easy bruising, bleeding gums, or fatigue.
- Use measures to prevent pregnancy while taking INH; this drug may be harmful to the developing fetus.

RIFAMPIN (RIFADIN, RIMACTANE)

Rifampin is commonly used in combination with INH and other antituberculars drugs. It is relatively low in toxicity, although it can cause hepatitis, a flu-like immune response, and, rarely, renal failure. Rifampin stimulates the microsomal enzymes of the liver, increasing the rate of metabolism of many drugs and decreasing their effectiveness.

Nursing Responsibilities

- Administer on an empty stomach.
- Monitor CBC, liver function studies, and renal function studies for evidence of toxicity.
- Rifampin reduces the effect of oral contraceptives, quinidine, corticosteroids, warfarin, methadone, digoxin, and hypoglycemics. Monitor for the effectiveness of these drugs.

Health Education for the Patient and Family

- Rifampin causes body fluids, including sweat, urine, saliva, and tears, to turn red-orange. This is not harmful. Avoid wearing soft contact lenses, however, because they may be permanently stained.
- Aspirin may interfere with rifampin absorption and should not be taken concurrently.
- Fever, flu-like symptoms, excessive fatigue, sore throat, or unusual bleeding may indicate an adverse reaction to the drug and should be reported to your doctor.

PYRAZINAMIDE (TEBRAZID)

Pyrazinamide typically is given with INH and rifampin for the first 2 months of TB treatment. Concurrent use of pyrazinamide allows a shorter course of therapy. As with many of the antitubercular agents, pyrazinamide is toxic to the liver. Its other principal adverse effect is hyperuricemia. Gout, however, rarely develops.

Nursing Responsibilities

- Administer with meals to reduce gastrointestinal side effects.
- Monitor liver function studies and serum uric acid levels. Notify the healthcare provider if changes are noted.

Health Education for the Patient and Family

- Notify your doctor if you develop loss of appetite, nausea, vomiting, jaundice, or symptoms of gout (a painful, red, hot, swollen joint, often the great toe or elbow).
- While taking this drug, avoid using alcohol or other substances that may be harmful to the liver.

ETHAMBUTOL (MYAMBUTOL)

Ethambutol is added to the initial treatment regimen or substituted for INH when an INH-resistant strain of TB is suspected. Ethambutol is a bacteriostatic drug that reduces the development of resistance to the bactericidal first-line agents. Its principal toxic effect is optic neuritis; fortunately, this is reversible. Early signs of optic neuritis include decreased visual acuity and loss of red-green discrimination. This drug may be safe for use in pregnancy.

Nursing Responsibilities

- Record a baseline visual examination prior to therapy. Schedule periodic eye exams during the course of treatment.
- Administer with meals to reduce gastrointestinal side effects.
- Monitor liver and renal function studies and neurologic status while taking this drug. Notify the healthcare provider of abnormal findings or significant changes.

Health Education for the Patient and Family

- Monitor vision daily by reading newspapers and looking at the same blue object (using usual corrective lenses, if appropriate). Notify your doctor if changes in vision or color perception occur.

STREPTOMYCIN

An aminoglycoside antibiotic, streptomycin is highly effective in treating most mycobacterial infections. Resistance may develop if it is used alone. Streptomycin has two primary drawbacks: (1) It must be administered parenterally because it is not absorbed in the gastrointestinal tract, and (2) it has toxic effects on the kidneys and ears.

Nursing Responsibilities

- Administer by deep intramuscular injection into a large muscle mass, rotating sites to minimize tissue trauma.
- Monitor urine output, weight, and renal function studies (including BUN and serum creatinine) to detect early signs of nephrotoxicity. Report significant changes to the healthcare provider.
- Maintain fluid intake at 2000 to 3000 mL/day to minimize the concentration of drug in the kidney tubules.
- Assess hearing and balance frequently. Have audiometric testing performed as indicated.

Health Education for the Patient and Family

- Maintain a daily fluid intake of at least 2.5 to 3 quarts.
- Weigh yourself on the same scale at least twice a week; report any significant weight gain to your doctor.
- Notify your doctor if hearing acuity decreases, ringing or buzzing sensations in the ear develop, or dizziness occurs.

Moving Evidence into Action

Cultural Interventions on Adherence to TB Therapy

TB is an important cause of morbidity and mortality worldwide. In the United States, foreign-born persons make up a significant portion of the population who present with TB. According to the CDC, Latinos account for about 15.1% of the U.S. population, but have 29% of the active TB cases. These findings led to a study conducted by Ailinger and colleagues (2010) where they examined the effect of a cultural intervention on adherence to latent TB medications in a Latino immigrant population. The study used a pre-experimental design with nonprobability sampling to select a group who were starting TB medication (n = 86), comparing them to a historical sample of 131 randomly selected patient records from the previous year of therapy. The intervention was based on Latino cultural values and included five components that were consistently delivered by the same interventionist who was fluent in Spanish. The intervention allowed for development of personal attention (by consistent staff interaction), inquiry about family members (familism), and the use of a common Latino proverb, translated to "It is better to prevent than to lament." All educational materials were also modified for the study population of interest; they used pictures of Latino families and were written at a sixth-grade level. The outcome of interest was adherence, which was measured by number of pills taken reported by the patients over an 8-month period. The study found that the intervention group took a greater number of pills (more adherent to the regimen) compared to the historical group (p = 0.028). The authors report that the overall difference was 28 doses, or almost a month's treatment.

Implications for Nursing

Outreach to immigrant populations for health services has personal and public health benefits. Culture is complex and varies among Latino immigrants who come from different countries and regions. This study is the first step in tailoring a medication adherence intervention based on culture and shows promise. Use of a cultural intervention may also extend to other ethnic groups. Because medication compliance is an extremely important component of the public health management and control of communicable diseases like TB, use of cultural interventions is cost effective and allows nurses to conduct culturally appropriate practice.

Moving Knowledge into Action

1. What values were identified as important to the Latino population of interest that led to their inclusion in the intervention?
2. The participants in this study received the intervention from interventionist nurses who were fluent in Spanish. How could this impact the quality of the patient's interaction with the healthcare system versus nonfluent nurses who require bilingual outreach workers to translate healthcare interactions?
3. Design a TB screening program using a multidisciplinary team to reach a specific culturally diverse population. Identify members of the team and discuss your rationale for their inclusion on the team.

be successful in treating the disease. The patient with HIV infection faces a potentially fatal disease and costly treatment that may well override concerns about TB management.

Expected Outcome: Patient will be compliant with therapeutic regimen as evidenced by adherence to medication regimen and follow-up appointments.

- Assess self-care abilities and support systems. *Assessment is used to help determine the patient's ability to follow the prescribed regimen.*
- Assess knowledge and understanding of the disease, its complications, treatment, and risks to others. Provide additional teaching and reinforcement as indicated. *Lack of understanding is a barrier to compliance with and management of the treatment regimen.*
- Work collaboratively to identify barriers or obstacles to managing the prescribed treatment. *Working collaboratively with the patient and other members of the healthcare team provides insight for overcoming identified barriers to effective treatment.*
- Assist the patient, significant others (if available), and healthcare team members to develop a plan for managing the prescribed regimen. *Including the patient in developing a plan to manage care increases the sense of control and ownership and helps ensure that personal, cultural, and lifestyle factors are considered. This increases the likelihood of compliance.*
- Provide verbal and written instructions that are clear and appropriate for level of literacy, knowledge, and understanding. *Clearly written directions provide support and reinforcement for the patient.*
- Provide active intervention for homeless people, including shelter placement or other housing and ongoing follow-up by easily accessed healthcare providers (clinics and public health workers in the neighborhood that do not present transportation or access problems, either real or perceived). *Simple referral will not ensure compliance, especially among disenfranchised populations. Active intervention is needed to help ensure treatment compliance.*
- Refer patients who are unlikely to comply with the treatment regimen to the public health department for management and follow-up. *Because TB presents a significant public health risk, public health follow-up is essential. In some cases, it is necessary for nurses to administer medications, observing the patient swallow all pills.*

Risk for Infection

The spread of TB is a risk in any facility housing many people. It is especially high in residential care facilities for older patients and for people with AIDS. The increasing incidence of TB among homeless people and members of lower socioeconomic groups increases the risk in hospitals, emergency departments, and public and urgent care clinics. Respiratory precautions are necessary to prevent the spread of TB via microscopic airborne droplets to other patients and to healthcare workers.

Expected Outcome: Patient will describe measures to protect healthy tissue and prevent infection.

- Place the patient in a private room with airflow control that prevents air within the room from circulating into the hallway or other rooms. A negative-flow room in which air is diluted by at least six fresh-air exchanges per hour is recommended. *A negative flow room and multiple fresh-air exchanges dilute the concentration of droplet nuclei within the room and prevent their spread to adjacent areas.*
- Use standard precautions and TB isolation techniques as recommended by the CDC, including wearing masks and gowns when caring for patients who do not reliably cover the mouth when coughing. *These measures are important to prevent the spread of TB to others.*
- Discuss the reasons for and importance of respiratory isolation procedures during initial hospitalization. When treatment

is provided as an outpatient, instruct to avoid crowds and close physical contact and maintain ventilation in living facilities, particularly during the first 3 weeks of treatment. *These measures help protect others during initial treatment, when sputum is still likely to contain significant numbers of bacilli.*

SAFETY ALERT

Use personal protective devices to reduce the risk of transmission during patient care. The Occupational Safety and Health Administration (OSHA) requires use of a HEPA-filtered respirator for protection against occupational exposure to TB. Surgical masks are ineffective to filter droplet nuclei, necessitating the use of protective devices capable of filtering bacteria and particles smaller than 1 micron.

- Place a mask on the patient when transporting to other parts of the facility for diagnostic or treatment procedures. *Covering the patient's nose and mouth during transport minimizes air contamination and the risk to visitors and personnel.*
- Inform all personnel having contact with the patient of the diagnosis. *This allows personnel to take appropriate precautions.*
- Assist visitors to mask prior to entering the room. *Providing visitors with appropriate masks or respirators reduces their risk of infection.*
- Teach the patient how to limit transmitting the disease to others:
  a. Always cough and expectorate into tissues.
  b. Dispose of tissues properly, placing them in a closed bag.
  c. Wear a mask if you are sneezing or unable to control respiratory secretions.
  d. The disease is not spread by touching inanimate objects, so no special precautions are required for eating utensils, clothing, books, or other objects used.
  Teaching appropriate precautions helps prevent the spread of TB to others while allowing as much freedom from restraints as possible.

CASE STUDY & NURSING CARE PLAN A Patient with Tuberculosis

Harry Facée, age 53, arrives at a metropolitan public health clinic complaining of aching chest pain that has lasted for the past few days. He also says that his sputum is bloody. He is afraid he might have lung cancer, so he came in to see a physician.

ASSESSMENT

Raj Kamil, RN, the public health nurse at the clinic, obtains an admission history and physical examination of Mr. Facée. Mr. Kamil notes that Mr. Facée is a homeless person who has lived on the streets and in various shelters for the past "10 years or so." He usually prefers to sleep outdoors, taking refuge in shelters only during very cold or very wet weather. He has a small disability income, but usually scrounges for food or eats with other homeless people at soup kitchens. Mr. Facée states that he has had a cough for a long time, which has become worse recently. It is now productive, especially in the mornings. He also admits that he has recently been waking up drenched with sweat in the middle of the night and is more tired than usual.

Although Mr. Facée's clothes are tattered, he is fairly clean. He answers questions appropriately and intelligently. Mr. Kamil does not detect any odor of alcohol on his breath. He is very thin, almost emaciated. Mr. Facée's vital signs are BP 152/86 mmHg, P 92 bpm, R 20/min, and T 37.8°C (100.2°F).

Suspecting tuberculosis, Mr. Kamil obtains a sputum specimen for Gram stain and culture, administers a tuberculin test, and sends Mr. Facée for a chest x-ray before he sees the clinic healthcare provider. Although the chest x-ray is inconclusive, the Gram stain is positive for acid-fast bacilli. The diagnosis of probable active pulmonary tuberculosis is made. The healthcare provider prescribes isoniazid, 300 mg orally; rifampin, 600 mg orally; and pyrazinamide, 1500 mg orally daily for 2 months, to be followed by twice weekly isoniazid 900 mg orally and rifampin 600 mg orally. The healthcare provider also orders weekly sputum cultures for the first month.

DIAGNOSES

- *Ineffective Health Maintenance* related to homelessness
- *Risk for Noncompliance with Prescribed Treatment* related to lack of understanding and resources
- *Imbalanced Nutrition: Less Than Body Requirements* related to increased metabolic needs associated with infection
- *Risk for Disturbed Sensory Perception: Kinesthetic* related to effects of isoniazid therapy

EXPECTED OUTCOMES

- Patient will keep all follow-up appointments as scheduled.
- Patient will verbalize an understanding of his disease and its treatment.
- Patient will follow the prescribed plan of care.
- Patient will demonstrate measures to prevent spread of the organism to others.
- Patient will gain 0.5 to 1 kg (1 to 2 lb) of weight per week.
- Patient will promptly report symptoms of peripheral neuropathy, including numbness, tingling, or burning sensations.

PLANNING AND IMPLEMENTATION

- Teach about tuberculosis, and provide a patient education pamphlet about the disease.
- Instruct about the prescribed medications, potential adverse effects, and the importance of completing the entire prescribed regimen.
- Emphasize the importance of continued follow-up.
- Teach and demonstrate sputum and droplet control measures.
- Escort to the local incentive shelter program for directly observed medical therapy and meals.
- Identify verbally and in writing manifestations to report to the healthcare provider.

EVALUATION

Mr. Kamil successfully enrolls Mr. Facée in the local incentive shelter program. In this program, a healthcare worker administers Mr. Facée's medications daily, watching him swallow them. He is assigned a small individual room and can eat three daily meals at the shelter. He still prefers to sleep outside when the weather permits, but he complies with the requirement for supervised medication administration because he "likes the food there." Always a clean person, Mr. Facée is able to demonstrate appropriate sputum control measures and practices them faithfully. The sputum culture done after 2 months of treatment is negative for tubercle bacilli, and his chest x-ray indicates no disease progression.

Clinical Reasoning in Patient Care

1. Many homeless people have schizophrenia or other mental diseases. How would you adapt the care plan for a homeless schizophrenic patient with active tuberculosis?
2. Mr. Kamil was fortunate in having access to an incentive shelter with healthcare workers to supervise medication compliance. Identify available resources in your area for homeless patients infected with tuberculosis.
3. Develop a care plan for the nursing diagnosis *Ineffective Airway Clearance* related to mucopurulent sputum and weak cough.

See Evaluating Your Response in Appendix B.

- Teach how to collect sputum specimens. If necessary, have the patient step outside to collect a sputum specimen. *This minimizes the risk of exposure to healthcare personnel and provides for rapid dilution of any droplet nuclei produced and their exposure to ultraviolet light (which kills the bacteria).*
- Teach the importance of complying with prescribed treatment for the entire course of therapy. *Completion of the entire treatment regimen is important to reduce the risk of relapse and creation of drug-resistant organisms.*

Continuity of Care

Most patients with TB are managed in community settings; few require institutionalization. The accompanying Case Study & Nursing Care Plan presents community-based nursing care for a patient with TB. In addition to the teaching topics and strategies identified earlier, discuss the following topics when preparing the patient and significant others for home care:

- Importance of screening close contacts for infection and possibly prophylactic treatment
- Effect, dose, and timing for all medications, and potential side effects and their management
- Importance of long-term therapy in eradicating the disease
- Principles of good nutrition, dietary guidelines for a patient with TB, and other measures to help maintain good health, such as balancing rest with exercise
- Signs and symptoms of complications to report to the healthcare provider.

Provide referrals as appropriate:

- Smoking cessation clinics or support groups
- Alcohol treatment facilities, Alcoholics Anonymous, other treatment programs or support groups
- Drug treatment facilities, Narcotics Anonymous, other outpatient or inpatient treatment programs or support groups
- Low-cost community clinics and incentive programs for people with TB
- Counseling, support groups, and other community resources that provide additional assistance and support.

THE PATIENT WITH INHALATION ANTHRAX

Inhalation anthrax is a potential threat in the United States. This disease rarely affects humans in nature, even though both wild and domestic animals can be infected. However, *Bacillus anthracis*, the spore-forming rod responsible for causing anthrax, has been identified as an agent likely to be used as a biologic weapon. Anthrax spores can be aerosolized so they remain suspended in the air, allowing them to be inhaled into the lungs. Person-to-person transmission does not occur.

Inhalation anthrax causes initial flu-like symptoms, including malaise, dry cough, and fever. This is followed by an abrupt onset of severe dyspnea, stridor, and cyanosis. Lymph nodes in the mediastinum and thorax become inflamed and enlarged. Septic shock and/or meningitis may develop. Untreated, death results from hemorrhagic thoracic lymphadenitis and hemorrhagic mediastinitis. Even with treatment, inhalation anthrax has a 45% mortality rate (CDC, 2011a).

Blood cultures and chest x-ray are used to diagnose inhalation anthrax. However, because death can quickly result from the disease, people who are known or suspected to have been exposed to anthrax spores often are treated prophylactically. Ciprofloxacin (Cipro) is used to both prevent and treat inhalation anthrax. Doxycycline (Vibramycin) is an alternative to ciprofloxacin. Although an anthrax vaccine exists, its use at this time is considered experimental (CDC, 2011a). See the section on bioterrorism in Chapter 7 for more information about anthrax and the section of this chapter on respiratory failure for nursing care measures for the patient with inhalation anthrax.

THE PATIENT WITH A FUNGAL INFECTION

Fungal spores are endemic, present in the air everyone breathes. Normal respiratory defense mechanisms allow few of these spores to reach the lungs. If they reach the lungs, pulmonary macrophages and neutrophils efficiently remove them in most people. When they do cause infection, it is typically mild and self-limiting. Most fungi are opportunistic, able to cause infection only in people who are immunocompromised. For this reason, patients with AIDS, renal failure, leukemia, burns, or chronic diseases, as well as people receiving corticosteroids or immunosuppressants, are particularly susceptible to fungal diseases.

Many fungal lung diseases have a geographic distribution pattern. Histoplasmosis and blastomycosis are more common in the southeastern, mid-Atlantic, and central states. California, Arizona, and western Texas are the primary sites for coccidioidomycosis, also known as *San Joaquin Valley fever*.

The course and manifestations of fungal lung diseases resemble those of TB. Lung lesions are slow to develop, and symptoms are mild. The fungus can disseminate from the lung to other organs.

Pathophysiology

HISTOPLASMOSIS

Histoplasmosis, an infectious disease caused by *Histoplasma capsulatum*, is the most common fungal lung infection in the United States. The organism is found in the soil and is linked to exposure to bird droppings and bats. Infection occurs when the spores are inhaled and reach the alveoli. Most infections develop into *latent asymptomatic disease*, much like TB, or *primary acute histoplasmosis*, a mild, self-limiting influenza-like illness. Initial chest x-rays are nonspecific; later ones show areas of calcification. *Chronic progressive disease*, usually seen in older adults, typically is limited to the lung but may involve any organ. Progressive lung changes and cavitation occur, with increasing dyspnea and eventual disabling pulmonary disease.

Regional lymph vessels spread the organism from the lungs to other parts of the body, much like the process that occurs in TB. In the healthy host, normal immune responses inactivate and remove the organism. In the immunocompromised host, however, macrophages remove the fungi but are unable to destroy them, resulting in *disseminated histoplasmosis*. This type of histoplasmosis is often fatal. Manifestations of fever, dyspnea, cough, weight loss, and muscle wasting are usual. Ulcerations of the mouth and oropharynx may be present, and the liver and spleen are enlarged.

COCCIDIOIDOMYCOSIS

Coccidioidomycosis is an infectious disease caused by the fungus *Coccidioides immitis*. This mold grows in the soil of the arid Southwest,

Mexico, and Central and South America. When inhaled, the fungus typically causes an acute, self-limiting pulmonary infection that often is asymptomatic and goes unrecognized. If manifestations do occur, they resemble those of influenza, with malaise, fever, body aches, and cough. Pleuritic pain, skin rash, and arthritis of the knees and ankles also may develop. Disseminated disease, which may affect the lymph nodes, meninges, spleen, liver, kidney, skin, and adrenal glands, is rare in immunocompetent people. When it does occur, the mortality rate is high. Meningitis is the usual cause of death.

BLASTOMYCOSIS

The fungus *Blastomyces dermatitidis* causes the infectious disease blastomycosis. It occurs primarily in the south-central and Midwestern regions of the United States and in Canada. Men are affected more frequently than women. The lungs are the primary site for the disease, although it may spread to involve the skin, bones, genitourinary system, and, rarely, the CNS. Pulmonary symptoms include fever, dyspnea, pleuritic chest pain, and cough, which may become productive of bloody or purulent sputum. If untreated, the disseminated disease is slowly progressive and ultimately fatal.

PARACOCCIDIOIDOMYCOSIS

The fungus *Paracoccidioides brasiliensis* causes paracoccidioidomycosis. It is also known as *Brazilian blastomycosis* or *Lutz-Spendore-de Almeida disease*. As with blastomycosis, it often enters through the lungs but can spread to the lymph nodes and bone. It can occur in immunocompetent persons, often with onset in childhood. The pulmonary presentation includes lobar pneumonia or pleurisy that continues past the ninth day. Sulfa drugs and antifungals are used to eradicate the disease.

ASPERGILLOSIS

Aspergillus spores are common in the environment, but rarely cause disease except in the immunocompromised. When they do cause infection, *Aspergillus* species invade blood vessels and produce hyphae that branch at acute angles, frequently causing venous or arterial thrombosis. In the lungs, aspergillosis can cause an acute, diffuse, self-limited pneumonitis. The manifestations of pulmonary aspergillosis include dyspnea, nonproductive cough, pleuritic chest pain, chills, and fever. If the organism invades a pulmonary blood vessel, hemoptysis or massive pulmonary hemorrhage can occur. In patients with underlying lung disease, balls of *Aspergillus* hyphae may form within cysts or cavities, usually in the upper lobes of the lung. Symptoms often are milder and more insidious in onset, with fever, weight loss, night sweats, and cough.

●○● INTERPROFESSIONAL CARE

Most fungal lung infections can be diagnosed by microscopic examination of a sputum specimen for the fungus. Blood cultures may be done, as well as cultures of cerebrospinal fluid if indicated. Chest x-ray may show typical changes in lung tissue or widening of the mediastinum, depending on the infecting organism.

Acute pulmonary histoplasmosis and acute pulmonary coccidioidomycosis usually resolve without treatment, although antifungal drugs may be given to shorten the disease course. Oral itraconazole (Sporanox), a broad-spectrum antifungal agent, is commonly prescribed to treat histoplasmosis. Other fungal lung diseases and patients who are immunocompromised are often treated with intravenous amphotericin B. Surgery (lobectomy) may be indicated for patients with severe hemoptysis associated with aspergillosis.

●○● NURSING CARE

Patients with fungal lung infections have different nursing care needs, depending on the disease and their immune status. For most patients, nursing care focuses on education. People living in high-prevalence areas or who have specific risk factors such as exposure to bird droppings (for example, by cleaning chicken coops, pigeon lofts, or barns where birds roost), decomposed vegetation, rotting wood, or stored grain need to be aware of the risk, common symptoms, and measures to reduce the risk. Patients with latent histoplasmosis may need education to maintain good general health to prevent reactivation. Teach patients receiving antifungal drugs about the specific drug, its intended and adverse effects, the duration of therapy, and symptoms to report to the healthcare provider. Include teaching about any specific precautions such as drug or food interactions. Itraconazole interacts with many medications; verify the safety of concurrent usage with all other prescribed drugs. Its use is contraindicated during pregnancy and lactation; emphasize the importance of effective birth control and of notifying the healthcare provider immediately if pregnancy occurs. Amphotericin B is a toxic drug. Administer the initial intravenous dose slowly after premedicating with an antihistamine and antiemetic as ordered to manage its adverse effects. Monitor carefully during infusion and therapy for changes in vital signs, hydration, nutrition, weight, or urine output.

Disorders of the Pleura

The *pleura* is a thin membrane with two layers: the visceral pleura, which overlies the lung surface, and the parietal pleura, which lines the inner chest wall. Between the layers of pleura is a potential space, the *pleural cavity*, which contains a thin layer of serous fluid. As the thoracic cavity expands during inspiration, the pressure in this space becomes negative in relation to atmospheric and alveolar pressure. The expansible lung is drawn out, and air rushes into the alveoli. When the pleura is inflamed or affected by disease or injury, air or fluid can collect in the pleural cavity, restricting lung expansion, air movement, and ventilation.

THE PATIENT WITH PLEURITIS

Pleuritis (*pleurisy*), inflammation of the pleura, irritates sensory fibers of the parietal pleura, causing characteristic pain. Pleural inflammation usually occurs secondarily to another process, such as a viral respiratory illness, pneumonia, or rib injury.

The onset of pleuritis is typically abrupt. The pain is unilateral and well localized; it is usually sharp or stabbing in nature. Pain may be referred to the neck or the shoulder. Deep breathing, coughing, and movement aggravate the pain. Respirations are rapid and shallow, and chest wall movement is limited on the affected side. Breath

sounds are diminished, and a pleural friction rub may be heard over the site.

The diagnosis of pleuritis is based on its manifestations. Chest x-ray and ECG may be ordered to rule out other causes of chest pain. Treatment for pleuritis is symptomatic. Analgesics and NSAIDs, indomethacin (Indocin) in particular, help relieve the pain. Codeine may be ordered, both to relieve pain and to suppress the cough.

Nursing care for the patient with pleuritis is directed toward promoting comfort, including administration of NSAIDs and analgesics. Positioning and splinting the chest while coughing also are helpful. Although wrapping the chest with 6-inch-wide elastic bandages may help relieve pain, this may excessively restrict chest motion, increasing the risk of impaired airway clearance.

Teach the patient and family that pleuritis is generally self-limited and of short duration. Discuss symptoms to report to the healthcare provider: increased fever, productive cough, difficulty breathing, or shortness of breath. Provide information about prescription and nonprescription NSAIDs and analgesics, including the drug ordered, how to use it, and its desired and possible adverse effects.

THE PATIENT WITH A PLEURAL EFFUSION

The pleural space normally contains only about 10 to 20 mL of serous fluid. **Pleural effusion** is a collection of excess fluid in the pleural space. Pleural effusions result from either systemic or local disease. Systemic disorders that may lead to pleural effusion include heart failure, liver or renal disease, and connective tissue disorders, such as rheumatoid arthritis and systemic lupus erythematosus. Pneumonia, atelectasis, TB, lung cancer, and trauma are local conditions that may cause pleural effusion.

Pathophysiology and Manifestations

Excess pleural fluid may be either *transudate*, formed when capillary pressure is high or plasma proteins are low, or *exudate*, the result of increased capillary permeability. Heart failure is the most common precipitating factor in transudate formation; it also may accompany renal failure, nephrosis, liver failure, and malignancy. Exudate, a protein-rich fluid, is seen with inflammatory processes such as infections, systemic inflammation (e.g., rheumatoid arthritis or systemic lupus erythematosus), pulmonary infarction (leading to tissue necrosis and an inflammatory response), and malignancy (Huether & McCance, 2011). Other pleural fluid collections include *empyema*, pus in the pleural cavity; *hemothorax*, the presence of blood in the cavity; *hemorrhagic pleural effusion*, a mixture of blood and pleural fluid; and *chylothorax*, a collection of lymph in the pleural space. In adults, chylothorax may result from thoracic surgery or placement of a central catheter in one of the great veins (Huether & McCance, 2011).

A large pleural effusion compresses adjacent lung tissue. This causes the characteristic manifestation of dyspnea. Pain may develop, although with inflammatory processes pleuritic pain often is relieved by formation of an effusion, because the fluid reduces friction between inflamed visceral and parietal pleura. Breath sounds are diminished or absent, and a dull percussion tone is heard over the affected area. Chest wall movement may be limited.

●○● INTERPROFESSIONAL CARE

Chest x-ray often provides the first evidence of a pleural effusion. Because fluid typically collects in dependent regions, it is seen at the base of the affected lung on an upright chest x-ray, and along the lateral wall when the patient is positioned on the affected side. CT scans and ultrasonography also are used to localize and differentiate pleural effusions.

NURSING CARE OF THE PATIENT

Undergoing a Thoracentesis

PREPROCEDURE CARE

- Verify a signed informed consent for the procedure. *This invasive procedure requires informed consent.*
- Assess knowledge and understanding of the procedure and its purpose; provide additional information as needed. *An informed patient will be less apprehensive and more able to cooperate during the thoracentesis.*
- Preprocedure fasting or sedation is not required. *Only local anesthesia is used in this procedure, and the gag and cough reflexes remain intact.*
- Administer a cough suppressant if indicated. *Movement and coughing during the procedure may cause inadvertent damage to the lung or pleura.*
- Obtain a thoracentesis tray, sterile gloves, injectable lidocaine, povidone-iodine or chlorhexidine, dressing supplies, and an extra overbed table or Mayo stand. *These supplies are used by the healthcare provider performing the procedure.*
- Position the patient upright, leaning forward with arms and head supported on an anchored overbed table. *This position spreads the ribs, enlarging the intercostal space for needle insertion.*
- Inform the patient that although local anesthesia prevents pain as the needle is inserted, a sensation of pressure may be felt. *A pressure sensation occurs as the needle punctures the parietal pleura to enter the pleural space.*

POSTPROCEDURE CARE

- Monitor pulse, color, oxygen saturation, and other signs during thoracentesis. *These are indicators of physiologic tolerance of the procedure.*
- Apply a dressing over the puncture site, and position on the unaffected side for 1 hour. *This allows the pleural puncture to heal.*
- Label obtained specimen with name, date, source, and diagnosis; send specimen to the laboratory for analysis. *Fluid obtained during thoracentesis may be examined for abnormal cells, bacteria, and other substances to determine the cause of the pleural effusion.*
- During the first several hours after thoracentesis, frequently assess and document vital signs; oxygen saturation; respiratory status, including respiratory excursion, lung sounds, cough, or hemoptysis; and puncture site for bleeding or crepitus. *Frequent assessment is important to detect possible complications of thoracentesis, such as pneumothorax.*
- Obtain a chest x-ray. *Chest x-ray is ordered to detect possible pneumothorax.*
- Normal activities generally can be resumed after 1 hour if no evidence of pneumothorax or other complication is present. *The puncture wound of thoracentesis heals rapidly.*

THORACENTESIS

If the cause of pleural effusion is not apparent, a thoracentesis may be done. **Thoracentesis** is an invasive procedure in which fluid (or occasionally air) is removed from the pleural space with a needle. Aspirated fluid is analyzed for appearance, cell counts, protein and glucose content, the presence of enzymes such as LDH and amylase, abnormal cells, and culture.

When pleural effusion is significant and interferes with respirations, thoracentesis is the treatment of choice to remove the fluid (Figure 36–7 ■). Thoracentesis may be performed at the bedside, in a procedure room, or in an outpatient setting. Local anesthesia is used, and the procedure requires less than 30 minutes to complete. Percussion, auscultation, radiography, or ultrasonography may be used to locate the effusion and needle insertion site. The amount of fluid removed is limited to 1200 to 1500 mL at one time to reduce the risk of cardiovascular collapse from rapid removal of too much fluid. Pneumothorax is a possible complication of thoracentesis if the visceral pleura is punctured or a closed-drainage system not maintained during the procedure. Nursing care for the patient undergoing a thoracentesis is outlined in the accompanying box.

TREATMENTS

Because pleural effusion usually occurs secondarily to another disease or disorder, medical management also focuses on treating the underlying condition to prevent further fluid accumulation. An empyema may require repeated drainage, as well as high doses of parenteral antibiotics. Occasionally, thoracotomy and surgical excision may be necessary. Recurrent pleural effusions, often due to cancer, may be prevented by instilling an irritant, such as doxycycline, bleomycin, or talc, into the pleural space to cause adhesion of the parietal and visceral pleura (*pleurodesis*). Water-seal chest tube drainage is often employed for hemothorax.

Evidence for Nursing Care

The Patient with Pleural Effusion

Selected resources that nurses may find helpful when planning evidence-based nursing care follow.

- Walker, S. J., & Bryden, G. (2010). Managing pleural effusions: Nursing care of patients with a Tenckhoff catheter. *Clinical Journal of Oncology Nursing, 14* (1), 59–64.

●○● NURSING CARE

Nursing care for the patient with a pleural effusion is directed toward supporting respiratory function and assisting with procedures to evacuate collected fluid. With a large pleural effusion and partial lung collapse, impaired gas exchange and activity intolerance are high-priority nursing problems. Risk for impaired gas exchange is also a priority problem during the initial period following thoracentesis.

Teaching for home care focuses on symptoms of recurrent effusion or complications following a thoracentesis to report to the healthcare provider: increasing dyspnea or shortness of breath, cough, and hemoptysis. Pleuritic pain may be an early sign of effusion and also should be reported. Further teaching about an underlying condition also may be necessary; for example, the patient with heart failure may need teaching about a salt-restricted diet.

THE PATIENT WITH PNEUMOTHORAX

Accumulation of air in the pleural space is called **pneumothorax**. Pneumothorax can occur spontaneously, without apparent cause, as a complication of preexisting lung disease, as a result of blunt or penetrating trauma to the chest, or from an iatrogenic cause (e.g., following thoracentesis).

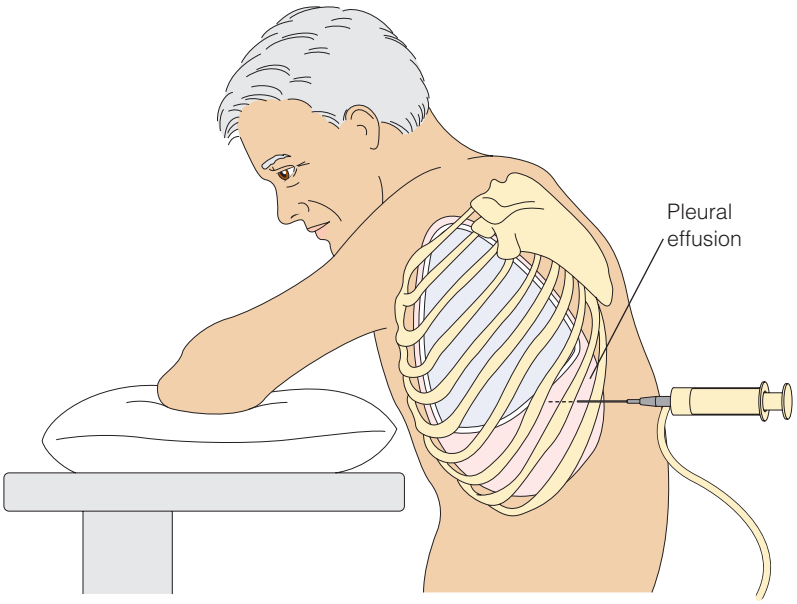

Figure 36–7 ■ Thoracentesis. With the patient seated, a needle is inserted between the ribs into the pleural space to withdraw accumulated fluid.

Pathophysiology

Pressure in the pleural space is normally negative in relation to atmospheric pressure. This negative pressure is vital to the process of breathing. Contraction of the diaphragm and the intercostal muscles enlarges the thoracic space. Negative intrapleural pressure draws the lung outward, increasing its volume so air rushes in to fill the expanded lung space.

When either the visceral or parietal pleura is breached, air enters the pleural space, equalizing this pressure. Lung expansion is impaired, and the natural recoil tendency of the lung causes it to collapse to a greater or lesser extent, depending on the size and rapidity of air accumulation. Table 36–7 illustrates the classifications of pneumothorax.

Spontaneous Pneumothorax

Spontaneous pneumothorax develops when an air-filled bleb, or blister, on the lung surface ruptures. Rupture allows air from the airways to enter the pleural space. Air accumulates until pressures are equalized or until collapse of the involved lung section seals the leak. Spontaneous pneumothorax may be either *primary* (*simple*) or *secondary* (*complicated*).

Primary pneumothorax affects previously healthy people, usually tall, slender men between ages 16 and 24. The cause of primary pneumothorax is unknown. Risk factors include smoking and familial factors. Air-filled blebs tend to form in the apices of the lungs. This is considered to be a benign condition, although recurrences are common. Certain activities, such as high-altitude flying and rapid decompression during scuba diving, also increase the risk of spontaneous pneumothorax.

Secondary pneumothorax, generally caused by overdistention and rupture of an alveolus, is more serious and potentially life threatening. It develops in patients with underlying lung disease, usually COPD. Middle-aged and older adults are primarily affected. Secondary pneumothorax also may be associated with asthma, cystic fibrosis, pulmonary fibrosis, tuberculosis, acute respiratory distress syndrome (ARDS), and other lung diseases. Rarely, a form of secondary pneumothorax called *catamenial pneumothorax* can develop in affected women within 24 to 48 hours of the onset of menstrual flow.

MANIFESTATIONS

The manifestations of spontaneous pneumothorax depend on the size of the pneumothorax, extent of lung collapse, and any underlying lung disease. Typically, pleuritic chest pain and shortness of breath begin abruptly, often while at rest. The respiratory and heart rates increase as gas exchange is affected. Chest wall movement may be asymmetrical, with less movement on the affected side than the unaffected side. The affected side is hyperresonant to percussion, and breath sounds may be diminished or absent. Hypoxemia may develop, although normal mechanisms that shunt blood flow to the unaffected lung often maintain normal oxygen saturation levels. Hypoxemia is more pronounced in secondary pneumothorax.

TRAUMATIC PNEUMOTHORAX

Blunt or penetrating trauma of the chest wall and pleura can cause pneumothorax. Blunt trauma, for example, due to a motor vehicle crash, fall, or during cardiopulmonary resuscitation (CPR), can lead to a *closed pneumothorax*. Fractured ribs penetrating the pleura are the leading cause of pneumothorax due to blunt trauma. Fracture of the trachea and a ruptured bronchus or esophagus also may result from blunt trauma, leading to closed pneumothorax.

Open pneumothorax (*sucking chest wound*) results from penetrating chest trauma such as a stab wound, gunshot wound, or impalement injury. With open pneumothorax, air moves freely between the pleural space and the atmosphere through the wound. Pressure on the affected side equalizes with the atmosphere, and the lung collapses rapidly. The result is significant hypoventilation.

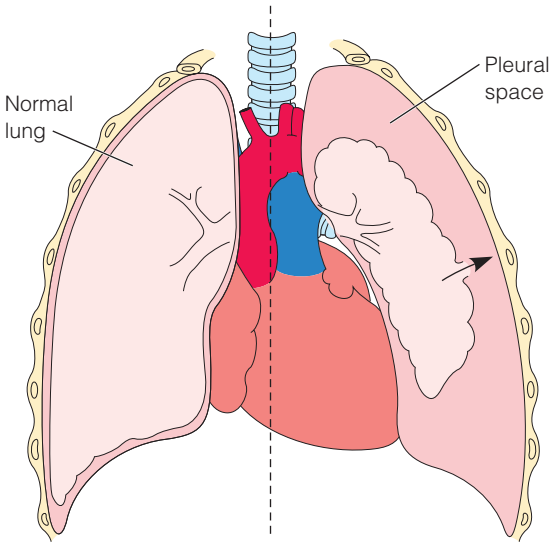
Iatrogenic pneumothorax may result from puncture or laceration of the visceral pleura during central-line placement, thoracentesis, or lung biopsy. During bronchoscopy, bronchi or lung tissue can be disrupted. Alveoli can become overdistended and rupture during anesthesia, resuscitation procedures, or mechanical ventilation.

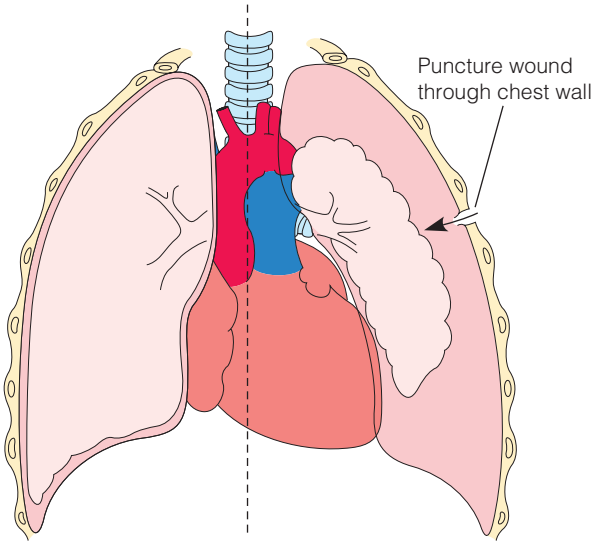
MANIFESTATIONS With traumatic pneumothorax, manifestations of pain and dyspnea may be masked or missed due to other injuries. Tachypnea and tachycardia may be attributed to the primary injury. Focused assessment for evidence of pneumothorax is vital. Chest wall movement on the affected side is diminished, and breath sounds are absent. If a penetrating wound is present, air may be heard and felt moving through it with respiratory efforts. Hemothorax frequently accompanies traumatic pneumothorax. The manifestations of iatrogenic pneumothorax are similar to those of spontaneous pneumothorax.

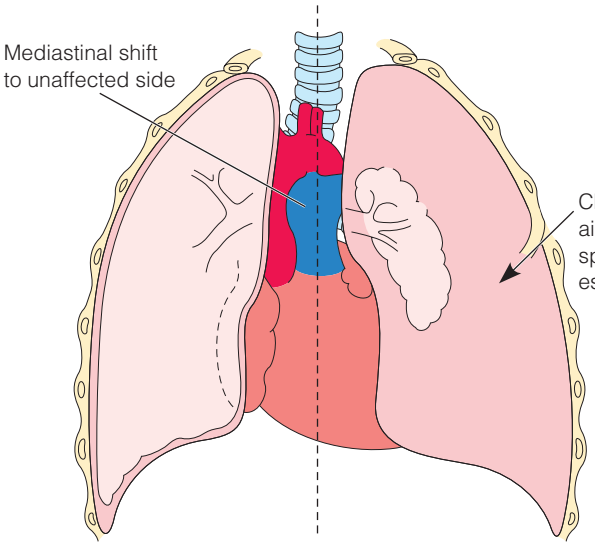
TENSION PNEUMOTHORAX

Tension pneumothorax develops when injury to the chest wall or lungs allows air to enter the pleural space but prevents it from escaping. Pressure within the pleural space becomes positive in relation to atmospheric pressure as air rapidly accumulates with each breath. The lung on the affected side collapses, and pressure on the mediastinum shifts thoracic organs to the unaffected side of the chest, placing pressure on the opposite lung as well. Ventilation is severely compromised, and venous return to the heart is impaired. Tension pneumothorax is a medical emergency requiring immediate intervention to preserve respiration and cardiac output.

MANIFESTATIONS In addition to manifestations of pneumothorax, hypotension and distended neck veins are evident as venous return and cardiac output are affected. The trachea is displaced toward the unaffected side as a result of the mediastinal shift. Signs of shock may be present. Refer to Chapter 11 for the manifestations and treatment of shock.







●○● INTERPROFESSIONAL CARE

Treatment for pneumothorax depends on the severity of the problem. A small simple pneumothorax may require no treatment other than monitoring with serial x-rays. Air is absorbed from the pleural space, allowing most small pneumothoraces to resolve spontaneously. A large pneumothorax or significant symptoms usually requires treatment with *thoracostomy*, or the placement of chest tubes. Surgical intervention may be necessary to prevent recurrent spontaneous pneumothorax.

DIAGNOSIS

Oxygen saturation measurements are obtained to evaluate the effect of pneumothorax on gas exchange. ABGs may be obtained to further assess gas exchange.

TABLE 36–7 Types of Pneumothorax

Type	Pathophysiology	Manifestations
Spontaneous 	Rupture of a bleb on the lung surface allows air to enter pleural space from airways. • *Primary pneumothorax* affects previously healthy people. • *Secondary pneumothorax* affects people with preexisting lung disease (e.g., COPD).	• Abrupt onset • Pleuritic chest pain • Dyspnea, shortness of breath • Tachypnea, tachycardia • Unequal lung excursion • Decreased breath sounds and hyperresonant percussion tone on affected side
Traumatic 	Trauma to the chest wall or pleura disrupts the pleural membrane. • *Open* occurs with penetrating chest trauma that allows air from the environment to enter the pleural space. • *Closed* occurs with blunt trauma that allows air from the lung to enter the pleural space. • *Iatrogenic* involves laceration of visceral pleura during a procedure such as thoracentesis or central-line insertion.	• Pain • Dyspnea • Tachypnea, tachycardia • Decreased respiratory excursion • Absent breath sounds in affected area • Air movement through an open wound
Tension 	Air enters pleural space through chest wall or from airways but is unable to escape, resulting in rapid accumulation. Lung on affected side collapses. As intrapleural pressure increases, heart, great vessels, trachea, and esophagus shift toward the unaffected side.	• Hypotension, shock • Distended neck veins • Severe dyspnea • Tachypnea, tachycardia • Decreased respiratory excursion • Absent breath sounds on affected side • Tracheal deviation toward unaffected side

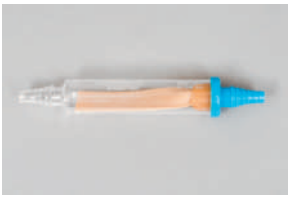


Figure 36–8 ■ The Heimlich one-way valve allows air to escape from the pleural space, helping reestablish negative pressure and allowing the lung to reexpand.

The chest x-ray is an effective diagnostic tool for pneumothorax. In tension pneumothorax, air is evident on the affected side, and mediastinal structures are shifted toward the opposite or unaffected side.

TREATMENTS

CHEST TUBES The treatment of choice for significant pneumothorax is placement of a closed-chest catheter to allow the lung to reexpand. When a tube is placed in the pleural cavity to remove air or fluid, it must be sealed to prevent air from also entering the tube and, in essence, creating an open pneumothorax. Chest tubes are sealed with a Heimlich (one-way) valve (Figure 36–8 ■) or connected to a closed-drainage system with a "water seal." The valve or water seal prevents air from entering the chest cavity during inspiration and allows air to escape during expiration. Applying a low level of suction to the system helps to reestablish negative pressure in the pleural space, allowing the lung to reexpand.

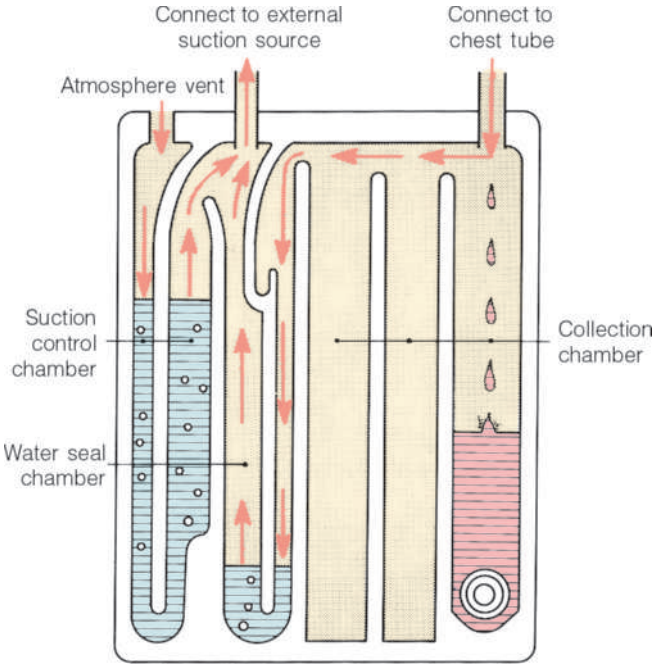

Figure 36–9 ■ A closed-chest drainage system.

A number of closed-drainage chest tube systems are available. Most are self-contained disposable systems (Figure 36–9 ■). Drainage from the chest tube is collected in the first collection chamber. This sealed chamber is connected to the water-seal

NURSING CARE OF THE PATIENT

With Chest Tubes

PREPROCEDURE CARE

- Ensure a signed informed consent for chest tube insertion has been obtained. *This invasive procedure requires informed consent.*
- Provide additional information as indicated. Explain that local anesthesia will be used but that pressure may be felt as the trocar is inserted. Reassure that breathing will be easier once the chest tube is in place and the lung reexpands. *The patient may be extremely dyspneic and anxious and may need reassurance that this invasive procedure will provide relief.*
- Gather all needed supplies, including thoracostomy tray, injectable lidocaine, sterile gloves, chest tube drainage system, sterile water, and a large sterile catheter-tipped syringe to use as a funnel for filling water-seal and suction chambers. *These supplies are used during the insertion procedure to establish a water-seal drainage system.*
- Position as indicated for the procedure. *Either an upright position (as for thoracentesis) or side-lying position may be used, depending on the site of the pneumothorax.*
- Assist with chest tube insertion as needed. The procedure may be performed in a procedure room, in the surgical suite, or at the bedside. *Although chest tube insertion is a relatively simple procedure, nursing assistance is necessary to support the patient and rapidly establish a closed-drainage system.*

POSTPROCEDURE CARE

- Assess respiratory status at least every 4 hours. *Frequent assessment is necessary to monitor respiratory status and the effect of a chest tube.*
- Maintain a closed system. Tape all connections, and secure the chest tube to the chest wall. *These measures are important to prevent inadvertent tube removal or disruption of the system integrity.*
- Keep the collection apparatus below the level of the chest. *Pleural fluid drains into the collection apparatus by gravity flow.*
- Check tubes frequently for kinks or loops. *These could interfere with drainage.*
- Check the water seal frequently. The water level should fluctuate with respiratory effort. If it does not, the system may not be patent or intact. Periodic air bubbles in the water-seal chamber are normal and indicate that trapped air is being removed from the chest. *Frequent assessment of the system is important to ensure appropriate functioning*
- Measure drainage every 8 hours, marking the level on the drainage chamber. Report drainage that is cloudy, in excess of 70 mL per hour, or red, warm, and free flowing. *Red, free-flowing drainage indicates hemorrhage; cloudiness may indicate an infection.*
- Periodically assess water level in the suction control chamber, adding water as necessary. *Adequate water in the suction control chamber prevents excess suction from being placed on delicate pleural tissue*
- Assist with frequent position changes and sitting and ambulation as allowed. *Chest tubes should not prevent performance of allowed activities. Care is needed to prevent inadvertent disconnection or removal of the tubes.*
- When the chest tube is removed, immediately apply a sterile occlusive petroleum jelly dressing. *An occlusive dressing prevents air from reentering the pleural space through the chest wound.*

chamber, which is in turn connected to the suction-control chamber. Nursing care of the patient with chest tubes is discussed in the accompanying box.

A large-bore needle or plastic intravenous catheter may be inserted through the chest wall as emergency treatment of a tension pneumothorax. This allows air to escape from the affected side, relieving pressure on mediastinal structures and the opposite lung.

PLEURODESIS Although controversial, *pleurodesis*, or creation of adhesions between the parietal and visceral pleura, may be used to prevent recurrent pneumothorax. This procedure involves instilling a chemical agent such as doxycycline into the pleural space. The subsequent inflammatory response creates scar tissue and adhesions between the pleural layers. This procedure reduces the recurrence rate to as low as 2% but can make subsequent surgery more difficult.

SURGERY

The risk for recurrence of spontaneous pneumothorax increases with each attack. Patients at high risk for recurrent pneumothorax may have surgery to reduce the risk of future ruptures. A thoracotomy is done to excise or oversew blebs (usually at the apices of the lungs). The overlying pleura is then roughened or irritated to induce scarring and adhesion to the surface of the lung. In some cases, the parietal pleura may be partially excised. These procedures can be done using video-assisted thoracoscopic surgery (VATS), a minimally invasive surgical technique.

●○● NURSING CARE

Health Promotion

Health promotion activities to prevent spontaneous and traumatic pneumothorax primarily involve health teaching. Initiate and participate in programs to prevent smoking among children and teenagers. Teach safe behaviors such as always wearing a seat beat in an automobile, driving safely, and using precautions to prevent falls when working or recreating in high places.

Assessment

See the Manifestations and Interprofessional Care sections for the assessment of the patient with pneumothorax.

The patient with pneumothorax may be in acute respiratory distress, necessitating rapid and focused assessment.

- *Health history:* current symptoms and their duration; precipitating factors or activities if known; previous episodes of pneumothorax; smoking history; chronic pulmonary diseases such as COPD.
- *Physical assessment:* general appearance and degree of apparent respiratory distress; evidence of chest trauma; vital signs, oxygen saturation, skin color, level of consciousness; respiratory excursion, percussion tone, and breath sounds anterior and posterior chest; neck vein inspection, position of trachea; peripheral pulses.
- *Laboratory data:* chest x-ray, arterial blood gases.

Priorities of Care

Collaborating with the interprofessional team to ensure adequate treatment of the underlying etiology that led to the pneumothorax while providing care that promotes lung expansion and supports the physical and psychologic responses to the disorder

Diagnoses, Outcomes, and Interventions

Maintaining or restoring adequate alveolar ventilation and gas exchange is of highest priority for the patient with a pneumothorax. Chest tubes may interfere with physical mobility, contributing to a high risk for injury.

Impaired Gas Exchange

Loss of negative pressure in the pleural cavity and the resulting collapse of lung tissue can cause poor chest expansion and loss of alveolar ventilation. As the pneumothorax is removed or reabsorbed, ventilation and gas exchange improve.

Expected Outcome: Improved ventilation and adequate oxygenation as evidenced by blood gas levels within normal limits for the individual patient.

- Assess and document vital signs and respiratory status, including rate, depth, lung sounds, and oxygen saturation at least every 4 hours. *Frequent assessment is important to monitor the adequacy of respirations and lung expansion.*
- Evaluate chest wall movement, position of the trachea, and neck veins frequently. *Early identification of tension pneumothorax and appropriate interventions are vital to preserve cardiorespiratory function.*
- Place in Fowler's or high-Fowler's position. *This position facilitates lung expansion.*
- Administer oxygen as ordered. *Supplemental oxygen is given to improve oxygenation of the blood and tissues.*
- Provide emotional support, particularly in early stages and during chest tube insertion. *Dyspnea and hypoxemia can cause extreme anxiety and apprehension, impairing the ability to cooperate with procedures.*
- Assess chest tube, system function, and drainage at least every 2 hours. *The system must remain patent and intact to function effectively.*
- Provide for rest. *Adequate rest is important to conserve energy and reduce oxygen demand.*

Risk for Injury

Pain and the presence of chest tubes can reduce the perceived ability to ambulate and provide self-care. Moderate activity is encouraged unless respiratory function is significantly impaired. Caution is taken to maintain integrity of the chest tube system. If the tube is inadvertently pulled out or system integrity is disrupted, the pneumothorax may increase or infection may develop.

Expected Outcome: Patient will practice effective risk control through use of close and careful chest tube monitoring.

SAFETY ALERT

Avoid placing tension on chest tubes during positioning, ambulation, and care activities. The chest tubes are minimally secured to the chest wall and can be dislodged if tension is placed on them.

- Secure a loop of drainage tubing to the sheet or gown. *Looping the drainage tubing prevents direct pressure on the chest tube itself.*

- When turning to the affected side, ensure that neither the chest tube nor drainage tubing is kinked or occluded under the patient. *This maintains patency of the system.*
- Teach the patient how to ambulate with the drainage system, keeping the system lower than the chest. In most cases, suction can be discontinued during ambulation. *Ambulation facilitates lung ventilation and expansion. Drainage systems are portable to allow ambulation while chest tubes are in place. Keeping the drainage system lower than the chest promotes drainage and prevents reflux.*
- Observe insertion site when changing chest tube dressings for redness, swelling, pain, or drainage. Report any signs of infection, including fever, to the healthcare provider. *Interruption of skin integrity by chest tube insertion increases the risk for infection.*
- Ensure all tubing connections are taped per hospital policy or provider preference. If a connection does come loose, reconnect it as soon as possible. *A closed, sealed system is vital to prevent air from entering the pleural space and an open pneumothorax.*

SAFETY ALERT

Seal the wound of an open pneumothorax or from inadvertent tube removal as soon as possible with a sterile occlusive dressing, such as gauze impregnated with petroleum jelly. If a sterile dressing is not available, other occlusive material such as foil or plastic wrap can be used. Tape the dressing on three sides only. An occlusive dressing taped on three sides prevents the development of a tension pneumothorax by inhibiting air from entering the wound during inhalation but allowing it to escape during exhalation.

Continuity of Care

Patients who have experienced spontaneous pneumothorax need education about their future risk. After a single episode of spontaneous pneumothorax, the risk of recurrence is 40% to 50%. This risk increases with subsequent episodes. Stress the importance of quitting smoking to reduce the risk. Other activities that can precipitate recurrent episodes include mountain climbing or those involving exposure to high altitudes, flying in unpressurized aircraft, and scuba diving. The patient may be advised to avoid contact sports.

Following a pneumothorax, instruct the patient to gradually increase exercise and activity to previous levels. Stress the importance of follow-up care and monitoring. Discuss manifestations to report to the healthcare provider: upper respiratory infections; fever, cough, or difficulty breathing; sudden, sharp chest pain; or redness, pain, swelling, tenderness, or drainage from the chest tube puncture wound.

THE PATIENT WITH HEMOTHORAX

Hemothorax, or blood in the pleural space, usually occurs as a result of chest trauma, surgery, or diagnostic procedures. Hemothorax develops in about 25% of patients with chest trauma, usually due to laceration of the lung, an intercostal vessel, or the internal mammary artery. If a major thoracic vessel is disrupted, hemorrhage can be massive. Tumors, pulmonary infarction, and infections such as TB also can cause hemothorax. When blood collects in the pleural space, pressure on the affected lung impairs ventilation and gas exchange. With significant hemorrhage, a risk of shock exists.

Hemothorax causes symptoms similar to those of pneumothorax or pleural effusion. Lung sounds are diminished, and a dull percussion tone is noted over the collected blood, typically at the base of the lung. Chest x-ray is used to confirm the diagnosis of hemothorax.

Thoracentesis or thoracostomy with chest tube drainage is used to remove blood from the pleural space. With significant hemorrhage (e.g., due to trauma or surgery), the blood may be collected for subsequent autotransfusion. Blood for autotransfusion should be collected and reinfused within 4 hours. Strict aseptic technique is used in collecting the blood. It is collected through a gross particulate filter into a container primed with anticoagulant and reinfused when the container is full or when transfusion is necessary. Air is removed from the blood container prior to reinfusion and a filter used to eliminate debris, such as degenerating blood cells, fat particles, and fibrin.

Priority nursing care for the patient with hemothorax focuses on assessing and maintaining adequate respiratory function and cardiac output. The priority of care depends on the rate and extent of hemothorax. In a large, slow-developing hemothorax, ventilatory status may be affected significantly. In this instance, *Impaired Gas Exchange* and *Ineffective Breathing Pattern* are priority nursing diagnoses (Perrin & MacLeod, 2012). When hemothorax develops rapidly and hemorrhage is significant, additional priority nursing diagnoses include *Decreased Cardiac Output* and *Risk for Deficient Fluid Volume.*

When preparing the patient for home care following a hemothorax, discuss the importance of avoiding smoking and preventing respiratory infection. Include symptoms to report to the healthcare provider. If trauma or infection caused the hemothorax, discuss measures to prevent future trauma and continuing treatment for the infection as indicated.

Trauma of the Chest or Lung

Chest injury is a leading cause of death from trauma. It is commonly associated with motor vehicle crashes, violent crime, and falls. Chest injuries can range from mild, such as a simple rib fracture, to severe and fatal. Traumatic injury to the chest may involve both the chest wall and underlying thoracic structures, including the lungs, heart, great vessels, and esophagus. Chest and lung injury can result from several different mechanisms: penetrating trauma, such as a stab or gunshot wound; blunt trauma, such as a fall, motor vehicle crash, vehicle–pedestrian impact, or crush injury; or inhalation injury, such as smoke inhalation or near-drowning.

Rapid and continuing assessment of the airway, breathing, and circulation (ABCs) is vital in chest or lung injuries. Chest trauma can disrupt any or all of these functions. Chest injuries that may be life threatening include airway obstruction, tension pneumothorax, open pneumothorax, massive hemothorax, and flail chest with pulmonary contusion.

THE PATIENT WITH A THORACIC INJURY

Thoracic injuries may be minor and have little effect on respiratory status, for example, a simple rib fracture in a previously healthy patient. When pain or chest wall instability impair breathing or the underlying lung tissue is damaged, the risk is more significant. Motor vehicle crashes or falls are the usual causes of thoracic trauma.

Pathophysiology and Manifestations

Acceleration–deceleration injury and direct mechanisms of injury (e.g., crush injuries) are the most common mechanisms of thoracic injuries. Acceleration–deceleration injuries are caused by a rapid change in velocity as occurs in a motor vehicle crash or fall. The body stops suddenly, but the tissues and organs within the chest cavity continue to move forward until they impact the chest wall. Injuries sustained can be significant, depending on the velocity (speed) of the vehicle or body at the point of impact, the surface with which the body impacts, and individual characteristics (e.g., size and bone structure).

RIB FRACTURE

Simple rib fracture, usually involving a single rib, is the most common chest wall injury. Rib fracture generally is tolerated well and heals rapidly in a young, previously healthy person. In an older adult or person with preexisting lung disease, however, a fractured rib may lead to significant complications, such as pneumonia, atelectasis, and, potentially, respiratory failure. Displaced fractured ribs can penetrate the pleura, leading to pneumothorax and possible hemothorax. Fractures of certain ribs are more frequently associated with underlying tissue damage. Intrathoracic vessels may be damaged or torn with fractures of the first and second ribs. Fractures of the seventh through tenth ribs may cause liver or spleen injuries.

Rib fracture causes pain on inspiration and coughing. This leads to voluntary splinting, with rapid, shallow respirations and inhibited cough. Bruising may be seen over the fracture, and crepitus may be palpated with respiratory movement. Breath sounds are diminished, especially in the bases, due to splinting. If pneumothorax develops, chest wall movement on the affected side may be reduced, and breath sounds absent or significantly diminished. A hyperresonant percussion tone usually is noted. Hemothorax also causes diminished or absent breath sounds on the affected side, with a dull percussion note.

FLAIL CHEST

Multiple rib fractures may impair chest wall stability and normal chest wall function. When two or more consecutive ribs are fractured in multiple places, a free-floating segment of the chest wall, or **flail chest**, results. Physiologic function of the chest wall is impaired as the flail segment is sucked inward during inhalation and moves outward with exhalation. This is known as *paradoxic movement* (Figure 36–10 ■).

Flail chest can significantly affect ventilation and, consequently, gas exchange. Lung expansion is impaired and the work of breathing increases. Flail chest is frequently associated with underlying pulmonary contusion, which may lead to respiratory failure.

Flail chest causes dyspnea and pain, especially on inspiration. Paradoxic chest movement is evident with inspection. Chest expansion is unequal, and palpable crepitus is present. Breath sounds are diminished, and crackles may be heard on auscultation.

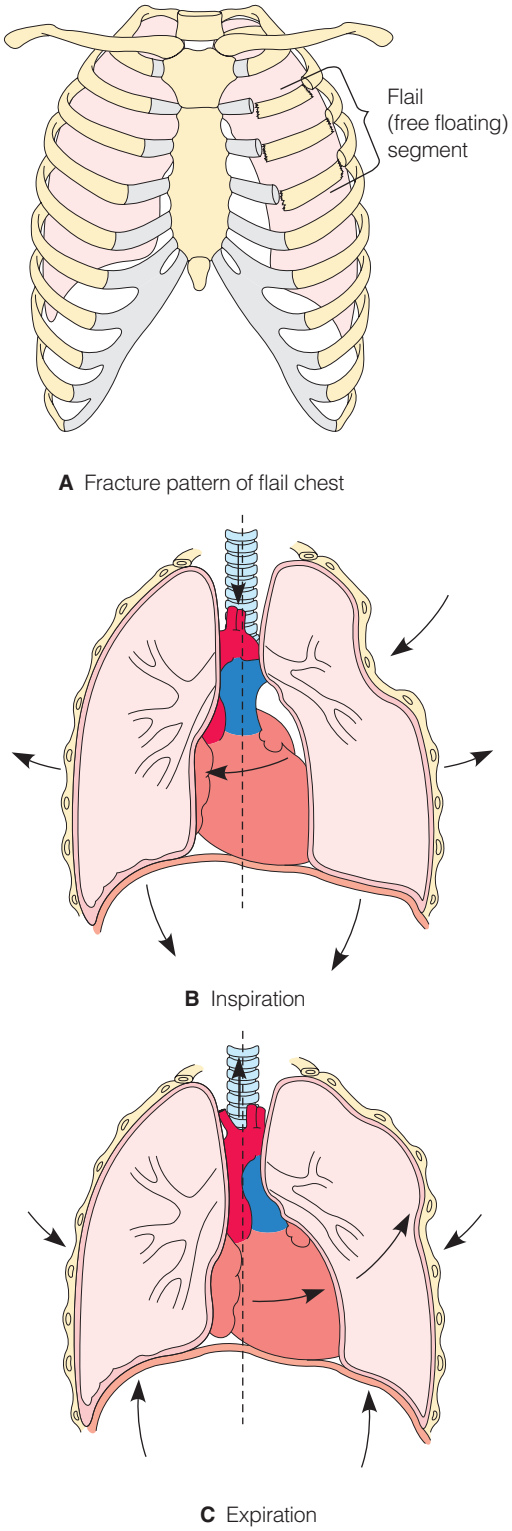

Figure 36–10 ■ Flail chest with paradoxical movement.

PULMONARY CONTUSION

Pulmonary contusion, or lung tissue injury, is frequently associated with flail chest and other blunt chest trauma. It may occur unilaterally or bilaterally. Pulmonary contusion often results from abrupt chest compression followed by sudden decompression, as can occur with a motor vehicle crash, significant fall, or crush injury. Alveoli and pulmonary arterioles rupture, causing intra-alveolar hemorrhage and interstitial and bronchial edema. The resulting inflammatory response increases capillary permeability, leading to edema that may be localized to the damaged lung tissue or more generalized. Inflammation and edema impair the production of surfactant within the alveoli, decreasing compliance. Pulmonary vascular resistance increases and blood flow decreases. Airway obstruction, atelectasis, and impaired gas diffusion result. Associated chest wall injury impairs the ability to clear secretions effectively, and the work of breathing is significantly increased.

Manifestations of pulmonary contusion may not be apparent until 12 to 24 hours after the injury. Increasing shortness of breath, restlessness, apprehension, and chest pain are early signs. Copious sputum, which may be blood tinged, is present. Later manifestations include tachycardia, tachypnea, dyspnea, and cyanosis. Even with appropriate treatment, pulmonary contusion can lead to acute respiratory distress and potential death.

●○● INTERPROFESSIONAL CARE

Chest x-ray is used to identify most chest wall injuries. Rib fractures are evident on x-ray. Pulmonary contusion may show as initial patchy opacifications progressing to diffuse opacification, or "white-out." Changes in oxygen saturation and arterial blood gases depend on the degree to which ventilation and gas exchange are affected by the injury.

Simple rib fractures typically heal uneventfully. Providing adequate analgesia to promote breathing, coughing, and movement is the primary intervention. With multiple rib fractures, an intercostal nerve block may be used to ensure adequate ventilation. Rib belts, binders, and taping to stabilize the rib cage are not recommended, because they may interfere with ventilation and lead to atelectasis. Even with simple rib fracture, older patients and patients with preexisting lung disease require close monitoring to prevent and detect atelectasis, pneumonia, and other complications.

Intercostal nerve blocks or continuous epidural analgesia may be employed to manage the pain associated with flail chest. For a small flail chest, analgesia combined with supplemental oxygen therapy may be adequate. In some cases, internal or external fixation of the flail segment may be done.

The preferred treatment for flail chest is intubation and mechanical ventilation. Positive-pressure ventilation provides support and stabilization of the flail segment and improves ventilation and gas exchange. The work of breathing is decreased and healing improved.

Patients with pulmonary contusion often are critically ill, requiring intensive care management. Treatment is supportive, directed at maintaining adequate ventilation and alveolar gas exchange. Endotracheal intubation and mechanical ventilation are necessary in most cases. Repeated bronchoscopy may be done to remove secretions and cellular debris, preventing atelectasis. Although adequate hydration is necessary to prevent shock, overhydration can increase pulmonary edema. Pulmonary arterial pressure monitoring with a Swan-Ganz catheter and frequent arterial blood gas measurement is required for optimal fluid replacement and management of ventilatory support. Refer to Chapter 31 for more information about pulmonary artery pressure monitoring, and Chapter 37 for nursing care of the patient who is intubated and ventilated.

Unilateral pulmonary contusion may present a unique management problem. Mechanical ventilation with positive end-expiratory pressure (PEEP) to maintain open alveoli and adequate gas exchange can damage the unaffected lung. Intubation with a double-lumen endotracheal tube that permits independent ventilation of each lung may be used.

●○● NURSING CARE

Health Promotion

Encourage the use of seat belts, shoulder harness, and supplemental restraint systems such as airbags to significantly reduce the incidence of thoracic injury associated with motor vehicle crashes. Discuss the importance of appropriate protective equipment and gear for people engaging in potentially hazardous activities such as contact sports, mountain climbing, and occupations such as roofing or house painting.

Assessment

See the Manifestations and Interprofessional Care sections for the assessment of the patient with a thoracic injury.

The nursing assessment of the patient with a thoracic injury may need to be rapid and focused.

- *Health history:* pain, difficulty breathing; circumstances of the injury, including position in the motor vehicle, use of restraints, speed and type of impact; distance of a fall, surface and position on impact; history of chronic lung or heart disease; smoking history.
- *Physical assessment:* airway, breathing, circulation; level of consciousness; color, vital signs; respiratory rate, depth, ease; symmetry of chest movement; lung sounds and percussion tone; presence of bruising, crepitus, or paradoxical chest movement.

Priorities of Care

Collaborating with the interprofessional team to ensure adequate treatment of the underlying injury while providing care that supports the physical and psychologic responses to the injury including pain management is a priority of nursing care.

Diagnoses, Outcomes, and Interventions

Chest wall trauma can interfere with adequate chest expansion and alveolar ventilation. When a pulmonary contusion is also present, gas exchange is affected as well. Priorities for nursing management include controlling pain, ensuring adequate ventilation, and promoting gas exchange.

Acute Pain

With many thoracic injuries, pain interferes with lung expansion and coughing, leading to such complications as pneumonia and atelectasis. Adequate pain management is a key component of medical and nursing management for these patients.

Expected Outcome: Patient will experience adequate pain control as evidenced by physical well-being.

- Frequently assess pain, using a standard pain scale and objective data. *Increased respiratory rate, shallow respirations, diminished breath sounds, and reluctance to move and cough may indicate inadequate pain control in a thoracic injury.*
- Administer analgesics by patient-controlled analgesia or on a schedule to maintain pain control. *Analgesics are more effective when pain is not allowed to become intense.*

SAFETY ALERT

Assess for possible respiratory depression due to narcotic analgesia. Respiratory depression can further compromise ventilation in the patient with thoracic injury.

- Notify the healthcare provider if pain relief is inadequate or excess sedation and respiratory depression occur. *An intercostal nerve*

block may be done to reduce the need for narcotic analgesia. Assess for bleeding and adequate ventilation following a nerve block.

Ineffective Airway Clearance

Aggressive respiratory hygiene may be necessary to maintain open airways and adequate ventilation.

Expected Outcome: Patient will use techniques to promote airway clearance such as coughing and deep breathing.

- Assess lung sounds and respiratory rate, depth, and effort frequently. Encourage to cough, deep breathe, and change position every 1 to 2 hours, and use the incentive spirometer. *Frequent assessment and measures to maintain airway patency are vital to prevent complications in the patient with thoracic injury.*
- Teach how to splint the affected area with a blanket or pillow when coughing. *Splinting reduces movement and discomfort of the affected area.*
- Suction airway as indicated. Work with respiratory therapy to maintain optimal mechanical ventilation. Secure the endotracheal tube to maintain appropriate position and lung ventilation. *Endotracheal tube security is particularly important when a double-lumen endotracheal tube is in place, because malposition can occlude one main bronchus and prevent ventilation of the affected lung.*
- Elevate the head of the bed. *Elevating the head of the bed facilitates lung expansion and reduces the work of breathing.*

SAFETY ALERT

Promptly report to the healthcare provider signs of complications, such as diminished breath sounds, increasing crackles (rales) or rhonchi, dull or hyperresonant percussion tones, unequal chest movement, hemoptysis, chills or fever, or changes in vital signs. Prompt intervention for complications is vital to promote healing and recovery.

Impaired Gas Exchange

Impaired gas exchange is of particular concern in pulmonary contusion. Alveolar damage and pulmonary edema can significantly impair oxygenation of the blood and removal of carbon dioxide.

Expected Outcome: Patient will achieve improved ventilation and adequate oxygenation as evidenced by blood gas levels within normal limits for the individual patient.

- Monitor vital signs, color, oxygen saturation, and arterial blood gases. Assess for manifestations such as anxiety or apprehension, restlessness, confusion or lethargy, or complaints of headache. *These assessment data alert the nurse and care providers to potential hypoxemia or hypercapnia due to impaired gas exchange.*
- Maintain oxygen therapy and mechanical ventilation as ordered. Hyperoxygenate prior to suctioning. *Oxygen and mechanical ventilation support alveolar gas exchange. Hyperoxygenation prior to suctioning reduces the degree of hypoxemia that occurs during suctioning.*
- Monitor intake and output, weigh daily, and monitor central venous pressure and pulmonary artery pressure as ordered. Maintain any ordered fluid restriction. *Fluid volume status is monitored to reduce the effects of pulmonary edema on lung tissues.*
- Maintain bed rest or activity restriction as ordered. Space activities to allow periods of uninterrupted rest. *Rest reduces the metabolic rate and oxygen consumption.*

Continuity of Care

Simple rib fracture and minor chest wall injuries often are managed on an outpatient basis. Include the following topics when teaching for home care:

- Pain management and its importance in preventing respiratory complications
- Importance of coughing and deep breathing; how to splint the rib cage during coughing
- Reasons for not taping or wrapping the chest continuously
- Symptoms to report to the healthcare provider: chills and fever, productive cough, purulent or bloody sputum, shortness of breath or difficulty breathing, and increasing chest pain
- Importance of avoiding respiratory irritants, such as cigarette smoke and occupational or environmental pollutants.

Significant pulmonary contusion can result in long-term respiratory insufficiency. Discuss activity modifications and occupational changes with the patient and family as indicated. Refer to home care services such as respiratory therapy and home health if needed.

THE PATIENT WITH INHALATION INJURY

The internal environment of the lungs normally is protected from noxious substances by respiratory defense mechanisms. If these defenses are breached, inhaled agents, such as gases, fumes, toxins, and water, can cause internal trauma to the lungs.

Pathophysiology and Manifestations

SMOKE INHALATION

Pulmonary injury due to inhalation of hot air, toxic gases, or particulate matter is the leading cause of death in burn injury (Perrin & MacLeod, 2012). Smoke inhalation affects up to one-third of patients admitted to burn units. Smoke inhalation can significantly affect normal respiratory function through three different mechanisms:

- Thermal damage to the airways, leading to impaired ventilation
- Carbon monoxide or cyanide poisoning, resulting in tissue hypoxia
- Chemical damage to the lung from noxious gases, which can impair gas exchange.

Smoke inhalation is suspected whenever a burn occurs in a closed space; if there are burns to the face or upper torso or singed nasal hairs; if sputum contains ash-like material; and when manifestations such as dyspnea, wheezing, rales, or rhonchi develop.

The lower airways of the lungs typically are protected from thermal damage by cooling of the inhaled gases in the upper airway and laryngeal spasm. Upper airway obstruction due to tissue edema and laryngeal spasm can occur quickly, however, resulting in **asphyxiation**, or oxygen deprivation, without lung damage. Steam inhalation can cause thermal damage to tissues of the lower respiratory tract.

Inhalation of carbon monoxide or cyanide gas poses an immediate threat to life. Carbon monoxide is a colorless, odorless gas produced in a fire. It binds readily with hemoglobin. The affinity of carbon monoxide for hemoglobin is 200 to 250 times stronger than that of oxygen. Hemoglobin bound to carbon monoxide reduces the oxygen-carrying capacity of blood and oxygen delivery to cells of the

body. Carbon monoxide poisoning is suspected if the burn occurred in a closed space, if there is evidence of inhalation injury, or if dyspnea develops.

The manifestations of carbon monoxide poisoning depend on the level of carboxyhemoglobin saturation. When hemoglobin is 10% to 20% saturated with carbon monoxide, symptoms include headache, dizziness, dyspnea, and nausea. A characteristic "cherry-red" skin color and mucous membranes may be seen. With increasing levels, confusion, visual disturbances, irritability, hallucinations, hypotension, seizures, and coma develop. Permanent neurologic deficit can occur in survivors of severe acute carbon monoxide poisoning.

Many other toxic chemicals may be present in smoke, especially in a house fire or industrial plant fire. Hydrogen cyanide can be lethal when inhaled. Inhalation of toxic chemicals causes bronchospasm and edema of the airways and alveoli. Acute respiratory distress syndrome may develop within 1 to 2 days. Sloughing of damaged mucosa leads to airway obstruction and atelectasis. Pneumonia is common following smoke inhalation.

NEAR-DROWNING

Drowning is a leading preventable cause of accidental death in the United States. Approximately 5500 people die of drowning every year in the United States. Alcohol ingestion is a factor in about 25% of adult drowning deaths. Other circumstances that may contribute to drowning and near-drowning include excessive fatigue, a sudden acute condition such as seizure or myocardial infarction, and head or spinal cord injury associated with diving.

Asphyxiation and aspiration are the primary problems associated with drowning and near-drowning. About 10% of victims do not aspirate water; instead, laryngeal spasm causes asphyxia. This is known as "dry drowning." In most cases, however, asphyxia and hypoxemia are the result of fluid aspiration. The effects of hypoxemia occur rapidly; loss of consciousness can occur within 3 to 5 minutes after total immersion. Circulatory impairment, brain injury, and brain death can occur within 5 to 10 minutes. Immersion in very cold water and the *dive reflex*, a protective mechanism that slows the heartbeat, constricts peripheral vessels, and shunts blood to the brain and heart, may prolong survival.

Water aspiration can cause delayed death from near-drowning. Respiratory and systemic effects differ, depending on whether freshwater or saltwater has been aspirated. Freshwater is hypotonic; when aspirated, it is rapidly absorbed from the alveoli, leading to hypervolemia and hemodilution. Hemolysis occurs as blood cells are subjected to a hypotonic environment, and serum electrolytes are diluted. Electrolyte imbalances can cause cardiac dysrhythmias and death. Hemolysis can lead to acute tubular necrosis and acute renal failure. Aspiration of freshwater impairs pulmonary surfactant and damages the alveolar-capillary membrane. Respiratory failure can result.

Nearly the opposite effects occur with saltwater aspiration. As a hypertonic fluid, saltwater draws fluid into the alveoli, resulting in hypovolemia and hemoconcentration. Hemolysis is insignificant, and small elevations in serum sodium and chloride levels rarely cause life-threatening effects. With either type of near-drowning episode, inhaled microorganisms and debris can lead to pneumonia. The pathophysiologic changes associated with freshwater and saltwater near-drowning are illustrated in Figure 36–11 ■.

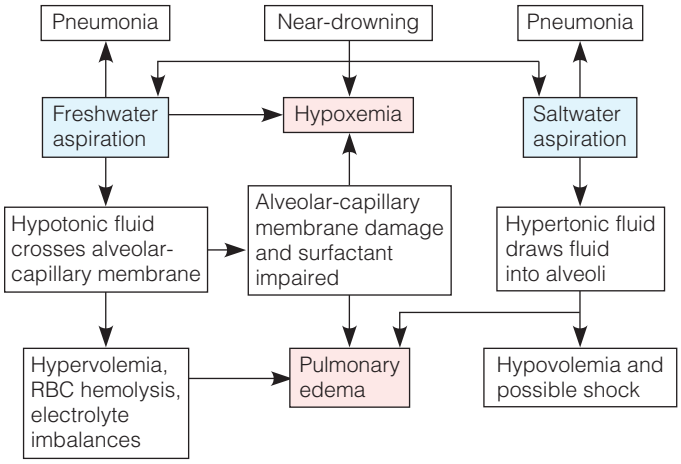

Figure 36–11 ■ The pathogenesis of near-drowning, freshwater and saltwater.

Manifestations of near-drowning may include altered level of consciousness, restlessness, and apprehension. The patient may complain of headache or chest pain. Other signs include vomiting, possible cyanosis, apnea, tachypnea, and wheezing. If pulmonary edema is present, pink froth may be visible in the mouth and nose. Other manifestations include tachycardia, dysrhythmias, hypotension, shock, and cardiac arrest. Hypothermia may be present.

The near-drowning victim who never loses consciousness or is conscious on admission to the emergency department has a good prognosis for recovery. The prognosis is less optimistic when neurologic damage has occurred.

●○● INTERPROFESSIONAL CARE

With inhalation injuries, the most effective treatment is prevention. A working smoke detector (with functioning batteries) could prevent the majority of deaths from smoke inhalation occurring in the home. The line "A smoke detector was found, but the batteries had been removed" is all too familiar in news reports of fire-related deaths.

To prevent drowning, life preservers and flotation vests or jackets should be worn on the body, not stored in the hold of the boat. These devices are designed to keep the head above water. Even accomplished swimmers should never enter the water alone in unguarded areas. Just as alcohol and driving do not mix, neither do alcohol and boating or other water sports.

The second most important line of defense against death or permanent injury from inhalation injuries is removing the victim from the area of the fire or water and administering effective cardiopulmonary resuscitation. In many cases, immediate restoration of effective breathing and circulation is key to preserving life. Hypoxemia progresses rapidly until breathing is restored; reversal of tissue hypoxia depends on adequate circulation. In both smoke inhalation and near-drowning, intubation may be necessary to establish an airway. Oxygen is administered as soon as possible. Attempts to drain water from the lungs of the near-drowning victim waste time and are generally ineffective in restoring alveolar ventilation. External cardiac defibrillation may be necessary to reestablish an effective cardiac rhythm and circulation. When the victim is hypothermic, resuscitation measures are continued until the core body temperature reaches approximately 32°C (90°F). The basic rule in hypothermia is that the patient is not

declared dead until the body has been rewarmed and signs of life remain absent.

DIAGNOSIS

When inhalation injury is known or suspected, the following diagnostic tests may be done:

- *ABGs* are drawn to evaluate gas exchange and the degree of hypoxemia. Combined respiratory and metabolic acidosis may be apparent. With effective ventilation and supplemental oxygen, acidosis may reverse quickly. With carbon monoxide poisoning, arterial Po_2 may be normal, but oxyhemoglobin saturation is less than normal.
- *Carboxyhemoglobin levels* are drawn in suspected carbon monoxide poisoning. Normal levels are less than 5% in nonsmokers and less than 10% in smokers. Higher levels indicate carbon monoxide poisoning. Levels less than 20% are considered mild poisoning; between 20% and 40% is moderate poisoning; and 40% to 60% is severe poisoning. Levels higher than 60% are generally fatal.
- *Serum electrolytes* and *osmolality levels* vary in near-drowning, depending on the type of water aspirated. In freshwater drowning, serum electrolyte levels and osmolality may be significantly reduced. With saltwater drowning, serum sodium and chloride may be somewhat high, and osmolality is increased because of hypovolemia.
- *Chest x-ray* is done, but may not show changes until 12 or more hours after the insult. Evidence of acute respiratory distress syndrome may be seen 24 to 48 hours after inhalation injury.
- *Bronchoscopy* may be ordered to inspect damaged lung tissue, particularly with smoke inhalation and possible thermal injury.

TREATMENTS

Treatment of inhalation injury is generally supportive. Endotracheal intubation and mechanical ventilation often are required to maintain the airway and provide adequate alveolar ventilation and oxygenation. All patients with inhalation injury require supplemental oxygen, even when intubation and ventilation are not required. *Hyperbaric oxygen therapy*, the delivery of 100% oxygen at increased atmospheric pressure, may be used to treat carbon monoxide poisoning. This treatment carries some risks, such as oxygen toxicity and potential trauma to lung tissues, sinuses, and ears due to the increased pressures.

Other treatment measures may include bronchodilator therapy to manage bronchospasm. Bronchodilators can be administered by aerosol inhalation or intravenous infusion. Coughing and suctioning is important to remove secretions and debris. Chest physiotherapy with percussion and postural drainage may be performed.

Intravenous fluids may be ordered; if significant hemolysis has occurred, packed red blood cells may be given to improve the oxygen-carrying capacity of the blood. Fluid therapy is monitored carefully, using pulmonary artery or central venous pressures to reduce the risk of pulmonary edema.

With near-drowning victims, measures such as inducing hypothermia or barbiturate-induced coma and administering corticosteroids and osmotic diuretics may be employed to help prevent neurologic damage. Careful monitoring for complications such as pneumonia and acute respiratory distress syndrome is vital throughout the course of treatment. Respiratory status, vital signs, and other data are frequently assessed to identify complications and allow early intervention.

●○● NURSING CARE

Health Promotion

Prevention of inhalation injuries is an important nursing responsibility. Teach everyone the value of a working smoke detector, especially in the sleeping areas of the house. Encourage families to develop an escape plan in case of fire and to use fire drills to rehearse getting out of the house. Smoldering cigarettes are a leading cause of house fires; help patients develop a plan to stop smoking. Teach people to drop and roll should clothing catch fire. (Flames and smoke rise, increasing the risk of respiratory injury when upright.)

Learning to swim safely is important to prevent drowning. Teach patients never to swim alone, when fatigued, or immediately following a meal. Remind patients that knowing how to swim will not prevent drowning in very cold water or in large bodies of water, such as lakes, rivers, or the ocean. Instruct to always wear flotation devices while boating, water-skiing, surfing, or wind-surfing. Wet suits help prevent hypothermia during activities in very cold water. Advise covering or fencing swimming pools, hot tubs, and ponds to prevent inadvertent entry and drowning.

A population well trained in effective, safe cardiopulmonary resuscitation (CPR) provides the best second line of defense against inhalation injury. Rapid restoration of breathing is essential to prevent hypoxia and brain damage. Encourage all people to be trained and regularly update CPR skills. Work with communities to increase the number of trained people. Refer patients to local chapters of the American Red Cross or American Heart Association for classes.

Assessment

See the Manifestations and Interprofessional Care sections for the assessment of the patient with an inhalation injury.

Inhalation injuries may be medical emergencies, necessitating focused and timely nursing assessment.

- *Health history:* circumstances of the injury, including duration of exposure to smoke or time under water, explosion or fire in a closed area, type and temperature of water immersed in; resuscitation measures used; allergies, and current medical problems
- *Physical assessment:* airway, breathing, circulation; level of consciousness; color, oxygen saturation level; vital signs; heart and lung sounds; urine output; evidence of burns or soot around nares or mouth
- *Laboratory data:* carboxyhemoglobin levels, serum electrolytes, and osmolality; arterial blood gases; chest x-ray.

Priorities of Care

Collaborating with the interprofessional team to ensure adequate treatment of the underlying etiology in response to the inhalation injury while providing care that supports the physical and psychologic responses to the injury, promoting salvage of optimal lung function, is a priority of nursing care.

Diagnoses, Outcomes, and Interventions

Nursing care priorities for the patient with an inhalation injury are determined by the type of injury or tissue damage. Airway clearance is a major concern in all inhalation injuries, as is impaired gas exchange. Tissue hypoxia also can be a significant problem.

Ineffective Airway Clearance

Nursing measures to maintain an adequate airway begin with careful and frequent assessment of respiratory status, including rate, depth, and effort, as well as breath sounds. Note amount, color, and consistency of sputum. Assist to cough frequently; suction the intubated patient as needed to remove secretions. Elevate the head of the bed to facilitate alveolar ventilation unless otherwise ordered. Stabilize endotracheal tube with tape and ties to prevent displacement into a mainstem bronchus, which could lead to ventilation of only one lung. Report changes in the character of secretions that may indicate complications: pink, frothy sputum suggesting pulmonary edema, or purulent sputum suggestive of pneumonia. Administer bronchodilators as ordered. Perform percussion and postural drainage as ordered.

Expected Outcome: Patient will use techniques to promote airway clearance such as coughing and deep breathing.

Impaired Gas Exchange

Support gas exchange by administering supplemental oxygen, with or without mechanical ventilation. Frequently assess oxygen saturation, skin color, and mental status. Decreasing level of consciousness may be an early sign of hypoxemia. Monitor exhaled carbon dioxide, arterial blood gases, and pulmonary artery pressures as ordered and indicated. Report changes to the healthcare provider. Maintain oxygen flow rates as ordered. Provide frequent mouth care to reduce the discomfort of dry mucous membranes and prevent tissue breakdown. Work with respiratory therapy to maintain effective oxygen delivery with mechanical ventilation. Administer sedation as required. Maintain fluid restriction if ordered.

Ineffective Tissue Perfusion: Cerebral

Impaired cerebral tissue perfusion is a priority problem, especially with near-drowning. Hypoxia and possible hypervolemia can lead to cerebral edema and increased intracranial pressure (IICP), further impairing blood flow. Monitor vital signs and neurologic status frequently. A change in level of consciousness or behavior is typically the earliest sign of IICP. Changes noted on an intracranial pressure monitor also provide early evidence of IICP. Increasing systolic blood pressure and pulse pressure and slowed heart rate are late signs. Other manifestations may include pupillary changes and decreasing muscle strength. Report changes promptly to the healthcare provider. Elevate the head of the bed and keep the head in neutral position to promote drainage from the cranial vault. Maintain effective ventilation and oxygenation; hypercapnia and hypoxemia increase cerebral edema. Administer sedation, osmotic diuretics, or corticosteroids as ordered to reduce cerebral edema. Maintain fluid restriction. Space activities and promote rest to reduce metabolic demands.

Expected Outcome: Patient will experience improved ventilation and adequate oxygenation as evidenced by blood gas levels within normal limits for the individual patient.

Continuity of Care

Teach patients who do not require hospitalization for inhalation injury about symptoms that may indicate a complication and should be reported to the healthcare provider: increasing dyspnea, cough productive of purulent or pink frothy mucus, confusion, or other changes. Manifestations of respiratory damage may not be apparent for 24 to 48 hours following the injury.

Significant hypoxia due to near-drowning or carbon monoxide poisoning may cause permanent neurologic effects. Work with the family to develop communication techniques and identify remaining strengths. Help the family identify future care needs and means for meeting them, such as home health, personal care aides, or long-term care facilities. Provide social services and support group referrals.

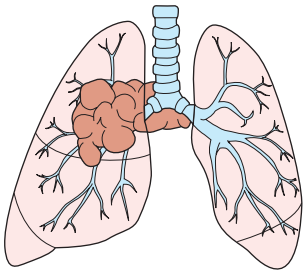
Lung Cancer

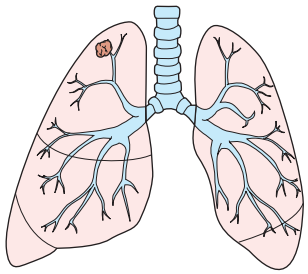
THE PATIENT WITH LUNG CANCER

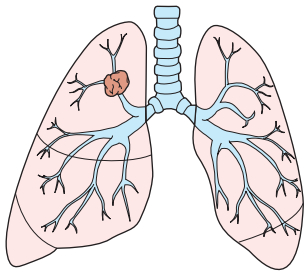
Lung cancer is the leading cause of cancer deaths in the United States, accounting for 31% of all cancer deaths. In 2009, about 219,440 people died from lung cancer in the United States; an estimated 159,390 new cases were diagnosed in that same year (ACS, 2012). It is a major health problem with a grim prognosis: Most people with lung cancer die within 1 year of the initial diagnosis.

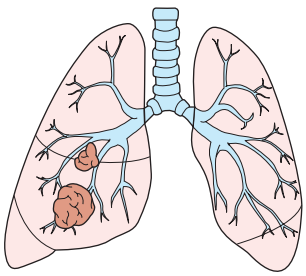
Pathophysiology

Lung cancer develops as damaged bronchial epithelial cells mutate over time to become neoplastic. The genetic abnormality commonly seen is on chromosome 3, with loss of genetic material. Alterations of tumor suppressor genes also are seen in some types of lung cancer.









The vast majority of primary lung lesions are *bronchogenic carcinoma*, tumors of the airway epithelium. These tumors are further differentiated by cell type: small-cell carcinoma, adenocarcinoma, squamous cell carcinoma, and large-cell carcinoma. For clinical purposes, the latter three cell types frequently are classified together as non–small-cell carcinomas. *Small-cell carcinomas*, which account for approximately 25% of lung cancers, grow rapidly and spread early. These tumors have paraneoplastic properties; that is, they produce manifestations at sites that are not directly affected by the tumor. Small-cell lung carcinomas can synthesize bioactive products and hormones such as adrenocorticotropic hormones (ACTH), antidiuretic hormone (ADH), a parathormone-like hormone, and gastrin-releasing peptide. *Non–small-cell carcinoma* accounts for about 75% of lung cancers. Each cell type differs in its incidence, presentation, and manner of spread. Table 36–8 outlines the incidence and unique characteristics of each cell type.

Bronchogenic cancer, regardless of cell type, tends to be aggressive, locally invasive, and have widespread metastatic lesions. Tumors begin as mucosal lesions that grow to form masses that obstruct the bronchi or invade adjacent lung tissue. All types frequently spread via the lymph system to nodes and other organs such as the brain, bones, and liver.

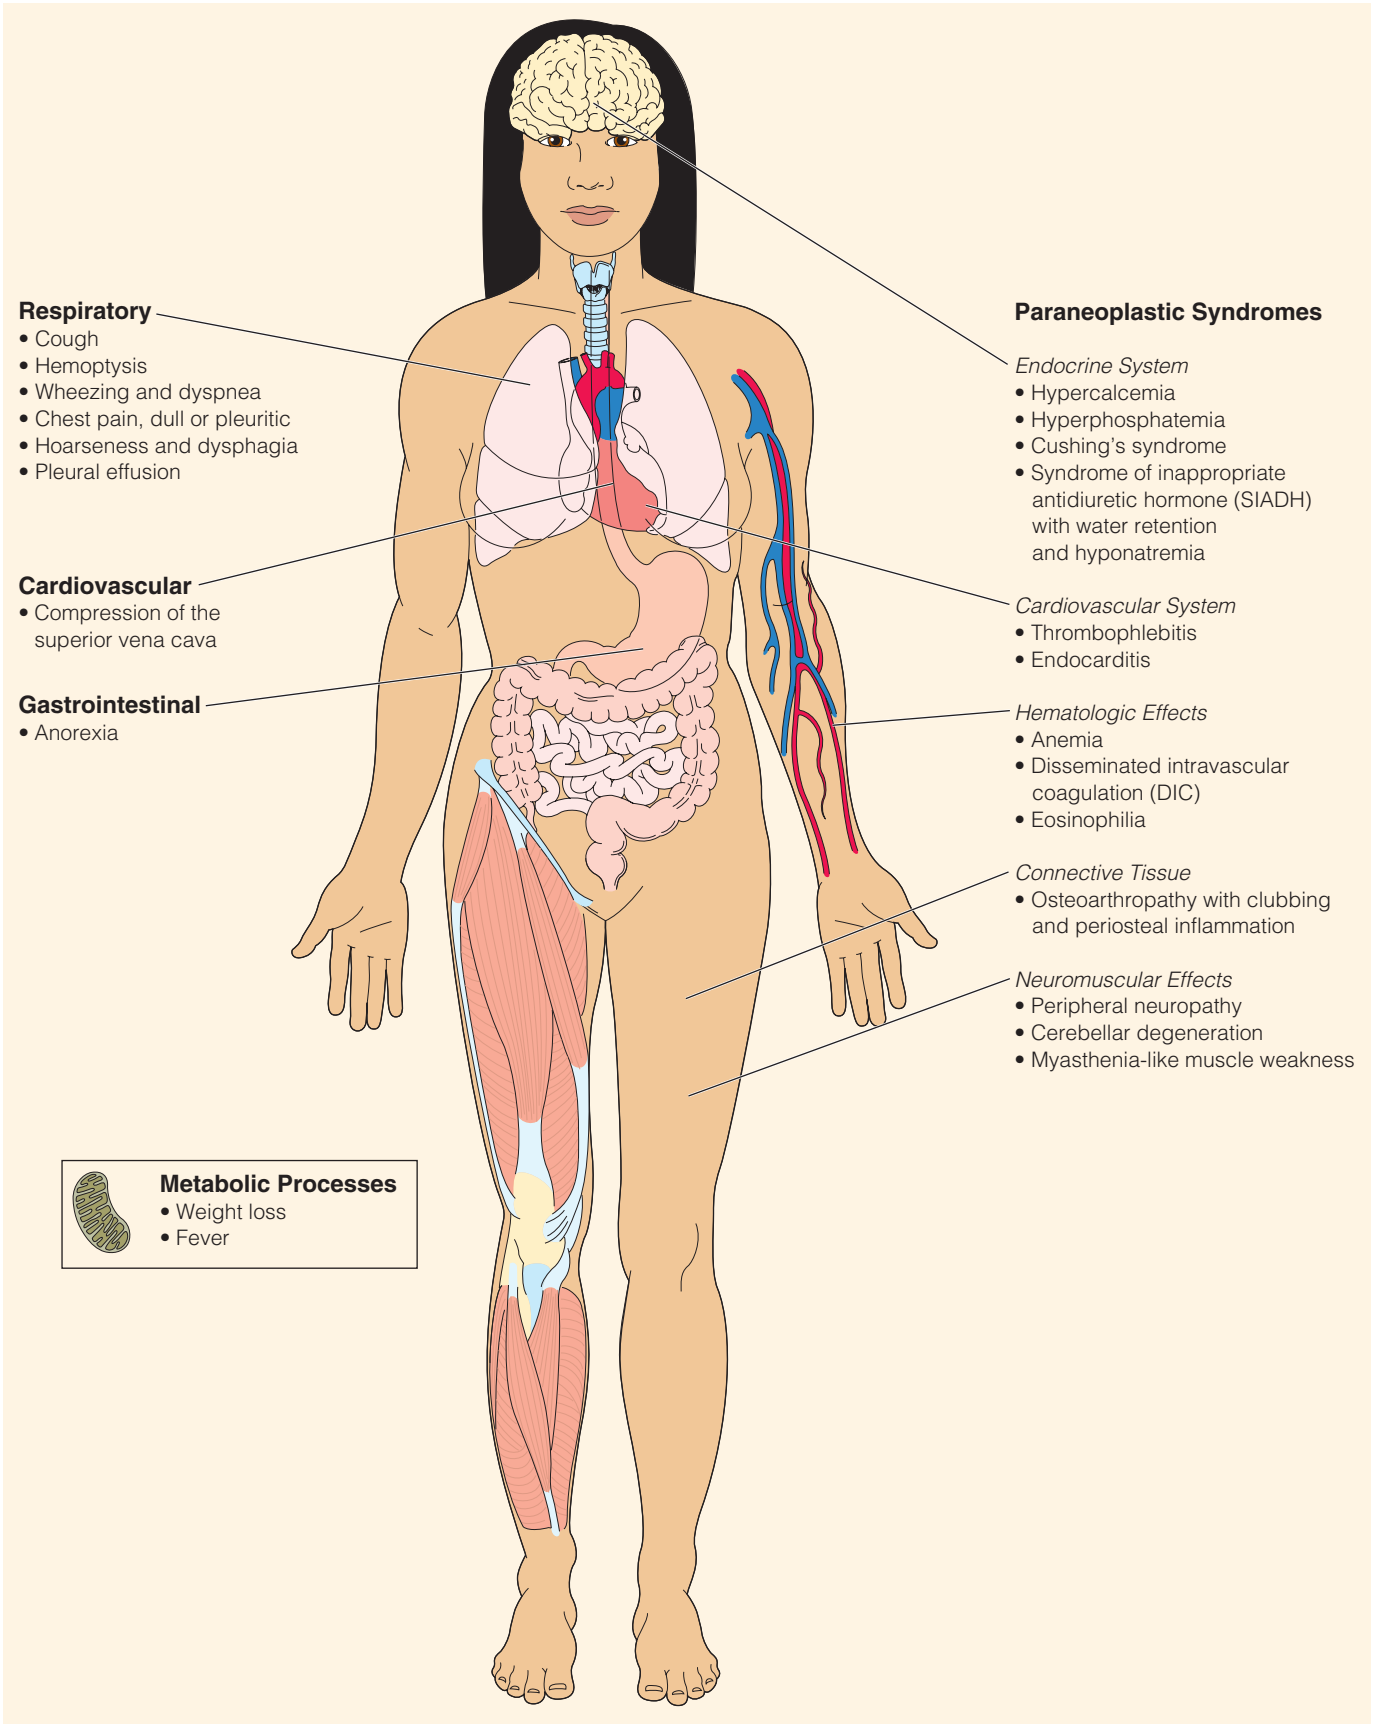
Manifestations

The manifestations of lung cancer are related to the location and spread of the tumor. Patients may present with symptoms related to the primary tumor, manifestations of metastatic disease, or with

TABLE 36–8 Comparison of Lung Cancer Cell Types

	Cell Type and Prevalence	Presentation and Associated Manifestations	Spread
	Small-cell (oat cell) carcinoma; 20%–25% of all lung cancers	Central lesion with hilar mass common, early mediastinal involvement, no cavitation; SIADH, Cushing's syndrome, thrombophlebitis	Aggressive tumor; more than 40% of patients have distant metastasis at time of presentation
	Adenocarcinoma; 20%–40% of all lung cancers	Peripheral mass involving bronchi; few local symptoms; hypertrophic pulmonary osteoarthropathy	Early metastasis to central nervous system, skeleton, and adrenal glands
	Squamous cell carcinoma; 30%–32% of all lung cancers	Central lesion located in large bronchi; patient presents with cough, dyspnea, atelectasis, and wheezing; hypercalcemia common	Spreads by local invasion
	Large-cell carcinoma; 10%–15% of all lung cancers	Usually peripheral lesion that is larger than that associated with adenocarcinoma and tends to cavitate; gynecomastia, thrombophlebitis	Early metastasis

systemic symptoms. Initial symptoms often are attributed to smoking or chronic bronchitis. Chronic cough is common, as is hemoptysis. Wheezing and shortness of breath occur as a result of airway obstruction. Dull, aching chest pain occurs as the tumor spreads to the mediastinum; pleuritic pain occurs when the pleura is invaded. Hoarseness and/or dysphagia indicates pressure of the tumor on the trachea or esophagus.



Systemic and paraneoplastic manifestations of lung cancer include weight loss, anorexia, fatigue, and weakness; bone pain, tenderness, and swelling; clubbing of the fingers and toes; and various endocrine, neuromuscular, cardiovascular, and hematologic symptoms. See the Multisystem Effects of Lung Cancer illustration on page 1156.

Confusion, impaired gait and balance, headache, and personality changes may indicate brain metastasis. Bone metastases cause bone pain, pathologic fractures, and possible spinal cord compression, as well as thrombocytopenia and anemia if bone marrow is invaded. When the liver is affected, symptoms of liver dysfunction and biliary obstruction—including jaundice, anorexia, and upper right quadrant pain—are evident.

Complications and Course

Superior vena cava syndrome, partial or complete obstruction of the superior vena cava, is a potential complication of lung cancer, particularly when the tumor involves the superior mediastinum or the mediastinal lymph nodes. Obstructed venous flow from the head and neck produces the symptoms of superior vena cava syndrome (edema of the neck and face, headache, dizziness, vision disturbances, and syncope) and may develop acutely or more gradually. Veins of the upper chest and neck are dilated; flushing occurs, followed by cyanosis. Cerebral edema may affect the level of consciousness; laryngeal edema may impair respirations.

MULTISYSTEM EFFECTS OF
Lung Cancer

Paraneoplastic syndromes commonly associated with lung cancer include syndrome of inappropriate ADH secretion (SIADH) with fluid retention, hyponatremia, edema, Cushing's syndrome related to abnormal ACTH production, and hypercalcemia. Lung tumors also may produce procoagulation factors, increasing the risk for venous thrombosis, pulmonary embolism, and thrombotic endocarditis. In lung cancer, neuromuscular symptoms such as muscle weakness and wasting of the limbs may be the first indication of the disease (Huether & McCance, 2011).

At the time of diagnosis, cancer of the lung typically is well advanced, with distant metastasis present in 39% of patients and regional lymph node involvement in another 37%. The prognosis is generally poor: The overall 5-year survival rate is only 15% (ACS, 2012).

Incidence and Risk Factors

The incidence of lung cancer varies from state to state and among nations. It increases with age, occurring most commonly in patients over age 50. Family clusters of lung cancer suggest a genetic predisposition; however, exposure to tobacco smoke may be necessary for expression of the trait. Cigarette smoke, which contains 43 known chemical carcinogens and cancer promoters, is clearly the most significant cause of lung cancer (ACS, 2012). More than 80% of lung cancer cases are related to smoking, and the disease is 23 times more common in male smokers than male nonsmokers. There is a dose–response relationship between smoking and lung cancer; the more the person smokes and the longer the person smokes, the greater the risk. Even former smokers who have abstained for a number of years have a higher risk of developing lung cancer than nonsmokers. Exposure to ionizing radiation and inhaled irritants, asbestos in particular, is also recognized as a risk factor for lung cancer (Huether & McCance, 2011). Exposure to radon, a radioactive gas, also is identified as a lung cancer risk factor (ACS, 2012). Radon forms as radium, an element present in the earth's crust, disintegrates. Radon tends to accumulate in closed spaces where air circulation is poor, such as caves, mines, and energy-efficient houses.

FAST FACTS

- In the United States, the incidence of lung cancer is second to prostate cancer in men and breast cancer in women.
- Lung cancer is, however, the leading cause of cancer deaths (28%) in the United States, responsible for 87,750 cancer deaths in men and 73,590 cancer deaths in women.
- Lung cancer kills more women than breast, cervical, uterine, and ovarian cancers combined.
- Tobacco use and exposure to cigarette smoke are the leading risk factors for lung cancer.

●○● INTERPROFESSIONAL CARE

Because lung cancer typically is advanced when diagnosed and the prognosis generally is poor, prevention of the disease must be a primary goal for all healthcare providers. With 80% of lung cancer related to cigarette smoking, reducing tobacco use can have a significant impact on the death rate from lung cancer—a far greater impact than advances in treatment.

Establishing an accurate diagnosis is the first step in treating lung cancer. Treatment decisions are based on the tumor location, type of cancer cell, staging of the tumor, and the patient's ability to tolerate treatment. Lung cancer is staged by the tumor size, location, degree of invasion of the primary tumor, and the presence of metastatic disease. Lung cancer staging is summarized in Table 36–9. Surgery is the treatment of choice for most forms of lung cancer.

DIAGNOSIS

- *Chest x-ray* usually provides the first evidence of lung cancer. It is particularly reliable as a diagnostic tool when compared with a previous chest x-ray. In high-risk populations, the chest x-ray may be used as a screening tool for lung cancer.
- *Sputum specimen* is sent for *cytologic examination* to establish the diagnosis of lung cancer. The sputum sample is collected on arising in the morning. If malignant cells are found in the sputum, more expensive and invasive examinations may be unnecessary. However, a sputum sample negative for malignant cells does not

TABLE 36–9 Lung Cancer Staging

	Primary Tumor (T-Stage)	Regional Lymph Nodes (N)	Distant Metastasis (M)
	T_0—No evidence of primary tumor		
Stage 0	T_X—Malignant cells in bronchopulmonary secretions, but no tumor visualized		M_X—Presence of distant metastasis cannot be assessed
Stage I	T_1S—Carcinoma *in situ*	N_0—No regional lymph node metastasis	M_0—No distant metastasis
	T_1—Tumor that is 3 cm diameter or less, with no evidence of invasion		
Stage II	T_2—Tumor that is greater than 3 cm diameter, or invades visceral pleura, or has associated atelectasis or pneumonitis	N_1—Metastasis or direct extension to peribronchial or ipsilateral hilar nodes	
Stage III	T_3—Tumor with direct extension into an adjacent structure, or any tumor with associated pleural effusion or atelectasis or pneumonitis of entire lung	N_2—Metastasis to ipsilateral mediastinal or subcarinal nodes	
Stage IV	T_4—Tumor that invades mediastinum or involves the heart, great vessels, trachea, esophagus, vertebral body, or carina; presence of malignant pleural effusion	N_3—Metastasis to contralateral mediastinal, scalene, or supraclavicular nodes	M_1—Distant metastasis present

rule out lung cancer; it may simply indicate that the tumor is not shedding cells into mucous secretions.

- *Bronchoscopy* is frequently done to visualize and obtain tissue for biopsy from the tumor. When a tumor mass or suspicious tissue is identified visually, a cable-activated instrument is used to obtain a biopsy specimen. If the tumor cannot be seen, the airways may be flushed with a saline solution (bronchial washing) to obtain cells for cytologic examination.
- *CT scan* is used to evaluate and localize tumors, particularly tumors in the lung parenchyma and pleura. It also is done prior to needle biopsy to localize the tumor. CT scanning can also detect distant tumor metastasis and evaluate tumor response to treatment.
- Cells or tissue for *cytologic examination and biopsy* may be obtained by aspirating fluid from a pleural effusion, percutaneous needle biopsy, and lymph node biopsy. These procedures may be done in an outpatient or a surgical setting.
- *CBC, liver function studies*, and *serum electrolytes* including calcium are obtained to evaluate for evidence of metastatic disease or paraneoplastic syndromes.
- *Tuberculin test (PPD)* is performed to rule out tuberculosis as the cause of symptoms and abnormalities seen on chest x-ray.
- *Pulmonary function tests (PFTs)* and *arterial blood gases* may be performed prior to the initiation of treatment if the patient has manifestations of respiratory insufficiency (e.g., dyspnea, activity intolerance, low oxygen saturation levels).

MEDICATIONS

Combination chemotherapy (often combined with radiation therapy and/or surgery) is the treatment of choice for small-cell lung cancer because of its rapid growth, dissemination, and sensitivity to cytotoxic drugs. Used in combination, chemotherapeutic drugs allow tumor cells to be attacked at different parts of the cell cycle and in different ways, increasing the effectiveness of therapy. Fifty percent of patients with tumors at early stages achieve complete tumor remission with combination chemotherapy. When a complete tumor response is achieved in the first few cycles of chemotherapy, the chances for long-term survival are much greater.

Combination chemotherapy is used also as an adjunct to surgery or radiation therapy for other types of lung cancer. It may be used to reduce the size of advanced local tumors prior to surgery, and to lengthen survival when distant metastases are present. Refer to Chapter 14 for further discussion of chemotherapy.

Bronchodilators may be prescribed to reduce airway obstruction. Analgesics and pain management strategies are vital when the cancer is advanced. Refer to Chapter 9 for more information about postoperative and cancer pain management.

SURGERY

Surgery offers the only real chance for a cure in non–small-cell lung cancer. Unfortunately, most tumors are inoperable or only partially resectable at the time of diagnosis. The 5-year survival rate following curative surgery in patients with resectable tumors is about 30%, with most patients succumbing to metastatic disease within 5 years. The type of surgery performed depends on the location and size of the tumor, as well as the patient's pulmonary and general health. The goal of surgery is to remove all involved tissue while preserving as much functional lung as possible. Table 36–10 outlines various surgical procedures used to treat lung cancer. Nursing care for the patient having lung surgery is outlined in an accompanying box on page 1159.

RADIATION THERAPY

Radiation therapy is used alone or in combination with surgery or chemotherapy for lung cancer. The treatment goal may be either cure or symptom relief (palliative). Prior to surgery, radiation therapy is used to "debulk" tumors. When cancer has spread by direct extension to other thoracic structures and surgery is not feasible, radiation therapy may be the treatment of choice. It also may be used to relieve manifestations such as cough, hemoptysis, pain due to bone metastasis, and dyspnea from bronchial obstruction. Complications of lung cancer, such as superior vena cava syndrome, may be treated with radiation.

Radiation therapy may be delivered by external beam to the primary tumor site or by intraluminal radiation, or brachytherapy. Radiation therapy and related nursing care are discussed further in Chapter 14. Specific nursing measures for the patient undergoing radiation therapy for lung cancer are outlined in the accompanying Nursing Care box.

TABLE 36–10 Types of Lung Surgery for Lung Cancer

Procedure	Description	Used For
Laser bronchoscopy	Bronchoscopy-guided laser used to resect tumor	Tumors localized in a main bronchus
Mediastinoscopy	Visualization of the mediastinum using an endoscope passed through a suprasternal incision	Evaluation and biopsy of a mediastinal tumor and lymph nodes
Thoracotomy	Incision into the chest wall	Access the lung and thoracic cavity for surgery
Wedge resection	Removal of a small section (wedge) of peripheral lung tissue	Small, peripheral lung tumors
Segmental resection	Removal of an individual bronchovascular segment of a lobe	Peripheral lung tumor with no evidence of extension to the chest wall or metastasis
Sleeve resection (bronchoplastic reconstruction)	Resection of a section of a major bronchus with reconstruction of remaining normal bronchus	Small lesion of a major bronchus
Lobectomy	Removal of a single lung lobe	Tumors confined to a single lobe
Pneumonectomy	Removal of an entire lung	Tumor widespread throughout the lung, involving the main bronchus, or fixed to the hilum

COMPLEMENTARY THERAPIES

Research indicates that a significant number of patients diagnosed with lung cancer use complementary and alternative medicine (CAM). In a systematic review of CAM in lung cancer, between 10% and more than 60% of cancer patients use at least one form of CAM (Deng et al., 2013). The CAM remedies used included herbal medicines, medicinal teas, homeopathy, animal extracts, and spiritual therapies. Although these therapies may be safe when used alone, the potential for interactions with conventional medical treatment must be considered. Inquire of patients about their use of complementary and alternative therapies, and inform members of the healthcare team when present.

●○● NURSING CARE

Health Promotion

The incidence of lung cancer is decreasing as the use of tobacco products declines. Teach people of all ages, particularly children and teenagers, about the link between cigarette smoking and lung cancer. Not smoking and avoiding exposure to secondhand smoke is the primary preventive measure for lung cancer. In addition, explain the risk of lung cancer to patients with occupational risk factors, exposure to asbestos products in particular.

Assessment

See the Manifestations and Interprofessional Care sections for the assessment of the patient with lung cancer.

Nursing assessment related to lung cancer focuses on identifying risk factors for the disease, early manifestations of lung cancer, and respiratory function in the patient undergoing treatment.

- *Health history:* current symptoms, including chronic cough, shortness of breath, blood-tinged sputum; systemic manifestations such as recent weight loss, fatigue, anorexia, bone pain; smoking history; occupational exposure to carcinogens; chronic diseases such as COPD
- *Physical assessment:* general appearance; skin color, evidence of clubbing; weight and height; vital signs; respiratory rate, depth, excursion; lung sounds to percussion and auscultation.
- *Laboratory tests:* CBC and coagulation studies, serum electrolytes and osmolality, liver and renal function studies; chest x-ray and CT scan results; arterial blood gases and oxygen saturation levels.

Priorities of Care

Collaborating with the interprofessional team to ensure adequate treatment of the lung cancer while providing care that supports the physical

NURSING CARE OF THE PATIENT

Undergoing Lung Surgery

PREOPERATIVE CARE

- Provide routine preoperative nursing care, as outlined in Chapter 4.
- Note any history of smoking, respiratory and cardiac diseases, and other chronic conditions in the nursing history. *These factors may affect the response to surgery and the risk for postoperative complications.*
- Provide emotional and psychologic support for the patient and family. *In addition to facing surgery, the patient may be adjusting to a new diagnosis of cancer and the possibility that surgical intervention will be only partially successful.*
- Instruct about postoperative procedures, including respiratory therapy, breathing exercises, and coughing techniques. Allow practice time. *Learning will be easier in the preoperative period, when pain and analgesia are not affecting mental function.*
- If the patient will return from surgery with an endotracheal tube and mechanical ventilation, establish a means of communication using hand or eye signals or a magic slate. *Establishing a means of communication prior to surgery reduces postoperative anxiety at being unable to speak.*
- If the patient will return to the ICU, introduce the patient and family to the unit and any machines, such as ventilators and monitors, that will be used. *The knowledge that this is an expected part of surgical recovery reduces the patient's and family's postoperative anxiety.*

POSTOPERATIVE CARE

- Assess and provide routine postoperative care, as outlined in Chapter 4.
- Assess for adequate pain control, and provide analgesics as needed. *Incisional pain commonly causes altered breathing patterns in the patient who has undergone lung surgery.*
- Frequently assess respiratory status, including color, oxygen saturation, respiratory rate and depth, chest expansion, lung sounds, percussion tone, and arterial blood gases. *Maintaining adequate ventilation and gas exchange postoperatively is vital to reduce mortality and morbidity. Gas exchange may be impaired by complications of lung surgery, including pneumothorax, atelectasis, bronchospasm, pulmonary embolus, bronchopleural fistula, and acute respiratory distress syndrome (ARDS).*
- Assist with effective coughing techniques, postural drainage, and incentive spirometry. Perform endotracheal suctioning as needed while intubated. *Surgical manipulation and anesthesia can increase the mucous production, leading to airway obstruction. Aggressive pulmonary hygiene is important to prevent this complication.*
- Monitor and maintain effective mechanical ventilation. *This is vital to ensure adequate ventilation and gas exchange in the early postoperative period.*
- Maintain patent chest tubes and a closed-drainage system. Monitor chest tube output every hour initially, then every 2 to 4 or 8 hours as indicated. Notify the healthcare provider if chest tube output exceeds 70 mL per hour and/or is bright red, warm, and free flowing. *Maintaining a patent, intact chest drainage system is vital to reestablish negative pressure within the chest cavity and reexpansion of the lungs. Increased amounts of warm, free-flowing blood indicate intrathoracic hemorrhage that may necessitate surgical intervention.*
- Assess for signs of infection involving the incision or chest tube site(s). Use strict aseptic technique in caring for incisions and invasive monitoring devices. *The postoperative patient is at risk for incisional infections, empyema in the chest cavity, and pneumonia.*
- Assist with turning and to ambulate as soon as possible. *Early mobility is important to prevent possible complications, such as pneumonia or pulmonary embolus.*
- Assess and maintain nutritional status. Initiate enteral or parenteral nutrition early if intubation and mechanical ventilation will be required for an extended period. Provide frequent small feedings once extubated. *Maintaining nutritional status promotes wound healing and prevents negative nitrogen balance. Frequent small feedings reduce the fatigue associated with eating.*

NURSING CARE OF THE PATIENT

Receiving Radiation Therapy

Although radiation therapy is well controlled and specifically directed toward the tumor cells, some normal cells are also damaged in the process of treatment. Nursing care and patient teaching help the patient cope with uncomfortable side effects associated with radiation therapy.

NURSING RESPONSIBILITIES

- Monitor for potential complications:
  a. Radiation pneumonitis—dyspnea on exertion, dry cough, fever
  b. Pericarditis—chest pain, pericardial friction rub; muffled heart sounds, paradoxical pulse, ECG abnormalities (Notify the healthcare provider if symptoms develop.)
  c. Esophagitis—pain, sore throat, difficulty swallowing.
- Encourage adequate fluid intake to liquefy respiratory secretions.
- Provide local analgesics and local anesthetics such as viscous lidocaine as ordered to relieve dysphagia and sore throat.
- Offer small frequent meals of soft, cool foods and liquids to maintain nutritional status.

PATIENT AND FAMILY TEACHING

- If dyspnea or pneumonitis develop, teach positioning, pursed-lip techniques, and relaxation exercises to facilitate breathing.
- Reassure that pneumonitis is generally a self-limiting process and should resolve when the course of radiotherapy is completed.
- Teach the manifestations of pericarditis, which may develop during treatment or up to 1 year after its completion. Chest pain or pressure, rapid heartbeat, and fever may signal pericarditis; increasing fatigue, dyspnea, and light-headedness can indicate a chronic process with pericardial effusion and possible cardiac tamponade.
- Instruct to eliminate hot, spicy, or acidic foods from the diet if esophagitis is a problem. Alcohol and tobacco should also be avoided.
- Adequate rest and nutrition are important to alleviate the symptoms of radiation fatigue, which is common in patients receiving radiation therapy for lung cancer. The fatigue is generally temporary.

and psychologic responses to the disease focusing on symptom management and treatment adherence is a priority of nursing care.

Diagnoses, Outcomes, and Interventions

The patient with lung cancer is facing invasive treatments with undesirable side effects, possibly surgery, and typically a poor prognosis for long-term survival. Nursing care needs are diverse, related to respiratory status, the cancer itself and possible metastases, and the treatment plan. Priority nursing diagnoses related to respiratory function include *Ineffective Breathing Pattern* and *Activity Intolerance*. Pain and anticipatory grieving also are likely to be high-priority problems. See the accompanying Case Study & Nursing Care Plan on page 1162.

Ineffective Breathing Pattern

Breathing pattern and ventilation may be affected by the tumor itself or by treatment of the tumor. Thoracic surgery increases the risk due to the incision and disruption of the muscles of respiration. Maintaining effective lung ventilation is particularly important postoperatively to reexpand remaining lung tissue and prevent surgical complications.

Expected Outcome: Patient will utilize techniques to promote adequate ventilation such as deep breathing and incentive spirometry.

- Assess and document respiratory rate, depth, and lung sounds at least every 4 hours; evaluate more frequently in the immediate postoperative period or as indicated by condition. *Early detection of signs of respiratory compromise or adventitious lung sounds is vital for effective intervention.*
- Monitor oxygen saturation, exhaled carbon dioxide, and/or blood gas results, reporting changes from normal. *Changes in levels of blood oxygen or exhaled CO_2 may be early indications of respiratory compromise.*
- Frequently assess and document pain level (using a standard pain scale); provide analgesics as needed. *Pain and attempting to avoid chest movement to prevent additional pain can lead to rapid, shallow respirations and ineffective ventilation.*
- Elevate the head of the bed to 60 degrees. *Elevating the head of the bed reduces pressure on the diaphragm and permits optimal lung expansion.*
- Assist to turn, cough, and deep breathe and use incentive spirometry. Help splint the chest with a pillow or blanket when coughing. *These measures promote airway clearance.*
- Suction airway as needed. *Suctioning may be required to remove secretions that the patient is unable to cough up and expectorate.*

SAFETY ALERT

Maintain chest tube integrity and patency by ensuring uninterrupted gravity flow. Chest tubes help reestablish negative pressure in the thoracic cavity, allowing the lung to fully reexpand.

- Provide chest physiotherapy with percussion and postural drainage as needed or ordered. *Percussion and postural drainage help maintain airway patency and effective respirations.*
- If mechanical ventilation is instituted, work with respiratory therapy and use analgesia or sedation as needed to synchronize respirations with the ventilator. *Coordination of the patient's respiratory effort with ventilator-delivered breaths is important for fully effective mechanical ventilation.*
- Provide reassurance and emotional support. *These measures help relieve anxiety and promote an effective breathing pattern.*

Activity Intolerance

Both resectional lung surgery and inoperable lung cancer reduce the amount of functional lung tissue and surface area for gas diffusion. This can lead to activity intolerance if the oxygen supply is insufficient to meet the body's oxygen demand.

Expected Outcome: Patient will participate in physical activity as tolerated.

- Assess and document physiologic responses to activity, including pulse, respiratory rate, dyspnea, and fatigue. *These assessments are good indicators of activity tolerance.*

- Plan rest periods between activities and procedures. *Rest periods reduce oxygen demands and fatigue.*
- Assist the postoperative patient to increase activities gradually. *Increasing activity levels gradually improves exercise tolerance.*
- Teach measures to conserve energy while performing ADLs, such as sitting while showering and dressing and wearing slip-on shoes. *These energy-conserving measures reduce oxygen demand and allow the patient to remain independent as long as possible.*
- Keep frequently used objects within easy reach. *This helps conserve energy.*
- Administer oxygen as prescribed. Teach the patient and family about home oxygen use if appropriate. *Supplemental oxygen can help improve activity and exercise tolerance.*
- Encourage maintenance of physical activity to tolerance. *Maintaining activity levels to the degree possible improves physical and emotional well-being.*
- Allow family members to provide assistance as needed. *This helps the patient conserve energy and allows the family to retain a sense of usefulness.*

Pain

Pain is a priority problem in both the postoperative period as well as in the terminal stages of cancer. Poorly managed pain prolongs recovery from surgery. In the terminal cancer patient, chronic and acute pain must be managed effectively to allow a peaceful death.

Expected Outcome: Patient will achieve adequate pain control as evidenced by physical well-being.

- Assess and document pain using a standardized pain scale and objective data. *Pain is a subjective experience, best evaluated by the patient. Changes in vital signs, guarded movement, or unwillingness to move may indicate unreported pain.*
- Provide analgesics as needed to maintain comfort. *Postoperative recovery and restoration of function is facilitated by adequate pain management.*
- For cancer pain, maintain an around-the-clock medication schedule using narcotic, nonsteroidal anti-inflammatory drugs, and other medications as ordered. *Addiction is not a concern in terminal cancer; providing adequate pain relief that does not allow "breakthrough" pain is important.*
- Provide or assist with comfort measures, such as massage, positioning, distraction, and relaxation techniques. *These techniques promote relaxation and enhance pain relief.*
- Assist the patient and family to plan and engage in activities that distract from pain such as reading, watching television, and engaging in social interactions. *Distraction helps the patient focus away from the pain.*
- Spend as much time with the patient as possible; allow family members to remain with the patient. *Physical presence of the nurse and family provides emotional support for the patient.*

Anticipatory Grieving

Because lung cancer often is advanced when diagnosed, the patient faces the very real prospect of dying from the disease. Grieving for the anticipated loss of life is a normal response as the patient and family begin to adapt to the diagnosis. Nursing care goals are to promote expression of feelings and thoughts about the loss, and to help the patient and family initiate grief work, make decisions, and use appropriate resources and coping mechanisms to deal with the loss.

Expected Outcome: Patient and family will discuss the meaning of losses (anticipated or actual) to the patient and family's life.

- Spend time with the patient and family. *Time is necessary to develop a trusting, therapeutic relationship.*
- Answer questions honestly; do not deny the probable outcome of the disease. *Honesty reinforces reality and provides a sense of control over decisions to be made.*
- Encourage the patient and family to express their feelings, fears, and concerns. *Open expression of feelings helps to promote understanding and acceptance.*
- Assist with understanding the grieving process and acceptance of feelings as normal. *Feelings of guilt, anger, or depression may cause the patient to withdraw from others. Explanation of the grieving process enhances understanding and ability to cope.*
- Help identify strengths and coping measures that have been used effectively in the past. Provide positive reinforcement for effective coping behavior. *Past effective coping measures can help the patient and family deal with the present situation and regain a sense of control.*
- Help the patient and family make decisions regarding treatment and care. *This also is important to give them a sense of control.*
- Encourage use of other support systems, such as spiritual and social groups. Refer the patient and family to support groups, social support services, and hospice care as indicated. Provide American Cancer Society literature and information as appropriate. *These support systems provide emotional support and help the patient and family cope with the diagnosis.*
- Discuss advance directives (the living will) and power of attorney for healthcare with the patient and family. *These documents give the patient and family a sense of control over medical care provided if the patient is no longer able to express his or her own wishes.*

Continuity of Care

A primary teaching need to prepare the patient and family affected by lung cancer for home care is information about the disease itself, expected prognosis, and planned treatment strategies. Provide honest information; do not promote false hope. Include the following additional topics in teaching for home care:

- Importance of quitting smoking, especially if surgery has been performed (The patient with lung cancer may have difficulty recognizing the need to stop smoking. Include information about the effects of nicotine and the tars in cigarette smoke on healing and already compromised lung tissue.)
- Planned treatments such as chemotherapy or radiation therapy, including expected effects and usual side effects of each
- Strategies to cope with noxious effects of radiation or chemotherapy
- Activities and exercises to improve strength and regain function for the postoperative patient
- The need to continue coughing and deep-breathing exercises at home
- Symptoms to report to the healthcare provider: fever, increasing or continued shortness of breath, cough, increased or purulent sputum, redness, pain, swelling, or incisional drainage

CASE STUDY & NURSING CARE PLAN A Patient with Lung Cancer

After coughing up bloody sputum one morning, James Mueller, a 68-year-old retired millworker, sees his healthcare provider. A chest x-ray shows a suspicious density in the central portion of his right lung. Mr. Mueller is admitted to the hospital the following Monday for diagnostic tests.

ASSESSMENT

Anita Sarros, RN, admits Mr. Mueller to the oncology unit and obtains a nursing history. Mr. Mueller is married and has three grown children. He worked in a local paper mill for 35 years before retiring at age 62. He describes himself as "pretty healthy," except for a chronic smoker's cough. He started smoking as a young man in the army. He has a 50 pack-year smoking history, having smoked a pack a day for 50 years, since age 18. Mr. Mueller says he briefly quit smoking following a small heart attack 3 years ago, but started again after 4 months. On further questioning, Mr. Mueller says his cough has been productive for the past few months, especially in the morning, and that he is shorter of breath than usual with activity.

Mr. Mueller's examination data includes BP 162/86 mmHg, P 78 bpm and regular, R 20/min, and T 36.9°C (98.4°F). Color good, skin warm and dry. Inspiratory and expiratory wheezes noted in right chest but good breath sounds throughout. No other abnormal findings are noted on examination. The healthcare provider orders early-morning sputum specimens times 3 days for cytologic examination and schedules a CT scan of the chest the morning after admission.

Mr. Mueller's CBC shows mild anemia, but remaining routine laboratory tests are essentially normal. Sputum cytology is positive for small-cell bronchogenic cancer. The CT scan shows a central mass approximately 4 cm in diameter with involved mediastinal and subclavicular lymph nodes. A small mass is also noted on the lumbar spine. After conferring with his healthcare provider and an oncologist, Mr. Mueller decides to undergo a trial course of chemotherapy.

DIAGNOSES

- *Ineffective Airway Clearance* related to tumor mass
- *Risk for Imbalanced Nutrition: Less Than Body Requirements* related to effects of chemotherapy
- *Risk for Compromised Family Coping* related to new diagnosis of lung cancer
- *Deficient Knowledge* about lung cancer and aids to smoking cessation

EXPECTED OUTCOMES

- Patient will maintain a patent airway.
- Patient will maintain current weight.
- Patient will express feelings and concerns about the effect of cancer on the family unit.
- Patient will participate in care.
- Patient will contact appropriate support groups.
- Patient will verbalize an understanding of the disease, its treatment, and prognosis.
- Patient will develop a plan to stop smoking.

PLANNING AND IMPLEMENTATION

- Teach coughing, deep breathing, and hydration measures to facilitate airway clearance.
- Discuss symptoms to report to the healthcare provider: increased dyspnea or hemoptysis, severe stridor or wheezing, chest pain.
- Discuss measures to relieve nausea associated with chemotherapy, including premedication with a prescribed antiemetic.
- Have dietitian consult with Mr. and Mrs. Mueller to develop a diet plan for maintaining ideal weight.
- Discuss possible effects of lung cancer with Mr. and Mrs. Mueller.
- Encourage Mr. and Mrs. Mueller to call a family conference to discuss the disease with their children and grandchildren.
- Evaluate family members' knowledge and understanding of lung cancer, correcting misinformation and teaching as needed.
- Have an American Cancer Society volunteer contact the family.
- Refer to local cancer support group.
- Refer to home health department for follow-up and further teaching.
- Work with Mr. Mueller to develop a plan to stop smoking.
- Ask the healthcare provider for a prescription for nicotine patches or gum for Mr. Mueller.

Make Mr. Mueller aware of decisions that will need to be made regarding end-of-life issues. Encourage him to discuss his wishes with family if he is able.

EVALUATION

Mr. Mueller had his first chemotherapy treatment in the hospital and was discharged 4 days after admission. After 3 months of chemotherapy, his tumor shows little regression, and a liver scan reveals further metastasis. He and his wife decide to stop chemotherapy, a decision with which the children reluctantly agree. Mr. and Mrs. Mueller are referred to hospice services. With the help of hospice nurses and volunteers, Mr. Mueller is able to remain at home. His pain is managed initially with oral MS Contin, a sustained-release form of morphine sulfate, and later with an intravenous morphine infusion. Mr. Mueller dies at home with his family at his side 9 months after his diagnosis of lung cancer.

Clinical Reasoning in Patient Care

1. The oncologist prescribed a chemotherapy regimen of cyclophosphamide, doxorubicin, and vincristine. Describe how each of these drugs works against cancer cells, and discuss the rationale for using this combination.
2. Develop a care plan to deal with the specific side effects for the treatment regimen given in question 1.
3. Mr. Mueller had small-cell (oat cell) cancer. How would his presentation and treatment differ if the diagnosis had been non–small-cell adenocarcinoma, stage $T_2N_2M_0$?

See Evaluating Your Response in Appendix B.

- Use of prescribed medications, including desired and potential side effects and interactions with other drugs or foods
- Use of analgesics and other pain relief measures for postoperative or cancer pain
- Information about hospice services, home health, local cancer support groups for patients and caregivers, and American Cancer Society services.

Refer the patient and family for home health services including nursing care, assistance with ADLs, respiratory care, and respite care as needed.

CHAPTER HIGHLIGHTS

- **Pneumonia, inflammation of the respiratory bronchioles and alveoli, usually is bacterial in origin. Different organisms commonly are found in healthcare-associated pneumonia than in community-acquired pneumonia. Nursing care focuses on promoting airway clearance, supporting effective gas exchange, and promoting rest.**
- Infection control measures, including standard, airborne, and contract precautions, are vital to prevent the spread of viral severe acute respiratory syndrome (SARS) or related novel respiratory viruses.
- **Tuberculosis affects many people worldwide. In the United States, the primary affected populations are immigrants, people with compromised immunity, and people living in crowded or unsanitary conditions.**
- The tuberculin test (PPD) detects a cellular immune response to *M. tuberculosis*, indicating infection, but not necessarily active disease.
- Effective tuberculosis treatment is a public health concern, requiring therapy and compliance monitoring, contact follow-up, and assessment for adverse treatment effects.
- Fungal lung infections tend to have a geographic pattern of distribution. People with compromised immune status are more likely to be affected. Their manifestations resemble those of pneumonia or tuberculosis.
- **Disorders of the pleura, such as pleural effusion and pneumothorax, can affect lung expansion, ventilation, and gas exchange when significant.**
- Tension pneumothorax develops when air enters the pleural space but is unable to escape, collapsing the lung on the affected side and placing pressure on the unaffected lung and mediastinum. Ventilation, gas exchange, venous return, and cardiac output can be significantly affected.
- **Trauma may affect the chest wall, or the airways and alveoli. Flail chest and pulmonary contusion often occur concurrently; hemothorax also frequently develops with chest trauma. Chest trauma can endanger effective ventilation and gas exchange.**
- **Lung cancer, the leading cause of cancer deaths, typically is advanced when diagnosed. Surgery, radiation therapy, and chemotherapy are used to treat lung cancer, often in combination.**
- Superior vena cava syndrome and paraneoplastic syndromes may complicate lung cancer.

TEST YOURSELF NCLEX-RN® REVIEW

1. The nurse is providing care to a patient newly admitted with bacterial pneumonia. Which action should the nurse perform first?
   1. Provide a meal for diet as tolerated.
   2. Obtain a sputum specimen for culture and sensitivity.
   3. Apply oxygen per nasal cannula at 5 L/min as prescribed.
   4. Insert an intravenous catheter and start the prescribed antibiotic.

2. The nurse notes that a patient with bacterial pneumonia has an overall gray skin tone with a bluish tinge around the lips. In which order should the nurse provide the listed interventions?
   1. Start oxygen.
   2. Assess breath sounds.
   3. Raise the head of the bed.
   4. Obtain oxygen saturation level
   5. Notify the healthcare provider.

3. The nurse evaluating a tuberculin test result 72 hours after it was administered notes an area of induration 9 m in diameter. What additional information indicates to the nurse that this is a positive result?
   1. The patient has HIV.
   2. The patient is an injection drug user.
   3. The patient was born in Southeast Asia.
   4. The patient resides in a long-term care facility.

4. The nurse is teaching a patient who is prescribed prophylactic daily isoniazid (INH) for conversion of a tuberculin test. What should the nurse include in this patient's teaching?
   1. This drug turns the urine red-orange, which is harmless.
   2. Periodic eye examinations are required during treatment.
   3. Report numbness and tingling of extremities to the physician.
   4. Do not use aspirin while taking this drug, because abnormal bleeding may occur.

5. The nurse is evaluating teaching provided to a patient with lung cancer. Which patient statement indicates that teaching has been effective?
   1. "Having the 'big C' is very scary; I'm just glad it is one of the more curable forms of cancer."
   2. "Even though I can't undo the damage caused by cigarette smoking, I will try to quit preventing further damage to my lungs."
   3. "Well, since I'm going to die anyway, I may as well go home, put my affairs in order, and spend the rest of my time in the easy chair."
   4. "I understand that because the cancer has already spread I will be undergoing aggressive cancer treatment for the next several years to beat this thing."

6. The nurse caring for a patient following a lobectomy notes 100 mL of red drainage in the chest drainage container since checking it 30 minutes previously. What should the nurse do to help this patient? (Select all that apply.)
   1. Notify the surgeon.
   2. Empty the chest tube drainage system.
   3. Assess vital signs and level of consciousness.
   4. Apply pressure to the chest tube insertion site.
   5. Note the finding and reevaluate drainage in 30 minutes.

7. A patient is scheduled for a thoracentesis. What should the nurse do to assist the patient for this procedure?
   1. Encourage to cough as the fluid is withdrawn.
   2. Coach to breathe deeply as the needle is inserted.
   3. Help to sit upright and leaning forward during the procedure.
   4. Remind to remain on quiet bed rest for 4 hours following the procedure.

8. The nurse is providing discharge teaching to a patient with a fractured rib. What should the nurse instruct the patient to do?
   1. Use a small pillow to splint the area when coughing.
   2. Avoid using pain medications to prevent respiratory depression.
   3. Remain on bed rest for a week to allow the fracture to stabilize.
   4. Use elastic roller bandages like ACE wraps to stabilize the chest wall and promote comfort.
9. A victim of a house fire was transported to the emergency department for treatment of smoke inhalation. Which assessment finding should cause the nurse the greatest concern?
   1. respiratory rate of 36
   2. fine crackles in bilateral bases
   3. ash-like material in the sputum
   4. skin and mucous membranes pink
10. The nurse is planning care for a patient with a tension pneumothorax. Which diagnoses should the nurse identify as the highest priority for this patient?
    1. *Acute Pain*
    2. *Risk for Aspiration*
    3. *Impaired Gas Exchange*
    4. *Ineffective Breathing Pattern*

See Test Yourself answers in Appendix B.

37 Nursing Care of Patients with Gas Exchange Disorders

LEARNING OUTCOMES

1. Relate the pathophysiology and manifestations of obstructive, pulmonary vascular, and critical respiratory disorders to their effects on ventilation and respiration (gas exchange).
2. Compare and contrast the etiology, risk factors, and vulnerable populations for disorders affecting ventilation and gas exchange within the lungs.
3. Describe interprofessional care and the nursing role in health promotion and caring for patients with disorders that affect the ability to ventilate the lungs and exchange gases with the environment.
4. Discuss interprofessional interventions to provide airway and ventilatory support for the patient with respiratory failure, and nursing responsibilities in caring for patients who require airway and ventilatory support.
5. Describe the nursing implications for medications used to promote ventilation and gas exchange.

CLINICAL COMPETENCIES

1. Assess functional health status of patients with disorders affecting ventilation and gas exchange.
2. Use assessed data and knowledge of the effects of a disorder and its prescribed treatment to identify priority nursing diagnoses and plan care for patients with disorders affecting ventilation and gas exchange.
3. Use the nursing process and evidence-based nursing research to plan and implement individualized nursing care for patients, including measures to promote ventilation and gas exchange.
4. Plan and provide appropriate teaching for health promotion among vulnerable populations and to prepare patients and families for continuity of care.
5. Evaluate the effectiveness of nursing interventions and teaching, revising strategies and teaching plans as needed.
6. Knowledgably and safely coordinate interprofessional care and administer prescribed medications and treatments for patients with disorders affecting ventilation and gas exchange.

MAJOR CHAPTER CONCEPTS

- Obstructive disorders of the lower respiratory system, including asthma, COPD, and cystic fibrosis, impair airflow into and out of the lungs, often affecting the outflow of air to a greater extent than inflow.
- Smoking and exposure to tobacco smoke are the two greatest risk factors for COPD.
- Inherited as an autosomal recessive disorder, cystic fibrosis causes thick, viscous secretions in affected organs, primarily the lungs, pancreas, sweat glands, and reproductive tract.
- Occupational lung diseases, pneumoconiosis and hypersensitivity pneumonitis, damage interstitial tissues of the lungs, leading to fibrosis and scarring that causes the lungs to become stiff and noncompliant.
- Pulmonary vascular disorders affect blood flow through the pulmonary vascular system.
- The manifestations of respiratory failure relate directly to the effects of hypoxemia and hypercapnia.
- Respiratory support often is required, using positive-pressure ventilators.
- ARDS is noncardiac pulmonary edema caused by a diffuse inflammatory response leading to alveolar edema, impairing gas exchange. The mortality rate, however, remains high at about 40%.

pulmonary hypertension (PHTN), *1195*
respiratory failure, *1196*
sarcoidosis, *1190*
status asthmaticus, *1167*
weaning, *1203*

Normal function of the lower respiratory system depends on several organ systems: the central nervous system (CNS), which stimulates and controls breathing; chemoreceptors in the brain, aortic arch, and carotid bodies, which monitor the pH and oxygen content of blood; the heart and circulatory system, which provide for blood supply and gas exchange; the musculoskeletal system, which provides an intact thoracic cavity capable of expanding and contracting; and the lungs and bronchial tree, which allow air movement and gas exchange. Impaired function of any of these systems affects ventilation and respiration. As a result, tissues may become *hypoxic*, with inadequate oxygen to support metabolic activity.

Although some of the disorders discussed in this chapter can affect ventilation (air movement into and out of the airways and alveoli), all can have significant effects on gas exchange. The mechanisms by which they affect gas exchange differ:

- In reactive airway disease (asthma) and obstructive disorders, air trapping reduces the amount of oxygen available to drive gas exchange.
- Interstitial lung disorders affect the ability of the lungs to expand and the work of breathing, reducing alveolar oxygenation and gas exchange.
- Pulmonary vascular disorders affect blood flow to the lungs or a portion of the lungs, reducing gas exchange through their effects on perfusion of the lungs.
- Respiratory failure is the ultimate consequence of impaired gas exchange; the lungs cannot adequately oxygenate the blood or eliminate carbon dioxide.

With a few exceptions, the disorders discussed in this chapter are relatively common, chronic lung diseases.

FAST FACTS

- Chronic obstructive pulmonary disease (COPD) is currently the third leading cause of death in the United States and worldwide.
- Since 2001, the death rate for chronic lower respiratory diseases has been higher for women, with women who smoke being 13 times as likely to die from COPD versus nonsmoking women.
- Whites have a higher death rate for chronic lower respiratory diseases than Blacks, Native Americans, or Hispanics. People of Asian heritage have the lowest death rate due to chronic lower respiratory diseases.
- Adults ages 45 and older have the greatest risk: Chronic lower respiratory diseases are not among the leading causes of death for adults ages 25 to 44. In the 45- to 64-year-old-age grouping they are the sixth leading cause of death, jumping to the fourth leading cause of death for people ages 65 years and older.

Source: (National Center for Health Statistics, 2011).

Disorders of other body systems, such as neurologic disorders (e.g., head injury, spinal cord trauma or disorders, amyotrophic lateral sclerosis [ALS], myasthenia gravis), also can affect gas exchange through their effects on the central or peripheral nervous systems. These disorders and their effects on the respiratory system are discussed in subsequent chapters of this text.

Aging affects pulmonary ventilation and gas exchange as well. The number of alveoli decrease, and emphysematous changes (senile emphysema) reduce the surface area for gas exchange. Alveoli become less elastic, causing increased air trapping and dead space. For most older adults who remain active, these changes have minimal effect on exercise tolerance and activities of daily living (ADLs). When combined with lung disease, however, age-related pulmonary changes increase the patient's risk for developing respiratory failure.

Reactive Airway Disorders

In reactive airway disorders, the airways narrow in response to a stimulus. Airway narrowing limits airflow both into and out of the alveoli. Limited airflow increases the work of breathing and the residual volume of the lungs as air is trapped distal to narrowed airways. Inspired air mixes with an abnormally large volume of residual air, effectively reducing the amount of oxygen available in the alveoli. Decreased alveolar ventilation further reduces oxygen available for exchange.

THE PATIENT WITH ASTHMA

Asthma is a chronic inflammatory disorder of the airways characterized by recurrent episodes of wheezing, breathlessness, chest tightness, and coughing. Inflammation causes increased responsiveness of the airways to multiple stimuli. The widespread airflow obstruction that occurs during acute episodes usually reverses either spontaneously or with treatment. Although most episodes of asthma attacks are relatively brief, some patients with asthma may experience longer episodes with some degree of airway impairment daily. In rare cases, an acute episode of asthma is so severe that respiratory failure and death results.

Physiology Review

Airways within the lungs contain crisscrossing strips of smooth muscle that control their diameter. This muscle is innervated by the autonomic nervous system. Parasympathetic (cholinergic) stimulation leads to bronchoconstriction, or narrowing of the airways. Sympathetic stimulation through beta$_2$-adrenergic receptors causes bronchodilation, or expansion of the airways. Slight bronchoconstriction normally dominates. However, when increased airflow is necessary (e.g., during exercise), the parasympathetic system is inhibited, and stimulation of the sympathetic system causes bronchodilation. Inflammatory mediators (such as histamine) released during an antigen–antibody response act directly on bronchial smooth muscle to produce bronchoconstriction.

Pathophysiology

In asthma, the airways are in a persistent state of inflammation. During symptom-free periods, airway inflammation in asthma is subacute or quiet. Even during these periods, however, inflammatory cells such as eosinophils, neutrophils, and lymphocytes may be found in airway tissues and edema may be present. An acute inflammatory response, during which resident inflammatory cells interact with inflammatory mediators, cytokines, and additional infiltrating inflammatory cells, may be triggered by a variety of factors. Common triggers for an acute asthma attack include exposure to allergens, respiratory tract infection, exercise, inhaled irritants, and emotional upsets.

ATTACK TRIGGERS

Childhood asthma (which may continue into adulthood) is most often linked to inhalation of allergens such as pollen, animal dander, or household dust. Patients with allergic asthma often have a history of other allergies. Environmental pollutants, such as tobacco smoke and irritant gases (e.g., sulfur dioxide, nitrogen dioxide, and ozone), can provoke asthma. Exposure to secondhand smoke as a child is associated with a higher risk for and increased severity of asthma. Agents found in the workplace, such as noxious fumes and gases, chemicals, and dusts, may cause occupational asthma.

Respiratory infections, viral in particular, are a common internal stimulus for an asthma attack. Exercise-induced asthma attacks also are common, affecting 40% to 90% of people with bronchial asthma (Huether & McCance, 2011). Loss of heat or water from the bronchial surface may contribute to exercise-induced asthma. Exercising in cold, dry air increases the risk of an asthma attack in susceptible people.

Emotional stress is a significant etiologic factor for attacks in as many as half of patients with asthma. Common pharmacologic triggers include aspirin and other NSAIDs, beta-blockers, and sulfites (which are used as preservatives in wine, beer, fresh fruits, and salad).

RESPONSES

When a trigger such as inhalation of an allergen or irritant occurs, an *acute* or *early response* develops in the hyperreactive airways predisposed to bronchospasm. Sensitized mast cells in the bronchial mucosa release inflammatory mediators such as histamine, prostaglandins, and leukotrienes. Resident and infiltrating inflammatory cells also produce inflammatory mediators such as cytokines, bradykinin, and growth factors. These mediators stimulate parasympathetic receptors and bronchial smooth muscle to produce bronchoconstriction. They also increase capillary permeability, which allows plasma to escape and leads to mucosal edema. Mucous production is stimulated; excess mucus collects in the narrowed airways.

The attack is prolonged by the *late phase response*, which develops 4 to 12 hours after exposure to the trigger. Inflammatory cells such as basophils and eosinophils are activated, which damage airway epithelium, produce mucosal edema, impair mucociliary clearance, and produce or prolong bronchoconstriction. The degree of hyperreactivity depends on the extent of inflammation. Together, bronchoconstriction, edema and inflammation, and mucous secretion narrow the airway. Airway resistance increases, limiting airflow and increasing the work of breathing (Figure 37–1 ■).

Limited expiratory airflow traps air distal to the spastic, narrowed airways. Trapped air mixes with inspired air in the alveoli, reducing its oxygen tension and gas exchange across the alveolar-capillary membrane. Distended alveoli compress alveolar capillaries, reducing blood flow and further affecting gas exchange. As a result, hypoxemia develops. Hypoxemia and increased lung volume due to trapping stimulate the respiratory rate. Hyperventilation causes the $PaCO_2$ to fall, leading to respiratory alkalosis. (Refer to Chapter 10 for more information about acid–base imbalances.)

To summarize, in an acute asthma attack, inflammatory mediators are released from sensitized airways followed by activation of inflammatory cells. These events lead to bronchoconstriction, airway edema, and impaired mucociliary clearance. Airway narrowing limits airflow and increases the work of breathing; trapped air mixes with inhaled air, impairing gas exchange.

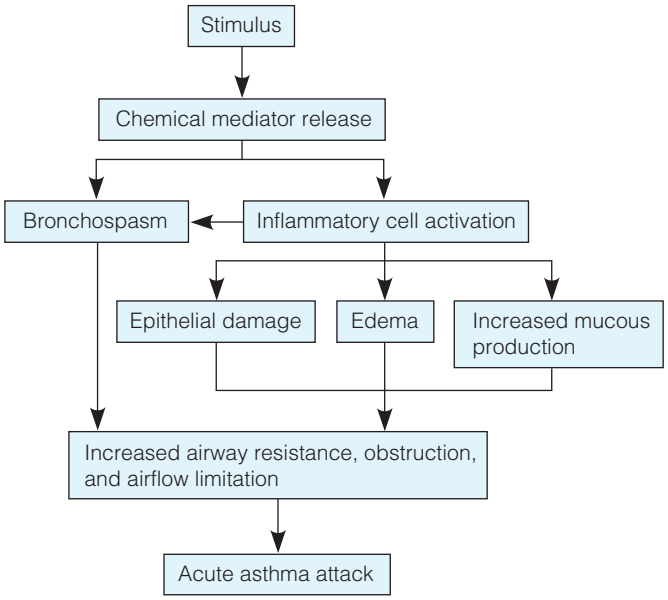

Figure 37–1 ■ The pathogenesis of an acute episode of asthma.

Manifestations and Complications

An asthma attack is characterized by a subjective sensation of chest tightness, cough, dyspnea, and wheezing (see the accompanying box). The onset of symptoms may be either abrupt or insidious, and an attack may subside rapidly or persist for hours or days. A sense of chest constriction and nonproductive cough are common early manifestations of an attack. During an attack, tachycardia, tachypnea, and prolonged expiration are common. Diffuse wheezing is heard on auscultation. With more severe attacks, use of accessory muscles of respiration, intercostal retractions, loud wheezing, and distant breath sounds may be noted. Fatigue, anxiety, apprehension, and severe dyspnea that allows speaking only one or two words between breaths may occur with persistent severe episodes. The onset of respiratory failure is marked by inaudible breath sounds with reduced wheezing and an ineffective cough. Without careful assessment, this apparent relief of symptoms can be misinterpreted as an improvement.

The frequency of attacks and severity of symptoms vary greatly from person to person. Although some people have infrequent, mild episodes, others have nearly continuous manifestations of cough, dyspnea on exertion, and wheezing with periodic severe exacerbations (Table 37–1).

Status asthmaticus is severe, prolonged asthma that does not respond to routine treatment. Without aggressive therapy, status asthmaticus can lead to respiratory failure with hypoxemia, hypercapnia, and acidosis. Endotracheal intubation, mechanical ventilation, and aggressive drug treatment may be necessary to sustain life.

MANIFESTATIONS OF ACUTE ASTHMA

- Chest tightness
- Cough
- Dyspnea
- Wheezing
- Tachypnea and tachycardia
- Anxiety and apprehension

TABLE 37–1 Classification of Asthma Severity

Classification	Symptom Frequency	Nighttime Symptoms
Mild intermittent	• No more than twice a week • Brief attacks (hours to days) of varied intensity • Asymptomatic and normal peak expiratory flow (PEF) rate between attacks	No more than twice a month
Mild persistent	• More than twice a week but less than once a day • Exacerbations may affect activity	More than twice a month
Moderate persistent	• Daily symptoms • Daily short-acting bronchodilator use • Exacerbations affect activity • Exacerbations more than twice a week; may last for days	More than once a week
Severe persistent	• Continual symptoms • Limited physical activity • Frequent exacerbations	Frequent

Source: Sveum, R., Bergstrom, J., Brottman, G., Hanson, M., Heiman, M., Johns, K., . . . Uden, D. (2012). Health care guidelines: Diagnosis and management of asthma. *Institute for Clinical Systems Improvement*. Retrieved from https://www.icsi.org/_asset/rsjvnd/Asthma.pdf.

In addition to acute respiratory failure, other complications associated with acute asthma include dehydration, respiratory infection, atelectasis, pneumothorax, and cor pulmonale.

COUGH-VARIANT ASTHMA

Asthma is one of the three most common causes of chronic cough (the other two being postnasal drip and gastroesophageal reflux disease [GERD]). Cough can be initiated by either upper airway irritants (e.g., postnasal drip or GERD) or by inflammation or constriction of the lower airways. Most commonly, cough associated with asthma is accompanied by classic asthma symptoms such as chest constriction, dyspnea, and wheezing. Patients with *cough-variant asthma*, however, have persistent cough without wheezing or dyspnea, often delaying diagnosis. These patients do have significant airway inflammation and demonstrate the pathophysiologic features of asthma.

Incidence and Risk Factors

In the United States, approximately 18.7 million adults had asthma in 2012. Asthma is a serious disease, causing about 3388 deaths in the United States in 2009 (Centers for Disease Control and Prevention [CDC], 2012).

FAST FACTS

- Asthma is more common in children (9.5%) than adults (7.3%) (CDC, 2012).
- Across races, the mortality rate associated with asthma is higher in women than in men.
- The asthma mortality rate of Blacks is nearly three times that of Whites and is higher than that of Hispanics and other ethnic groups.
- Deaths due to asthma are rare in children, but increase with age, particularly in middle and late adulthood and old age (CDC, 2012).

A number of risk factors can be identified for asthma, although many patients develop the disease in the absence of known risk factors. Allergies play a strong role in childhood asthma, although less so in adults. There is a strong genetic component to the disease, although a specific pattern of inheritance has not been identified. Multiple regions on several chromosomes appear to contribute to asthma-related factors such as airway hyperreactivity and high IgE levels. Environmental factors, including air pollution and occupational exposure to industrial compounds, may contribute. Respiratory viruses such as rhinovirus and influenza can precipitate asthma attacks. Other contributory factors include exercise (particularly in cold air) and emotional stress.

●○● INTERPROFESSIONAL CARE

The diagnosis of asthma is based primarily on the history and manifestations. Treatment goals are twofold. Daily management focuses on controlling symptoms and preventing acute attacks. During an acute attack, therapy is directed toward restoring airway patency and alveolar ventilation.

DIAGNOSIS

Diagnostic tests are used to determine the degree of airway involvement during and between acute episodes and identify causative factors such as allergens.

- *Pulmonary function tests (PFTs)* are used to evaluate the degree of airway obstruction. Pulmonary function testing done before and after use of an aerosolized bronchodilator helps determine the reversibility of airway obstruction. Airway reversibility is a cardinal sign seen on pulmonary function testing in asthma. The residual volume (RV) of the lungs may be increased and vital capacity decreased or normal even during periods of remission. The forced expiratory volume (FEV_1) and peak expiratory flow rate (PEFR), commonly referred to as *peak flow,* are the most valuable pulmonary function studies to evaluate the severity of an asthma attack and the effectiveness of treatment measures.
- *Challenge* or *bronchial provocation testing* uses an inhaled substance such as methacholine or histamine with PFTs to confirm the diagnosis of asthma by detecting airway hyperresponsiveness.
- *ABGs* are drawn during an acute attack to evaluate oxygenation, carbon dioxide elimination, and acid–base status. ABGs initially show hypoxemia with a low PO_2, and mild respiratory alkalosis with an elevated pH and low PCO_2 due to tachypnea. Severe airflow obstruction causes significant hypoxemia and respiratory acidosis (pH less than 7.35 and PCO_2 greater than 45 mmHg),

indicative of respiratory failure and the need for mechanical ventilation. Refer to Chapter 10 for more information about arterial blood gases and their interpretation.

- *Skin testing* may be done to identify specific allergens if an allergic trigger is suspected for asthma attacks. See Chapter 36 for more information about skin testing.

DISEASE MONITORING

Peak expiratory flow rate (PEFR) is used on a day-to-day basis to evaluate the severity of bronchial hyperresponsiveness. Small, inexpensive meters to measure PEFR are available. Readings taken at varying times of day over several weeks are used to establish the patient's personal best or normal PEFR. This value is then used to evaluate the severity of airway obstruction. Traffic signal colors are used for simplicity: *green* (80% to 100% of personal best) indicates asthma that is under control; *yellow* (50% to 80%) is caution, indicating a need for further medication or treatment; and *red* (50% or less) signals an immediate need for a bronchodilator and medical treatment if the level does not immediately return to the yellow range (Huether & McCance, 2011).

PREVENTIVE MEASURES

By avoiding allergens and environmental triggers asthma attacks often can be prevented. Modifying the home environment by controlling dust, removing carpets, covering mattresses and pillows to reduce dust mite populations, and installing air filtering systems may be useful. Pets may need to be removed from the household. Eliminating all tobacco smoke in the home is vital. Wearing a mask that retains humidity and warm air while exercising in cold weather may help prevent attacks of exercise-induced asthma. Early treatment of respiratory infections is vital to prevent asthma exacerbations.

MEDICATIONS

Medications are used to prevent and control asthma symptoms, reduce the frequency and severity of exacerbations, and reverse airway obstruction. Drugs used for long-term control of asthma are taken daily to maintain control of the disease. The primary drugs in this group are anti-inflammatory agents, long-acting bronchodilators, and leukotriene modifiers. Quick-relief medications provide prompt relief of bronchoconstriction and airflow obstruction with associated wheezing, cough, and chest tightness. Short-acting adrenergic stimulants (rapid-acting bronchodilators), anticholinergic drugs, and methylxanthines fall into this category.

A stepwise approach for managing asthma is recommended (see Table 37–2). This approach is based on the severity of disease (refer to Table 37–1). For all patients, a short-acting inhaled $beta_2$-agonist is recommended for quick relief of acute symptoms. Up to three treatments at 20-minute intervals or a single nebulizer treatment may be used as needed. Strategies for long-term control may need to be modified if a short-acting bronchodilator is needed more than twice a week (Sveum et al., 2012).

Many of the drugs used for continued asthma management and relief of an acute attack can be administered by a metered-dose inhaler (MDI), dry powder inhaler (DPI), or nebulizer. The advantages of administering medications locally by inhalation include rapid onset and reduced systemic effects of the drugs. In an MDI, a chemical propellant is used to deliver the medication when the canister is depressed. DPIs, in contrast, contain no propellant. Instead, the medication is released by inhaling rapidly through the mouthpiece. Box 37–1 outlines patient teaching for use of an MDI or DPI.

BRONCHODILATORS Most people with asthma need bronchodilator therapy to control their symptoms. Inhalation of nebulized medication is the preferred means of administration. The primary bronchodilators used include adrenergic stimulants, anticholinergic agents, and methylxanthines. These drugs often are administered in combination with an anti-inflammatory agent.

Adrenergic stimulants ($beta_2$-agonists) affect receptors on smooth muscle cells of the respiratory tract, causing smooth muscle relaxation and bronchodilation. Long-acting adrenergic stimulants such as inhaled salmeterol and oral sustained-release albuterol are used in conjunction with anti-inflammatory drugs to control symptoms, but are not appropriate to treat an acute episode of asthma. Inhaled short-acting beta-adrenergic agonists such as albuterol, bitolterol, pirbuterol, and terbutaline, administered by MDI or DPI, are the treatment of choice for quick relief. They act within minutes, but their duration generally is short, lasting only 4 to 6 hours. Tachycardia and muscle tremors, common side effects of adrenergic agonists, are minimal with inhalation therapy.

Anticholinergic medications prevent bronchoconstriction by blocking parasympathetic input to bronchial smooth muscle. Ipratropium bromide, an anticholinergic drug administered by MDI or handheld nebulizer, is useful when asthma symptoms are poorly controlled by adrenergic stimulants alone. Anticholinergic drugs act more slowly than adrenergic stimulants, requiring up to 60 to 90 minutes to achieve maximal effect.

TABLE 37–2 Stepwise Approach to Asthma Management for Adults

Step/Disease Severity	Preferred Treatment	Alternate or As-Needed Treatment
Step 1 Mild intermittent	No daily medication needed	Systemic corticosteroids for severe exacerbations
Step 2 Mild persistent	Low-dose inhaled corticosteroids	Cromolyn, leukotriene modifier, nedocromil, or sustained-release theophylline
Step 3 Moderate persistent	Low-to-moderate dose inhaled corticosteroids *and* long-acting inhaled $beta_2$-agonist	Increase inhaled corticosteroid dose *or* combine inhaled corticosteroid with leukotriene modifier or theophylline
Step 4 Severe persistent	High-dose inhaled corticosteroid *and* long-acting inhaled $beta_2$-agonist	Add systemic corticosteroid

Source: Sveum, R., Bergstrom, J., Brottman, G., Hanson, M., Heiman, M., Johns, K., . . . Uden, D. (2012). Health care guidelines: Diagnosis and management of asthma. *Institute for Clinical Systems Improvement*. Retrieved from https://www.icsi.org/_asset/rsjvnd/Asthma.pdf.

BOX 37–1 Patient Teaching: Using a Metered-Dose Inhaler or Dry Powder Inhaler

METERED-DOSE INHALER

- Firmly insert a charged MDI canister into the mouthpiece unit or spacer (if used).
- Remove mouthpiece cap. Shake canister vigorously for 3 to 5 seconds.
- Exhale slowly and completely.
- Holding the canister upside down, place the mouthpiece in the mouth, closing lips around it, if a spacer is being used. When no spacer is used, hold the mouthpiece directly in front of the mouth.
- Press and hold the canister down while inhaling deeply and slowly for 3 to 5 seconds (see accompanying figure).
- Hold breath for 10 seconds, release pressure on the container, remove from mouth, and exhale. Wait 20 to 30 seconds before repeating the procedure for a second puff.
- Rinse the mouth after using the inhaler to minimize systemic absorption and drying of the mucous membranes.
- Rinse the inhaler mouthpiece and spacer after use; store in a clean location.

DRY POWDER INHALER

- Keep the inhaler and medication in a clean, dry location. Do not refrigerate or store in a humid place (for example, the bathroom).
- Remove the cap and hold the inhaler upright. Inspect to be sure that the mechanism is clean and the mouthpiece is clear.
- If necessary, load the dose into the inhaler following manufacturer's directions.
- Hold the inhaler level with the mouthpiece end facing down.
- Breathe slowly and completely. Tilt your head back slightly.
- Place the mouthpiece in your mouth with your teeth over the mouthpiece. Seal your lips around the mouthpiece. Do not block the inhaler with your tongue.
- Breathe in rapidly and deeply through your mouth over 2 to 3 seconds to activate the flow of medication.
- Remove the inhaler from your mouth and hold your breath for 10 seconds.
- Exhale slowly through pursed lips to allow the medication to enter distal airways. Never exhale into the inhaler mouthpiece to prevent clogging.
- Rinse your mouth or brush your teeth after using the inhaler to avoid a bad taste from the medication and to prevent a yeast infection (if a corticosteroid medication is being used).
- Store the inhaler in a clean, sealed plastic bag; do not wash the inhaler unless so directed by the manufacturer. The mouthpiece should be cleaned weekly using a dry cloth.

Theophylline is a methylxanthine used as adjunctive treatment for asthma. It relaxes bronchial smooth muscle and may also inhibit the release of chemical mediators of the inflammatory response. Monitoring of serum theophylline levels is necessary because of wide individual variations in metabolism and elimination of the drug and its toxic effects. Serum levels of 10 to 20 μg/mL or lower are recommended. Theophylline may be used as a long-term bronchodilator, given once or twice daily. A related drug, aminophylline, may be administered intravenously to treat an acute, severe exacerbation of the disease.

ANTI-INFLAMMATORY AGENTS Corticosteroids and two nonsteroidal anti-inflammatory agents, cromolyn sodium and nedocromil, are used to suppress airway inflammation and reduce asthma symptoms.

Corticosteroids block the late response to inhaled allergens and reduce bronchial hyperresponsiveness. The preferred route of administration is by MDI or DPI to minimize systemic absorption and reduce the adverse effects of prolonged steroid use (cushingoid effects). For a severe acute attack, corticosteroids may be given systemically to alleviate symptoms and induce remission.

Cromolyn sodium and nedocromil are used to prevent acute episodes of asthma. They reduce airway hyperreactivity and inhibit the release of mediator substances. These drugs are used for long-term control of asthma, not quick relief. They have a wide margin of safety and few side effects.

LEUKOTRIENE MODIFIERS Leukotriene modifiers montelukast (Singulair), zafirlukast (Accolate), and zileuton (Zyflo Filmtab) are oral medications that reduce the inflammatory response in asthma. They appear to improve lung function, diminish symptoms, and reduce the need for short-acting bronchodilators. These drugs affect the metabolism and excretion of other medications such as warfarin and theophylline and may cause liver toxicity.

Nursing implications for medications used to treat asthma are outlined in an accompanying box.

COMPLEMENTARY THERAPIES

A number of herbal preparations and other complementary therapies have been shown to be helpful in treating asthma. Dietary therapies, environmental medicine, and nutritional supplements are the complementary therapies most widely recommended by healthcare professionals for asthma. Nutritional and dietary therapies may include elimination of certain foods or food additives (e.g., sulfite) from the diet, often in the absence of a documented food allergy or relationship between consumption and the onset of asthma symptoms. Although the evidence is inconsistent, some studies suggest that increasing intake of ascorbic acid, an antioxidant, zinc, and magnesium may help alleviate manifestations of asthma. People with mild asthma may benefit from addition of omega-3 polyunsaturated fatty acids to the diet, thereby experiencing less severe and fewer acute attacks.

Herbal preparations may include *Atropa belladonna* (the natural form of atropine) or ephedra (also called ma huang), an herb that contains ephedrine. These herbals have effects similar to those of drugs used to treat asthma, and should not be used in combination

MEDICATION ADMINISTRATION

Asthma

ADRENERGIC STIMULANTS

epinephrine

isoproterenol (Isuprel)

metaproterenol (Alupent, Metaprel)

terbutaline (Brethaire, Brethine)

isoetharine (Bronkosol, Bronkometer)

albuterol (Proventil, Ventolin)

bitolterol (Tornalate)

pirbuterol (Maxair)

salmeterol (Serevent)

formoterol (Foradil)

Combined Forms: *albuterol/ipratropium* (Combivent); *salmeterol/fluticasone* (Advair)

Adrenergic stimulants affect sympathetic receptors in the respiratory tract. Administered by MDIs or DPIs, these drugs are the treatment of choice for acute bronchial asthma. Nearly all of the drugs in this class (epinephrine and isoproterenol being the exceptions) selectively activate beta$_2$-receptors at the doses typically used to treat asthma. Beta$_2$-receptor activation results in smooth muscle relaxation and bronchodilation. Formoterol and salmeterol are highly selective to beta$_2$-receptors, resulting in fewer adverse effects. Formoterol and salmeterol have been shown to increase the risk of serious asthma exacerbations and death, however. The Food and Drug Administration recommends using these drugs only when the disease cannot be adequately controlled with other medications.

Oral forms of adrenergic agonists may be used for prophylaxis but are not effective in treating an acute attack because of their slow onset. When administered orally or parenterally, their effect on sympathetic nervous system receptors can produce undesirable side effects such as nervousness, irritability, tachycardia, and cardiac dysrhythmias.

Nursing Responsibilities

- Use with caution in patients with hypertension, cardiovascular disease, dysrhythmias, hyperthyroidism, or diabetes.
- When given to a patient who is hypoxemic and acidotic, these drugs may cause potentially dangerous cardiac stimulation.
- When given by MDI wait 1 to 2 minutes between puffs to allow airways to dilate, permitting the second dose to reach distal airways.
- Observe for desired effect of reduced dyspnea and wheezing. CNS stimulation (anxiety, irritability, and insomnia) and tremor are common side effects.

Health Education for the Patient and Family

- Use the prescribed inhaler or nebulizer as directed.
- If you are taking a bronchodilator along with another medication by inhalation, use the bronchodilator first to open airways and enhance the effectiveness of the second medication.
- Rinse the mouth after using inhalers to reduce systemic absorption of the medication.
- Keep a log to track your bronchodilator use. If the drug becomes less effective, or if you need a higher dosage or more frequent doses than prescribed, contact your physician.
- Report palpitations, irregular pulse, and other side effects to your physician.

METHYLXANTHINES

Theophylline (Bronkotabs, Quibron, Slo-Phyllin, Theolair, Theo-Dur, others), aminophylline (Somophyllin)

The methylxanthines are CNS stimulants chemically related to caffeine. These drugs produce bronchodilation through relaxation of bronchial smooth muscle. As CNS stimulants, they produce adverse effects such as nervousness, insomnia, and tremors. When administered in large doses, convulsions may result.

Once the drugs of choice for preventing and treating asthma attacks, they are now used primarily to prevent nocturnal asthma in affected adult patients. Theophylline has a narrow margin of safety and high potential for toxicity. Because the metabolism and excretion of theophylline vary significantly from person to person—affected by such factors as age, smoking, genetic factors, alcoholism, and other chronic diseases—monitoring of serum levels is vital.

Nursing Responsibilities

- The therapeutic blood level for theophylline is 10 to 20 μg/mL.
- Monitor for manifestations of toxicity. Anorexia, nausea, vomiting, restlessness, insomnia, cardiac dysrhythmias, and seizures are early manifestations. Other manifestations include epigastric pain, hematemesis, diarrhea, headache, irritability, muscle twitching, palpitations, tachycardia, flushing, and circulatory failure.
- Administer with meals or a full glass of water or milk to minimize gastric irritation.
- Monitor the effect closely when administering concurrently with other medications such as barbiturates, anticonvulsants, thyroid hormone, beta-blockers, bronchodilators, and others.
- Aminophylline is incompatible with many other intravenous drugs. Use a separate line or flush the line with normal saline before and after administering any other preparation.

Health Education for the Patient and Family

- Oral methylxanthines are ineffective to treat an acute asthma attack; do not delay other treatment by using these drugs.
- Check with the physician before taking any over-the-counter (OTC) medications or other prescription drugs while on theophylline.
- Do not smoke while using this drug.
- Report adverse effects to the physician.

ANTICHOLINERGICS

atropine

ipratropium bromide (Atrovent)

tiotropium bromide (Spiriva)

Combination Products: *albuterol/ipratropium* (Combivent)

Anticholinergics are potent bronchodilators, blocking muscarinic receptors of the parasympathetic nervous system. Activation of muscarinic receptors produces smooth muscle contraction and bronchoconstriction; blockade of these receptors facilitates smooth muscle relaxation and bronchodilation. Atropine is used infrequently because of its tendency to dry secretions of the mucous membranes and other side effects. Ipratropium and tiotropium bromide are available as inhalers and have fewer side effects than atropine.

Nursing Responsibilities

- Assess for possible contraindications to the drug, including hypersensitivity, glaucoma, prostatic hypertrophy, or bladder-neck obstruction.
- Assess for desired and/or adverse effects: improving or worsening symptoms; nausea, vomiting, abdominal cramping, anxiety, dizziness; headache.
- Provide ice chips, fluids, or hard candy to relieve dry mouth.

Health Education for the Patient and Family

- To prevent overdose, take no more than the prescribed number of doses per day.
- If the drug becomes less effective over time, notify the physician; an adjustment in dosage may be needed.

(*continued*)

MEDICATION ADMINISTRATION (*continued*)

CORTICOSTEROIDS

beclomethasone dipropionate (Vanceril, Beclovent)

triamcinolone acetonide (Azmacort)

flunisolide (AeroBid)

fluticasone propionate (Flovent)

dexamethasone sodium phosphate (Decadron Phosphate Respihaler)

Combination Products: *salmeterol/fluticasone (Advair)*

The anti-inflammatory effect of corticosteroids helps both prevent and treat acute episodes. Corticosteroids are used to reduce the frequency and severity of asthma attacks and allow reduced dosages of other drugs. The beneficial effects of corticosteroids for asthma result from their ability to decrease the synthesis and release of inflammatory mediators (such as histamine and leukotrienes), reduce inflammatory cell activation and infiltration, and decrease airway edema. Corticosteroids also decrease mucous production in the airways and increase the number and receptivity of beta$_2$-receptors (Vallerand & Sanoski, 2012). The cushingoid side effects of corticosteroids, always a major concern with their use, are minimized when they are inhaled. Note that the combination product salmeterol/fluticasone is associated with an increased risk of serious asthma exacerbations and death. It is a second-line drug, recommended for use only when asthma is inadequately controlled using other preparations.

Nursing Responsibilities

- Administer inhaler doses after bronchodilators to facilitate transit of the medication to distal airways.
- Assess for common side effects: sore throat; hoarseness; and oropharyngeal or laryngeal *Candida albicans* infection.
- Administer antifungal medications or gargles as ordered.

Health Education for the Patient and Family

- Rinse the mouth after using the inhaler and maintain good oral hygiene to reduce the risk of fungal infections.
- These medications should not be used to alleviate the symptoms of an acute attack.
- Several weeks of continued therapy may be required before a beneficial effect is noticed.
- Notify the physician if you develop weight gain, fluid retention, muscle weakness, redistribution of fat, or mood changes.

MAST CELL STABILIZERS

cromolyn sodium (Intal, NasalCrom)

nedocromil (Tilade)

Cromolyn sodium and nedocromil inhibit inflammatory cells in the airway, blocking early and late responses to inhaled antigens. Both drugs also prevent bronchoconstriction in response to inhaling cold air. These drugs act primarily by stabilizing the cytoplasmic membrane of mast cells, preventing the cells from releasing inflammatory mediators such as histamine (Vallerand & Sanoski, 2012). These drugs are used only for preventing asthma attacks, not to treat an acute attack. They are administered by MDI, and have a wide margin of safety. Patients using nedocromil may complain of an unpleasant taste.

Nursing Responsibilities

- Evaluate for potential adverse effects of wheezing and bronchoconstriction.

Health Education for the Patient and Family

- Gargling or sipping water can decrease the throat irritation associated with nebulizer treatment.
- Use appropriate technique. Inhale deeply with head tipped back to open airways, hold breath, and then exhale. Repeat until all of the drug has been inhaled.
- These drugs are used only to prevent asthma attacks; they are not effective in treating an acute attack.
- Several weeks may be required before a beneficial effect is noted.

LEUKOTRIENE MODIFIERS

montelukast (Singulair)

zafirlukast (Accolate)

zileuton (Zyflo)

Leukotriene modifiers interfere with the inflammatory process in the airways by suppressing the effects of leukotrienes, a group of inflammatory mediators. Leukotrienes are powerful bronchoconstrictors and vasodilators; blocking their synthesis or their receptors improves airflow, decreases symptoms, and reduces the need for short-acting bronchodilators. They are used for maintenance therapy in adults and children over the age of 12 as an alternative to inhaled corticosteroid therapy. They are not used to treat an acute attack.

Nursing Responsibilities

- Administer at least 1 hour before or 2 hours after meals.
- These drugs inhibit some liver enzymes, affecting the metabolism of warfarin and possibly terfenadine and theophylline. Monitor prothrombin times and theophylline blood levels.
- Monitor liver enzymes, because these drugs may be toxic to the liver.

Health Education for the Patient and Family

- Take the drugs as prescribed on an empty stomach.
- Notify the physician if a change in color of stools or urine is noted or if jaundice develops.

Note: Drugs identified in *italics* are among the 200 most commonly prescribed medications in the U.S.

with sympathetic stimulants or anticholinergic preparations. Because of the dangers associated with use of ephedra, sale of herbal products containing ephedra has been banned. Advise patients inquiring about the use of Chinese herbal remedies to treat asthma to inquire if any recommended product contains ma huang or ephedra, and to avoid such products. Capsaicin also may relieve acute asthma symptoms. Other herbal preparations include quercetin and grape seed extract. Refer patients interested in using natural preparations to a qualified herbalist, and emphasize the importance of talking to a physician before using these preparations along with conventional treatment.

In addition to herbals, other complementary therapies such as biofeedback, yoga, breathing techniques, acupuncture, homeopathy, and massage have been found to alleviate or help control asthma symptoms.

●○● NURSING CARE

Nurses encounter patients with asthma both in the acute care setting during an acute exacerbation and as outpatients or in homes. The priority nursing care needs differ with each setting.

Health Promotion

Although specific measures to prevent asthma have not yet been identified, the link between parental smoking and childhood asthma is strong. Discuss this link with young people and families with

children. Encourage all patients to not start smoking, and if they do smoke, to quit. Provide referrals to smoking cessation clinics, help groups, or a care provider for nicotine patches as needed to facilitate quitting. Additional evidence suggests that early exposure to certain infectious diseases and to other children and limited use of antibiotics reduces the risk for developing asthma (Sveum et al., 2012).

Assessment

See the Manifestations and Interprofessional Care sections for the assessment of the patient with acute asthma.

Assessment of the patient experiencing an acute asthma attack must be very focused and timely.

- *Health history:* current symptoms, including chest tightness, shortness of breath, dyspnea; duration of current attack; measures used to relieve symptoms and their effect; identified precipitating factors for the attack; frequency of attacks; current medications; known allergies
- *Physical assessment:* apparent level of distress; color; vital signs; respiratory rate and excursion, breath sounds throughout lung fields; apical pulse
- *Laboratory data:* forced expiratory volume, peak expiratory flow rate; arterial blood gases.

Priorities of Care

Collaborating with the interprofessional team to ensure adequate treatment of the acute asthmatic process while providing care that supports the patient's optimal airway function and physical and psychologic responses to the disorder is a priority of nursing care.

Diagnoses, Outcomes, and Interventions

An acute asthma attack causes fear as breathing becomes increasingly difficult and hypoxemia develops. Anxiety in turn tends to increase the severity and manifestations of the attack. Priority nursing care needs during an acute attack focus on improving airway clearance and reducing fear and anxiety. Teaching about prevention of future attacks and home management must be postponed until adequate ventilation is restored.

Ineffective Airway Clearance

Bronchospasm and bronchoconstriction, increased mucous secretion, and airway edema narrow the airways and impair airflow during an acute attack of asthma. Both inspiratory and expiratory volume are affected, decreasing the oxygen available at the alveolus for the process of respiration. Narrowed air passages increase the work of breathing, increasing the metabolic rate and tissue demand for oxygen.

Expected Outcome: Patient will use techniques to promote airway clearance such as coughing and deep breathing.

SAFETY ALERT

Frequently assess respiratory status (at least every 1 to 2 hours): respiratory rate and depth, chest movement or excursion, breath sounds, and peak expiratory flow rate. Respiratory status can change rapidly during an acute asthma attack and its treatment. A decreasing PEFR indicates worsening airflow restriction. Slowed, shallow respirations with significantly diminished breath sounds and decreased wheezing may indicate exhaustion and impending respiratory failure. Immediate intervention is necessary.

- Monitor skin color and temperature and level of consciousness. *Cyanosis, cool clammy skin, and changes in level of consciousness (agitation, lethargy, or confusion) indicate worsening hypoxia.*
- Assess arterial blood gas results and pulse oximetry readings; notify the physician of abnormal values or changes in status. *These values provide information about gas exchange and the adequacy of alveolar ventilation. A fall in oxygen saturation levels is an early indicator of impaired gas exchange.*
- Assess cough effort and sputum for color, consistency, and amount. *Ineffective cough may also signal impending respiratory failure.*
- Place in Fowler's, high-Fowler's, or orthopneic (with head and arms supported on the overbed table) position to facilitate breathing and lung expansion. *These positions reduce the work of breathing and increase lung expansion, especially of basilar areas.*
- Administer oxygen as ordered. If a mask is used, monitor closely for feelings of claustrophobia or suffocation. *Supplemental oxygen reduces hypoxemia. Although the mask is a very effective oxygen delivery system, it may increase anxiety.*
- Administer nebulizer treatments and provide humidification as ordered. *Nebulizer treatments are used to administer bronchodilators and other medications; humidity helps loosen secretions.*
- Initiate or assist with chest physiotherapy, including percussion and postural drainage. *Percussion and postural drainage facilitate the movement of secretions and airway clearance.*
- Increase fluid intake. *Increasing fluids helps keep secretions thin.*
- Provide endotracheal suctioning as needed. *Endotracheal suctioning may be necessary to remove secretions and improve ventilation if the patient is unable to clear secretions by coughing.*

Ineffective Breathing Pattern

The physiologic changes in lung ventilation that occur during an acute asthma attack impair both lung expansion and emptying. Anxiety caused by hypoxia and dyspnea compounds the problem by increasing the respiratory rate. Collaborative and nursing interventions can help restore a more normal breathing pattern and adequate lung ventilation.

Evidence for Nursing Care

The Patient with Asthma

Selected resources that nurses may find helpful when planning evidence-based nursing care follow.

- Bateman, E. D., Bousquet, J., FitzGerald, M., Haahtela, T., O'Byrne, P., Ohta, K., et al. (2011). *Global strategy for asthma management and prevention*. Bethesda, MD: Global Initiative for Asthma (GINA). Retrieved from http://www.ginasthma.org/uploads/users/files/GINA_Report2011_May4.pdf
- Kaufman, G. (2011). Asthma: Pathophysiology, diagnosis and management. *Nursing Standard, 26*(5), 48–56.

Expected Outcome: Patient will demonstrate uncompromised ventilatory status as evidenced by absence of dyspnea, orthopnea, accessory muscle use, and adventitious lung sounds.

- Frequently assess respiratory rate, pattern, and breath sounds. Note manifestations of ineffective breathing, including rapid rate, shallow respirations, nasal flaring, use of accessory muscles, intercostal retractions, and diminished or absent breath sounds. *Early identification of ineffective respirations allows timely initiation of interventions.*
- Monitor vital signs and laboratory results. *Tachypnea, tachycardia, an elevated blood pressure, and increasing hypoxemia and hypercapnia are signs of compromised respiratory status.*
- Assist with ADLs as needed. *This conserves energy and reduces fatigue.*
- Provide rest periods between scheduled activities and treatments. *Scheduled rest is important to prevent fatigue and reduce oxygen demands.*
- Teach and assist to use techniques to control breathing pattern:
  a. Pursed-lip breathing
  b. Abdominal breathing
  c. Relaxation techniques including visualization and meditation.
  Pursed-lip breathing helps keep airways open by maintaining positive pressure, and abdominal breathing improves lung expansion. Relaxation techniques reduce anxiety and its effect on the respiratory rate.
- Administer medications, including bronchodilators and anti-inflammatory drugs, as ordered. Monitor for desired and possible adverse effects. *Medications are used to improve airway status and facilitate breathing.*

Anxiety

Acute exacerbations of asthma can produce significant anxiety. Fear of being unable to breathe and feelings of suffocation associated with acute asthma are significant. Financial or other concerns may cause the patient to want to avoid hospitalization. Increasingly frequent and severe episodes may cause fear for the future. Hypoxia contributes to anxiety as well, stimulating the sympathetic nervous system and the fight-or-flight response.

Expected Outcome: Patient will be able to control anxiety as evidenced by verbalized decrease in subjective distress.

- Assess level of anxiety. *Interventions for severe anxiety or panic differ from those for mild or moderate anxiety.*
- Assist to identify coping skills that have been successful in the past. *Successful coping helps the patient regain control of the situation, reducing anxiety.*
- Provide physical and emotional support. Remain with the patient during episodes of severe anxiety; schedule time every 1 to 2 hours to be with the mildly or moderately anxious patient, or more frequently if needed. Answer call lights promptly. *The severely anxious patient may fear being alone or believe that he or she will die if someone is not on hand. Knowing that the nurse is readily available and will return regardless if help is needed reduces anxiety.*
- Listen actively to concerns; do not deny or negate the fear of dying or of being unable to breathe. *Active listening promotes trust and helps the patient express concerns.*
- Provide clear, concise directions and explanations about procedures. Avoid presenting more information than the patient is able to assimilate. *Anxiety interferes with the ability to learn. Explanations may need to be repeated frequently.*
- Include the patient in care planning and decisions as appropriate, without making excessive demands. *Participating in decision making increases the patient's sense of control. Because high levels of anxiety interfere with the ability to make decisions, however, it is important to avoid placing demands on the patient that may further increase the level of anxiety.*
- Reduce excessive environmental stimuli, and maintain a calm demeanor. *This promotes rest.*
- Allow supportive family members to remain with the patient. *Significant others provide additional support and can help reduce anxiety.*
- Assist to use relaxation techniques, such as guided imagery, muscle relaxation, and meditation. *These techniques help restore psychologic balance and reduce sympathetic stimulation and responses.*

Ineffective Therapeutic Regimen Management

Once acute asthma is under control and effective respirations have been reestablished, it is important to help the patient identify contributing factors to the attack. This helps the patient prevent future episodes.

Expected Outcome: Patient will be compliant with therapeutic regimen as evidenced by adherence to medication regimen and follow-up appointments.

- Assess level of understanding about asthma and the prescribed treatment regimen. Provide additional information and teaching as indicated. *Assessment helps to identify and clarify misperceptions and difficulties with disease management.*
- Discuss the patient's perception of the illness and its effect on his or her lifestyle. *Open discussion can help identify conflicts between lifestyle and the treatment regimen.*

SAFETY ALERT

Assist to identify factors that contributed to the acute episode. Identifying contributing factors increases the patient's awareness of the disease and strategies to prevent future exacerbations.

- Assist the patient and significant others to identify problems or difficulties integrating the treatment regimen into their lifestyle. *Asthma and its management may necessitate lifestyle modifications to prevent acute exacerbations. These modifications, such as eliminating cigarette smoking or pets from the household, removing carpets, or daily damp-dusting to remove dust mites, can significantly impact family members.*
- Assess knowledge and understanding of prescribed medications and use of OTC preparations. *This is important to determine misperceptions or possible misuse of medications.*
- Provide verbal and written instructions. *Written instructions reinforce teaching and allow future reference.*
- Refer to counseling, support groups, or self-help organizations. *Counseling, support groups, and self-help organizations can help the patient and family adapt to living with asthma and the treatment regimen.*

Continuity of Care

Asthma is a chronic disease that is best managed by the patient with assistance from medical personnel. Teaching for home care focuses on promoting the highest level of wellness and preventing and managing acute episodes and exacerbations of the disease. Topics to include in teaching are as follows:

- Suggestions for lifestyle changes to avoid specific triggers for asthma attacks:
  - Warm up slowly before exercising in cold weather; wear a special mask or scarf to retain air warmth and humidity while exercising.
  - Substitute indoor exercises during cold, dry weather.
  - Reduce the risk for respiratory infections (e.g., adequate rest, good nutrition, and stress management to maintain immune function, yearly influenza vaccines, and immunization against pneumococcal pneumonia).
  - Use techniques to reduce or manage physical and psychologic stress.
- Using a PEFR meter to monitor airway status; how to manage the disease based on results.
- Using prescribed medications, including the following:
  - Name, frequency, dose, and desired effect
  - Potential adverse effects and their management, including effects to report to the physician
  - Potential interactions with other drugs (including OTC herbal preparations) or foods
  - If tolerance is a potential risk, how to identify it and steps to take.

Provide referrals to local or regional resources for further teaching and support as needed. Consider the need for home health services, home respiratory care services, and others as needed.

THE PATIENT WITH CHRONIC OBSTRUCTIVE PULMONARY DISEASE

Patients with chronic airflow obstruction due to chronic bronchitis and/or emphysema are said to have **chronic obstructive pulmonary disease (COPD)**.

Pathophysiology

COPD is characterized by slowly progressive obstruction of the airways. The disease is one of periodic exacerbations, often related to respiratory infection, with increased symptoms of dyspnea and sputum production. Unlike acute processes in which lung tissues recover, airways and lung parenchyma do not return to normal following an exacerbation; instead, they demonstrate progressive destructive changes.

Although one or the other may dominate, COPD typically includes components of both chronic bronchitis and emphysema, two distinctly different processes. Small airways disease, narrowing of small bronchioles, is also part of the COPD complex.

Through different mechanisms, these processes cause airways to narrow, resistance to airflow to increase, and expiration to become slow or difficult (Figure 37–2 ■). The result is a mismatch between alveolar ventilation and blood flow or perfusion, leading to impaired gas exchange.

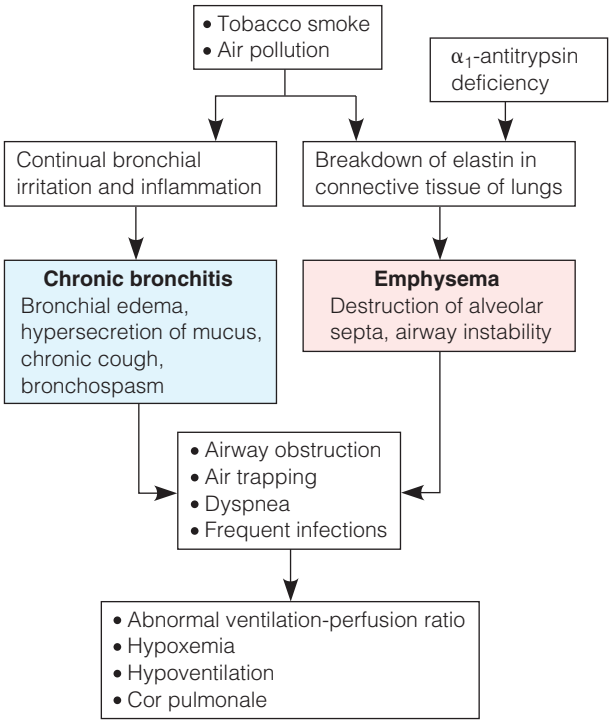

Figure 37–2 ■ The pathogenesis of chronic obstructive pulmonary disease.

CHRONIC BRONCHITIS

Chronic bronchitis is a disorder of excessive bronchial mucous secretion. It is characterized by a productive cough lasting 3 or more months in 2 consecutive years (Huether & McCance, 2011). Cigarette smoke is the major factor implicated in the development of chronic bronchitis.

Inhaled irritants lead to a chronic inflammatory process with vasodilation, congestion, and edema of the bronchial mucosa. Goblet cells increase in size and number, and mucous glands enlarge. Thick, tenacious mucus is produced in increased amounts. Changes in bronchial squamous cells impair the ability to clear mucus. Narrowed airways and excess secretions obstruct airflow; expiration is affected first, then inspiration. Because ciliary function is impaired, normal defense mechanisms are unable to clear the mucus and any inhaled pathogens. Recurrent infection is common in chronic bronchitis. An imbalance between ventilation and perfusion leads to hypoxemia, hypercapnia, and pulmonary hypertension. Pulmonary hypertension often leads to right-sided heart failure.

EMPHYSEMA

Emphysema is characterized by destruction of the walls of the alveoli, with resulting enlargement of abnormal air spaces. As in chronic bronchitis, cigarette smoking is strongly implicated as a causative factor in most cases of emphysema. Macrophages from the alveoli (air sacs) and CD-8 T lymphocytes increase and destroy lung tissue. Cytokines also play a role in the inflammation. Additionally antiproteinases, which protect lung tissue, become inactivated, leading to reductions in lung repair. This results in alveolar wall destruction. Alveolar wall destruction causes alveoli and air spaces to enlarge with loss of corresponding portions of the pulmonary capillary bed. As a result, the surface area for alveolar-capillary diffusion is reduced,

BOX 37–2 Classification of COPD by Severity

Stage 0: At risk. Lung function normal, but chronic cough and sputum production are present

Stage 1: Mild COPD. Mild airflow limitation, usually with chronic cough and sputum production

Stage 2: Moderate COPD. Worsening airflow limitation, usually with progressing manifestations including dyspnea on exertion

Stage 3: Severe COPD. Further worsening of airflow limitation, increased shortness of breath, and repeated exacerbations impacting quality of life

Stage 4: Very Severe COPD. Severe airflow limitation with significantly impaired quality of life and potentially life-threatening exacerbations

Source: Adapted from Global Initiative for Chronic Obstructive Lung Disease (GOLD). (2013). *Global strategy for the diagnosis, management and prevention of chronic obstructive pulmonary disease.* Media Communications Inc. Retrieved from http://www.goldcopd.org.

affecting gas exchange. Elastic recoil is lost, reducing the volume of air that is passively expired. The loss of support tissue also affects airways, increasing the risk of expiratory collapse and further air trapping. Anatomically, either respiratory bronchioles or alveoli may be the primary tissue involved. Deficiency of alpha$_1$-antitrypsin, an enzyme that normally inhibits the activity of proteolytic enzymes and tissue destruction in the lungs, contributes to the development of emphysema, especially when combined with exposure to cigarette smoke.

To summarize, COPD is a progressive, nonreversible process of airway narrowing and loss of supporting tissue. Three separate processes typically are involved:

- Chronic bronchitis with persistent airway edema, excessive mucous production, and impaired airway clearance
- Emphysema with loss of alveolar walls, capillary bed, and airway support tissue resulting in airway collapse and reductions in gas exchange
- Small airways disease with bronchoconstriction.

The result of these processes and their combined effects is increased work of breathing, impaired expiration with air trapping, and impaired gas exchange.

Manifestations

The clinical presentation of COPD varies from simple chronic bronchitis without disability to chronic respiratory failure and severe disability. Box 37–2 outlines the classifications of COPD severity. Manifestations are typically absent or minor early in the disease. When the patient finally seeks care, productive cough, dyspnea, and exercise intolerance often have been present for as long as 10 years. The cough typically occurs in the mornings and often is attributed as *smoker's cough*. Initially, dyspnea occurs only on extreme exertion; as the disease progresses, activity tolerance spirals downward. Patients abandon activity to avoid dyspnea, leading to further deconditioning. This results in a patient so deconditioned that dyspnea occurs with light activity or even at rest. The clinical features and manifestations of COPD are summarized in Table 37–3.

Manifestations of chronic bronchitis are a cough productive of copious amounts (at least 1/2 cup/day) of thick, tenacious sputum, cyanosis, and evidence of right-sided heart failure, including distended neck veins, edema, liver engorgement, and an enlarged heart. Adventitious sounds, including loud rhonchi and possible wheezes, are prominent on auscultation.

Emphysema is insidious in onset. Dyspnea is the initial symptom. Initially occurring only with exertion, dyspnea may progress to become severe even at rest. Cough is minimal or absent. Air trapping and hyperinflation increase the anteroposterior chest diameter, causing *barrel chest*. The patient often is thin, tachypneic, uses accessory muscles of respiration, and often assumes a position of sitting and leaning forward (Figure 37–3 ■). The expiratory phase of the respiratory cycle is prolonged. On auscultation, breath sounds are diminished, and the percussion tone is hyperresonant.

Incidence and Risk Factors

In 2009, approximately 11.8 million Americans were affected by COPD (CDC, 2011). It is more common among Whites than

TABLE 37–3 Clinical Features and Manifestations of COPD

	Feature	Chronic Bronchitis	Emphysema
History	Onset	After age 35; recurrent respiratory infections	After age 50; insidious progressive dyspnea
	Smoking	Usual	Usual
	Cough	Persistent; productive of copious mucopurulent sputum	Absent or mild with scant clear sputum, if any
Physical examination	Appearance	Often obese; edematous and cyanotic; distended neck veins and other symptoms of right-sided heart failure	Usually thin and cachectic; barrel chest; prominent accessory muscles of respiration
	Chest	Adventitious sounds with wheezing and rhonchi; normal percussion note	Distant or diminished breath sounds; hyperresonant percussion note
Other features	Blood gases	Hypercapnia and hypoxemia; respiratory acidosis	Normal or mild hypoxemia; normal pH
	Pulmonary function studies	Normal or decreased total lung capacity; moderately increased residual volume	Increased total lung capacity; markedly increased residual volume
	Pulmonary hypertension	May be severe	Only when advanced

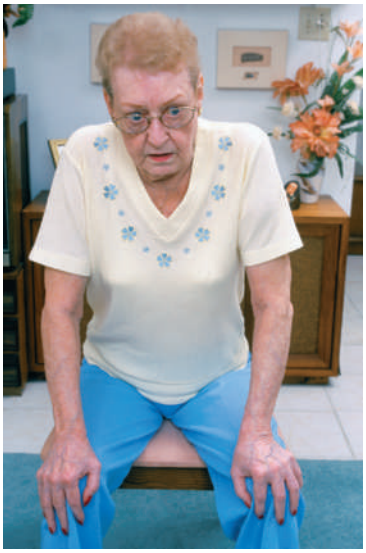

Figure 37–3 ■ Typical appearance of a patient with emphysema. Note the patient's anxious expression and assumption of the tripod position, leaning forward with the hands on the knees.

Blacks and affects men more frequently than women. It is the fourth leading cause of death in the United States. The death rate from COPD continues to rise among Puerto Rican males and females of all ethnic groups; the death rate is stable in Whites, Hispanics, and Asians. In 2009, COPD and other chronic obstructive lung diseases accounted for more than 120,000 deaths (CDC, 2011). In addition, COPD morbidity is significant. In people under age 65, COPD is second only to heart disease as a cause of disability, resulting in an estimated 250 million lost work-hours yearly.

FAST FACTS

- Since 2001, the number of deaths due to COPD in women has exceeded that of men.
- Chronic bronchitis was diagnosed in 9.8 million Americans in 2009.
- Females are now more than twice as likely to be diagnosed with chronic bronchitis as males.
- Approximately 3.7 million Americans have emphysema.
- Although more men than women have emphysema, its prevalence is increasing in women and decreasing in men.

Source: (CDC, 2011).

Obstructive lung disease typically affects middle-age and older adults. Cigarette smoking is clearly implicated as the primary cause of COPD. Even though COPD develops in a minority of smokers, smokers are 12 to 13 times more likely to die from COPD than nonsmokers. Cigarette smoke and the irritants it contains impair ciliary movement, inhibit the function of alveolar macrophages, and cause mucous-secreting glands to hypertrophy. Smoking also produces emphysema or airway destruction and constricts smooth muscle, increasing airway resistance. Other contributing factors include air pollution, occupational exposure to noxious dusts and gases, airway infection, and familial and genetic factors (see the accompanying Genetic Considerations box).

GENETIC CONSIDERATIONS

Chronic Obstructive Pulmonary Disease

Severe alpha$_1$-antitrypsin (α_1AT or ATT) deficiency, present in about 1% to 2% of patients with COPD, is a proven risk factor for COPD. Normal α_1AT levels are associated with the common M allele. Two other alleles, the S allele and the Z allele, lead to reduced α_1AT levels. An estimated 25 million Americans carry a single gene associated with α_1AT deficiency and can pass that gene on to their offspring. People who inherit two Z alleles or one Z allele and one null allele have severe α_1AT deficiency. Approximately 1 in 3000 people in the United States inherit severe α_1AT deficiency. An estimated 100,000 people in the United States have emphysema related to α_1AT deficiency (American Lung Association [ALA], 2011). Although studies suggest additional genetic factors in the development of COPD, at this time none have been proven.

●○● INTERPROFESSIONAL CARE

Although COPD can be prevented in most people, it cannot be cured. Smoking abstinence is the only certain way to prevent COPD and to slow its progression. To a certain extent, airway obstruction can be reversed and disability minimized early in the disease. Treatment generally focuses on relieving symptoms, minimizing obstruction, and slowing disability.

DIAGNOSIS

Diagnostic tests are used to help establish the diagnosis of COPD and identify the predominant component, emphysema or chronic bronchitis. These procedures also are used to assess respiratory status and monitor treatment effectiveness.

- *Pulmonary function testing* is performed to establish the diagnosis and evaluate the extent and progress of COPD (refer to Box 34–1). Results are based on calculated norms for each person by age, height, sex, and weight; note these as well as all current medications on the requisition. In COPD, the total lung capacity and residual volume typically are increased. The forced expiratory volume (FEV_1) and forced vital capacity (FVC) are decreased due to narrowed airways and resistance to airflow.
- *Ventilation–perfusion scanning* may be performed to determine the extent of ventilation–perfusion mismatch—that is, the extent to which lung tissue is ventilated but not perfused (dead space), or perfused but inadequately ventilated (physiologic shunting) (Figure 37–4 ■). A radioisotope is injected or inhaled to illustrate areas of shunting and absent capillaries.
- *Serum alpha$_1$-antitrypsin levels* may be drawn to screen for deficiency, particularly in patients with a family history of obstructive airway disease, those with an early onset, women, and nonsmokers. Normal adult serum alpha$_1$-antitrypsin levels range from 80 to 260 mg/dL. Fasting is not required prior to this test.
- *Arterial blood gases (ABGs)* are drawn to evaluate gas exchange, particularly during acute exacerbations of COPD. Patients with predominant emphysema often have mild hypoxemia and normal or low carbon dioxide tension. Respiratory alkalosis may be present due to an increased respiratory rate. Predominant chronic bronchitis and airway obstruction may cause marked hypoxemia and hypercapnia with respiratory acidosis. Oxygen saturation levels are low due to marked hypoxemia. Refer to Chapter 10, page 214, for steps to interpret ABGs.

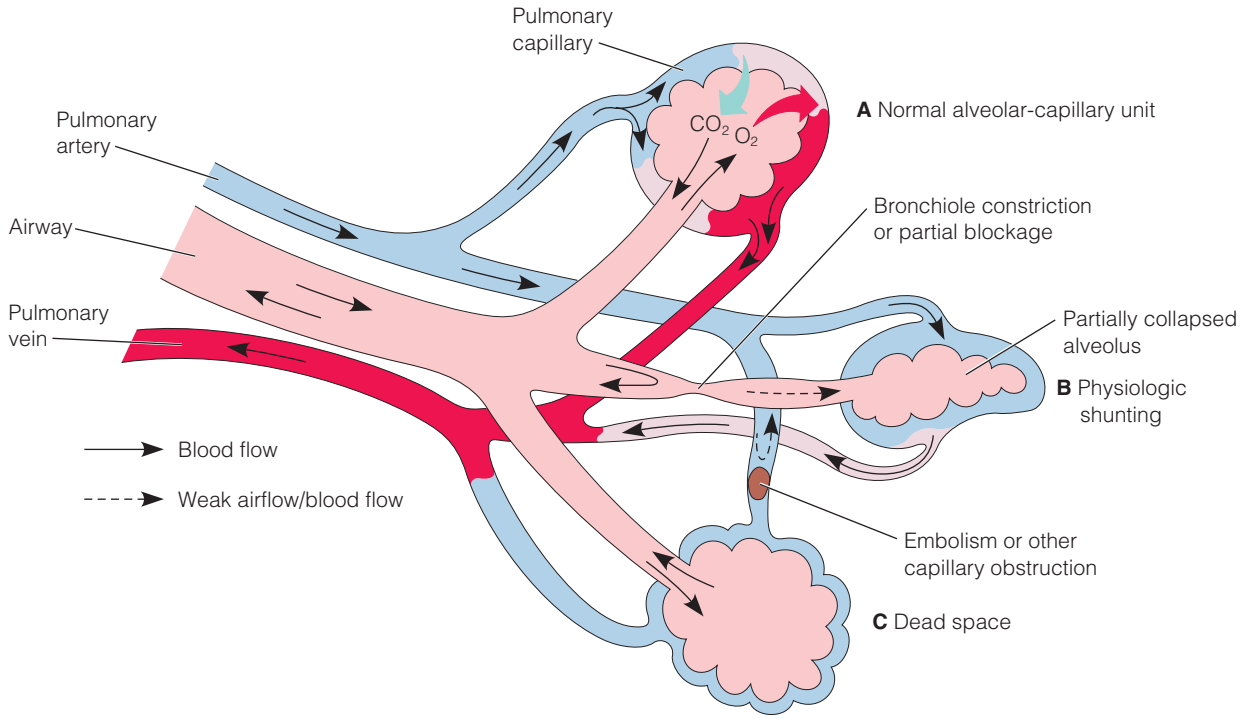

Figure 37–4 ■ Ventilation–perfusion relationships. A, Normal alveolar-capillary unit with an ideal match of ventilation and blood flow. Maximum gas exchange occurs between alveolus and blood. B, Physiologic shunting: A unit with adequate perfusion but inadequate ventilation. C, Dead space: A unit with adequate ventilation but inadequate perfusion. In the latter two cases, gas exchange is impaired.

PRACTICE ALERT!

Hypercapnia (elevated $PaCO_2$ levels) often is chronic in patients with COPD (CO_2 retainers). In these patients, administering oxygen can actually increase the $PaCO_2$, leading to somnolence and acute respiratory failure. Although oxygen is the drug of choice for treating patients with COPD, close monitoring is necessary during oxygen therapy.

- *Pulse oximetry* is used to monitor oxygen saturation of the blood. Marked airway obstruction and hypoxemia often cause oxygen saturation levels less than 95%. Pulse oximetry may be continuously monitored to assess the need for supplemental oxygen.
- *Exhaled carbon dioxide* (*capnogram* or *ETCO*$_2$) may be measured in ventilated patients to evaluate alveolar ventilation. The normal $ETCO_2$ reading is 35 to 45 mmHg; it is elevated when ventilation is inadequate, and decreased when pulmonary perfusion is impaired. $ETCO_2$ monitoring can reduce the frequency of ABG determinations.
- *CBC with WBC differential* often shows increased RBCs and hematocrit (erythrocytosis) as chronic hypoxia stimulates increased erythropoiesis to increase the oxygen-carrying capacity of the blood. *Polycythemia*, increased numbers of all blood cells, may be evident. Increased WBC count and a higher percentage of immature WBCs (bands) are often indicative of bacterial infection.
- *Chest x-ray* may show flattening of the diaphragm due to hyperinflation and evidence of pulmonary infection if present.

SMOKING CESSATION

Smoking cessation can not only prevent COPD from developing, but also can improve lung function once the disease has been diagnosed. Forced expiratory volume (FEV_1) improves, and survival is prolonged, largely due to lower rates of lung cancer and heart disease. Sustained quitting is difficult; only 6% of smokers succeed in long-term abstinence from smoking. Use of nicotine patches or gum and an antidepressant such as bupropion (Wellbutrin, Zyban) or varenicline (Chantix) improve the chances of success (Fiore, 2012).

MEDICATIONS

Immunization against pneumococcal pneumonia and a yearly influenza vaccine are recommended to reduce the risk of respiratory infections. A broad-spectrum antibiotic is prescribed if infection is suspected. Recent studies indicate that patients with purulent sputum and increased dyspnea will likely benefit from antibiotic therapy even if no other signs of infection are present. Prophylactic antibiotics may be ordered for patients who experience four or more disease exacerbations per year.

Bronchodilators improve airflow and reduce air trapping in COPD, resulting in improved dyspnea and exercise tolerance. Bronchodilators may be given by metered-dose inhaler (MDI), dry powder inhaler (DPI), by nebulizer, or orally. Oral administration may promote adherence, but is associated with much higher rates of adverse effects. A spacer or holding chamber may facilitate effective use of an MDI. Ipratropium bromide, an anticholinergic agent administered by MDI, is frequently prescribed. It has a longer duration of action than the short-acting beta$_2$-adrenergic stimulant bronchodilators and few side effects. Salmeterol, a longer-acting beta$_2$-agonist, may be used in combination therapy. Oral theophylline, a methylxanthine, is a weak bronchodilator and has a narrow therapeutic range, but often is prescribed for its other effects. Theophylline stimulates the respiratory drive, strengthens diaphragmatic contractions, and improves cardiac output. As a result, dyspnea, exercise tolerance, and quality of life improve for the patient with COPD. Bronchodilators are discussed in further detail in the section on asthma, and their nursing implications are outlined in the Medication Administration box earlier in this chapter.

Corticosteroid therapy may be used when asthma is a major component of COPD. It also improves symptoms and exercise tolerance, and may reduce the severity of exacerbations and the need for hospitalization. Oral corticosteroids, such as prednisone, are used initially. If a beneficial response occurs, the amount is reduced to the lowest effective dose. Every other day dosing or administration by inhaler is preferred to minimize steroid side effects, such as cushingoid effects and an increased risk for osteoporosis and vertebral fractures.

Alpha$_1$-antitrypsin (α_1AT) replacement therapy is available for patients with emphysema due to a genetic deficiency of the enzyme. Although expensive and inconvenient (α_1AT is administered weekly by intravenous infusion), it has been shown to reduce the rate of airflow decline and mortality.

TREATMENTS

In addition to refraining from smoking, exposure to other airway irritants and allergens should be avoided. The patient should remain indoors during periods of significant air pollution to prevent exacerbations of the disease. Air filtering systems or air conditioning may be useful.

Pulmonary hygiene measures, including hydration, effective cough, percussion, and postural drainage, are used to improve clearance of airway secretions. Maintaining adequate systemic hydration is essential to keep secretions thin. Forceful coughing is often less effective than leaning forward and repeatedly "huffing," with relaxed breathing between huffs. Percussion and postural drainage may be necessary if the patient is unable to clear secretions by usual means. Cough suppressants and sedatives generally are avoided because they may cause retention of secretions.

While optimal medical management is helpful it cannot reverse the pathologic changes of COPD. Pulmonary rehabilitation (PR) teaches patients how to manage their symptoms and attain their maximum level of functioning. PR includes exercise, education, and psychologic support. PR is most commonly delivered in the outpatient setting with exercise sessions of 30 to 90 minutes, three to five times per week. While PR does not change lung function, improvements in exercise and functional capacity and quality of life are seen. Both lower and upper extremity exercise should be used to promote activity tolerance during ADLs. See the accompanying Moving Evidence into Action feature.

Breathing exercises are used to slow the respiratory rate and relieve accessory muscle fatigue. Pursed-lip breathing slows the respiratory rate and helps maintain open airways during exhalation by keeping positive pressure in the airways. Abdominal breathing relieves the work of accessory muscles of respiration.

OXYGEN

Long-term oxygen therapy is used for severe and progressive hypoxemia. Oxygen therapy improves exercise tolerance, mental functioning, and quality of life in advanced COPD. It also reduces the rate of hospitalization and increases length of survival. Oxygen may be used intermittently, at night, or continuously. For severely hypoxemic patients, the greatest benefit is seen with continuous oxygen. Home oxygen may be supplied as liquid oxygen, compressed gas cylinders, or oxygen concentrators. Patients may be provided a combination of delivery systems to promote mobility outside of the home (i.e., oxygen concentrator and compressed gas).

An acute exacerbation of COPD may necessitate oxygenation and inspiratory positive-pressure assistance with a face mask or intubation and mechanical ventilation. The administration of oxygen without intubation and mechanical ventilation requires caution: Administering oxygen to patients with chronic elevated carbon dioxide levels in the blood can actually increase the $PaCO_2$, leading to increased somnolence and even respiratory failure. Close monitoring of level of consciousness and ABGs during oxygen therapy is vital (Fishman et al., 2004; Global Initiative for Chronic Obstructive Lung Disease, 2013).

SURGERY

When medical therapy is no longer effective, lung transplantation may be an option. Both single and bilateral transplants have been performed successfully, with a 2-year survival rate of 75%. Lung reduction surgery is an experimental surgical intervention for advanced diffuse emphysema and lung hyperinflation. The procedure reduces the overall volume of the lung, reshapes it, and improves elastic recoil. As a result, pulmonary function and exercise tolerance improve and dyspnea is reduced. Refer to the box on page 1159 of Chapter 36 for nursing care of the patient undergoing lung surgery. Special nursing care considerations related to lung or heart-lung transplant are summarized in Box 37–3.

Moving Evidence into Action

The Patient with COPD

Exercise-induced dynamic hyperinflation is believed to be a significant factor in reduced activity tolerance in patients with COPD. This development is a particularly important consideration in pulmonary rehabilitation exercise.

A study by Collins and colleagues (2008) and a literature update by Carlin and Roitman (2009) evaluated the impact of a ventilation-feedback intervention + exercise vs. exercise alone or ventilation-feedback alone. The ventilation-feedback intervention used a computer interface with the patient to provide a visual representation of breathing pattern. This visual representation was used to assist patients to modify their breathing pattern, thereby reducing dynamic hyperinflation. This randomized controlled trial found that the combination of ventilation-feedback plus exercise-training decreased exercise-induced dynamic hyperinflation and increased exercise duration more than ventilation-feedback alone.

Implications for Nursing

These studies and others support a program of regular physical activity to maintain functional status and reduce symptom progression. Additionally, the studies suggest the importance of developing and testing innovative interventions to reduce dynamic hyperinflation, thereby improving exercise duration.

Moving Knowledge into Action

1. Consider other populations for whom regular exercise is recommended (e.g., patients who are overweight, patients with heart failure). What strategies have been shown to reduce symptoms during exercise in these groups? How could these strategies be adapted for patients with COPD?
2. Use the physiologic and psychologic effects of regular exercise to explain its correlation with improved symptoms in the patient with COPD.
3. Consider the age of most patients with COPD. What other physical or psychosocial factors commonly limit physical activity in this population? How can you use this information in designing an appropriate exercise program?

BOX 37–3 Nursing Considerations Related to Lung Transplant

Although immediate postoperative care for patients undergoing lung or heart-lung transplant is provided by specially trained interprofessional teams in transplant centers, increased survival following transplant means that these patients increasingly are seen in community-based settings, nontransplant hospitals, and on general nursing care units. An understanding of common post-transplant complications and the care needs of the post-transplant patient facilitates appropriate nursing care.

COMMON POST-TRANSPLANT COMPLICATIONS

In the early post-transplant period, the most common complications relate to the surgical procedure itself or to rejection of the transplanted organ(s).

Rejection. Acute organ rejection can occur at any time following the transplant. An acute change in FEV_1 and FVC on home spirometry often is the first indication of acute rejection. Other manifestations of rejection include fever, shortness of breath, and an elevated WBC. Because these manifestations are similar to those of infection, the patient is instructed to return to the transplant clinic or center for a transbronchial biopsy. Acute rejection is treated with increased corticosteroids and adjustment of the immunosuppressive regimen (see Chapter 13). Chronic rejection is less amenable to therapy, ultimately necessitating retransplant.

Infection. Prevention of infection is vital in lung transplant patients. The patient is encouraged to reduce his or her risk of infection by avoiding contact with people who have an infectious disease (e.g., URI, shingles, diseases of childhood). Prophylactic trimethoprim-sulfamethoxazole (TMP-SMZ) is administered weekly to prevent *Pneumocystis* pneumonia (see Chapter 36).

Bacterial endocarditis prophylaxis also is provided as needed (see Chapter 31). The post-transplant patient may not have typical manifestations of infection due to immunosuppression. Any vague symptoms with or without fever or leukocytosis are investigated. Recurrent viral infections such as CMV have been associated with chronic rejection, so are aggressively treated with antiviral therapy. Treatment of other infections is targeted to the infectious organism.

NURSING CONSIDERATIONS FOR THE POST-TRANSPLANT PATIENT

Reverse isolation procedures are not necessary unless the neutrophil count is very low ($<500/mm^3$). Use good hand hygiene and standard precautions at all times, and aseptic technique for dressing changes, IV starts and site care, and other invasive procedures (such as urinary catheterization). Do not allow caregivers or visitors with URI to have contact with the patient; a mask may be provided for short visits if contact is unavoidable. Skin surveillance and care are vital following transplant. Intact skin reduces the risk of infection; however, corticosteroid therapy increases the risk for skin tears and breakdown.

The effect of all medications on immunosuppressive therapy and the transplanted organ(s) should be carefully investigated prior to administration. Some antibiotics and other drugs can affect blood levels of immunosuppressants.

Particular attention must be paid to pulmonary hygiene. Denervation of the transplanted lung eliminates the usual cough stimuli. Regularly scheduled coughing and deep breathing, and the use of vibration, percussion, and postural drainage, are important to prevent accumulation of secretions.

COMPLEMENTARY THERAPIES

Complementary therapies may be useful to help manage symptoms of COPD. Dietary measures such as minimizing intake of dairy products and salt may help reduce mucous production and keep mucus more liquefied. Be sure to recommend measures to replace the protein and calcium in dairy products to help maintain nutritional balance.

Herbal teas made with peppermint and yarrow, coltsfoot, or comfrey may act as expectorants to help relieve chest congestion. Licorice root, which may be taken in several forms, also has expectorant and anti-inflammatory effects that may be beneficial. Licorice root can, however, cause toxicity when used for extended periods of time. Refer patients to a qualified herbalist for treatment.

Acupuncture may help the patient with smoking cessation, and also has been used to treat asthma and other respiratory conditions. Hypnotherapy and guided imagery are used to assist with smoking cessation. These techniques also can help the patient control anxiety and breathing patterns. Refer patients to a trained professional. Nurses, physicians, psychologists, counselors, social workers, and others can take professional training in hypnotherapy and guided imagery.

●○● NURSING CARE

Health Promotion

Avoiding smoking is the best preventive measure for chronic obstructive pulmonary disease. Even in patients with COPD, smoking cessation improves lung function and increases survival. Educate all patients, including preschool and school-age children, about the risks of smoking (see Box 37–4).

Assessment

See the Manifestations and Interprofessional Care sections for the assessment of the patient with COPD.

Focused assessment for the patient with chronic obstructive pulmonary disease includes the following:

- *Health history:* current symptoms, including cough, sputum production, shortness of breath or dyspnea, activity tolerance; frequency of respiratory infections and most recent episode; previous diagnosis of emphysema, chronic bronchitis, or asthma; current medications; smoking history (in pack-years—packs per day times number of years smoked), history of exposure to secondhand smoke, occupational or other pollutants
- *Physical assessment:* general appearance, weight for height, mental status; vital signs including temperature; skin color and temperature; anteroposterior-to-lateral chest diameter ratio, use of accessory muscles, nasal flaring or pursed-lip breathing; respiratory excursion and diaphragmatic excursion; percussion tone; breath sounds throughout; neck veins, apical pulse and heart sounds, peripheral pulses, edema
- *Laboratory data:* forced vital capacity (FVC) and forced expiratory volume in 1 second (FEV_1), ABGs, and hematocrit.

Priorities of Care

Collaborating with the interprofessional team to ensure adequate treatment of the underlying process while providing care that supports the physical and psychologic responses to the disorder is a priority of nursing care.

BOX 37–4 Cigarette Smoking and Tobacco Use

The use of tobacco reaches back to early civilizations, when it was used in religious ceremonies and as an offering of friendship. At one time, tobacco was thought to have medicinal qualities effective against all common diseases. Widespread use of tobacco among the male population of the industrialized world began during World War I.

Tobacco is now recognized as the leading cause of preventable illness in the world. Diseases directly related to tobacco use are responsible for the deaths of more than 438,000 Americans every year. Smoking will lead to the deaths of about half of all regular cigarette smokers. In spite of this knowledge, aggressive marketing of the product continues, and its worldwide use is increasing, especially in underdeveloped countries.

The link between tobacco use and lung cancer was reported as early as 1912. In 1987, lung cancer became the leading cause of cancer-related death in the United States among both men and women.

Cigarette smoke contains over 4800 chemicals (69 of which are known to cause cancer), including nicotine (Fiore, 2012). Nicotine is a highly addictive psychoactive substance that is relatively cheap and readily available. It produces euphoria, which acts as a positive reinforcer for continued use. In North American society, tobacco is more acceptable than many other dependency-producing drugs.

Tar is the particulate matter in cigarette smoke that is responsible for most of its carcinogenic and pathologic effects on the lungs. Smoke also paralyzes the cilia, reducing their ability to remove tars from contact with the respiratory epithelium. The risk for cancer and other lung diseases is dose related, affected by the age at which smoking began, the number of cigarettes smoked per day, and the number of years smoked. Smoking cessation reduces the risks associated with tobacco use. For some, such as the risk of coronary heart disease, quitting smoking yields rapid benefits. For others, the degree of risk reduction is less immediate, but still significant.

Nurses need to do more than simply advise patients to quit smoking and talk about the risks of smoking. Nurses can take an active role in smoking cessation. Identify smoking habits, smoking-related illnesses, and previous efforts to quit. Work with the patient to identify barriers and obstacles to quitting. Educate about the addictive nature of nicotine, and explain the manifestations of nicotine withdrawal (anxiety, irritability, headache, and disturbed sleep). Develop a plan with the patient that specifies a target date to quit and includes ways to deal with obstacles to quitting, withdrawal symptoms, and the temptation to resume smoking. Offer self-help material at an appropriate reading level. Refer to a counselor, physician, self-help group, or smoking cessation clinic. If a relapse occurs, accept it as a normal part of rehabilitation from any addictive substance. Continue to provide support and encouragement, helping the patient avoid further relapses.

Nurses can be especially effective in primary prevention of cigarette smoking and the diseases associated with it. Just as tobacco companies direct advertising at women and teens, nurses can target these populations and younger children for programs to prevent smoking. In addition, nurses need to become active in reducing minors' access to tobacco products, especially cigarettes and chewing tobacco (often the first product used by teens).

Nursing diagnoses that may be appropriate related to smoking include the following:

- *Ineffective Health Maintenance* related to tobacco use
- *Decisional Conflict* related to tobacco use
- *Ineffective Denial* related to acknowledgment of substance abuse and dependence.

Diagnoses, Outcomes, and Interventions

Patients with chronic obstructive pulmonary disease, whether hospitalized or in the community, have multiple nursing care needs. Because of the obstructive nature of the disease, airway clearance is a high priority. Nutritional deficit is common, particularly when emphysema is predominant. Because this chronic disease affects all functional health patterns, psychosocial issues are also of concern in planning nursing care. In addition to the nursing diagnoses presented here, see the Case Study & Nursing Care Plan that follows.

Ineffective Airway Clearance

Both chronic bronchitis and emphysema affect the ability to maintain open airways. In chronic bronchitis, copious amounts of thick, tenacious mucus are produced. Ciliary action is impaired, making it difficult to clear mucus from the airways. The loss of supporting tissue caused by emphysema increases the risk for airway collapse. In both cases, air is trapped distally, and less oxygen is available to the alveoli for diffusion. Normal respiratory defense mechanisms are impaired, and mucous-plugged airways provide an ideal environment for bacterial growth. Respiratory infection further impairs airway clearance and is often the cause of an acute exacerbation.

Expected Outcome: Patient will demonstrate movement of air into and out of the lungs.

- Assess respiratory status every 1 to 2 hours or as indicated. Assess rate and pattern; cough and secretions (color, amount, consistency, and odor); and breath sounds, both normal and adventitious. *Frequent assessment is vital to monitor current status and response to treatment. Adventitious sounds should decrease with effective intervention. Diminished or absent breath sounds may indicate increasing airway obstruction and possible atelectasis.*
- Promptly report changes in oxygen saturation, skin color, or mental status. A drop in oxygen saturation levels, increasing cyanosis, or altered level of consciousness indicates hypoxemia, possibly related to airway obstruction.
- Monitor ABG results. *Increasing hypoxemia, hypercapnia, and respiratory acidosis may indicate increasing airway obstruction.*
- Weigh daily, monitor intake and output, and assess mucous membranes and skin turgor. *Dehydration causes respiratory secretions to become thicker, more tenacious, and difficult to expectorate; fluid overload can further compromise respiratory status.*
- Encourage a fluid intake of at least 2000 to 2500 mL per day unless contraindicated. *Adequate fluid intake helps keep mucous secretions thin.*
- Place in Fowler's, high-Fowler's, or orthopneic position; encourage movement and activity to tolerance. *Upright positions improve ventilation and reduce the work of breathing. Activity helps mobilize secretions and prevent them from pooling.*
- Assist with coughing and deep breathing at least every 2 hours while awake. Position seated upright, leaning forward during coughing. *The upright position promotes chest expansion, increasing the effectiveness of coughing and reducing the work involved.*

Evidence for Nursing Care

The Patient with COPD

Selected resources that nurses may find helpful when planning evidence-based nursing care follow.

- Bauldoff, G. S. (2009). When breathing is a burden: How to help patients with COPD. *American Nurse Today*, *4*(9), 17–21.
- Global Initiative for Chronic Obstructive Lung Disease (GOLD). (2013). *Global strategy for the diagnosis, management and prevention of chronic obstructive pulmonary disease.* Media Communications Inc. Retrieved from http://www.goldcopd.org.

- Provide tissues and a paper bag to dispose of expectorated sputum. *This important infection control measure reduces the spread of respiratory organisms to other people.*
- Refer to a respiratory therapist, and assist with or perform percussion and postural drainage as needed. *Percussion helps loosen secretions in airways; postural drainage facilitates movement of these secretions out of the respiratory tract.*
- Provide endotracheal, oral, or nasopharyngeal suctioning as necessary. *Suctioning may be necessary to clear secretions and may stimulate a cough.*
- Provide rest periods between treatments and procedures. *The patient with COPD fatigues easily; adequate rest is important to conserve energy and reduce fatigue.*
- Administer expectorant and bronchodilator medications as ordered. Correlate timing with respiratory treatments. *Using expectorants and bronchodilators prior to coughing, percussion, and postural drainage increases their effectiveness in clearing airways.*
- Provide supplemental oxygen as ordered. *Supplemental oxygen helps maintain adequate blood and tissue oxygenation.*

SAFETY ALERT

Prepare for intubation and mechanical ventilation if respiratory status deteriorates (increasing hypoxemia and hypercapnia, decreased level of consciousness, cyanosis, or worsening airway obstruction). Respiratory failure is a possible complication of an acute exacerbation of COPD and requires immediate intervention to preserve life.

Imbalanced Nutrition: Less Than Body Requirements

With advanced COPD, minimal activity, including eating, can cause fatigue and dyspnea. The patient may be unable to consume a full meal without resting. At the same time, the increased work of breathing (8 to 10 times that of normal) increases metabolic demands, and more calories are required. The patient may appear cachectic (thin and wasted). Poor nutritional status further impairs immune function and increases the risk of a complicating infection.

Expected Outcome: Patient will consume adequate nourishment to promote weight within normal range.

- Assess nutritional status, including diet history, weight for height (use reference tables of desired weights), and anthropometric (skinfold) measurements. *It is important to differentiate nutritional status from body type rather than assume a nutritional impairment.*
- Observe and document food intake, including types, amounts, and caloric intake. *This information can provide direction for supplementation, if needed.*
- Monitor laboratory values, including serum albumin, prealbumin, and electrolyte levels. *These values provide information about the adequacy of nutritional intake, including protein.*
- Consult with a dietitian to plan meals and nutritional supplements that meet caloric needs. *More concentrated sources of high-energy foods may be required to maintain caloric intake without excess fatigue. A diet high in proteins and fats without excess carbohydrates is recommended to minimize carbon dioxide production during metabolism (carbohydrates are metabolized to form CO_2 and water).*
- Provide frequent, small feedings with between-meal supplements. *Frequent, small meals help maintain intake and reduce fatigue associated with eating.*
- Place seated or in high-Fowler's position for meals. *An upright position promotes lung expansion and reduces dyspnea.*
- Assist to choose preferred foods from the menu; encourage family members to bring food from home if allowed. *Providing preferred foods encourages eating.*
- Keep snacks at the bedside. *Snacks provide additional caloric intake.*
- Provide mouth care prior to meals. *This helps enhance the appetite.*
- If unable to maintain oral intake, consult with the physician about enteral or parenteral feedings. *Maintenance of caloric and nutrient intake is vital to prevent catabolism.*

Compromised Family Coping

Chronic illness affects the entire family structure. Roles and relationships change; additional demands are placed on the family. Family members may become overprotective of the patient. Conversely, family members may blame the patient for causing the illness or have distorted perceptions about it, even denying its existence. In the most severe cases, they may refuse to assist or participate in care. The patient may develop an attitude of helplessness or dependence or may demonstrate anger, hostility, or aggression.

Expected Outcome: Patient will identify three healthy coping behaviors that family members can employ to facilitate a shift toward improved family functioning.

- Assess interactions between patient and family. *Assessment helps identify desired and potential destructive behaviors.*
- Assess the effect of the illness on the family. *Assessment of family interactions, roles, and relationships assists in planning appropriate interventions.*
- Help the patient and family identify strengths for coping with the situation. *Identifying personal and family strengths helps the family regain a sense of control.*
- Provide information and teaching about COPD. *Education helps the family gain an understanding of the patient's condition and needs.*
- Encourage expression of feelings. Avoid judging feelings expressed or family members as "good" or "bad," "right" or "wrong." *It is important for the nurse to remain objective to maintain the therapeutic relationship.*
- Help family members recognize behaviors and attitudes that may hinder effective treatment, such as continuing to smoke in the house. *Family members may be unaware of the effect of their*

CASE STUDY & NURSING CARE PLAN A Patient with COPD

Helen Mercurio, known as "Happy" to all her friends, is an 83-year-old widow who lives with her two adult sons. During the past 15 years, Mrs. Mercurio has become increasingly short of breath while gardening and walking, two of her favorite activities. She also has developed a chronic cough that is particularly bad in the mornings. Ten years ago, her family physician told her that she had emphysema. She is admitted to the hospital with possible pneumonia and acute exacerbation of COPD.

ASSESSMENT

Jeff Harris, RN, admits Mrs. Mercurio to the medical unit. In the nursing history, Mr. Harris notes that she denies ever smoking, but says that her husband and two sons have been smokers "for practically their whole lives." She says she lived an active life before developing lung disease, but now her breathing and cough have progressed so that she now must rest after just a few minutes of housework or other activity. Her cough is productive of moderate to large amounts of sputum, particularly in the mornings. She developed increasing shortness of breath and sputum 2 days ago; this morning, she could not complete her morning activities without resting, so she contacted her physician.

On physical examination, Mr. Harris notes the following: skin very warm and dry, color dusky. Pauses frequently while speaking to breathe. Respiratory rate 36/min, fairly shallow; coughs frequently, producing large amounts of thick, tenacious green sputum. Other vital signs: P 115 bpm and irregular, BP 186/60 mmHg, T 39°C (102.4°F). Appears very thin; weight 43.6 kg (96 lb), height 160 cm (63 in.). Anteroposterior-to-lateral chest diameter ratio approximately 1:1 indicating barrel chest; moderate kyphosis noted. Chest hyperresonant to percussion. Auscultation reveals distant breath sounds with scattered wheezes and rhonchi throughout lung fields. Chest x-ray shows flattening of diaphragm, slight cardiac enlargement, prominent vascular and bronchial markings, and patchy infiltrates. Initial laboratory work reveals moderate erythrocytosis, leukocytosis, and low serum albumin. Arterial blood gas results: pH 7.19; PO_2 54 mmHg; PCO_2 59 mmHg; HCO_3^- 30 mg/dL, and O_2 saturation 88%. Admitting orders include sputum specimen for culture; intravenous penicillin G, 2 million units every 4 hours; albuterol/ipratropium (Combivent) inhaler, two puffs every 6 hours; salmeterol/fluticasone (Advair) dry powder inhaler, twice a day; bed rest with bathroom privileges; oxygen per nasal cannula at 2 L continuously; and regular diet.

DIAGNOSES

- *Ineffective Airway Clearance* related to pneumonia and COPD
- *Impaired Gas Exchange* related to acute and chronic lung disease
- *Risk for Impaired Spontaneous Ventilation* related to loss of hypoxemic respiratory drive and respiratory muscle fatigue
- *Impaired Home Maintenance* related to activity intolerance

EXPECTED OUTCOMES

- Patient will expectorate secretions effectively.
- Patient will return to level of pulmonary function prior to acute exacerbation.
- Patient will demonstrate improved arterial blood gas and oxygen saturation values.
- Patient will maintain spontaneous respirations without excess fatigue.
- Patient will verbalize willingness to allow sons or a housekeeper to assist with daily household tasks.

PLANNING AND IMPLEMENTATION

- Assess respiratory status and level of consciousness every 1 to 2 hours until stable, then at least every 4 hours.
- Closely monitor response to oxygen therapy, including skin color, oxygen saturation, sputum consistency, and respiratory drive.
- Increase fluid intake to at least 2500 mL/day and provide bedside humidifier.
- Elevate head of bed to at least 30 degrees at all times.
- Teach huff coughing technique.
- Administer medications as ordered; provide ipratropium inhaler before beclomethasone inhaler. Provide mouth care after inhalers.
- Contact respiratory therapy for percussion and postural drainage following inhaler treatments.
- Provide for uninterrupted rest periods following treatments and procedures.
- Meet with Mrs. Mercurio and her sons to develop a postdischarge care plan.
- Refer to home health department for nursing follow-up.
- Refer to social services for possible assistance with home maintenance.

EVALUATION

After the first day in the hospital, Mrs. Mercurio's condition begins to improve slowly. On discharge 6 days later, she is able to provide self-care with less fatigue and dyspnea. She is using oxygen at night only, admitting that it is just for security. Although a few scattered wheezes and rhonchi are still present in her lungs, Mrs. Mercurio's sputum is thinner, white, and easily expectorated. She will continue taking oral penicillin V for an additional 10 days at home. She will also continue using the Advair and Combivent inhalers as prescribed at home. Although Mrs. Mercurio's sons admit they will probably never be able to quit smoking, they have agreed to smoke only in the garage or outside. A home health nurse will initially evaluate Mrs. Mercurio's progress three times weekly. Arrangements have been made for a housekeeper to come twice a week for cleaning and laundry. Mrs. Mercurio is glad to be returning home and grateful for the arrangements that have been made.

Clinical Reasoning in Patient Care

1. Mrs. Mercurio has never been a smoker but had long-term exposure to secondhand smoke. How does secondhand smoke contribute to lung diseases in adults and children?
2. Mr. Harris's nursing care plan included the nursing diagnosis *Risk for Impaired Spontaneous Ventilation* related to loss of hypoxemic respiratory drive and respiratory muscle fatigue. Identify the normal physiologic events that stimulate breathing, and describe how these differ for the patient with chronic hypoxemia and hypercapnia.
3. The patient with an acute exacerbation of COPD is at risk for respiratory failure. What changes in Mrs. Mercurio's assessment findings could indicate this complication?
4. Develop a nursing care plan for Mrs. Mercurio for the nursing diagnosis *Deficient Diversional Activities* related to inability to continue preferred activities.

See Evaluating Your Response in Appendix B.

behavior on the patient's ability to change habits and cope with a disabling disease.

- Encourage family members to participate in care. *This helps develop skills for use at home.*
- Initiate a care conference involving the patient, family, and health-care team members from a variety of disciplines. *A wide range of perspectives and areas of expertise aids in problem solving and facilitates communication.*

- If dysfunctional family relationships interfere with measures to enhance coping, advocate for the patient, reaffirming his or her right to make decisions. *Dysfunctional family relationships are not likely to change simply because of illness. The nurse can better meet the patient's needs by accepting his or her limitations in dealing with family members.*
- Refer the patient and family to support groups and pulmonary rehabilitation programs, as available. *Support groups and structured rehabilitation programs enhance coping abilities.*
- Arrange a social services consultation. *This can help the patient and family identify care and support service needs.*
- Refer community agencies or services such as home health, homemaker services, or Meals-on-Wheels as appropriate. *Agencies or community services can provide additional support beyond the family's means or capability.*

Decisional Conflict: Smoking

Smoking is more than a habit; it is an addiction. The patient who must quit is facing a significant loss, not only of nicotine but also of a lifestyle. Although the patient may fully comprehend the consequences of continuing to smoke, the decision to give up a part of his or her life is not easy. This fear may be expressed in such concerns as "I'll gain weight" or "What will I do with my hands?" In addition to providing practical information, a plan, and assistance with nicotine withdrawal, the nurse must support the patient's decision-making process to comply with an order to stop smoking.

Expected Outcome: Patient will express an interest in smoking cessation.

- Assess knowledge and understanding of the choices involved and possible consequences of each. *The decision to quit smoking ultimately belongs to the patient. He or she needs a full understanding of the consequences of quitting or continuing to smoke.*
- Acknowledge concerns, values, and beliefs; listen nonjudgmentally. *The nurse needs to avoid imposing his or her values and beliefs about smoking on the patient.*
- Spend time with the patient, encouraging expression of feelings. *This demonstrates acceptance of the patient and his or her right to make the decision.*
- Help plan a course of action for quitting smoking and adapt it as necessary. *When the patient develops the plan, he or she has more ownership in it and interest in making it work.*
- Demonstrate respect for decisions and the right to choose. *Respect supports self-esteem and the ability to cope.*
- Provide referral to a counselor or other professional as needed. *Counselors or other people trained to assist with smoking cessation can help with decision making.*

Continuity of Care

As with any chronic disease, the patient and family will have primary responsibility for disease management. Teaching is vital to promote optimal health and slow disease progression. Teaching for home care focuses on effective coughing and breathing techniques (Box 37–5), preventing exacerbations, and managing prescribed therapies.

In addition, include the following topics when teaching for home care:

- Maintaining adequate fluid intake, at least 2.0 to 2.5 quarts of fluid daily
- Avoiding respiratory irritants, including cigarette smoke, both primary and secondary, other smoke sources, dust, aerosol sprays, air pollution, and very cold dry air
- Preventing exposure to infection, especially upper respiratory infections
- Importance of pneumococcal vaccine and annual influenza immunization
- Prescribed exercise program, maintaining ADLs, and balancing rest and exercise
- Maintaining nutrient intake (e.g., eating small frequent meals and using nutritional supplements to provide adequate calories)
- Ways of reducing sodium intake if prescribed
- Identifying early signs of an infection or exacerbation and the importance of seeking medical attention for the following: fever, increased sputum production, purulent (green or yellow) sputum, upper respiratory infection, increased shortness of breath or difficulty breathing, decreased activity tolerance or appetite, increased need for oxygen
- Prescribed medications, including purpose, proper use, and expected effects

BOX 37–5 Patient Teaching: Effective Coughing and Breathing Techniques

Pursed-lip and diaphragmatic breathing techniques help minimize air trapping and fatigue. Pursed-lip breathing helps maintain open airways by maintaining positive pressures longer during exhalation. Teach the patient to do the following:

1. Inhale through the nose with the mouth closed.
2. Exhale slowly through pursed lips, as though whistling or blowing out a candle, making exhalation twice as long as inhalation.

Diaphragmatic or abdominal breathing helps conserve energy by using the larger and more efficient muscles of respiration. Teach the patient to do the following:

1. Place one hand on the abdomen, the other on the chest.
2. Inhale, concentrating on pushing the abdominal hand outward while the chest hand remains still.
3. Exhale slowly, while the abdominal hand moves inward and the chest hand remains still.

Repeat these exercises as often as necessary until the techniques become incorporated into normal breathing.

Several different coughing techniques may be useful. For controlled cough technique, teach the patient to do the following:

1. Following prescribed bronchodilator treatment, inhale deeply, and hold breath briefly.
2. Cough twice, the first time to loosen mucus, the second to expel secretions.
3. Inhale by sniffing to prevent mucus from moving back into deep airways.
4. Rest. Avoid prolonged coughing to prevent fatigue and hypoxemia.

For huff coughing, teach the patient to do the following:

1. Inhale deeply while leaning forward.
2. Exhale sharply with a "huff" sound, to help keep airways open while mobilizing secretions.

- Avoiding use of OTC medications unless approved by the physician
- Other prescribed therapies, such as use of home oxygen, percussion, postural drainage, and nebulizer treatments
- Use, cleaning, and maintenance of any required special equipment
- Importance of wearing an identification band and carrying a list of medications at all times in case of an emergency.

Provide referrals to home care services such as home health, assistance with ADLs as needed, home maintenance services, respiratory therapy and home oxygen services, and other agencies such as Meals-on-Wheels and senior services as indicated.

THE PATIENT WITH CYSTIC FIBROSIS

Cystic fibrosis (CF) is an autosomal recessive disorder that affects epithelial cells of the respiratory, gastrointestinal, and reproductive tracts and leads to abnormal exocrine gland secretions (see the accompanying box). Although it can affect many organ systems, CF is particularly damaging to the lungs, leading to COPD in childhood and early adulthood. Respiratory manifestations of CF are the usual cause of morbidity and death from this disease. The gastrointestinal tract also is affected significantly; exocrine pancreatic insufficiency is characteristic of CF. Abnormally high sweat electrolytes also occur in CF.

Pathophysiology

The CFTR protein is involved in membrane transport of chloride and sodium in cells lining the ducts of exocrine glands (sweat glands, pancreas, liver, and reproductive systems). The genetic abnormality of CF leads to a lack or abnormality of this protein, with resulting abnormal electrolyte transport across epithelial cell membranes. Defective chloride transport causes more water and sodium reabsorption than normal. Secretions in affected organs become thick and viscous, obstructing glands and ducts. This obstruction causes dilation of secretory glands and damage to exocrine tissue. The hallmark pathophysiologic effects of CF include the following:

- Excess mucous production in the respiratory tract with impaired ability to clear secretions and progressive COPD
- Pancreatic enzyme deficiency and impaired digestion
- Abnormal elevation of sodium and chloride concentrations in sweat.

In the lungs, viscous mucous plugs small airways and impairs mucociliary clearance, leading to atelectasis, infection, bronchiectasis, and dilation of distal airways. Lower respiratory infections with *Staphylococcus aureus* and *Pseudomonas* are common (Huether & McCance, 2011). Acute and chronic damage to lung parenchyma causes tissue loss and extensive scarring and fibrosis. The upper lobes are involved to a greater extent than the lower lobes. Severe airway obstruction and chronic hypoxemia lead to pulmonary hypertension, right ventricular hypertrophy, and eventual cor pulmonale. Death usually results from a combination of cardiovascular changes and respiratory failure.

Pancreatic insufficiency is a frequent component of CF. It can range from slight pancreatic dysfunction to complete absence of function due to obstruction of pancreatic ducts with thick mucus and degenerative and fibrotic changes. Pancreatic insufficiency and impaired enzyme secretion lead to impaired digestion and absorption of proteins, carbohydrates, and fats.

About 8% of patients with CF develop diabetes mellitus (Huether & McCance, 2011). Liver failure is another potential complication of the disease. Because the genetic defect also affects cells of the reproductive tract, males with CF usually are sterile. Although females may have difficulty conceiving, pregnancies usually are carried to term.

Manifestations

Manifestations of CF in a young adult include a history of chronic lung disease. Recurrent pneumonia, exercise intolerance, and chronic cough are typical. Other pulmonary manifestations include *clubbing* of the fingers and toes (Figure 37–5 ■), increased anteroposterior chest diameter (barrel chest), hyperresonant percussion tone, and basilar crackles on auscultation. Distended neck veins, ascites, and peripheral edema accompany right-sided heart failure. Abdominal pain and *steatorrhea* (excess fat in the stools, causing frequent, bulky, foul-smelling stool) commonly result from associated pancreatic insufficiency. Growth and development are often retarded, resulting in small stature.

GENETIC CONSIDERATIONS

Cystic Fibrosis

The gene responsible for cystic fibrosis is at a single locus on the long arm of chromosome 7. This gene codes for a protein known as the *cystic fibrosis transmembrane conductance regulator* (CFTR). More than 1000 mutations of this gene have been identified. The most common mutation, identified as ΔF508, accounts for about 66% of cystic fibrosis. Cystic fibrosis is an autosomal recessive disorder: It is not transmitted as a sex-linked trait, and the normal gene is dominant. People with one abnormal gene do not have the disorder but can transmit this abnormal gene to their offspring. When a child inherits an abnormal gene from both parents, the disorder is seen. Genetic screening of family members of a CF patient can detect 70% to 75% of carriers of the CF gene. Screening for the CF gene is not recommended for the general population.

Figure 37–5 ■ Clubbing of fingers caused by chronic hypoxemia.

Incidence and Prevalence

CF is the most common lethal genetic disease in Caucasian Americans, affecting about 1 in 2500 live births. It is less common in African Americans and rare in Asians. About 5% of Caucasians in the United States carry the CF trait. Although the manifestations of CF usually develop in childhood, about 7% of patients with CF are diagnosed as adults. Adults now make up more than 45% of the CF population in the United States, with the median survival at 37 years. Children born in 2012 with CF can expect to survive into their 50s and beyond (Cystic Fibrosis Foundation [CFF], 2012).

●○● INTERPROFESSIONAL CARE

The treatment plan for cystic fibrosis is multidisciplinary, with the goals of preventing or treating respiratory complications and maintaining adequate nutrition. Psychosocial care is vital, as is genetic and occupational counseling.

DIAGNOSIS

Although evidence of lung disease and pancreatic insufficiency suggest CF, analysis of Cl^- concentration in sweat is used to confirm the diagnosis. In CF, the Cl^- concentration is $>$ 70 mEq/L. Pilocarpine (a parasympathomimetic agent) and a small electric current are used to increase sweat production on the forearm. Absorbent paper or gauze is used to collect the sweat for analysis.

ABGs and oxygen saturation levels show hypoxemia. Pulmonary function studies reveal reduced airflow, reduced forced vital capacity, and reduced total lung capacity. Alveolar-capillary diffusion also is typically reduced.

MEDICATIONS

Immunization against respiratory infections is vital to promote optimal health. Yearly influenza vaccine is recommended, along with measles and pertussis boosters as needed.

Bronchodilator inhalers may be used to control airway constriction. Acute pulmonary infections are treated with appropriate antibiotic therapy as determined by sputum culture and sensitivity tests. A prolonged treatment course or multiple antibiotics may be required to eradicate pulmonary infections. Antibiotics may be administered by several routes, including inhalation, to achieve the desired concentration in large airways. Dornase alfa, recombinant human DNase, breaks down the excess DNA in the sputum of patients with CF, decreasing its viscosity and making it easier to clear. Dornase alfa, administered by aerosol, reduces the frequency of hospitalizations and the need for antibiotics for some patients.

TREATMENTS

Chest physiotherapy with percussion and postural drainage is used to promote airway clearance. Newer airway clearance techniques include the use of the huff cough technique with specified breathing cycles or patterns. In one technique, a valved mask or mouthpiece is used to maintain positive expiratory pressure (PEP) for approximately 20 breaths, followed by three to five huff coughs. This cycle is repeated for a total of 20 minutes. The autogenic drainage technique, a form of biofeedback, involves controlled breathing at specific lung volumes and patterns to facilitate the movement of mucus into larger airways, where it can be cleared with the huff cough. Oscillating positive expiratory pressure uses a flutter valve device, which looks like a fat pipe and contains a steel ball within an inner cone. The weight of the ball provides intermittent PEP, which vibrates airway walls to loosen secretions (CFF, 2012).

Oxygen therapy may be required for hypoxemia. A liberal fluid intake helps reduce the viscosity of mucous secretions. A diet high in protein, fat, and calories may be necessary to maintain weight. Vitamins and minerals are supplemented to counteract excess losses in the sweat and stools. Enteral or parenteral nutrition may be required during acute exacerbations of the disease.

SURGERY

Lung transplantation currently offers the only definitive treatment for CF, but is not considered a cure—the patient trades CF for the lifelong management of transplanted organs. Lung transplantation lengthens life span and improves quality of life. In CF, double lung transplant is indicated. Single-lung transplant is contraindicated due to the chronic infection in the lungs. Because the donor lungs do not have the CF gene, they do not develop the pathophysiologic changes of CF. Although the other defects characteristic of CF remain, these can be managed with pharmacologic therapy.

●○● NURSING CARE

Nursing care for the patient with cystic fibrosis is much the same as that for any chronic obstructive lung disease. Promoting airway clearance is the priority of nursing care. The genetic component of the disease and the patient's age are important considerations. Adults with CF are just entering their productive years and face a life span that is likely to be shortened significantly. Females who do conceive face the prospect of transmitting the defective gene to their offspring.

Ineffective Airway Clearance

Bronchial hygiene measures, including vibration, percussion, and postural drainage, are the mainstay of treatment for patients with CF.

Expected Outcome: Patient will use techniques to promote airway clearance such as coughing, deep breathing and mechanical clearance techniques including chest physical therapy.

- Assess respiratory status, including vital signs, breath sounds, SaO_2, and skin color at least every 4 hours. *Early identification of respiratory compromise allows intervention before tissue hypoxia is significant.*
- Assess cough and sputum (amount, color, consistency, and possible odor). *Assessment of the cough and nature of sputum produced allows evaluation of the effectiveness of respiratory clearance and the response to therapy.*
- Monitor arterial blood gas results; report increasing hypoxemia and other abnormal results to the physician. *Blood gas changes may be an early indicator of impaired gas exchange due to airway obstruction.*
- Place in Fowler's or high-Fowler's position. Encourage frequent position changes and ambulation as allowed. *The upright position promotes lung expansion; position changes and ambulation facilitate the movement of secretions.*
- Assist to cough, deep breathe, and use assistive devices. Provide endotracheal suctioning using aseptic technique as ordered. *Coughing, deep breathing, and suctioning help clear airways.*

- Provide a fluid intake of at least 2500 to 3000 mL/day. *A liberal fluid intake helps liquefy secretions, facilitating their clearance.*
- Work with the physician and respiratory therapist to provide pulmonary hygiene measures, such as postural drainage, percussion, and vibration. *These techniques help mobilize and clear secretions.*
- Administer prescribed medications as ordered, and monitor their effects. *If the infecting organism is resistant to the prescribed antibiotic, little improvement may be seen with treatment. Bronchodilators help maintain open airways but may have adverse effects such as anxiety and restlessness.*

Anticipatory Grieving

The patient with CF and family members face the knowledge that life span is likely to be short: The median survival is 36.8 years (CFF, 2012).

Expected Outcome: Patient and family will discuss the meaning of losses (actual or perceived) to the patient and family's life.

- Spend time with the patient and family. *Time is necessary to develop a trusting, therapeutic relationship.*
- Answer questions honestly; do not deny the probable outcome of the disease. *Honesty reinforces reality and provides a sense of control over decisions to be made.*
- Encourage the patient and family to express their feelings, fears, and concerns. *Open expression of feelings helps to promote understanding and acceptance.*
- Assist with understanding the grieving process and acceptance of feelings as normal. *Feelings of guilt, anger, or depression may cause the patient to withdraw from others. Explanation of the grieving process enhances understanding and ability to cope.*
- Help the patient and family make decisions regarding treatment and care. *This also is important to give them a sense of control.*
- Encourage use of other support systems, such as spiritual and social groups. Refer the patient and family to support groups, social support services, and hospice care as indicated. *These support systems provide emotional support and help the patient and family cope with the diagnosis.*
- Discuss advance directives (the living will) and power of attorney for healthcare with the patient and family. *These documents give the patient and family a sense of control over medical care provided if the patient is no longer able to express his or her own wishes.*

Continuity of Care

Education of the patient and family affected by cystic fibrosis is essential to maintaining optimal health. The adult whose disease was diagnosed in infancy or childhood has grown up with the disease and often has a much greater knowledge level than many caregivers. However, when the initial diagnosis is made as an adolescent or young adult, teaching needs are significant. Include the following topics when teaching for home care:

- Respiratory care techniques, including percussion, postural drainage, and controlled cough techniques
- Specific breathing and coughing exercises and procedures
- The importance of avoiding respiratory irritants, such as cigarette smoke, air pollution, and occupational dusts and gases
- Measures to prevent respiratory infection, such as maintaining immunizations and optimal general health, and avoiding exposure to large crowds and infected people.

Refer to a dietitian for planning and teaching to maintain adequate nutrition and minimize gastrointestinal symptoms. Referral to community agencies and support groups is also helpful.

Discuss the genetic transmission of cystic fibrosis and refer for counseling and possible genetic testing. Help the patient and family sort through the impact of the disease on future pregnancies and generations. Remember that the possibility of CF may present an ethical dilemma regarding future pregnancies. Provide support as needed.

THE PATIENT WITH ATELECTASIS

Atelectasis is not a disease but a condition associated with many respiratory disorders. It is a state of partial or total lung collapse and airlessness. It may be acute or chronic. The most common cause of atelectasis is obstruction of the bronchus ventilating a segment of lung tissue. The affected segment may be small or an entire lobe. Other causes include compression of the lung by pneumothorax, pleural effusion, or tumor; or loss of pulmonary surfactant and inability to maintain open alveoli.

The manifestations of atelectasis depend on its size. Diminished breath sounds over the affected area may be the only sign of a small atelectasis. If a large lung segment is affected, manifestations may include tachycardia, tachypnea, dyspnea, cyanosis, and other signs of hypoxemia. Chest expansion may be reduced and breath sounds absent on the affected side. Fever and other manifestations of infection may be present.

Chest x-ray shows an area of airless lung. CT scan may help determine the cause of atelectasis.

The primary therapy for atelectasis is prevention. High-risk patients, such as those with COPD, smokers undergoing surgery, and people on prolonged bed rest or mechanical ventilation, should have vigorous chest physiotherapy to maintain open airways. Frequently assess respiratory status, including rate, breath sounds, and spirometry readings for early detection and treatment.

When atelectasis develops, treatment focuses on the underlying cause. Vigorous coughing and chest therapy may relieve obstruction by a mucous plug. Bronchoscopy may be necessary to remove the obstruction. Antibiotic therapy is ordered to treat infectious causes.

Nursing care to prevent and treat atelectasis is directed toward airway clearance. Position the patient with atelectasis on the unaffected side to promote gravity drainage of affected segment. Encourage frequent position changes, ambulation, coughing, and deep breathing. Unless contraindicated, encourage fluids to help liquefy secretions. Teach the patient at high risk for developing atelectasis about pulmonary care measures, fluid intake, and preventing pulmonary infections.

THE PATIENT WITH BRONCHIECTASIS

Bronchiectasis is characterized by permanent abnormal dilation of one or more large bronchi and destruction of bronchial walls. Infection often is present. The destructive process of bronchiectasis is initiated by inflammation, usually due to recurrent airways infection.

About half of all cases of bronchiectasis are related to cystic fibrosis. Other causes include infections, such as severe pneumonia, tuberculosis, or fungal infections; lung abscess; exposure to toxic gases; abnormal lung or immunologic defenses; and localized airway obstruction due to a foreign body or tumor. Inflammation and airway obstruction are common to all these processes. Bronchial walls become weakened and dilated as a result, leading to pooling of secretions and further infection and inflammation.

A chronic cough productive of large amounts of mucopurulent sputum is characteristic. Other manifestations of bronchiectasis include hemoptysis, recurrent pneumonia, wheezing and shortness of breath, malnutrition, right-sided heart failure, and cor pulmonale.

Collaborative care for bronchiectasis focuses on maintaining optimal pulmonary function and preventing progression of the disorder. The diagnosis is typically based on the history and physical examination. Chest x-ray and CT scan may be ordered to help confirm the diagnosis and determine the extent of lung damage.

Antibiotics are prescribed at the first indication of infection and may also be used prophylactically. Inhaled bronchodilators may be ordered. Chest physiotherapy is a vital component of continuing care for bronchiectasis. Percussion and postural drainage help mobilize secretions. Oxygen may be prescribed. Bronchoscopy may be used to clear retained secretions or obstruction or to evaluate hemoptysis. If lung destruction is localized and unresponsive to conservative management, surgical lung resection may be necessary.

Nursing care of the patient with bronchiectasis is similar to that for patients with other obstructive lung diseases. Airway clearance is a primary problem, as is ineffective breathing pattern. Other applicable nursing diagnoses may include *Impaired Gas Exchange*, *Imbalanced Nutrition: Less Than Body Requirements*, and *Self-Care Deficit*.

Interstitial Lung Disease

There are more than 130 pulmonary disorders that are considered interstitial lung diseases (ILDs). These damage the interstitial or connective tissue of the lung. Occupational lung diseases, sarcoidosis, and rheumatologic diseases such as scleroderma or systemic lupus erythematosus can result in ILD. Toxic drugs and radiation also cause interstitial damage. Table 37–4 identifies common causes of interstitial lung disorders.

These disorders may be acute or insidious. Their rate of progression varies from person to person, as does the degree of disability they produce.

THE PATIENT WITH AN OCCUPATIONAL LUNG DISEASE

Occupational lung diseases are a diverse group of disorders directly related to inhalation of noxious substances in the work environment. There are two major classifications of occupational lung diseases:

- *Pneumoconioses*, chronic fibrotic lung diseases caused by inhalation of inorganic dusts and particulate matter. These include silicosis, coal worker's pneumoconiosis, and asbestosis.
- *Hypersensitivity pneumonitis*, allergic pulmonary diseases caused by exposure to inhaled organic dusts. These include farmer's lung, hot tub lung, and pigeon-breeder's lung.

FAST FACTS

- In the United States, occupational illnesses and injuries account for more than $128 and $150 billion, respectively, in direct and indirect costs per year.

Physiology Review

Lung tissue contains elastin and collagen fibers. Elastin fibers are easily stretched, facilitating lung expansion. Collagen fibers, in contrast, resist stretching. This increases the work of breathing. Both elastin and collagen affect lung compliance, or the ease with which the lungs are inflated. Other factors affecting compliance include the water content of lung tissue and surface tension (Huether & McCance, 2011).

Pathophysiology and Manifestations

When a noxious substance is inhaled, the response to that substance depends on the following:

- The size of particulates
- Its nature (organic or inorganic)
- Where it deposits in the respiratory tract
- The susceptibility of the individual.

TABLE 37–4 Selected Causes of Interstitial Lung Disorders

Cause	Examples
Inorganic dusts	Silica (silicosis), asbestos (asbestosis), coal (coal worker's pneumoconiosis), talc (talcosis)
Organic dusts	Cotton (byssinosis), sugar cane (bagassosis), moldy hay (farmer's lung)
Drugs	Antineoplastic agents, antibiotics, gold salts, phenytoin
Radiation	External radiation or inhaled radioactive materials
Infections	Widespread TB or fungal infections, viral or *Pneumocystis jiroveci* pneumonia
Poisons and noxious gases	Paraquat, nitrogen dioxide, chlorine, ammonia, sulfur dioxide
Systemic diseases	Uremia, pulmonary edema
Unknown causes	Sarcoidosis, idiopathic pulmonary fibrosis, connective tissue disorders

Relatively large particles, larger than 6 microns, are too big to reach lower airways and often are deposited in the nose. Smaller particles can be carried with inspired air into the alveoli. Normal lung defenses, including alveolar macrophages, lymph channels, and the mucociliary escalator, attempt to remove particulate matter from the alveoli. Cigarette smoking, alcohol ingestion, or hypersensitivity reactions can impair these defenses.

The inhaled substance damages alveolar epithelium, leading to an inflammatory process of the alveoli and interstitial tissue of the lung. The inflammatory response produces further damage, and abnormal fibrotic (scar) tissue replaces the elastin fibers of normal lung tissue. As a result, the lungs become stiff and noncompliant. Lung volumes decrease, the work of breathing increases, and alveolar-capillary diffusion is impaired, leading to hypoxemia.

ASBESTOSIS

Inhalation of asbestos fibers is a common cause of occupational lung disease. *Asbestosis* is a diffuse interstitial fibrotic disease involving the terminal airways, alveoli, and pleurae. Exposure to asbestos fibers occurs during mining, milling, manufacturing, and application of asbestos products. Although symptoms may not become apparent until 20 years after exposure, they tend to progress, even when further exposure has been halted. Asbestosis is also associated with an increased risk of bronchogenic carcinoma, especially in cigarette smokers. Mesothelioma, a rare cancer of the pleural membrane, is also associated with asbestos exposure. The period between asbestos exposure and tumor development in mesothelioma is long, ranging from 20 to 30 years. People exposed to asbestos prior to imposition of strict environmental controls may only now be developing manifestations of this disease.

The manifestations of asbestosis include exertional dyspnea, exercise intolerance, and inspiratory crackles. Diffuse, small, irregular, or linear opacities appear on chest x-ray, primarily in the lower lobes. As the disease progresses, respiratory failure and marked hypoxemia may develop.

SILICOSIS

Inhalation of silica dust by hard-rock miners, foundry workers, sandblasters, pottery makers, and granite cutters can lead to *silicosis*, a nodular pulmonary fibrosis. Silicosis affects 1.2 to 3 million workers in the United States. Although generally associated with long-term exposure to silica, it can develop in as little as 10 months of intense exposure. In silicosis, macrophages are destroyed as they engulf silica particles, releasing substances that damage lung tissue and lead to fibrosis and scarring.

Simple silicosis is asymptomatic with no demonstrable respiratory impairment. In contrast, complicated silicosis is characterized by large conglomerate densities in the upper lungs. These patients may be severely dyspneic and have a productive cough. Pulmonary function testing shows both restrictive and obstructive changes. Increasing size of conglomerate masses can lead to severe disability, cor pulmonale, and death.

COAL WORKER'S PNEUMOCONIOSIS

Ingestion of coal dust by alveolar macrophages causes "coal macules" to form, leading to *coal worker's pneumoconiosis*, or *black lung disease.* This occupational lung disease affects 12% of all miners, with a higher incidence in the eastern United States than in the West. Coal macules appear on chest x-ray as diffuse, small opacities primarily affecting the upper lungs.

Simple coal worker's pneumoconiosis (CWP) generally is asymptomatic. A small percentage of patients (1% to 2%) develop progressive massive fibrosis, which destroys the pulmonary vascular bed and airways of the upper lungs. This progressive form of the disease causes symptoms similar to those of complicated silicosis.

HYPERSENSITIVITY PNEUMONITIS

Workers exposed to organic dusts and gases may develop *hypersensitivity pneumonitis*, an allergic pulmonary disease affecting the airways and alveoli. Byssinosis (resulting from cotton dust exposure), bagassosis (due to exposure to moldy sugar cane fiber), farmer's lung, and pigeon-breeder's lung are examples of hypersensitivity pneumonitis.

Either acute or subacute illness can occur. Acute illness occurs 4 to 8 hours after exposure and is heralded by sudden onset of malaise, chills and fever, dyspnea, cough, and nausea. The subacute syndrome is characterized by an insidious onset of chronic cough, progressive dyspnea, anorexia, and weight loss. Diffuse fibrosis occurs after repeated exposure to the organic material, leading to respiratory insufficiency.

●○● INTERPROFESSIONAL CARE

Prevention is a key strategy for all occupational lung diseases. Containing dust and wearing personal protective devices that limit the amount of inhaled particles are essential for people who work in industries with known risks.

Chest x-ray, pulmonary function studies, bronchoscopy, and possibly lung biopsy are used to establish the diagnosis of pneumoconioses. Characteristic patterns are seen for each disorder on x-ray. Pulmonary function testing shows restrictive impairment of lung ventilation, with reduced vital capacity and reduced total lung capacity. The diffusing capacity of the lungs is also decreased. Blood gas analysis reveals hypoxemia, especially with exercise. Bronchoscopy may be performed to obtain tissue for biopsy. Specialized lung scans may be used to determine the extent of fibrosis.

Eliminating further exposure to the offending agent is an important part of disease management. There is no specific therapy. Anti-inflammatory drugs, such as corticosteroids, may reduce the inflammatory response and slow the progression of the disease. Preventing exposure to other damaging substances such as cigarette smoke and pollution is vital. Pneumococcal vaccine and annual influenza immunizations are recommended to reduce the risk of lower respiratory infections. Other care is supportive, similar to that for COPD.

●○● NURSING CARE

Health Promotion

Teaching about the dangers of occupational lung diseases and ways to reduce their risk needs to begin early, before the disease develops. Nurses in industrial and public health settings can begin by recognizing potential dangers and teaching workers about measures to reduce dust in their work area and the use of personal protective devices such

as masks. Nurses working with affected families have an excellent opportunity to begin educating children about the risks associated with the occupation.

Assessment

See the Manifestations and Interprofessional Care sections for the assessment of the patient with occupational lung diseases.

Priorities of Care

Collaborating with the interprofessional team to ensure adequate treatment of the underlying process while providing care that supports the physical and psychologic responses to the disorder is a priority of nursing care.

Diagnoses, Outcomes, and Interventions

Nursing care for patients with occupational lung diseases is similar to that for patients with COPD. Activity intolerance is a high-priority problem for many patients. Severe dyspnea can significantly interfere with ADLs. Nursing measures to reduce energy expenditures and provide for rest are essential. Caregiver role strain, either actual or potential, must be considered when the patient with severe disability is being cared for at home.

Both patient and family coping may be compromised. Many of these diseases develop after 20 to 30 years of exposure to the hazardous material. Patients who entered the industry following high school may develop evidence of disease in their 40s and face the possibility of changing their occupation or developing significant disability. The resulting role strain affects all members of the family.

Other nursing diagnoses to consider for the patient with an occupational lung disease follow:

- *Ineffective Breathing Pattern* related to restrictive lung disease
- *Anticipatory Grieving* related to potential loss of employment and income
- *Situational Low Self-Esteem* related to change of occupation.

Continuity of Care

The affected patient and family need teaching in preparation for home care, including the following:

- Prevention of further lung damage (e.g., avoiding cigarette smoke and heavy air pollution)
- Recommendations for pneumococcal and annual influenza immunizations; yearly tuberculin testing for patients with silicosis
- Pulmonary hygiene measures, such as liberal fluid intake, coughing, and deep-breathing exercises
- Use and care of oxygen therapy equipment if required
- Use and effects of any prescribed or recommended OTC medications.

THE PATIENT WITH SARCOIDOSIS

Sarcoidosis is a chronic, multisystem disease characterized by an exaggerated cellular immune response in involved tissues. This abnormal immune response leads to granuloma formation in the lungs, lymph nodes, liver, eyes, skin, and other organs. Its cause is unknown. Sarcoidosis primarily affects young adults between the ages of 20 and 40. In the United States, the incidence is highest in African Americans. Women are affected at a slightly higher rate than men.

In sarcoidosis, multiple granulomas form; these lesions may resolve spontaneously or proceed to fibrosis. The lungs are affected in about 90% of patients with sarcoidosis. Sarcoidosis has a low mortality rate—less than 3%—but a relatively high rate (approximately 10%) of serious disability from ocular, respiratory, or other organ damage. Pulmonary hemorrhage and cardiac and respiratory failure from pulmonary fibrosis are the leading causes of death from sarcoidosis.

The manifestations of sarcoidosis vary, depending on the organ system affected. It may be asymptomatic, diagnosed by characteristic findings on routine chest x-ray. Symptoms may be insidious, with anorexia, fatigue, weight loss, fever, dyspnea, arthralgias, and myalgias. Skin lesions, uveitis, lymphadenopathy, hepatomegaly, or other manifestations may also develop.

Leukopenia, eosinophilia, and an elevated erythrocyte sedimentation rate (ESR) typically are noted in sarcoidosis. The chest x-ray helps to determine the extent of pulmonary involvement. Biopsy of a granulomatous lesion may be required to confirm the diagnosis. Pulmonary function tests reveal decreased compliance and impaired diffusing capacity.

Sarcoidosis often resolves spontaneously, therefore treatment is indicated only when symptoms are severe or disabling. Corticosteroid therapy is prescribed to suppress the inflammatory process when indicated. Relapse frequently occurs when corticosteroids are discontinued. Other anti-inflammatory or immune-modifier medications may also be used, including chloroquine, indomethacin, azathioprine, and methotrexate.

Nursing care for patients with sarcoidosis is directed by involved organ systems and related manifestations. Respiratory care is supportive and includes avoiding respiratory irritants and maintaining adequate ventilation. Refer for smoking cessation assistance as needed.

Teach patients with limited symptoms about the disease and symptoms to report to a healthcare provider, including shortness of breath, tearing and eye inflammation, chest pain or irregular pulse, skin lesions, and swollen and painful joints. If corticosteroid therapy is prescribed, teach the importance of taking the drug as prescribed and not stopping it abruptly. Include information about managing the side effects of corticosteroids by limiting sodium and increasing potassium in the diet, taking the medication with food or milk to minimize gastric irritation, and identifying early signs of infection.

Pulmonary Vascular Disorders

The cardiovascular and respiratory systems are closely interrelated. As blood flows through the capillary network of the pulmonary vascular system, oxygen diffuses into it, and carbon dioxide diffuses out. An effective match of alveolar ventilation and capillary perfusion is essential to maintain this process and, ultimately, tissue oxygenation and function of all organ systems. Both vascular and alveolar changes can alter gas exchange. Arteriosclerotic changes in pulmonary vasculature reduce blood flow to the alveolus. Nearly

all lower respiratory system disorders potentially can affect ventilation. Many also have a secondary effect on lung perfusion, because breakdown or fibrosis of alveolar walls destroys the capillary network as well. This section focuses on primary disorders of the pulmonary vascular system.

THE PATIENT WITH A PULMONARY EMBOLISM

A **pulmonary embolism** (or *thromboembolism*) is obstruction of blood flow in part of the pulmonary vascular system by an embolus. Thromboemboli, or blood clots, that develop in the venous system (deep venous thrombosis or DVT) or right side of the heart are the most frequent cause of pulmonary embolism. Other sources of emboli include tumors that have invaded venous circulation, fat or bone marrow entering the circulation due to fracture or other trauma, amniotic fluid released into the circulation during childbirth, and intravenous injection of air or other foreign substances.

Pulmonary embolism is a medical emergency. Fifty percent of deaths from pulmonary embolism occur within the first 2 hours following embolization. In many cases, DVT has not been recognized or treated; often embolization also goes undetected. Prevention is the most effective treatment strategy for pulmonary embolism.

Physiology Review

The right heart receives deoxygenated blood from the systemic venous circulation. The entire output of the right ventricle enters the pulmonary circulation via the pulmonary artery. This artery branches into successively smaller arteries, arterioles, and capillaries of the pulmonary vascular system. Each alveolus of the lungs is surrounded by a meshwork of capillaries. Oxygen and carbon dioxide readily diffuse across the alveolar-capillary membrane, driven by a concentration gradient. The partial pressure of oxygen in the alveolus is greater than in the capillary, therefore it diffuses into the blood. Carbon dioxide diffuses from the capillaries into the alveoli, driven by the higher pressure of dissolved carbon dioxide in venous blood.

A match between blood flow through the pulmonary vascular system (perfusion) and lung ventilation is necessary for effective *respiration* (gas exchange) (refer to Figure 37–4). Local factors regulate ventilation and perfusion to maintain this match. A low alveolar PO_2 constricts alveolar capillaries, directing blood flow to better ventilated areas of the lung. High alveolar PCO_2 levels cause local bronchodilation, increasing airflow and eliminating excess carbon dioxide.

Pathophysiology

Thrombi affecting only the deep veins of the calf rarely embolize to the pulmonary circulation. However, thrombi often propagate proximally to the popliteal and ileofemoral veins. From there, they may break loose to become an embolus. As vessels of the venous system become progressively larger, the embolus moves freely until it enters the pulmonary arterial system with its progressively smaller vessels leading to the pulmonary capillary beds (Figure 37–6 ■).

The impact of a pulmonary embolus depends on the extent to which pulmonary blood flow is obstructed, the size of the embolus, its nature, and secondary effects of the obstruction. The effects can range widely:

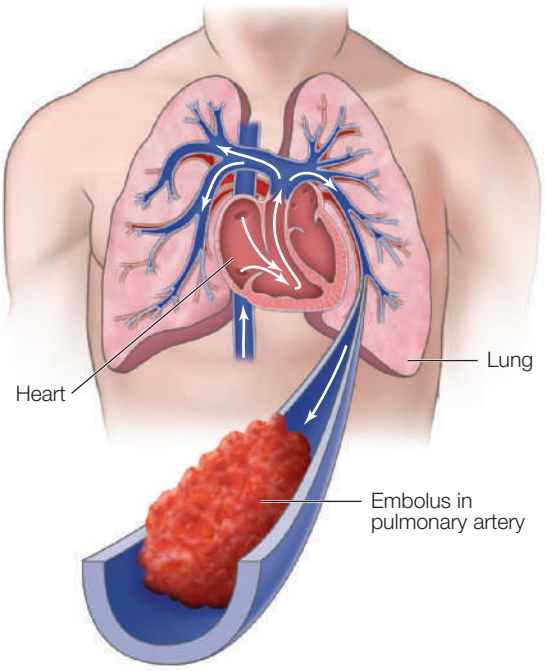

Figure 37–6 ■ A thromboembolism lodged in a pulmonary vessel.

- Occlusion of a large pulmonary artery with sudden death. Gas exchange is significantly reduced or prevented, and cardiac output falls dramatically as blood fails to move through the pulmonary vascular system and return to the left heart.
- Lung tissue infarction due to occlusion of a significant portion of pulmonary blood flow. Fewer than 10% of pulmonary emboli result in pulmonary infarction.
- Obstruction of a small segment of the pulmonary circulation with no permanent lung injury.
- Chronic or recurrent small emboli, which may be multiple.

Obstruction of pulmonary blood flow by an embolus affects both perfusion and ventilation. Neurohumoral reflexes triggered by obstruction cause vasoconstriction increasing pulmonary vascular resistance. In severe cases, this can lead to pulmonary hypertension and right ventricular heart failure. Systemically, hypotension and a drop in cardiac output may develop. Bronchoconstriction occurs in the affected area of lung. Dead space (areas of the lung that are ventilated but not perfused) increases. Alveolar surfactant decreases, increasing the risk for atelectasis.

If infarction does not occur, the fibrinolytic system (refer to Chapter 30) ultimately dissolves the clot, and pulmonary function returns to normal. Infarcted tissue becomes scarred and fibrotic.

Fat emboli are the most common nonthrombotic pulmonary emboli. A fat embolism usually occurs after fracture of long bone (typically the femur) releases bone marrow fat into the circulation. Adipose tissue or liver trauma may also lead to fat emboli.

Manifestations

The manifestations of pulmonary embolism depend on its size and location. Small emboli may be asymptomatic. Manifestations usually develop abruptly, over a period of minutes. The most common

MANIFESTATIONS OF PULMONARY EMBOLISM

COMMON	LESS COMMON
• Dyspnea and shortness of breath	• Diaphoresis
• Chest pain	• Hemoptysis
• Anxiety and apprehension	• Syncope
• Cough	• Cyanosis
• Tachycardia and tachypnea	• S_3 and/or S_4 gallop
• Crackles (rales)	
• Low-grade fever	

symptoms are dyspnea and pleuritic chest pain. Anxiety, a sense of impending doom, and cough are also common. See the accompanying box. Diaphoresis and hemoptysis may develop. Massive pulmonary embolus can cause syncope and cyanosis. On examination, tachycardia and tachypnea are noted. Crackles may be heard on auscultation of the chest, and a cardiac gallop (S_3 and possibly S_4) may be noted. A low-grade fever may develop. It is difficult to differentiate pulmonary embolism from myocardial infarction or pneumonia by manifestations.

Characteristic manifestations of fat emboli include sudden onset of cardiopulmonary and neurologic symptoms: dyspnea, tachypnea, tachycardia, confusion, delirium, and decreased level of consciousness. Petechiae often develop on the chest and arms.

Incidence and Risk Factors

Pulmonary embolism causes an estimated 60,000 deaths annually, occurring in more than 600,000 patients per year. Although many substances can become emboli, thrombus arising from the deep veins of the legs is the leading cause of pulmonary embolism. *Deep venous thrombosis (DVT)* develops in approximately 5 million people per year in the United States. The risk factors for pulmonary embolus are those for DVT: stasis of venous blood flow, vessel wall damage, and altered blood coagulation.

Prolonged immobility; trauma, including hip and femur fractures; surgery (orthopedic, pelvic, and gynecologic surgery in particular); myocardial infarction and heart failure; obesity; and advanced age are risk factors for DVT. Women who use oral contraceptives or estrogen therapy are at risk, as are women during pregnancy and childbirth. See Chapter 32 for more information about DVT.

●○● INTERPROFESSIONAL CARE

Because deep venous thrombosis may not be identified until pulmonary embolism occurs, prevention is the primary goal in treating pulmonary embolism. Prophylactic anticoagulation can be used to prevent the development of DVT. Early ambulation of medical and surgical patients is an effective means of preventing venous stasis and reducing the incidence of pulmonary embolism. External pneumatic compression of the legs is also effective for patients undergoing neurosurgery, urologic surgery, or major surgery of the hip or knee, or when anticoagulant therapy is contraindicated. Other preventive measures include elevating the legs and active and passive leg exercises.

When pulmonary embolism occurs, treatment is supportive. Oxygen therapy is initiated, and analgesics may be ordered to relieve severe pleuritic pain and anxiety. Pulmonary artery and wedge pressures may be monitored with a balloon (Swan-Ganz) catheter. Although cardiac outputs also may be assessed, this is rarely done in this population. Cardiac rhythm is monitored to detect dysrhythmias.

DIAGNOSIS

The studies performed to identify DVT differ from those used to diagnose a pulmonary embolism. Refer to Chapter 32 for diagnostic studies for venous thrombosis.

- *Plasma D-dimer levels* are highly specific to the presence of a thrombus. D-dimer is a fragment of fibrin formed during lysis of a blood clot; elevated blood levels indicate thrombus formation and lysis (e.g., DVT and pulmonary embolism).
- *Chest CT with contrast* is the principal test used to diagnose pulmonary embolism. Chest CT effectively shows large, central PE; newer generation scanners also can detect peripheral emboli.
- *Lung scans*, including perfusion and ventilation scans, may be used. In a perfusion lung scan, radiotagged albumin is injected intravenously and distributed in the lungs by the pulmonary blood flow. The lungs are then scanned for distribution of the isotope. An area of lung in which the isotope is undetectable is suggestive of occluded blood flow and pulmonary embolism. For a ventilation scan, a radiotagged gas is inhaled and the lungs are scanned for gas distribution. Combined perfusion and ventilation scans allow identification of areas of the lungs that are ventilated but not perfused, a characteristic of pulmonary embolism.
- *Pulmonary angiography* is the definitive test for pulmonary embolism when other, less invasive tests are inconclusive. It is possible to detect very small emboli with angiography. A contrast medium injected into the pulmonary arteries illustrates the pulmonary vascular system on x-ray.
- *Chest x-ray* often shows pulmonary infiltration and occasionally pleural effusion.
- *Electrocardiogram (ECG)* is ordered to rule out acute myocardial infarction as the cause of symptoms. ECG findings commonly associated with pulmonary embolism include tachycardia and nonspecific T-wave changes.
- *ABGs* usually show hypoxemia ($PO_2 < 80$ mmHg), and often respiratory alkalosis ($pH > 7.45$, $PCO_2 < 38$ mmHg) due to tachypnea and hyperventilation.
- *Exhaled carbon dioxide ($ETCO_2$)* may be measured to evaluate alveolar perfusion. The normal $ETCO_2$ reading is 35 to 45 mmHg; it is decreased when pulmonary perfusion is impaired.
- *Coagulation studies* are ordered to monitor the response to therapy. The *activated partial thromboplastin time* (*aPTT* or *PTT*) is used to assess the intrinsic clotting pathway and the response to heparin therapy. Desired levels with anticoagulant therapy are 1.5 to 2 times the control value. The risk of recurrent thromboembolism is high at lower levels; the risk of bleeding increases at higher levels. The *International Normalized Ratio (INR)* is used to assess the extrinsic clotting system and oral anticoagulation with warfarin (Coumadin). The goal of anticoagulant therapy is to achieve a therapeutic range of 2.0 to 3.0.

MEDICATIONS

Anticoagulant therapy is the standard treatment to prevent pulmonary emboli. It is often instituted in high-risk patients who have no evidence of pulmonary embolism, to prevent possible devastating effects (Karch, 2012). In the patient with DVT or a pulmonary embolus, anticoagulants

are administered to prevent further clotting and embolization. Refer to Chapter 32, the Medication Administration box on pages 974 and 975, for the nursing implications for anticoagulant therapy.

For pulmonary embolus, heparin therapy is initiated with an intravenous bolus of 5000 to 10,000 units of heparin, followed by continuous infusion at the rate of 1000 to 1500 units per hour. The aPTT or PTT is monitored frequently until stabilized. Heparin therapy is typically continued for about 5 days or until oral anticoagulant therapy has become fully effective. Refer to Chapter 32 for further information on low-molecular-weight heparin.

Oral anticoagulant therapy with warfarin sodium (Coumadin) is initiated at the same time as heparin. Warfarin alters the synthesis of vitamin K–dependent clotting factors and requires 5 to 7 days to be fully effective. Anticoagulant therapy is continued for 2 to 3 months when few risk factors for thromboemboli exist; long-term therapy is used when chronic disorders that increase the risk of thromboemboli are present.

Bleeding is a risk associated with anticoagulant therapy. Although major hemorrhage is uncommon, it occurs in approximately 5% of patients receiving intravenous heparin. Cardiac, hepatic, and renal disease increase the risk of significant bleeding, as does age over 60 years. Protamine, a protein that combines with heparin to inactivate it, is used to stop its anticoagulant effect if major bleeding occurs. Vitamin K is given to treat bleeding associated with Coumadin therapy.

Thrombolytic therapy may be used to treat massive pulmonary embolus and hypotension. Streptokinase, urokinase, or tissue plasminogen activator (tPA) is used to *lyse* (disintegrate) the embolus, restore pulmonary blood flow, and reduce pulmonary artery and right heart pressures. Although thrombolytic therapy may not reduce mortality associated with pulmonary embolus, it may reduce the incidence of pulmonary hypertension, which develops 3 to 5 years after an embolism. Thrombolysis significantly increases the risk of bleeding, particularly cerebral bleeding. Contraindications to thrombolysis include intracranial disease, recent stroke, active bleeding or a bleeding disorder, pregnancy, severe hypertension, and recent surgery or trauma. Because of the increased risk of hemorrhage, invasive procedures are avoided after thrombolysis. Refer to Chapter 30 for further discussion of thrombolytic therapy and its nursing implications.

SURGERY

When anticoagulant therapy fails to prevent recurrent emboli, an umbrella-like filter may be inserted into the inferior vena cava to trap large emboli while allowing continued blood flow (refer to Figure 32–11A). The filter usually is inserted percutaneously, via either the femoral or jugular vein.

●○● NURSING CARE

Health Promotion

Nurses are key in preventing pulmonary embolism. Encouraging patients to ambulate after surgery or illness, applying compression stockings or pneumatic compression devices, teaching and encouraging leg exercises, discouraging the use of pillows under the knees—all these measures help prevent DVT and subsequent pulmonary emboli.

Teach patients to reduce the risks associated with long periods of immobility, stopping every 1 to 2 hours during long automobile trips for a brief stretch and walk, getting up every hour or so and doing leg exercises while seated during long flights, and avoiding crossing the legs to prevent venous stasis and pooling. Regular exercise such as walking also reduces the risk of DVT. Instruct patients who stand for long periods to use well-fitted elastic stockings, being careful to avoid hose that bind around the knee or thigh.

Assessment

See the Manifestations and Interprofessional Care sections for the assessment of the patient with a pulmonary embolism.

Because pulmonary embolus can be a medical emergency, assessment may be very focused. In other instances, when emboli are small and not life threatening, a more extensive nursing assessment may be done.

- *Health history:* chest pain, shortness of breath, other symptoms, including onset, severity, precipitating factors; history of recent surgery, venous thrombosis, or other risk factors such as childbirth or malignancy; current medications
- *Physical assessment:* level of consciousness, presence of respirations and pulse; color, skin temperature, and moisture; vital signs including apical pulse and temperature; breath sounds and heart sounds; oxygen saturation level; neck vein distention, peripheral edema
- *Laboratory data:* plasma D-dimer levels, coagulation studies; chest x-ray and other imaging studies; oxygen saturation and ABGs; ECG.

Priorities of Care

Collaborating with the interprofessional team to ensure adequate treatment of the underlying process while providing care that supports the physical and psychologic responses to the disorder is a priority of nursing care.

Diagnoses, Outcomes, and Interventions

A large pulmonary embolus can cause a significant mismatch between pulmonary ventilation and circulation. Impaired gas exchange is a priority problem and focus for interventions. Cardiac output may be significantly affected by obstructed pulmonary blood flow. Thrombolytic and anticoagulant therapy affect the clotting process, increasing the risk for bleeding. Anxiety accompanies pulmonary embolism almost universally.

Impaired Gas Exchange

Pulmonary embolism results in areas of the lung that are ventilated but not perfused; they receive no capillary blood flow. If the embolus is large and a major segment of the lung is unperfused, gas exchange is significantly affected. Nursing interventions are directed toward compensating for impaired gas exchange.

Expected Outcome: Patient's tissue perfusion will be effective as evidenced by adequate arterial flow as evidenced by absence of symptoms of cardiac, pulmonary, and neurologic ischemia.

- Frequently assess respiratory status, including rate, depth, effort, lung sounds, and oxygen saturation. *Impaired ventilation will further compromise gas exchange and worsen hypoxemia. Oxygen saturation can be monitored continuously and noninvasively to evaluate gas exchange.*
- Monitor and record level of consciousness, mental status, and skin color. Hypoxemia often causes confusion and agitation; hypercapnia may reduce level of consciousness. Cyanosis indicates significant hypoxemia.

- Place in Fowler's or high-Fowler's position, with the lower extremities dependent. *This position facilitates maximal lung expansion and reduces venous return to the right side of the heart, lowering pressures in the pulmonary vascular system.*

SAFETY ALERT

Start oxygen per nasal cannula or mask. Obtain a physician's order if one has not been written. Supplemental oxygen increases alveolar and arterial oxygenation. Oxygen is a drug and must be prescribed by the physician. It may, however, be initiated by the nurse in an emergency to prevent tissue hypoxia.

- Monitor arterial blood gas results, reporting abnormal findings as indicated. *ABGs are used to assess gas exchange and tissue oxygenation. An arterial line may be inserted for monitoring arterial pressure and arterial blood sampling.*
- Maintain bed rest. *Bed rest reduces metabolic demands and tissue needs for oxygen.*

Decreased Cardiac Output

The impact of a large pulmonary embolus on hemodynamic status can be significant. Pressures in the pulmonary vascular system and right heart increase; blood return to the left heart and cardiac output may significantly decrease. Nursing interventions focus on preserving an adequate blood pressure and organ function until cardiopulmonary status stabilizes. A central line for hemodynamic monitoring may be instituted (refer to Chapter 30 for nursing care related to hemodynamic monitoring).

Expected Outcome: Patient will demonstrate adequate cardiac output as evidenced by blood pressure and pulse rate within normal parameters for the patient.

SAFETY ALERT

Assess and record vital signs and cardiopulmonary status every 15 to 30 minutes initially, then every 2 to 4 hours as condition stabilizes. Frequent assessment facilitates timely interventions to maintain cardiovascular status and preserve organ function.

- Auscultate heart sounds every 2 to 4 hours, reporting any abnormalities. *Sounds such as an S_3 or S_4 gallop may indicate cardiac compromise.*
- Record intake and output hourly. Decreased urinary output often is an early indicator of decreased cardiac output. Maintaining renal perfusion is vital to preserve renal function and prevent acute renal failure.
- Assess skin color and temperature. *These assessments monitor tissue perfusion.*
- Monitor cardiac rhythm. *A drop in cardiac output and other hemodynamic alterations resulting from pulmonary embolism can precipitate dysrhythmias. Dysrhythmias, in turn, can further impair cardiac output.*
- Administer vasopressors and other medications as ordered. Carefully monitor the response to prescribed medications. *Drugs may be prescribed to maintain adequate arterial pressure and tissue perfusion. Potent drugs such as vasopressors require careful monitoring for desired and adverse effects.*
- Monitor pulmonary artery pressures, neck vein distention, and peripheral edema. Report findings as indicated. *Right-sided heart failure is a potential complication of pulmonary embolism because of increased pulmonary artery pressures.*
- Maintain intravenous and arterial access sites as well as central lines. *The patient may be in unstable and critical condition, potentially needing immediate interventions to maintain life.*
- Provide frequent skin care. *Impaired tissue perfusion and oxygenation increase the risk of skin and tissue breakdown.*
- Instruct to report chest pain or other symptoms. *Decreased cardiac output and an increased workload due to pulmonary hypertension may cause anginal pain.*

Ineffective Protection

Thrombolytics and anticoagulant therapy impair normal clotting mechanisms, increasing the risk for bleeding and hemorrhage. This risk is particularly acute during the first 24 to 48 hours following thrombolytic drug administration.

Expected Outcome: Patient will remain free of any evidence of new bleeding and take precautions to prevent bleeding.

- Assess frequently for overt and covert signs of bleeding: bleeding gums; hematuria; obvious or occult blood in stool or vomitus; incisional bleeding, bleeding or bruising of injection sites or with minor trauma; joint pain or immobility; abdominal or flank pain. *Careful monitoring is necessary to identify early signs of abnormal bleeding and prevent potential hemorrhage.*

SAFETY ALERT

Promptly report changes in neurologic status. Although cerebral bleeding is not evident externally, changes in level of consciousness and other neurologic signs suggest it and should be reported immediately.

- Report coagulation study results outside the desired range for anticoagulant therapy. *Levels less than the target range may indicate an increased risk for further clot development and pulmonary emboli; levels above the target range indicate an increased risk for bleeding.*
- Keep protamine sulfate available for heparin therapy and vitamin K available for warfarin (Coumadin) therapy. *Bleeding or hemorrhage due to excess anticoagulant may require antidote administration to rapidly reverse anticoagulant effects.*
- Assess medication regimen for possible drug interactions that could potentiate or inhibit anticoagulant effects. *Drug interactions can increase the risk for hemorrhage or further embolus formation.*
- Avoid invasive procedures, injections, and venous punctures when possible, particularly during and following thrombolytic therapy. *Invasive procedures increase the risk of tissue trauma and bleeding.*
- Maintain firm pressure on injection and venipuncture sites. Maintain pressure for 30 minutes following arterial puncture. *Firm pressure reduces the risk for bleeding into the tissues.*

SAFETY ALERT

Use an infusion device to administer heparin infusion, which helps prevent administration of excess medication.

- Maintain adequate fluid intake. Administer stool softeners as ordered. *These measures help prevent constipation and straining, which may precipitate bleeding of hemorrhoids.*

Anxiety

Pulmonary embolism is a physiologic and psychologic threat to safety and integrity. It is a major physiologic stressor, eliciting a strong neuroendocrine stress response. The feeling of suffocation and inability to catch one's breath that accompanies a pulmonary embolus is also a strong psychologic stressor. Fear, anxiety, and apprehension are common responses.

Expected Outcome: Patient will be able to control anxiety as evidenced by verbalized decrease in subjective distress.

- Assess anxiety level. *Appropriate interventions are determined by the level of anxiety.*
- Provide reassurance and emotional support, listening to fears. Do not negate the fear of dying, but reassure that treatment usually restores effective respiratory function. *The fear of death is very real and must not be discounted; however, it is important to provide reassurance to alleviate excess anxiety.*
- Remain with the patient as much as possible. *The presence of a caring nurse helps reduce fear.*
- Explain procedures and treatments, using short, simple sentences. *Providing clearly understood, simple instructions reduces fear of the unknown.*
- Reduce environmental stimuli, and use a calm, reassuring manner. *These measures help reduce anxiety (for both the nurse and the patient).*
- Allow supportive family members to remain with the patient as much as possible. *Calm, supportive family members provide further reassurance.*
- Administer morphine sulfate as ordered. *Morphine is given to reduce pain and anxiety.*

Continuity of Care

Discuss the following topics when preparing the patient with pulmonary embolism and family members for home care:

- Use of prescribed anticoagulant, including drug interactions, scheduled laboratory testing, and manifestations of bleeding to report to the primary care provider
- Using a soft toothbrush and electric razor to reduce the risk of bleeding
- Avoiding aspirin (unless prescribed) and other over-the-counter medications without approval by the physician
- Importance of wearing a medical alert tag for anticoagulant use
- Health promotion measures to reduce the risk of recurrent pulmonary embolism
- Symptoms of recurrent pulmonary embolism, such as sudden chest pain, shortness of breath, and possibly bloody sputum.

THE PATIENT WITH PULMONARY HYPERTENSION

The pulmonary vascular system is normally a high-flow, low-pressure, low-resistance system that can accommodate large increases in blood flow when necessary (e.g., during exercise). The normal mean arterial pressure in the pulmonary system is 12 to 15 mmHg (25 to 28 systolic/8 diastolic). **Pulmonary hypertension (PHTN)** is abnormal elevation of the pulmonary arterial pressure.

Pathophysiology

Pulmonary hypertension can develop as a primary disorder, but can also occur secondarily to another condition. In both instances, changes in the pulmonary artery lead to abnormal growth and remodeling of pulmonary vessels. Smooth muscle cells and fibroblasts proliferate, leading to abnormal vasoconstriction and fibrosis of pulmonary vessels. Once initiated, pulmonary vascular changes are progressive and nonreversible. Vasoconstrictive substances such as endothelin 1 and thromboxane A2 are produced in excess, while the production of vasodilating substances such as nitric oxide is reduced. This further contributes to vasoconstriction and increased pulmonary artery pressures. Thromboxane A2 also stimulates platelet aggregation, promoting clot formation in pulmonary vessels. The development of plexiform lesions is also a hallmark of PHTN. Inflammation may contribute to progression of the disease. Vasoconstriction and increased pressures in the pulmonary system increase the workload of the right ventricle, ultimately leading to right ventricular failure.

PRIMARY PULMONARY HYPERTENSION

Primary pulmonary hypertension is an uncommon disorder without an identified cause. It occurs in both familial and sporadic patterns. In the 50% of persons with the familial form, the bone morphogenetic protein receptor (*BMPR2*), a gene transmitted in an autosomal dominant pattern, affects the walls of pulmonary arteries, leading to abnormal vessel growth and remodeling This gene is located at chromosomal region 2q32. Presence of the mutation carries a 10% to 20% risk of developing pulmonary arterial hypertension (PAH) over the lifetime. Primary pulmonary hypertension affects primarily women in their 30s and 40s.

FAST FACTS

- An estimated 500 to 1000 new cases of primary pulmonary hypertension are diagnosed annually, primarily in women between 20 and 40 years (American Heart Association, 2012).
- Median survival after being diagnosed with primary pulmonary hypertension is 3 years without effective treatment, but this has increased with new treatment modalities.

SECONDARY PULMONARY HYPERTENSION

Secondary pulmonary hypertension is more common than primary. HIV infection and collagen diseases such as scleroderma and lupus may lead to secondary pulmonary hypertension. However, its usual cause is reduced size of the pulmonary vascular bed, which may be due to vasoconstriction or widespread vessel destruction or obstruction. Hypoxemia is a potent pulmonary vasoconstrictor and a common initiating factor in pulmonary hypertension. Chronic lung diseases, sleep apnea, and hypoventilation due to obesity or neuromuscular disease can lead to hypoxemia. Alveolar wall destruction associated with emphysema leads to loss of pulmonary capillaries. Large or multiple pulmonary emboli may cause significant vessel obstruction. Other factors such as left ventricular failure or mitral stenosis also can lead to elevated pulmonary pressures. Once initiated, pulmonary hypertension becomes self-sustaining, as pulmonary vessels undergo changes that further narrow the pulmonary bed.

Manifestations

The manifestations of pulmonary hypertension are progressive dyspnea, fatigue, angina, and syncope with exertion. In secondary

pulmonary hypertension, the signs and symptoms often are masked by those of the underlying disease. Dull, retrosternal chest pain may occur in addition to the manifestations of the primary disease. Primary pulmonary hypertension is a progressive disorder that generally causes a steady decline to death within 3 to 4 years.

Complications

Cor pulmonale is a condition of right ventricular hypertrophy and failure resulting from long-standing pulmonary hypertension. Chronic obstructive pulmonary disease is the most common cause of cor pulmonale.

The manifestations of cor pulmonale are those of the underlying pulmonary disorder and right-sided heart failure. Chronic productive cough, progressive dyspnea, and wheezing are common. With right-sided heart failure, peripheral edema and distended neck veins are seen. Skin is warm, moist, and both ruddy and cyanotic because of increased numbers of RBCs and hypoxemia.

●○● INTERPROFESSIONAL CARE

The CBC commonly shows *polycythemia*, increased numbers of red blood cells. ABGs and oxygen saturation measurements reveal hypoxemia. The chest x-ray shows right heart enlargement and dilation of central pulmonary arteries. Typical ECG changes are those of right ventricular hypertrophy. An echocardiogram may be done to identify cardiac changes occurring either as a cause or result of pulmonary hypertension. Doppler ultrasonography is a noninvasive means of estimating pulmonary artery pressure, but cardiac catheterization may be required for definitive diagnosis. Refer to Chapter 30 for nursing care of the patient having a percutaneous coronary revascularization procedure.

Treatment for pulmonary hypertension focuses on slowing the course of the disease, preventing thrombus formation, and reducing pulmonary vasoconstriction. Oxygen is administered to reduce hypoxemia and improve activity tolerance. If polycythemia is present, phlebotomy is performed to reduce the viscosity of the blood.

The calcium channel blockers nifedipine (Procardia) or diltiazem (Cardizem) may be given to reduce pulmonary vascular resistance and improve cardiac output. Short-acting direct vasodilators such as intravenous epoprostenol (Flolan) or treprostinil (Remodulin), or oral bosentan (Tracleer), may be used for patients who do not respond to calcium channel blockers. An oral anticoagulant (warfarin [Coumadin]) is given to prevent clotting.

Bilateral lung or heart-lung transplant is the most effective long-term treatment for primary pulmonary hypertension. When cor pulmonale is present, salt and water restrictions as well as diuretic therapy are added to the previously mentioned regimen to manage the right-sided heart failure.

Evidence for Nursing Care

The Patient with Pulmonary Hypertension

Selected resource that nurses may find helpful when planning evidence-based nursing care follow.

- Ventetuolo, C. E., & Klinger, J. R. (2012). WHO Group 1 pulmonary arterial hypertension: Current and investigative therapies. *Progress in Cardiovascular Disease, 55*(2), 89–103.

●○● NURSING CARE

Nursing care for the patient with pulmonary hypertension or cor pulmonale is largely supportive. The focus is toward the underlying lung disease. Impaired gas exchange due to contraction of the pulmonary vascular system is a significant problem that causes many secondary problems, such as activity intolerance, anxiety, and fatigue. Nursing interventions for impaired gas exchange are directed toward maintaining adequate alveolar ventilation, oxygenation, and perfusion. The following measures may be included:

- Monitoring breath sounds, respiratory rate, skin color, and use of accessory muscles
- Positioning for optimal lung expansion
- Coughing, deep breathing, and chest physiotherapy
- Administering prescribed vasodilators.

It is important to assess fatigue and dyspnea with activities and to plan frequent rest periods. Assist with self-care as needed to conserve energy.

With primary pulmonary hypertension, *Anticipatory Grieving* and *Hopelessness* are additional potential nursing diagnoses. When cor pulmonale is present, *Decreased Cardiac Output*, *Excess Fluid Volume*, and *Ineffective Individual Coping* must be considered.

Continuity of Care

Most care for these chronic conditions is provided in the home and community settings. Teaching is directed both at the underlying lung disease, if present, and the resulting hypertensive process. Refer to the section on COPD for teaching related to this disease, the most frequent underlying cause of cor pulmonale.

In addition, provide teaching about the following topics for the patient and family:

- Disease process, its management, and the prognosis
- Manifestations or changes in condition to report to the physician, such as a change in activity tolerance, increased edema, and signs of respiratory infection or exacerbation
- Importance of planned rest periods between activities and measures to conserve energy, such as using a shower chair
- Importance of not smoking due to its irritant and vasoconstrictive effects
- Prescribed medications, including their use and effects.

Respiratory Failure

Many of the conditions discussed in this chapter and in Chapter 36, from pneumonia to acute respiratory distress syndrome (ARDS), can lead to respiratory failure. In **respiratory failure**, the lungs are unable to oxygenate the blood and remove carbon dioxide adequately to meet the body's needs, even at rest.

THE PATIENT WITH ACUTE RESPIRATORY FAILURE

Respiratory failure is not a disease but a consequence of severe respiratory dysfunction. It is often defined by arterial blood gas values. An arterial oxygen level (PO_2) of less than 50 to 60 mmHg and an arterial carbon dioxide level (PCO_2) of greater than 50 mmHg are generally accepted as indicators of respiratory failure. However, patients with advanced COPD may be alert and functional with blood gas values that would indicate respiratory failure in someone whose respiratory function was previously normal. In patients with COPD, respiratory failure is indicated by an acute drop in blood oxygen levels along with increased carbon dioxide levels.

Respiratory failure can result from inadequate alveolar ventilation (hypoventilation), impaired gas exchange, or a significant ventilation–perfusion mismatch. COPD is the most common cause of respiratory failure. Other lung diseases, chest injury, inhalation trauma, neuromuscular disorders, and cardiac conditions can also lead to respiratory failure. Selected causes of acute respiratory failure are identified in Table 37–5.

TABLE 37–5 Selected Causes of Respiratory Failure

Type of Dysfunction	Examples
Impaired ventilation:	
• Airway obstruction	Laryngospasm, foreign body aspiration, airway edema
• Respiratory disease	Asthma, COPD
• Neurologic causes	Spinal cord injury, poliomyelitis, Guillain-Barré syndrome, drug overdose, stroke
• Chest wall injury	Flail chest, pneumothorax
Impaired diffusion:	
• Alveolar disorders	Pneumonia, pneumonitis, COPD
• Pulmonary edema	Heart failure, acute respiratory distress syndrome (ARDS), near-drowning
Ventilation–perfusion mismatch	Pulmonary embolism

Pathophysiology

Respiratory failure may be characterized by primary hypoxemia or a combination of hypoxemia and hypercapnia (Figure 37–7 ■). In hypoxemic respiratory failure, PO_2 is significantly reduced, whereas PCO_2 remains normal or is low due to stimulation of the respiratory center and tachypnea. Impaired diffusion across the alveolar-capillary membrane, and a ventilation–perfusion mismatch can cause a drop in arterial oxygen levels that is more rapid than the rise in carbon dioxide. Metabolic acidosis results from tissue hypoxia. The increased work of breathing can eventually lead to respiratory muscle fatigue and hypoventilation.

Hypoventilation, or reduced movement of air into and out of the lung, causes carbon dioxide retention. With significant hypoventilation, the carbon dioxide level in the blood rises rapidly, leading to respiratory acidosis. Hypoxemia develops more slowly, and responds readily to administration of oxygen unless gas exchange also is impaired.

In summary, hypoxemia without a corresponding rise in carbon dioxide levels indicates a failure of oxygenation; hypoxemia with hypercapnia is the result of lung hypoventilation.

Manifestations and Course

The manifestations of respiratory failure are caused by hypoxemia and hypercapnia, as well as the underlying disease process. Hypoxemia causes dyspnea and neurologic symptoms such as restlessness, apprehension, impaired judgment, and motor impairment. Tachycardia and hypertension develop as the cardiac output increases in an effort to bring more oxygen to the tissues. Cyanosis is present. As hypoxemia progresses, dysrhythmias, hypotension, and decreased cardiac output may develop.

Increased carbon dioxide levels depress CNS function and cause vasodilation. Dyspnea and headache are early signs. Other manifestations include peripheral and conjunctival vasodilation, papilledema,

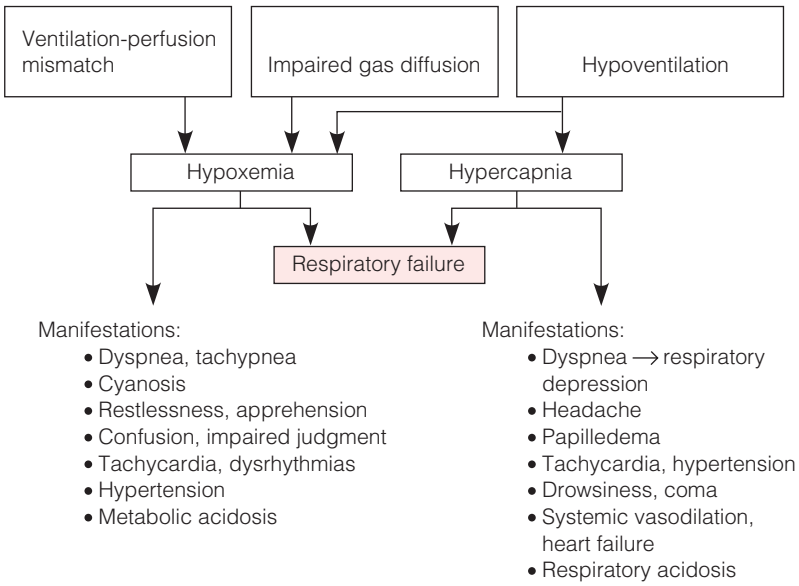

Figure 37–7 ■ Causes and manifestations of respiratory failure.

neuromuscular irritability, and decreased level of consciousness. As hypercapnia worsens, the respiratory center may be depressed, reducing dyspnea and slowing respirations. Increased carbon dioxide and hydrogen ion concentrations no longer stimulate the respiratory center; hypoxemia provides the primary active breathing stimulus. Administering oxygen without ventilatory support may further reduce the drive to breathe, leading to respiratory arrest.

The prognosis for acute respiratory failure varies, depending on the underlying disease process. Respiratory failure resulting from uncomplicated drug overdose generally resolves quickly without long-term effects. The course may be prolonged and the outcome less favorable when respiratory failure results from underlying lung disease.

FAST FACTS

Among adults requiring mechanical ventilation for acute respiratory failure:

- An estimated 62% survive to be weaned from the ventilator.
- Only 43% survive to be discharged from the hospital.
- About 30% remain alive at 1 year after discharge.

●○● INTERPROFESSIONAL CARE

Treatment of respiratory failure focuses on correcting the underlying cause or disease, supporting ventilation, and correcting hypoxemia and hypercapnia. Care related to disorders that can precipitate respiratory failure is discussed in the sections specific to each disorder.

DIAGNOSIS

Exhaled carbon dioxide and arterial blood gases are used to diagnose and monitor treatment of respiratory failure.

- *Exhaled carbon dioxide ($ETCO_2$)* is used to evaluate alveolar ventilation. The normal $ETCO_2$ is 35 to 45 mmHg; it is elevated when ventilation is inadequate, and decreased when pulmonary perfusion is impaired.
- *Arterial blood gases* also are used to evaluate alveolar ventilation and gas exchange. With hypoxemic respiratory failure, the PCO_2 may be normal, 35 to 45 mmHg, or even low due to tachypnea. A pH of less than 7.35 and low bicarbonate levels indicate metabolic acidosis, typical of hypoxemic respiratory failure.

In respiratory failure due to hypoventilation, the PCO_2 is elevated, usually greater than 50 mmHg. The pH is low due to respiratory acidosis. Acidosis develops rapidly in hypoxemia and hypercapnia because of increased acid production (metabolic) and decreased acid elimination (respiratory).

MEDICATIONS

Drugs used in treating respiratory failure depend on the underlying cause of the failure and the need for intubation and mechanical ventilation.

Beta-adrenergic (sympathomimetic) or anticholinergic medications may be administered by inhalation to promote bronchodilation. If mechanical ventilation is required, the drugs may be given by nebulizer attached to the ventilator. Methylxanthine bronchodilators (theophylline derivatives) may be given intravenously. See the Medication Administration feature and the asthma section earlier in this chapter for more information about bronchodilators and their nursing implications. Corticosteroids, administered by inhalation or intravenously, may be ordered to reduce airway edema. Antibiotics are given to treat any underlying infection.

Sedation and analgesia often are required during mechanical ventilation to decrease pain and anxiety. Benzodiazepines such as diazepam (Valium), lorazepam (Ativan), or midazolam (Versed) may be used for sedation and to inhibit the respiratory drive. Intravenous morphine or fentanyl provides analgesia and also inhibits the respiratory drive, allowing more effective mechanical ventilation. Occasionally, the patient's respiratory drive competes with the ventilator despite sedation, decreasing its effectiveness and increasing the work of breathing. A neuromuscular blocking agent in combination with sedation may be necessary to induce paralysis and suppress the ability to breathe. Nursing implications of neuromuscular blockers are described in the accompanying Medication Administration box.

OXYGEN THERAPY

Oxygen is administered to reverse hypoxemia in acute respiratory failure. In general, the goal is to achieve an oxygen saturation of 90% or greater without oxygen toxicity. A PO_2 of about 60 mmHg usually is adequate to meet the oxygen needs of body tissues. Higher levels do not significantly increase oxygen saturation and may lead to hypoventilation in patients with chronic hypercapnia. As little as 1 to 3 L of oxygen per nasal cannula or 28% oxygen per Venturi mask may correct hypoxemia in advanced COPD. Oxygen concentrations of 40% to 60% may be required when diffusion is impaired (e.g., in pneumonia or acute respiratory distress syndrome). High concentrations are used only for short periods to avoid oxygen toxicity. Both the oxygen concentration and duration of therapy contribute to oxygen toxicity. Continued high oxygen concentrations impair the synthesis of surfactant, reducing lung compliance (ease of inflation). Acute respiratory distress syndrome or absorption atelectasis may develop.

When respiratory failure is caused by hypoventilation or usual oxygen delivery systems do not correct hypoxemia, a tight-fitting mask to maintain *continuous positive airway pressure (CPAP)* may be used. CPAP increases lung volume, opening previously closed alveoli, improving ventilation of underventilated alveoli, and improving ventilation–perfusion relationships.

AIRWAY MANAGEMENT

If the upper airway is obstructed or positive-pressure mechanical ventilation is necessary to correct hypoxemia and hypercapnia, an endotracheal tube that extends from the mouth or nose into the trachea is inserted (Figure 37–8 ■). To maintain positive-pressure

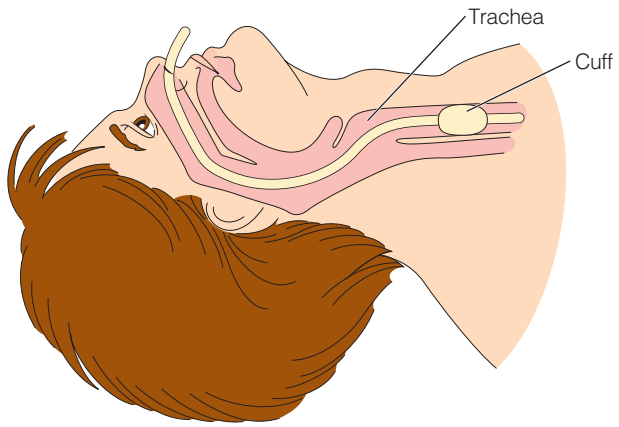

Figure 37–8 ■ Nasal endotracheal (nasotracheal) intubation.

ventilation, the tube is cuffed with an air-filled or foam sac just above the end of the tube. When the cuff is inflated, it obstructs the upper airway, preventing air from escaping back into the nose or mouth. Excess pressure of the cuff can cause tissue ischemia and necrosis of the trachea. To minimize this risk, high-volume, low-pressure ("floppy") cuffs are used. Tubes with low-pressure cuffs may be left in place for 3 to 4 weeks.

A tracheostomy may be performed if long-term ventilatory support is required. Although a tracheostomy is more comfortable and easier to secure in place, complications such as cuff necrosis and increased risk of infection are associated with tracheostomy as well as endotracheal intubation. Table 37–6 compares the advantages, disadvantages, and possible complications of the various types of endotracheal tubes and a tracheostomy.

When the patient is able to maintain effective respirations and ventilatory support is no longer required, the endotracheal tube is removed (*extubation*). Gag, cough, and swallow reflexes must be intact to prevent aspiration. After oxygenation and suctioning, the cuff is deflated and the tube removed. Humidified oxygen is provided immediately following removal. Close observation for respiratory distress is vital following extubation. Inspiratory stridor within the first 24 hours indicates laryngeal edema, which may necessitate reintubation. Sore throat and a hoarse voice are common after extubation. Oral intake is reinitiated slowly, with careful assessment of swallowing.

MECHANICAL VENTILATION

Mechanical ventilation is indicated when alveolar ventilation is inadequate to maintain blood oxygen and carbon dioxide levels. Specific indications for mechanical ventilation include the following:

- Apnea or acute ventilatory failure
- Hypoxemia unresponsive to oxygen therapy alone
- Increased work of breathing with progressive patient fatigue.

The most common indicator for ventilation support is actual or potential respiratory muscle fatigue. Drug overdose, neural disorders, chest wall injury, and airway problems such as severe asthma or COPD can lead to acute ventilatory failure. Disorders that affect alveolar-capillary diffusion, such as pulmonary contusion, pneumonia, and ARDS, may necessitate mechanical ventilation to attain adequate oxygenation. Positive-pressure ventilation increases lung volume, helps redistribute fluid from the alveolar to the interstitial space, and helps reduce the oxygen demand caused by increased work of breathing.

TYPES OF VENTILATORS Two broad general classifications of mechanical ventilators are available. Negative-pressure ventilators create negative (subatmospheric) pressure externally to draw the chest outward and air into the lungs, mimicking spontaneous breathing. The iron lung, cuirass ventilator, and PulmoWrap are examples of negative-pressure ventilators. Patients with neuromuscular disorders (e.g., post-polio syndrome, amyotrophic lateral sclerosis) that interfere with the ability to maintain adequate ventilation are the primary users of negative-pressure ventilators. They may also be used by patients who require ventilator support during sleep.

Positive-pressure ventilators are more commonly used than negative-pressure ventilators, especially in treating acute respiratory failure (Figure 37–9 ■). These ventilators push air into the lungs, rather than drawing it in like negative-pressure ventilators. Either invasive ventilation using an endotracheal tube or tracheostomy or noninvasive positive-pressure ventilation may be used. Increasingly, noninvasive techniques, which use a nasal or face mask, nasal plugs, or an oral mouthpiece, are used.

Several variables are used to trigger, cycle, and limit airflow with positive-pressure ventilators. The *trigger* prompts the ventilator to deliver a breath. The patient's inspiratory effort triggers *ventilator-assisted breaths. Ventilator-controlled breaths* usually are triggered by a preset time interval (e.g., a breath is delivered every 5 seconds for a rate of 12 breaths per minute). The ventilator *cycle*, or duration of inspiration, can be limited by volume, pressure, flow, or time. *Volume-cycled ventilators* deliver air until a preset volume is delivered. *Pressure-cycled ventilators* cycle off when a preset pressure is achieved within the airways. *Flow-cycled ventilators* are cycled by a preset inspiratory flow rate, and *time-cycled ventilators* deliver air for a set time interval. Airflow delivered by the ventilator also can be limited by factors such as airway pressure (e.g., a volume-cycled ventilator can be set to immediately stop inspiratory flow if airway pressure exceeds a preset value).

TABLE 37–6 A Comparison of Endotracheal Tubes and Tracheostomy

	Advantages	Disadvantages	Potential Complications
Oral endotracheal tube	• More easily inserted • Larger tube can be used, facilitating work of breathing, suctioning	• More difficult to secure • Can be obstructed by biting • Communication and mouth care more difficult • Increased risk of lower respiratory infection	• Obstruction or displacement • Pressure necrosis of lip • Tracheoesophageal fistula
Nasal endotracheal tube	• More easily secured and stabilized • Well tolerated by patient • Facilitates communication and oral hygiene	• Necessitates smaller tube, which may impede removal of secretions • Increased risk of lower respiratory infection	• Obstruction or displacement • Pressure necrosis of nares • Obstruction of sinus drainage, possible sinusitis • Tracheoesophageal fistula
Tracheostomy	• Easily secured and stabilized • Enables swallowing, speech, and oral hygiene • Avoids upper airway complications	• Requires surgical incision • Increased risk of lower respiratory infection	• Hemorrhage due to incision or vessel erosion by tube • Wound infection • Subcutaneous emphysema • Tracheoesophageal fistula • Tracheal infarction and stenosis

MEDICATION ADMINISTRATION

Neuromuscular Blockers

NONDEPOLARIZING NEUROMUSCULAR BLOCKERS

rocuronium (Zemuron)

pancuronium bromide (Pavulon)

atracurium besylate (Tracrium)

cisatracurium (Nimbex)

Nondepolarizing neuromuscular blockers competitively block the action of acetylcholine (ACh) at skeletal muscle receptors, preventing muscle depolarization and contraction. Complete muscle paralysis is achieved within minutes. Facial muscles are affected first, followed by muscles of the limbs, neck, and trunk. The muscles of respiration (the diaphragm and intercostal muscles) are least sensitive to the effects of neuromuscular blockers and are paralyzed last. When the drug is discontinued or an antagonist is given, respiratory function is recovered first as the muscle groups recover in reverse order.

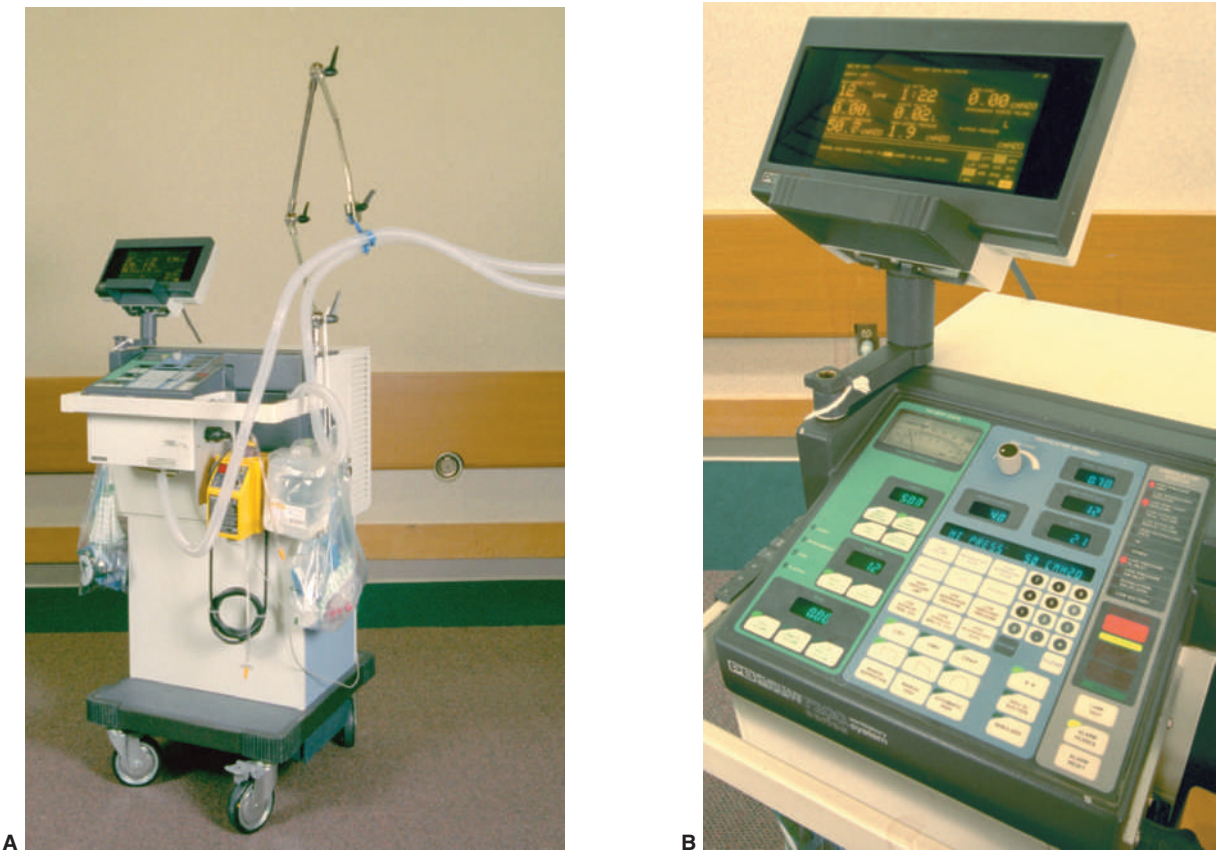
Nursing Responsibilities

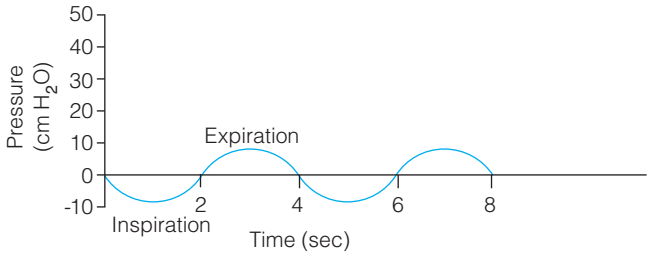
- Prior to administering, assess endotracheal tube placement and ensure effective mechanical ventilator function. The risk of hypoxemia and organ damage is significant if respiratory muscles are paralyzed without adequate ventilatory support in place.
- Administer the drug by slow intravenous injection and/or intravenous infusion as prescribed.
- Keep an acetylcholinesterase (AChE) inhibitor such as neostigmine (Prostigmin) available at the bedside to rapidly reverse neuromuscular effects if needed.
- Administer morphine sulfate, diazepam (Valium), or other antianxiety agent or sedative as ordered. Neuromuscular blockers provide no sedation or pain relief; muscle paralysis produces extreme anxiety.
- Instill artificial tears every 2 to 4 hours.
- Suction oral cavity as needed to remove saliva.
- *Never* turn off ventilator alarms when administering neuromuscular blockers. Should the tubing become disconnected or plugged, the patient is unable to breathe independently or call for help.
- Treat the patient as though awake and alert. Although unable to respond, mental function is unaffected.

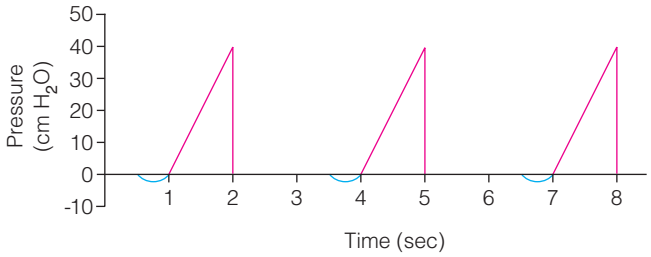
Health Education for the Patient and Family

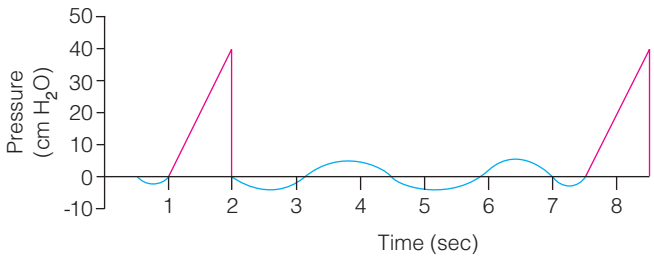
- Reassure that the ability to move and communicate will return when the drug is discontinued.
- Teach the family about the effects of the drug and the reason for its use. Explain that the patient can hear and understand what is going on.

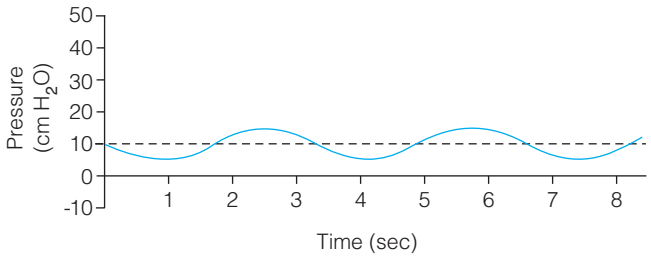
MODES OF VENTILATION A number of different *modes* or patterns of ventilation may be used with positive-pressure ventilators. The mode determines whether a breath is initiated by the patient or the ventilator, and the pattern of airway support provided by the ventilator. Continuous positive airway pressure, bilevel airway pressure support, assist-control mode ventilation, synchronized intermittent mandatory ventilation, positive end-expiratory pressure (PEEP), pressure support ventilation, and pressure-control ventilation are common modes and adjuncts of ventilation in use today (Table 37–7).

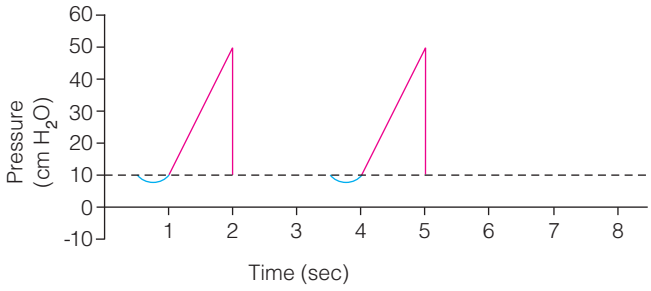












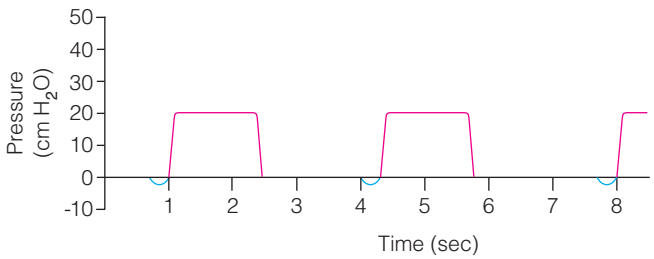


Figure 37–9 ■ A, Positive-pressure ventilator. B, Control panel used to set the mode, rate, limits, and percentage of oxygen.

TABLE 37–7 Modes of Positive-Pressure Ventilator Operation

Mode	Description	Pattern
Spontaneous breathing	Patient has full control of rate, tidal volume, pressures.	
Assist-control mode ventilation (ACMV)	Patient can trigger ventilator to deliver breaths at preset volume or pressure and inspiratory flow rate; breaths will be delivered at preset rate if patient does not initiate.	
Synchronized intermittent mandatory ventilation (SIMV)	Mandatory breaths delivered by ventilator are synchronized with patient's inspiratory effort.	
Continuous positive airway pressure (CPAP)	Positive pressure is maintained in airways; all breaths are spontaneous.	
Positive end-expiratory pressure (PEEP)	Used in conjunction with other ventilator modes; positive airway pressure is maintained throughout respiratory cycle.	
Pressure support ventilation (PSV)	Pressurized inspiratory flow supports the patient's inspiratory effort, decreasing the work of breathing.	

Noninvasive ventilation (NIV) provides ventilator support using a tight-fitting face mask, thus avoiding intubation. Its primary use is to support patients with obstructive sleep apnea, neuromuscular disease, or impending respiratory failure (e.g., advanced COPD). NIV also can be used for patients in respiratory failure who refuse intubation. The degree of success varies, primarily limited by patient intolerance due to the physical and psychologic discomfort of wearing a mask when dyspneic. NIV tends to be more successful in patients without significant underlying lung disease (e.g., respiratory failure related to neuromuscular disease).

Continuous positive airway pressure (CPAP) applies positive pressure to the airways of a spontaneously breathing patient. CPAP may be used with either endotracheal intubation or a tight-fitting face mask. All breathing is spontaneous (patient triggered) and pressure controlled. CPAP is used to help maintain open airways and alveoli, decreasing the work of breathing. *BiPAP* provides inspiratory positive airway pressure as well as airway support during expiration. BiPAP ventilation is primarily used at night with a tight-fitting mask (nasal, facial, or oral). Bilevel ventilation is a ventilator mode with high PEEP and low PEEP. Three modes of ventilation can be used with BiPAP: spontaneous breathing (S); timed mode (T), in which pressure supported breaths are delivered at a predetermined rate; and spontaneous/timed (S/T), in which the ventilator switches to timed mode if spontaneous breathing falls below a preset rate.

Assist-control mode ventilation (*ACMV* or *AC*) is frequently used to initiate mechanical ventilation and when the patient is at risk for respiratory arrest (e.g., overdose or head injury). Assisted breaths are triggered by inspiratory effort; however, if the respiratory rate falls below a preset number (e.g., 14 per minute), ventilator-controlled breaths are delivered. All breaths, assisted and controlled, are delivered at a specific tidal volume or pressure and inspiratory flow rate.

Synchronized intermittent mandatory ventilation (SIMV) allows the patient to breathe spontaneously, without ventilator assistance, between delivered ventilator breaths. Mandatory or ventilator-controlled breaths are delivered at a preset rate, volume, and/or pressure, coordinated with the patient's inspiratory efforts. This mode of ventilation is used to support ventilation, to exercise respiratory muscles between ventilator-assisted breaths, and during the weaning process.

Positive end-expiratory pressure (PEEP) requires intubation and can be applied to any of the previously described ventilator modes. With PEEP, a positive pressure is maintained in the airways during exhalation and between breaths. Keeping alveoli open between breaths improves ventilation–perfusion relationships and diffusion across the alveolar-capillary membrane. This reduces hypoxemia and allows use of lower percentages of inspired oxygen. PEEP is particularly useful for treating ARDS.

In *pressure support ventilation (PSV)*, ventilator-assisted breaths are delivered when the patient initiates an inspiratory effort. The cycle is flow limited; inspiration is terminated when inspiratory airflow falls below a preset rate. This mode decreases the work of breathing. It can be used in combination with SIMV when the respiratory drive is depressed. Ventilatory support can be gradually withdrawn during weaning.

Pressure-control ventilation (PCV), in contrast, controls pressure within the airways to reduce the risk of airway trauma (e.g., following thoracic surgery). Ventilation is time triggered and time cycled, but pressure is limited. The ventilator maintains a preset airway pressure throughout inspiration. Because all breaths are controlled by the ventilator, heavy sedation may be required to prevent competition between inspiratory effort and ventilator control.

Independent lung ventilation provides separate ventilation for each lung. Indications include unilateral lung disease. It can be used after lung transplantation to address pulmonary pressure differences between the native lung and allograft. It requires a double-lumen endotracheal tube and two ventilators. Patients may require heavy sedation.

High-frequency ventilation provides small gas volumes delivered at a rapid rate. It is indicated in patients who are hemodynamically unstable and intolerant of conventional MV. Use requires sedation and possibly pharmacologic paralysis (Perrin & MacLeod, 2012).

VENTILATOR SETTINGS In addition to choosing the mode of ventilation, other parameters are set to meet individual patient needs when positive-pressure ventilation is used (Table 37–8).

For most adult patients, the rate is initially set between 12 and 15 breaths per minute. With ACMV or SIMV, the patient's respiratory rate often is higher than the ventilator setting due to spontaneous breathing. Exhaled carbon dioxide ($ETCO_2$) or the PCO_2 may be used to determine the rate. A PCO_2 less than 35 mmHg indicates hyperventilation and respiratory alkalosis; the set rate is reduced. A PCO_2 above 45 mmHg or an $ETCO_2$ greater than 45 mmHg indicates hypoventilation and a need to increase the rate.

The tidal volume setting controls the amount of gas delivered with each ventilator breath. The normal adult tidal volume at rest is about 7 mL/kg of body weight, or 400 to 550 mL. The tidal volume delivered by mechanical ventilation is slightly higher (500 to 750 mL) to compensate for tubing dead space. Higher tidal volumes can cause lung tissue trauma.

The percentage of oxygen delivered with ventilator breaths is adjusted to maintain the oxygen saturation and PO_2 within acceptable

TABLE 37–8 Ventilator Settings

Parameter	Description
Rate (*f*)	Number of ventilator-delivered breaths per minute; usually 12 to 15 in adults using ACMV, may be lower in SIMV
Tidal volume (V_t)	Amount of gas delivered with each ventilator breath; usually 8 to 10 mL/kg of body weight
Oxygen concentration (FIO_2)	Percentage of oxygen delivered with ventilator breaths; can be set between 21% (room air) and 100%
I:E ratio	Duration of inspiration to expiration; usually 1:2 to 1:1.5
Flow rate	Speed at which air is delivered
Sensitivity	Effort required by patient to initiate a ventilator-assisted breath
Pressure limit	Maximal pressure within airways that will terminate a ventilator breath

ranges. Because prolonged delivery of high oxygen concentrations increases the risk of oxygen toxicity and pulmonary fibrosis, the FIO_2 is set at the lowest possible level for adequate tissue oxygenation. For most patients, the goal is to maintain an oxygen saturation greater than 90%. Lower oxygen saturation levels may be appropriate for patients with long-standing COPD.

COMPLICATIONS Although endotracheal intubation and mechanical ventilation can be lifesaving in respiratory failure, they are not without risk. Improper endotracheal tube placement or advancement of the tube into a mainstem bronchus can result in ventilation of one lung only. The inflated lung becomes overdistended and traumatized, and the uninflated lung develops atelectasis. In noninvasive ventilation, associated complications include gastric dilation, aspiration, facial skin necrosis, drying of the eyes and mucous membranes, stress, and claustrophobia.

NOSOCOMIAL PNEUMONIA Infection is a significant risk associated with intubation and mechanical ventilation. Normal upper respiratory tract defense mechanisms are bypassed, with loss of air humidification and trapping of pathogens. Oral secretions and gastric contents can enter the respiratory tree through the open epiglottis. Frequent, meticulous oral hygiene is vital in preventing ventilator-associated pneumonia. Often the cough reflex is inhibited or impaired by the underlying disease process and the continued presence of the endotracheal tube. Even when strict asepsis is used for suctioning and other respiratory procedures, the lower airways are contaminated within 24 hours of intubation. Secretions often become thick and tenacious, increasing the risk of atelectasis.

BAROTRAUMA *Barotrauma* (also called *volutrauma*) is lung injury due to alveolar overdistention. Both the volume of delivered gas and the pressures under which it is delivered can contribute to barotraumas. As a result, overdistended alveoli rupture, allowing air to escape into the pulmonary interstitial spaces and the mediastinum, pleural space, and other tissues. Subcutaneous emphysema, pneumothorax, and pneumomediastinum are possible results of barotrauma. *Subcutaneous emphysema,* or air in the subcutaneous tissue, causes tissue swelling of the chest, neck, and face. A "crackling" or air-bubble-popping sensation is felt on palpation of subcutaneous emphysema. Swelling may be massive. Once the cause is corrected, the air is gradually reabsorbed over weeks.

Pneumothorax is identified by signs of unequal chest expansion, a sudden loss or significant decrease in breath sounds on the affected side, and a hyperresonant percussion tone. Rapid chest tube insertion is necessary to prevent tension pneumothorax and cardiovascular compromise. *Pneumomediastinum* is the presence of air in the mediastinum, the space between the lungs that contains the heart, great vessels, trachea, and esophagus. Air in the mediastinal space can interfere with the function of all these organs and lead to such complications as pneumopericardium (air in the pericardial sac). Pneumomediastinum may have few manifestations, but the chest x-ray shows widening of the mediastinal space.

CARDIOVASCULAR EFFECTS Positive-pressure ventilation increases intrathoracic pressure, which can interfere with venous return to the heart and ventricular filling. As a result, cardiac output falls. Use of PEEP increases the effects of mechanical ventilation on cardiac output. The decreased cardiac output can affect liver and kidney function secondarily.

GASTROINTESTINAL EFFECTS Gastrointestinal complications are commonly associated with prolonged mechanical ventilation. Stress ulcers (erosive gastritis) may develop, leading to painless gastrointestinal hemorrhage. Histamine H_2-receptor blockers or sucralfate are often used to prevent stress ulcers. Air leaks around the endotracheal tube can cause gastric distention; a nasogastric tube often is inserted to prevent vomiting. Sedation and other medications used during mechanical ventilation can slow intestinal motility, leading to constipation.

WEANING The process of removing ventilator support and reestablishing spontaneous, independent respirations is called **weaning**. Weaning begins only after the underlying process causing respiratory failure has been corrected or stabilized. The process and time required for weaning depend on factors such as preexisting lung condition, duration of mechanical ventilation, and the patient's general condition, both physical and psychologic. In all cases, the vital signs, respiratory rate, extent of dyspnea, blood gases, and clinical status are used to evaluate weaning and its progress.

Following a brief period of mechanical ventilation, T-piece or CPAP may be used for weaning. In T-piece weaning, the ventilator is removed for brief periods during which oxygen is delivered using a T-piece (Figure 37–10 ■). The duration of periods off the ventilator is gradually increased until the patient can maintain adequate independent respirations for several hours. Vital signs, oxygen saturation, $ETCO_2$, and PO_2 are carefully monitored during the process. The patient is placed back on the ventilator at previous settings if signs of respiratory distress develop. When mechanical ventilation is no longer needed, the endotracheal tube is removed. CPAP weaning follows a similar process, with trials of spontaneous breathing supported by the ventilator in CPAP mode.

SIMV and PSV are used for weaning when the duration of mechanical ventilation has been longer and reconditioning of respiratory muscles is needed. When SIMV is used, the number of mandatory ventilator-assisted breaths is gradually decreased as ABGs, $ETCO_2$, and the respiratory rate are monitored. When the patient is able to tolerate SIMV at 4 breaths per minute without rest periods of greater ventilatory support, CPAP or T-piece weaning is attempted prior to extubation.

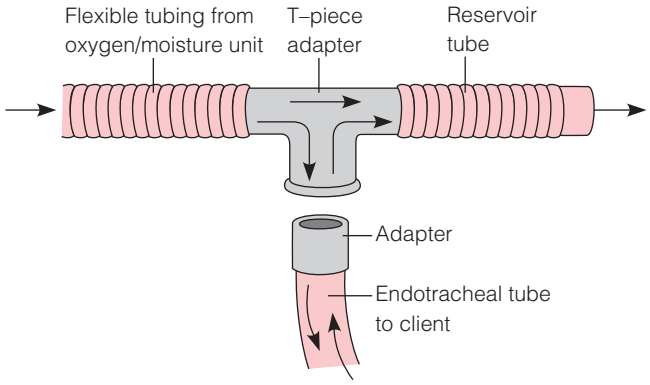

Figure 37–10 ■ A T-piece, or "blow-by" unit, for weaning from mechanical ventilation.

Weaning is the primary use for pressure support ventilation (PSV). Initially, PSV is set slightly below the peak inspiratory pressures required during volume-cycled ventilation. Pressure support levels are gradually decreased, often in a cyclic pattern of periods of minimal support alternating with higher support to recondition respiratory muscles. When the PSV level is just enough to overcome endotracheal tube resistance, support is discontinued and the patient is extubated.

TERMINAL WEANING When an illness is terminal or irreversible with a poor prognosis, terminal weaning may be requested by the patient or family. *Terminal weaning* is the gradual withdrawal of mechanical ventilation when survival without assisted ventilation is not expected. Unlike weaning when recovery is expected, which usually occurs in an intensive care unit (ICU), the patient is moved to a quiet medical-surgical or hospice room or even home prior to initiating terminal weaning. Family members are encouraged to remain with the patient throughout the process. If possible, decisions about sedation and analgesia prior to and during weaning are made with the patient, as are decisions about hydration and nutritional support following weaning. Ventilator support is withdrawn using the same modes described earlier (SIMV, PSV). Analgesia and sedation are given to promote comfort during weaning.

NUTRITION AND FLUIDS

Attention also must be paid to fluid and electrolyte status and adequate nutrition. Mechanical ventilation promotes sodium and water retention due to its effects on cardiac output. Renal perfusion is decreased, stimulating the renin–angiotensin–aldosterone system to retain sodium and water. A Swan-Ganz catheter is often inserted to monitor pulmonary artery pressures and cardiac output. An arterial line allows repeated blood gas analysis and continuous arterial pressure monitoring. Serum electrolytes are drawn frequently, and intake, output, and daily weight are carefully monitored.

Enteral or parenteral nutrition is provided during mechanical ventilation, because the endotracheal tube prohibits eating. A nasogastric, gastrostomy, or jejunostomy feeding tube is placed for enteral nutrition. A jejunostomy tube may be used to reduce the risk of regurgitation and aspiration.

●○● NURSING CARE

Health Promotion

Education is a primary strategy to prevent respiratory failure. Teach all patients and the public about the risks of smoking, water safety, the value of a working smoke detector, and measures to prevent smoke inhalation during a fire. Discuss the importance of pneumococcal vaccine and annual influenza immunizations for people who are at high risk, including those over age 65 and people with chronic diseases. Teach patients with spinal cord injury or neuromuscular disease to use effective breathing and coughing techniques to maintain airway patency. Work with patients addicted to narcotic drugs to attain and maintain drug-free status. Teach patients with COPD about measures to reduce their risk of respiratory infection and symptoms to report to the physician.

Assessment

See the Manifestations and Interprofessional Care sections for the assessment of the patient with respiratory failure.

Focused assessment data related to respiratory failure includes the following:

- *Health history:* current manifestations, their duration, and identified precipitating factors (may need to be obtained from family members if mental status is affected); history of previous episodes; chronic diseases such as COPD, occupational lung disease; current medications
- *Physical assessment:* level of consciousness, mental status; vital signs; color and oxygen saturation; respiratory assessment including rate and depth, use of accessory muscles, respiratory excursion, auscultation; cardiovascular assessment including heart rate and sounds, neck vein distention, peripheral pulses, evidence of clubbing
- *Laboratory data:* ABGs, chest x-ray, pulmonary artery pressure and wedge pressure readings, cardiac output.

Priorities of Care

Collaborating with the interprofessional team to ensure adequate treatment of the underlying process while providing care that supports the physical and psychologic responses to the disorder is a priority of nursing care.

Diagnoses, Outcomes, and Interventions

Patients in respiratory failure are often unstable and critically ill. They require both intensive medical care and intensive nursing care. Priority nursing needs relate to maintaining ventilation and a patent airway. Perhaps less obvious, but no less critical, nursing care needs relate to preventing injury and managing anxiety.

Impaired Spontaneous Ventilation

In acute respiratory failure, fatigue from the work of breathing may impair the ability to maintain adequate ventilation. This is a concern both prior to initiation of mechanical ventilation and during the weaning process.

Expected Outcome: Patient will maintain arterial blood gases within safe parameters while effectively maintaining airway and secretion mobilization.

- Assess and document respiratory rate, vital signs, and oxygen saturation every 15 to 30 minutes. *Close monitoring is vital to detect early signs of increasing respiratory distress and inability to sustain adequate breathing.*

Evidence for Nursing Care

The Patient with Acute Respiratory Distress Syndrome

Selected resources that nurses may find helpful when planning evidence-based nursing care follow.

- Jones, T. L. (2011). A retrospective exploration of patient-ventilator monitoring intensity, therapeutic intervention intensity, and compliance with lung protective guidelines in a cohort of patients with adult respiratory distress syndrome. *Worldviews of Evidence-Based Nursing, 8*(1), 40–50.
- Wright, A. D., & Flynn, M. (2011). Using the prone position for ventilated patients with respiratory failure: A review. *Nursing in Critical Care, 16*(1), 19–27.

SAFETY ALERT

Promptly report signs of respiratory distress, including tachypnea, tachycardia, nasal flaring, use of accessory muscles, intercostal retractions, cyanosis, increasing restlessness, anxiety, or decreased level of consciousness. These may be early manifestations of respiratory failure and inability to maintain ventilatory effort.

- Promptly report worsening arterial blood gases and oxygen saturation levels. *Close assessment of these values allows timely intervention as needed.*
- Administer oxygen as ordered, monitoring response. Observe closely for respiratory depression, especially in the patient with COPD. *Oxygen administration reduces the hypoxemic respiratory drive. Chronically high PCO_2 levels depress the respiratory center; hypoxemia may provide the only respiratory drive.*
- Place in Fowler's or high-Fowler's position. *Sitting positions decrease pressure on the diaphragm and chest, improving lung ventilation and decreasing the work of breathing.*
- Minimize activities and energy expenditures by assisting with ADLs, spacing procedures and activities, and allowing uninterrupted rest periods. *Rest is vital to reduce oxygen and energy demands.*
- Avoid sedatives and respiratory depressant drugs unless mechanically ventilated. *These medications can further depress the respiratory drive, worsening respiratory failure.*
- Prepare for endotracheal intubation and mechanical ventilation:
  a. Obtain an intubation tray with a selection of sterile endotracheal tubes and laryngoscope with a variety of adult blades.
  b. Check laryngoscope lamp; replace battery pack or bulb as needed.
  c. Set up for endotracheal suction, bringing continuous suction head, container, tubing, sterile catheter and glove kits, and sterile normal saline to the bedside.
  d. Notify respiratory therapy to set up the ventilator.
  e. Notify radiology that a portable chest x-ray will be needed on completion of intubation to verify correct placement of the endotracheal tube.

  Intubation and mechanical ventilation may be required to maintain ventilation and gas exchange.
- Explain the procedure and its purpose to the patient and family, providing reassurance that this is a temporary measure to reduce the work of breathing and allow rest. Alert that talking is not possible while the endotracheal tube is in place, and establish a means of communication. *Thorough explanation is important to relieve anxiety.*

Ineffective Airway Clearance

Ineffective airway clearance may either cause respiratory failure or occur as a result of interventions. Impaired ventilation frequently leads to acute respiratory failure, particularly in patients with COPD or asthma. Chest trauma also can impair airway patency as a result of pulmonary contusion and ineffective cough. Although intubation and mechanical ventilation can be lifesaving measures, they also increase the risk of respiratory infection and ineffective secretion management.

Expected Outcome: Patient will use techniques to promote airway clearance such as coughing and deep breathing when able. Patient's airway clearance will be maintained by the nurse during mechanical ventilation via suctioning as needed.

SAFETY ALERT

Frequently assess respiratory rate, chest movement, lung sounds, oxygen saturation, $ETCO_2$, and ABGs. Intubation and mechanical ventilation do not ensure adequate oxygenation and ventilation. Displacement of the endotracheal tube or obstruction by respiratory secretions impairs ventilation.

- Suction as needed to maintain a patent airway. Indicators for suctioning include crackles and rhonchi on auscultation, frequent coughing or setting off the high-pressure alarm, and increasing restlessness or anxiety. *Although patients with a tracheostomy can usually cough up secretions, the length and diameter of endotracheal tubes make this extremely difficult. Even with humidification, secretions often become thick and tenacious, further inhibiting their removal.*
- Obtain sputum for culture if it appears purulent or is odorous. *Culture is necessary to identify pathogens and guide antibiotic therapy.*
- Perform percussion, vibration, and postural drainage as ordered. *These techniques help loosen secretions and move them into larger airways for removal by coughing or suctioning.*

PRACTICE ALERT!

Evaluate endotracheal tube cuff pressure by measurement (should have no more than 20 to 25 mmHg of pressure) or by auscultating the suprasternal notch for a hissing sound at the end of inspiration. The minimum effective cuff pressure to maintain alveolar ventilation is used to reduce the risk of tracheal ischemia and necrosis.

- Firmly secure endotracheal or tracheostomy tube. Provide adequate slack on ventilator tubing to prevent tension on the tube when turning, positioning, or transferring to chair or stretcher. If necessary, loosely restrain hands. *These measures are important to ensure proper airway placement and prevent its inadvertent removal.*
- Assess fluid balance and maintain adequate hydration. *Adequate hydration helps liquefy secretions.*

Risk for Injury

Many factors increase the risk for injury in acute respiratory failure. Hypoxemia and hypercapnia affect the level of consciousness and may impair mental status. Endotracheal intubation and mechanical ventilation carry risks of tracheal damage and trauma to the lungs. Neuromuscular blockade, if used, presents a significant risk for injury because the patient is unable to breathe spontaneously, communicate, and move.

Expected Outcome: Patient will demonstrate understanding of plan to promote safe environment related to therapeutic needs (endotracheal tube, medications) as appropriate for patient condition.

- Assess frequently, noting the following:
  a. Level of consciousness, orientation, and awareness
  b. Condition of mucosa of mouth and nose
  c. Respiratory: lung sounds, chest excursion, and ventilator pressures
  d. Cardiovascular: vital signs, skin color, capillary refill, and peripheral pulses

e. Gastrointestinal: bowel sounds; test gastric secretions and feces for occult blood
f. Genitourinary: urine output, daily weight
g. Skin and extremities.

Complications associated with respiratory failure and mechanical ventilation can affect many body systems. Frequent assessment allows early detection and intervention.

SAFETY ALERT

Do not bypass or turn off any ventilator alarms. The intubated patient is unable to communicate verbally and cannot call for help. If neuromuscular blockers are used, the patient is also unable to breathe without ventilator support.

- Report condition changes such as increasing air leak around the cuff and decreased breath sounds or chest movement. *These may be manifestations of a complication of intubation and ventilation, such as tracheal necrosis, displacement of the endotracheal tube into the right mainstem bronchus, pneumothorax, or atelectasis.*
- Turn and reposition frequently, taking care to stabilize endotracheal tube during movement. *Repositioning helps maintain tissue perfusion and prevent skin and tissue breakdown.*
- Keep skin and linens clean, dry, and wrinkle free. Protect pressure areas with padding, egg crate, or heal and elbow protectors. *The patient may not be able to perceive and report pain or move voluntarily to reduce pressure, necessitating excellent skin care and potential specialty bed use.*
- Perform passive ROM exercises every 4 to 8 hours. *These exercises maintain joint flexibility and help prevent contractures associated with long-term immobility.*
- Keep side rails up and use soft restraints as needed. *These safety measures are important to prevent falls, inadvertent disconnection of the ventilator, or dislodging of the endotracheal tube.*
- Administer histamine H_2-blockers and sucralfate as ordered. *Stress gastritis and possible gastrointestinal hemorrhage are common, preventable complications of mechanical ventilation.*

Anxiety

Critical illness creates anxiety for any patient. In acute respiratory failure, this anxiety is compounded by the presence of an endotracheal tube or tracheostomy, mechanical ventilator, numerous monitors and equipment, and, potentially, neuromuscular blockade and paralysis of voluntary muscles. Fear of continued dependence on the mechanical ventilator and inability to return to a normal life may compound this anxiety.

Expected Outcome: Patient will control anxiety as evidenced by verbalized decrease in subjective distress.

- Frequently monitor anxiety level. *High levels of anxiety increase oxygen use and often interfere with the ability to work with the respirator. This can increase hypoxemia and further increase anxiety; intervention is necessary to break this cycle.*
- Remain with the patient as much as possible. *The frequent and continuing presence of a caregiver provides reassurance that help is readily available.*
- Explain all monitors, procedures, unusual sounds, and machinery. *Understanding of the environment and various sounds and alarms reduces anxiety.*
- Provide a simple means of communication, such as a slate, picture board, or alphabet board. If neuromuscular blockade is used, use methods such as looking to the right for "yes" and left for "no." Reassure that endotracheal tube removal restores the ability to speak. *The inability to speak and call out for help is frightening for the patient. Providing an alternate means of communication helps reduce anxiety.*
- Encourage frequent family visits, especially if the time of visitations is being limited. Encourage family participation in care. *Family visits help reduce anxiety and feelings of abandonment. Allowing family members to participate in care helps reduce their anxiety as well.*
- Explain to the family that the patient can hear and understand. Emphasize the importance of talking to the patient, not over or about the patient. *The family may not understand that the patient may be mentally alert although unable to respond. Talking to the patient about everyday things reduces the patient's sense of isolation and fear.*
- Provide distraction with radio or television if allowed. *Distraction helps reduce the focus on machines and unusual sounds of monitors and alarms.*
- Attend to physical needs promptly and completely. *This provides reassurance that needs will be met even though the patient is unable to ask for assistance.*
- Reassure that intubation and mechanical ventilation are temporary measures to allow the lungs to rest and heal. Reinforce that the patient will be able to breathe independently again. *The patient may fear continued dependence on mechanical ventilation.*

SAFETY ALERT

Provide sedation and antianxiety medications as needed, especially when neuromuscular blockade is used. Although neuromuscular blockade paralyzes voluntary muscles, the level of consciousness is unimpaired.

Continuity of Care

Prior to hospital discharge, teach the patient and family about the following topics:

- Factors that precipitated respiratory failure and measures to prevent it in the future (e.g., the impact of respiratory irritants on compromised lungs)
- Measures to prevent future episodes such as remaining indoors with an air filter or air conditioning when pollution levels are high, obtaining influenza and pneumonia immunizations, and avoiding exposure to cigarette smoke
- Effective coughing and pulmonary hygiene measures such as percussion, vibration, and postural drainage.

Acute respiratory failure resulting from an acute insult such as pneumonia or near-drowning often resolves with few long-term sequelae. When respiratory failure results from an underlying disease such as COPD, the prognosis is less optimistic. Patients with end-stage COPD may have repeated episodes of respiratory failure, with a gradual loss of respiratory function and reserve. These patients may choose terminal weaning rather than a future of increasing disability. Discuss what to expect during the terminal weaning process with the patient and family. Discuss use of sedation prior to and during the weaning process. Explain

Moving Evidence into Action

The Patient Who Is Intubated

Endotracheal tube (ETT) cuff pressure must be maintained within a narrow range to prevent complications such as inadequate ventilation or aspiration (too low of pressure) or tracheal wall damage (too high pressure). While ETT cuff pressure is routinely monitored on an intermittent basis as the standard of care, evaluation of continuous tube pressure monitoring has not been well described. Mary Lou Sole, PhD, RN, and colleagues (2009) conducted a study to assess the accuracy and feasibility of a continuous cuff pressure monitoring system. This pilot study included 10 patients who were orally intubated and receiving mechanical ventilation. A transducer and pressure monitor was attached to the cuff pilot balloon, recording cuff pressure every 0.008 second over a 12-hour shift. The data was reduced to 1-minute means for analysis. Sole and colleagues found that only 54% of cuff pressure measurements were within the recommended range with high pressures (> 30 cm H_2O) occurring in 16% of the measurements, while low pressure (< 20 cm H_2O) was seen in 30% of the measurements. Changes in cuff pressure were noted with activity, suctioning, and coughing. In conclusion, considerable variability in cuff pressure was noted and that intermittent cuff pressure measurement only provides a "snapshot" while not reflecting many of the factors that impact cuff pressure.

Implications for Nursing

Cuff pressure monitoring is an important consideration in the optimal management of the mechanically ventilated patient while reducing potential complications. This study found that continuous monitoring of ETT cuff pressure is feasible and accurate. This is a first step in developing and testing technology that can promote optimal patient ventilation while reducing complications of intubation.

Moving Knowledge into Action

1. Discuss the physiologic and pathophysiologic concepts that indicate the use of ETT cuff balloons.
2. What factors and activities might contribute to changes in ETT cuff pressure in the patient who is intubated and mechanically ventilated?
3. The study described is a pilot study using a novel methodology to assess ETT cuff tube pressure. What other factors should be tested before such technology is ready for widespread use in the clinical environment?

that medications are used to reduce respiratory distress and dyspnea during weaning. Assure the patient and family that nursing support is continuously available during the weaning process and that family and other supporters such as clergy are allowed to remain with the patient.

THE PATIENT WITH ACUTE RESPIRATORY DISTRESS SYNDROME

Acute respiratory distress syndrome (ARDS) is characterized by noncardiac pulmonary edema and progressive refractory hypoxemia. First identified in 1967, ARDS has been known by various names, such as shock lung and adult hyaline membrane disease. It is widely recognized as a severe form of acute respiratory failure.

FAST FACTS

- Approximately 190,000 Americans are affected by ARDS annually (National Heart, Lung, and Blood Institute [NHLBI], 2012).
- Most patients recover near-normal lung function within 6 months of developing ARDS.
- Mortality associated with ARDS is about 40% and often is due to multiple organ system dysfunction related to ineffective tissue oxygenation (NHLBI, 2012).

Although the exact cause of ARDS is unclear, it is known that ARDS does not occur as a primary process but may follow a number of diverse conditions producing direct or indirect lung injury (Table 37–9). Patients who develop ARDS as a complication of an acute lung injury or condition are more likely to fully recover than patients with chronic conditions (NHLBI, 2012).

Pathophysiology

The underlying pathology in ARDS is acute lung injury resulting from an unregulated systemic inflammatory response to acute injury or inflammation. Inflammatory cellular responses such as tumor necrosis factor (TNF), leukotrienes, macrophage inhibitory factor along with platelet sequestration and activation, as well as biochemical mediators, damage the alveolar-capillary membrane. This damage develops rapidly, often within 90 minutes of the systemic inflammatory response and within 24 hours of the initial insult (Figure 37–11 ■). Damaged capillary membranes allow plasma and blood cells to escape into the interstitial space. Increased interstitial pressure and damage to the alveolar membrane allow fluid to enter the alveoli. Within the alveolus, the fluid dilutes and inactivates surfactant. Surfactant-producing cells are damaged by the inflammatory process leading to a deficit of surfactant, increased alveolar surface tension, and alveolar collapse with atelectasis. The lungs become less compliant, and gas exchange is impaired. As the syndrome progresses, hyaline membranes form, further reducing gas exchange and compliance. Finally, fibrotic changes occur in the lungs. Intra-alveolar septa thicken, and alveolar surface area for gas exchange is reduced. Hypoxemia becomes refractory or resistant to

TABLE 37–9 Conditions Associated with the Development of ARDS

Conditions	Examples
Shock	Hemorrhagic shock, septic shock
Inhalation injuries	Aspiration of gastric contents, smoke and toxic gases, near-drowning, oxygen toxicity
Infections	Gram-negative sepsis, viral pneumonias, *Pneumocystis jiroveci* pneumonia, miliary tuberculosis
Drug overdose	Heroin, methadone, propoxyphene, aspirin
Trauma	Burns, head injury, lung contusion, fat emboli
Other	Disseminated intravascular coagulation (DIC), pancreatitis, uremia, amniotic fluid and air emboli, multiple transfusions, open heart surgery with cardiopulmonary bypass

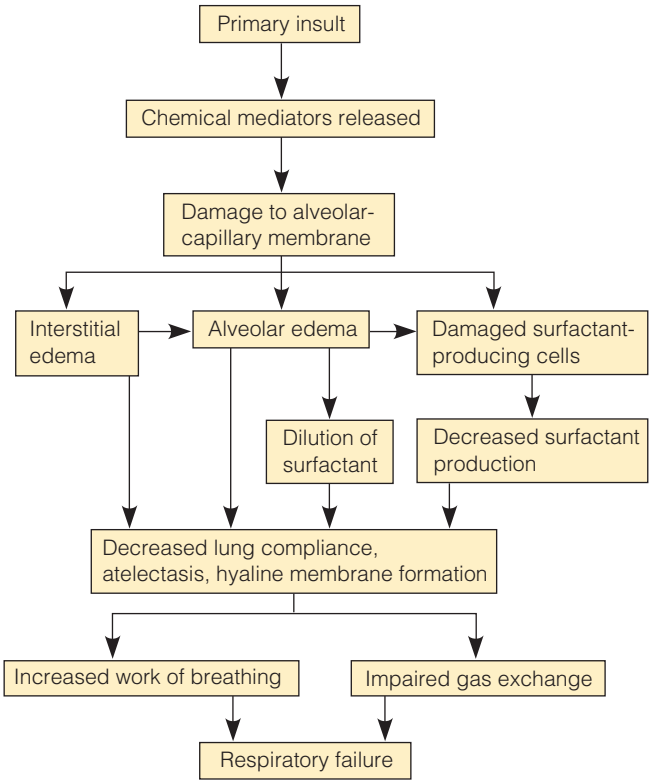

Figure 37–11 ■ The pathogenesis of ARDS.

improvement with supplemental oxygen, and the PCO_2 rises as diffusion is further impaired. The Pathophysiology Illustrated feature on pages 1210–1211 illustrates the pathophysiology of ARDS.

As ARDS progresses, tissue hypoxia becomes significant and metabolic acidosis develops. Carbon dioxide exchange is impaired as well as oxygen exchange, leading to combined respiratory and metabolic acidosis. Sepsis and multiple organ system dysfunction of the kidneys, liver, gastrointestinal tract, CNS, and cardiovascular system are the leading causes of death in ARDS. If the process is halted before this occurs, the long-term prognosis for recovery is good.

Manifestations

Initial manifestations of ARDS typically develop 24 to 48 hours after the initial insult. Dyspnea, tachypnea, and anxiety are early manifestations. Progressive respiratory distress develops with increasing respiratory rate, intercostal retractions, and use of accessory muscles of respiration. Cyanosis develops that may not improve with oxygen administration. Breath sounds are initially clear, but crackles (rales) and rhonchi develop later. As respiratory failure progresses, mental status changes such as agitation, confusion, and lethargy occur.

●○● INTERPROFESSIONAL CARE

ARDS management is directed toward identifying and treating its underlying cause and providing aggressive respiratory support.

DIAGNOSIS

Refractory hypoxemia (hypoxemia that does not improve with oxygen administration) is the hallmark of ARDS.

- *Arterial blood gases* initially show hypoxemia with a PO_2 of less than 60 mmHg and respiratory alkalosis due to tachypnea.
- *Chest x-ray* changes may not be evident for as long as 24 hours after the onset of ARDS. Diffuse infiltrates are seen initially, progressing to a "white-out" pattern. Chest *CT scan* provides a better illustration of the pattern of alveolar consolidation and atelectasis in ARDS.
- *Pulmonary function testing* shows decreased lung compliance with reduced vital capacity, minute volume, and functional vital capacity.
- *Pulmonary artery pressure monitoring* shows normal pressures in ARDS, helping distinguish ARDS from cardiogenic pulmonary edema.

MEDICATIONS

Although there is no definitive drug therapy for ARDS, a number of medications may be used. Inhaled nitric oxide reduces intrapulmonary shunting and improves oxygenation by dilating blood vessels in better-ventilated areas of the lungs. Surfactant therapy may be prescribed. Surfactant is a complex mixture of phospholipids, neutral lipids, and proteins that forms a thin layer atop a thin layer of water on the inner surface of the alveolus, reducing the surface tension within the alveoli. Surface tension tends to pull the walls of the alveoli together, increasing the likelihood of collapse during exhalation. Surfactant, by reducing surface tension, helps maintain open alveoli, decreasing the work of breathing, improving compliance and gas exchange, and preventing atelectasis.

Interventions to block the inflammatory response are under investigation, such as using nonsteroidal anti-inflammatory agents and corticosteroids. Corticosteroids may be used late in the course of ARDS to improve oxygenation and lung mechanics when fibrotic changes occur.

MECHANICAL VENTILATION

The mainstay of ARDS management is endotracheal intubation and mechanical ventilation. With ARDS, it is rarely possible to maintain adequate tissue oxygenation with oxygen therapy alone.

With mechanical ventilation, the FIO_2 is set at the lowest possible level to maintain a PO_2 higher than 60 mmHg and oxygen saturation of approximately 90%. When the PO_2 cannot be maintained with less than 50% inspired oxygen, there is a risk that oxygen toxicity will accentuate ARDS. Often it is necessary to use positive end-expiratory pressure (PEEP) during mechanical ventilation settings to maintain blood and tissue oxygenation. Maintaining open airways and alveoli enhances gas diffusion and reduces ventilation–perfusion mismatch. PEEP decreases cardiac output and increases the risk of barotrauma, necessitating close monitoring. Either assist-control or SIMV may be used along with PEEP or CPAP in treating ARDS.

It is important to remember that mechanical ventilation does not cure ARDS; it simply supports respiratory function while the underlying problem is being identified and treated.

TREATMENTS

The use of low-dose corticosteroids remains controversial in the treatment of ARDS. However, in a meta-analysis of research studies, low-dose corticosteroids were associated with improved

mortality and morbidity without increased risk for adverse reactions (Lamontagne et al., 2010).

Atelectasis frequently occurs in dependent lung regions in ARDS. Prone positioning in conjunction with mechanical ventilation reduces the pressure of surrounding tissue on dependent regions and improves oxygenation.

Other management strategies include careful fluid replacement, attention to nutrition, treatment of any infection, and correction of the underlying condition. A Swan-Ganz line is sometimes placed to monitor pulmonary artery pressures and cardiac output. Fluid replacement is carefully tailored to these measurements to avoid fluid imbalances, which may worsen hypoxia and ARDS. Enteral or parenteral feeding is necessary to maintain nutritional status and prevent tissue catabolism. Infections are treated with intravenous antibiotic therapy tailored to the causative organism. Low-molecular-weight heparin may be ordered to prevent thrombophlebitis and possible pulmonary embolus or disseminated intravascular coagulation (DIC), a possible complication of ARDS.

●○● NURSING CARE

The nursing care needs of the patient with ARDS are very similar to those of any patient with acute respiratory failure. Maintaining adequate ventilation and respirations are of highest priority, along with preventing injury and managing anxiety. See the section on acute respiratory failure for nursing care related to these diagnoses. Additional high-priority nursing care concerns for the patient with ARDS are related to the effects of PEEP on cardiac output and potential problems of weaning ventilatory support. See the Case Study & Nursing Care Plan that follows for additional nursing interventions for the patient with ARDS.

Decreased Cardiac Output

With positive-pressure ventilation, increased intrathoracic pressure decreases cardiac output. When PEEP is applied, intrathoracic pressure increases further; this can significantly decrease venous return, ventricular filling, stroke volume, and cardiac output. Manifestations of decreased cardiac output include hypotension and compensatory tachycardia as the heart attempts to maintain cardiac output despite decreased stroke volume. In the patient who is already hypoxic because of ARDS, this drop in cardiac output can increase tissue damage. Urine output falls, and dysrhythmias may develop.

Expected Outcome: Patient will demonstrate adequate cardiac output as evidenced by blood pressure and pulse rate within normal parameters for the patient.

- Monitor and record vital signs, including apical pulse, at least every 2 hours, and more frequently immediately following initiation of mechanical ventilation or addition of PEEP. *Frequent assessment is vital to detect early signs of decreased cardiac output.*
- Record urine output hourly. Because a significant portion of the cardiac output goes directly to the kidneys, a fall in urine output to less than 30 mL/h is often the first sign of decreased cardiac output.
- Assess level of consciousness at least every 4 hours. *Altered level of consciousness, confusion, and restlessness are early signs of cerebral hypoxia due to decreased cardiac output.*
- Monitor pulmonary artery pressures, central venous pressure, and cardiac output readings every 1 to 4 hours. *Changes in these measurements may indicate worsening cardiac status.*
- Assess heart and lung sounds frequently. *Increasing crackles or abnormal heart sounds may indicate heart failure.*
- Weigh daily at the same time. *Accurate daily weights are the best indicator of fluid volume status.*
- Frequently provide good skin care, keeping skin clean and dry and protecting pressure points. *Tissue hypoxia increases the risk of skin breakdown, which in turn increases the risk of infection and sepsis.*
- Maintain intravenous fluids as ordered. *Intravenous fluids are given to maintain vascular volume and prevent dehydration.*
- Administer analgesics, sedatives, and neuromuscular blockers as needed. *These medications may be prescribed to decrease cardiac workload.*

Dysfunctional Ventilatory Weaning Response

The patient with dysfunctional ventilatory weaning response has difficulty adjusting to reduced mechanical ventilator support, prolonging the weaning process. Airway congestion, inadequate rest or nutrition, pain, anxiety, and a nonsupportive environment are factors that can contribute to difficulty weaning. With ARDS, the pathologic processes of the disease and its effects on gas exchange may be responsible for a prolonged or ineffective weaning process.

Expected Outcome: Patient will maintain arterial blood gases within safe parameters while effectively maintaining airway and secretion mobilization.

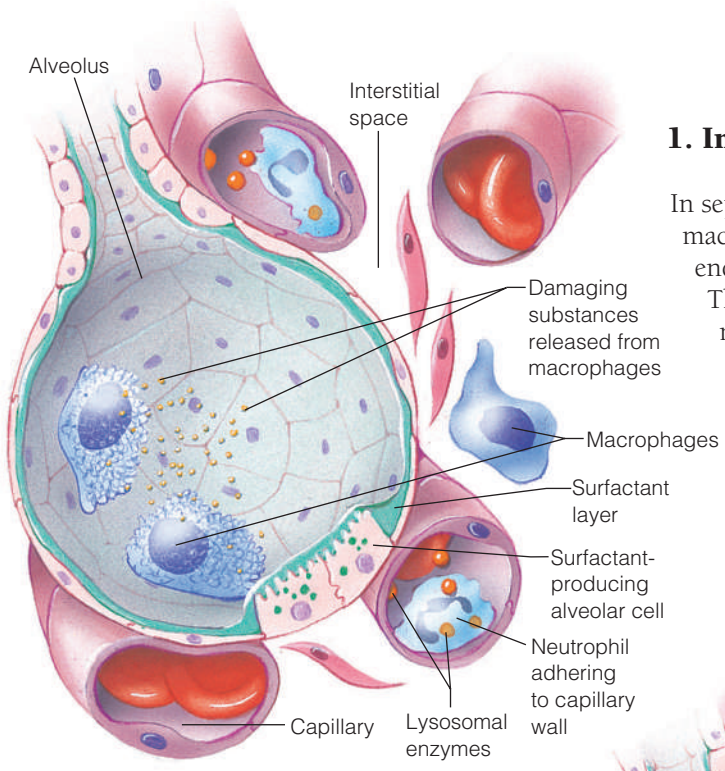
Assessment findings indicative of dysfunctional weaning include the following:

- Dyspnea, apprehension, or agitation
- Decreasing oxygen saturation level
- Cyanosis or pallor, diaphoresis
- Increased blood pressure, pulse, and respiratory rate
- Diminished or adventitious breath sounds, use of accessory muscles
- Decreased level of consciousness
- Deteriorating arterial blood gas values
- Shallow, gasping breaths or paradoxic abdominal breathing.

Nursing interventions for dysfunctional weaning include the following:

- Assess vital signs every 15 to 30 minutes following changes in ventilator settings and during T-piece trials. *Vital signs, heart and respiratory rates in particular, can provide early signs of hypoxemia and poor tolerance of the weaning process.*

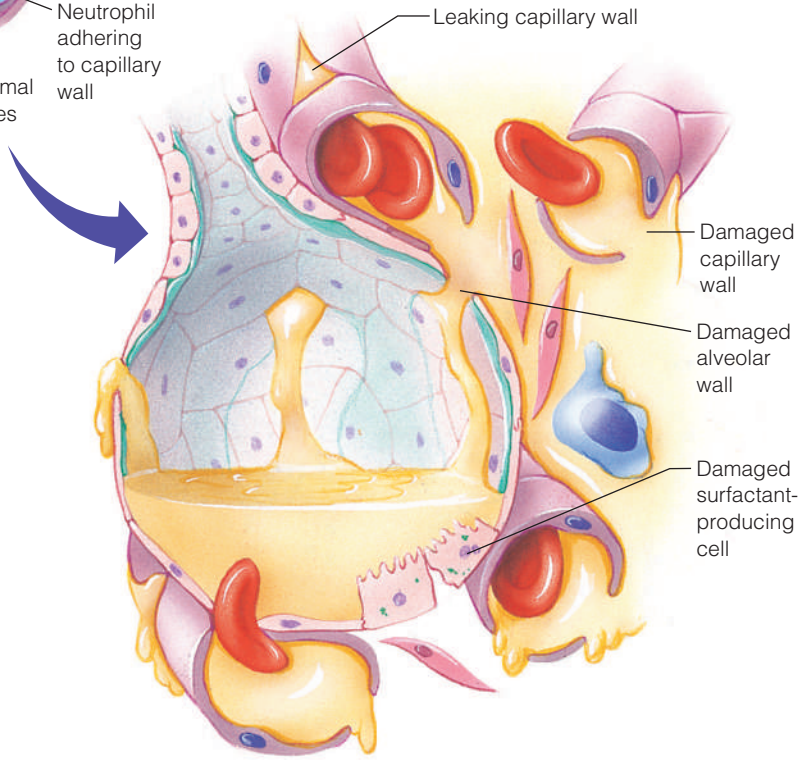
PRACTICE ALERT!



Frequently monitor oxygen saturation, $ETCO_2$, and ABGs following changes in ventilator settings. These values are used to assess the adequacy of ventilation and gas exchange during the weaning process.

- Place in Fowler's or high-Fowler's position. *Fowler's position facilitates lung expansion and reduces the work of breathing.*
- Fully explain all weaning procedures, along with expected changes in breathing. *Adequate explanations help reduce anxiety and improve the ability to cooperate.*
- Remain with the patient during initial periods following changes of ventilator settings or T-piece trials. *This provides reassurance and allows close monitoring of the response.*

PATHOPHYSIOLOGY ILLUSTRATED

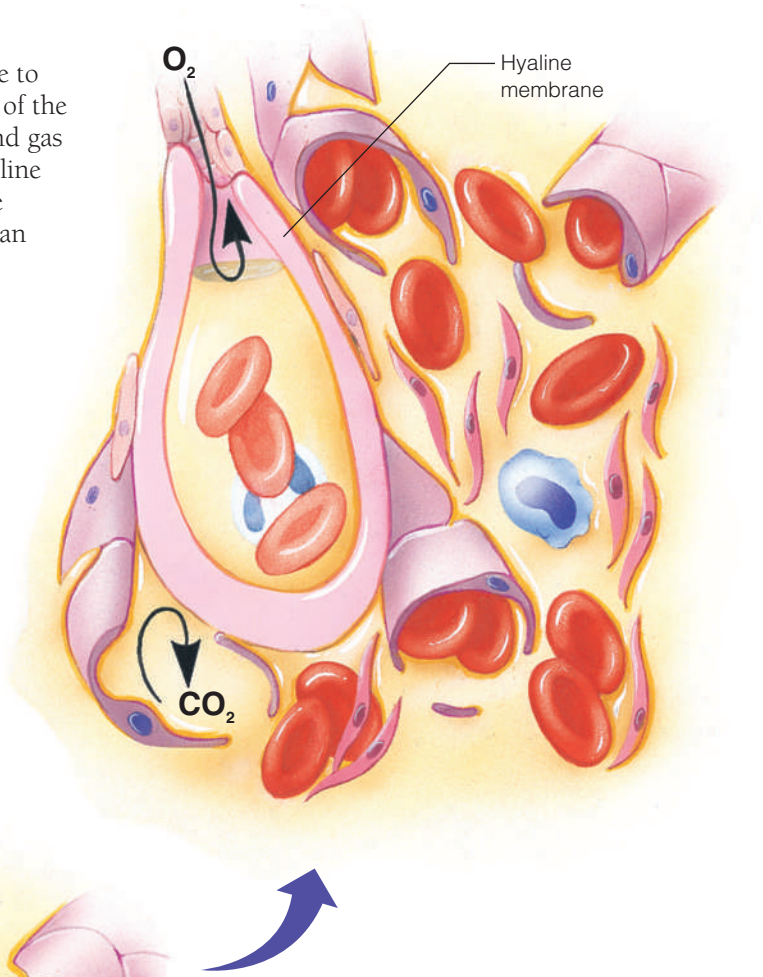


Acute Respiratory Distress Syndrome

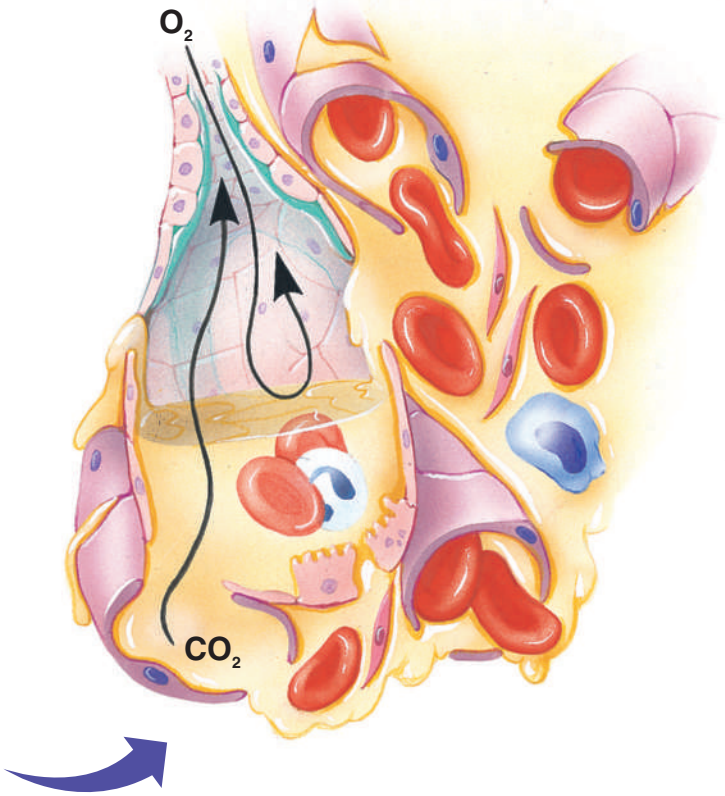
Acute respiratory distress syndrome (ARDS) is a severe form of acute respiratory failure that occurs in response to pulmonary or systemic insults. ARDS is characterized by noncardiogenic pulmonary edema caused by inflammatory damage to alveolar and capillary walls. Many disorders may precipitate ARDS, although sepsis is the most common.

1. Initiation of ARDS

In sepsis-induced ARDS, bacterial toxins cause macrophages and neutrophils to adhere to endothelial surfaces of the alveoli and capillaries. The macrophages release oxidants, inflammatory mediators, enzymes, and peptides that damage the capillary and alveolar walls. In response, neutrophils release lysosomal enzymes causing further damage.



2. Onset of Pulmonary Edema



The damaged capillary and alveolar walls become more permeable, allowing plasma, proteins, and erythrocytes to enter the interstitial space. As interstitial edema increases, pressure in the interstitial space rises and fluid leaks into alveoli. Plasma proteins accumulating in the interstitial space lower the osmotic gradient between the capillary and interstitial compartment. As a result, the balance is disrupted between the osmotic force that pulls fluid from the interstitial space into the capillaries and the normal hydrostatic pressure that pushes fluid out of the capillaries. This imbalance causes even more fluid to enter alveoli.

PATHOPHYSIOLOGY ILLUSTRATED (*continued*)

4. End-Stage ARDS

Fibrin and cell debris from necrotic cells combine to form hyaline membranes, which line the interior of the alveoli and further reduce alveolar compliance and gas exchange. Because CO_2 cannot diffuse across hyaline membranes, $PaCO_2$ levels now begin to rise while PaO_2 levels continue to fall. Rising $PaCO_2$ levels can lead to respiratory acidosis. Without respiratory support, respiratory failure will develop.
Even with aggressive treatment, almost 50% of clients with ARDS die.

3. Alveolar Collapse

Protein-rich fluid accumulates in the alveoli, inactivating surfactant and damaging type II alveolar cells that produce surfactant. (Surfactant is important in maintaining alveolar compliance—the ability of tissue to stretch or distend.) As active surfactant is lost, the alveoli stiffen and collapse, leading to atelectasis, which increases breathing effort.

Decreased alveolar compliance, atelectasis, and fluid-filled alveoli interfere with gas exchange across the alveolar-capillary membrane. Blood oxygen (PaO_2) levels fall. Because carbon dioxide diffuses more readily than oxygen, however, blood carbon dioxide ($PaCO_2$) levels also fall initially as tachypnea causes more CO_2 to be expired.

CASE STUDY & NURSING CARE PLAN A Patient with ARDS

Peggy Adamson is a 36-year-old single woman admitted to the hospital following a near-drowning in a local lake. On admission to the emergency department, Ms. Adamson is alert and oriented, having been rescued and resuscitated within 2 minutes of the accident. Rescuers report that she seemed to have aspirated "a lot" of water as she was water-skiing when the accident occurred. She is admitted to the intensive care unit for observation. Oxygen is started per nasal cannula at 6 L/min, intravenous fluids are administered to correct electrolyte imbalances, and 40 mg of furosemide (Lasix) is given intravenously for hypervolemia.

ASSESSMENT

Nadia Mucha cares for Ms. Adamson the evening of the day after her admission. Throughout her stay, Ms. Adamson has remained alert and oriented with stable vital signs. Her respiratory rate has been 20 to 24/min, with scattered crackles, oxygen saturations of around 94%, and a PO_2 of 75 to 80 mmHg on 6 L/min of oxygen. Her pulse has been 96 to 100 bpm and regular. On her initial assessment, Ms. Mucha notes that Ms. Adamson seems apprehensive and anxious.

Although her blood pressure is 116/74 mmHg, unchanged from previous levels, her heart rate is up to 106 bpm and respiratory rate is 28/min. Her lungs have scattered crackles but good breath sounds throughout, unchanged from previous assessments. Ms. Adamson's oxygen saturation has dropped to 84%, so Ms. Mucha orders ABGs and increases the oxygen to 8 L/min. ABG results show PO_2 65 mmHg, respiratory alkalosis pH 7.48, and PCO_2 32 mmHg.

Ms. Mucha orders a portable chest x-ray and notifies the physician of the ABG results and the change in Ms. Adamson's status. The physician orders a nonrebreather mask at 8 L/min and repeat ABGs in 1 hour. The chest x-ray reveals scattered infiltrates and a normal heart size.

Ms. Adamson's oxygen saturation continues to fall, and subsequent blood gases show a PO_2 of 55 mmHg. The attending physician diagnoses probable ARDS and orders nasotracheal intubation and mechanical ventilation.

DIAGNOSES

- *Ineffective Breathing Pattern* related to anxiety
- *Impaired Gas Exchange* related to effects of near-drowning
- *Anxiety* related to hypoxemia
- *Risk for Decreased Cardiac Output* related to mechanical ventilation
- *Risk for Injury* related to endotracheal intubation

EXPECTED OUTCOMES

- Patient will breathe effectively with the mechanical ventilator.
- Patient will demonstrate improved oxygen saturation, $ETCO_2$, and ABG values.
- Patient will express fears related to intubation and mechanical ventilation.
- Patient will demonstrate reduced anxiety levels (relaxed facial expression, ability to rest).
- Patient will maintain adequate cardiac output and tissue perfusion.
- Patient will tolerate endotracheal intubation and mechanical ventilation without evidence of infection or barotrauma.

PLANNING AND IMPLEMENTATION

- Obtain all necessary supplies and notify respiratory therapy and radiology in preparation for intubation and mechanical ventilation.
- Explain the purpose and procedure of intubation.
- Provide an opportunity to express fears related to intubation and mechanical ventilation; answer questions and provide reassurance.
- Discuss communication strategies while intubated; obtain a magic slate.
- Administer analgesics and/or sedatives as ordered.
- Monitor oxygen saturation and $ETCO_2$ levels every 30 to 60 minutes initially after instituting mechanical ventilation; report changes to the physician.
- Obtain ABGs as ordered or indicated; monitor and report results.
- Suction via endotracheal tube as needed to maintain clear airways.
- Allow periods of uninterrupted rest.
- Monitor vital signs every 1 to 2 hours.
- Assess skin color, capillary refill, and the presence of edema every 4 hours.
- Monitor urine output hourly; report output of less than 30 mL/h.
- Assess lung sounds and chest excursion every 1 to 2 hours.

EVALUATION

Ms. Adamson is intubated and placed on a volume-cycled ventilator at 50% FIO_2 and a tidal volume of 700 mL in the assist-control mode at 16 breaths per minute. She has difficulty working with the ventilator initially, so a fentanyl drip is ordered to reduce her anxiety. Ms. Adamson's oxygen saturation, $ETCO_2$, and ABG results do not begin to improve until 5 mmHg of PEEP is added to ventilator settings. After 3 days of mechanical ventilation with PEEP and aggressive fluid and diuretic therapy, Ms. Adamson begins to improve. She is placed on SIMV, and over the course of another 3 days she is gradually weaned off the ventilator to a face mask with CPAP. She eventually recovers fully, with minimal apparent long-term effects.

Clinical Reasoning in Patient Care

1. Endotracheal intubation and mechanical ventilation were effective in supporting Ms. Adamson's respiratory status as she recovered from ARDS. Discuss a possible sequence of events had it not been possible to wean her from the ventilator.
2. How might the presentation and management of an acute episode of respiratory failure due to ARDS differ from respiratory failure related to COPD?
3. What measures can nurses take to prevent the development of ARDS?
4. Develop a nursing care plan for Ms. Adamson for the nursing diagnosis *Powerlessness* related to endotracheal intubation and mechanical ventilation.

See Evaluating Your Response in Appendix B.

- Limit procedures and activities during weaning periods. *Reducing energy expenditures and cardiac work facilitates the weaning process.*
- Provide diversion, such as television or radio. *Diversion helps distract the focus from breathing.*
- Begin weaning procedures in the morning, when the patient is well rested and alert; weaning may be discontinued overnight to provide rest. *The work of breathing increases during the weaning process; adequate rest is important.*
- When SIMV is used for weaning, decrease the SIMV rate by increments of two breaths per minute. *Slow reduction of ventilator support allows respiratory muscle reconditioning and gradual resumption of the work of breathing.*
- Avoid administering drugs that may depress respirations during the weaning process (except as ordered at night to facilitate rest when ventilator support is provided). *Sedatives or analgesics that depress respirations can impair the weaning process.*

SAFETY ALERT

Frequently assess respiratory status following weaning and extubation. Keep an intubation kit readily available following extubation; be prepared for emergency reintubation. Laryngeal spasm or laryngeal edema may develop following extubation, necessitating reintubation to maintain respirations.

- Keep oxygen at the bedside following weaning and extubation. *Supplemental oxygen may be necessary to maintain adequate blood and tissue oxygenation.*
- Provide pulmonary hygiene with percussion and postural drainage. *Maintaining patent airways and adequate alveolar ventilation is vital during the weaning process.*

Continuity of Care

When preparing the patient who has recovered from ARDS and the family for home care, discuss the following topics:

- ARDS did not result from something they did or did not do, but developed as a consequence of serious illness. Provide factual information about ARDS.
- Maximal respiratory function following ARDS is usually achieved within 6 months; respiratory function may remain significantly impaired. This may necessitate changes in occupation, lifestyle, and family roles.
- Avoiding smoking and exposure to secondhand smoke and environmental pollutants is vital to prevent further lung damage.
- Obtain immunization for pneumococcal pneumonia and annual influenza immunizations to prevent further episodes of serious respiratory disease.

Provide referrals to home health and respiratory care services as indicated, as well as for occupational therapy and counseling as needed.

CHAPTER HIGHLIGHTS

- **Obstructive disorders of the lower respiratory system, including asthma, COPD, and cystic fibrosis, impair airflow into and out of the lungs, often affecting the outflow of air to a greater extent than inflow. As a result, air trapping in the alveoli increases the residual volume of the lungs and reduces functional residual capacity. Alveolar ventilation is reduced as well. The net result is less available oxygen in the alveoli and impaired gas exchange.**
- In many instances, acute episodes of asthma can be avoided through the use of inhaled steroids to reduce airway inflammation, inhaled long-acting bronchodilators, and frequent self-monitoring of expiratory flow rate. Nursing care focuses on teaching for self-management, and providing care during acute episodes of airway constriction.
- Chronic obstructive pulmonary disease (COPD) is a long-term process of progressive lung dysfunction. COPD involves two different disease processes: chronic bronchitis, characterized by airway edema and excessive mucous production, and emphysema, characterized by destruction of supporting tissue with enlargement of respiratory bronchioles and alveolar spaces and loss of surface area for gas exchange.
- **Smoking and exposure to tobacco smoke is the single greatest risk factor for COPD. A small percentage of cases result from an inherited deficiency of alpha$_1$-antitripsin, an enzyme that inhibits lung tissue destruction. Although smoking cessation does not reverse COPD, it does slow the progress of the disease.**
- Cystic fibrosis, inherited as an autosomal recessive disorder, causes thick, viscous secretions in affected organs, primarily the lungs, pancreas, sweat glands, and reproductive tract. In the lungs, small airway clearance is impaired, leading to atelectasis, bronchiectasis, infection, and dilation of distal airways with air trapping and impaired gas exchange. Chest physiotherapy and early treatment of respiratory infections are key components of disease management. Ultimately, lung or heart-lung transplant may be required.
- **Occupational lung diseases, pneumoconiosis and hypersensitivity pneumonitis, damage interstitial tissues of the lungs, leading to fibrosis and scarring that causes the lungs to become stiff and noncompliant. Lung volumes decrease, the work of breathing increases, and gas diffusion is impaired. Most occupational lung diseases are progressive and nonreversible. Interprofessional care is similar to that provided for patients with COPD.**
- **Pulmonary vascular disorders affect blood flow through the pulmonary vascular system and gas exchange. Pulmonary embolism, obstruction of pulmonary blood flow, is a potentially critical condition usually resulting from deep venous thrombosis. Sudden onset of chest pain and dyspnea with changes in hemodynamic status are possible manifestations of pulmonary embolism. Prevention through early ambulation, lower extremity exercises, and sequential compression devices is the most effective treatment for pulmonary embolism.**
- In primary and secondary forms of pulmonary hypertension, constriction of pulmonary vessels and remodeling of the pulmonary vascular bed increase pressure in the pulmonary system and right heart, ultimately leading to right-sided heart failure (cor pulmonale). Treatment focuses on slowing disease progression through oxygen therapy, administration of vasodilators and anticoagulants, and supporting patient function.
- Hypoventilation, impaired gas exchange, and significant ventilation–perfusion mismatch (e.g., pulmonary embolism) can lead to respiratory failure. Hypoventilation leads to hypoxemia and hypercapnia, whereas in impaired gas exchange or ventilation–perfusion mismatch, hypoxemia dominates.

- **The manifestations of respiratory failure relate directly to the effects of hypoxemia and hypercapnia.**
- **Respiratory support often is required, using positive-pressure ventilators. Variables of mechanical ventilation include the mode or cycle of ventilation, the flow rate and amount, pressures delivered, and the oxygen concentration. Either invasive or noninvasive techniques may be used.**
- Complications of mechanical ventilation include lung and mucous membrane trauma and infection, reduced cardiac output, gastric dilation, impaired communication, and stress.
- **ARDS is noncardiac pulmonary edema caused by a diffuse inflammatory response with increased pulmonary capillary permeability leading to interstitial and alveolar edema and impaired gas exchange. As the process continues, lung compliance decreases, increasing the work of breathing, and atelectasis and consolidation of lung tissue develop. Respiratory failure with refractory hypoxemia results.**
- Mechanical ventilation and measures to support physiologic function are the primary treatments for ARDS. The mortality rate, however, remains high at about 40%.

TEST YOURSELF NCLEX-RN® REVIEW

1. The nurse identifies nursing diagnoses that are appropriate for a patient with an acute asthma attack. Which diagnosis is of the highest priority?
   1. *Anxiety* related to difficulty breathing
   2. *Ineffective Breathing Pattern* related to anxiety
   3. *Ineffective Airway Clearance* related to bronchoconstriction and increased mucous production
   4. *Ineffective Health Maintenance* related of lack of knowledge about attack triggers and appropriate use of medications
2. The nurse caring for a patient with asthma notices that the patient's respirations have slowed and coughing has stopped. Breath sounds are diminished throughout his lung fields and absent in the bases. Which action should the nurse take?
   1. Obtain a chest x-ray.
   2. Ask family members to leave.
   3. Notify the healthcare provider.
   4. Allow the patient to rest undisturbed.
3. The nurse is instructing a patient with asthma on the use of a metered-dose inhaler (MDI) for medication administration. What should the nurse teach the patient about the medications being provided through this device?
   1. Use the anti-inflammatory drug as needed to treat acute episodes of wheezing.
   2. Take quick shallow breaths in rapid succession while holding the canister down.
   3. Rinse the mouth after using the inhaler to reduce systemic absorption of the drug.
   4. Use the inhaler containing the anti-inflammatory drug first, then the bronchodilator.
4. The nurse is assessing a patient with chronic obstructive airway disease. Which finding would be expected when conducting the physical examination of this patient?
   1. mental confusion and lethargy
   2. oxygen saturation readings of 85% or less
   3. three+ pitting edema of ankles and lower legs
   4. AP chest diameter equal to or greater than lateral chest diameter
5. The nurse is determining goals of care for a patient with chronic obstructive pulmonary disease. Which would be an appropriate goal for this patient?
   1. Will maintain SaO_2 of 90% or higher.
   2. Will verbalize self-care measures to regain lost lung function.
   3. Arterial blood gases will be within normal limits by discharge.
   4. Will identify strategies to help reduce number of cigarettes smoked per day.
6. The nurse is planning care for a patient with chronic obstructive pulmonary disease. Which information should the nurse consider when determining if the patient should have supplemental oxygen?
   1. Oxygen is used only at night for patients with COPD.
   2. Because oxygen is flammable, the patient should not smoke.
   3. The patient needs to be closely monitored for signs of respiratory depression.
   4. Oxygen is never used for patients with COPD because they may become dependent on it.
7. The home care nurse is providing direction to a home care aide who is scheduled to care for a patient with cystic fibrosis. Which information should the nurse instruct the aide to report immediately? (Select all that apply.)
   1. fever
   2. bulky, fatty stools
   3. difficulty clearing mucous secretions
   4. increasing shortness of breath and fatigue
   5. thick, tenacious, milky, and white sputum
8. A patient in skeletal traction suddenly develops right-sided chest pain and shortness of breath. What should the nurse do? (Select all that apply.)
   1. Check for Homans' sign.
   2. Start oxygen per nasal cannula.
   3. Place in the high-Fowler's position.
   4. Administer the prescribed analgesic.
   5. Auscultate heart sounds every 2 to 4 hours.
9. The nurse caring for a patient with COPD is concerned that the patient is developing respiratory failure. What did the nurse assess as an early sign of possible respiratory failure?
   1. deep coma
   2. decreased urine output
   3. restlessness and tachypnea
   4. hypotension and tachycardia
10. The nurse is caring for a patient undergoing mechanical ventilation for acute respiratory failure. Which measure should the nurse use to help maintain effective alveolar ventilation?
    1. Keep the patient in the supine position.
    2. Maintain ordered oxygen concentration.
    3. Increase the tidal volume on the ventilator.
    4. Perform endotracheal suctioning as indicated.

See Test Yourself answers in Appendix B.

UNIT

9 Building Clinical Competencies

Responses to Altered Respiratory Function

CLINICAL SCENARIO

Directions: *Read the following clinical scenarios and answer the questions that follow. To complete this exercise successfully, you will not only use knowledge of the content in this unit, but also principles related to priority setting and maintaining patient safety.*

You have been assigned to work with the following four patients for the 0700 shift on a respiratory medical-surgical unit. Significant data obtained during report is as follows:

- Jack Holt, a 65-year-old male, is admitted to the nursing unit with bacterial pneumonia. Vital signs are temperature 38.3°C (101°F), pulse 94 bpm, respirations 30/min. He is complaining of chest pain with breathing and has a productive cough of rusty-colored sputum. His pulse oximeter is reading 92% on room air.
- Maggie Sawyer is an 82-year-old female who is ready to be discharged today back to the nursing home. She was hospitalized for treatment for a deep venous thrombosis and chronic obstructive pulmonary disease (COPD). Suddenly she complains of difficulty breathing, chest pain, coughing, restlessness, and a feeling that she is going to die.
- James Mohr, a 25-year-old male, was transferred from ICU yesterday after being treated for head, neck, and chest injuries and has a tracheostomy from a motor vehicle crash. His vital signs were stable at the last assessment. He begins coughing and puts on his call light for assistance.
- Amy Campbell, a 30-year-old female, is being treated after having a severe asthma attack. Her current vital signs are temperature 37.2°C (99°F), pulse 64 bpm, respirations 26/min, and blood pressure 124/84 mmHg. She has inspiratory and expiratory wheezing. Her O_2 Sat reading is 94% on 4L/min O_2 via nasal cannula.

CLINICAL REASONING

1. What data provided on Ms. Sawyer leads you to suspect pulmonary embolism?

Priority Setting

2. In what order would you visit these patients after report? What is the rationale for your choice?
   A. _____
   B. _____
   C. _____
   D. _____

Health Promotion

3. In planning care for Ms. Sawyer, what will you teach her about nutrition for optimal respiratory function?
4. In planning care for Ms. Campbell, what will you teach her to help decrease anxiety during an asthma attack?

Nursing Process

5. Mr. Holt's bacterial pneumonia is spread by droplet infection. When using standard precautions, which protective equipment is necessary to prevent spread of the infection?
   A. Wear a gown when bathing the patient.
   B. Wear gown and gloves when touching the patient.
   C. Wear a mask and gloves when suctioning the patient.
   D. Wear a cap to keep hair from touching the patient.
6. If Mr. Holt is receiving percussion and vibration with postural drainage for left lower lobe pneumonia, which position most facilitates removal of secretions?
   A. semi-Fowler's position with arms elevated
   B. right Sims' position with head in Trendelenburg
   C. high-Fowler's position leaning on a bedside tray
   D. left Sims' position with head flat

Communication

7. Ms. Campbell asks if she will have to "put up with breathing problems for the rest of her life." How will you answer her?

Delegation

8. What data collection and interventions can be delegated to a nursing assistant for each patient?
   A. _____
   B. _____
   C. _____
   D. _____

Interprofessional Care

9. Which of the following ABG results should be promptly conveyed to the healthcare provider?
   A. Mr. Holt: pH: 7.36; pO_2: 92 mmHg; pCO_2: 40 mmHg; HCO_3: 25 mEq/L
   B. Ms. Sawyer: pH: 7.22; pO_2: 50 mmHg; pCO_2: 58 mmHg; HCO_3: 29 mEq/L
   C. Mr. Mohr: pH: 7.35; pO_2: 80 mmHg; pCO_2: 44 mmHg; HCO_3: 26 mEq/L
   D. Ms. Campbell: pH: 7.46; pO_2: 90 mmHg; pCO_2: 33 mmHg; HCO_3: 26 mEq/L

Continuity of Care

10. Upon discharge, the nurse teaches Mrs. Sawyer ways to prevent having another pulmonary embolism. Which intervention is appropriate for preventing pulmonary embolism?
   A. Use pillows under the knees when in bed.
   B. Apply knee-high elastic stockings when ambulating.
   C. Exercise the legs vigorously to encourage blood flow.
   D. Stop every 1 to 2 hours to stretch legs when traveling.

11. Mr. Mohr will be discharged with a tracheostomy. Which of the following points should the nurse teach the patient about the tracheostomy?
   A. The tracheostomy will not interfere with lifting when returning to work.
   B. Water skiing is allowed but swimming in a pool or lake is not allowed.
   C. Showering is allowed as long as the tracheostomy is covered with a washcloth.
   D. A small amount of alcohol is allowed but smoking is not allowed.

Safety

12. The alarm on the patient's continuous pulse oximeter is not functional. Which of the following nursing actions is most directed toward patient safety?
   A. Go into the patient's room every 30 minutes to 1 hour to check the pulse oximetry results.
   B. Contact the healthcare provider to determine if continuous pulse oximetry is necessary.
   C. Replace the defective device immediately.
   D. Notify the biomedical department that the device alarm is not functioning.

Quality Improvement

13. The nurse manager has noted that there has been an increase in the number of patients admitted with pneumonia to the nursing unit. Describe a quality improvement project aimed at reducing pneumonia readmissions.

Informatics

14. When caring for Amy Campbell, the patient who was admitted with a severe asthma attack, a new medication regimen is instituted. Exemplars of informatics incorporated into electronic medical record related to the new medication regimen include which of the following? (Select all that apply.)
   A. bar coding for use at medication administration
   B. paper documentation of medication administration
   C. electronic medication compatibility at order entry
   D. availability of printable patient teaching information regarding medications

UNIT

10

Responses to Altered Musculoskeletal Function

38 Assessing the Musculoskeletal System 1219

39 Nursing Care of Patients with Musculoskeletal Trauma 1234

40 Nursing Care of Patients with Musculoskeletal Disorders 1266

Activity–Exercise Pattern

Injury to or disorders of the musculoskeletal system often affect mobility and patterns of activity and exercise.

38 Assessing the Musculoskeletal System

LEARNING OUTCOMES

1. Describe the anatomy, physiology, and functions of the musculoskeletal system.
2. Identify specific topics for consideration during a health history interview of the patient with health problems involving the musculoskeletal system.
3. Describe normal variations in assessment findings for the older adult.
4. Give examples of genetic disorders of the musculoskeletal system.
5. Identify manifestations of impairment of the musculoskeletal system.

CLINICAL COMPETENCIES

1. Conduct and document a health history for patients who have or are at risk for alterations in the musculoskeletal system, eliciting patient values, preferences, and expressed needs as part of the interview.
2. Conduct and document a physical assessment of musculoskeletal structures and functions, demonstrating sensitivity and respect for the diversity of human experience.
3. Monitor the results of diagnostic tests and communicate abnormal findings within the interprofessional team.

MAJOR CHAPTER CONCEPTS

- Intact structure and function of the musculoskeletal system is vital to the ability to independently perform activities and usual daily living activities.
- Manifestations of dysfunction, injuries, and disorders affecting the musculoskeletal system may be detected during a general health assessment as well as during focused and functional musculoskeletal assessments.

KEY TERMS

bursitis, *1229*
crepitation, *1228*
hematopoiesis, *1220*
kyphosis, *1228*
lordosis, *1228*
ossification, *1222*
osteoblast, *1220*
osteoclast, *1220*
scoliosis, *1228*
synovitis, *1230*
tendonitis, *1229*

EQUIPMENT NEEDED

- Tape measure
- Goniometer

The tissues and structures of the musculoskeletal system perform many functions, including support, protection, and movement. The musculoskeletal system has two subsystems: the bones and joints of the skeleton, and the skeletal muscles. These subsystems work together to allow the body to perform both gross, simple movements such as closing a door, and fine, complex movements such as repairing a watch. Alterations in the structure and/or function of the musculoskeletal system affect and are affected by the integrity of the neurologic system; disorders of both of the systems place the patient at risk for functional alterations, including activity, self-care, and self-concept.

Anatomy, Physiology, and Functions of the Musculoskeletal System

The musculoskeletal system is composed of bones of the skeletal system, cartilage (a connective tissue), ligaments, tendons, and skeletal muscles and joints. The bones serve as the framework for the body and for the attachment of muscles, tendons, and ligaments. Innervated by the nervous system, contraction and relaxation of muscles permit movement at joints.

Bones

The human skeleton is made up of 206 bones (Figure 38–1 ■). Bones of the skeletal system are divided into the axial skeleton (the skull, thorax, and vertebrae) and the appendicular skeleton (shoulder, arms, pelvic girdle, and legs). Bones form the body's structure and provide support for soft tissues. They protect vital organs from injury and serve to move body parts by providing points of attachment for muscles. Bones also store minerals and serve as a site for **hematopoiesis** (blood cell formation).

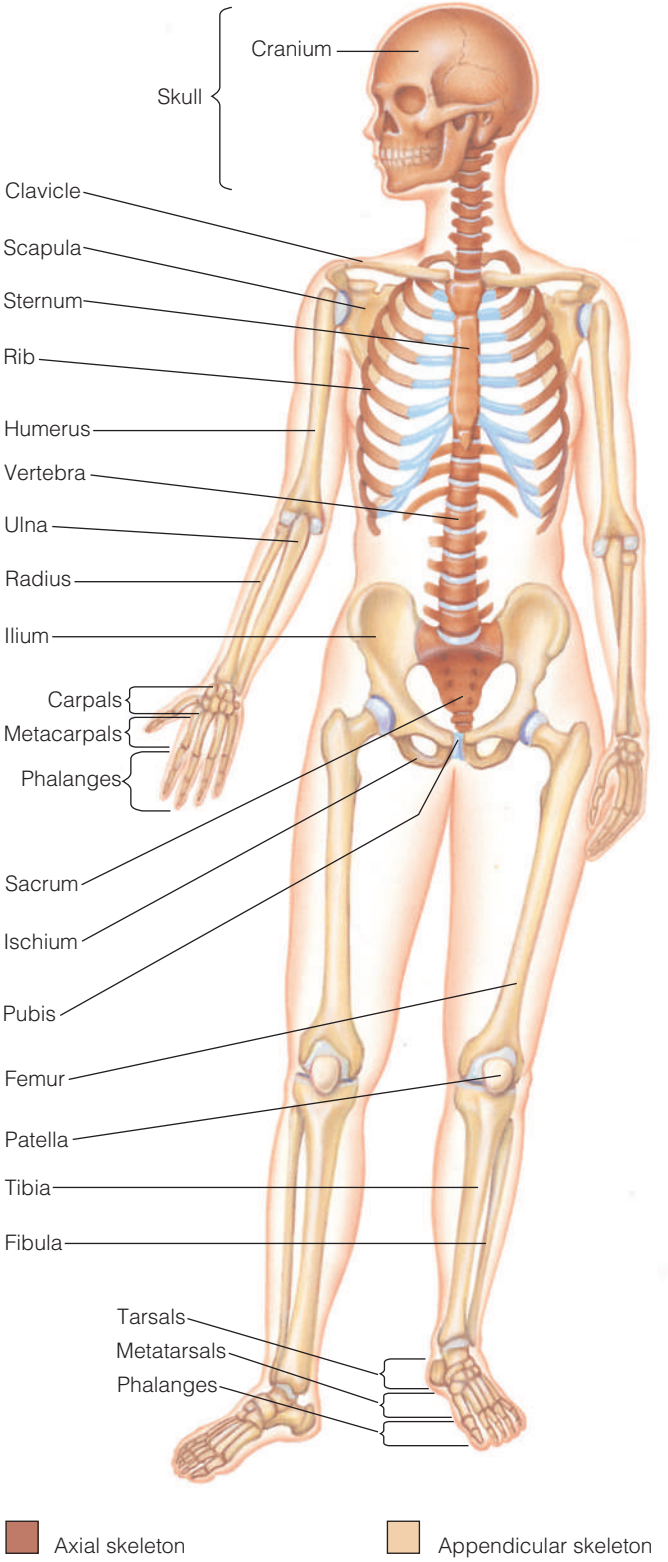

Figure 38–1 ■ Bones of the human skeleton.

BONE STRUCTURE

Bone cells include **osteoblasts** (cells that form bone), osteocytes (cells that maintain bone matrix), **osteoclasts** (cells that resorb bone), and osteoprogenitor cells (the source of all bone cells except osteoclasts). Bone matrix is the extracellular element of bone tissue; it consists of collagen fibers, minerals (primarily calcium and phosphate), proteins, carbohydrates, and ground substance. Ground substance is a gelatinous material that facilitates diffusion of nutrients, wastes, and gases between the blood vessels and bone tissue. Bones are covered with periosteum, a double-layered connective tissue. The outer layer of the periosteum contains blood vessels and nerves; the inner layer is anchored to the bone.

Bones consist of a rigid connective tissue called osseous tissue, of which there are two types: laminar bone (strong, mature bone found in the adult skeleton) and woven bone (which provides a temporary framework for support and is found in the developing fetus, as part of healing fractures, and in areas surrounding tumors and infections of bones). There are two types of mature bones: compact and spongy bone. Compact bone forms the outer shell of a bone, while spongy bone is found in the interior of bones. Spongy bone is composed of lattice-like structures (trabeculae), lined with osteogenic cells and filled with red or yellow bone marrow (Grossman & Porth, 2014).

The basic structural unit of laminar bone is the Haversian system (also called an osteon). The Haversian system consists of a central canal, called the Haversian canal; concentric layers of bone matrix, called lamellae; spaces between the lamellae, called lacunae; osteocytes within the lacunae; and small channels, called canaliculi (Figure 38–2 ■). The spongy sections of long bones and flat bones contain tissue for hematopoiesis. In the adult, these sections, called red marrow cavities, are present in the spongy center of flat bones (especially the sternum) and in only two long bones: the humerus and the head of the femur.

BONE SHAPES

Bones are classified by shape (Figure 38–3 ■):

- *Long bones* have a midportion, or shaft, called a diaphysis and two broad ends, called epiphyses (Figure 38–4 ■). The diaphysis is compact bone and contains the marrow cavity, which is lined with endosteum. Long bones include the bones of the arms, legs, fingers, and toes.
- *Short bones*, also called cuboid bones, include the bones of the wrist and ankle.
- *Flat bones* are thin and flat, and most are curved. Flat bones include most bones of the skull, the sternum, and the ribs.
- *Irregular bones* are of various shapes and sizes. Irregular bones include the vertebrae, the scapulae, and the bones of the pelvic girdle.

BONE REMODELING IN ADULTS

Although the bones of adults do not normally increase in length and size, constant remodeling of bones, as well as repair of damaged bone

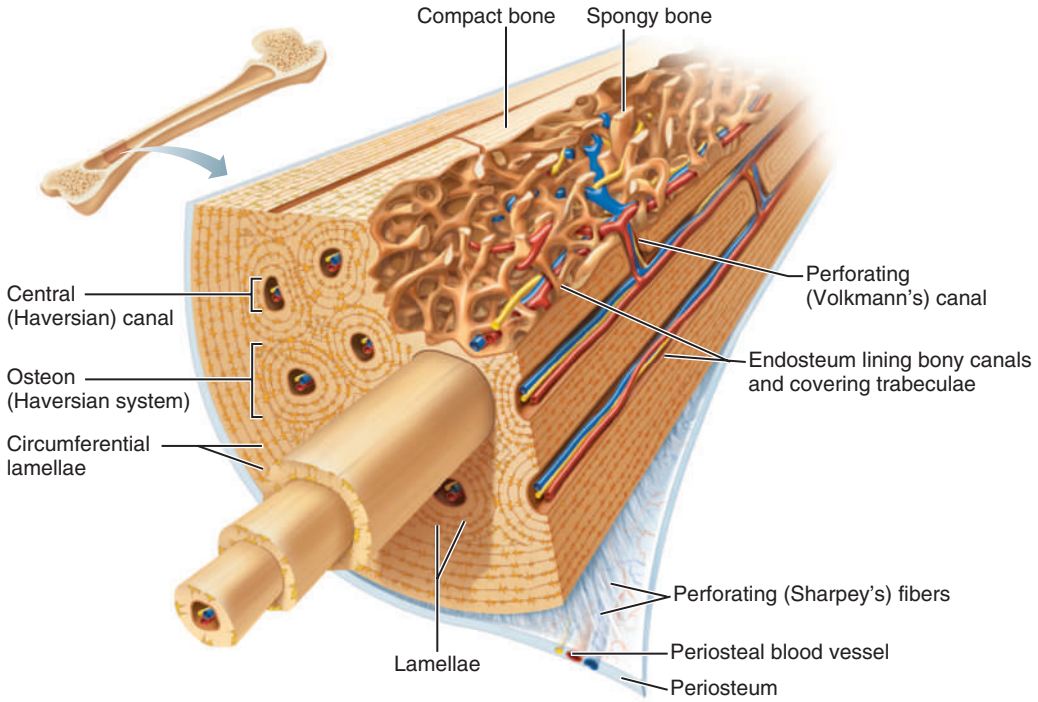

Figure 38–2 ■ The structure of compact bone and the Haversian system.

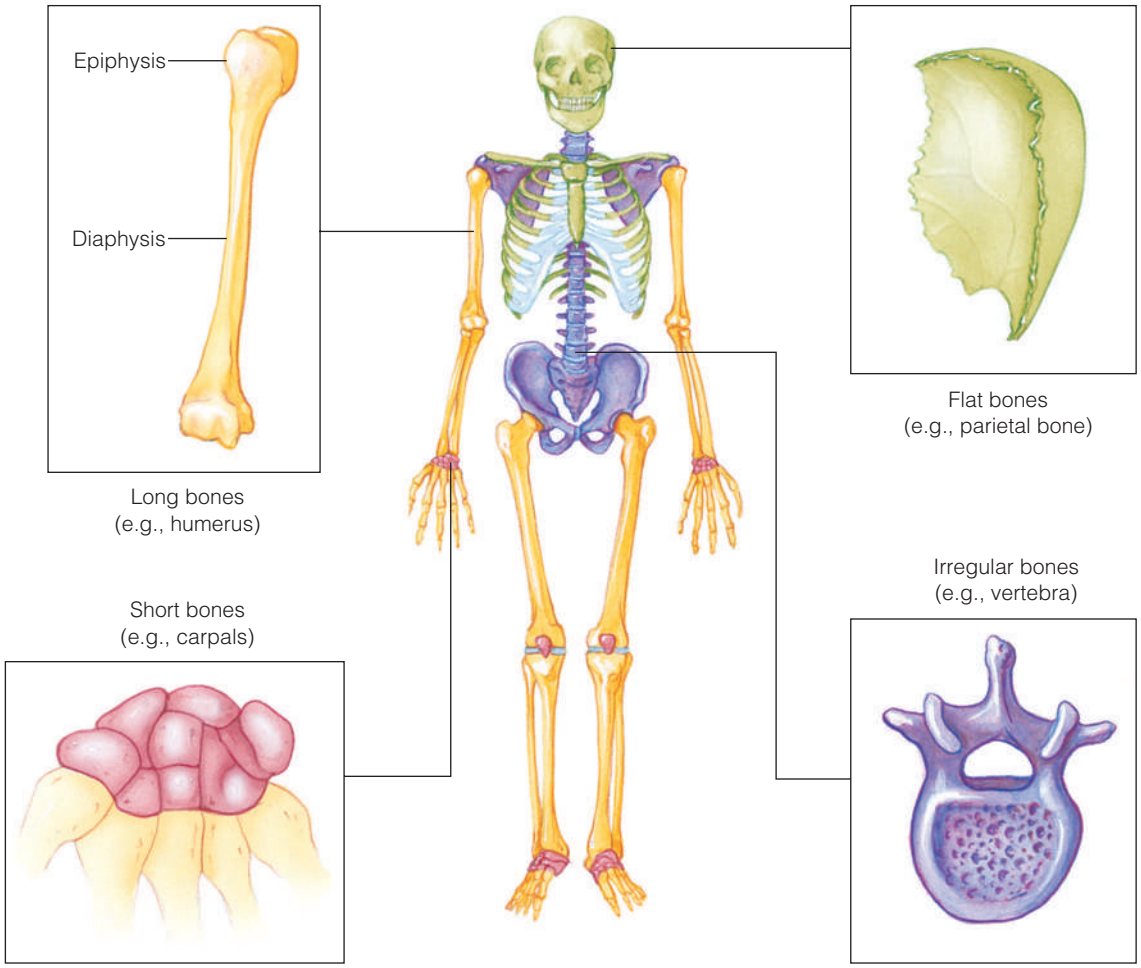

Figure 38–3 ■ Classification of bones according to shape.

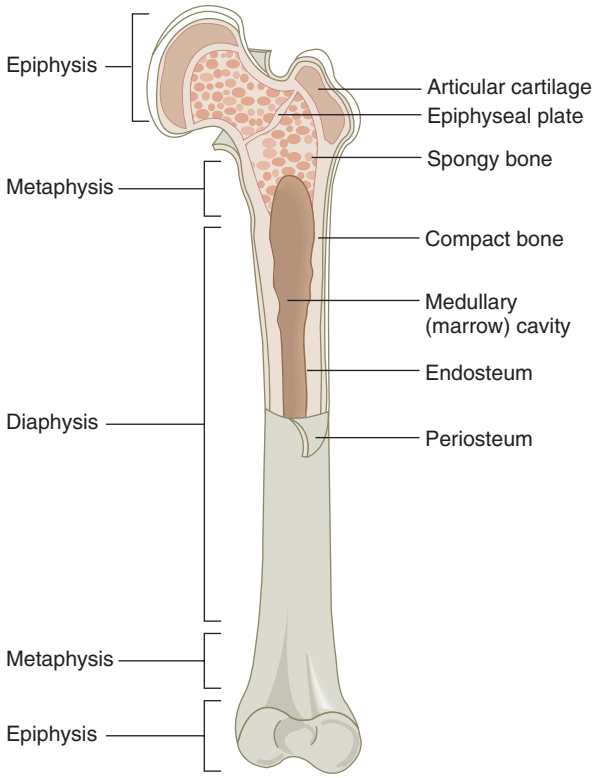

Figure 38–4 ■ Parts of a long bone.

tissue, occurs throughout life. In the bone remodeling process, bone resorption and bone deposit occur at all periosteal and endosteal surfaces. Hormones and forces that put stress on the bones regulate this process, which involves a combined action of the osteocytes, osteoclasts, and osteoblasts. Bones that are in use, and are therefore subjected to stress, increase their osteoblastic activity to increase **ossification** (the development of bone). Bones that are inactive undergo increased osteoclast activity and bone resorption.

The hormonal stimulus for bone remodeling is controlled by a negative feedback mechanism that regulates blood calcium levels. This stimulus involves the interaction of parathyroid hormone (PTH) from the parathyroid glands and calcitonin from the thyroid gland. When blood levels of calcium decrease, PTH is released. PTH then stimulates osteoclast activity and bone resorption so that calcium is released from the bone matrix. As a result, blood levels of calcium rise, and the stimulus for PTH release ends. Rising blood calcium levels stimulate the secretion of calcitonin, inhibit bone resorption, and cause the deposit of calcium salts in the bone matrix. Thus, bones are necessary to regulate blood calcium levels. Calcium ions are necessary for the transmission of nerve impulses, the release of neurotransmitters, muscle contraction, blood clotting, glandular secretion, and cell division. Bone remodeling is also regulated by the response of bones to gravitational pull and to mechanical stress from the pull of muscles. Bones that undergo increased stress are heavier and larger.

Cartilage

Cartilage is a firm, flexible connective tissue. There are three types of cartilage: elastic cartilage (found in the ear), hyaline cartilage (the cartilage that joins the ribs to the sternum and vertebrae, many cartilages of the respiratory tract, the articular cartilages, and the epiphyseal plates), and fibrocartilage (found in the intervertebral disks, the symphysis pubis, and the areas where tendons connect to bones).

Muscles

The three types of muscle tissue in the body are skeletal muscle, smooth muscle, and cardiac muscle (Table 38–1). This discussion focuses on skeletal muscle, the only type of muscle that allows musculoskeletal function. Skeletal muscles attach to and cover the bones of the skeleton. Skeletal muscles promote body movement, help maintain posture, and produce body heat. They may be moved by conscious, voluntary control or by reflex activity. The body has approximately 600 skeletal muscles.

Skeletal muscles are thick bundles of parallel multinucleated contractile cells called fibers (Figure 38–5 ■). Each single muscle fiber is itself a bundle of smaller structures called myofibrils. Myofibrils are strands of smaller repeating units called sarcomeres, which consist of thick filaments of myosin and thin filaments of actin, proteins that contribute to muscle contraction. Skeletal muscle cells have typical functional properties:

- *Excitability:* the ability to receive and respond to a stimulus. The stimulus is usually a neurotransmitter released by a neuron, and the response is the generation and transmission of an action potential along the plasma membrane of the muscle cell.
- *Contractibility:* the ability to respond to a stimulus by forcibly shortening.
- *Extensibility:* the ability to respond to a stimulus by extending and relaxing.
- *Elasticity:* the ability to resume its resting length after it has shortened or lengthened.

Skeletal muscle movement is triggered when motor neurons release acetylcholine, a neurotransmitter that crosses the neuromuscular junction and alters the permeability of the muscle fiber. Sodium ions enter the fiber, producing an action potential that causes muscle contraction. The more fibers that contract, the stronger the contraction of the entire muscle.

Prolonged strenuous activity causes continuous nerve impulses and eventually results in a buildup of lactic acid and reduced energy in the muscle, or muscle fatigue. However, continuous nerve impulses are also responsible for maintaining muscle tone. Regular exercise increases the size and strength of muscles, while lack of use results in muscle atrophy.

TABLE 38–1 Types of Body Muscle

Type	Description	Examples
Skeletal	Striated, voluntary muscle (can consciously move)	Biceps, triceps, deltoid, gluteus maximus
Smooth	Nonstriated, involuntary muscle (cannot consciously move)	Muscles in the walls of the bladder, stomach, and bronchi
Cardiac	Striated, involuntary muscle	Heart muscle

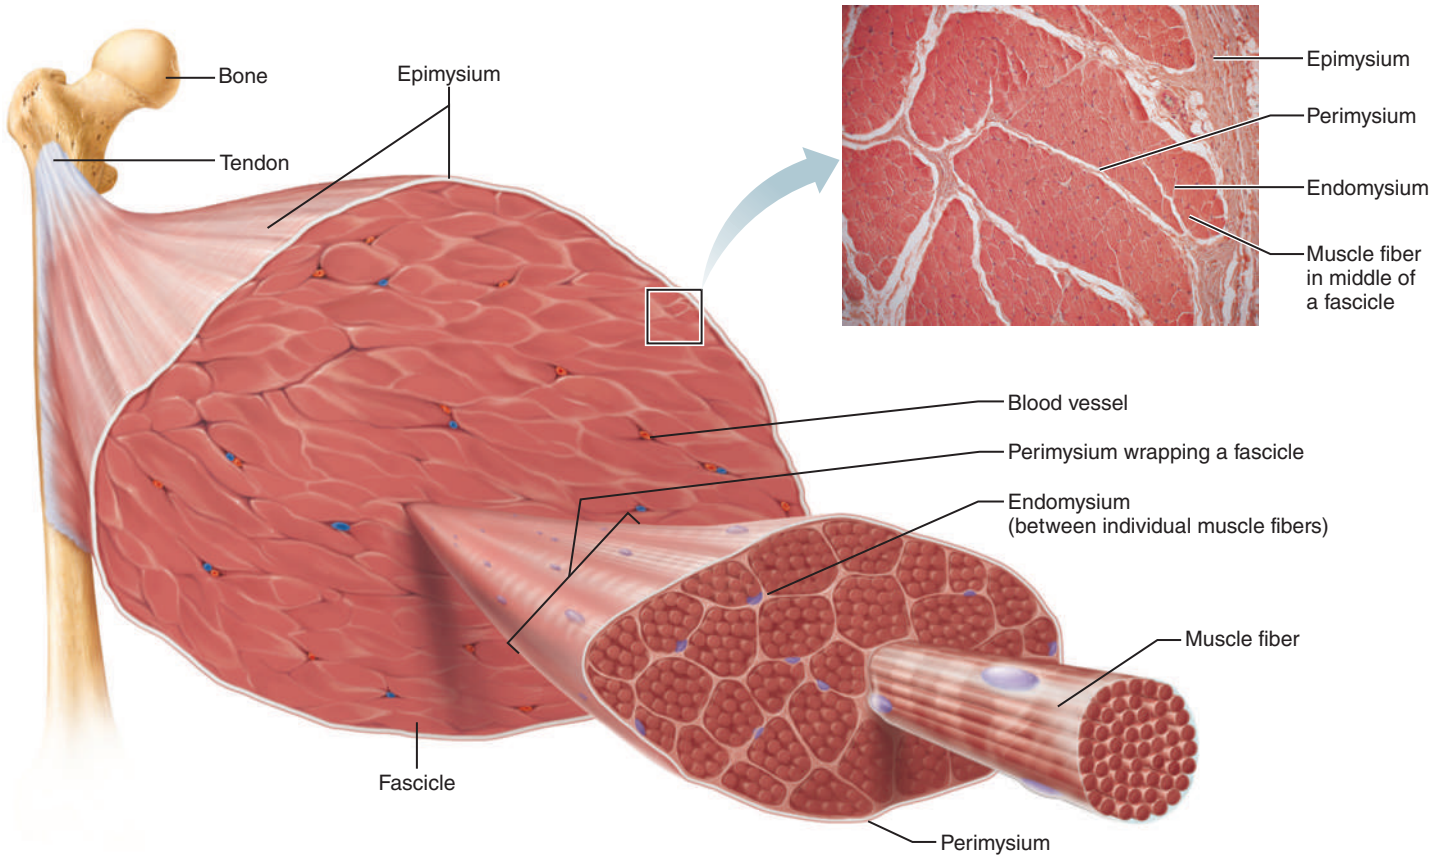

Figure 38–5 ■ Structure of skeletal muscle.

Joints, Ligaments, and Tendons

Joints, or articulations, are regions where two or more bones meet. Joints hold the bones of the skeleton together while allowing the body to move. Joints may be classified by function as *synarthroses*, immovable joints; *amphiarthroses*, slightly movable joints; or *diarthroses*, freely movable joints. Joints are also classified by structure as fibrous, cartilaginous, or synovial. Table 38–2 describes each of these types.

TABLE 38–2 Structural Classification of Joints

Type	Description	Examples
Fibrous	Bones united or connected by collagen fibers	Skull sutures Ligament connecting distal tibia and fibula Connection between a tooth and its socket
Cartilaginous	Bones united or connected by cartilage	Vertebral joints Joint between first rib and manubrium of sternum Joint of the symphysis pubis
Synovial	Bones separated by a cavity containing synovial fluid	Joints of the extremities Shoulder joints Hip joints

Fibrous joints permit little or no movement, because the articulating bones are joined either by short connective tissue fibers that bind the bones together or by short cords of fibrous tissue called ligaments that permit slight give but no true movement. Some cartilaginous joints, such as the sternocostal joints of the rib cage, are composed of hyaline cartilage growths that fuse together the articulating bone ends. These joints are immobile. In other cartilaginous joints, such as the intervertebral disks, the hyaline cartilage fuses to an intervening plate of flexible fibrocartilage. This structural feature accounts for the flexibility of the vertebral column.

Bones in synovial joints are enclosed by a cavity that is filled with synovial fluid, a filtrate of blood plasma (Figure 38–6 ■). Synovial joints are freely movable, allowing many kinds of movements, as listed and described in Table 38–3. Synovial fluid fills the free spaces of the joint capsule, enhancing the smooth movement of the articulating bones. Bursae are small sacs of synovial fluid that cushion and protect bony areas that are at high risk for friction, such as the knee and the shoulder. Tendon sheaths are a form of bursae, but they are wrapped around tendons in high-friction areas.

The fibrous capsules that surround synovial joints are supported by ligaments, dense bands of connective tissue that connect bones to bones. Ligaments limit or enhance movement, provide joint stability, and enhance joint strength. Tendons are fibrous connective tissue bands that connect muscles to the periosteum of bones and enable the bones to move when skeletal muscles contract. When muscles

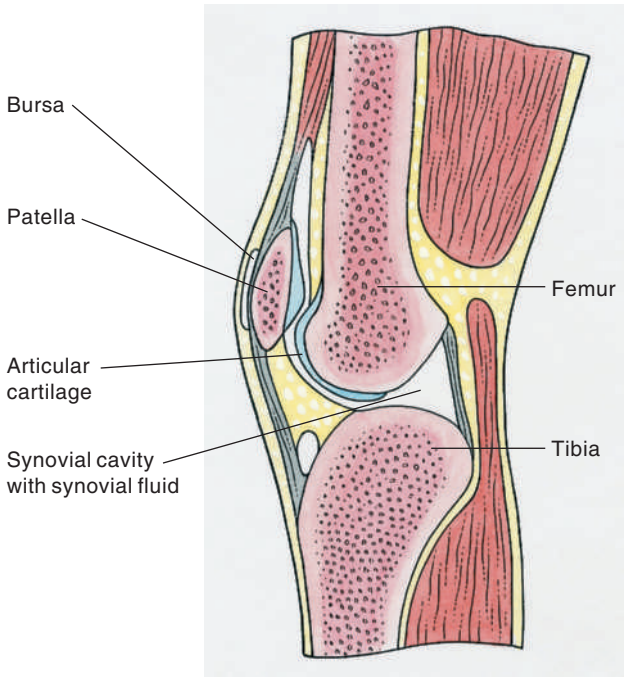

Figure 38–6 ■ Structure of a synovial joint (knee).

contract, increased pressure causes the tendon to pull, push, or rotate the bone to which it is connected.

ASSESSING THE MUSCULOSKELETAL SYSTEM

Structures and functions of the musculoskeletal system are assessed by findings from diagnostic tests, a health assessment interview to collect subjective data, and a physical assessment to collect objective data.

Diagnostic Tests

The results of diagnostic tests of musculoskeletal structure and function are used to support the diagnosis of a specific injury or disease, to provide information to identify or modify treatment of the disease, and to help the interprofessional team monitor the patient's responses to treatment and interventions. Diagnostic tests to assess the structures and functions of the musculoskeletal system are described in the table on page 1225. Many of these tests are invasive or require use of a contrast agent; hence, signed consent is required prior to the procedure.

Regardless of the type of diagnostic test, the nurse is responsible for explaining the procedure and any special preparation needed, assessing for medication use that may affect the outcome of the tests, supporting the patient during the examination as necessary, documenting the procedures as appropriate, ensuring the consent form is signed (if required), and monitoring the results of the tests. The nurse is also responsible for postprocedure care and patient teaching for self-care at home.

Genetic Considerations

When conducting a health assessment interview and a physical assessment, the nurse needs to consider genetic influences on the health of the adult. During the health assessment interview, ask about family members with health problems affecting musculoskeletal structure or function. In addition, ask about a family history of arthritis, abnormally long bones, children with muscular dystrophy, and amyotrophic lateral sclerosis (ALS). During the physical assessment, assess for any manifestations that might indicate a genetic disorder (see the accompanying box). If data are found to indicate genetic risk factors or alterations, ask about genetic testing and refer for appropriate genetic counseling and evaluation.

TABLE 38–3 Movements Allowed by Synovial Joints

Movement	Description
Abduction	Move limb away from body midline
Adduction	Move limb toward body midline
Extension	Straighten limbs at joint
Flexion	Bend limbs at joint
Dorsiflexion	Bend ankle to bring top of foot toward shin
Plantar flexion	Straighten ankle to point toes down
Pronation	Turn forearm to place palm down
Supination	Turn forearm to place palm up
Eversion	Turn out
Inversion	Turn in
Circumduction	Move in circle
Internal rotation	Move inward on a central axis
External rotation	Move outward on a central axis
Protraction	Move forward and parallel to ground
Retraction	Move backward and parallel to ground

GENETIC CONSIDERATIONS

Examples of Musculoskeletal Disorders

- Myotonic dystrophy is an inherited disorder in which the muscles become weak, have a decreased ability to relax, and eventually waste away. Other manifestations are mental deficiency, hair loss, and cataracts. Although rare, the disease does increase in severity with each successive generation.
- Marfan's syndrome, an autosomal dominant disorder of connective tissue, affects the bones, lungs, eyes, heart, and blood vessels. It is characterized by abnormally long extremities, hyperextensible joints, and a variety of spinal, skeletal, and other deformities. It is believed to have affected Abraham Lincoln. The aspect of the disease that is most life threatening is the effect on the cardiovascular system (Grossman & Porth, 2014).
- Duchenne's muscular dystrophy, an X-linked disorder, affects primarily males. It is one of the most common muscular dystrophies, and is characterized by rapid muscle degeneration early in life.
- Other musculoskeletal diseases believed to have a genetic component include rheumatoid arthritis, osteoarthritis, gout, muscular dystrophy, ankylosing spondylitis, lupus erythematosus, and scleroderma.

DIAGNOSTIC TESTS of the Musculoskeletal System

Name of Test	Purpose and Description	Related Nursing Interventions
Arthrocentesis	This procedure is done to obtain synovial fluid from a joint for diagnosis (such as infections) or to remove excess fluid. A needle is inserted through the joint capsule and fluid is aspirated.	After the procedure, apply a compression dressing and tell the patient to report any bleeding, leakage of fluid, or excessive pain to the healthcare provider.
Arthroscopy	An endoscopic examination of the interior surfaces of a joint, arthroscopy is used to perform surgery and diagnose diseases of the patella, meniscus, and synovial and extrasynovial membranes. In addition, fluid may be drained from the joint and tissue removed for biopsy. A fiberoptic endoscope is inserted into the joint, either with local anesthesia or general anesthesia. An arthrography (x-ray examination of the joint) is performed prior to an arthroscopy.	Instruct the patient about orders for fasting and use of current medications prior to the procedure. Following the procedure, assess for bleeding and swelling, apply ice to the area if prescribed, and instruct patient to avoid excessive use of the joint for 2 to 3 days.
Blood chemistry	See Table 38–4.	No special preparation is needed.
Bone mineral density (BMD), bone absorptiometry • Dual-energy x-ray absorptiometry (DEXA) • Quantitative ultrasonography (QUS)	These examinations are done to evaluate bone density, diagnose osteoporosis, and determine risk for osteoporosis-related fracture. DEXA of the hip and lumbar spine can calculate the size and thickness of bone. QUS, which does not expose the patient to ionizing radiation, evaluates density of the calcaneus (heel bone). Osteoporosis is diagnosed if the bone mass is more than 2.5 standard deviations below peak bone mass. **Normal value:** 1 standard deviation below peak bone mass	Instruct patient to remove all metal objects from the area to be scanned (such as jewelry, belt buckles, zippers).
Bone scan	During a bone scan, the concentration of an injected radioisotope in bone is determined using a scintillation (gamma) camera detector. Uptake is increased in osteomyelitis, osteoporosis, cancers of the bone, and in some fractures. Uptake is decreased in avascular necrosis.	No special preparation is needed, although the patient should be well hydrated. Advise the patient to drink three glasses of water during the waiting period (after the isotope is injected and before the scan is obtained). Instruct the patient to remove metal objects, jewelry, and keys prior to the scan.
Computed tomography (CT) scan—long bones and joints, spine	A CT of long bones and joints provides a three-dimensional picture used to evaluate musculoskeletal trauma (fractures) and bony abnormalities (such as tumors). A CT of the spine can identify tumors, cysts, vascular malformations, and herniated intervertebral disks.	If contrast dye is used, assess for allergy to iodine, seafood, or radiologic contrast (many contain iodine). Assess medications; noniodated contrast media may be necessary for patients taking oral hypoglycemic agents. Have spine x-rays available. If scheduling myelogram and spine CT, patient should have myelogram first. After the test, if contrast dye was used, monitor for delayed allergic reaction (rash, itching, headache, vomiting) and instruct patient to increase fluid intake.
Electromyogram (EMG)	An EMG measures the electrical activity of skeletal muscles at rest and during contraction; this information is useful in diagnosing neuromuscular diseases. Needle electrodes are inserted into affected skeletal muscles, allowing electrical activity to be heard, viewed on an oscilloscope, and recorded on graph paper. Normally, there is no electrical activity at rest.	Tell the patient not to drink fluids containing caffeine or to smoke for 3 hours before the test, and not to take medications such as muscle relaxants, anticholinergics, or cholinergics as ordered by the physician. If serum enzymes such as SGOT, CPK, or LDH are ordered, the specimen should be drawn before the EMG or 5 to 10 days after the EMG.
Magnetic resonance imaging (MRI)	An MRI of bony structures is used in diagnosis and evaluation of avascular necrosis, osteomyelitis, tumors, disk abnormalities, and tears in ligament or cartilage. It uses radio waves and magnetic fields; gadolinium may be injected to increase visualization of bony or muscular structures.	Inform patient of need to lie still during the examination. Assess for tattoos and any metallic implants (such as pacemakers, clips on brain aneurysms, body piercings, shrapnel). If present, notify imaging physician. Ask if patient is pregnant; if so, the test is not performed. Ask about claustrophobia; if a problem, instruct patient to ask for a relaxing medication to take prior to the MRI.

(*continued*)

DIAGNOSTIC TESTS of the Musculoskeletal System (*continued*)

Name of Test	Purpose and Description	Related Nursing Interventions
Musculoskeletal ultrasound (US)	Musculoskeletal ultrasound provides images of muscles, tendons, ligaments, joints, and soft tissue. It is used to help diagnose muscle and tendon tears; bleeding into muscle, soft tissue, or joints; tumors; and joint abnormalities.	This noninvasive test requires no special preparation, although the patient may be asked to remove jewelry in the area to be examined.
Skeletal x-ray	X-rays are done to identify and evaluate bone density and structure.	Ask women if they are pregnant; x-rays should be avoided during the first trimester. No special preparation is needed for skeletal x-rays.

TABLE 38–4 Blood Tests with Purposes Specific to the Musculoskeletal System

Name of Test	Purpose	Normal Value
Alkaline phosphatase (ALP)	To identify bone diseases. Increased in bone cancer, Paget's disease, healing fractures, rheumatoid arthritis, osteoporosis.	42–136 units/L ALP^1: 20–130 units/L ALP^2: 20–120 units/L (increases slightly with aging)
Calcium (Ca)	To monitor calcium levels and detect calcium imbalances. Decreased with inadequate calcium and vitamin D intake, and malabsorption from the gastrointestinal tract. Increased in bone cancer and multiple fractures.	4.5–5.5 mEq/L or 9–11 mg/dL (serum)
Creatine kinase (CK), creatinine phosphokinase (CPK)	To diagnose muscle trauma or disease. Increased in muscular dystrophy and traumatic injuries (specifically, CPK-MM isoenzyme).	Male: 50–170 units/L Female: 25–140 units/L CPK-MM: 94%–100%
Human leukocyte antigen (HLA)	To diagnose diseases such as juvenile RA or ankylosing spondylitis.	No normal value
Phosphorus (P), phosphate (PO_4)	To assess phosphorous levels. Increased with bone tumors and healing fractures.	1.7–2.6 mEq/L or 2.5–4.5 mg/dL
Rheumatoid factor (RF)	To diagnose rheumatoid arthritis (RA) (positive for RA at > 1:80). Also increased in lupus erythematosus and scleroderma.	< 1:20 titer
Uric acid	To diagnose and monitor the treatment of gout. Panic level considered > 12 mg/dL.	Male: 3.5–8.0 mg/dL Female: 2.8–6.8 mg/dL

Health Assessment Interview

A health assessment interview to determine problems with musculoskeletal structure and/or function may be conducted during a health screening, may focus on a chief complaint (such as joint pain), or may be part of a complete health assessment. Health problems affecting the neurologic system may manifest as problems with musculoskeletal function and an assessment of both systems may be necessary. If the patient has problems with musculoskeletal structure or function, analyze its onset, characteristics, course, severity, precipitating and relieving factors, and any associated symptoms, noting the timing and circumstances. For example, ask the patient the following:

- Describe the pain. Can you point to its location? Does the pain increase with movement? Have you noticed any redness or swelling?
- Did you injure your ankle before you began to experience difficulty walking?
- Is your pain worse in the morning, or does it get worse throughout the day?

The primary manifestations of altered musculoskeletal function are pain and limited mobility. Specific descriptors of the pain, its location, and its nature are important. Other significant information includes fever, fatigue, changes in weight, rash, and/or swelling. Collect information about the patient's lifestyle, including type of employment, ability to carry out activities of daily living (ADLs), and provide self-care, exercise or participation in sports, use of alcohol or drugs, and nutrition. Explore past injuries and measures to self-treat pain (such as over-the-counter medications, prescribed medications, application of heat or cold, splinting, wrapping, or rest).

Physical Assessment

Physical assessment of the musculoskeletal system may be performed either as part of a total assessment, or as a focused assessment for a patient with known or suspected problems. The techniques used to assess the musculoskeletal system are inspection, palpation, and measurement of muscle mass and joint range of motion (ROM). The patient should be comfortably dressed in clothing so that the movement of all joints is seen clearly. The patient may be standing, sitting, or lying down; the sequence of the examination should be such that the patient is not required to make frequent position changes. An assessment of the older adult, the patient in pain, or the patient who is weak may take extra time. Normal age-related findings for the older

NURSING CARE OF THE OLDER ADULT

Age-Related Changes in the Musculoskeletal System

Age-Related Change	Significance
BONES AND JOINTS:	
• Decreased bone mass and minerals. • Decreased calcium reabsorption, a slow resorption of the interior of long bones, and slower production of new bone on the outside surface of bones. • Thinning of intervertebral disks, erosion of vertebrae, and kyphosis often develop. • Cartilage on bone surfaces in joints deteriorates and bone spurs may occur. • Synovial fluid becomes less viscous.	Decreased bone mass and decreased calcium absorption contribute to bones that are often thinner and weaker, with an increased risk of fractures with trauma. As the spinal column shortens, height decreases. Changes in spine can shift center of gravity, increasing the risk for falls. Loss of joint cartilage and formation of bone spurs make movement more painful and may even limit mobility.
MUSCLES, LIGAMENTS, AND TENDONS:	
• Muscle fibers atrophy and fibrous tissue slowly replaces muscle tissue. • Decreased muscle mass and strength. • Ligaments and tendons lose elasticity resulting in loss of joint range of motion (Tabloski, 2014).	Regular exercise is very important in decreasing the loss of muscle mass and strength associated with aging.

adult are summarized in the accompanying Nursing Care of the Older Adult box.

Prior to the examination, collect all equipment and explain the techniques to decrease the patient's anxiety. The sequence for a musculoskeletal examination follows:

1. Begin the examination with an assessment of gait and posture. Inspect for overall appearance, posture, and position. Observe the patient's ability to rise from a chair, how the patient walks and pivots/turns, sits, and/or moves about in bed.
2. Proceeding in a cephalocaudal direction:
   - Inspect and palpate the bones for any obvious deformity or changes in size or shape. Palpation also will elicit tenderness or pain.
   - Inspect the extremities for symmetry, having equal length and muscle mass. If a difference is noted, measure extremity length and circumference, comparing limbs bilaterally.
   - Inspect and palpate joints for swelling, pain, redness, or warmth. Palpate large joints for crepitus as the patient moves the joint through ROM. For the patient with an upright posture, a relaxed, coordinated gait, and no specific complaints of joint pain, stiffness, or swelling, ROM may be assessed on selected joints only.
   - Providing resistance by gently pushing in the opposite direction, assess and document muscle strength on a scale of 0 to 5 (Table 38–5). Box 38–1 provides guidelines for testing the strength of various muscle groups.

TABLE 38–5 Muscle Grading Scale

Grading Scale	Assessment Description
0	No muscle contraction
1	Can feel contraction of muscle but there is no movement of limb
2	Passive ROM
3	Full ROM against gravity
4	Full ROM against some resistance
5	Full ROM against full resistance

BOX 38–1 Guidelines for Assessing Muscle Strength

In adults, muscles are bilaterally strong. However, neuromuscular diseases, disuse, metabolic disorders, inflammation, or infections can cause muscle weakness. Muscle strength is expected to be slightly greater in the dominant arm and leg.

The muscles and muscle groups listed in the following table are routinely tested. Instructions for patients are also provided.

Muscle	Patient Instructions
Ocular muscles and lids	Close eyes tightly.
Facial muscles	Blow out cheeks.
	Stick out tongue.
Jaw muscles	Clench the teeth.
Neck muscles	Rotate the head side to side.
	Bend head forward and backward.
Shoulder muscles	Shrug shoulders
Deltoid muscles	Hold arms up out to the side (abduction).
Biceps muscle	Bend the arm at the elbow.
Triceps muscle	Straighten the arm.
Wrist muscles	Bend hand forward and backward.
Finger muscles	Shake hands.
	Make a fist.
	Spread fingers.
Hip muscles	Raise straight leg while supine.
Gluteal and leg muscles	Alternately cross legs while sitting.
Quadriceps muscle	Straighten leg (extend the knee).
Ankle and foot muscles	Bend foot up and down.

Musculoskeletal Assessments

Technique/Normal Findings	Abnormal Findings
Gait and Body Posture Assessment	
Inspect posture and gait. *Posture should be upright; gait should be smooth and steady.*	• Joint stiffness, pain, deformities, and muscle weakness can cause changes in gait and posture.
Inspect the spine. Ask the patient to stand and bend back slowly as far as possible, bend slowly to the right and then to the left as far as possible, turn slowly to the right and left, and bend forward slowly and try to touch fingers to toes. *When viewed from the back, the cervical and lumbar spine are concave, the thoracic spine is convex, and the spine is straight; the hips and shoulders are level.*	• With herniated lumbar disks and some types of arthritis, the lumbar curve flattens and spinal mobility is decreased. • An increased lumbar curve, called **lordosis**, may be seen in obesity or pregnancy. • A lateral, S-shaped curvature of the spine is called **scoliosis**. Functional scoliosis usually is a compensatory response to painful paravertebral muscles, herniated disks, or discrepancy in leg length. It disappears with forward flexion. Structural scoliosis is often congenital and tends to become apparent during adolescence. It is accentuated with bending forward. • **Kyphosis** is an exaggerated thoracic curvature of the spine associated with disorders such as osteoporosis and Paget's disease.
Joint Assessment	
Inspect the joints for deformity, swelling, and redness. *There should be no visible deformity, swelling, or redness of joints.*	• Diseases of the joints may be manifested by signs of inflammation or such deformities as tissue loss, tissue overgrowth, or contractures; irreversible shortening of muscles and tendons may occur. • Edema in a joint and surrounding tissue may cause swelling; the joint may feel spongy to palpation. • Excess fluid in the synovial space may cause obvious bulging. • Redness, swelling, and pain are evidence of inflammation or infection in the joint. • Inflammation and injury cause joint pain. • Inflammatory arthritis, bursitis, tendonitis, and osteomyelitis (infection of a bone) result in painful, hot joints. • **Crepitation** (a grating sound and sensation) is present in a joint when the articulating surfaces have lost their cartilage, such as in arthritis.
Palpate the joints for tenderness, warmth, crepitation, consistency, and muscle mass. *Joints should be nontender and consistent bilaterally, and without visible or palpable excess warmth, crepitation, or enlargement.*	
Range-of-Motion Assessment	
Assess joint ROM by asking the patient to perform movements specific to each joint. *All bilateral joints should move through full range of motion.*	• Clicking or popping noises, decreased ROM, pain, and swelling may indicate temporomandibular joint syndrome or, in rare cases, osteoarthritis.
Temporomandibular joint: "Open your mouth wide, and then close your mouth." (As the patient opens and closes the mouth, palpate the temporomandibular joints with your index and middle fingers, as shown in Figure 38–7 ■.)	
Cervical spine: 45-degree flexion: "Touch your chin to your chest." 55-degree extension: "Look at the ceiling." 38-degree lateral flexion: "Try to touch your right ear to your right shoulder." Repeat with the left side. 70-degree rotation: "Try to touch your chin to each shoulder."	• Neck pain and limited extension with lateral flexion are seen with herniated cervical disks and in cervical spondylosis. • An immobile neck with head and neck thrust forward is seen with ankylosing spondylitis.

Figure 38–7 ■ Palpating the temporomandibular joints.

Musculoskeletal Assessments (*continued*)

Technique/Normal Findings	Abnormal Findings
Lumbar spine: 75- to 90-degree flexion: "Touch your toes with your fingers" (Figure 38–8A ■). 30-degree extension: "Bend backward slowly." 35-degree lateral flexion: "Bend right and left" (Figure 38–8B ■). 30-degree rotation: "Twist your shoulders right and left" (Figure 38–8C ■).	• Decreased movement or pain with movement may indicate an abnormal spinal curvature, arthritis, herniated disk, or spasm of paravertebral muscles.

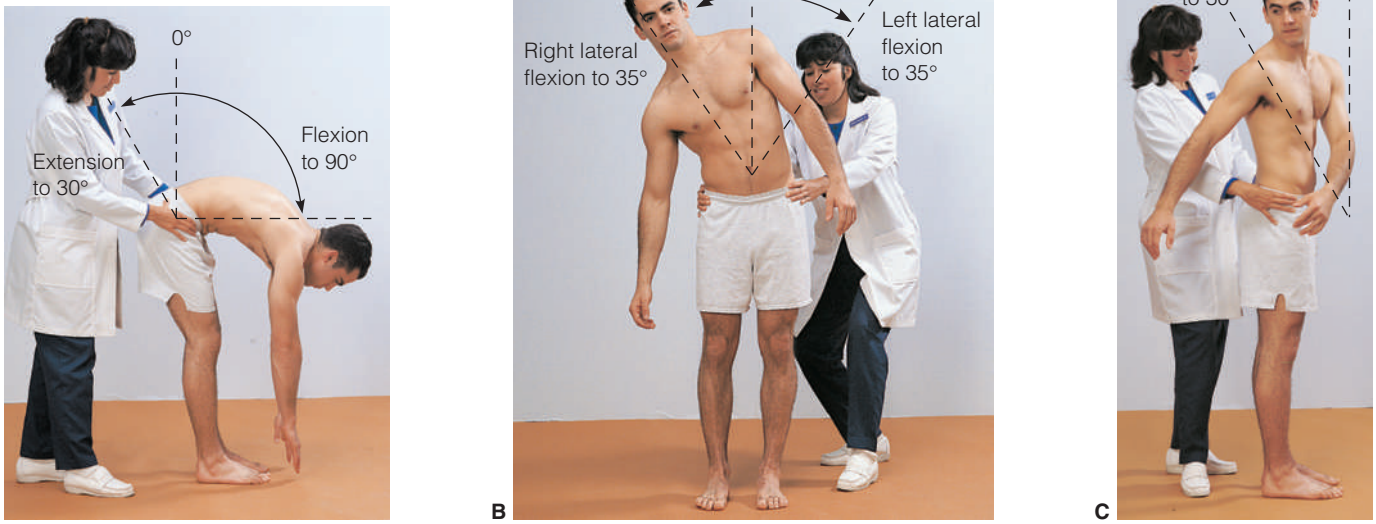

Figure 38–8 ■ A, Forward flexion of spine. B, Lateral flexion of spine. C, Rotation of spine.

Shoulders: 180-degree flexion: "Hold your arms straight up and out." 50-degree hyperextension: "Put your straight arm behind your back." 90-degree internal rotation: "Put your forearm behind your lower back." 180-degree abduction: "Raise your straight arm up and out to your side." 50-degree adduction: "Put your straight arm across your chest."	• Pain and tenderness over the biceps tendon occurs with **tendonitis** (inflammation of a tendon). • In a rotator cuff injury, the arm cannot be abducted fully and the movement causes pain and tenderness. • Pain and limited abduction is also seen with **bursitis** (inflammation of a bursa) and calcium deposits in this area.
Elbows: 160-degree flexion: "Touch your hands to your shoulders." 180-degree extension: "Straighten your elbows." 90-degree supination: "Bend your elbows 90 degrees, and turn hands palm up." 90-degree pronation: "Bend your elbows 90 degrees, and turn fists down."	• Swollen, tender, inflamed elbows occur in gouty arthritis and rheumatoid arthritis. • Pain and tenderness at the lateral epicondyle occur in tennis elbow.
Wrists: 90-degree flexion: "Bend wrist down." 70-degree extension: "Bend wrist up." 55-degree ulnar deviation: "Bend wrist toward little finger." 20-degree radial deviation: "Bend wrist toward thumb."	• Bilateral chronic tenderness and swelling in the wrist is seen in arthritis.

(*continued*)

Musculoskeletal Assessments (*continued*)

Technique/Normal Findings	Abnormal Findings
Fingers: Flexion: "Make a fist." Extension: "Open your hand." Abduction: "Spread your fingers." Adduction: "Close your fingers."	• Flexion and extension of fingers are decreased in arthritis. • Heberden's nodes and Bouchard's nodes are hard, nontender nodules on the dorsolateral parts of the distal and proximal interphalangeal joints, respectively. They are common in osteoarthritis. • Stiff, painful, swollen finger joints are seen in acute rheumatoid arthritis. • Boutonnière and swan-neck deformities are seen in chronic rheumatoid arthritis. • Swollen finger joints with a white chalky discharge may be seen in chronic gout. • Dupuytren's contracture, inability to extend the fourth and/or fifth fingers, may be seen in some older adults.
Hips (patient is lying down): 120-degree flexion: "Bring bent knee up to your chest." 30-degree hyperextension: "Lie on the abdomen, and lift up one leg at a time." 45-degree abduction: "Hold your leg straight, and move it out to the side." 38-degree internal rotation: "Bend your knee, and swing it toward your other leg." 45-degree external rotation: "Bend your knee, and swing it out to the side."	• Movement of the hip is limited and/or painful in arthritis. **PRACTICE ALERT!** Unless approved by the physician, do not have the patient who has a hip prosthesis perform these movements due to the risk of prosthesis dislocation.
Knees: 130-degree flexion: "Do a deep knee bend." 180-degree extension: "Sit down and hold your legs straight out in front of you."	• Swelling over the suprapatellar pouch is seen with inflammation and fluid in the articular capsule of the knee. **Synovitis** is inflammation of the synovial membrane lining the articular capsule of a joint. It is common with knee trauma. • Swelling over the patella is seen in bursitis.
Ankles: 20-degree dorsiflexion: "Point your foot to the ceiling." 45-degree plantar flexion: "Point your foot to the floor." 30-degree inversion: "Walk on the outside of your feet." 20-degree eversion: "Walk on the inside of your feet."	• Contractures of the Achilles tendon may occur in patients with rheumatoid arthritis or following prolonged bed rest.
Toes: 90-degree flexion: "Walk on your toes."	• The great toe is excessively abducted in hallux valgus (bunion). • The joint of the great toe is swollen, inflamed, and painful in acute gouty arthritis. • There is hyperextension of the metatarsophalangeal joint and flexion of the proximal interphalangeal joint with hammer toes.

Special Assessments

The following special techniques may be used to assess for suspected abnormalities.

Musculoskeletal Assessments (*continued*)

Technique/Normal Findings	Abnormal Findings
Perform Phalen's test. Ask the patient to hold the wrist in acute flexion for 60 seconds (Figure 38–9 ■). *There should be no tingling, numbness, or pain.*	• Numbness and burning in the fingers during Phalen's test may indicate carpal tunnel syndrome.

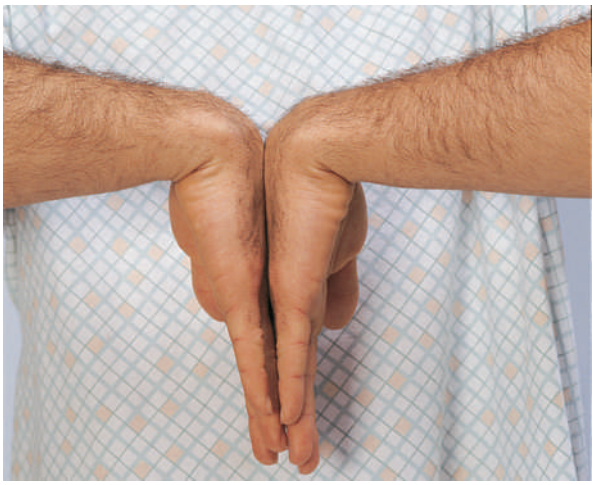

Figure 38–9 ■ Phalen's test.

Check for small amounts of fluid on the knee by assessing the bulge sign. Milk upward on the medial side of the knee, and then tap the lateral side of the patella (Figure 38–10 ■). *No fluid bulge should appear on the medial side of the knee.*	• A fluid bulge indicates increased fluid in the knee joint rather than soft-tissue swelling.

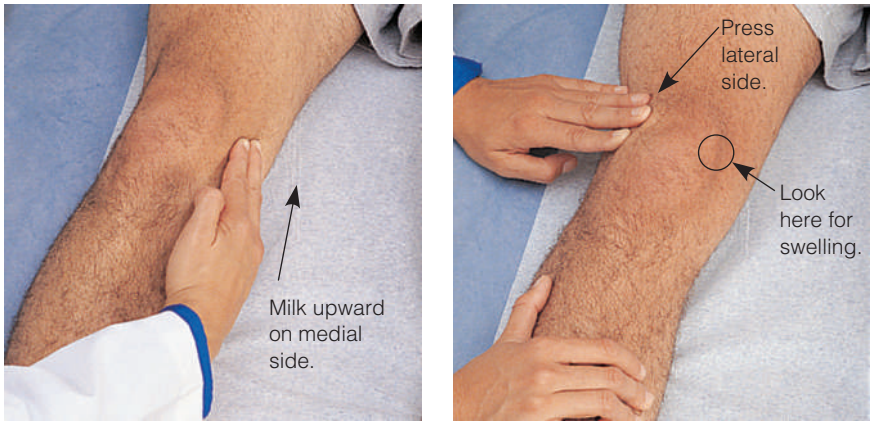

Figure 38–10 ■ Assessing the bulge sign.

Assess for ballottement, a maneuver to detect large amounts of fluid in the knee. Apply downward pressure on the knee with one hand while pushing the patella backward against the femur with the other hand (Figure 38–11 ■). *There should be little or no movement of the patella. The patella should rest firmly over the femur.*	• Increased fluid will cause a clicking sensation as the patella displaces the fluid and hits the femur.

Figure 38–11 ■ Assessing ballottement.

(*continued*)

Musculoskeletal Assessments (*continued*)

Technique/Normal Findings	Abnormal Findings
Perform McMurray's test. With the patient reclining, flex the hip and knee 90° or until the patient experiences pain. Palpating the medial and lateral aspects of the knee, externally rotate the foot and extend the knee; repeat the maneuver, internally rotating the foot and extending the knee (Figure 38–12 ■). *There should be no pain or clicking.*	• Pain, locking (inability to fully extend the knee), or a popping sound may indicate an injury to a meniscus, a disk of cartilaginous tissue in the knee.
Perform the Thomas test. Ask the patient to lie down and extend one leg while bringing the knee of the opposite leg to the chest. *The extended leg should not rise off the table.*	• A hip flexion contracture will cause the extended leg to rise off the table.

Figure 38–12 ■ McMurray's test.

SAMPLE DOCUMENTATION

Assessment of the Musculoskeletal System

58-year-old Hispanic male, employed as a roofer, comes to the orthopedic clinic for evaluation of chronic knee pain. Patient states, "The pain in my knees is worse when I get up in the morning and when I carry something heavy at work." Posture erect, gait even without obvious limp. Lower extremities appear equal in size and shape bilaterally. No swelling noted, bulge test negative for fluid around knee. Crepitus noted in both knees during flexion and extension. ROM in both knees slightly decreased. No obvious decrease in muscle mass. Patient states knee pain during ROM is a 3 on a 1 to 10 scale. Referred to clinic physician for further evaluation, including x-rays of both knees.

CHAPTER HIGHLIGHTS

- **Intact structure and function of the musculoskeletal system is vital to the ability to independently perform activities and usual daily living activities.**
- **Manifestations of dysfunction, injuries, and disorders affecting the musculoskeletal system may be detected during a general health assessment as well as during focused and functional musculoskeletal assessments.**
- Musculoskeletal disorders are diagnosed primarily using a targeted medical history, physical assessment, and functional assessments of the musculoskeletal system. Diagnostic tests help to identify and diagnose musculoskeletal injuries and disorders.

TEST YOURSELF NCLEX-RN® REVIEW

1. The nurse is caring for a patient with an epiphyseal fracture. What bone classification should the nurse keep in mind when planning this patient's care?
   1. flat
   2. long
   3. short
   4. irregular
2. During an assessment the nurse asks the patient to move an extremity away from the body midline. What movement is the nurse assessing?
   1. flexion
   2. extension
   3. abduction
   4. adduction
3. A patient with gout asks, "Why is my blood being examined for uric acid?" What should the nurse respond to this patient?
   1. "Tell me how you got that big bruise on your hip."
   2. "A uric acid test is done to diagnose rheumatoid arthritis."
   3. "Do you have a family history of muscle or bone disease?"
   4. "A uric acid test is done to see if your gout medication is effective."
4. The nurse is assessing the musculoskeletal status of a 70-year-old patient. What findings should the nurse consider as expected age-related changes in this body system? (Select all that apply.)
   1. decreased muscle mass
   2. reduced muscle strength
   3. edema of ankles, hips, and knees
   4. reduced range of motion of shoulders and hips
   5. loss of 1/2 inch in height from previous assessment
5. A patient is scheduled for an electromyogram. What should the nurse instruct the patient to do in preparation for this diagnostic test? (Select all that apply.)
   1. Do not smoke for 3 hours before the test.
   2. Avoid taking muscle relaxants before the test.
   3. Avoid taking oral hypoglycemic agents before the test.
   4. Alert the healthcare provider about an allergy to shellfish.
   5. Avoid fluids containing caffeine for 3 hours before the test.
6. The nurse is assessing muscle strength. What should the nurse ask the patient to do to assess facial muscle strength?
   1. "Clench your teeth."
   2. "Stick out your tongue."
   3. "Close your eyes tightly."
   4. "Bend your head forward."
7. The nurse hears a grating sound while assessing range of motion of a patient's hip. How should the nurse document this finding?
   1. crackles
   2. arthritis
   3. synovitis
   4. crepitation
8. While assessing for ballottement, a nurse notes that the patella rebounds against the fingers. What does this finding indicate?
   1. fluid in the knee joint
   2. deformity of the elbow
   3. crepitus in the hip joint
   4. infection of the metatarsals
9. During the physical assessment of a young adult, the nurse notes a lateral, S-shaped curve of the spine. What should the nurse suspect is occurring with this patient?
   1. lordosis
   2. scoliosis
   3. kyphosis
   4. musculosis
10. The nurse is preparing to assess a patient's musculoskeletal system. What should the nurse keep in mind as being the most common manifestations of musculoskeletal disorders?
    1. pain and limited mobility
    2. pallor and decreased ROM
    3. cyanosis and decreased pulses
    4. swelling and exaggerated reflexes

39 Nursing Care of Patients with Musculoskeletal Trauma

LEARNING OUTCOMES

1. Compare and contrast the causes, risk factors, pathophysiology, manifestations, interprofessional care, and nursing care of contusions, strains, sprains, joint dislocations, and fractures.
2. Describe the pathophysiology, interprofessional care, and nursing care for repetitive use injuries.
3. Describe the stages of bone healing.
4. Explain the pathophysiology, manifestations, and related treatment for complications of fractures: compartment syndrome, fat embolism syndrome, deep venous thrombosis, infection, delayed union and nonunion, and complex regional pain syndrome.
5. Discuss the purposes and related nursing interventions for casts, fixation devices, traction, and stump care.
6. Explain the causes, levels, types, and potential complications (infection, delayed healing, chronic stump pain, phantom pain, and contractures) of an amputation.

CLINICAL COMPETENCIES

1. Assess health status of patients with musculoskeletal injuries, including the patient's perception of the injury, its impact on lifestyle, and expectations for care.
2. Use evidence-based research and guidelines to plan, coordinate, and implement care for patients who have experienced musculoskeletal trauma.
3. Determine priority nursing diagnoses, based on assessed data, to plan and implement individualized nursing interventions and teaching for patients with musculoskeletal injuries.
4. Provide skilled care for patients with a cast, fixation device, traction, or amputation, maintaining patient and caregiver safety at all times.
5. Coordinate and integrate interprofessional care into care of patients with musculoskeletal trauma.
6. Communicate and document care for patients with traumatic injuries of the musculoskeletal system using electronic medical records and other communication methods as appropriate.

MAJOR CHAPTER CONCEPTS

- Musculoskeletal injuries, including strains, sprains, fractures, and joint injuries, are common, often associated with recreational activities or trauma. Nursing care includes assessing the circumstances and impact of the injury as well as neurovascular status distal to the injury, and teaching prescribed treatment and rehabilitation.
- Fractures are usually uncomplicated, but place the patient at risk for both acute and long-term complications and may necessitate surgery or other invasive interventions for healing. Nurses must promptly recognize complications, and initiate appropriate care.
- Amputation, the partial or total removal of an extremity, has significant physical and psychosocial effects on the patient and on the family. In addition to providing care and support for the patient and family, the nurse is actively involved in coordinating the interprofessional team for optimal patient care and rehabilitation.

KEY TERMS

amputation, *1257*
compartment syndrome, *1241*
contracture, *1260*
contusion, *1235*
dislocation, *1237*
fat embolism syndrome (FES), *1244*
flail chest, *1251*
fracture, *1239*
phantom limb pain, *1259*
sprain, *1235*
strain, *1235*
subluxation, *1237*

Musculoskeletal trauma is an injury to muscle, bone, or soft tissue that results from excessive external force. The external force transmits more kinetic energy than the tissue can absorb, and injury results. The severity of the trauma depends not only on the amount of force but also on the location of the impact, because different parts of the body can withstand different amounts of force. A wide variety of external forces can cause trauma, and the force involved can vary in severity (e.g., a step off the curb, a fall, being tackled in a football game, and a motor vehicle crash).

Traumatic musculoskeletal injuries include blunt tissue trauma, damage to tendons and ligaments, and fractures of bones. Various forces that cause musculoskeletal trauma are typical for a specific

environment, activity, or age group. For example, motorcycle crashes resulting in fractures of the distal tibia, midshaft femur, and radius are common in young men. Sports injuries, resulting from either overuse or acute trauma, are seen more often in adolescents and young adults. Falls are the most common cause of injury in people ages 65 and older, with fractures of the vertebrae, distal radius, and hip common (Grossman & Porth, 2014). Regardless of the cause, the injury may require rehabilitation and temporary or permanent changes in lifestyle.

Musculoskeletal trauma can result in mild to severe injuries. A patient may experience a soft tissue injury, a fracture, and/or a complete amputation. In addition, trauma to one part of the musculoskeletal system often produces dysfunction in adjacent structures. For example, a fracture of the femur prevents the adjacent muscles from abducting and adducting. Nursing care helps minimize the effects of trauma, prevents complications, and hastens restoration of function. This chapter discusses soft tissue injuries, dislocations, repetitive use injuries, fractures, and amputations.

Traumatic Injuries of the Muscles, Ligaments, and Joints

THE PATIENT WITH A CONTUSION, STRAIN, OR SPRAIN

Contusions, strains, and sprains are among the most commonly reported injuries. They account for about 50% of work-related injuries, with lower back injuries being the most commonly reported occupational injury. However, many sprains and strains are not work related and often are not reported. The lower back and cervical region of the spine are the most common sites for muscle strains; the ankle is the most commonly sprained joint, usually caused by forced inversion of the foot.

Pathophysiology and Manifestations

A **contusion**, the least serious form of musculoskeletal injury, is bleeding into soft tissue that results from a blunt force, such as a kick or striking a body part against a hard object. The skin remains intact, but small blood vessels rupture and bleed into soft tissues. A contusion with a large amount of bleeding is referred to as a *hematoma*. The manifestations of a contusion include swelling and discoloration of the skin. The blood in the soft tissue initially results in a purple and blue color commonly referred to as a *bruise*. As the blood begins to reabsorb, the area involved becomes brown and then yellow until it disappears.

A **strain** is a stretching injury to a muscle or a muscle-tendon unit caused by mechanical overloading. A muscle that is forced to extend past its elasticity will develop microscopic tears. Lifting heavy objects without bending the knees, or a sudden acceleration–deceleration, as in a motor vehicle crash, can cause strains. Common sites for a muscle strain are the lower back and the hamstring muscle in the back of the thigh. The manifestations of a strain include pain, limited motion, muscle spasms, swelling, and possible muscle weakness. Severe strains that partially or completely tear the muscle or tendon can be disabling with significant bleeding, swelling, and bruising around the muscle.

A **sprain** is a stretch and/or tear of one or more ligaments surrounding a joint. Forces going in opposite directions cause the ligament to overstretch and/or tear. The ligaments may be partially or completely torn. Although any joint may be involved, sprains of the ankle and knee are most common, with more than 628,000 people spraining an ankle annually in the United States (National Institute of Arthritis and Musculoskeletal and Skin Diseases [NIAMS], 2012). Manifestations include loss of the functional ability of the joint, a feeling of a pop or tear, discoloration, pain, and rapid swelling. Motion increases the joint pain. The intensity of the manifestations depends on the severity of the sprain. Grades of sprain severity are presented in Table 39–1.

●○● INTERPROFESSIONAL CARE

The goal of the initial stage of treating soft tissue trauma is to reduce swelling and pain. Patients should follow a regimen of rest, ice, compression, and elevation for the first 24 to 48 hours (see Table 39–2).

MEMORY CUE

Use the acronym RICE to remember initial measures to treat a musculoskeletal injury:

Rest
Ice
Compression
Elevation

When soft tissue trauma occurs, musculoskeletal ultrasound or x-rays and magnetic resonance imaging (MRI) may be done to rule

TABLE 39–1 Grades of Sprain Severity

Grade	Description	Manifestations
Grade 1 (mild)	Overstretching or minimal tear of ligaments with no joint instability	• Mild pain, swelling, tenderness • Little or no bruising • Minimal or no loss of joint function or ability to bear weight
Grade 2 (moderate)	Partial tear of the ligament	• Moderate pain, bruising, and swelling • Mild to moderate joint instability, functional disability • Weight bearing difficult
Grade 3 (severe)	Complete tear or rupture of the ligament	• Severe pain, swelling, and bruising • Significant functional loss and joint instability • Inability to bear weight

TABLE 39–2 RICE Therapy for Musculoskeletal Injuries

Action	Patient and Family Education
Rest	• Decrease regular daily living activities and exercise as needed. • Limit weight bearing on the injured extremity for 48 hours. • If you use a cane or crutch to avoid weight bearing, use it on the uninjured side so you can lean away from and relieve weight on the injured leg.
Ice	• To avoid cold injury or frostbite, apply an ice pack to the injured area for no more than 20 minutes at a time, four to eight times a day. • An ice bag, cold pack, plastic bag filled with crushed ice and wrapped in a towel, or a bag of frozen peas may be used.
Compression	• Loosen the compression bandage if you experience numbness, tingling, or swelling distal to the injury, or if the distal extremity becomes cool or cyanotic (bluish-grey). • Examples of compression bandages include Ace wraps, special boots, air casts, and splints.
Elevation	• Keep the injured extremity elevated on a pillow above heart level to help reduce swelling and pain.

out fracture and determine the extent of tissue damage. Nonsteroidal anti-inflammatory drugs (NSAIDs) are used to reduce pain, swelling, and inflammation associated with the injury. Alternately, acetaminophen may provide comparable pain relief (Bowie, 2011).

Ankle sprains may be immobilized with a cast or splint, with no limitations on weight bearing. A knee injury often requires a knee immobilizer. If an upper extremity is injured, a sling is provided. Surgery to repair the torn ligaments, muscle, or tendons may be required for severe sprains or strains. Physical therapy may be recommended for rehabilitation. Time required for healing depends on the severity of the injury; for example, a mild ankle sprain may require up to 3 to 6 weeks of rehabilitation, whereas a severe sprain may require up to 8 to 12 months to return to full activities (NIAMS, 2012).

●○● NURSING CARE

The nursing care of each patient is individualized. A strain or sprain may not be as devastating to an attorney as it is to a professional athlete; therefore, the nurse should determine what the injury means to the particular patient.

Diagnoses, Outcomes, and Interventions

Nursing diagnoses focus on providing information about self-care to decrease pain and return physical mobility to preinjury levels.

Acute Pain

The pain that results from soft tissue trauma is due primarily to the injury to the muscle or ligament and secondarily to bleeding and edema at the injury site.

Expected Outcome: Patient will verbalize pharmacologic and nonpharmacologic measures to manage pain within acceptable levels.

- Teach the patient to use RICE (rest, ice, compression, elevation) therapy to care for the injury. *The interventions included in RICE therapy allow the injured muscle, ligament, or tendon to heal (rest), cause vasoconstriction and reduce pain (ice), decrease edema formation and pain (compression), and promote venous return to decrease edema and pain (elevation).*
- Teach effective use of prescription and over-the-counter (OTC) analgesics and NSAIDs to manage pain. *An understanding of effective analgesic and NSAID use allows the patient to maintain comfort and activity within recommended limits.*

Impaired Physical Mobility

Pain causes the patient to avoid using or bearing weight with the injured extremity. Always observe the patient's use of assistive devices; if the device is inappropriate or used incorrectly, the risk of falling increases. As an individual ages, muscle mass in the upper extremities declines. As a result, an older patient with a sprained ankle may find a walker more useful than crutches, which require greater upper body strength.

- Teach the correct use of crutches, walkers, canes, or slings if prescribed. *Use of the correct technique increases safety and encourages use of these devices.*
- Encourage follow-up care. *Severe sprains may require further evaluation to determine if physical therapy or surgical intervention is indicated.*

THE PATIENT WITH JOINT TRAUMA

The synovial joints of the upper and lower extremities can be subjected to injury from trauma as a result of recreational activities or accidents.

Pathophysiology and Manifestations

Joint trauma affects the joint structure itself or the soft tissues supporting the joint.

ROTATOR CUFF INJURIES

The shoulder joint is particularly vulnerable to injuries because of factors such as its wide range of motion, complexity, and exposed position. Most shoulder problems result from rotator cuff injuries. The rotator cuff is the group of muscles that control arm movement. Rotator cuff disorders include tendinitis, bursitis, and partial and complete muscle tears. These injuries can be acute or may result from repetitive use injury or degenerative changes of the involved tissues.

Manifestations of rotator cuff damage include shoulder pain, which may be worse at night or when lying on the involved shoulder. Range of motion, abduction and flexion in particular, increases discomfort and often is limited.

KNEE INJURIES

The knee is vulnerable to ligament tears, meniscal injury, and patellar dislocation. These injuries frequently are associated with

sports activities that lead to falls or abnormal twisting of the knee joint. The medial collateral ligament (MCL) is the most commonly injured knee ligament; anterior cruciate ligament (ACL) tears also are common sports injuries (Luke & Ma, 2012). The menisci, two C-shaped plates of cartilage within each knee joint, act as shock absorbers. A tear of the medial meniscus is a common knee injury. The patella, or knee cap, can become partially or completely dislocated.

The patient with a knee injury often relates a history of an acute injury, with immediate pain, a tearing or popping sensation, or the knee "giving out." Swelling of the affected joint may develop immediately or over several hours after the injury.

JOINT DISLOCATION

A **dislocation** is an injury in which the ends of bones are displaced out of their normal position and joint articulation is lost. Dislocations usually follow trauma such as a fall or blow. They commonly occur during contact sports such as football or from falls resulting from activities such as skiing. Pathologic dislocations result from disease of the joint, including infection, rheumatoid arthritis, paralysis, and neuromuscular diseases.

Although dislocations may occur in any joint, they occur most frequently in the shoulder and acromioclavicular joints. A **subluxation** is a partial dislocation in which the bones of the joint remain in partial contact.

Dislocation causes pain, deformity, and limited motion of the affected joint.

●○● INTERPROFESSIONAL CARE

Care of the patient with a joint injury focuses on relieving pain, managing or correcting the resulting disorder, and preventing complications. The history and physical often are sufficient to identify joint trauma. Specific examination maneuvers may be performed. X-rays of the affected joint are obtained; an MRI also may be performed.

TREATMENT

The treatment is dictated by the type of injury. A dislocation is usually *reduced* (bone ends realigned) using manual traction. If closed reduction fails, surgery may be necessary to realign the joint and prevent complications such as neurovascular injury.

Dislocations of the shoulder joint usually can be managed with closed reduction and a limited period of postreduction immobilization. A dislocated hip requires immediate reduction to prevent necrosis of the femoral head and injury to the sciatic and femoral nerves. After reduction, the patient is placed on bed rest for several days or even weeks. If a hip dislocation is accompanied by a fracture, the patient will undergo surgery to increase mobility, decrease complications, and rapidly stabilize the joint.

Treatment for rotator cuff injuries usually is conservative, including joint rest, NSAIDs, moist heat, and, for persistent problems, physical therapy. Some patients require surgery to repair a torn rotator cuff.

Joint rest, with compression, ice, elevation, and restricted weight bearing, are initially prescribed for knee injuries. Physical therapy is ordered during rehabilitation. Patients with recurrent pain, swelling, or injuries may require surgery to repair the joint damage.

●○● NURSING CARE

Nursing care of the patient with joint trauma is individualized to the cause of injury and the age of the patient. It is important to teach patients to seek immediate medical attention for a joint dislocation, to splint the joint to prevent further damage, and to put ice on the injured joint.

Assessment

- *Health history:* Ask about history of trauma, including circumstances of injury if known; pain, including location, character, timing, and activities or movements that aggravate or relieve it; history of prior musculoskeletal injuries; chronic illnesses; medications.
- *Physical assessment:* Compare the position, color, size, and temperature of the affected joint to the corresponding unaffected joint. Palpate for tenderness, crepitus, temperature, and swelling. Instruct the patient or assist to move the joint through its normal range of motion, stopping and noting where pain is experienced. Do not move the affected joint beyond that point. When a joint dislocation is suspected, assess color, temperature, pulses, movement, and sensation of the limb distal to the affected joint.

Priorities of Care

Relieving pain, preventing complications, and teaching for self-care and rehabilitation are priorities of care for the patient with joint trauma.

Diagnoses, Outcomes, and Interventions

Risk for Peripheral Neurovascular Dysfunction

The patient with a dislocation requires frequent assessments to ensure that neurovascular compromise does not develop.

Expected Outcome: Patient's circulation, movement, and sensation distal to injury will remain intact.

- Monitor neurovascular status by assessing the "five Ps": pain, pulses, pallor, paralysis, and paresthesia. *Neurovascular compromise is indicated by increased pain, decreased or absent pulses, pale skin with decreased capillary refill, inability to move a body part or extremity, and changes in sensation (such as "pins and needles" sensations, or loss of sense of sharp/dull touch).*
- Maintain immobilization as ordered after reduction. *Immobilization prevents the joint from dislocating again.*

Acute Pain

Expected Outcome: Patient will use pharmacologic and nonpharmacologic strategies to manage pain and maintain comfort.

- Encourage use of an appropriate splint or joint immobilizer. *Splinting maintains joint alignment and reduces pain and inflammation.*
- Teach safe application of ice or heat to the affected joint as indicated. *Ice causes vasoconstriction and numbs the tender area; heat decreases swelling by increasing venous return. Inappropriately applied, both ice and heat can damage tissues.*
- Instruct about using NSAIDs as ordered. *Taken on a regular basis (not as needed for pain), NSAIDs decrease swelling and inflammation, reducing pain.*
- Teach use of assistive devices such as a sling, crutches, or cane to reduce stress on the affected joint or minimize weight bearing. *When used appropriately, assistive devices help minimize use of and stress on the affected joint, promoting joint rest and healing. When*

used inappropriately, these assistive devices can increase the risk of further injury or damage.

Impaired Physical Mobility

Expected Outcome: Patient will regain pre-injury level of mobility.

- Refer to physical therapy for appropriate exercises. *The physical therapist can teach exercises to strengthen supportive joint tissues and maintain or restore joint mobility.*
- Suggest occupational therapy. *Occupational therapy can help the patient learn new ways to perform tasks to prevent recurring symptoms.*

Continuity of Care

Teach about the specific joint injury or disorder and its causes and treatments. Joint injuries often tend to be recurring for patients actively participating in sports and vigorous physical activities. Prolonged immobilization (for several weeks after the injury) and aggressive rehabilitation following the initial injury can reduce the risk of recurrent problems. The following topics should be addressed:

- Importance of complying with the prescribed length of immobilization
- Skin care and ways to prevent skin-to-skin contact, particularly in the axillary area
- Prescribed rehabilitation exercises to strengthen muscles and other supportive structures in the affected joint, decreasing the risk of future trauma
- Alternatives to activities that precipitate recurrent trauma
- Instructions or referrals to physical therapy if needed for further teaching about using assistive devices
- Referrals to physical and occupational therapy and home health services as needed.

THE PATIENT WITH A REPETITIVE USE INJURY

Repeatedly twisting and turning the wrist, pronating and supinating the forearm, kneeling, or raising arms over the head can result in repetitive use injuries. Patients with repetitive use injuries pose a challenge to the healthcare team. Often these patients appear puzzled as they relate a history of manifestations that have worsened over time. They deny abrupt trauma and often worry about the ability to return to work. Repetitive use injuries are common. The number of worker's compensation claims for these types of injuries is steadily growing, with the increase believed to be a result of technology advances in the workplace.

Pathophysiology

Common repetitive use injuries include carpal tunnel syndrome, bursitis, and epicondylitis.

CARPAL TUNNEL SYNDROME

The carpal tunnel is a canal through which flexor tendons and the median nerve pass from the wrist to the hand. The syndrome develops from narrowing of the tunnel and irritation of the median nerve. Carpal tunnel syndrome involves compression of the median nerve as a result of inflammation and swelling of the synovial lining of the tendon sheaths. The patient complains of numbness and tingling of the thumb, index finger, and lateral ventral surface of the middle finger. The patient may also complain of pain in this area that interferes with sleep and is alleviated by shaking or massaging the hand and fingers. The affected hand may become weak and the patient may be unable to hold utensils or perform activities that require precision.

Carpal tunnel syndrome is one of the three most common work-related injuries. The incidence is believed to be related directly to the number of people using computers. The incidence of carpal tunnel syndrome is higher in women, especially postmenopausal women.

BURSITIS

Bursitis is an inflammation of a bursa. A bursa is an enclosed sac found between muscles, tendons, and bony prominences. The bursae that commonly become inflamed are in the shoulder, hip, knee, and elbow. Constant friction between the bursa and the musculoskeletal tissue around it causes irritation, edema, and inflammation. Manifestations develop as the sac becomes engorged. The area around the sac is tender, and extension and flexion of the joint near the bursa produce pain. The inflamed bursa is hot, red, and edematous. The patient guards the joint to decrease pain and may point to the area of the bursa when identifying joint tenderness.

EPICONDYLITIS

Epicondylitis or tendinopathy is inflammation of the tendon at its point of origin into the humerus. Epicondylitis is also referred to as *tennis elbow* or *golfer's elbow*. This disorder typically results from chronic repetitive wrist flexion and extension or pronation and supination against resistance. Manifestations of epicondylitis include point tenderness, pain radiating down the dorsal surface of the forearm, and a history of repetitive use.

●○● INTERPROFESSIONAL CARE

Medical management of repetitive use disorders focuses on relieving pain and increasing mobility. Once the diagnosis is made, treatment can range from conservative measures, such as rest, medications, and physical therapy, to aggressive measures such as surgery.

DIAGNOSIS

Carpal tunnel syndrome is diagnosed by the patient's history and physical examination. The history may reveal an occupation that involves areas such as computer work, jackhammer operation, mechanical work, or gymnastics. History of a radial bone fracture or rheumatoid arthritis also increases the risk of carpal tunnel syndrome. Tests specific for carpal tunnel include the Phalen's test. Ultrasound or MRI, electromyography (EMG), and nerve conduction studies may be done to confirm the diagnosis. Bursitis and epicondylitis are diagnosed by history and physical examination. Movements such as shaking hands may reproduce the pain of epicondylitis.

MEDICATIONS

The patient with a repetitive use injury usually receives NSAIDs. Narcotics may be administered for acute flare-ups and severe pain. For the patient who has epicondylitis or carpal tunnel syndrome, corticosteroids may be injected into the joint.

TREATMENTS

Initial treatment for repetitive use injuries is conservative, followed, if necessary, by surgery.

CONSERVATIVE MANAGEMENT The first steps in the care of all repetitive use injuries are to immobilize and rest the involved joint. The joint may be splinted, and ice may be applied (as described in Table 39–2) in the first 24 to 48 hours to decrease pain and inflammation. Ice application may be followed by heat application every 4 hours.

SURGERY Surgery is usually reserved for the patient who does not obtain relief with conservative treatment. Surgery for carpal tunnel syndrome includes resection of the carpal ligament to enlarge the tunnel. In epicondylitis and bursitis, calcified deposits may be removed from the area surrounding the tendon or bursa.

●○● NURSING CARE

The nursing care of a patient with a repetitive use injury focuses on relieving pain, teaching about the disease process and treatment, and improving physical mobility.

Diagnoses, Outcomes, and Interventions

Acute Pain

Swelling and nerve inflammation cause pain in the patient with a repetitive use injury.

Expected Outcome: Patient will report improved comfort and rest.

- Ask the patient to rate the pain on a scale of 0 to 10 (with 10 being the most severe pain) before and after any intervention. *This facilitates objective assessment of the effectiveness of the chosen pain relief strategy.*
- Encourage the use of immobilizers. *Splinting maintains joint alignment and prevents pain due to movement of inflamed tissues.*
- Teach the patient to apply ice and/or heat as prescribed. *Ice causes vasoconstriction and decreases the pooling of blood in the inflamed area. Ice may also numb the tender area. Heat decreases swelling by increasing venous return.*
- Encourage use of NSAIDs as prescribed. *NSAIDs decrease swelling by inhibiting prostaglandins and interrupting the inflammatory process.*
- Explain why treatment should not be abruptly discontinued. *Abrupt discontinuation of treatment may cause reinflammation of the injured area.*

Impaired Physical Mobility

Joint pain and swelling can limit range of motion of the affected joint.

Expected Outcome: Patient will regain previous level of mobility without pain.

- Suggest interventions to alleviate pain (such as using an immobilizer and taking pain medications). *If the joint is pain free, the patient will be more likely to take an active role in therapy.*
- Refer to a physical therapist for exercises. *The physical therapist can assist the patient with exercise to prevent joint stiffness.*
- Suggest consultation with an occupational therapist. *Occupational therapy can help the patient learn new ways to perform tasks to prevent recurring symptoms.*

Continuity of Care

Address the following topics for home care:

- Causes of and treatments for repetitive use injury.
- Rehabilitation to allow the patient to return to a state of independence.
- Ways to avoid unnecessary exposure to the activities that increase risk of redeveloping the injury. Suggest evaluation of the patient's work environment by an environmental risk manager who can prescribe measures to reduce the risk of repetitive use injuries. Wrist supports or an ergonomic keyboard may be useful for the patient who uses a computer extensively. Appropriate desk and chair height also are important in maintaining the correct anatomic position while working.
- Information about sources for braces or other assistive devices.

Traumatic Injuries of Bones

THE PATIENT WITH A FRACTURE

A **fracture** is any break in the continuity of a bone. Fractures vary in severity according to the location and the type of fracture. Although fractures occur in all age groups, they are more common in people who have sustained trauma and in older patients.

Pathophysiology

Any of the 206 bones in the body can be fractured. A fracture occurs when the bone is subjected to more kinetic energy than it can absorb. Fractures may result from a direct blow, a crushing force (compression), a sudden twisting motion (torsion), a severe muscle contraction, or disease that has weakened the bone (called a *stress* or *pathologic fracture*). Two basic mechanisms produce fractures: direct force and indirect force. With direct force, the kinetic energy is applied at or near the site of the fracture. The bone cannot withstand the force. With indirect force, the kinetic energy is transmitted from the point of impact to a site where the bone is weaker. The fracture occurs at the weaker point.

Fractures in adults are classified in the following ways:

- If the skin is intact, the fracture is considered a *closed (simple) fracture*. If the skin integrity is interrupted, the fracture is considered an *open (compound) fracture* (Figure 39–1 ■). An open fracture allows bacteria to enter the injured area and increases the risk of complications.
- *Complete* fractures involve the entire width of the bone (Figure 39–2A ■), whereas *incomplete* fractures involve only a part of the width of the bone (Figure 39–2B).
- The fracture line may be *oblique* (at an angle to the bone; Figure 39–2C) or *spiral* (curves around the bone). An *avulsed* fracture occurs when the fracture pulls bone and other tissues away from the point of attachment. Fractures may also be described as *comminuted* (the bone breaks in many pieces; Figure 39–2D), *compressed* (the bone is crushed), *impacted* (the broken bone ends are forced into each other), or *depressed* (the broken bone is forced inward).
- A *stable* (nondisplaced) fracture is one in which the bones maintain their anatomic alignment. An *unstable* (displaced)

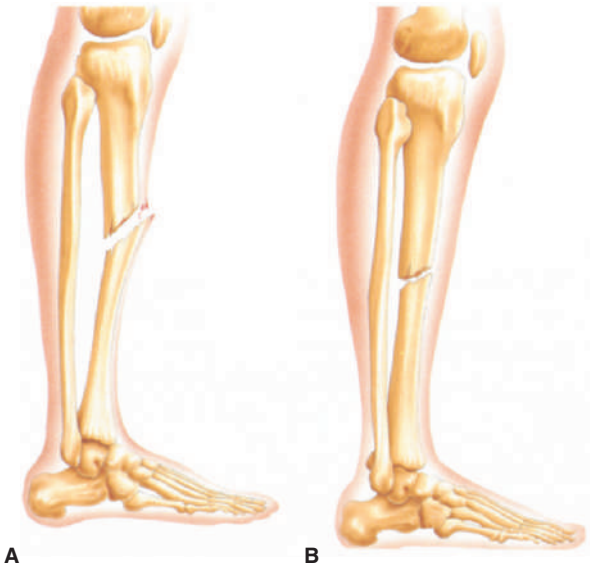

Figure 39–1 ■ A, An open fracture. B, A closed fracture.

fracture occurs when the bones move out of correct anatomic alignment. If a fracture is displaced, immediate interventions are required to prevent further damage to soft tissue, muscle, and bone.

Fractures may also be classified by the affected portion of the bone, such as proximal, midshaft, or distal. The point of reference may also be specific, such as intra-articular or diaphyseal.

Fracture Healing

Fracture healing progresses over four phases: hematoma formation, fibrocartilaginous callus formation, bony callus formation, and remodeling. (See the Pathophysiology Illustrated feature on pages 1242–1243.) When a bone fractures, bleeding and tissue damage at the site of the fracture initiate an inflammatory response. A hematoma forms between the fractured bone ends and around the bone surfaces. The fractured bone surfaces and fragments are deprived of oxygen and nutrients, leading to localized cellular necrosis, which heightens the inflammatory response and release of inflammatory mediators. These chemicals in turn cause vasodilation and edema. Fibroblasts, lymphocytes, and macrophages migrate to the fracture site, and fibroblasts within the hematoma form a fibrin meshwork. Lymphocytes and macrophages wall off the area, localizing and containing the inflammation.

Within 48 hours, fibroblasts and new capillaries growing into the fracture form granulation tissue that gradually replaces the hematoma. Phagocytes remove cell debris. Osteoblasts (bone-forming cells) migrate to the fracture site, where they build a web of collagen fibers from both sides of the fractured bone. Chondroblasts lay down patches of cartilage as a base for bone growth. This fibrocartilaginous callus connects bone fragments, splinting the fracture and maintaining bone alignment. However, it cannot yet support weight bearing.

The third stage of fracture healing, bony callus formation, begins 3 to 4 weeks after the injury and continues for 2 to 3 months. Osteoblasts continue to form collagen fibers and bone matrix, which are gradually mineralized with calcium and mineral salts. Osteoclasts migrate to the repair site to remove damaged and excess bone in the callus. Fibrocartilaginous callus is gradually replaced with spongy

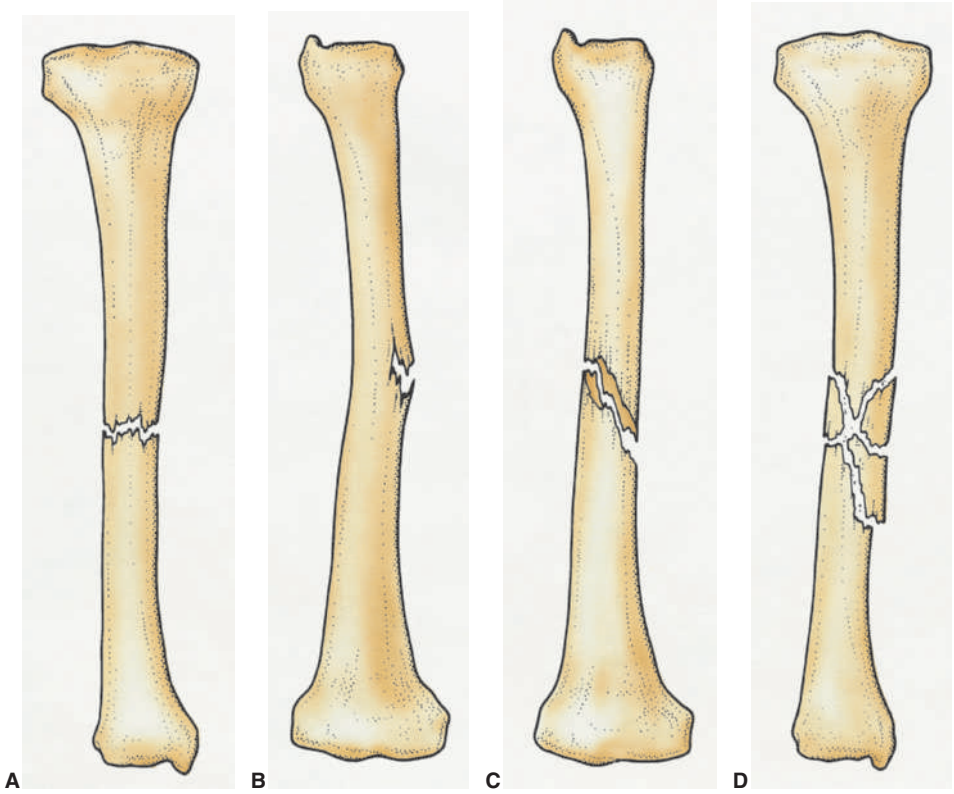

Figure 39–2 ■ Types of fractures. A, A complete fracture. B, An incomplete (greenstick) fracture. C, An oblique fracture. D, A comminuted fracture.

BOX 39–1 Factors Influencing Bone Healing

POSITIVE FACTORS

Local

- Immobilization
- Timely correction of displacement
- Application of ice
- Electrical stimulation

Systemic

- Adequate amounts of growth hormone, vitamin D, and calcium
- Adequate blood supply
- Absence of infection or diseases
- Younger age
- Moderate activity level prior to injury

NEGATIVE FACTORS

Local

- Delay in correction of displacement
- Open fracture (increases risk of infection)
- Presence of foreign body at fracture site

Systemic

- Immunocompromised status
- Decreased circulation (as in diabetes or peripheral vascular disease)
- Malnutrition
- Osteoporosis
- Advanced age

PATHOPHYSIOLOGY LINKAGE

Manifestations of Fractures

Manifestation	Pathophysiology
Deformity	Abnormal position of bones secondary to fracture and muscles pulling on fractured bone
Swelling	Edema from localization of serous fluid and bleeding
Pain/tenderness	Muscle spasm, direct tissue trauma, nerve pressure, movement of fractured bone
Numbness	Nerve damage or nerve entrapment
Guarding	Pain
Crepitus	Grating of bones or entrance of air in an open fracture (*Note:* Do not manipulate the extremity to elicit crepitus; doing so may cause additional damage.)
Hypovolemic shock	Blood loss or associated injuries
Muscle spasms	Muscle contraction near the fracture
Ecchymosis	Extravasation of blood into the subcutaneous tissue

bone. This process progresses from the outer surface of the bone toward the fracture site.

In the final phase of healing, remodeling, excess callus is removed and new bone is laid down along the fracture line. As the bone heals and again is subjected to the mechanical stress of everyday use, osteoblasts and osteoclasts remodel the repair site along the lines of force. Spongy bone is replaced by compact bone, and the remodeled area closely resembles the original, unbroken bone.

The age, physical condition of the patient, and the type of fracture influence healing. Other factors, both local and systemic, also influence bone healing either positively or negatively (Box 39–1). Healing time varies with the individual. An uncomplicated fracture of the arm or foot can heal in 6 to 8 weeks. A fractured vertebra will take at least 12 weeks to heal. Healing of a fractured hip may take from 12 to 16 weeks.

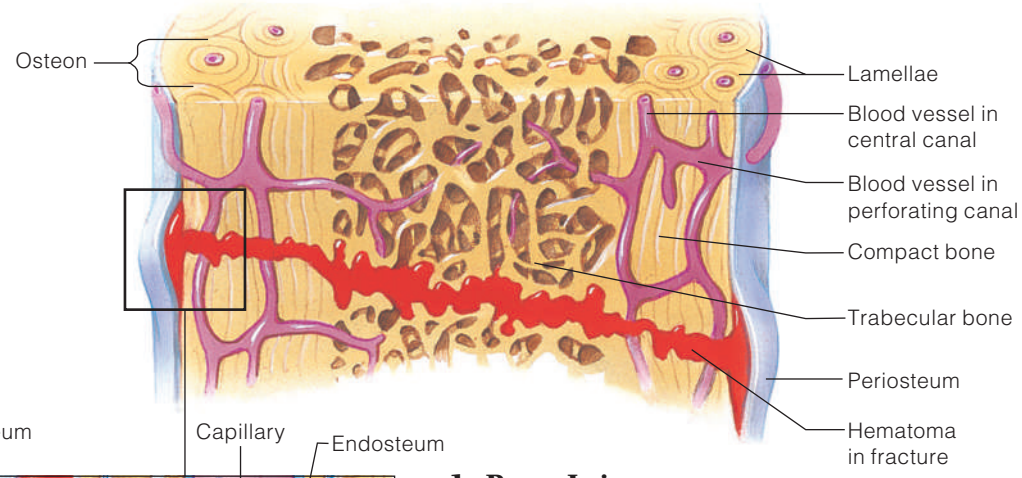
Manifestations

Fractures are often accompanied by soft tissue injuries that involve muscles, arteries, veins, nerves, or skin. The degree of soft tissue involvement depends on the amount of energy or force transmitted to the area. Fracture manifestations and their causes are outlined in the Pathophysiology Linkage box.

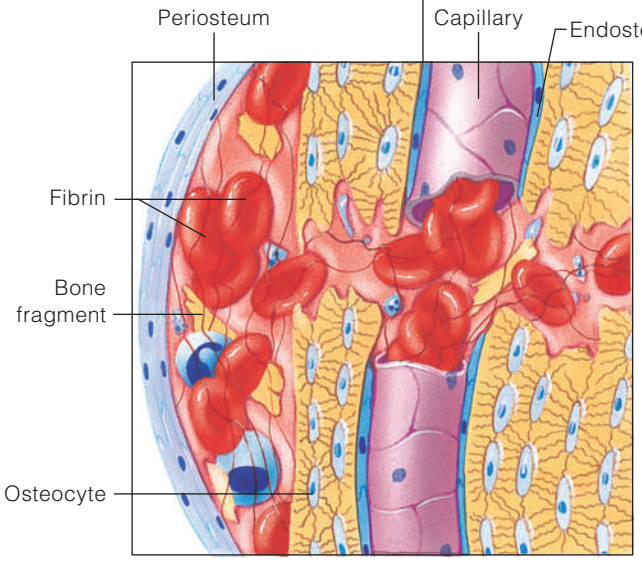
Complications

Complications of musculoskeletal trauma include pressure from edema and hemorrhage, development of fat emboli, deep venous thrombosis, infection, impaired healing, or disruption of neural transmission.

COMPARTMENT SYNDROME



Muscles, nerves, and blood vessels of the extremities are enclosed by a fibrous membrane or fascia. The fascia, which is nonexpansile, supports these tissues. **Compartment syndrome** occurs when increased pressure within this confined space constricts the structures within it, compromising circulation and tissue function. Acute compartment syndrome may result from hemorrhage and edema within the compartment following a fracture, crush injury, or surgery. External compression of the limb by a cast or dressing that constricts the limb also can lead to compartment syndrome.

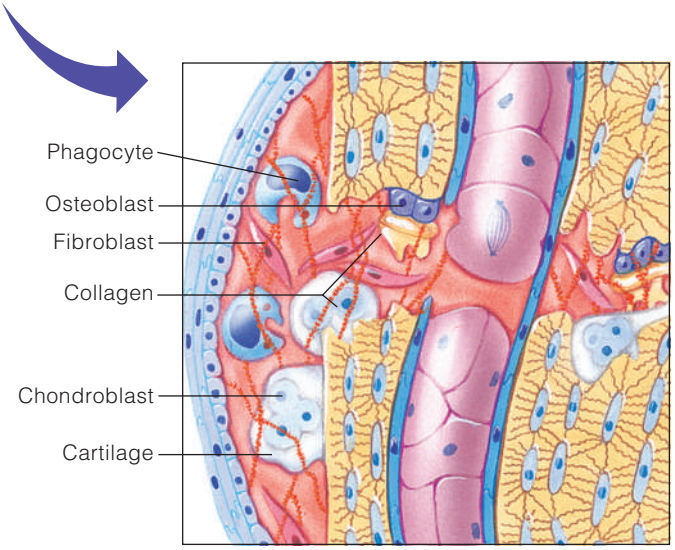


Compression of nerves within the compartment causes severe pain, paresthesias (burning, tingling, or loss of sensation), and diminished reflexes. Entrapment of the blood vessels limits tissue perfusion, beginning a cycle of events that may result in the loss of the limb. Inadequate oxygen supply causes cellular acidosis, which intensifies as cellular energy requirements are met through anaerobic metabolism. The capillaries inside the compartment dilate in an attempt to increase the supply of blood and oxygen. Additional blood and oxygen are not available, and plasma proteins leak out into the interstitial tissues. The interstitial tissue then pulls fluid in to balance the protein load. As a result, edema within the compartment increases. The edema causes further compression of the vascular network, and the cycle continues. Uninterrupted, this cycle threatens the patient's limb and increases the risk of sepsis. Acute kidney injury also is a risk if pressure is unrelieved, because the breakdown of muscle cells releases myoglobin, a protein toxic to the kidney tubules.

Compartment syndrome usually develops within the first 48 hours of injury, when edema is at its peak. Manifestations of compartment syndrome are listed in the box on page 1244. It is important to note that because major arteries are outside muscle compartments, arterial pulses often remain normal, even when pressure within the compartment significantly impairs tissue perfusion. Necrosis of affected muscle can develop within 4 to 8 hours, necessitating timely identification and treatment of the syndrome (Grossman & Porth, 2014).

PATHOPHYSIOLOGY ILLUSTRATED

Bone Healing



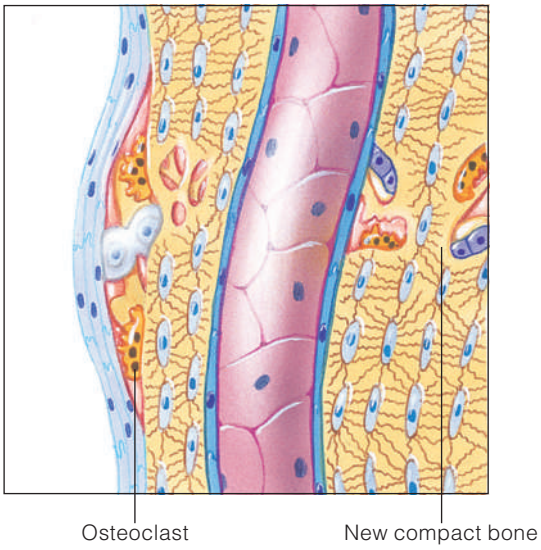
1. Bone Injury

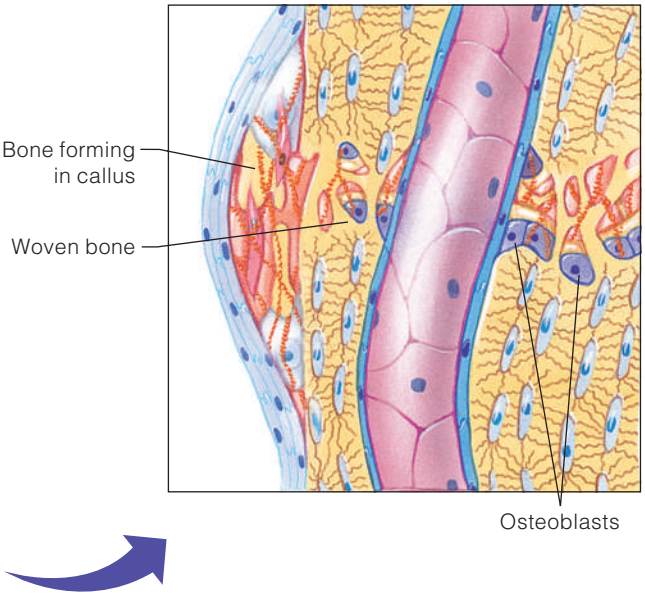
When a bone fractures, blood vessels within the bone and surrounding soft tissues tear and begin to bleed, forming a hematoma. Necrotic bone tissue adjacent to the fracture causes an intense inflammatory response characterized by vasodilation, exudate formation, and white cell migration to the fracture site.

2. Fibrocartilaginous Callus Formation

Clotting factors within the hematoma form a fibrin meshwork. Within 48 hours, fibroblasts and new capillaries growing into the fracture form granulation tissue that gradually replaces the hematoma. Phagocytes begin to remove cell debris.

Osteoblasts, bone-forming cells, proliferate and migrate into the fracture site, forming a fibrocartilaginous callus. The osteoblasts build a web of collagen fibers from both sides of the fracture site that eventually unites to connect bone fragments, thus splinting the bone. Chondroblasts lay down patches of cartilage that provide a base for bone growth.





PATHOPHYSIOLOGY ILLUSTRATED (*continued*)

4. Bone Remodeling

Osteoblasts continue to form new woven bone, which is in turn organized into the lamellar structures of compact bone. Osteoclasts resorb excess callus as it is replaced by mature bone.

As the bone heals and is subjected to the mechanical stress of everyday use, osteoblasts and osteoclasts respond by remodeling the repair site along the lines of force. This ensures that the repaired section of bone eventually resembles the structure of the uninjured part.

3. Bony Callus Formation

Osteoblasts continue to proliferate and synthesize collagen fibers and bone matrix, which are gradually mineralized with calcium and mineral salts to form a spongy mass of woven bone. The trabeculae of woven bone bridge the fracture. Osteoclasts migrate to the repair site and begin removing excess bone in the callus. Bony callus formation usually continues for 2 to 3 months.

MANIFESTATIONS OF COMPARTMENT SYNDROME

EARLY MANIFESTATIONS
- Pain
- Normal or decreased peripheral pulse

LATER MANIFESTATIONS
- Cyanosis
- Tingling, loss of sensation (paresthesias)
- Weakness (paresis)
- Severe pain, especially when the extremity is passively flexed

If compartment syndrome develops, interventions to alleviate pressure are implemented. Restrictive dressings are removed or a tight-fitting cast is split. *Fasciotomy*, surgical incision of the muscle fascia to relieve pressure within the compartment, may be necessary. After a fasciotomy, the incision is left open, leading to a potential infection risk.

Volkmann's contracture, an uncommon complication of elbow or forearm fractures, can result from unresolved compartment syndrome. Arterial blood flow decreases, leading to ischemia, degeneration, and contracture of forearm muscles. The severity of Volkmann's contracture varies from mild, limited to wrist flexors, to severe, affecting both flexor and extensor muscles of the forearm.

FAT EMBOLISM SYNDROME

Fat emboli commonly are released from adipose tissue or bone marrow after long bone fractures. In most cases, these are benign and asymptomatic (Powers & Talbot, 2011). **Fat embolism syndrome (FES)** is a rare complication characterized by neurologic dysfunction, pulmonary insufficiency, and a petechial rash on the chest, axilla, and upper arms (Grossman & Porth, 2014). Long bone fractures and other major trauma are the principal risk factors for fat emboli; hip replacement surgery also poses a risk for FES.

According to the mechanical theory of FES development, increased interstitial pressure at the site of the injury causes fat droplets from damaged adipose tissue and bone marrow to enter the circulation. These fat globules then lodge in small vessels, causing local ischemia and inflammation, with release of inflammatory mediators and vasoactive chemicals. The biochemical theory states that fat globules are released from tissue in response to stress-related catecholamines. Embolized fat is then broken down into free fatty acids, which cause pulmonary tissue inflammation and acute lung injury (Kirkland, 2011; Powers & Talbot, 2011).

Manifestations, the result of vascular occlusion and injury and the inflammatory response, usually develop within a few hours to up to a week after injury. Respiratory manifestations of dyspnea, tachypnea, and hypoxia often are the first indicators of FES. Pulmonary edema, impaired surfactant production, and atelectasis can result in significant respiratory insufficiency and manifestations of acute respiratory distress syndrome. Neurologic symptoms, including restlessness, acute confusion, and altered level of consciousness, follow (Powers & Talbot, 2011). Fat droplets activate the clotting cascade, causing thrombocytopenia. Petechiae (pin-sized purplish spots that do not blanch with pressure) appearing on the skin, soft palate, and conjunctiva are thought to result from either microvascular clotting or the accompanying thrombocytopenia.

Early immobilization of long bone fractures reduces the risk of FES. Surgical stabilization further reduces the risk. Prompt identification and treatment of the syndrome are necessary to maintain adequate pulmonary function. In severe cases, the patient may require intubation and mechanical ventilation to prevent hypoxemia. Fluid balance is closely monitored. Corticosteroids may be administered to decrease the inflammatory response of lung tissues, stabilize lipid membranes, and reduce bronchospasm (Grossman & Porth, 2014).

DEEP VENOUS THROMBOSIS

Deep venous thrombosis (DVT) is a condition in which a blood clot forms along the intimal lining of a large vein, accompanied by inflammation of the vein wall. Risk factors for DVT are (1) venous stasis, or decreased blood flow; (2) injury to blood vessel walls; and (3) altered blood coagulation (Table 39–3). Trauma to the vein stimulates the clotting cascade. Platelets aggregate (clump together) at the site, forming the thrombus. Fibrin, white blood cells (WBCs), and red blood cells (RBCs) begin to cling to the thrombus, and the inflammatory response is initiated. The tail of the clot or the entire thrombus may dislodge and become an embolus, ultimately lodging in the pulmonary circulation (pulmonary embolism). Pulmonary embolism is a leading cause of death in patients who have had hip fracture surgery (Grossman & Porth, 2014). If the thrombus remains in the vein, venous insufficiency may result from scarring and valve damage.

Although DVT often is asymptomatic, it may cause swelling, pain, tenderness, or cramping of the affected extremity. Doppler ultrasonography, a noninvasive diagnostic test that uses sound waves to form an image on a computer screen, commonly is used to identify DVT. In some cases, MRI or a venogram may be required for diagnosis.

The best treatment for DVT is prevention. Early immobilization of the fracture and early ambulation of the patient are imperative. Prophylactic anticoagulation is beneficial. Antiembolism stockings and compression boots increase venous return and prevent venous stasis. See Chapter 32 for more information about preventing venous thromboembolism.

INFECTION

Infection is more likely to occur in an open fracture than a closed fracture, but any complication that decreases blood supply increases the risk of infection. Infection may result from contamination at the time of injury or during surgery. *Pseudomonas*, *Staphylococcus*, or *Clostridium* organisms may invade the wound or bone. *Clostridium* infection is particularly serious because it may lead to severe gas gangrene and cellulitis, but any infection may delay healing and result in osteomyelitis, infection within the bone that can lead to tissue death and necrosis.

TABLE 39–3 Risk Factors for Deep Venous Thrombosis

Risk Factor	Implications for Fractures
Decreased blood flow	Muscle contractions facilitating venous flow may be impaired by immobility or stabilization of the fracture (e.g., with a cast or fixation device).
Injury to blood vessel wall	May occur as a direct result of trauma or from surgical manipulation.
Altered blood coagulation	The body's attempt to maintain homeostasis leads to increased production of platelets and clotting factors.

DELAYED UNION AND NONUNION

Delayed healing can affect any fracture, but it most commonly affects the long bones: the humerus, femur, or tibia. *Delayed union* is the prolonged healing of bones beyond the usual time period. Both injury-related factors (the type and location of fracture and accompanying soft tissue injury) and systemic factors (age, general health, immune status, chronic diseases, and smoking) can affect healing, Delayed union is diagnosed by means of serial x-ray studies. It is important to note that x-ray findings may lag 1 to 2 weeks behind the healing process; for example, a patient may be completely healed by week 13, but this fact may not be apparent on the x-ray until week 14.

Delayed union may lead to nonunion, which can cause persistent pain and movement at the fracture site. Nonunion may require surgical interventions, such as internal fixation and bone grafting. If infection is present, the bones are surgically debrided. Electrical or ultrasonic stimulation of the fracture site may be effective to promote healing. Biologic agents such as growth hormone or parathyroid hormone may be given to stimulate bone growth.

COMPLEX REGIONAL PAIN SYNDROME

Complex regional pain syndrome (CRPS) may occur after musculoskeletal or nerve trauma. It is characterized by intense pain in the affected limb, as well as sensory, autonomic, motor, skin, and bone changes of the extremity (Goebel, 2011). Female gender and older age are risk factors for CRPS. The pain of CRPS is severe, diffuse, and burning. Initially the affected extremity appears inflamed and edematous, later becoming cool and pale. Muscle wasting, skin and nail changes, and bone abnormalities can develop. In CRPS, it appears that pain receptors in the affected extremity become sensitized to catecholamines, neurotransmitters associated with sympathetic nervous system activity. Its cause is unclear; it may be related to central or peripheral nervous system damage, an inflammatory process, disrupted healing, or an autoimmune process. Diagnosis is made by the patient's history and physical examination. X-rays may demonstrate spotty osteoporosis, and bone scans may reveal increased uptake of radionuclide. Treatment requires an interprofessional team approach, including analgesics, nerve blocks, occupational and physical therapy, and psychologic therapies (Montana & Kautz, 2011).

●○● INTERPROFESSIONAL CARE

A fracture requires treatment to stabilize the fractured bone(s), maintain bone alignment, prevent complications, and restore function. The diagnosis of a fracture is primarily based on physical examination and x-rays.

EMERGENCY CARE

Emergency care of the patient with a fracture includes immobilizing the fracture, maintaining tissue perfusion, and preventing infection. In the case of serious trauma, the cervical spine is immobilized and normal body alignment is maintained. Once the patient is in a secure location, he or she is assessed for instability or deformity of the bone. If any deformity or instability is detected, the extremity is immobilized. Open wounds are covered with sterile dressings, and bleeding is controlled with a pressure dressing. The extremities are assessed for the presence and equality of pulses, movement, and sensation. The joint above and below the deformity is immobilized.

The fracture is splinted to maintain normal anatomic alignment and prevent the fracture from dislocating. Splinting relieves pain and prevents further damage to the arteries, nerves, and bones. Pulses, movement, and sensation are reevaluated after splinting.

DIAGNOSIS

Diagnosis of a fracture usually is confirmed by radiographic tests. X-rays and bone scans are used to identify fractures (Figure 39–3 ■). Blood chemistry studies, complete blood count (CBC), and coagulation studies may be used to assess blood loss, renal function, muscle breakdown, and the risk of excessive bleeding or clotting.

MEDICATIONS

Most patients with a fracture initially require analgesia to relieve pain. In the case of multiple fractures or fractures of large bones, opioids are administered initially. NSAIDs are prescribed to decrease

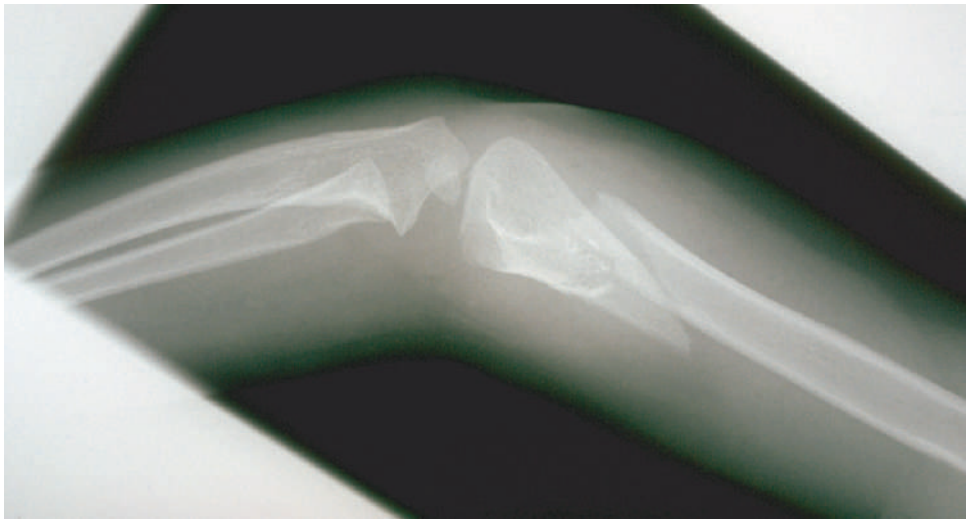


Figure 39–3 ■ X-ray of an oblique fracture of the femur.
Source: Charles Stewart and Associates.

BOX 39–2 Pain Management for the Patient with a Fracture

The patient who has had musculoskeletal trauma experiences pain from many different causes:

- Disruption of the continuity of the bone
- Damage to ligaments and tendons
- Inflammation and swelling of tissues around the trauma site
- Muscle spasms
- Tissue ischemia from swelling inside a cast, splint, or the muscle fascia sheath
- Hematoma formation
- Pressure over bony prominences from casts or splints.

The pain is often severe and may be described as sharp, aching, or burning. Carefully assess any complaint of pain, including the location, character, and duration of pain. Nursing interventions for acute pain due to fracture include the following:

1. Administer prescribed analgesics, including NSAIDs and opioid analgesics. For serious fractures or following orthopedic surgery, patient-controlled analgesia (PCA) or epidural analgesia may be used. Administer NSAIDs and analgesics at regular intervals for the first 24 to 48 hours, then instruct the patient to request or take the medication before the pain is severe. Reassure the patient that addiction does not result from taking medications to relieve fracture or surgical pain. Most patients require only oral analgesics by the third or fourth day after orthopedic surgery.
2. Elevate the involved extremity, and apply cold (if prescribed) to help decrease swelling.
3. Monitor and drain accumulated fluids in any drainage devices to ensure patency, reduce swelling, and decrease the possibility of hematoma formation.
4. Encourage the patient to wiggle fingers or toes on an extremity in a cast or traction to improve venous return and decrease edema.
5. Assist the patient to frequently change positions to relieve pressure and use pillows to provide support.
6. Teach the patient adjunctive pain management techniques, such as relaxation and guided imagery.
7. Notify the physician of severe or unrelieved pain, which may indicate a serious complication such as compartment syndrome or neurovascular impairment.

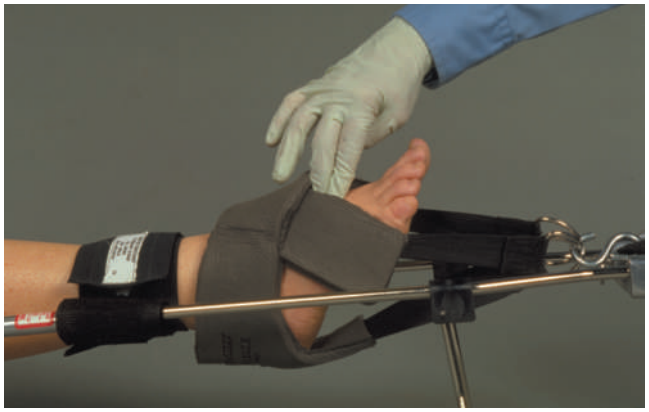
inflammation and supplement analgesia. Pain management for the patient with a fracture is described in Box 39–2.

Antibiotics may be administered prophylactically, particularly to patients with open or complex fractures. Anticoagulants may be prescribed to prevent DVT, particularly if surgery or prolonged immobilization is necessary. Stool softeners may be given to decrease the risk of constipation secondary to narcotics and immobility. Patients who have sustained trauma are often placed on antiulcer medications or antacids to reduce the risk of gastrointestinal bleeding.

TREATMENTS

Before the fractured bone is stabilized for healing, the fracture is *reduced* or restored to its normal alignment. In *closed reduction*, the bone is repositioned using external manipulation. Local or regional anesthesia or conscious sedation usually is given before closed reduction. The fracture is then immobilized with a splint, cast, or traction. An x-ray may be done to verify proper position, and pulses, movement, and sensation are assessed distal to the fracture. An *open reduction* is done in surgery. The bone is exposed and realigned; nails or screws may be used to maintain its position.

TRACTION Muscle spasms usually accompany fractures and may pull bones out of alignment. Traction applies a straightening or pulling force to return or maintain the fractured bones in normal anatomic position. Types of traction are as follows:



- *Manual traction* is applied by physically pulling on the extremity. Manual traction often is used to reduce a fracture or dislocation (Figure 39–4A ■).
- *Skin traction* (*straight traction*) is used to control muscle spasms and to immobilize a part of the body during transport or before surgery, with traction exerting its grabbing and pulling force through the patient's skin (Figure 39–4B). Skin traction is noninvasive and is relatively comfortable for the patient. The most common type of skin traction is Buck's traction, used to immobilize the leg before surgery to repair a hip or proximal femur fracture. Buck's traction uses traction tape or a foam boot applied to the lower leg and attached to a free-hanging weight to immobilize the leg.
- *Balanced suspension traction* involves more than one force of pull to raise and support vthe injured extremity off the bed and maintain its alignment (Figure 39–4C). Balanced suspension traction increases mobility while maintaining bone position. It also makes it easier to change linen and perform back care.
- In *skeletal traction*, the pulling force is applied directly through pins inserted into the bone (Figure 39–4D). Local, spinal, or general anesthetic is provided during pin placement. One or more pulling forces may be applied with skeletal traction. Skeletal traction allows more weight to be used to maintain the proper anatomic alignment. The risk of infection is greater, however, and it may cause more discomfort. The weights used for skeletal traction are not removed by the nurse. Nursing interventions for patients in traction are described in Box 39–3.

CASTS A cast is a rigid device applied to immobilize the injured bones and promote healing. The cast immobilizes the joint above and the joint below the fractured bone so that the bone will not move during healing. A fracture is first reduced manually and a cast is then applied. Casts are applied on patients who have relatively stable fractures.

The cast, which may be composed of plaster or fiberglass, is applied over a thin cushion of padding and molded to the normal contour of the body (Figure 39–5 ■). The cast must be allowed to dry before any pressure is applied to it; simply palpating a wet cast with the fingertips will leave dents that may cause pressure ulcers. A plaster cast may require up to 48 hours to dry, whereas a fiberglass cast dries within an hour. The type of cast applied is determined by the location of the fracture (Figure 39–6 ■). Nursing care of the patient with a cast is discussed in the box on page 1249. During follow-up appointments, the physician may x-ray the bone to assess alignment and healing, and possibly remove the cast for skin assessment.

A

B

C

D

Figure 39–4 ■ Traction is the application of a pulling force to restore or maintain bone alignment for fracture healing. A, Manual traction is applied to restore or maintain alignment during emergency treatment of a fracture. B, Skin traction (also called straight traction), such as is shown here, is often used to temporarily maintain alignment. C, Balanced suspension traction is commonly used for fractures of the femur. D, Skeletal traction, in which the pulling force is applied directly to the bone, may be used to treat fractures of the spine and other bones.

BOX 39–3 Nursing Interventions for Patients in Traction

- Maintain the pulling force and direction of the traction:
  a. In most instances, the patient's weight provides countertraction.
  b. Center the patient on the bed; maintain body alignment with the direction of pull.
  c. Do not wedge the patient's foot or place it flush with the footboard of the bed.
  d. Ensure that weights hang freely and do not touch the floor.
  e. Ensure that nothing is lying on or obstructing the ropes.
  f. Do not allow the knots at the end of the rope to come into contact with the pulley.
- Perform neurovascular assessments frequently.
- Assess for common complications of immobility, including pressure ulcer formation, renal calculi, deep venous thrombosis, pneumonia, paralytic ileus, and loss of appetite.
- If a problem is detected, assist in repositioning. Stabilize the fracture site during repositioning.
- Teach the patient and family about the type and purpose of the traction.
- For skin traction:
  a. Frequently assess skin, bony prominences, and pressure points for evidence of pressure, shearing, or pending breakdown.
  b. Protect pressure sites with padding and protective dressings as indicated.
  c. Remove weights only if intermittent traction has been ordered to alleviate muscle spasm.
- For skeletal traction:
  a. Never remove the weights.
  b. Frequently assess pin insertion sites and provide pin site care per policy.
  c. Report signs of infection at the pin sites, such as redness, drainage, and increased tenderness.

Figure 39–5 ■ Padding to protect the skin is applied under the cast.

SURGERY Surgery is indicated for a fracture that requires direct visualization and repair, a fracture with common long-term complications, or a fracture that is severely comminuted and threatens vascular supply.

The simplest type of surgery is application of an external fixator device. An external fixator consists of a frame connected to pins that are inserted perpendicular to the long axis of the bone (Figure 39–7 ■). The number of pins inserted varies with the type and site of the fracture; in general, the same number of pins is inserted above and below the fracture line. The pins require care similar to that provided for skeletal traction pins. The patient is monitored for infection, and frequent neurovascular assessment is performed. The fixator increases independence while maintaining immobilization.

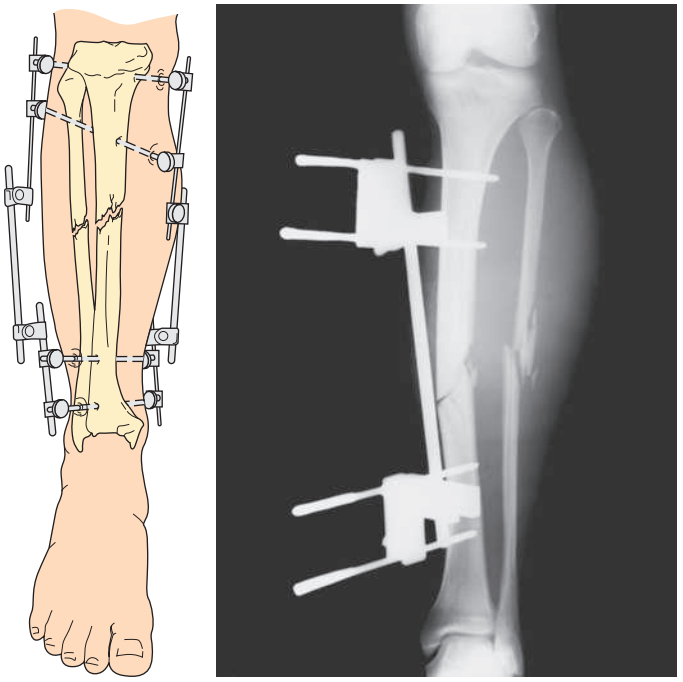


Figure 39–7 ■ In external fixation, pins are placed through the bone above and below the fracture site to immobilize the bone. External fixation rods hold the pins in place.

Internal fixation can be accomplished through a surgical procedure called an *open reduction and internal fixation (ORIF)* or through closed reduction followed by percutaneous intramedullary (IM) fixation. In ORIF, the fracture is reduced (placed in correct anatomic alignment) and nails, screws, plates, or pins are inserted to hold the bones in place (Figure 39–8 ■). Open fractures

Figure 39–6 ■ A short arm cast that also immobilizes the thumb is used to stabilize a wrist fracture.

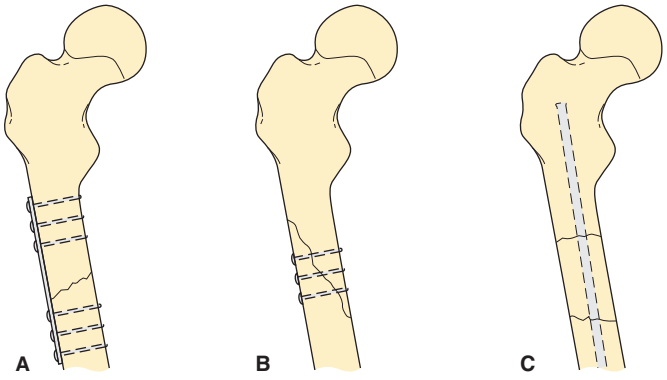

Figure 39–8 ■ Internal fixation hardware is entirely within the body. A, Fixation of a short oblique fracture using a plate and screws above and below the fracture. B, Fixation of a long oblique fracture using screws through the fracture site. C, Fixation of a segmental fracture using a medullary nail.

NURSING CARE OF THE PATIENT

With a Cast

NURSING INTERVENTIONS

- Perform frequent neurovascular assessments.
- Inspect the cast for drainage and palpate for "hot spots" that may indicate the presence of underlying infection.
- Promptly report increased or severe pain, changes in neurovascular status, or a hot spot or drainage on the cast.

HEALTH EDUCATION FOR THE PATIENT AND FAMILY

- The cast dries from the inside out; do not use a blow dryer to speed drying; do not cover the cast while it is drying.
- A sensation of warmth during drying is normal.
- Do not put anything into the cast.
- Keep the cast clean and dry; use plastic wrap as needed to protect it.
- If the cast is made of fiberglass, dry it with a blow dryer on the cool setting if it becomes wet.
- Notify your doctor immediately if you develop increased pain, coolness, changes in color, increased swelling, and/or loss of sensation.
- Use a blow dryer on the cool setting to relieve itching by blowing cool air into the cast.
- A sling may be used to distribute the weight of the cast evenly around the neck. Do not roll the sling; this can impair circulation to the neck.
- If crutches are used, arrange for physical therapist to teach correct crutch walking.
- When the cast is removed, an oscillating cast saw will be used. It is noisy and you will feel its vibration, but a guard prevents it from penetrating past the depth of the cast, so it will not cut the skin.

of the extremities are most commonly repaired in this way. Hip fractures in older patients are frequently repaired with ORIF to prevent complications and to allow early rehabilitation. Prolonged fasting before ORIF is associated with negative outcomes in the older adult; timely scheduling and appropriate preoperative care are important (Björkelund et al., 2011). Interventions for postoperative nursing care are presented in Box 39–4. In percutaneous IM fixation, the intramedullary nail or rod is inserted into the marrow cavity and across the fracture site through a small incision. Because of the small incision required, scarring and the risk for significant blood loss and infection are lower with this procedure. IM fixation allows early resumption of limited weight bearing and use of the extremity, promoting bone healing and minimizing muscle wasting and loss of range of motion (ROM).

ELECTRICAL BONE STIMULATION Electrical bone stimulation is the application of an electrical current at the fracture site. It is a painless method of treating fractures that are not healing appropriately. The electrical stress increases the migration of osteoblasts and osteoclasts to the fracture site. Mineral deposition increases, promoting bone healing. Electrical bone stimulation can be accomplished invasively or noninvasively (Figure 39–9 ■). In invasive stimulation, the surgeon inserts a cathode and a lead wire at the fracture site. The lead wire is attached to an internal or external generator, which delivers electricity to the cathode 24 hours a day. In noninvasive inductive stimulation, a treatment coil encircles the cast or skin directly over the fracture site. The coil is attached to an external generator that runs on batteries. The electricity goes through the skin to the fracture site. The time period for external stimulation can vary from 3 to 10 hours per day. The patient may be taught to self-administer noninvasive electrical stimulation. Electrical bone stimulation is contraindicated in the presence of infection and for upper extremities if the patient has a pacemaker.

Figure 39–9 ■ External electrical bone growth stimulator.
Source: Courtesy of Orthologic, Inc.

BOX 39–4 Nursing Interventions for Patients with Internal Fixation

- Frequently assess type, location, and severity of pain. Report pain that is increasing in severity, unexpected, or unrelieved by prescribed analgesia.
- Perform neurovascular assessments frequently, promptly reporting any change in pulses, color, temperature, capillary refill, movement, or sensation of the affected extremity.
- Assess the following:
  a. Amount, color, odor of drainage on dressing and in wound drain device (e.g., Hemovac, Jackson-Pratt)
  b. Bowel sounds
  c. Lung sounds.
- Administer medications, such as analgesics and antibiotics, per physician's orders.
- Maintain position of affected part or extremity as ordered, using positioning aids as appropriate.
- Arrange for physical and occupational therapy, as ordered.
- Collaborate with physical therapists to promote allowed activity.
- Encourage early mobilization, coughing, and deep breathing, as appropriate to help prevent complications.

Fractures of Specific Bones or Bony Areas

Causes, manifestations, complications, treatment, and selected nursing interventions are described for the following fractures: skull, face, spine, clavicle, humerus, elbow, radius/ulna, wrist/hand, ribs, pelvis, hip, femur, tibia/fibula, and ankle/foot.

FRACTURE OF THE SKULL

A skull fracture may result from either a fall or a direct blow. The patient must be assessed for neurologic changes and any loss of consciousness must be documented. A complete neurologic assessment is conducted: level of consciousness (LOC) and orientation to person, place, and time, pupillary reaction to light, movement and strength of all extremities, and complaints of nausea and vomiting are noted. A displaced skull fracture, which is referred to as *depressed*, may press on the brain and cause neurologic damage.

FRACTURE OF THE FACE

Fracture of the facial bones may result from a direct blow. The patient presents with hematomas, pain, edema, and bony deformity. Nondisplaced fractures are monitored to ensure the airway is not compromised. The patient is observed for any neurologic deficits. Severely displaced or multiple facial fractures are treated with ORIF with wires or plates.

Nursing care focuses on maintaining the airway by helping the patient clear secretions from the oropharynx. The nurse monitors the patient's breathing for increased effort or tachypnea and notifies the physician immediately if these findings are noted. Pain is treated with analgesics, and body image disturbances are addressed. If the patient asks to see his or her face, the nurse should plan to stay with the patient and answer questions while the patient looks in a mirror.

FRACTURE OF THE SPINE

The spine can be injured in many ways, including sports injuries, falls, and motor vehicle crashes. Cervical and lumbar fractures occur most commonly, but the thoracic and sacral spine also can be fractured. The most severe complication of spine fracture is injury to the spinal cord. A displaced or unstable fracture of the vertebrae may apply pressure on the spinal cord. This pressure on the spinal cord may result in ischemia and permanent paralysis.

A nondisplaced cervical spinal fracture may be treated with a cervical collar or a halo immobilizing brace (refer to Figure 39–4). The displaced cervical fracture is reduced by manual or skeletal traction and eventually by the application of a brace and/or surgical stabilization of the bones with plates and screws. Immobilization after a spinal fracture may last as long as 6 months.

FRACTURE OF THE CLAVICLE

A fracture of the clavicle commonly results from a direct blow or a fall. The most common location is midclavicular. An individual with a midclavicular fracture typically assumes a protective slumping position to immobilize the arm and prevent shoulder movement. A less common fracture occurs along the distal third of the clavicle. This type of fracture may be associated with ligament damage. Injuries to the clavicle may be associated with skull or cervical fractures. Displaced clavicular fractures may damage subclavian vessels, leading to hemorrhage, or the lung, with resulting pneumothorax. Injury to the brachial plexus may result in numbness and decreased movement of the arm on the affected side. Malunion of a clavicular fracture can result in asymmetry of the shoulders.

A deformity may be observed or palpated along the clavicle. The fractured bone is immobilized in normal anatomic position by applying a clavicular strap, or via surgical repair.

FRACTURE OF THE HUMERUS

The severity of humerus fractures and appropriate treatment is determined by the location of the fracture, the presence of displacement, and the presence of neurovascular compromise. Treatment focuses on immobilizing the fractured bone in normal anatomic position. Common complications of humeral fracture include nerve and ligament damage, frozen or stiff joints, and malunion. Early interventions may prevent permanent damage.

Fractures of the proximal humerus are common in older adults. A simple nondisplaced fracture of the proximal humerus (near the humeral head) with a normal neurovascular assessment can be safely treated with immobilization. A more complicated displaced fracture of the proximal humerus with bone fragmentation requires surgical intervention. The risk for impaired range of motion (ROM) of the shoulder increases with fracture severity and soft tissue damage. Rehabilitative measures focus on increasing ROM.

The humerus may fracture along the shaft, usually as a result of direct trauma. If the humeral shaft fracture is simple and nondisplaced, a hanging arm cast is applied. This cast maintains alignment of the fracture by using the pulling force of gravity; therefore, the patient is instructed not to rest the cast on anything to alleviate the weight. If the patient is immobilized, external skeletal traction is used to maintain alignment. This traction places the injured arm in an upright position over the face, and weights are hung off the distal portion of the humerus. Nursing interventions for patients with fractures of the humerus are presented in Box 39–5.

FRACTURE OF THE ELBOW

The most common location of an elbow fracture is the distal humerus. Elbow fractures usually result from a fall or direct blow to the elbow. The patient guards the injured extremity, holding the arm rigidly in a flexed position or an extended position. Because the radius, ulna, or humerus may be involved in the elbow fracture, all three bones must be visualized by x-ray.

BOX 39–5 Nursing Interventions for Patients with Fractures of the Humerus

- Perform neurovascular assessments frequently.
- Administer prescribed medications to alleviate pain.
- Encourage exercises for patients with a hanging cast:
  a. Finger exercises: Move each finger of the affected arm through complete range of motion.
  b. Pendulum shoulder exercises: Dangle the affected arm at the side, and move it forward and backward about 30 degrees in each direction.
- Instruct the patient and family in cast care and sling application, neurovascular assessments, exercises, prescribed pain medications, and manifestations of complications.
- If the fracture requires surgical correction, provide preoperative teaching.

Complications of an elbow fracture include nerve or artery damage and hemarthrosis, a collection of blood in the elbow joint. The most serious complication of an elbow fracture is Volkmann's contracture, which results from arterial occlusion and muscle ischemia. The patient complains of forearm pain, impaired sensation, and loss of motor function. Rapid interventions are aimed at relieving pressure on the brachial artery and nerve and preventing muscle atrophy.

Nondisplaced elbow fractures are treated by immobilizing the fracture with a posterior splint or cast. The displaced fracture is first reduced and then immobilized. Nursing interventions focus on alleviating pain, maintaining immobilization, and educating the patient about neurovascular assessments.

FRACTURE OF THE RADIUS AND/OR ULNA

Fractures of the radius and ulna may result from either indirect injury, such as twisting or pulling on the arm, or direct injury, such as that resulting from a fall. The usual treatment of radius fractures depends on the location. The proximal radial head may be fractured from a fall on an outstretched hand. Blood commonly collects in the elbow joint and must be aspirated. If the fracture is nondisplaced, a sling is applied. A displaced fracture is surgically repaired and a posterior plaster splint is applied. The patient avoids movement for the first week and then initiates movement gradually.

When both bones are broken, the fracture is usually displaced. The patient complains of pain and cannot supinate the hand (turn the palm up). A nondisplaced fracture is casted for about 6 weeks, followed by application of a shorter cast or a brace for 6 more weeks. Displaced fractures are surgically repaired with ORIF. After the surgery, a cast is applied, and the patient is encouraged to exercise the fingers.

Complications after a radius and/or ulnar fracture include compartment syndrome, delayed healing, and decreased wrist and finger movement. After surgery, the patient also has an increased risk of infection. Nursing interventions focus on alleviating pain, maintaining immobilization, and educating patients in neurovascular assessments, the importance of elevation, and the need to inform the physician of changes in sensation or an increase in pain.

FRACTURES IN THE WRIST AND/OR HAND

Wrist fractures often result from a fall onto an outstretched hand or onto the back of the hand. A common type of wrist fracture is *Colles' fracture*, in which the distal radius fractures after a fall onto an outstretched hand. The patient with a wrist fracture presents with a bony deformity, pain, numbness, weakness, and decreased ROM of the fingers. The capillary refill and sensation of the hand must be assessed.

The hand is composed of many bones. Most commonly, the metacarpals and phalanges are involved in a hand fracture. The injuring mechanism varies from striking an object with a closed fist to closing a hand in a door. The patient presents with complaints of pain, edema, and decreased ROM.

Comparative x-rays of both the injured and uninjured wrist and hand may be obtained to identify the fracture. Complications of wrist and hand fractures are compartment syndrome, nerve damage, ligament damage, and delayed union. A wrist fracture is commonly treated with closed reduction, cast application, and elevation of the injured extremity. A hand fracture is splinted and elevated.

Nursing interventions focus on alleviating pain and teaching the patient about neurovascular assessments, the importance of elevation, and how to exercise the fingers to prevent stiffness. If the dominant hand is injured, the patient may require assistance in performing daily living activities.

FRACTURE OF THE RIBS

Rib fractures commonly result from blunt chest trauma. The location of the fracture and involvement of underlying organs determine the severity of the injury. Fractures of the first through third ribs may damage the subclavian artery or vein. Fractures of the lower ribs may cause spleen and liver injuries.

The patient typically presents with a history of recent chest trauma and complaints of pain along the lateral portion of the rib. Palpation of the rib reveals a bony deformity and increases pain. Deep inspiration also increases pain. The skin over the fracture site may be ecchymotic (bruised).

Flail chest results from the fracture of two or more adjacent ribs in two or more places and the formation of a free-floating segment that moves in the opposite direction of the rib cage. The bony instability impairs respirations. The flail segment is surgically stabilized and respirations are supported.

Potential complications of rib fractures include pulmonary contusion, pneumothorax, and/or hemothorax. The fractured rib may pierce the lung and injure it. The lower ribs may pierce the liver or spleen, resulting in intra-abdominal bleeding. Pneumonia may also develop from ineffective clearing of respiratory secretions.

A simple rib fracture is treated with pain medication and instructions for coughing, deep breathing, and splinting. The patient is also instructed to return to the emergency department if shortness of breath develops. Nursing interventions focus on alleviating pain and teaching the patient about splinting. Because deep inspiration increases pain, patients frequently avoid it. The patient may be instructed to splint the injured rib with the hand or a pillow and take deep breaths and cough to decrease the chance of developing pneumonia and/or atelectasis. Incentive spirometry is encouraged.

FRACTURE OF THE PELVIS

Pelvic fractures are often caused by trauma, such as a fall or an automobile crash. Pelvic fracture may result from a fall from the standing position in the older adult. Hemorrhage with significant blood loss and damage to organs contained within the pelvis (e.g., the bladder, urethra, reproductive organs, and bowel) are significant risks associated with pelvic fracture. Trauma to extrapelvic organs such as the kidneys is common.

The patient with a pelvic fracture presents with pain in the back or hip area. A single fracture in the pelvis is treated conservatively with analgesia and activity limitation. Logrolling increases patient comfort.

A pelvic sling is used to stabilize unstable pelvic fractures pending surgical reduction and fixation. If necessary, an external fixator may be applied to stabilize the pelvis.

Nursing care focuses on alleviating discomfort, maintaining immobilization, and identifying potential complications. The nurse monitors for increased heart rate, decreased blood pressure, and decreasing hemoglobin levels. Any blood in the urine should be reported to the physician; this may indicate kidney, bladder, or

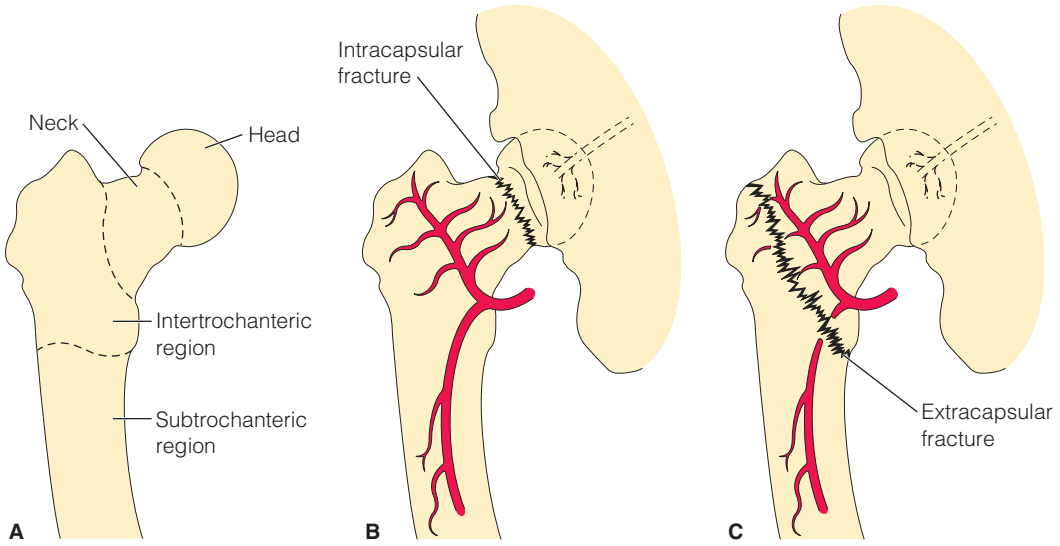

Figure 39–10 ■ A, The head of the femur, the neck of the femur, and the trochanteric regions of the femur. B, Femoral neck fractures are common. Fractures of the femoral neck and head, located within the hip capsule, are classified as intracapsular fractures. C, Intertrochanteric fractures, classified as extracapsular fractures, occur in the intertrochanteric region between the greater and lesser trochanters. Note how both femoral neck fractures and intertrochanteric fractures disrupt the blood supply to the bone.

urethral damage. Urethral catheterization is avoided until bladder and urethral trauma have been ruled out.

FRACTURE OF THE HIP

A hip fracture refers to a fracture of the femur at the head, neck, or trochanteric regions (Figure 39–10 ■). Hip fractures are classified as intracapsular or extracapsular. *Intracapsular fractures* involve the head or neck of the femur; *extracapsular fractures* involve the trochanteric region. The majority of hip fractures involve the neck or trochanteric regions. The femoral head and neck lie within the joint capsule and are not covered in periosteum; thus, they do not have a large blood supply. Fractures at this location usually fragment, further decreasing blood supply and increasing the risk of nonunion and avascular necrosis. The trochanteric region is covered in periosteum and therefore has more blood supply than the head or neck.

Hip fractures result from falls and are the most common injury in the older population, requiring hospitalization of more than 258,000 older adults each year in the United States. They result in serious health problems and increase the risk of dying in people ages 65 years and older. The annual number of hip fractures has remained relatively stable in recent years, even declining among some age groups (Centers for Disease Control and Prevention, [CDC], 2013). Factors contributing to falls include problems with gait and balance, neurologic and musculoskeletal impairments, dementia, psychoactive medications, and visual impairments. Modifiable risk factors, identified through research, include lower body weakness, problems with walking and balance, and taking four or more medications or any psychoactive medications. See the accompanying Moving Evidence into Action box for evidence-based fall prevention for older adults.

Moving Evidence into Action

Preventing Falls in Hospitalized Older Adults

Evidence-based clinical guidelines for specific patient care interventions, such as fall prevention, should be based on research. The recommendations provided by the Hartford Institute for Geriatric Nursing are made based on published research. Falls are identified as a geriatric syndrome with identifiable risk factors and precipitating causes. Assessment for fall risk includes intrinsic factors such as age (particularly over 75 years); chronic conditions (e.g., dementia, arthritis, Parkinson's disease, diabetes, or depression); use of an assistive device; impaired vision, gait, or balance; urge urinary incontinence; and use of high-risk medications. Regular assessment of the patient care environment for factors such as spills, lighting, grab bars, and equipment repair is recommended. Care planning to prevent falls is individualized to identified risks, and involves an integrated, multidisciplinary team.

Implications for Nursing

Although advancing age is a fall risk factor, it is only one of many. Nurses need to evaluate each patient as an individual, assessing and planning care to address those fall risk factors that can be changed. Use of standardized environmental checklists to identify extrinsic risk factors and standardized or empirically tested fall risk tools to evaluate intrinsic risk factors is recommended.

Moving Knowledge into Action

1. Several intrinsic risk factors for falls, including age, medications, and chronic diseases, are identified here. List at least five additional intrinsic risk factors common among older adults for which you should assess.
2. This practice guideline notes that 50% to 75% of residents in long-term care settings experience falls annually. What intrinsic and extrinsic factors contribute to place residents of these facilities at greater risk for falling?
3. Use of physical restraints is identified as a fall risk factor. Identify three alternatives to using physical restraints in a confused older adult.

Source: Data from Gray-Micelli, Quigley, 2012.

FAST FACTS

Hip Fracture in Older Adults

- More than one-third of all adults over age 65 fall each year. Of those, White men have the highest fall-related death rates, followed by White women. Overall, non-Hispanic Whites are more likely to die as a result of a fall than are Hispanics or Blacks.
- Older adults most often fracture the hip from falls; in contrast, motor vehicle crashes are the most common cause in young and middle adults.
- The risk for a fractured hip increases with each decade of life, especially in White postmenopausal women, who have the highest incidence of osteoporosis. Women have about 75% of all hip fractures. Women who smoke are at greater risk, because smoking reduces bone density among menopausal women.
- Complications are related both to the fracture and to the resulting treatment. Only a small number of patients regain their previous mobility, while up to 30% require nursing home care.

Source: Data from CDC (CDC, 2013).

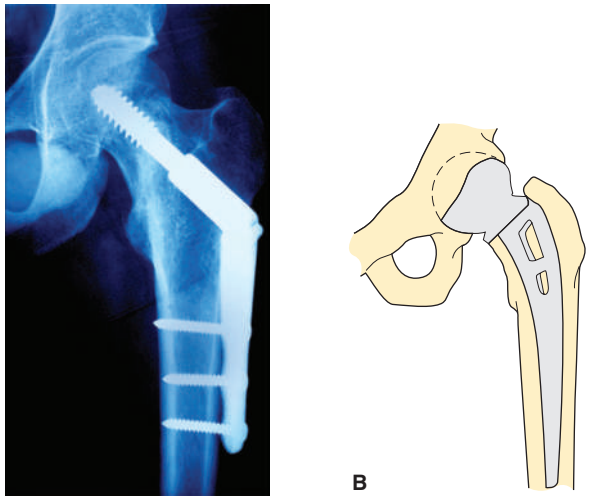

Figure 39–11 ■ Surgical fixation of hip fractures. A, A surgical nail or screw used to stabilize an intertrochanteric fracture. B, Use of a hip prosthesis (artificial hip) to replace a damaged femoral head.
Source: B, BSIP Agency.

Hip fractures are common in older adults as a result of decreases in bone mass and the increased tendency to fall. Whether the femur breaks spontaneously and causes the fall or whether the fall causes the fracture is not always clear; regardless of the cause of the fracture, rapid interventions are required to prevent bone necrosis. Assessment findings commonly associated with a hip fracture are pain, inability to walk, and shortening and external rotation of the affected lower extremity. Rarely, the fracture dislocates posteriorly; if that occurs, the extremity may internally rotate. However, some patients with a hip fracture have only vague pain in the buttocks, knees, thighs, groin, or back, and their ability to walk is unaffected. If the fracture is not visible on x-ray, a bone scan or MRI may be done to confirm the presence of the fracture.

A hip fracture may be initially treated with traction to decrease muscle spasms, followed by surgery; or surgery may be performed immediately or within the first 24 hours. The goal of surgery is to reduce and stabilize the fracture, thereby increasing mobility, decreasing pain, and preventing complications such as pulmonary congestion and thrombophlebitis (Rothrock, 2011). Surgery usually consists of ORIF of the fracture. Fixation is accomplished by securing the femur in place with pins, screws, nails, or plates (Figure 39–11A ■). An ORIF works well for fractures in the trochanteric area. Fractures of the femoral neck frequently disrupt blood supply to the femoral head. If blood supply is disrupted, the surgeon will replace the femoral head with a prosthesis (Figure 39–11B). If the acetabulum has been damaged, the surgeon may insert a metal cup. Replacement of either the femoral head or the acetabulum with a prosthesis is called a *hemiarthroplasty*. Replacement of both the femoral head and the acetabulum is a *total hip arthroplasty (THA)*. See Chapter 40 for more information about nursing care of the patient undergoing arthroplasty or other hip surgery.

Nursing care for a patient with a hip fracture focuses on maintaining skin integrity, preventing infection, alleviating pain, maintaining circulation to the injured extremity, and increasing mobility. This is discussed in more detail in the following nursing care section.

FRACTURE OF THE FEMORAL SHAFT

A large amount of force, such as from motor vehicle crashes, falls, or acts of violence, is required to fracture the shaft of the femur. Patients with femoral shaft fractures often have associated multiple traumas. Pathologic fractures also may occur in the femoral shaft (Rothrock, 2011). A fracture of the femoral shaft is manifested by an edematous, deformed, painful thigh. The patient is unable to move the hip or knee. Initial assessment focuses on the circulation and sensation present in the affected extremity. Pedal pulses and capillary refill in the affected extremity are compared to the unaffected extremity. Complications of a femoral shaft fracture include hypovolemia due to blood loss (which may be as great as 1.0 to 1.5 L), fat embolism, dislocation of the hip or knee, muscle atrophy, and ligament damage.

Treatment of fractures of the shaft of the femur initially includes skeletal traction to separate the bony fragments and reduce and immobilize the fracture, followed by surgical fixation with an intramedullary rod (refer to Figure 39–8C). Although full weight bearing is usually restricted until x-rays demonstrate bone union, partial weight bearing may be encouraged to promote new bone growth (Rothrock, 2011).

The nurse assesses pulses in the extremity and compares them bilaterally. Sensation is evaluated by asking whether the patient can feel touch and discriminate sharp from dull objects. Nursing interventions include providing pain medication, providing reassurance and decreasing anxiety, and assisting with exercises of the lower legs, feet, and toes.

FRACTURE OF THE TIBIA AND/OR FIBULA

Fractures of the lower extremities often result from automobile or motorcycle crashes or sports injuries. The patient presents with edema, pain, bony deformity, and a hematoma at the level of injury.

Circulation and sensation are assessed to rule out common complications of the fracture, including damage to the peroneal nerve or tibial artery, compartment syndrome, hemarthroses, and ligament damage. An inability to point the toe upward on the affected side may indicate peroneal nerve damage. Absence of the dorsalis pedis pulse on the affected side may indicate tibial artery damage. Potential manifestations of compartment syndrome include pain on passive movement and paresthesias. An edematous knee may indicate a collection of blood in the knee joint. Ligament damage may be present if the patient cannot move the knee and/or ankle.

If the fracture is nondisplaced, a closed reduction and casting are frequently performed. A long leg cast or splint that allows for partial weight bearing is used. Partial weight bearing usually is allowed within 10 days of the fracture. After 3 to 4 weeks, the cast is replaced with a functional brace that provides continued support and protection. External fixation or ORIF using an intermedullary rod is used to treat more complex fractures. After surgery, a cast may be applied, and weight bearing begins according to the physician's orders, usually in about 6 weeks.

Nursing care is designed to increase comfort, monitor neurovascular status, and prevent complications. The nurse instructs the patient in cast care, on the use of assistive devices, how to perform neurovascular assessment, and when to follow up with the physician.

FRACTURE IN THE ANKLE AND/OR FOOT

The patient with an ankle fracture presents with pain, limited ROM, hematoma, edema, and difficulty ambulating. Nondisplaced ankle fractures are often treated by closed reduction and casting. Multiple or displaced fractures are treated by surgical intervention and splinting.

The patient with a foot fracture presents with similar symptoms; however, ROM of the ankle is not usually affected. Most foot fractures are nondisplaced and treated with closed reduction and casting. More severe displaced foot fractures may require surgery and the placement of wires to maintain reduction of the fracture.

Nursing care focuses on increasing comfort, increasing mobility, and educating the patient. Analgesia is given for pain. The extremity should be elevated, and ice can be applied. The patient is taught cast or splint care, neurovascular assessment, and crutch walking.

●○● NURSING CARE

In planning and implementing nursing care for the patient with fractures, the nurse should consider the patient's physical and psychologic responses to the traumatic experience, as well as teaching needs to promote self-care.

Health Promotion

Trauma prevention can save lives. Trauma is the leading cause of death among adults under the age of 45 years (National Center for Health Statistics, 2012). Young adults face a high risk of sustaining trauma. They need to be taught the importance of safety equipment—such as automobile seat belts, bicycle and motorized vehicle helmets, football pads, proper footwear, protective eyewear, and hard hats—in preventing or decreasing the severity of injury from trauma. Older adults should have regular screenings for osteoporosis (with a bone density test), activity levels, cognitive and affective disorders, vision impairments, and risk for falls. Older adults can reduce their risk of falling by increasing lower body strength and balance through regular physical activity, and by asking their healthcare provider or pharmacist to review their medications. Educational programs about workplace and farm safety, including information about ergonomic principles, can also help prevent musculoskeletal injuries.

Exercising regularly and avoiding obesity are important factors in maintaining good bone health in all adults. An adequate intake of calcium is essential to ensure proper growth, development, and maintenance of strong bones throughout life. It is important that women ensure good bone health prior to menopause, because the loss of estrogen during and after menopause decreases calcium use and increases the risk of osteoporosis. Strong bones are formed by calcium intake and weight-bearing exercise, both of which are equally important in the postmenopausal woman.

Older patients are at higher risk for musculoskeletal trauma due to falls. For these patients, home assessments must be performed and potential hazards corrected. Specific teaching topics for preventing falls in older adults are outlined in the accompanying Meeting Individualized Needs box.

Assessment

Collect the following data through the health history and physical examination:

- *Health history:* age, history of traumatic event, history of prior musculoskeletal injuries, chronic illnesses, medications (ask the older adult specifically about anticoagulants and calcium supplements).
- *Physical assessment:* pain with movement, pulses, edema, skin color and temperature, deformity, range of motion, touch. The five Ps of neurovascular assessment, as follows, are included in both the initial assessment and ongoing focused assessments:
  - *Pain.* Assess pain in the injured extremity by asking the patient to grade it on a scale of 0 to 10, with 10 as the most severe pain.

Meeting Individualized Needs

Teaching Older Adults to Prevent Falls

- Begin a regular exercise program; lack of exercise leads to weakness and an increased chance of falling. Exercises that improve balance and coordination (such as yoga or tai chi) are the most helpful.
- Make your home safer:
  - Remove any items in your pathway, including from stairs, to avoid tripping.
  - Remove small throw rugs or use double-sided tape to keep rugs from slipping.
  - Place frequently used items within easy reach to avoid use of a step stool.
  - Install grab bars next to your toilet and in the tub or shower.
  - Use nonslip mats in the bathtub and on shower floors.
  - Improve lighting, using lamp shades or frosted bulbs to reduce glare. Install nightlights in hallways and bathroom.
  - Install handrails and lights in all staircases.
  - Wear shoes that give good support and have thin, nonslip soles. Avoid wearing slippers and athletic shoes with deep treads.
- Ask your healthcare provider to review your medications, including prescriptions and over-the-counter medications. Some medications or a combination of medications may cause dizziness or drowsiness, leading to falls.
- Have your vision checked by an eye doctor. Your glasses may no longer have the correct prescription, or you may have developed an eye condition such as cataracts or glaucoma that limits your vision.

- *Pulses.* Assess distal pulses beginning with the unaffected extremity. Compare the quality of pulses in the affected extremity to those of the unaffected extremity.
- *Pallor.* Observe for pallor and skin color in the injured extremity. Paleness and coolness may indicate arterial compromise, whereas warmth and a bluish tinge may indicate venous blood pooling. Assess capillary refill, comparing the affected and unaffected extremities.
- *Paralysis/paresis.* Assess ability to move body parts distal to the fracture site. Inability to move indicates paralysis. Loss of muscle strength (weakness) when moving is paresis. A finding of limited ROM may lead to early recognition of problems such as nerve damage and paralysis.
- *Paresthesia.* Ask the patient to identify any changes in sensation such as burning, numbness, prickly feeling, or stinging. Assess sensation distal to the injury, including ability to discriminate sharp and dull touch and two-point discrimination.

Priorities of Care

Nursing care priorities for the patient with a fracture focus on associated acute pain, impaired physical mobility, and the risks for impaired tissue perfusion and neurovascular compromise.

Diagnoses, Outcomes, and Interventions

Nursing care for patients with fractures ranges from teaching for home care following treatment in the emergency or urgent care department to providing interventions to maintain health and decrease the risk of complications in patients with complex or multiple fractures. Teaching is also necessary for caregivers of a patient who is discharged home or to a long-term care or rehabilitation facility following a fracture. See the accompanying Case Study & Nursing Care Plan for a patient with hip fracture on page 1256.

Acute Pain

Pain is caused by soft tissue damage and is compounded by muscle spasms and swelling.

Expected Outcome: Patient will report pain within acceptable range on a standardized pain scale.

- Monitor vital signs. *Some analgesics decrease respiratory effort and blood pressure.*
- Ask the patient to rate the pain on a scale of 0 to 10 (with 10 as the most severe pain) before and after any intervention. *This facilitates objective assessment of the effectiveness of the chosen pain relief strategy. Pain that increases in intensity or remains unrelieved with analgesics can indicate compartment syndrome.*
- For the patient with a hip fracture, apply Buck's traction per physician's orders. Keep the traction weights hanging freely. *Buck's traction immobilizes the fracture and decreases pain and additional trauma.*
- Move the patient gently and slowly. Support a fractured extremity above and below the fracture when moving. *Gentle moving and support of the injured extremity help prevent the development of severe muscle spasms.*
- Elevate the injured extremity above the level of the heart. *Elevating the extremity promotes venous return and decreases edema, which decreases pain.*

Evidence for Nursing Care

The Patient with Fracture

Selected resources that nurses may find helpful when planning evidence-based nursing care follow.

- Björkelund, K., Hommel, A., Thorngren, K., Lundberg, D., & Larsson, S. (2011). The influence of perioperative care and treatment on the 4-month outcome in elderly patients with hip fracture. *AANA Journal, 79*(1), 51–61.
- Degelau, J., Belz, M., Bungum, L., Flavin, P. L., Harper, C., Leys, K., . . . Webb, B. (2012, April). *Health care protocol: Prevention of falls (acute care).* Bloomington, MN: Institute for Clinical Systems Improvement.
- U.S. Preventive Services Task Force. (2012). Prevention of falls in community-dwelling older adults: U.S. Preventive Services Task Force recommendation statement. *Annals of Internal Medicine, 157*(3), 197–204.

- Encourage distraction or other adjunctive methods of pain relief, such as deep breathing and relaxation. *Distraction, deep breathing, and relaxation help decrease the focus on the pain and may lessen the intensity of pain.*
- Administer NSAIDs and pain medications as prescribed. For home care, explain the importance of taking pain medications before the pain becomes severe. *Analgesics alleviate pain by stimulating opiate receptor sites. NSAIDs mediate inflammation and provide an analgesic effect.*

Risk for Peripheral Neurovascular Dysfunction

In the patient with a fracture, compartment syndrome or deep venous thrombosis can impair circulation and, in turn, tissue perfusion. Furthermore, peripheral nerves may be damaged as a result of the initial trauma, during movement of the affected extremity, or as a consequence of compartment syndrome.

Expected Outcome: Peripheral circulation and neurologic function will remain within expected parameters.

- Support the injured extremity above and below the fracture site when moving the patient. *Supporting the injured extremity above and below the fracture site helps prevent displacement of bony fragments and decreases the risk of further nerve damage.*
- Assess the five Ps every 1 to 2 hours. Report abnormal findings immediately. *Unrelenting pain, pallor, paresthesias, and paresis are strong indicators of compartment syndrome.*

PRACTICE ALERT!

Pulses may remain strong while capillary circulation within the affected extremity is severely impaired in compartment syndrome.

- Assess nail beds for capillary refill. If nails are too thick or discolored, assess the skin around the nail. *Delayed capillary refill may indicate decreased tissue perfusion.*
- Monitor the extremity for edema and swelling. *Excessive swelling and hematoma formation can compromise circulation.*
- Assess for deep, throbbing, unrelenting pain. *Pain that is not relieved by analgesics may indicate neurovascular compromise.*

CASE STUDY & NURSING CARE PLAN A Patient with a Hip Fracture

Stella Carbolito is a 74-year-old Italian American with a history of osteoporosis. She lives alone in a two-story row home. Mrs. Carbolito is retired and takes pride in making all her own food from scratch. While walking to the market one day, Mrs. Carbolito falls and fractures her left hip. She is transported by ambulance to the nearest emergency department.

ASSESSMENT

During the initial assessment, abnormal findings are that Mrs. Carbolito's left leg is shorter than her right leg and is externally rotated. Distal pulses are present and bilaterally strong; both legs are warm. Mrs. Carbolito complains of severe pain but denies any numbness or burning. She is able to wiggle the toes on her left leg and has full movement of her right leg. Initial vital signs are as follows: T 36.6°C (98.0°F), P 100 bpm, R 18/min, BP 120/58 mmHg. Diagnostic tests include CBC, blood chemistry, and x-ray studies of the left hip and pelvis. The CBC reveals a hemoglobin of 11.0 g/dL and a normal WBC count. Blood chemistry findings are within normal limits. The x-ray reveals a fracture of the left femoral neck. Mrs. Carbolito is admitted to the hospital with an order for 10 lb of straight leg traction. An open reduction and internal fixation (ORIF) is planned for the following day.

DIAGNOSES

- *Acute Pain* related to fractured left femoral neck and muscle spasms
- *Impaired Physical Mobility* related to bed rest and fractured left femoral neck
- *Risk for Peripheral Neurovascular Dysfunction* related to unstable bones and swelling

EXPECTED OUTCOMES

- Patient will verbalize a decrease in pain.
- Patient will verbalize the purpose of traction and surgery.
- Patient will maintain normal neurovascular status.
- Patient will demonstrate postoperative exercises.

PLANNING AND IMPLEMENTATION

- Assess pain on a scale of 0 to 10 before and after implementing measures to reduce pain.
- Administer analgesics per the physician's order.
- Perform neurovascular assessment every 2 to 4 hours, and document findings.
- Apply straight leg traction per physician's order.
- Teach the purpose of traction and surgery.
- Teach the purpose of and the procedure for performing isometric and flexion/extension exercises.

EVALUATION

On the day after surgery, Mrs. Carbolito is out of bed and in a chair. She verbalizes a decrease in pain. There have been no abnormal neurovascular assessments. She is able to independently perform isometric and flexion/extension exercises in both lower extremities. Discharge planning includes referrals for home care. A home health nurse will visit, and the social worker at the hospital has ordered a trapeze for her bed, an elevated toilet seat, an elevated cushion for her chair, and a walker.

Clinical Reasoning in Patient Care

1. What factors placed Mrs. Carbolito at risk for a hip fracture?
2. Mrs. Carbolito says, "I don't understand why they had to put that heavy thing on my leg before I went to surgery to get my hip fixed." What would you tell her? What preoperative factors might have decreased teaching effectiveness?
3. Describe how each of the following, if manifested by Mrs. Carbolito, would increase her risk for postoperative complications: urinary incontinence, weight more than 20% under normal for her height, chronic constipation. What nursing diagnoses and interventions would you include in her plan of care to decrease the risk?

See Evaluating Your Response in Appendix B.

- Assess the ability to differentiate between sharp and dull touch and the presence of paresthesias and paralysis every 1 to 2 hours. *Paresthesias develop as a result of pressure on nerves and may indicate compartment syndrome. Paralysis is a late sign of nerve entrapment and requires that the physician be notified immediately.*
- Monitor the tightness of the cast. *Edema can cause the cast to become tight; a tight-fitting cast may lead to compartment syndrome or paralysis.*
- If the cast is tight, be prepared to assist the physician with bivalving (Figure 39–12 ■). *Bivalving, the process of splitting a cast down both sides, alleviates pressure on an injured extremity.*
- If compartment syndrome is suspected, assist the physician in measuring compartment pressure. Normal compartment pressure is 0 to 8 mmHg. *Compartment pressure greater than 30 mmHg indicates compartment syndrome and circulatory compromise* (Grossman & Porth, 2014).
- Unless contraindicated, elevate the injured extremity above the level of the heart. *Elevating the extremity increases venous return and decreases edema. It may be contraindicated, however, if compartment syndrome develops, because elevation may further reduce arterial flow to the extremity.*
- Administer anticoagulant per physician's order. *Prophylactic anticoagulation decreases the risk of clot formation.*

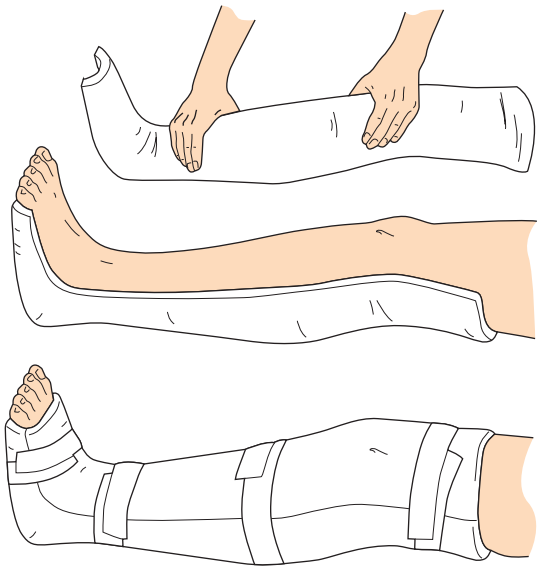

Figure 39–12 ■ Bivalving is the process of splitting a cast down both sides to alleviate pressure on or allow visualization of an extremity.

Risk for Infection

An open fracture carries significant risk for wound contamination and subsequent infection. Wound healing in orthopedic patients is affected by the cause of the wound as well as the therapies used to repair musculoskeletal structures. It is important to understand normal wound healing processes, characteristics of musculoskeletal wounds, contamination, and drainage, and potential complications to plan for and implement appropriate interventions.

Expected Outcome: Patient will remain free of infection until healing is complete.

- For patients with skeletal pins, follow established guidelines for skeletal pin site care. *Pins or wires attached to traction, casts, or external fixators stabilize a segment of bone so optimal healing can occur.*
- Monitor vital signs and lab reports of WBCs. *Increases in pulse rate, respiratory rate, temperature, and WBCs may indicate infection.*
- Use sterile technique for dressing changes. *Aseptic technique is necessary to avoid introducing organisms into the operative site.*
- Assess the wound for size, color, and the presence of any drainage. *Redness, swelling, and purulent drainage indicate infection.*
- Administer antibiotics per physician's orders. *Prophylactic antibiotic administration inhibits bacterial reproduction and thereby helps prevent skin flora from entering the wound. In the case of "dirty wounds," such as those occurring from vehicular crashes, antibiotics are routinely administered.*

Impaired Physical Mobility

The patient who has experienced a fracture requires immobilization of the fractured bone(s). Immobilization alters normal gait and mobility. The patient will need to use assistive devices such as crutches, canes, slings, or walkers.

Expected Outcome: Patient will remain free of injury or adverse effects of reduced mobility.

- Teach or assist patient with ROM exercises of the unaffected limbs. *ROM exercises help prevent muscle atrophy and maintain strength and joint function. Flexion and extension exercises prevent the development of foot drop, wrist drop, or frozen joints.*
- Teach isometric exercises, and encourage the patient to perform them every 4 hours. *Isometric exercises help prevent muscle atrophy and force synovial fluid and nutrients into the cartilage.*
- Encourage ambulation when able; provide assistance as necessary. *Ambulation maintains and improves circulation, helps prevent muscle atrophy, and helps maintain bowel function.*

SAFETY ALERT

Teach and observe the patient's use of assistive devices (such as canes, crutches, walkers, slings) in conjunction with the physical therapist. Proper use of devices is necessary for safe ambulation and helps prevent the loss of joint function secondary to complications and falls.

- Turn the patient on bed rest every 2 hours. If the patient is in traction, teach the patient to shift his or her weight every hour. *Turning and shifting weight increase circulation and help prevent skin breakdown.*

Continuity of Care

Patient and family teaching focuses on individualized needs. The type of fracture and its location and treatment determine how much teaching the patient and family will require. For example, a patient who has a simple nondisplaced tibial fracture may need to be taught only cast care and crutch walking. An older patient who has sustained a hip fracture and requires surgical intervention, by contrast, has a wider array of teaching needs, including activity and positioning, proper bending, and proper sitting. Address the following topics for home care of the patient who has fractured a hip:

- Encourage independence in ADLs:
  - Explain that the patient should sit only on high chairs to prevent excess flexion of the hip; an elevated toilet seat can be added to a regular toilet seat.
  - Encourage the patient and family to equip the shower with a hand rail to aid stability and prevent falls.
  - If a walker is needed, teach the patient its proper use: Do not carry the walker, but lift it, advance it, and then take two steps, or use a rolling walker.
  - If a cane is needed, instruct the patient to use it on the affected side.
- Stress the importance of well-balanced meals, and explain all prescribed medications.

Patients who have experienced a fracture or who have had orthopedic surgery often have a cast and may require an extended period of limited activities. Address the following topics for home care:

- Do not scratch under a cast with a sharp object; use a blow dryer on the cool setting to relieve itching.
- Do not get a plaster cast wet.
- Follow the physician's order for weight bearing.
- Physical therapy departments or offices often can evaluate the home environment for safety and suggest modifications as needed. Physical therapists also teach crutch walking, limited weight bearing, transferring, and other activities.
- Home care agencies can teach wound care and provide ongoing monitoring of wound healing.
- Local medical equipment and supply sources rent or sell durable equipment such as crutches, walkers, wheelchairs, overhead trapeze units, shower chairs, elevated toilet seats, grab bars, and bedside commodes. Slings or braces may be purchased through medical equipment dealers.
- Local pharmacies are good resources for dressing supplies such as antiseptic solutions or ointments, dressings, and tape.
- Fitness equipment suppliers may be able to provide rehabilitation equipment such as hand or ankle weights for strengthening exercises.

THE PATIENT WITH AN AMPUTATION

An **amputation** is the partial or total removal of an extremity. Amputation may be the result of a traumatic event or a chronic condition such as peripheral vascular disease or diabetes mellitus. Regardless of the cause, an amputation is devastating to the patient.

FAST FACTS

Amputation

- It is estimated that 2 million people with amputations live in the United States, and that 134,000 new amputations occur each year.
- In the United States, the most common cause of lower extremity amputations is vascular disease (82%). Men and Blacks have the greatest risk of undergoing lower extremity amputation due to vascular disease.
- Trauma is the second leading cause of amputation in the United States, most of which are upper extremity amputations. Men have a significantly higher risk of traumatic amputation than women.
- Injuries experienced during military service have resulted in more than 1,200 young adults who have lost a major limb and nearly 400 with loss of a hand, foot, fingers, or toes.
- Cancer-related amputations affect men and women equally; cancer-related lower extremity amputations are more common than are upper extremity amputations.

Source: Data from Amputee Coalition, 2014 and Fischer, 2010.

The loss of all or part of an extremity has a significant physical and psychosocial effect on the patient and family. Adaptation may take a long time and require much effort. Interprofessional healthcare is always important, but is especially necessary to meet the patient's physical, socioeconomic, spiritual, cultural, and emotional needs after an unexpected or planned amputation.

Causes of Amputation

Peripheral vascular disease (PVD) is the major cause of amputation of the lower extremities. Common risk factors for the development of PVD include hypertension, diabetes, smoking, and hyperlipidemia. Peripheral neuropathy also places the person with diabetes at risk for amputation. In peripheral neuropathy, loss of sensation frequently leads to unrecognized injury and infection. Untreated infection may lead to gangrene and the need for amputation.

The incidence of traumatic amputations is highest among young men. Most amputations in this group result from motor vehicle crashes or accidents involving machinery at work. Combat-related trauma also accounts for a significant number of traumatic amputations in young adults. The patient presents to the trauma center with an injury that may be life threatening; significant loss of blood and tissue may have already occurred, and shock may develop. Other traumatic events that may necessitate an amputation are frostbite, burns, or electrocution.

Amputations result from or are necessitated by interruption in blood flow, either acute or chronic. In acute trauma situations, the limb is partially or completely severed, and tissue death ensues. However, replantation of fingers, small body parts, and entire limbs has been successful. In chronic disease processes, circulation is impaired, venous pooling begins, proteins leak into the interstitium, and edema develops. Edema increases the risk of injury and further decreases circulation. Stasis ulcers develop and readily become infected because impaired healing and altered immune processes allow bacteria to proliferate. The presence of progressive infection further compromises circulation and ultimately leads to gangrene (tissue death), which requires amputation.

Levels of Amputation

The level of amputation is determined by local and systemic factors. Local factors include ischemia and gangrene; systemic factors include cardiovascular status, renal function, and severity of diabetes mellitus. The goals are to alleviate symptoms, to maintain healthy tissue, and to increase functional outcome. When possible, the joints are preserved because they allow greater function of the extremity. Figure 39–13 ■ illustrates common sites of amputation.

Types of Amputation

Amputations may be open (*guillotine*) or closed (*flap*). Open amputations are performed when infection is present. The wound is not closed but remains open to drain. When infection is no longer present, surgery is performed to close the wound. In closed amputations, the wound is closed with a flap of skin that is sutured in place over the stump. Terms used to refer to amputations are defined in Table 39–4.

Amputation Site Healing

For the prosthesis to fit well, the amputation site must heal properly. To promote healing, a compression dressing is applied to prevent infection and minimize edema. A soft compression dressing is applied when frequent wound checks are necessary. When this type of dressing is used, a splint is sometimes applied to help mold the extremity to fit the prosthesis. After the wound is dressed, the patient is encouraged to toughen the stump skin by pushing it into first soft and then harder surfaces. The stump is wrapped in an Ace bandage to allow a conical shape to form and to prevent edema. The bandage is applied from the distal to the proximal extremity (Figure 39–14 ■). A commercial "stump shrinker" sheath may be used as well.

Complications

Complications that may occur after an amputation include infection, delayed healing, chronic stump pain and phantom pain, and contractures.

TABLE 39–4 Amputation Terms

Term	Meaning
Arm	Amputation of a portion of the arm, either above or below the elbow
Disarticulation	Amputation through a joint
Forequarter	Removal of the entire arm and disarticulation of the shoulder
Closed (flap)	Amputation in which a flap of skin is formed to cover the end of the wound
Open (guillotine)	Perpendicular cutting of the extremity in which the wound is left open; used when infection is present
Leg	Amputation below the knee (BK)
Thigh	Amputation above the knee (AK)
Finger or toe	Amputation of one or all of the fingers or toes
Syme	Modified disarticulation of the ankle
Foot	Amputation of part of the foot and toes

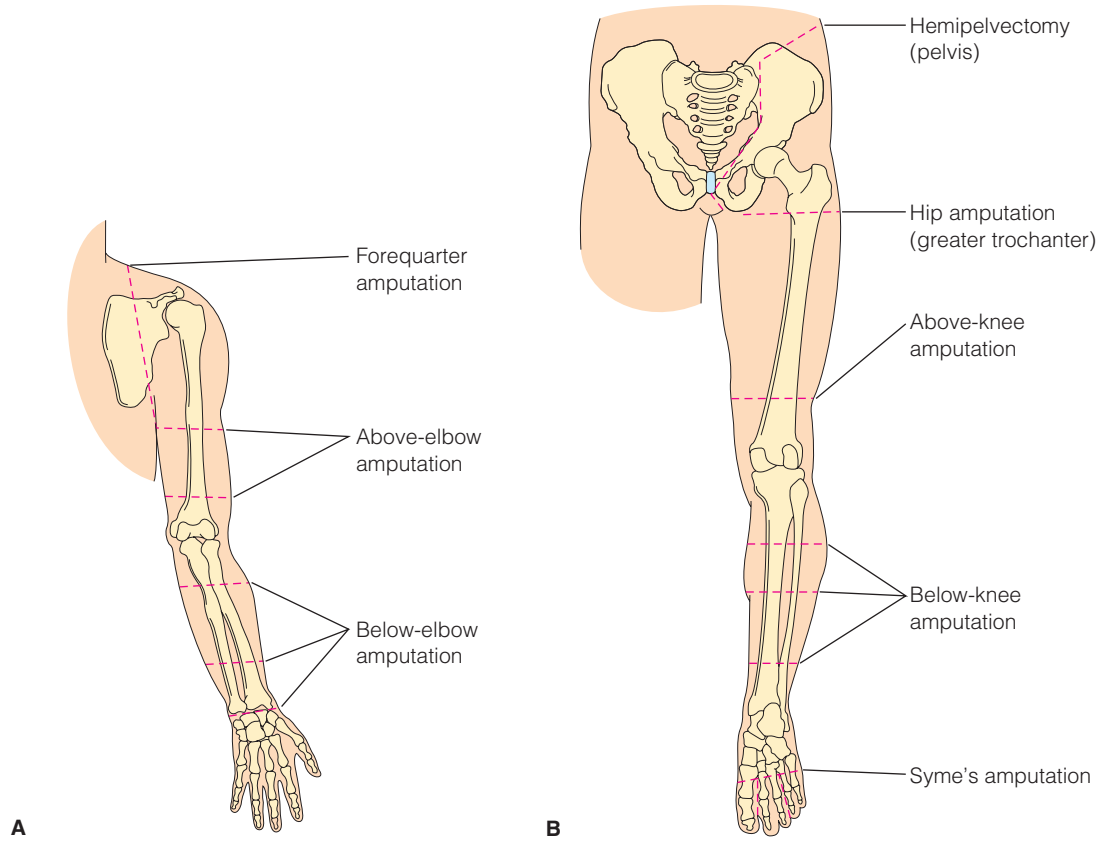

Figure 39–13 ■ Common sites of amputation. A, The upper extremities. B, The lower extremities. The surgeon determines the level of amputation based on blood supply and tissue condition.

INFECTION

Generally, the patient who experiences a traumatic amputation has a greater risk of infection than the person who has a planned amputation. However, even planned amputations carry a risk of infection. The patient who is older, has diabetes mellitus, or suffers peripheral neurovascular compromise is at a particularly high risk for infection. Infection may present itself locally or systemically. Local manifestations of infection include drainage, odor, redness, and increased discomfort at the suture line. Systemic manifestations include fever, an increased heart rate, a decrease in blood pressure, chills, and positive wound or blood cultures.

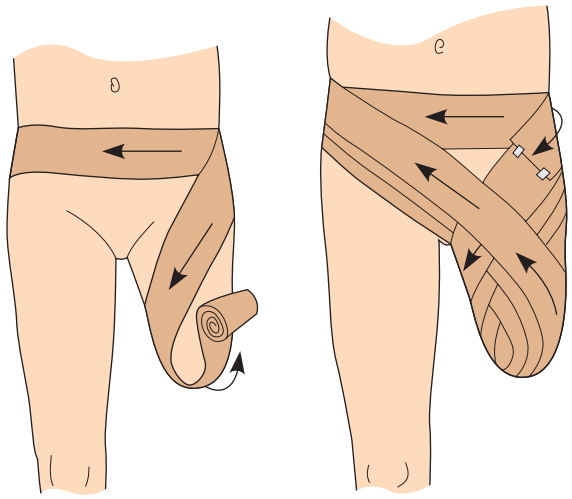

Figure 39–14 ■ Stump dressings increase venous return, decrease edema, and help shape the stump for a prosthesis. With an above-knee amputation, a figure-eight bandage is started by bringing the bandage down over the stump and back up around the hips.

DELAYED HEALING

If infection is present or if the circulation remains compromised, delayed healing (occurring at a slower rate than expected) will result. In older patients, other preexisting conditions can increase the risk of delayed healing. In patients of any age, electrolyte imbalances can contribute to delayed healing processes, as can a diet that lacks the proper nutrients to meet the body's increased metabolic demands during healing. Smoking compromises healing by causing vasoconstriction and decreasing blood flow to the stump. Deep venous thrombosis and compromised venous return, which may result from prolonged immobilization, are other potential factors. Decreased cardiac output decreases blood flow and thus also delays healing.

CHRONIC STUMP PAIN AND PHANTOM LIMB PAIN

Chronic stump pain is the result of neuroma formation, causing severe burning pain. Interventions to relieve this pain include medications, nerve blocks, transcutaneous electrical nerve stimulation (TENS), and surgical stump reconstruction. **Phantom limb pain** is not the same as phantom limb sensation. A majority of amputees experience phantom limb sensation (sensations such as tingling, numbness, cramping, or

itching in the phantom foot or hand) early in the postoperative period. It is often self-limited, but may last for decades in some patients. When phantom limb sensation is painful, it is referred to as *phantom limb pain*. Phantom limb pain more frequently affects people who had pain in the amputated limb prior to its removal than those who did not. Several theories for phantom limb pain have been developed. These include regeneration of severed peripheral nerves and abnormal impulses generated by spinal cord neurons that no longer receive normal sensory input from the body (Grossman & Porth, 2014). Treatments include pain management, TENS, and a variety of surgical procedures. The management of phantom limb pain is difficult for both patients and healthcare professionals. Patients with phantom limb pain often benefit from referral to a pain clinic for a comprehensive pain management program.

CONTRACTURES

A **contracture** is an abnormal flexion and fixation of a joint caused by muscle atrophy and shortening. Contracture of the joint above the amputation is a common complication. The patient needs to be taught to extend the joint and to perform muscle-strengthening exercises. The patient with an above-the-knee amputation should not sit for prolonged periods of time; prolonged sitting can lead to hip contracture. Additionally, the patient should lie prone for periods throughout the day. The patient with a below-the-knee amputation should elevate the stump, keeping the knee extended. A knee immobilizer may be used to help maintain joint extension (U.S. Department of Veterans Affairs, 2007). The same principles apply to the upper extremities. All joints should receive either active or passive ROM exercises every 2 to 4 hours. A trapeze frame should be added to the bed to encourage the patient to change position every 2 hours. The patient who has an upper extremity amputation should exercise both shoulders. Postural exercises can help prevent the patient from hunching over secondary to the loss of weight on the affected side.

●○● INTERPROFESSIONAL CARE

Interprofessional care is essential for the patient who has sustained an amputation. Physical therapy and occupational retraining are necessary, and the patient may also benefit from the presence of clergy. The entire healthcare team must view both the positive and the negative effects of amputation; that is, they must see amputation as a means to increase the patient's independence and to relieve symptoms. The patient should be able to become familiar with the members of the healthcare team and their roles; this allows the patient greater control over his or her care and rehabilitation and promotes independence.

DIAGNOSIS

Preoperatively, the patient has routine laboratory and diagnostic tests. Preoperative tests, including Doppler flowmetry, segmental blood pressure determination, transcutaneous partial pressure oxygen readings, and angiography, are performed to assess the circulation present in the limb at different levels and to determine the level of viable tissue. Postoperative tests include CBC to monitor for hemorrhage, WBC count to monitor for infection, blood chemistries to evaluate electrolytes and fluid balance, and a vascular Doppler ultrasonography if a DVT is suspected.

MEDICATIONS

Medications are used to manage pain, to prevent or treat infection, and as needed to maintain cardiac output and tissue perfusion.

Moving Knowledge into Action

Recent conflicts in the Middle East have resulted in significant numbers of military veterans returning with traumatic amputation affecting one or more limbs.

1. What associated injuries would you expect when traumatic amputation occurs as a result of terrorism or military conflict? What are the immediate priorities of care for these individuals?
2. How do you think the needs of these veterans differ from those of a patient undergoing amputation as a result of chronic peripheral vascular disease or diabetes mellitus? Consider factors such as age, general health, family, culture, and socioeconomic status as you develop your response.

Postoperatively, the patient resumes any routinely prescribed medications and in addition may receive antibiotics and analgesics. Steroids may be administered to decrease swelling. A histamine H_2 antagonist may also be ordered to decrease the risk of peptic ulcer formation. Stool softeners may be administered to prevent constipation.

PROSTHESIS

The type of prosthesis selected for the patient with an amputation depends on the level of the amputation as well as the patient's occupation and lifestyle. Each prosthesis is based on a detailed prosthetic prescription and is custom made for the patient. Most are made of plastic and foam materials. Many factors influence the patient's use of the prosthesis, including the status of the remaining limb, cognitive status, cardiovascular status, preoperative activity level, and motivation to use the prosthesis.

Patients with a lower extremity amputation are often fitted with early walking aids. Pneumatic devices that fit over the stump are used in the immediate postoperative period to allow early ambulation, decrease postoperative swelling, and improve morale. Patients may begin weight bearing as soon as 2 weeks after surgery. Patients with upper extremity amputations may be fitted for a prosthesis immediately after surgery. Rehabilitation of the patient with an amputation is a team effort, involving the patient, nurse, physician, physical therapist, occupational therapist, social worker, prosthetist, and vocational counselor.

●○● NURSING CARE

Health Promotion

Health promotion activities focus on preventing the progression of chronic diseases such as PVD and diabetes mellitus, and on safety. Patients with PVD from any cause need education about foot care and early recognition of decreased circulation. Education within both urban and rural populations should provide knowledge about working safely with lawn care equipment as well as farm and occupational machinery.

In addition, it is important for the public to know what to do if a traumatic amputation occurs in the home, community, or workplace. Preserving life is the first priority: First ensure that the patient can breathe; administer CPR as necessary, and control bleeding with direct pressure. The following guidelines may help preserve the amputated part until it can be surgically reattached:

- Keep the person in a supine position with the legs elevated.
- Apply firm pressure to the bleeding area, using a towel or article of clothing.

- Wrap the amputated part in a clean cloth. If possible, soak the cloth in saline (such as contact lens solution).
- Put the amputated part in a plastic bag and put the bag on ice. Do not let the amputated part come into direct contact with the ice or water.
- Send the amputated part to the emergency department with the injured person, and be sure the emergency personnel know what it is.

Assessment

Collect the following data through the health history and physical examination. Further focused assessments are described in the following nursing interventions sections.

- *Health history:* mechanism of injury, current and past health problems, pain, occupation, ADLs, changes in sensation in the feet, cultural and/or religious guidelines for handling the amputated part
- *Physical assessment:* bilateral neurovascular status of the extremities, bilateral capillary refill time, skin over the lower extremities (discoloration, edema, ulcerations, hair, gangrene).

Priorities of Care

Effective pain management is an immediate priority of care for the patient undergoing amputation. Monitoring for and preventing complications also are high-priority nursing activities. Although a focus toward rehabilitation begins prior to surgery, rehabilitation is the primary focus of nursing and interprofessional care following amputation.

Diagnoses, Planning, and Interventions

The goals of nursing care for an individual with an amputation are to relieve pain, promote healing, prevent complications, support the patient and family during the process of grieving and adaptation to alterations in body image, and restore mobility. Care is individualized, and the circumstances that led to the amputation (e.g., traumatic injury or disease) also must be addressed. See the accompanying Case Study & Nursing Care Plan on page 1262.

Acute Pain

Pain from the surgical procedure can be compounded by muscle spasms, swelling, and phantom limb pain.

Expected Outcome: Patient will report pain at an acceptable level using a standardized pain scale.

- Ask the patient to rate the pain on a scale of 0 to 10 (with 10 as the most severe pain) before and after any intervention. *This facilitates objective assessment of the effectiveness of the chosen pain relief strategy. Pain that increases in intensity or remains unrelieved with analgesics can indicate compartment syndrome.*
- Splint and support the injured area. *Splinting prevents additional injury by immobilizing the stump and decreasing edema while molding the stump for a good prosthetic fit.*
- Unless contraindicated, elevate the stump on a pillow for the first 24 hours after surgery. *Elevating the stump promotes venous return and decreases edema, which will decrease pain.*
- Move and turn the patient gently and slowly. *Gentle moving and turning prevents the development of severe muscle spasms.*
- Administer pain medications as prescribed. A PCA pump may be ordered by the physician. *Analgesics alleviate pain by stimulating opiate receptor sites. PCA pumps increase patient control over and allow early relief of pain before it intensifies.*
- Encourage deep breathing and relaxation exercises. *These techniques increase the effectiveness of analgesics and modify the pain experience.*
- Reposition patient every 2 hours; turn from side to side and onto abdomen. *Repositioning alleviates pressure from one area and distributes it throughout the body and helps prevent cramping of muscles.*

Evidence for Nursing Care

The Patient with Amputation

Selected resources that nurses may find helpful when planning evidence-based nursing care follow.

- Benetato, B. (2011). Posttraumatic growth among Operation Enduring Freedom and Operation Iraqi Freedom amputees. *Journal of Nursing Scholarship, 43*(4), 412–420.
- Holt, P. (2012). Pre and post-operative needs of patients with diabetes. *Nursing Standard, 26*(50), 50–56.
- Liu, F., Williams, R., Liu, H., & Chien, N. (2010). The lived experience of persons with lower extremity amputation. *Journal of Clinical Nursing, 19*(15–16), 2152–2161.

Risk for Infection

The patient who has an amputation is at risk for wound infection. Early recognition of infection can lead to early treatment and prevent wound dehiscence.

Expected Outcome: Patient's wound will heal without evidence of infection.

- Assess the wound for redness, drainage, temperature, edema, and suture line approximation. *Redness is normal in the immediate postoperative period; if it persists, however, it can indicate infection. A hot area that is palpated over the incision or increased drainage may also indicate infection.*
- Take the patient's temperature every 4 hours. *Increased body temperature may indicate infection.*
- Monitor WBC count. *The WBC count rises in the presence of infection.*
- Use aseptic technique to change the wound dressing. *Aseptic technique prevents the contamination of the wound with bacteria.*
- Administer antibiotics as ordered. *Antibiotics inhibit bacterial cell replication and help prevent or eradicate infection.*
- Teach the patient stump-wrapping techniques. *Correctly wrapping the stump from the distal to proximal extremity increases venous return and prevents pooling of fluid, thereby reducing the chance of infection.*

Risk for Impaired Skin Integrity

Stump care is essential, not only in the postoperative healing period, but also throughout life with a prosthesis. A variety of skin problems may be caused by a prosthesis, including epidermoid cysts, abrasions, blisters, and hair follicle infections. The patient must be taught stump care prior to discharge.

Expected Outcome: Patient's skin will remain intact without evidence of adverse effects of prosthesis.

- Each day, preferably at night, wash the stump with soap and warm water and dry thoroughly. Inspect the stump for redness, irritation, or abrasions. *It is essential to maintain intact skin to ensure successful use of the prosthesis.*

CASE STUDY & NURSING CARE PLAN A Patient with a Below-the-Knee Amputation

John Rocke is a 45-year-old divorcee with a history of type 1 diabetes mellitus and poor control of blood glucose levels. Mr. Rocke is unemployed and lives alone. Mr. Rocke failed to seek prompt medical attention for a foot infection; as a result, a left below-the-knee amputation was necessary.

Mr. Rocke is in his second postoperative day and his vital signs are stable. The stump is splinted and has a soft dressing. The wound is approximating well without signs of infection. He has not performed ROM exercises or turning since his surgery, complaining of severe pain. When the nurse goes into the room, he yells, "Get out! I don't want anyone to see me like this." No one has visited him since his hospitalization. He is tolerating an 1800-kcal diabetic diet and is using a urinal independently. He has an order for morphine, 10 mg IM every 3 to 4 hours prn for pain, and cefazolin (Ancef), 1 g IV every 8 hours. He is on blood glucose coverage with regular insulin subcutaneously.

Clinical Reasoning in Patient Care

1. How would you respond when Mr. Rocke yells at you to leave?
2. What do you believe is the highest priority of nursing care for Mr. Rocke at this time?
3. What members of the interprofessional healthcare team should the nurse ensure are involved in Mr. Rocke's care at this time?

ASSESSMENT

Jane Simmons, RN, has just come on duty. She notes that Mr. Rocke will not let anyone enter the room to give him medication or assess his vital signs.

DIAGNOSES

- *Disturbed Body Image* related to amputation of left lower leg
- *Complicated Grieving* related to anger and loss of left lower leg
- *Situational Low Self-Esteem* related to appearance
- *Ineffective Self-Health Management* related to refusal of care
- *Acute Pain* related to surgery

EXPECTED OUTCOMES

- Patient will verbalize his feelings about the amputation.
- Patient will allow the staff to monitor his vital signs and administer medications.
- Patient will be allowed to control his pain with a PCA pump.
- Patient will verbalize a decrease in pain.
- Patient will verbalize the importance of turning.
- Patient will turn every 2 hours.

PLANNING AND IMPLEMENTATION

- Encourage verbalization of feelings.
- Actively listen to the patient.
- Offer to arrange a visit with a fellow amputee.
- Ask the physician if the patient can be placed on a PCA pump.
- Teach the patient the importance of turning every 2 hours to prevent contractures.
- Encourage turning and lying prone.
- Teach the importance of antibiotics in preventing and treating infection.

EVALUATION

One week after his surgery, Mr. Rocke is actively participating in his care. He has apologized for his behavior and has explained to Ms. Simmons that he was angry about the loss of his leg. He states, "I thought I knew what to expect but I didn't."

Clinical Reasoning in Patient Care

4. Once Mr. Rocke is ready to assist with his stump care, how would you proceed? Would you give him full responsibility for care and dressings, or would you gradually increase his participation? Why?
5. What factors in Mr. Rocke's home environment and medical history may make self-care more difficult? Do you expect Mr. Rocke to follow up on care after his discharge? Why or why not?
6. Mr. Rocke states, "Why should I exercise this leg—it was already cut off!?" How would you respond? What is the purpose of exercising the stump?

See Evaluating Your Response in Appendix B.

- Massage the end of the stump, beginning 3 weeks after surgery. *Massage helps desensitize the remaining part of the limb and prevents scar tissue formation. If the skin adheres to the underlying tissue, it will tear when stressed by wearing a prosthesis.*
- Expose any open areas of skin on the remaining part of the limb for 1 hour four times a day. *Air exposure promotes healing.*
- Change stump socks and elastic wraps each day. Wash these in mild soap and water, and allow to completely dry before using again. *Stump socks and elastic wraps must be kept clean and dry to prevent skin breakdown.*

Risk for Complicated Grieving

The patient who has lost an extremity is at risk for complicated grieving. Denial of the need for surgery and the inability to discuss feelings compound this risk.

Expected Outcome: Patient will verbalize grief and the meaning of the loss.

- Encourage verbalization of feelings, using open-ended questions. *Asking open-ended questions allows the patient to discuss feelings and communicates the listener's willingness to listen.*
- Actively listen and maintain eye contact. *Active listening and eye contact communicate respect for what the patient is expressing.*
- Reflect on the patient's feelings. *Reflection statements such as "You seem angry" allow the patient to recognize feelings and perhaps develop a plan for resolution.*
- Allow the patient to have unlimited visiting hours, if possible. *Unlimited visiting hours allow increased social support.*
- If desired by the patient, provide spiritual support by encouraging activities such as visits from a spiritual leader, prayer, and meditation. *These activities often provide support during the grieving process.*

Disturbed Body Image

Although amputation is a reconstructive surgery, the patient's body image will be disturbed. Risk for body image disturbance is higher in young trauma patients, in whom body image is a particularly important component of self-image.

Expected Outcome: Patient will demonstrate acceptance of appearance and resume self-care activities.

- Encourage verbalization of feelings. *This allows the patient to communicate concerns and fears and lets the patient know the nurse is willing to listen.*
- Allow the patient to wear clothing from home. *Familiar clothing provides emotional comfort and helps the patient retain a sense of his or her own identity.*

- Encourage the patient to look at the stump. *Looking at and touching the stump helps the patient face his or her fear of the unknown and move from denial to acceptance.*
- Encourage the patient to care for the stump. *Active participation in care increases self-esteem and independence.*
- Offer to have a fellow amputee visit the patient. *A support person who has experienced the same change gives the patient the hope that he or she can regain independence.*
- Encourage active participation in rehabilitation. *Active participation in rehabilitation increases independence and mobility.*

Impaired Physical Mobility

If time allows, the patient should begin strengthening muscles preoperatively. If the amputation is the result of an emergency, exercises begin within 24 to 48 hours of surgery. The return of independent mobility boosts self-esteem and promotes adaptation to amputation.

Expected Outcome: Patient will participate in prescribed activities, demonstrating correct use of assistive devices.

- Perform ROM exercises on all joints. *ROM exercises help prevent the development of joint contractures that limit mobility.*
- Maintain postoperative stump shrinkage devices. These may be elastic bandages, shrinker socks, an elastic stockinette, or a rigid plaster cast. *Postoperative dressings decrease edema and shape the stump for prosthetic wear.*
- Turn and reposition the patient every 2 hours. *The patient with a lower extremity amputation should lie prone every 4 hours. Repositioning increases blood flow to muscles, forces synovial fluid into joints, and helps prevent contractures.*
- Reinforce teaching by the physical therapist in crutch walking or the use of assistive devices. *These devices increase mobility by balancing the patient and facilitating ambulation.*
- Encourage active participation in physical therapy. *Physical therapy will fatigue the patient in the early stage of healing. Encouragement may increase the patient's participation in the physical therapy regimen and thereby increase activity tolerance.*

Continuity of Care

Patient and family teaching includes stump care, prosthesis fitting and care, medications, assistive devices, exercises, rehabilitation, counseling, support services, and follow-up appointments. The depth of teaching depends on the cause and site of the amputation and the needs of the patient. See the accompanying Meeting Individualized Needs box.

Holistic nursing care is especially important for the older patient with an amputation. The normal aging process decreases renal and

Meeting Individualized Needs

The Patient with an Amputation

Amputation of a limb has significant long-term consequences for the patient. The patient will grieve the loss of a body part and must adjust to a new self-image. The patient's ability to perform normal daily living activities and to maintain his or her usual family and social roles may be significantly affected, at least initially. Depending on the patient's occupation, job performance may be affected, necessitating a change of career.

The nurse may be responsible for involving multiple members of the healthcare team in the patient's care and rehabilitation and coordinating their activities. Following an amputation, the patient may need the services of any or all of the following:

- Social services to help with rehabilitative and financial arrangements
- Physical therapists to teach ambulation techniques, and to provide deep heat or massage
- Occupational therapists to assist the patient in developing adaptive techniques to deal with the loss of a limb
- Prosthetists to develop a prosthesis for the missing limb that will meet the patient's needs for ADLs and other activities
- Home health services for nursing care such as assessments and wound care
- Support group services to assist in adapting to the body image change and effects of amputation on ADLs.

ASSESSING FOR HOME CARE

Preparing the amputee for home care includes a careful assessment of the patient, the family, available support services, and the home for possible barriers to the patient's safety and independence.

Assess the patient's acceptance of the amputation and knowledge base about care needs, any activity restrictions or special needs, and resources for home care. Discuss home management—who is responsible for household activities such as cleaning and cooking. Inquire about arrangements that have been made for home care activities and ADLs. Evaluate the patient's use of prescription and nonprescription medications, paying particular attention to possible interactions and drugs that may affect the patient's balance, mental alertness, or appetite. Ask about social habits, such as cigarette smoking, alcohol use, or other drug use, that may affect healing or the patient's ability to provide self-care.

Assess the patient's home environment for possible safety hazards or barriers to ambulation, such as the following:

- Scatter rugs
- Stairs between living areas of the house
- Presence of grab bars to facilitate toileting and bathing
- Access to clean water and other needs for wound care.

TEACHING FOR HOME CARE

The new amputee needs a great deal of teaching to learn to adapt to loss of a limb, whether it is an upper or lower extremity that has been lost. Because the patient must be ready to learn before teaching can be effective, use therapeutic communication techniques to encourage the patient to verbalize feelings about the amputation and its effects. Use active listening and teach the patient ways to reduce anxiety and deal with feelings of helplessness and loss. Encourage the patient to participate in care of the stump to build self-esteem and reinforce teaching. Include the following in teaching for home care:

- Teach the patient to wrap the stump appropriately in preparation for fitting the prosthesis.
- Discuss positioning of the stump. Contractures are a particular problem for patients with an above-knee amputation, and can interfere with ability to effectively use a prosthesis.
- Teach the patient how to perform stump exercises to maintain joint mobility and muscle tone of the affected limb.
- Encourage the patient to resume physical activities as soon as possible. This improves the patient's health and well-being, as well as the patient's self-esteem.
- Discuss household modifications to promote independence, such as grab bars in the bathroom, faucets with single-handle controls for water flow and temperature, and handheld shower heads and shower chairs for bathing.

liver function; hence, medications have longer half-lives. Altered circulation prolongs wound healing, and slowing of reflexes and alterations in gait may disrupt balance. A walker may be more appropriate than crutches, because older patients have less strength in the upper extremities. Safety issues, such as decreasing the risk for recurrent falls, must be addressed. The nurse should also assess the patient's need for in-home assistance and make appropriate referrals to visiting nurses and home health aides.

In addition, suggest the following resources:

- The Amputee Coalition of America
- Amputee Resource Foundation of America.

CHAPTER HIGHLIGHTS

- **Musculoskeletal injuries, including strains, sprains, fractures, and joint injuries, are common, often associated with recreational activities or trauma. Nursing care includes assessing the circumstances and impact of the injury as well as neurovascular status distal to the injury, and teaching prescribed treatment and rehabilitation.**
- Immediate treatment for contusions, strains, and sprains includes RICE (rest, ice, compression, elevation) therapy.
- Joint trauma may damage soft tissue, cartilage, or even result in joint dislocation. Monitor neurovascular status, assessing the affected extremity for increased pain, decreased or absent pulses, pale skin, inability to move the extremity, and changes in sensation.
- Repetitive use injuries, especially common in the workplace, include carpal tunnel syndrome, bursitis, and epicondylitis.
- **Fractures are usually uncomplicated, but place the patient at risk for both acute and long-term complications and may necessitate surgery or other invasive procedures for healing. Nurses must promptly recognize complications, and initiate appropriate care.**
- Fractures are closed or simple (skin is intact) or open or compound (skin integrity is interrupted); open fractures are at risk for infection. Other fracture descriptors include oblique or spiral, avulsed, comminuted, compressed, impacted, or depressed.
- Fractures heal through four phases: hematoma, fibrocartilaginous callus, bony callus, and remodeling. Healing is influenced by the age and physical condition of the patient and by the type of fracture.
- Fracture complications include compartment syndrome, fat embolism syndrome, deep venous thrombosis, infection, delayed union and nonunion, and complex regional pain syndrome.
- Fractures are treated with surgery, traction, and/or casts to stabilize the fractured bone, maintain bone immobilization, prevent complications, and restore function.
- Fractures of the hip are most often sustained by older adult women, and are usually the result of a fall. Hip fractures present a serious health problem for people ages 65 years and older, potentially impacting the patient's independence and even shortening the life span.
- Nursing care for the patient with a fracture focuses on interventions for acute pain, risk for peripheral neurovascular dysfunction, risk for infection, and impaired physical mobility.
- **Amputation, the partial or total removal of an extremity, has significant physical and psychosocial effects on the patient and on the family. In addition to providing care and support for the patient and family, the nurse is actively involved in coordinating the interprofessional team for optimal patient care and rehabilitation.**
- The most common cause for amputation of a lower extremity is peripheral vascular disease. Trauma is the most common cause for upper extremity amputation.
- Complications that may follow an amputation include infection, delayed healing, chronic stump pain, phantom pain, and contractures. Stump care is necessary to prevent complications and to prepare the stump for a prosthesis.
- Nursing care for the patient with an amputation is focused on a return to functional health, with interventions to meet needs for acute pain, impaired skin integrity, grieving, disturbed body image, and impaired physical mobility.

TEST YOURSELF NCLEX-RN® REVIEW

1. The nurse is teaching a patient self-care approaches for a sprained ankle. For which reason should the nurse emphasize the use of ice after this type of injury?
   1. Increases white blood cells.
   2. Lowers the blood pressure and pulse.
   3. Increases the diameter of blood vessels.
   4. Decreases the diameter of blood vessels.

2. A patient with a compound, open fracture of the femur is scheduled for immediate surgery. Which nursing diagnosis would be most appropriate in the immediate postoperative period?
   1. *Risk for Falls*
   2. *Risk for Infection*
   3. *Impaired Transfer Ability*
   4. *Risk for Post-Trauma Syndrome*

3. The nurse is concerned after performing a neurovascular assessment on an older patient with a lower arm cast. Which finding caused the nurse to become concerned?
   1. pale, cold fingers
   2. slightly edematous fingers
   3. warm, pink skin above the cast
   4. pain rating of 2 on a 0-to-10 scale
4. The nurse is preparing instructional materials for a patient recovering from a fractured leg. What mineral should the nurse teach as being essential in bone healing?
   1. sodium
   2. calcium
   3. potassium
   4. magnesium
5. The nurse reviews documentation on a patient with a long leg cast for a fracture in which the pulses in the foot were decreased and the patient was experiencing a pain rating of 8 on a scale of 0 to 10 during the previous shift. Which additional findings should the nurse immediately report to the healthcare provider? (Select all that apply.)
   1. fever
   2. weakness
   3. cyanotic foot
   4. tingling in the foot
   5. severe pain with passive flexion
6. The nurse is caring for a patient with a deep venous thrombosis of the left lower extremity. What additional body system should the nurse carefully monitor in this patient?
   1. renal
   2. digestive
   3. respiratory
   4. hematologic
7. The nurse is identifying diagnoses appropriate for patients with orthopedic injuries. Which diagnosis should the nurse identify as being common to all musculoskeletal injuries?
   1. *Acute Pain*
   2. *Chronic Pain*
   3. *Risk for Infection*
   4. *Disturbed Body Image*
8. The nurse is caring for a patient recovering from a below-the-knee amputation. What should be included in this patient's plan of care? (Select all that apply.)
   1. Elevate the stump.
   2. Keep the knee extended.
   3. Apply a knee immobilizer.
   4. Avoid sitting for prolonged periods of time.
   5. Provide passive ROM exercises every 2 to 4 hours.
9. The day following a below-the-knee amputation, the patient complains of toes cramping in the amputated foot. What should the nurse realize the patient is experiencing?
   1. contractures
   2. attention-seeking
   3. chronic stump pain
   4. phantom limb sensation
10. The nurse is preparing an educational session for employees of a manufacturing plant regarding emergency care of amputated digits. What should the nurse include when teaching about this type of injury?
    1. Immediately transport the person to the hospital.
    2. Place the amputated digit in a storage bag filled with warm water.
    3. Wrap the amputated digit in a towel, place in a plastic bag, and lay it on ice.
    4. Tape the amputated digit to the hand so the emergency personnel will know where it is.

40 Nursing Care of Patients with Musculoskeletal Disorders

LEARNING OUTCOMES

1. Explain the etiology, pathophysiology, manifestations, complications, interprofessional care, and nursing care of patients with musculoskeletal disorders.
2. Compare and contrast the pathophysiology, manifestations, diagnosis, and management of osteoporosis, osteoarthritis, Paget's disease, and rheumatoid arthritis.
3. Discuss the purposes, nursing implications, and health education for the patient and family for medications used to prevent and treat specific musculoskeletal disorders.
4. Describe the surgical procedures used to treat patients with arthritis.

CLINICAL COMPETENCIES

1. Assess functional status of patients with musculoskeletal disorders, eliciting patient values, preferences, and expressed needs.
2. Use evidence-based research and practice guidelines to plan, provide, and manage safe and effective individualized care for patients with musculoskeletal disorders.
3. Determine priority nursing diagnoses, based on assessed data, to select and implement patient-centered nursing interventions for patients with musculoskeletal disorders.
4. Monitor patient responses to interprofessional and nursing interventions, recognizing, documenting, and reporting adverse or unanticipated responses.
5. Demonstrate effective use of strategies to reduce the risk of harm to patients with musculoskeletal disorders.
6. Integrate and coordinate interprofessional care into care of patients with musculoskeletal disorders.
7. Use quality measures to identify gaps between local and best practices when caring for patients with musculoskeletal disorders.
8. Use the electronic medical record to plan care, document care provided, and revise plan of care as appropriate.

MAJOR CHAPTER CONCEPTS

- Disorders of the musculoskeletal system can have significant physical, psychosocial, and financial consequences. Patients with musculoskeletal disorders experience a variety of individualized responses to their altered health status. Nurses are responsible for coordinating interprofessional care, providing education, and ensuring psychologic support for the patient and family, as well as providing physical care.
- Metabolic bone and joint disorders arise from disrupted metabolic processes or impaired elimination of metabolic wastes. As a result, bones may be weak and easily fractured, leaving the patient at risk for fractures. Metabolic wastes such as urate crystals may accumulate, damaging joints and causing acute pain.
- Degenerative disorders of the joints and muscles can lead to impaired mobility and chronic pain. These problems may in turn cause disability, especially in the performance of daily living activities.
- Autoimmune and inflammatory disorders of the musculoskeletal system are systemic in nature and often chronic, potentially leading to significant disability. Care is multidimensional, involving pharmacologic and nonpharmacologic strategies to maintain optimal function.
- Connective tissue is the most abundant and widely distributed body tissue. It connects body parts and provides support; forms bones, cartilage, and the walls of blood vessels; and attaches muscles to bones. Disorders that affect connective tissue have diverse manifestations, and patients need interprofessional team support to achieve effective disease management.
- Infectious disorders of bone and joints are caused by a pathogen, and are often difficult to treat. Effective treatment is vital, however, to prevent chronic pain, deformity, and disability. The nurse coordinates, provides, and monitors treatment measures and responses in acute care settings and the home, and provides patient, family, and caregiver education.
- Bone tumors may be benign or malignant, primary or metastatic. The primary manifestations of a bone tumor are pain, a mass, and impaired function. Nursing care is directed toward teaching to prevent injury and interventions to relieve pain.
- Musculoskeletal disorders characterized by chronic pain and discomfort can have significant physical and psychosocial effects on the patient. The nursing role in caring for these patients focuses on providing support and educating patients about their condition so they can be active partners in managing their condition.

systemic lupus erythematosus (SLE), *1302*
tophi, *1276*

Arthritis refers to inflammation of the joints, while **rheumatic disorders** refer to diseases of the muscles and bones as well as the joints. These diseases affect not only the joints but also the connective tissues of the body. Arthritis and other rheumatic disorders are widespread, affecting about 50 million (nearly 1 in 5) adults in the United States (Centers for Disease Control and Prevention [CDC], 2011a). Arthritic disorders are a leading cause of disability; however, their very prevalence may lead the public and healthcare professionals to treat them as normal aging processes or discount the validity of the pain and disability experienced by the person with arthritis.

There are more than 100 different types of arthritis, but the most common are osteoarthritis, rheumatoid arthritis, fibromyalgia, and gout (CDC, 2011a). The etiology of rheumatic disorders often is not clear; in many cases, the pathophysiologic processes involved are complex and poorly understood. Many are primary disorders; others occur as secondary processes associated with another disease. The wear and tear of aging, autoimmune processes, metabolic disorders, genetic factors, and infection are also implicated as causative factors in some forms of rheumatic disease.

Metabolic Disorders

Metabolic bone disorders disrupt the bone remodeling process, which normally involves a sequence of bone reabsorption and formation. Trabecular (spongy) bone, the honeycomb-like interior portion of bone, has a significantly higher turnover rate than cortical (compact) bone. Adults constantly replace existing bone through resorption of old bone by osteoclasts and formation of new bone by osteoblasts. Ideally, the amount of new bone formed is equal to the amount of bone resorbed. Metabolic bone disorders may result from a variety of factors, including aging, calcium and phosphate imbalances, genetics, and changes in hormone levels. Gout, a metabolic joint disorder, results from altered uric acid metabolism and elimination.

THE PATIENT WITH OSTEOPOROSIS

Osteoporosis, literally defined as "porous bones," is a metabolic bone disorder characterized by loss of bone mass, increased bone fragility, and an increased risk of fractures. The reduced bone mass is caused by an imbalance of the processes that influence bone growth and maintenance. Although osteoporosis may result from an endocrine disorder or malignancy, it is most often associated with aging.

The National Osteoporosis Foundation (NOF) (2011) has found that osteoporosis is a health threat for an estimated 44 million Americans; 10 million people have osteoporosis and 34 million have low bone mass, increasing their risk for the disease. Although osteoporosis can occur at any age and in both men and women, 80% of those with osteoporosis are women. One in two women and one in four men over age 50 will have an osteoporosis-related fracture in his or her remaining lifetime.

Risk Factors

The risk of developing osteoporosis depends on how much bone mass is achieved between ages 25 and 35, and how much is lost later. Certain diseases, lifestyle habits, and ethnic backgrounds increase the risk of developing osteoporosis (see the Focus on Cultural Diversity box). Different variables affect one's risk of osteoporosis—some can be modified and others cannot. The risk factors are summarized in Box 40–1.

FOCUS ON CULTURAL DIVERSITY

The Patient with Osteoporosis

- Significant risk is reported for people of all ethnic backgrounds, but the highest percentage of cases occurs in non-Hispanic and Asian women ages 50 and older, with 20% estimated to have osteoporosis, and 52% estimated to have low bone mass. Ten percent of Hispanic women ages 50 and older are affected, with 49% estimated to have low bone mass.
- Non-Hispanic Black women over the age of 50 have a lower incidence, with an estimated 5% having osteoporosis and 35% low bone mass.
- In men ages 50 and older, 7% of non-Hispanic White and Asian men have osteoporosis, compared with 4% of non-Hispanic Black men, and 3% of Hispanic men.

BOX 40–1 Risk Factors for Osteoporosis

NONMODIFIABLE
- Older age
- A family history of osteoporosis
- History of fracture in a first-degree relative
- Being female, especially Caucasian or Asian
- Being thin and/or having a small frame

MODIFIABLE
- Low estrogen levels in women (amenorrhea, menopause)
- Low testosterone levels in men
- Dietary: low lifetime calcium intake, vitamin D deficiency
- Medication use: corticosteroids, some anticonvulsants
- Lifestyle: inactivity, cigarette smoking, excess alcohol use

NONMODIFIABLE RISK FACTORS

Both men and women are susceptible to osteoporosis as they age, because the activity of osteoblasts and osteoclasts diminishes. Women have a significantly higher risk for manifestations and complications of osteoporosis because their peak bone mass is 10% to 15% less than that of men. In addition, age-related bone loss begins earlier and proceeds more rapidly in women, beginning in their 30s and accelerating before menopause. Estrogen in women and testosterone in men appear to help prevent bone loss; decreasing levels of these hormones associated with aging contribute to bone loss. Age-related bone loss in men occurs 15 to 20 years later than in women and at a slower rate.

European Americans and Asians are at a higher risk for osteoporosis than African Americans, who have greater bone density (bone mass positively correlates with the amount of skin pigmentation). Patients who have an endocrine disorder such as hyperthyroidism, hyperparathyroidism, Cushing's syndrome, or diabetes mellitus are at high risk for osteoporosis. These disorders affect the metabolism, in turn affecting nutritional status and bone mineralization. Malabsorption disorders such as celiac disease, pancreatic disorders, and inflammatory bowel disease affect calcium absorption and increase the risk for osteoporosis.

MODIFIABLE RISK FACTORS

Modifiable risk factors include behaviors that place an individual at risk for developing osteoporosis, as well as physical changes such as menopause whose contribution to osteoporosis can be modified by preventive strategies. Calcium deficiency is an important modifiable risk factor contributing to osteoporosis. Calcium is an essential mineral in the process of bone formation and other significant body functions. When dietary intake of calcium is insufficient, the body compensates by removing calcium from the skeleton, weakening bone tissue. Acidosis, which may result from a high-protein diet, contributes to osteoporosis in two ways. Calcium is withdrawn from the bone as the kidneys attempt to buffer the excess acid. Acidosis may directly stimulate osteoclast function. A high intake of diet soda containing significant phosphate also can deplete calcium stores.

In women, estrogen levels affect osteoporosis risk. Estrogen promotes the activity of osteoblasts, increasing new bone formation, and inhibits osteoclast activity. In addition, estrogen enhances calcium absorption and stimulates the thyroid gland to secrete calcitonin, a hormone that suppresses osteoclast activity and increases osteoblast activity. With menopause and decreasing estrogen levels, bone loss accelerates in women. Premature osteoporosis is increasing in female athletes, who have a greater incidence of eating disorders and amenorrhea. Poor nutrition and intense physical training can result in a deficient production of estrogen. Decreased estrogen, combined with a lack of calcium and vitamin D, results in a loss of bone density (Grossman & Porth, 2014).

Both cigarette smoking and excess alcohol intake (more than three drinks per day) are risk factors for osteoporosis. Smoking decreases the blood supply to bones. Nicotine slows the production of osteoblasts and impairs the absorption of calcium, contributing to decreased bone density. Alcohol has a direct toxic effect on osteoblast activity, suppressing bone formation during periods of alcohol intoxication. In addition, heavy alcohol use may be associated with nutritional deficiencies that contribute to osteoporosis. Interestingly, moderate alcohol consumption in postmenopausal women actually may increase bone mineral content, possibly by increasing levels of estrogen and calcitonin.

Sedentary lifestyle is another modifiable risk factor that can cause osteoporosis. Weight-bearing exercise, such as walking, influences bone metabolism in several ways. The stress of this type of exercise increases blood flow to bones, which brings growth-producing nutrients to the cells. Walking increases osteoblast growth and activity.

Anyone who takes a glucocorticoid medication (prednisone or dexamethasone, for example) for more than 3 months is at risk for glucocorticoid-induced osteoporosis. These medications, often prescribed to manage rheumatic diseases, can directly affect bone cells, slowing the rate of bone formation. They also interfere with how the body uses calcium and affect levels of sex hormones, leading to bone loss. The American College of Rheumatology (2010) recommends counseling about calcium and vitamin D supplements for all patients starting glucocorticoid treatment. Other medications known to increase the risk for osteoporosis and fracture include anticonvulsants, immunosuppressants, and some other drugs.

MEMORY CUE

Osteoporosis Risk Factors

ACCESS

Alcohol
Corticosteroid
Calcium low
Estrogen low
Smoking
Sedentary lifestyle

Pathophysiology

Although the exact pathophysiology of osteoporosis is unclear, it is known to involve an imbalance of the activity of osteoblasts that form new bone and osteoclasts that resorb bone. Until adulthood when peak bone mass is reached, bone formation occurs more rapidly than does resorption. After peak bone mass is achieved at about age 30, however, resorption exceeds formation and slightly more bone is lost than is gained (about 0.7% per year). This loss is accelerated if the diet is deficient in vitamin D and calcium. In women, bone loss further increases after menopause (with loss of estrogen), then slows but does not stop at about age 60. While testosterone levels in men decline with aging, this is a more gradual process and associated bone loss occurs more slowly.

The rate of bone loss varies both among individuals and at different skeletal sites. The spine, which is 66% to 75% trabecular bone, may show significant osteoporotic changes before bones such as the forearm or wrist, which are predominantly cortical bone. *Postmenopausal osteoporosis* primarily affects bones such as vertebral bodies. Accelerated bone loss at one site magnifies the imbalance of bone resorption and formation. Cortical bone becomes more porous with increased remodeling activity. When coupled with changes to internal bone structure, this reduces the biomechanical strength of long bones and increases the risk for fracture (Lindsay & Cosman, 2012).

Senile osteoporosis, associated with aging, tends to affect cortical bone (Grossman & Porth, 2014).

Manifestations

The most common manifestations of osteoporosis are loss of height, progressive curvature of the spine, low back pain, and fractures of the forearm, spine, or hip. Osteoporosis is often called the "silent disease," because bone loss occurs without symptoms.

The loss of height occurs as vertebral bodies collapse. Acute episodes generally are painful, with radiation of the pain around the flank into the abdomen. Vertebral collapse can occur with little or no stress; minimal movements such as bending, lifting, or jumping may precipitate the pain. In some patients, vertebral collapse may occur slowly, accompanied by little discomfort. Along with loss of height, characteristic dorsal kyphosis and cervical lordosis develop, accounting for the "dowager's hump" often associated with aging. The abdomen tends to protrude and knees and hips flex as the body attempts to maintain its center of gravity (Figure 40–1 ■).

Complications

Fractures are the most common complication of osteoporosis, with the disease being responsible for an estimated 2 million fractures each year. These include 547,000 vertebral compression fractures, 297,000 hip fractures, 397,000 wrist fractures, 135,000 pelvic fractures, and 675,000 fractures at other sites (NOF, 2011). There may be no obvious manifestations of osteoporosis until fractures occur. Some fractures are spontaneous; others may result from everyday activities. Trends are seen in fracture occurrence: Wrist fractures increase in frequency until about age 60, whereas after age 70, the incidence of hip fractures doubles every 5 years (Lindsay & Cosman, 2012).

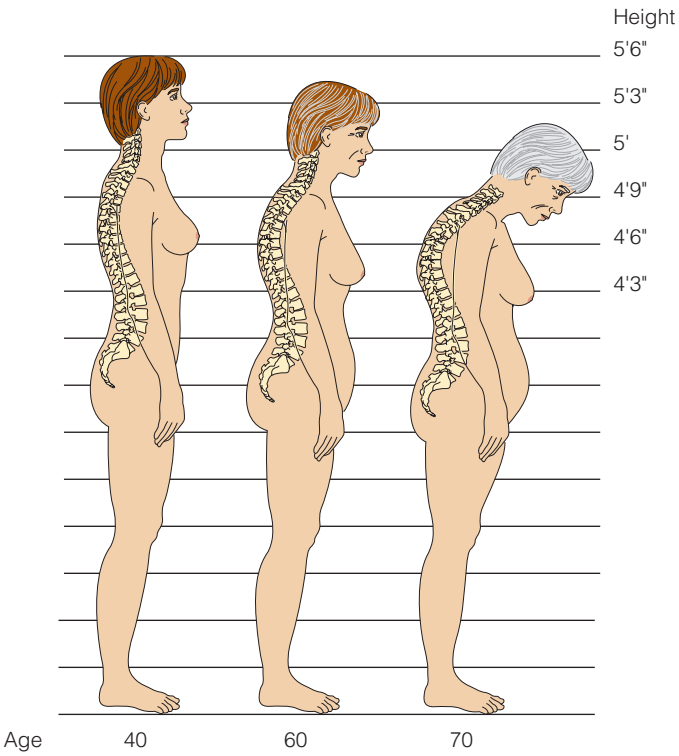

Figure 40–1 ■ Spinal changes caused by osteoporosis. As the condition progresses, height can be reduced by as much as 18 cm (7 in.).

●○● INTERPROFESSIONAL CARE

Care of the patient with osteoporosis focuses on early identification of risk, stopping or slowing the process, alleviating symptoms, and preventing complications. Proper nutrition and exercise are important components of treatment. The U.S. Preventive Services Task Force (2011) recommends osteoporosis screening for all women ages 65 years and older; White women with an increased fracture risk benefit from earlier screening. The FRAX (Fracture Risk Assessment) tool, which uses clinical data such as age, body mass index (BMI), parental fracture history, and tobacco and alcohol use, is commonly used to assess fracture risk. The task force found insufficient evidence to recommend screening for men who have not had previous fractures or known causes of osteoporosis.

DIAGNOSIS

Bone mineral density (BMD) tests are used to estimate skeletal mass or density in patients at risk for osteoporosis.

Dual-energy x-ray absorptiometry (DEXA) measures bone density in the lumbar spine or hip. Current diagnostic and treatment recommendations rely on DEXA measurements. Quantitative ultrasonography, which transmits painless sound waves through the heel of the foot to measure bone density, is a less expensive screening test that may be used. CT scanning of the spine, hip, forearm, or tibia also may be used to evaluate fracture risk. It is more costly, however, and exposes the patient to more radiation. Laboratory tests such as a complete blood count (CBC), serum and urine calcium, and liver and renal function studies may be done to rule out other causes of bone loss. The serum 25(OH) D test measures total body vitamin D levels and may be ordered for patients at risk for deficiencies, for example, older adults with minimal sun exposure. Biochemical markers of bone turnover, including serum bone-specific alkaline phosphatase, osteocalcin, and others, may be used to monitor treatment response (Lindsay & Cosman, 2012). A comparison of laboratory tests for metabolic bone diseases is outlined in Table 40–1.

MEDICATIONS

An adequate intake of calcium and vitamin D beginning in childhood is critical to prevent and treat osteoporosis. By ages 18 to 20, 85% to 90% of adult bone mass is present (NOF, 2011). See Table 40–2 for recommended calcium and vitamin D intakes for adults. Food sources of calcium include dairy products (milk, yogurt, and cheese), as well as foods fortified with calcium.

Bisphosphonates are the current drugs of choice for preventing and treating osteoporosis. Bisphosphonates are potent inhibitors of bone resorption that preserve bone mass and increase bone density in the hip and vertebrae. Alendronate, risedronate, and oral ibandronate are approved for preventing and treating postmenopausal osteoporosis. Alendronate and risedronate also may be prescribed for men and to prevent or treat glucocorticoid-induced osteoporosis. The nursing implications of bisphosphonates are found in the Medication Administration box. Adverse effects such as heartburn,

TABLE 40–1 Differential Features of Osteoporosis, Osteomalacia, and Paget's Disease

Differentiating Features	Osteoporosis	Osteomalacia	Paget's Disease
Pathophysiology	Bone resorption outpaces bone formation	Inadequate mineralization of bone matrix	Excessive osteoclastic activity and formation of poor-quality bone
Calcium level (serum)	Normal	Low or normal	Normal or elevated (especially in immobilized patients)
Phosphate level (serum)	Normal	Low or normal	Normal
Parathyroid hormone level (serum)	Normal	High or normal	Normal
Alkaline phosphatase level (serum)	Normal	Elevated	Increased; not a reliable test for patients who have liver disease or are pregnant
Hydroxyproline (urine)	Not applicable	Not applicable	Increased
Radiographic findings	Osteopenia, fractures	Decreased bone density, radiolucent bands known as Looser's zones, or pseudofractures	"Punched-out" appearance of bone, increase in bone thickness, linear fractures, mosaic pattern of bone matrix

difficulty swallowing, and gastric upset may limit long-term adherence to bisphosphonate therapy. Denosumab (Prolia) is a monoclonal antibody for treating postmenopausal osteoporosis in women. This drug has a different mechanism of action, blocking the formation of osteoclasts, the cells that break down bone. It is administered by subcutaneous injection every 6 months. Its long-term safety is not yet known.

Estrogen replacement therapy reduces bone loss, increases bone density in the spine and hip, and reduces the risk of fractures in postmenopausal women. It is particularly recommended for women who have undergone surgical menopause before age 50, and often is prescribed for women with other osteoporosis risk factors. Estrogen therapy alone is associated with an increased risk of endometrial cancer, so it usually is prescribed in combination with progestin (hormone replacement therapy or HRT). The choice of using HRT to prevent osteoporosis is one that must be made between the woman and her healthcare provider.

Raloxifene (Evista) and tamoxifen (Nolvadex, Tamofen) are selective estrogen receptor modulators (SERMs) that prevent bone loss by mimicking estrogen's beneficial effects on bone density in postmenopausal women. SERMs do not have the risks of estrogen and have the added benefit of reducing the risk for invasive breast cancer. Hot flashes are a common side effect. These drugs should not be taken by women with a history of blood clots.

Calcitonin (Fortical, Miacalcin) is a hormone that increases bone formation and decreases bone resorption. Calcitonin increases spinal bone density and reduces the risk of compression fractures; it may reduce the risk of hip fracture as well. Calcitonin usually is prescribed as a nasal spray, although it also is available in parenteral form. Because calcitonin is a protein, it can precipitate anaphylactic-type allergic responses. Teriparatide (Forteo) is a synthetic parathyroid hormone, administered subcutaneously to stimulate new bone formation and mass. It is used to decrease the risk of bone fracture from osteoporosis in postmenopausal women and in men with high risk for fracture (Wells et al., 2012).

TABLE 40–2 Recommended Adult Intake of Calcium and Vitamin D

Ages	Elemental Calcium (mg)	Vitamin D (units)
19–50 years	1000	200
51–70 years	1200	400
> 70 years	1200	600

●○● NURSING CARE

Osteoporosis is both preventable and treatable; therefore, nursing care focuses primarily on planning and implementing interventions to prevent the disease, its manifestations, and the resulting injuries. An important aspect of preventing osteoporosis is educating patients under age 35. See the accompanying Case Study & Nursing Care Plan for a patient with osteoporosis.

Health Promotion

Health promotion activities to prevent or slow osteoporosis focus on calcium intake, exercise, and health-related behaviors.

Nutrition

For patients of all ages, stress the importance of maintaining a daily calcium intake that meets National Institutes of Health (NIH) recommendations (refer to Table 40–2). This is particularly important for adolescent girls and young adult women who may avoid eating many high-calcium foods such as dairy products because of concerns about weight. Optimal calcium intake before ages 30 to 35 probably increases peak bone mass. Emphasize that low-fat (or nonfat) dairy products also contain calcium, although some fat in the product may enhance calcium absorption.

Milk and milk products are the best sources of calcium. The lactose in milk facilitates calcium absorption as well. Other food sources of calcium include sardines, clams, oysters, and salmon, as well as dark green, leafy vegetables such as broccoli, collard greens, bok choy, and spinach. For patients who avoid dairy products because of lactose intolerance or a vegetarian diet, suggest alternate sources.

MEDICATION ADMINISTRATION

The Patient with Osteoporosis

BISPHOSPHONATES

alendronate (Fosamax)
ibandronate (Boniva)
risedronate (Actonel)
zoledronic acid (Reclast, Zometa)
etidronate (Didronel)
pamidronate (Aredia)
tiludronate (Skelid)

The bisphosphonates inhibit bone resorption, increasing the mineral density of bones and reducing the incidence of fractures. They are used both in the prevention and treatment of osteoporosis. When used for Paget's disease, bisphosphonates slow the accelerated bone turnover associated with this disease.

Nursing Responsibilities

- Administer oral forms with water 30 minutes before food or other medications.
- Do not give foods high in calcium, vitamins with mineral supplements, or antacids within 2 hours of administering oral bisphosphonates.
- Instruct the patient to avoid lying down for 30 to 60 minutes after taking the drug.
- Assess renal function studies before initiating therapy; alendronate is not recommended for use in patients with renal insufficiency.
- Dilute the prescribed dose of intravenous preparations and administer by slow intravenous injection or infusion as recommended. Do not add to calcium-containing solutions such as Ringer's or lactated Ringer's solutions.
- Monitor the IV site for signs of thrombophlebitis.
- Assess the patient for signs of electrolyte imbalance or other adverse responses such as a drug fever.

Health Education for the Patient and Family

- Take the medication as directed with clear water only. Consuming other beverages or food within 30 minutes of taking the drug may interfere with its absorption and effectiveness.
- Do not lie down until after you have eaten because the drug can irritate the esophagus.
- Report symptoms such as new or worsening heartburn, difficult or painful swallowing, or jaw pain to your primary care provider.
- Fever with or without chills and flu-like symptoms may occur while receiving intravenous bisphosphonates; this will subside without treatment.
- Report any abnormal symptoms such as tingling around the mouth or numbness and tingling of the fingers or toes, which may indicate an imbalance of electrolytes in the blood.
- Take calcium and vitamin D supplements as instructed by your primary care provider.
- Response to these medications is gradual, and continues for months after the drug is stopped.

CALCITONIN

calcitonin–salmon (Fortical, Miacalcin)

In postmenopausal osteoporosis, calcitonin prevents further bone loss and increases bone mass if the patient consumes adequate amounts of calcium and vitamin D. Calcitonin may be used in combination therapy with a bisphosphonate or for patients who cannot use bisphosphonates.

Nursing Responsibilities

- Calcitonin is protein in nature; both the parenteral and nasal spray forms may cause an anaphylactic-type allergic response. Observe the patient for 20 minutes after administration; have appropriate emergency equipment and drugs available to treat anaphylaxis.
- Alternate nostrils daily when administering calcitonin nasal spray.
- Review medical history for conditions that contraindicate use of calcitonin products: hypersensitivity to calcitonin–salmon and lactation (calcitonin is secreted in breast milk and may inhibit lactation).
- Observe for side effects: nausea and vomiting, anorexia, mild transient flushing of the palms of the hands and the soles of the feet, and urinary frequency.
- Teach the patient the proper technique for handling and injecting the drug at home.

Health Education for the Patient and Family

- Take the medication in the evening to minimize side effects.
- Warm nasal spray to room temperature before using.
- Rhinitis (runny nose) is the most common side effect with calcitonin nasal spray. Other possible side effects include sores, itching, or other nasal symptoms. Report nosebleeds to your primary care provider.
- Nausea and vomiting may occur during initial stages of therapy; they disappear as treatment continues.
- While taking the medication, be sure to consume adequate amounts of calcium and vitamin D.

Note: Drugs identified in *italics* are among the 200 most commonly prescribed medications in the U.S.

Calcium supplements are available in many forms. Most supplements (including Tums) provide calcium carbonate in the range of 200 to 600 mg per tablet. Recommend limiting doses to no more than 600 mg of calcium as the amount absorbed declines at higher doses (Lindsay & Cosman, 2012). A combination of calcium with vitamin D is recommended, particularly for older adults who may have a vitamin D deficiency that impairs their ability to absorb and use calcium.

Exercise

Teach patients the importance of physical activity and weight-bearing exercises in preventing and slowing bone loss and reducing fall risk (Elliott, 2011). Suggest that patients participate in regular exercise such as walking, stair climbing, or tai chi for at least 20 minutes five or more times a week. Inform patients that swimming and pool aerobic exercises are not as beneficial for maintaining bone density because of the lack of weight-bearing activity.

Healthy Behaviors

Behaviors that help prevent osteoporosis include not smoking, avoiding excessive alcohol intake, and limiting caffeine intake to two or three cups of coffee each day.

Assessment

Collect the following data through the health history and physical examination:

- *Health history:* age, risk factors, history of fractures, smoking history, alcohol intake, medications, usual diet, menstrual history including menopause, usual exercise/activity level, low back pain
- *Physical assessment:* height, spinal curves; FRAX assessment (see Box 40–2).

BOX 40–2 Using FRAX to Assess Fracture Risk

FRAX (Fracture Risk Assessment) is a computer-based algorithm used to assess the probability of osteoporosis-related fracture in people ages 40 and older. It is readily available online and uses easily obtained clinical data, including:

- Age and gender
- Height and weight (to calculate BMI)
- Current smoking and alcohol consumption
- Previous personal or parental fracture
- Other risk factors (e.g., use of glucocorticoids, rheumatoid arthritis, diabetes)
- BMD if known.

Although the FRAX tool has limitations (Vernon & King, 2011), it can be used by nurses and other health professionals to help the patient and interprofessional team make informed decisions regarding BMD testing and osteoporosis treatment.

Priorities of Care

Although the immediate nursing focus for the patient with osteoporosis may change, depending on the setting and patient's condition, maintaining safety and preventing fractures are priorities of care.

Diagnoses, Outcomes, and Interventions

Nursing care of patients who have osteoporosis focuses on teaching about the disease process, helping maintain physical mobility and nutrition, and solving problems associated with pain and injury.

Readiness for Enhanced Self-Health Management

At multiple points in the patient's lifetime, nurses can provide vital information that will help patients use self-care strategies to reduce their risk of developing osteoporosis.

Expected Outcome: Patient will verbalize dietary, activity, and lifestyle measures to maintain bone health and prevent fracture.

- Assess the patient's health habits, including diet, exercise, smoking, and alcohol use. *The risk of developing osteoporosis in later life is affected by such things as diet, regular participation in weight-bearing exercise, and personal habits such as smoking and alcohol consumption (Elliott, 2011).*
- Teach women and men of all ages the importance of maintaining an adequate calcium intake. Provide a list of calcium-rich foods, and discuss the use of calcium supplements with patients who do not consume adequate dietary calcium. *Calcium needs vary during the course of a lifetime; however, many patients never consume adequate amounts of calcium. This affects their peak bone mass and the rate of bone loss with aging. Calcium in foods is more completely absorbed than that supplied by calcium supplements.*
- Discuss the importance of maintaining a regular schedule of weight-bearing exercise, either through an exercise program or regular physical activity. *Weight-bearing exercise promotes osteoblast activity, helping maintain bone strength and integrity.*
- Refer patients to smoking cessation programs and alcohol treatment programs as appropriate. *Smoking interferes with estrogen's protective effects on bones, promoting bone loss. Excess alcohol intake affects the nutritional status of the patient, increasing the risk of calcium and vitamin D deficiency.*
- Refer patients with significant risk factors for osteoporosis or fracture to primary care providers or clinics for bone density evaluation. *Early identification and treatment of osteoporotic changes in bones can reduce the risk and possible long-term consequences of falls and fractures.*

Risk for Injury

Falls that would result in little or no injury in the healthy adult may cause fractures in the patient with osteoporosis. Even normal movements such as twisting, bending, lifting, or rising from bed can precipitate a vertebral fracture.

Expected Outcome: Patient will remain free of osteoporosis-related fracture.

- Implement safety precautions as necessary for the patient who is hospitalized or in a long-term care facility. Maintain the bed in low position; use side rails if indicated to prevent the patient from getting up alone; provide nighttime lighting to toilet facilities. *Most falls are preventable, particularly in hospitals and long-term care facilities.*
- Avoid using restraints (if hospitalized or a resident in a long-term care facility) if at all possible. *Restraints may actually increase the patient's risk of falling and increase the risk of injury associated with a fall.*

SAFETY ALERT

Patients may fracture osteoporotic bones when pulling against restraints.

- Teach patients who are able to participate in weight-bearing exercises to perform exercises at least three times a week for a sustained period of 30 to 40 minutes. The mechanical force of weight-bearing exercises promotes bone growth. *Bones weaken and demineralize without exercise. Walking is an easy, low-impact form of exercise. Swimming (including walking on the bottom of the pool) does not provide the needed weight-bearing activity.*
- Encourage older adults to use assistive devices to maintain independence in ADLs. *Walking sticks, canes, and other assistive devices*

Evidence for Nursing Care

The Patient with Osteoporosis

Selected resources that nurses may find helpful when planning evidence-based nursing care follow.

CASE STUDY & NURSING CARE PLAN A Patient with Osteoporosis

Nancy Bauer is a 53-year-old woman who has smoked one pack of cigarettes a day for 30 years and drinks one to two glasses of wine with dinner each evening. She does not routinely exercise. Mrs. Bauer has had symptoms of menopause for 8 years, including hot flashes in the early years and mood swings of late. She has never been on hormone replacement therapy.

Mrs. Bauer is currently seeking medical advice for continuous low back pain. The pain is not relieved with an over-the-counter (OTC) analgesic, and she frequently wakes up during the night because of the pain. She is diagnosed with osteoporosis.

ASSESSMENT

The nurse practitioner notes that Mrs. Bauer's vital signs are within normal limits. She has full range of motion (ROM) of all extremities and is able to stand and bend over, but she reports discomfort when returning to the upright position. Mrs. Bauer has a slightly pronounced "hump" on her upper back and is 1 inch shorter than her stated height on admission. Her current height is 65 inches, weight is 145 pounds. Her muscle strength is symmetric and strong.

Clinical Reasoning in Patient Care

1. Locate the FRAX WHO Fracture Risk Assessment Tool online. Using the data provided, determine Mrs. Bauer's 10-year risk for experiencing a fracture.
2. Do you need additional data to complete this assessment? If so, what additional subjective and objective data will you obtain?
3. How will you explain the results of this calculation to Mrs. Bauer?

DIAGNOSES

- *Acute Pain* of the lower spine related to vertebral compression
- *Readiness for Enhanced Knowledge* related to osteoporosis and treatment to prevent further damage
- *Risk for Injury* related to effects of change in bone structure secondary to osteoporosis

EXPECTED OUTCOMES

- Patient will verbalize a decrease in back pain.
- Patient will be able to describe ways to treat her osteoporosis and prevent further complications.
- Patient will verbalize how stopping smoking can help prevent further progression of osteoporosis.
- Patient will seek consultation for supplements and medications to prevent further bone loss.
- Patient will design a program of physical activity to prevent complications of osteoporosis.
- Patient will verbalize safety precautions to prevent fractures due to falls.

PLANNING AND IMPLEMENTATION

- Teach back-strengthening exercises.
- Refer to an osteoporosis support group, if available.
- Provide realistic, yet optimistic, feedback about loss of height and bone integrity and the potential outcomes of treatment.
- Assess current knowledge base, and correct misconceptions regarding treatment of osteoporosis.
- Instruct in dietary and calcium supplements that help prevent effects of osteoporosis.
- Discuss physical exercises that help prevent complications due to osteoporosis.
- Review safety and fall precautions, and provide literature regarding how to create a safe home environment.

EVALUATION

On her return visit 6 months later, Mrs. Bauer reports that she feels much better. She is no longer irritable and does not experience mood swings, because she has been taking her prescribed hormone replacements for 6 months. She is eating products rich in calcium and taking a daily supplement of calcium with vitamin D. Mrs. Bauer has reduced her wine intake to one glass in the evening and now drinks decaffeinated coffee and tea. She also states that since she stopped smoking, she has been walking 30 to 45 minutes every day.

Clinical Reasoning in Patient Care

4. What is the rationale for stopping smoking and limiting caffeine and alcohol intake in the treatment of osteoporosis?
5. What foods would you encourage for patients at high risk for osteoporosis whose serum cholesterol and LDL/HDL ratios indicate a high risk for cardiovascular disease?
6. What physical activities would you consider beneficial in helping to prevent the effects of osteoporosis in the female patient who is wheelchair-bound or has limited mobility?

See Evaluating Your Response in Appendix B.

encourage patient independence and support activities that promote bone growth.

- Teach older patients about safety and fall precautions. *An assessment of the patient's home for safety and fall risks may reduce the risk of fractures and, in turn, the cost of hospitalization and potential disability and/or death.*

Readiness for Enhanced Nutrition

Most Americans do not maintain their recommended daily intake of calcium. Patients must therefore be made aware of the relationship between an adequate calcium intake and maintaining strong bones.

Expected Outcome: Patient will consume recommended amounts of calcium, vitamin D, and other nutrients daily.

- Teach adolescents, pregnant or lactating women, and adults through age 50 to eat foods high in calcium and to maintain a daily calcium intake of 1000 mg. *The NIH recommends a daily calcium intake of 1000 mg per day for all adults until age 50 years.*
- Encourage older adults and postmenopausal women to maintain a calcium intake of 1200 mg daily, either through diet or a calcium supplement. *Calcium needs for older adults and postmenopausal women are higher than for young adults.*
- Teach patients taking calcium supplements the importance of taking the medication at the proper time and the side effects that may occur. *Free hydrochloric acid is needed for calcium absorption. Calcium carbonate supplements (e.g., Tums) should be taken with food to allow adequate absorption. Calcium citrate supplements should be taken with meals to prevent gastrointestinal (GI) distress.*

PRACTICE ALERT!

Calcium supplements should be taken in divided doses (two to three times daily) for improved absorption.

Acute Pain

Advanced stages of osteoporosis can result in pain and limit mobility. Acute pain usually results from a complicating fracture, especially a compression fracture of the vertebrae.

Expected Outcome: Patient will report pain within an acceptable range.

- Suggest anti-inflammatory pain medications for treatment of both acute and chronic phases of pain. Patients should be instructed in the amount and frequency as noted on the manufacturer's labels. *Continuous administration of ibuprofen or other nonsteroidal anti-inflammatory drugs (NSAIDs) can be useful to provide relief from pain, but patients must be cautioned not to exceed dosage recommendations.*

SAFETY ALERT

Gastrointestinal bleeding is a risk for patients taking NSAIDs. Teach patients to watch for bright red bleeding from the stomach (in vomitus) or dark black bowel movements.

- Suggest the application of heat to relieve pain. *A heating pad may offer temporary pain relief. To avoid the "rebound effect," the heat should be removed every 20 to 30 minutes.*

Delegating Nursing Care Activities

With appropriate training and supervision, nursing care activities such as assisting with ambulation and daily living activities, and helping ensure safety for the patient with osteoporosis may be delegated to assistive personnel as allowed within their designated duties and responsibilities.

Continuity of Care

The patient who has osteoporosis needs education on safety and preventing falls. In addition to home safety, outdoor safety is important, too. Patients should be taught to use assistive devices for added stability, to wear rubber-soled shoes for traction, to walk on the grass when sidewalks are slippery, and to sprinkle salt or cat litter on icy sidewalks in the winter.

Address the following topics when discussing home care:

- Resources for medical supplies and assistive devices
- Diet, exercise, and medications
- Pain management
- Maintaining good posture to help prevent stress on the spine
- Helpful resources:
  - National Osteoporosis Foundation
  - Osteoporosis and Related Bone Diseases National Resource Center (NIH)
  - National Women's Health Resource Center
  - Older Women's League
  - American College of Rheumatology.

THE PATIENT WITH PAGET'S DISEASE OF BONE

Paget's disease of bone, also called *osteitis deformans*, is a progressive metabolic skeletal disorder that results from localized excessive metabolic activity in bone, with excessive bone resorption followed by excessive bone formation. This chronic remodeling results in the affected bones being larger and softer, causing bone pain, arthritis, obvious skeletal deformities, and fractures. The disorder can affect any bone or bones; however, the femur, tibia, pelvis, vertebrae, and skull are most commonly involved. It is the second most common bone disease in the United States.

Both genetic and environmental factors appear to play a role in the development of Paget's disease. A reported 15% to 25% of patients report a family history of Paget's disease. Viral particles have been found in osteoclasts of people with Paget's disease, suggesting that viral infection plays a role in its development (Favus & Vokes, 2012; Grossman & Porth, 2014).

Paget's disease occurs in both men and women, affecting about 3% of the population over the age of 40 in many countries. It is less common in native peoples of Africa, the Americas, Asia, and the Middle East (Favus & Vokes, 2012).

Pathophysiology

In Paget's disease, the number, size, and activity of osteoclasts increase significantly, resulting in excessive osteoclastic bone resorption and hyperemia in affected segments of bone. This initial phase of hyperactive bone resorption is followed by very active bone formation. In this phase, normal laminar bone is replaced by haphazard or disorganized bone. This bone is not as structurally sound as normal bone, and can bow and fracture more easily. During this phase, normal bone marrow may be replaced by fibrous connective tissue. When the excessive bone cell activity decreases in the third or "burned-out" phase of the disease, the newly formed bone becomes hard and brittle. This brittleness may lead to fractures. Multiple areas of the skeleton may be affected by Paget's disease, often in different phases at various sites.

Manifestations

Most patients with Paget's disease are asymptomatic for years, and the disease often is discovered when typical changes are seen on an incidental x-ray (Figure 40–2 ■). Manifestations are often vague and depend on the specific area involved (see the accompanying box). The most common manifestation is localized pain of the long bones,

MANIFESTATIONS OF PAGET'S DISEASE

MUSCULOSKELETAL EFFECTS

- Pain (in the long bones of lower extremities or joints and back), headache (with skull involvement)
- Deformity (enlargement of skull, bowing of lower extremities, and deformity of elbows and knees)
- Abnormal gait
- Increased head size
- Pathologic fractures (upper femur, pelvis)
- Compression fractures
- Collapse of the vertebrae, resulting in kyphosis and loss of height
- Muscle weakness

METABOLIC EFFECTS

- Symptoms of hypercalcemia in immobilized patients
- Hypercalciuria and renal calculi
- Increased skin temperature over affected bone

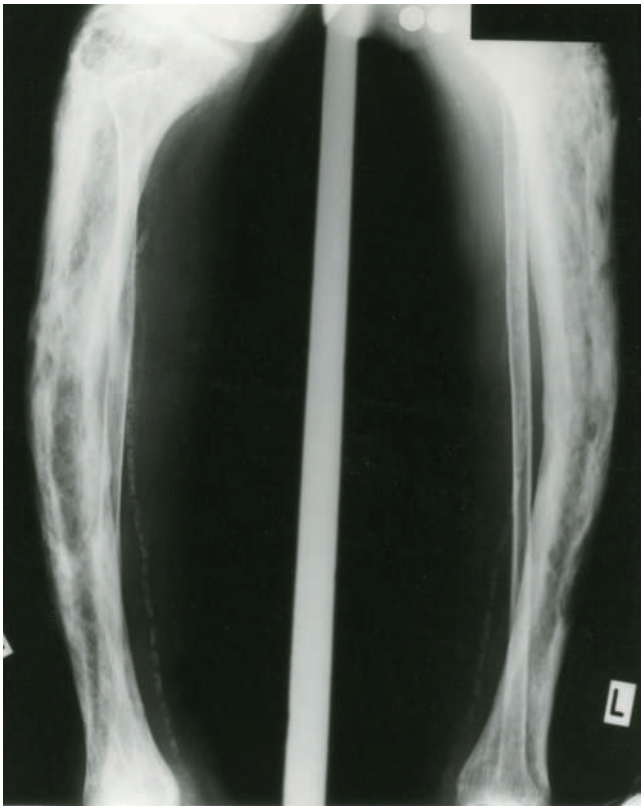

Figure 40–2 ■ An x-ray of a leg bone affected by Paget's disease. Note how the bone is misshapen, curved, and has a "punched-out" appearance.

spine, pelvis, and cranium. The pain is described as a mild to moderate deep ache that is aggravated by pressure and weight bearing. It is more noticeable at night or when the patient is resting. The pain usually is due to metabolic bone activity, secondary degenerative osteoarthritis, fractures, or nerve impingement. Because of the increase in blood flow to pagetic bone, flushing and warmth of the overlying skin may be apparent.

Complications

Pathologic fractures resulting from loss of bone structure are a serious complication of Paget's disease. Involvement of the skull and vertebrae may cause neurologic complications such as cranial nerve palsies, headache, paresis, and hearing loss. Cardiovascular disease resulting from increased vascularity of the affected bones is a common and serious complication of Paget's disease (Favus & Vokes, 2012; Grossman & Porth, 2014). Sarcomas, an uncommon complication, may develop.

●○● INTERPROFESSIONAL CARE

Care of the patient with Paget's disease focuses on relieving pain, suppressing active disease, and preventing or minimizing the effects of complications. Pharmacologic therapy is commonly used to treat Paget's disease.

DIAGNOSIS

Many of the diagnostic tests that are useful for the diagnosis of osteoporosis are equally useful for patients with Paget's disease (refer to Table 40–1). These include x-rays and bone scans to illustrate localized areas of demineralization in the early stages, seen as "punched-out" areas that lend a coarse, irregular appearance to the bone (refer to Figure 40–2). In the later phase, x-rays show enlargement of the bones, tiny cracks in the long bones, and/or bowing of the weight-bearing bones. Computed tomography (CT) scans and magnetic resonance imaging (MRI) help identify possible causes of pain, including degenerative problems, spinal stenosis, or nerve root impingement. A bone scan may be performed to determine the full extent of the disease.

Laboratory tests used in diagnosis include a serum alkaline phosphatase, which can increase dramatically in active disease; the normal level (30 to 115 International Units/L) may be elevated to over 3000 International Units/L when the disease is active.

MEDICATIONS

Bisphosphonates such as alendronate (Fosamax), pamidronate (Aredia), and tiludronate (Skelid) are the primary treatments used for Paget's disease. These drugs inhibit bone resorption, possibly by attaching to the surface of the calcium/phosphate phase of bone and inhibiting osteoclast activity. They are safe and usually are well tolerated by the patient. Bone pain is relieved, and the incidence of pathologic fractures is reduced. Cardiac and vascular manifestations of the disease also improve. Alendronate and several other bisphosphonates are available for oral administration. Oral preparations are poorly absorbed from the GI tract, and may cause gastric or esophageal irritation. They should be given with a full glass of water on an empty stomach, at least 30 minutes before other medications or food. Pamidronate is given as an intravenous infusion in D_5W or normal saline. It is given for 3 successive days, generally promoting a rapid response with reduced urinary excretion of hydroxyproline and pyridinium and a fall in alkaline phosphatase. Intravenous pamidronate may cause flu-like symptoms, but these generally are brief. Intravenous zoledronic acid (Zometa) also is approved for treating Paget's disease; one 5-mg infusion of this drug produces a prolonged response (more than a year) in most patients (Favus & Vokes, 2012). Calcium and vitamin D supplements also are prescribed for patients receiving bisphosphonates. After bisphosphonate treatment, patients often experience remission of symptoms for a year or more. See the Medication Administration box on page 1271 for nursing implications for bisphosphonates.

Patients who cannot tolerate bisphosphonate drugs may be treated with calcitonin. Calcitonin inhibits osteoclastic resorption of bone. Calcitonin is available in both parenteral and nasal spray forms. The parenteral form of calcitonin is used in treating Paget's disease. (Refer to the Medication Administration box on page 1271 for nursing implications.)

Treatments to suppress Paget's disease activity (bisphosphonates or calcitonin) generally are effective to relieve pain associated with the disease. Pain due to complications such as bone deformity, arthritis, or neurologic complications may be treated with an analgesic such as acetaminophen or with NSAIDs (Paget Foundation, 2012b).

SURGERY

Surgical interventions may be necessary for patients with Paget's disease, such as repairing a complete fracture through pagetic bone, realigning a knee through tibial osteotomy to decrease pain, or

replacing a hip and/or knee for osteoarthritis. Excessive operative bleeding is a risk in Paget's disease due to increased vascularity of affected bone. Pretreatment with a potent bisphosphonate reduces disease activity prior to surgery and decreases the risk of excessive operative blood loss (Paget Foundation, 2012b).

●○● NURSING CARE

Priorities of Care

The nursing interventions for the patient with Paget's disease focus on pain control, prevention of injury or fractures, and education regarding the disease process and prescribed therapies.

Diagnoses, Outcomes, and Interventions

Because Paget's disease often goes unrecognized until it is advanced, it is important for nurses to recognize its manifestations and seek additional information from the patient when those manifestations are present.

Chronic Pain

The most common manifestation of Paget's disease is bone pain. This usually is the manifestation that prompts the patient to seek healthcare.

Expected Outcome: Patient will verbalize an understanding of the relationship of pain to disease activity.

- Assess the location and extent of the pain to determine the bone areas involved. *Bone pain in Paget's disease may be poorly localized and described as "aching and deep."*
- Explain the relationship between pain and disease activity and the importance of overall disease management to improve comfort. *Pain associated with Paget's disease often is relieved by treatment to suppress disease activity (Paget Foundation, 2012a).*
- Teach the patient to take NSAIDs on a regular basis as prescribed. Acetaminophen may be taken as needed for pain (Paget Foundation, 2012b). *Pain is most noticeable at night or when the patient is resting. The pain can become evident when it is aggravated by pressure and weight bearing.*
- Ensure correct placement of prescribed brace or corset. The patient may be required to wear a light brace or corset to relieve back pain and provide support when assuming an upright position. *The patient may need instruction in the correct application of the device and in the evaluation of pressure areas that may result from wearing the device.*

Impaired Physical Mobility

Patients with Paget's disease need to maintain or improve mobility so that they can perform necessary self-care activities and prevent complications of immobility.

Expected Outcome: Patient will be able to maintain activities and mobility without experiencing complications such as fracture.

- Provide an assistive device for use when ambulating. *During the active phase of Paget's disease, the patient is prone to fractures. Bone deformities, activity intolerance, fear of falling, and pain are all factors that may make the patient more prone to falls. An assistive device can provide both physical and psychologic support during ambulation, permit the patient to ambulate further, and provide a device for resting during ambulation.*
- Teach good body mechanics. *The patient with bone deformities should avoid activities that require lifting and twisting. In the patient with Paget's disease, activities as seemingly simple as lifting a heavy box may result in a fracture.*
- Reinforce information about exercise protocols and activity regimens. *Exercise and activity protocols should be planned carefully to prevent injury and to minimize fatigue.*

Continuity of Care

A diagnosis of Paget's disease can be frightening for the patient and family. It is important that they understand that this is a treatable disease, and that many manifestations of the disease will be relieved with treatment. Inform the patient that remissions of the disease often last for a year or more after effective treatment. The Paget Foundation should be suggested as a resource. Discuss the following topics:

- The importance of following the prescribed treatment regimen and keeping scheduled follow-up appointments
- Because it may take several weeks to notice a response to treatment, the importance of continuing therapy during this time and after a response is obtained
- If bisphosphonates such as alendronate or pamidronate are ordered, the importance of taking supplemental calcium to prevent low blood calcium levels
- The importance of remaining active
- Safety in the home and outdoor environment to prevent falls
- The need to report to the primary care provider any sudden pain or disability, even if no trauma has occurred, because pathologic fractures are possible.

THE PATIENT WITH GOUT

Gout is a metabolic disorder characterized by an episodic acute inflammatory arthritis triggered by crystallization of urate within the joints. It develops in response to an excess of uric acid in the body, resulting in high levels of uric acid in the blood (hyperuricemia) and deposition of urate crystals in synovial fluid and other tissues (Khanna, Fitzgerald, et al., 2012). Deposits in the synovial fluids cause acute inflammation of the joint (*gouty arthritis*). Acute gouty arthritis typically has an abrupt onset, usually at night, and often involves the first metatarsophalangeal joint (great toe). The initial acute attack is usually followed by a period of months or years without manifestations. As the disease progresses, urates are deposited in various other connective tissues. Urate deposits in subcutaneous tissues cause the formation of small white nodules called **tophi**. Deposits of crystals in the kidneys can form urate kidney stones and result in kidney failure.

Gout affects an estimated 8.3 million Americans, the majority of whom are men (Schumacher & Chen, 2012). In women, attacks of gout are rarely seen until after menopause. The incidence and prevalence of gout are increasing (Khanna, Fitzgerald, et al., 2012).

A number of risk factors for gout have been identified (Box 40–3). Of these, male gender and aging cannot be modified; the others can be. Obesity and metabolic syndrome (abdominal obesity, hyperlipidemia, hypertension, and insulin resistance) are strongly correlated

BOX 40–3 Risk Factors for Gout

- Male gender
- Age
- Hypertension
- Obesity
- Metabolic syndrome
- Type 2 diabetes mellitus
- Chronic kidney disease
- Medications: diuretics, aspirin

with hyperuricemia and gout (Choi, 2009). The role of diet as a risk factor for gout appears to relate primarily to its contribution to chronic diseases such as obesity, metabolic syndrome, and type 2 diabetes (Khanna, Fitzgerald, et al., 2012). Consumption of a diet rich in meat and seafood is associated with a higher risk of developing gout. Although alcohol intake has long been known to increase the risk for hyperuricemia and gout, recent studies have shown that consumption of soft drinks sweetened with sugar or fructose (corn syrup) also increases the risk for gout in men.

Pathophysiology

Uric acid is the breakdown product of purine metabolism. Normally, a balance exists between its production and excretion, with approximately two-thirds of the amount produced each day excreted by the kidneys and the rest in the feces. The serum uric acid level is normally maintained between 3.5 and 8.0 mg/dL in men and 2.8 and 6.8 mg/dL in women. At levels greater than 8.0 mg/dL, the serum is saturated with urate, the ionized form of uric acid. As the concentration increases, plasma becomes supersaturated, creating a risk for formation of monosodium urate crystals. Hyperuricemia results from either an underexcretion of uric acid by the kidneys or an overproduction of uric acid. In hyperuricemia, increased urate levels are present in other extracellular fluids, including synovial fluid, as well as in plasma. Synovial fluid, however, is a poorer solvent for urate than plasma, increasing the risk for urate crystal formation.

Monosodium urate crystals may form in the synovial fluid or in the synovial membrane, cartilage, or other joint connective tissues. Crystals tend to form in peripheral tissues of the body, where lower temperatures reduce the solubility of the uric acid. They may also form in connective tissue and the kidneys. These crystals stimulate and continue the inflammatory process, during which neutrophils respond by ingesting the crystals. The neutrophils release their phagolysosomes, causing tissue damage, which perpetuates the inflammation. Ultimately, the inflammatory process destroys joint cartilage and underlying bone.

Manifestations

The manifestations of gout range from asymptomatic hyperuricemia to repeated episodes of acute gouty arthritis, and advanced gout with chronic arthritis and the development of tophi. See the accompanying Manifestations box.

Early gout is characterized by asymptomatic hyperuricemia, with serum levels averaging 9 to 10 mg/dL. Most people with hyperuricemia do not progress to further stages of the disease.

MANIFESTATIONS OF GOUT

ACUTE GOUTY ARTHRITIS

- Usually monoarticular, affecting metatarsophalangeal joint of great toe, instep, ankle, knee, wrist, or elbow
- Acute pain
- Red, hot, swollen, and tender joint
- Fever, chills, malaise
- Elevated WBC and sedimentation rate

ADVANCED GOUT

- Tophi evident on joints, bursae, tendon sheaths, pressure points, helix of ear
- Joint stiffness, limited ROM, and deformity
- Ulceration of tophi with chalky discharge

An acute gouty arthritis attack, usually affecting a single joint, occurs unexpectedly, often beginning at night. An attack may be triggered by trauma, alcohol ingestion, dietary excess, or a stressor such as surgery. The affected joint becomes red, hot, swollen, and exquisitely painful and tender.

Approximately 50% of initial attacks of acute gouty arthritis occur in the metatarsophalangeal joint of the great toe. Other sites for acute attacks include the instep of the foot, ankles, heels, knees, wrists, fingers, and elbows. The pain, often intense, peaks within several hours and may be accompanied by fever and an elevated white blood cell (WBC) count and sedimentation rate. The affected joints are swollen, and the skin over the joint is warm and dusky red (Figure 40–3 ■).

Acute attacks of gouty arthritis last from several hours to up to 10 days and typically subside spontaneously. Approximately 60% of people experience a recurrent attack within 1 year. Successive attacks tend to last longer, occur with increasing frequency, involve more than one joint, and resolve less completely than the initial attack.

When hyperuricemia is not treated, the urate pool expands, and urate crystal deposits (tophi) develop in cartilage, synovial membranes, tendons, and soft tissues. They are seen most often in the helix of the ear, in tissues surrounding joints and bursae (especially around the elbows and knees), along tendons of the fingers or ankles, and on ulnar surfaces of the forearms. The skin over tophi may ulcerate, exuding chalky material containing inflammatory cells and urate crystals. Tophi can also develop in the tissues of the heart and spinal epidura. Although tophi themselves are not painful,

Figure 40–3 ■ Acute gouty arthritis affecting the distal interphalangeal joints of an elderly woman.

they may restrict joint movement and cause pain and deformities of the affected joints. Tophi may also compress nerves and erode and drain through the skin.

Complications

Kidney disease may occur in patients with untreated gout, particularly when hypertension is also present. Urate crystals are deposited in interstitial tissue of the kidneys. Uric acid crystals also form in the collecting tubules, renal pelvis, and ureter, forming stones. The stones can range in size from a grain of sand to a massive structure filling the spaces of the kidney. Uric acid stones can potentially obstruct urine flow and lead to acute kidney injury.

●○● INTERPROFESSIONAL CARE

The classic presentation of acute gouty arthritis is so distinctive that the diagnosis can often be based on the patient's history and physical examination. Treatment is directed toward terminating an acute attack, preventing recurrent attacks, and reversing or preventing complications resulting from crystal deposition in tissues and formation of uric acid kidney stones. Lifestyle changes such as weight loss, exercise to achieve physical fitness, smoking cessation, reduced intake of foods rich in purines or containing high-fructose corn syrup, and limited alcohol intake are important to reduce serum uric acid levels. Because of the association between hyperuricemia, hypertension, and the metabolic syndrome, patients with asymptomatic hyperuricemia and gout should undergo cardiovascular risk factor screening.

DIAGNOSIS

Diagnostic testing is performed to establish an accurate diagnosis and direct long-term therapy.

The serum uric acid level is nearly always elevated (usually above 8.5 mg/dL) in patients with gout, but may actually be low or within the normal range during an acute attack (Schumacher & Chen, 2012). The WBC count shows significant elevation, reaching levels as high as 20,000/mm^3 during an acute attack. Erythrocyte sedimentation rate (ESR or sed rate) is elevated during an acute attack from the acute inflammatory process that accompanies deposits of urate crystals in a joint. Serum creatinine is obtained to evaluate kidney function. In addition, a 24-hour urine specimen is analyzed to determine uric acid production and excretion, and analysis of fluid aspirated from the acutely inflamed joint or material aspirated from a tophus shows typical needle-shaped urate crystals, providing the definitive diagnosis of gout.

MEDICATIONS

Medications are used to terminate an acute attack, prevent further attacks, and reduce serum uric acid levels to prevent long-term sequelae of the disease. It is important to treat the acute attack of gouty arthritis before initiating treatment to reduce serum uric acid levels, because an abrupt decrease in serum uric acid may lead to further acute manifestations. Pharmacologic therapy is a mainstay of treatment in achieving these goals.

ACUTE ATTACK Treatment for an acute gouty arthritis attack may be initiated with a nonsteroidal anti-inflammatory drug, systemic corticosteroid, or colchicine. NSAIDs are the treatment of choice for most patients experiencing an acute attack of gout. Indomethacin (Indocin) is the most frequently used NSAID for acute attacks. Other NSAIDs that may be prescribed include naproxen (Naprosyn, Anaprox), or sulindac (Clinoril), although anti-inflammatory doses of other NSAIDs may be equally effective (Khanna, Khanna, et al., 2012). Although extremely effective, NSAIDs are contraindicated for patients with active peptic ulcer disease, impaired renal function, or a history of hypersensitivity reactions to the drugs. As with other anti-inflammatory drugs, patients should be aware of possible risks and follow recommended doses carefully.

Colchicine may be used to terminate an acute attack. Joint pain begins to diminish within 12 hours of the initiation of treatment and disappears within 2 days. Colchicine apparently acts by interrupting the cycle of urate crystal deposition and inflammation in an acute attack of gout. It has no anti-inflammatory effect in other forms of arthritis, and its use is limited to gout. The use of colchicine is limited by significant side effects. When administered orally, many patients develop abdominal cramping, diarrhea, nausea, or vomiting. It is contraindicated for patients who have significant GI, renal, hepatic, or cardiac disease.

Corticosteroids may be prescribed for the patient with acute gouty arthritis. The intra-articular route may be used for monoarticular arthritis to avoid the multiple systemic effects of steroid therapy. When multiple joints are involved, corticosteroids may be administered either orally or parenterally.

PROPHYLACTIC THERAPY In addition to dietary and lifestyle modifications, pharmacologic therapy to lower uric acid levels is recommended for patients with gout (Khanna, Fitzgerald, et al., 2012).

Allopurinol (Zyloprim) or febuxostat (Uloric) is the drug of choice for lowering serum urate levels (Khanna, Fitzgerald, et al., 2012). These drugs are xanthine oxidase inhibitors that lower plasma uric acid levels and facilitate the mobilization of tophi. Because of their effectiveness in lowering serum uric acid levels, initiation of therapy may trigger an attack of acute gout.

Uricosuric drugs block the tubular reabsorption of uric acid, promoting its excretion and reducing serum levels. Uricosuric agents are primarily used for patients who do not eliminate uric acid adequately or who cannot tolerate allopurinol. These drugs reduce the frequency of acute attacks, particularly when administered with colchicine. Probenecid (Benemid) and sulfinpyrazone (Aprazone, Anturane, Zynol) are the primary uricosuric drugs employed.

Pegloticase (Krystexxa), an enzyme that prompts the conversion of uric acid to a metabolite excreted by the kidneys, is a relatively new antigout medication. This drug is administered by intravenous infusion and carries a risk for anaphylaxis (Wilson et al., 2013).

The nursing implications for medications used to treat gout are included in the Medication Administration box.

COMPLEMENTARY AND ALTERNATIVE THERAPIES

A variety of nutritional and herbal supplements may be used to help prevent gout or decrease the onset of manifestations. These include the following:

- Vitamin E and selenium may decrease tissue inflammation.
- Amino acids (alanine, aspartic acid, glutamic acid, and glycine) increase the ability of the kidneys to excrete uric acid.

MEDICATION ADMINISTRATION

The Patient with Gout

XANTHINE OXIDASE INHIBITORS

allopurinol (Alloprin, Zyloprim, Others)

febuxostat (Uloric)

Xanthine oxidase inhibitors act on purine metabolism, reducing the production of uric acid and decreasing serum and urinary concentrations of uric acid. They are used for patients with manifestations of primary or secondary gout, including acute attacks, tophi, joint destruction, urinary stones, and nephropathy.

Nursing Responsibilities

- Monitor intake and output.
- Monitor for desired effect of decreased serum uric acid levels, and for adverse effects such as nausea, diarrhea, and rash.
- Assess renal and liver function tests prior to the initiation of and during treatment. Report signs of impaired renal or liver function to the physician.
- Administer with meals to minimize gastric distress.
- Monitor CBC periodically because allopurinol therapy may cause bone marrow depression.
- Allopurinol interacts with multiple drugs; check for potential interaction before administering any other medications.
- Discontinue allopurinol and notify the physician immediately if the patient develops a rash or fever. These symptoms may indicate potentially life-threatening drug toxicity.

Health Education for the Patient and Family

- Stop taking the drug and report any skin rash, painful urination, blood in the urine, eye irritation, or swelling of the lips or mouth to the physician immediately.
- Take the medication after meals to minimize gastric distress.
- Drink 3 to 4 quarts of fluid daily to maintain a urinary output greater than 2 L/day.
- Acute gouty attacks may occur during the initial stages of therapy; continue therapy prescribed for attacks (such as colchicine or an NSAID) to minimize acute episodes.
- Do not take a double dose of medication if you miss a dose.

ANTIGOUT MEDICATION

colchicine

Colchicine is used to treat acute gouty arthritis and prevent recurrent episodes of the disease. Colchicine does not alter serum uric acid levels, but appears to interrupt the cycle of urate crystal deposition and inflammatory response. It is given once or twice daily by mouth. Colchicine is also available as a fixed-dose combination with a uricosuric agent, probenecid (Benemid).

Nursing Responsibilities

- Assess for possible contraindications to colchicine therapy, including serious GI, renal, hepatic, or cardiac disease.
- Administer oral colchicine on an empty stomach to facilitate absorption.
- Evaluate for adverse effects, including abdominal cramping, nausea, vomiting, and diarrhea, and report promptly because these side effects may necessitate discontinuation of the drug.

Health Education for the Patient and Family

- Drink 3 to 4 quarts of liquid per day.
- Report adverse responses, including GI problems, fatigue, bleeding, easy bruising, or recurrent infections, to the physician.
- Do not drink alcohol.

URICOSURIC DRUGS

probenecid (Benemid)

sulfinpyrazone (Anturane)

Probenecid is a uricosuric drug that inhibits the tubular reabsorption of urate, promoting the excretion of uric acid and decreasing serum uric acid levels. Sulfinpyrazone is a uricosuric drug that potentiates the renal excretion of uric acid, reducing serum uric acid levels. These drugs are used to prevent recurrent attacks of acute gouty arthritis and treat chronic gout.

Nursing Responsibilities

- Assess for prior hypersensitivity responses to the drug.
- Administer after meals or with milk to minimize gastric distress.
- Do not administer these drugs during or within the 2 to 3 weeks following an attack of acute gouty arthritis.
- Increase fluid intake to at least 3 L/day to prevent the formation of uric acid kidney calculi.
- Do not administer aspirin or products containing aspirin to patients receiving these drugs because salicylates interfere with the action of the drug.
- These drugs interact with multiple other medications; check for interactions before administering any drug to a patient taking one of these drugs.
- Monitor for and report possible adverse or toxic effects, including headache, dizziness, nausea and vomiting, bone marrow depression, hypersensitivity responses, and impaired kidney or liver function.
- Assess for contraindications to therapy with sulfinpyrazone, including active peptic ulcer disease, a history of hypersensitivity to phenylbutazone or other pyrazoles, or blood dyscrasias.

Health Education for the Patient and Family

- Do not take aspirin or products containing aspirin while taking this drug. Use acetaminophen for relief of mild pain.
- Drink at least 3 quarts of fluids per day to minimize the risk of kidney stone formation.
- Take the drug with or after meals to minimize gastric distress, and report epigastric pain, nausea, or black stools to the physician promptly.

Note: Drugs identified in *italics* are among the 200 most commonly prescribed medications in the U.S.

- Dark reddish-blue berries (such as cherries and blackberries) are good sources of flavonoids, which help lower uric acid levels, decrease inflammation, and prevent or repair joint tissue damage.
- Acupuncture can provide pain relief.

TREATMENTS

Treatments for gout, in addition to medications, include dietary management and rest.

NUTRITION Dietary purines contribute only slightly to uric acid levels in the body, and no specific diet may be recommended. Current evidence-based recommendations are that patients with gout limit their intake of purine-rich foods such as organ meats and certain seafoods (e.g., sardines and shellfish), as well as drinks sweetened with high-fructose corn syrup. Intake of low-fat or non-fat dairy products and vegetables, including purine-rich vegetables like spinach, asparagus, cauliflower, and mushrooms, is encouraged. The patient who is obese is advised to lose weight, but fasting is contraindicated for patients with gout. Alcohol intake should be limited, and avoided altogether during an acute gouty arthritis attack (Khanna, Fitzgerald, et al., 2012). A liberal fluid intake to maintain a daily urinary output of 2000 mL or more is

recommended to increase urate excretion and reduce the risk of urinary stone formation.

REST During an acute attack of gouty arthritis, rest of the involved joint(s) is prescribed. The affected joint may be elevated and ice packs applied for comfort.

●○● NURSING CARE

Patients with gout provide self-care at home. Teaching focuses on self-management of pain and altered mobility.

Diagnoses, Outcomes, and Interventions

Pain is a primary focus for nursing interventions in the patient experiencing an acute attack of gout. The patient's mobility is also impaired during an acute attack, both because of pain and prescribed activity limitations.

Acute Pain

The pain associated with an attack of acute gouty arthritis is intense and accompanied by exquisite tenderness of the affected joint. Measures to alleviate the pain are vital in the initial period until anti-inflammatory medications become effective and the acute inflammatory response is relieved. The following are important in teaching about pain relief.

Expected Outcome: Patient will verbalize measures to effectively manage the pain of acute gouty arthritis.

- Position the affected joint for comfort. Elevate the joint or extremity (usually the foot) on a pillow, maintaining alignment. A cold pack or ice may be applied intermittently to the affected joint(s), protecting the skin from cold injury. *Elevation and normal body alignment facilitate blood return from the affected joint, alleviating some of the edema. Ice is identified as an appropriate adjunctive measure to reduce pain and inflammation associated with acute gouty arthritis (Khanna, Khanna, et al., 2012).*
- Protect the affected joint from pressure, placing a foot cradle on the bed to keep bed covers off the foot. *A foot cradle keeps bed linens from applying pressure on the affected joint.*
- Take anti-inflammatory and antigout medications as prescribed. In the initial period, colchicine may be given several times a day. *These medications reduce the acute inflammatory response, gradually relieving discomfort. Taking the medications around the clock is important to attain and maintain a therapeutic blood level.*
- Take analgesics as prescribed. Avoid aspirin. *Supplemental analgesia may be necessary in the acute period until the inflammatory response is mediated. Aspirin interferes with the action of some anti-inflammatory drugs.*
- Maintain joint rest. *It is important to immobilize the affected joint and promote rest to prevent exacerbation of joint inflammation.*

Continuity of Care

Discuss the following topics with the patient:

- *The disease and its manifestations.* Tell the patient that initial attacks cause no permanent damage but that recurrent attacks can lead to permanent damage and joint destruction. Discuss other potential effects of continued hyperuricemia, including tophaceous deposits in subcutaneous and other connective tissues. Discuss the potential for kidney damage and kidney stones.
- *The rationale for and use of prescribed medication.* Stress the need to continue the medication until the physician discontinues it, even though the patient is free of manifestations of gout. Tell the patient to avoid, if possible, drugs that increase uric acid blood levels: hydrochlorothiazide (HydroDIURIL), cyclosporine (Neoral, Sandimmune), furosemide (Lasix), and high doses of aspirin. Patients who need to reduce their risk of heart attacks may safely take one baby aspirin each day.
- *The importance of a high intake of fluids each day and avoiding the use of alcohol.*

THE PATIENT WITH OSTEOMALACIA

Osteomalacia, often referred to as adult rickets, is a metabolic bone disorder characterized by inadequate or delayed mineralization of bone matrix in mature compact and spongy bone, resulting in softening of bones. Bone mineralization requires adequate calcium and phosphate ions in extracellular fluid. When either of these ions is insufficient due to (1) inadequate calcium intake or decreased calcium absorption from the intestines, or (2) increased renal losses or decreased intestinal absorption of phosphate, the bone matrix is not mineralized and cannot sustain weight bearing. Marked deformities of weight-bearing bone and pathologic fractures occur. Vitamin D deficiency is the most common cause of osteomalacia.

Osteomalacia has been rare in the United States because many foods are fortified with vitamin D, but its incidence is increasing among older adults and people who have limited sun exposure. In the United States, nearly 30% of postmenopausal women and 25% of men over age 65 have low vitamin D levels. Among institutionalized older adults, the incidence exceeds 60% (Fitzgerald, 2012).

The major risk factors for vitamin D deficiency are a diet low in vitamin D, inadequate sun exposure, impaired intestinal absorption of fats (vitamin D is a fat-soluble vitamin), liver or kidney disorders that interfere with the metabolism of vitamin D to its active forms, and certain drugs (Box 40–4). Aging plays a role; the body's ability to synthesize vitamin D in response to sun exposure declines with aging (Tabloski, 2014).

Hypophosphatemia can result from insufficient dietary intake, excessive losses through the urine or stool, or a shift into the cells. Alcohol abuse is the most common cause of hypophosphatemia, because of related dietary deficiencies, vomiting, antacid use, and increased renal excretion of phosphate. Ingesting large amounts of nonabsorbable antacids increases phosphate losses in the stool. Several acquired and genetic disorders cause increased losses of phosphate in the urine.

Pathophysiology

The two main causes of osteomalacia are (1) insufficient calcium absorption in the intestine due to a lack of calcium intake or vitamin D deficiency or resistance, and (2) decreased phosphate absorption or increased losses of phosphate through the urine (Grossman & Porth, 2014). In its natural form, vitamin D is obtained from certain foods and ultraviolet radiation of the sun. Vitamin D maintains adequate serum levels of calcium and phosphate for normal mineralization of

BOX 40–4 Causes of Osteomalacia

VITAMIN D DEFICIENCY
- Inadequate dietary intake
- Lack of sun exposure
- Malabsorption: gastric bypass, small-bowel disorders, gallbladder disease, chronic pancreatic insufficiency, treatment with orlistat (Alli, Xenical) or cholestyramine (LoCHOLEST, Questran)
- Drug effects: isoniazid, rifampin, anticonvulsants

PHOSPHATE DEPLETION
- Inadequate intake
- Impaired absorption due to chronic antacid use
- Impaired renal tubular reabsorption due to either acquired or genetic disorders

SYSTEMIC ACIDOSIS
- Renal tubular acidosis
- Ureterosigmoidostomy
- Fanconi's syndrome

BONE MINERALIZATION INHIBITORS
- Hypophosphatasia
- Sodium fluoride or disodium etidronate (Didronel)
- Aluminum intoxication

CHRONIC KIDNEY DISEASE

CALCIUM MALABSORPTION

the bone. Vitamin D deficiency or resistance to its action disrupts the normal mineralization of the bone, causing softening of the bone.

Vitamin D is inactive when it is absorbed from the intestine or synthesized from exposure to ultraviolet light. For vitamin D to become active, a two-step process must occur. Vitamin D (and its metabolites) is transported in the blood to the liver, where it is converted to calcidiol. Calcidiol is then transported to the kidney and transformed to an active form, calcitriol.

The active form of vitamin D is needed for optimal absorption of calcium and phosphorus from the intestine. Calcium and phosphorus are transported in the blood to the bones for normal mineralization. If vitamin D is deficient, calcium and phosphorus are not absorbed from the intestine, and serum calcium and phosphorous levels therefore fall. A deficiency in these minerals in turn activates the parathyroid glands, with loss of calcium and phosphorus from bone. The continued loss of calcium and phosphate in the bone disrupts bone mineralization.

Impaired bone mineralization causes abnormalities in both spongy and compact bone. The osteoid (the soft, noncalcified part of the matrix) continues to be produced but is not mineralized. This abnormal buildup of demineralized bone leads to gross deformities of the long bones, spine, pelvis, and skull, because the bone is soft and unable to bear the weight and stress of body movement.

Manifestations

Muscle fatigue and weakness, manifestations of vitamin D deficiency, may be noted before overt manifestations of osteomalacia are seen. The manifestations of osteomalacia include bone pain and tenderness (see the accompanying box). Fractures occur as the disease progresses. In contrast to osteoporosis, osteomalacia is not associated with a significant occurrence of hip fractures. Instead, pathologic fractures occur in the commonly weakened areas (e.g., distal radius and proximal femur).

MANIFESTATIONS OF OSTEOMALACIA
- Bone pain: may be vague and generalized at first, becoming more intense with activity as the disease progresses; occurs most frequently in the pelvis, long bones of the extremities, spine, and ribs
- Muscle weakness: may be an early sign of vitamin D deficiency
- Difficulty changing from lying to sitting position and sitting to standing position
- Waddling gait: may be due to pain and muscle weakness
- Dorsal kyphosis: may occur in severe cases
- Pathologic fractures

●○● INTERPROFESSIONAL CARE

Osteomalacia may be difficult to differentiate from osteoporosis because the manifestations are very similar; however, once the specific cause is determined, appropriate therapy will correct the disorder.

DIAGNOSIS

A history of inadequate dietary intake, chronic kidney disease, or some malabsorption states may suggest osteomalacia. Table 40–1 compares the diagnostic findings of osteomalacia with those of osteoporosis and Paget's disease. X-rays demonstrate the effects of generalized bone demineralization: trabecular bone loss, cyst formation, compression fractures, bowing and bending deformities of the long bones, and osteoid deposits, particularly in the vertebral bodies and pelvis.

Laboratory tests include serum calcium, parathyroid hormone, phosphate, vitamin D (25-hydroxy $[OH]D_3$ or $1.25[OH]_2D_3$), and alkaline phosphatase levels. Calcium may be normal or low, depending on the cause of the disease. Calcium levels may be reduced when calcium absorption is impaired or in severe vitamin D deficiency. Secondary hypoparathyroidism may shift calcium from the bone into extracellular fluid, maintaining a normal serum calcium level. Parathyroid hormone is frequently elevated as a compensatory response to hypocalcemia in renal failure or vitamin D deficiency. Alkaline phosphatase usually is elevated.

MEDICATIONS

Therapeutic management of osteomalacia usually involves administration of calcium and vitamin D (800 International Units daily) supplements. Patients in whom metabolic activation of vitamin D is impaired may require a metabolite of the vitamin that does not require activation, such as ergocalciferol (D_2). Phosphate supplements may be indicated. Radiologic evidence of healing often is apparent within weeks of initiating therapy.

●○● NURSING CARE

Managing the patient with osteomalacia includes assessing the patient's current dietary intake of vitamin D, calcium, and phosphorus and exposure to ultraviolet light. It also includes managing patient responses to bone pain and tenderness, fractures, and muscle weakness.

Teaching is important, not only for the patient with osteomalacia, but also for people at risk for developing the disease. When milk and other dairy products began to be fortified with vitamin D, the incidence of childhood rickets decreased dramatically. Now many patients are unaware of the importance of vitamin D, calcium, and phosphorus to bone health.

Older adults as a group are at high risk for osteomalacia because of dietary deficiencies, age-related intestinal malabsorption, less effective vitamin D synthesis, and possible physical mobility limitations that restrict their exposure to sunlight. Teach older adults about the importance of maintaining an adequate intake of milk and other dairy products that are not only rich in calcium and phosphorus, but also are fortified with vitamin D. Few other food sources provide enough vitamin D to meet recommended levels. Cod liver oil may be used as a supplement because it contains significant amounts of vitamin D. Supplements are not recommended, however, for patients who get adequate vitamin D through dietary sources and sun exposure, because this fat-soluble vitamin may become toxic at very high levels. Instruct patients who are taking supplements to report to their primary care provider symptoms such as anorexia, nausea and vomiting, frequent urination, muscle weakness, and constipation that may be indicative of hypervitaminosis D.

Teach the patient with osteomalacia about safety measures to prevent falls. Discuss the importance of eliminating scatter rugs and clutter from living areas to prevent tripping. Teach the patient to place a night-light in hallways and the bathroom to prevent falls associated with nighttime toileting. Suggest installing grab bars in the shower and tub and next to the toilet for safety.

Teach patients with bone pain and muscle weakness to use assistive devices such as walkers, canes, or crutches when ambulating. Provide referrals to physical therapy for teaching patients how to safely use these devices. Encourage patients to participate in a supervised exercise program such as water aerobics or tai chi to improve muscle strength and balance.

Degenerative Disorders

Degenerative joint disorders, osteoarthritis in particular, are among the most common causes of pain and disability in older adults. Muscular dystrophy, a degenerative muscle disorder, affects significantly fewer people but can have devastating effects.

THE PATIENT WITH OSTEOARTHRITIS

Osteoarthritis (OA) (also labeled *degenerative joint disease*) is the most commonly occurring of all forms of arthritis, and a leading cause of pain and disability in older adults (CDC, 2011b). This disease is characterized by progressive loss of joint cartilage, synovitis (inflammation of the synovium lining the joint), joint pain, stiffness, and loss of joint motion. OA may be idiopathic (without known cause) or secondary (associated with known risk factors), although it may be difficult to differentiate between primary and secondary OA.

OA affects nearly 27 million Americans; it is uncommon in adults under age 40 and prevalent in older adults (CDC, 2011b). While nearly all older adults have x-ray evidence of OA, many have no symptoms of the disorder (Felson, 2012). Men are affected more than women at an earlier age, but the rate of OA in women exceeds men by the middle adult years. The joints most affected are in the hand, neck, lower back, hip, and knee. Men are more likely than women to have hip OA, whereas postmenopausal women more often have hand OA.

While x-ray evidence of OA of the hand is extremely prevalent, most patients have few symptoms. The knee is the joint most frequently affected by symptomatic OA, followed by the hand and the hip (Felson, 2012).

Risk Factors

Increasing age is the primary risk factor for OA. Its incidence and prevalence increase significantly with age. Joint cartilage thins with aging, and is less able to respond to joint loading than cartilage in younger adults. Age-related decreases of muscle strength and ligament stretching, as well as slowed sensory input, reduce protection of the joints from injury, further increasing the risk of OA with aging (Felson, 2012). Genetics also plays a role: A strong genetic linkage has been identified for OA of the hand and the hip. The role of genetics in knee OA is less clear.

Excessive weight contributes to the development of OA, especially in the hip and knee. Increasing body weight significantly increases the load placed on the knees during walking. An increased risk for OA of the hands suggests there also may be a metabolic risk factor associated with obesity. Inactivity is another risk factor. Moderate recreational exercise has been shown to both decrease the chance of developing OA and the progression of manifestations when OA is present. Repetitive joint use, however, also increases the risk for OA. People involved in occupations that require regular bending of the knee or hips or carrying heavy loads have increased risk for hip, knee, or spine OA. Textile mill workers have a higher rate of OA involving the interphalangeal joints. People involved in strenuous, repetitive exercise (such as participating in sports) have an increased risk of developing OA, particularly of the hip or knee.

Pathophysiology

The cartilage that lines joints provides a smooth surface, so that the bones of the joint glide over one another without friction, and it distributes the load from one bone to the next, dissipating the mechanical stress that occurs with joint loading. This cartilage normally contains more than 70% water. More than 90% of its dry weight is collagen, which provides strength, and proteoglycans, which provide elasticity and stiffness to compression. Cartilage cells, the chondrocytes, nest in this meshwork of collagen and proteoglycans. Chondrocytes regularly break down worn joint cartilage and synthesize the components to replace it. Normal articular cartilage exudes some of its water with compression, providing lubrication for joint surfaces. This water is reabsorbed during relaxation of the joint.

In OA, proteoglycans and collagen are lost from the cartilage as a result of enzymatic degradation. The water content of the cartilage increases as the collagen matrix is destroyed. With the loss of proteoglycans and collagen fibers, the cartilage becomes yellow or brownish gray and loses its tensile strength. Surface ulcerations occur, and fissures develop in deeper layers of the cartilage. Eventually, large areas of articular cartilage are lost, and underlying bone is exposed. The bone thickens in exposed areas, reducing its ability to absorb energy in joint loading. Cysts can develop in the bone as synovial fluid leaks through damaged cartilage. Cartilage-coated *osteophytes* (bony outgrowths often called *joint mice*) change the anatomy of the joint.

Figure 40–4 ■ Typical interphalangeal joint changes associated with osteoarthritis.
Source: L. Samsuri/Custom Medical Stock Photo.

As these spurs or projections enlarge, small pieces may break off, leading to mild synovitis (inflammation of the synovial membrane).

Manifestations

The onset of OA is usually gradual and insidious, and the course slowly progressive. Pain and stiffness in one or more joints (usually weight bearing) are the first manifestations of OA. The pain is localized to the affected joints and may be described as a deep ache. It typically is associated with use or motion of the joint and relieved by rest, although it may become persistent as the disease progresses. Pain at night may be accompanied by paresthesias (numbness, tingling). Pain may be referred to other parts of the body; for example, OA of the lumbosacral spine may cause severe pain along the path of the sciatic nerve. Following periods of immobility, such as sleeping all night or after a long automobile ride, involved joints may stiffen. Usually only a few minutes of activity are necessary to relieve the stiffness. Range of motion (ROM) of the joint decreases as the disease progresses, and grating or crepitus may be noted during movement. Bony overgrowth may cause joint enlargement (Figure 40–4 ■), and flexion contractures may occur because of joint instability. In OA, enlarged joints are characteristically bony-hard and cool on palpation. Manifestations specific to affected joints are outlined in an accompanying box.

The presentation of OA in older patients is similar to that in younger adults. However, in this population, the risk of debilitation because of OA is greater, and the disease may progress faster. In addition, pain, stiffness, and limited ROM increase the risk of falls and fractures in the older adult.

MANIFESTATIONS OF OSTEOARTHRITIS

Affected Site	Manifestations
Interphalangeal joints	• *Heberden's nodes*—bony enlargements of distal interphalangeal (DIP) joints • *Bouchard's nodes*—bony enlargement of proximal interphalangeal (PIP) joints
First carpometacarpal	• Swelling, tenderness at base of thumb • Crepitus with movement • "Squared" appearance of joint
Spine	• Localized pain and stiffness • Muscle spasm • Limited range of motion • Nerve root compression with radicular pain and motor weakness
Hips	• Pain referred to inguinal area, buttock, thigh, or knee • Loss of internal rotation • Limited extension, adduction, and flexion
Knees	• Pain and bony enlargement • Effusions • Crepitus • Instability (buckling) and deformity with advanced disease • Flexion contracture may develop

●○● INTERPROFESSIONAL CARE

The primary treatment goals for the patient with osteoarthritis are to (1) control discomfort, (2) improve or maintain joint function and mobility, and (3) reduce or prevent physical disability.

DIAGNOSIS

The diagnosis of OA is generally based on the patient's history, physical examination, and x-rays of affected joints.

Characteristic changes of OA are visible in x-ray studies of affected joints. Initially, irregular joint space narrowing is seen. Progressive changes include increased density of subchondral (under cartilage) bone, osteophyte formation at the joint periphery, and the formation of cysts in the bone. In some cases, MRI may be done to determine the extent of joint damage. Examination of synovial fluid from involved joints can help rule out other types of arthritis (e.g., inflammatory arthritis, gout).

MEDICATIONS

The pain of OA often can be managed through the use of mild analgesics such as acetaminophen or OTC NSAIDs such as ibuprofen. Acetaminophen (Tylenol) is generally preferred for long-term use because it has fewer toxic side effects. NSAIDs such as ibuprofen (Motrin) or naproxen (Aleve) are prescribed to relieve the pain and stiffness associated with OA of the hip or knee. Treatment guidelines recommend that NSAIDs be given together with a proton-pump inhibitor to reduce the risk for gastrointestinal bleeding (Hochberg et al., 2012). A selective COX-2 inhibitor (celecoxib or Celebrex) may be ordered for patients with a history of GI bleeding or who do not tolerate other NSAIDs. The following section on rheumatoid arthritis provides more information about these drugs.

Strong evidence also supports the use of topical NSAIDs (e.g., diclofenac topical gel [Pennsaid]) and capsaicin (Capzasin, Zostrix) for relief of OA pain, particularly for people ages 75 and older (Hochberg et al., 2012). These drugs have the advantage of minimizing systemic adverse effects. The patient should be taught to keep the medications away from the eyes, nose, mouth, or any open skin, and not to bandage or apply heat to the treated area. The products should be used no more than three or four times a day and discontinued immediately if severe irritation occurs. Up to 2 weeks of regular use may be necessary for full effect. Caution the patient to avoid taking oral

NSAIDs while using these topical preparations to prevent an additive effect (Wells et al., 2012).

Potent anti-inflammatory medications, such as systemic corticosteroids, are seldom prescribed for patients with OA, although intra-articular corticosteroid injections may be used. With intra-articular injections, a long-acting corticosteroid medication, often mixed with a local anesthetic such as lidocaine, is injected directly into the joint space of the affected joints. Although this procedure may provide marked pain relief, it may be short lived (Felson, 2012). Intra-articular hyaluronic acid (HA) is an option for patients with OA of the knee joint. HA is a component of synovial fluid; it also appears to have anti-inflammatory effects. It is given in a series of three or five weekly intra-articular injections, and may be effective for as long as 6 months following completion of the series.

Prescription analgesics such as tramadol or an opioid analgesic may be necessary for patients with advanced OA and moderate to severe pain. See Chapter 9 for a more detailed discussion about acute and chronic pain management.

TREATMENTS

Conservative measures, including regular exercise and weight loss as indicated, are primary components of the treatment plan for OA. These may include any or all of the following:

- ROM exercises, muscle-strengthening exercises, aerobic exercises. Walking, quadriceps-strengthening exercises, yoga, tai chi, and water-based exercises are recommended.
- Heat and ice.
- A balance between exercise and rest.
- Use of a cane, crutches, or a walker as needed.
- Weight loss, if indicated.

Surgery

Surgical procedures can provide dramatic results for patients with significant chronic pain and loss of joint function. Although elective surgical procedures are frequently avoided in the older adult, even older patients can benefit significantly if they do not have a chronic medical condition that contraindicates surgery.

ARTHROSCOPY

An **arthroscopy** is a surgical procedure in which an arthroscope (a thin tube that is lighted and has a camera in one end) is inserted into a joint. It may be done to diagnose the type of arthritis or to perform debridement by smoothing rough cartilage and flushing out the joint to remove debris. Although arthroscopic debridement and lavage of involved joints have been used, arthroscopy has not proven effective in the treatment of knee OA (Felson, 2012). It may be useful to remove large pieces of debris or repair a torn cartilage.

OSTEOTOMY

An *osteotomy*, an incision into or transection of the bone, may be performed to realign an affected joint, particularly when significant bony overgrowth or osteophyte formation has occurred. This procedure may also be used to shift the joint load toward areas of less severely damaged cartilage. Although osteotomy does not halt the progress of OA, it may have a beneficial effect on joint function and pain, delaying the need for a joint replacement by several years.

JOINT ARTHROPLASTY

A joint **arthroplasty** is the reconstruction or replacement of a joint. Arthroplasty is usually indicated when the patient has severely restricted joint mobility and pain at rest. Pain is virtually eliminated, and the function of the joint is generally improved. Arthroplasty may involve partial joint replacement or reshaping of the bones of a joint. For most patients with OA, both surfaces of the affected joint are replaced with prosthetic parts in a procedure known as a *total joint replacement*. Joints that may be replaced include the hip, knee, shoulder, elbow, ankle, wrist, and joints of the fingers and toes.

In a total joint replacement, some or all of the synovium, cartilage, and bone on both sides of the joint are removed. A metallic prosthesis is inserted to replace one joint surface (generally the load-end or distal portion of a weight-bearing joint). The other joint surface is replaced by a silicone-lined ceramic or polyethylene (plastic) prosthesis.

Prosthetic joints may be either cemented or uncemented. Uncemented joints are made of porous components that are inserted such that they fit tightly into existing bone. The implant is secured by new bone growth into the prosthesis, a process that requires approximately 3 months. Although a longer period of limited weight bearing is necessary until the prosthesis is fixed in place by the bony growth, the implant appears to have a longer useful life span than cemented prostheses. In a cemented joint replacement, a pliable polymer that hardens to hold the prosthesis in place is used to secure the prosthesis to existing bone. Cemented joint replacements are more commonly used in older adults and those who have osteoporosis.

- In a *total hip replacement*, the articular surfaces of the acetabulum and femoral head are replaced. The entire head of the femur and part of the femoral neck are removed and replaced with a prosthesis (Figure 40–5 ■). The acetabulum is remodeled, and a prosthesis of high-molecular-weight polyethylene is inserted. The success rate for total hip replacement is reported to be greater than 90%. Approximately 233,000 total hip replacements are done each year in the United States; most are for treatment of OA (CDC, 2011b). Most hip replacements last 10 to 15 years, after which a second joint replacement, called a revision, can be performed. Potential problems associated with a total hip replacement include blood clots in leg veins, dislocation within the prosthesis, loosening of

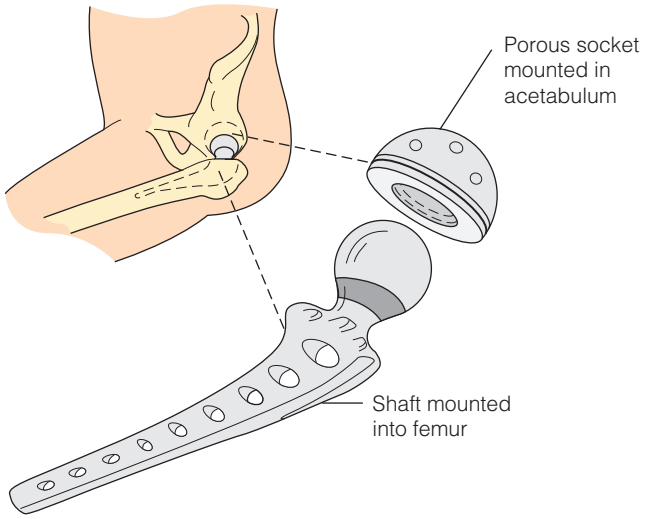

Figure 40–5 ■ Total hip prosthesis.

joint components from surrounding bone, and infection. Minimally invasive total hip arthroplasty is a recent innovation in total hip replacement that shortens healing time and has a lower risk of associated complications (Rothrock, 2011).

- *Total knee replacement* is performed if the patient has intractable pain and x-ray films show evidence of arthritis of the knee. More than 450,000 knee replacements are performed in the United States each year (CDC, 2011a), a number that has been increasing in recent years (National Institute of Arthritis and Musculoskeletal and Skin Diseases, 2012). Several prosthetic devices involving removal of varying amounts of bone are available for knee joint replacement (Figure 40–6 ■). The femoral side of the joint is replaced with a metallic surface, and the tibial side with polyethylene. More than 80% of patients obtain significant or total relief of pain with a total knee replacement. They must, however, engage in a vigorous program of rehabilitation to achieve the best results. Joint failure is more common with knee replacement than with a total hip replacement. Loosened joint components, often on the tibial side, are the most common cause of failure. The possible complications following a total knee replacement are the same as for a total hip replacement.
- *Total shoulder replacement* is indicated for unremitting pain and marked limitation of ROM because of arthritic involvement of both the humeral and glenoid joint surfaces of the shoulder. The joint is immobilized in a sling or abduction splint for 2 to 3 weeks following arthroplasty. Dislocation, loosening of the prosthesis, and infection are potential problems associated with total shoulder replacement.
- *Total elbow replacement* involves replacement of the humeral and ulnar surfaces of the elbow joint with a metal and polyethylene prosthesis. Pain and disabling stiffness of the joint are indications for an elbow arthroplasty. Complications, including dislocation, fracture, tricep weakness, loosening, and infection, occur frequently.

Infection is the major complication associated with total joint replacement. Not only does infection interfere with healing and prolong recovery, but it may also necessitate removal of the prosthesis and may lead to loss of joint function. Other potential complications include circulatory impairment to the affected limb, thromboembolism, nerve damage, and dislocation of the joint.

Nursing care for the patient undergoing total joint replacement is outlined in the box on page 1287. The Moving Evidence into Action box provides evidence nurses can use in planning and providing individualized care for patients undergoing joint replacement surgery.

PHYSICAL THERAPY AND REHABILITATION Recovery from all types of joint replacement requires postoperative physical therapy, focusing on building strength and regaining joint flexibility. Rehabilitation begins in the hospital, most often the day following surgery, and may be continued during home care. Recovery from a hip replacement is 80% complete in 4 weeks and 100% complete in 6 months. Recovery from a knee replacement is 80% complete in 4 weeks and 100% complete after 1 year. During rehabilitation, the patient must follow a regimen of exercise, rest, and medication.

COMPLEMENTARY AND ALTERNATIVE THERAPIES The following complementary therapies are examples of those that may be used by people with OA to relieve pain and stiffness. These same therapies are used by people with rheumatoid arthritis.

- Biomagnetic therapy.
- Acupuncture. Studies have demonstrated a beneficial effect of acupuncture for relieving pain and promoting mobility in patients with OA (Barrows, 2013; Manheimer et al., 2010).
- Eliminating nightshade foods such as potatoes, tomatoes, peppers, eggplant, tobacco.
- Taking nutritional supplements, such as glucosamine, chondroitin, boron, zinc, copper, selenium, manganese, flavonoids, and/or SAM-e. The evidence supporting use of glucosamine with or without chondroitin shows these agents often are helpful to reduce pain associated with hip and knee osteoarthritis. There is limited evidence that glucosamine and/or chondroitin slow the progression of OA (Barrows, 2013).
- Herbal therapy.
- Massage therapy.
- Osteopathic manipulation.
- Vitamin therapy.
- Yoga.

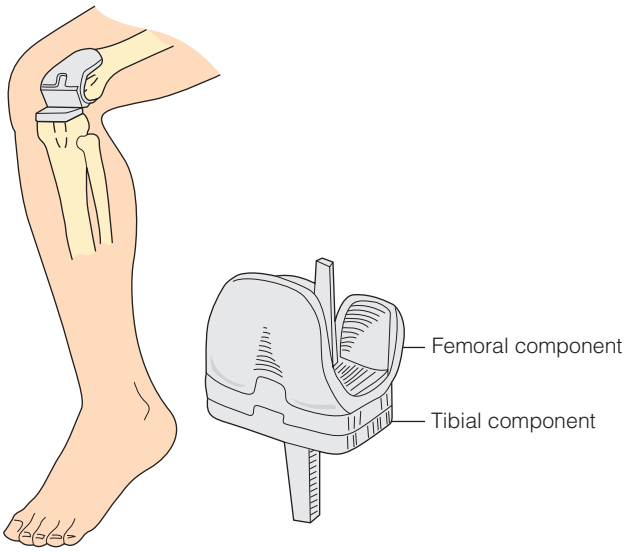

Figure 40–6 ■ One type of total knee implant.

Moving Evidence into Action

The Patient Having Joint Replacement Surgery

Studies by nurses in Scandinavia (Gustafsson et al., 2007; Montin et al., 2011) and the United States (Jacobson et al., 2008) provide insight into the experience of patients undergoing hip or knee replacement surgery. In these studies, patients describe an extended period of increasing pain and disability, letting go of previous activities, and learning to live with a now unreliable body. The decision to undergo surgery was difficult and often delayed; however, when made, patients began to dream of becoming as able-bodied as previously (Gustafsson et al., 2007). Most patients related being unprepared for the period of recovery after surgery. Although postoperative pain was anticipated and the need for rehabilitation cognitively understood, patients expressed surprise at their inability to provide self-care, the fatigue experienced, and the difficulty regaining mobility.

Implications for Nursing

Joint replacement surgery has become very common. Healthcare providers, including nurses, therefore may not always understand the anxiety experienced by patients preoperatively or the need for psychologic as well as physical support postoperatively. These studies demonstrate the need for teaching that includes not only usual postoperative information, but also what to expect in terms of functional recovery. Patients expressed the desire to have someone of whom they could ask questions rather than simply being provided with written information. Many would have appreciated the ability to talk with other patients who previously underwent joint replacement surgery. Nursing care should include strategies to support the patient's physical and psychosocial recovery in their care. Pain management is critical and continues beyond the immediate postoperative period. So too is providing information about and support during the expected process of recovery and rehabilitation.

Moving Knowledge into Action

1. Many patients reported delaying the decision to undergo joint replacement despite increasing pain and disability. How can nurses provide support for the patient and family during this period of decision making?
2. Postoperatively, many patients expressed surprise about initially feeling very helpless and the amount of time and work required for full recovery and rehabilitation. What do you think healthcare providers can or should do to better prepare patients preoperatively?
3. Design a strategy to support patients considering joint replacement surgery and, for those who choose to have the surgery, a plan for the postoperative period. Include a mechanism to evaluate the effectiveness of your planned interventions.

●○● NURSING CARE

OA is a chronic process for which there is no cure. The focus of nursing care for the patient with OA is providing comfort, helping maintain mobility and ADLs, teaching, and assisting with adaptations to maintain life roles. See the Case Study & Nursing Care Plan for a patient with OA.

Health Promotion

Although OA cannot be prevented, maintaining a normal weight and having a program of regular, moderate exercise will reduce risk factors. Moderate exercise is protective; however, sports-related injuries have been shown to increase the risk for OA. Advise patients that protective devices such as a knee brace can reduce this risk, particularly when a joint is unstable due to previous damage (for example, ligament tears).

Assessment

Collect the following data through the health history and physical examination:

- *Health history:* family history of OA; occupation; recreational activities; joint pain, stiffness; ability to carry out daily living activities
- *Physical assessment:* height/weight; gait; joints: symmetry, size, shape, color, appearance, temperature, pain, crepitus, ROM, Heberden's nodes, Bouchard's nodes.

Priorities of Care

Nursing care priorities for the patient with OA vary with the circumstances of the patient's interaction with the healthcare system. Maintaining circulation and tissue perfusion is of highest priority for the patient admitted with acute gastrointestinal bleeding related to chronic aspirin or NSAID use, whereas promoting comfort and mobility are priorities for the patient for whom osteoarthritis is either the primary or a secondary health issue.

Diagnoses, Outcomes, and Interventions

Nursing interventions for patients with OA are directed toward managing chronic pain, facilitating physical mobility, and improving ability to provide self-care.

Chronic Pain

Pain is a primary manifestation of OA. As joint tissues degenerate and changes in joint structure occur, the amount of discomfort generally increases. The pain associated with OA increases with activity and tends to be relieved with rest. Nonpharmacologic comfort measures are appropriate, with mild analgesics used to supplement these as needed.

Evidence for Nursing Care

The Patient with Osteoarthritis

Selected resources that nurses may find helpful when planning evidence-based nursing care follow.

- Hochberg, M., Altman, R., April, K., Benkhalti, M., Guyatt, G., McGowan, J., . . . Tugwell, P. (2012). American College of Rheumatology 2012 recommendations for the use of nonpharmacologic and pharmacologic therapies in osteoarthritis of the hand, hip, and knee. *Arthritis Care & Research, 64*(4), 465–474.
- Tsai, P.-F., Kuo, Y.-F., Beck, C., Richards, K. C., Means, K. M., Pate, B. L., & Keefe, F. J. (2011). Nonverbal cues to osteoarthritic knee and/or hip pain in elders. *Research in Nursing & Health, 34*(3), 218–227.
- Weathers, E., & Creedon, R. (2011). The impact of osteoarthritis on psychological wellbeing. *British Journal of Nursing, 20*(4), 243–246.

NURSING CARE OF THE PATIENT

Having Total Joint Replacement

PREOPERATIVE CARE

- Assess the patient's knowledge and understanding of the planned operative procedure. Provide further explanations and clarification as needed. *It is important for the patient to have a clear and realistic understanding of the surgical procedure and expected results. Knowledge decreases anxiety and increases the patient's ability to assist with postoperative care procedures*.
- Obtain a health history and physical assessment, including ROM of the affected joints. *This information not only allows nurses to tailor care to the needs of the individual but also serves as a baseline for comparison of postoperative assessment data*.
- Explain necessary postoperative activity restrictions. Teach how to use the overhead trapeze for changing positions. *The patient who learns and practices moving techniques before surgery can use them more effectively in the postoperative period*.
- Provide or reinforce teaching of postoperative exercises specific to the joint on which surgery is to be performed. *Exercises are prescribed postoperatively to (1) strengthen muscles providing joint stability and support, (2) prevent muscle atrophy and joint contractures, and (3) prevent venous stasis and possible thromboembolism*.
- Teach respiratory hygiene procedures such as the use of incentive spirometry, coughing, and deep breathing. *Adequate respiratory hygiene is imperative for all patients undergoing joint replacement to prevent respiratory complications associated with immobility and the effects of anesthesia. In addition, many patients undergoing total joint replacement are elderly and may have reduced mucociliary clearance*.
- Discuss postoperative pain control, including use of patient-controlled analgesia (PCA) or epidural infusion as appropriate. *It is important for the patient to understand the purpose and use of postoperative pain control measures to allow early mobility and reduce complications associated with immobility*.
- Teach or provide prescribed preoperative skin preparation such as shower, shampoo, and skin scrub with antibacterial solution. *These measures help reduce transient bacteria that may be introduced into the surgical site*.
- Administer intravenous antibiotic as ordered. *Antibiotic therapy is initiated before or during surgery and continued postoperatively to further reduce the risk of infection*.

POSTOPERATIVE CARE

- Monitor vital signs, including temperature and level of consciousness, every 4 hours or more frequently as indicated. Report significant changes or unanticipated findings to the physician. *These routine assessments provide information about the patient's cardiovascular status and can give early indications of complications such as excessive bleeding, fluid volume deficit, and infection*.
- Perform neurovascular checks (color, temperature, pulses and capillary refill, movement, and sensation) on the affected limb hourly for the first 12 to 24 hours, then every 2 to 4 hours. Report abnormal findings to the physician immediately. *Surgery can disrupt the blood supply to or innervation of the affected extremity. If so, rapid intervention is important to preserve the function of the extremity*.
- Monitor incisional bleeding by emptying and recording suction drainage every 4 hours and assessing the dressing frequently. *Significant blood loss can occur with a total joint replacement, particularly a total hip replacement*.
- Reinforce the dressing as needed. *The dressing is usually changed 24 to 48 hours after surgery but may need reinforcement if excess bleeding occurs*.
- Maintain intravenous infusion and accurate intake and output records during the initial postoperative period. *The patient is at risk for fluid volume deficit in the initial postoperative period because of blood and fluid loss during surgery, as well as the effects of the anesthetic*.
- Maintain prescribed position of the affected extremity using a sling, abduction splint, brace, immobilizer, or other prescribed device. *Proper positioning of the affected extremity is vital in the initial postoperative period so that the joint prosthesis does not become dislocated or displaced*.
- Remind the patient to use the incentive spirometer, to cough, and to breathe deeply at least every 2 hours. *These measures are important to prevent respiratory complications such as pneumonia*.
- Assess the patient's level of comfort frequently. Maintain PCA, epidural infusion, or other prescribed analgesia to promote comfort. *Adequate pain management promotes healing and mobility*.
- Help the patient get out of bed as soon as allowed. Teach and reinforce the use of techniques to prevent weight bearing on the affected extremity, such as the overhead trapeze, pivot turning, and toe touch. *Early mobility prevents complications such as pneumonia and thromboembolism, but appropriate techniques must be used to prevent injury to the operative site*.
- Initiate physical therapy and exercises as prescribed for the specific joint replaced, such as quadriceps setting, leg raising, and passive and active ROM exercises. *These exercises help prevent muscle atrophy and thromboembolism and strengthen the muscles of the affected extremity so that it can support the prosthetic joint*.
- Use sequential compression devices or antiembolism stockings as prescribed. *These help prevent thromboembolism and pulmonary embolus for the patient who must remain immobile following surgery*.
- For the patient with a total hip replacement, prevent hip flexion of greater than 90 degrees or adduction of the affected leg. Provide a seat riser for the toilet or commode. *These measures prevent dislocation of the joint*.
- Assess the patient with a total hip replacement for signs of prosthesis dislocation, including pain in the affected hip or shortening and internal rotation of the affected leg.
- For the patient with a total knee replacement, use a continuous passive range-of-motion (CPM) device or ROM exercises as prescribed. *Dislocation is not a problem with a knee replacement, and more emphasis is placed on ROM exercises in the early postoperative period*.
- Maintain fluid intake and encourage a high-fiber diet. Administer stool softeners or rectal suppositories as needed. *Immobility and analgesia contribute to the potential problem of constipation; these measures help maintain regular fecal elimination*.
- Encourage consumption of a well-balanced diet with adequate protein. *Adequate nutrition promotes tissue healing*.
- Teach or reinforce postdischarge exercises and activity restrictions. Emphasize the importance of scheduled follow-up physician visits. *Patients are discharged from the acute care facility before healing is complete. Exercises are prescribed and activities are resumed gradually to protect the integrity of the joint replacement and prevent contractures*.
- For those patients needing additional direct care after discharge, arrange placement in a long-term care or rehabilitation facility. *Activity restrictions may preclude discharge to home for some patients*.
- Make referrals as needed to home health agencies and physical therapy. *Patients often require home healthcare for both nursing care needs and continued physical therapy following discharge from acute or long-term care*.

Expected Outcome: Patient will report pain within an acceptable level.

- Monitor the level of pain, including intensity, location, quality, and aggravating and relieving factors. *Accurate assessment of pain provides a basis for evaluation of the effect of interventions.*
- Teach patients to take prescribed analgesic or anti-inflammatory medication as directed. *Analgesics reduce the perception of pain and may decrease muscle spasm as well. Anti-inflammatory medication may be ordered to decrease local inflammatory response in affected joints. Regularly scheduled doses of an analgesic or NSAID may be prescribed to prevent severe pain, muscle spasm, or inflammation.*
- Encourage rest of painful joints. *The pain of OA is often relieved by joint rest.*
- Suggest applying heat to painful joints using the shower, a tub or sitz bath, warm packs, hot wax baths, heated gloves, or diathermy, which uses high-frequency electrical currents to generate heat. *Heat application reduces pain and disability, and improves quality of life in patients with osteoarthritis (Yildirim et al., 2010).*

CASE STUDY & NURSING CARE PLAN A Patient with Osteoarthritis

Robert Cerulli, a 72-year-old retired fisherman, seeks medical attention for pain in his right hip that has become severe during the past year. Significant degenerative changes in both hip joints are noted on x-ray films. The physician recommends a total replacement of the right hip. Mr. Cerulli has preoperative teaching and tests the afternoon prior to his surgery, scheduled for 0800 the following morning.

ASSESSMENT

Christie Phlaugh, RN, completes an admission health history and examination. She notes that Mr. Cerulli has mild Parkinson's disease and is taking carbidopa/levodopa (Sinemet 25-100) four times a day to control his symptoms. No other chronic medical conditions have been reported. Mr. Cerulli says he has been essentially healthy his entire life. He has no known allergies to medications, has never smoked, and consumes only small amounts of alcohol.

On examination, Ms. Phlaugh notes that he is alert and oriented. His vital signs are BP 116/64 mmHg, P 68 bpm and regular, R 18/min, T 36.3°C (97.4°F) PO. Peripheral pulses are strong and equal in the upper extremities, and slightly weaker but equal in the lower extremities. His feet are cool to touch but have immediate capillary refill. He has full ROM of his shoulders, elbows, and wrists. The ROM of both hips is significantly restricted. Hip flexion beyond 90 degrees prompts pain on both sides. Both flexion and extension of the knees are limited slightly. Mr. Cerulli walks with a limp, favoring his right hip, and has a shuffling gait.

Preoperative laboratory studies including CBC, coagulation studies, chemistry panel, and urinalysis show a serum creatinine of 1.7 mg/dL and BUN of 30 mg/dL, with no other abnormal values noted. Cefazolin (Ancef) 500 mg is to be administered intravenously at 0600 prior to surgery, and Mr. Cerulli is to shower and shampoo with antibacterial soap at bedtime. The physical therapist meets with Mr. Cerulli to evaluate his mobility and begin teaching him about postoperative weight-bearing restrictions.

DIAGNOSES (POSTOPERATIVE)

- *Acute Pain* related to surgical incision
- *Risk for Infection* related to disruption in skin integrity
- *Risk for Ineffective Peripheral Tissue Perfusion, Right Leg* related to vascular disruption and edema

EXPECTED OUTCOMES

- Patient will maintain an adequate level of comfort postoperatively as demonstrated by verbal reports of pain at 2 or lower on a standard pain scale of 0 to 10.
- Patient will remain free of infection.
- Patient will maintain adequate perfusion of affected leg.
- Patient will remain free of injury postoperatively.

PLANNING AND IMPLEMENTATION

- Assess pain at least hourly during first 24 to 48 hours postoperatively, and as needed thereafter.
- Instruct in the use of PCA and monitor its effectiveness.
- Maintain sequential compression device and antiembolic stocking as ordered; remove for 1 hour daily.
- Encourage the use of an incentive spirometer hourly for first 24 hours, then at least every 2 hours while awake.
- Assist out of bed three times a day after the first 24 hours.
- Maintain abduction of the right hip with pillows.
- Assess the surgical site frequently; report signs of excess bleeding or inflammation.
- Monitor temperature every 4 hours.
- Assess pulses, color, movement, and sensation of right foot hourly for the first 24 hours, then every 2 hours for 24 hours, then every 4 hours.

EVALUATION

Mr. Cerulli returns to the orthopedic unit from the postanesthesia care unit. He becomes confused and disoriented during the first 36 hours after surgery, but his orientation and thought processes gradually clear. His family has stayed with him, and he has not experienced injury or other adverse consequences from his confusion. Otherwise, Mr. Cerulli has had an uneventful postoperative recovery. Six days after surgery, he is transferred to an extended care rehabilitation facility for further therapy until he is able to ambulate with partial weight bearing on his affected leg. He returns home 3 weeks after surgery, able to use a walker for ambulation. Arrangements are made for an overbed trapeze, elevated toilet seat, and shower chair in his home. A home health nurse and physical therapist visit Mr. and Mrs. Cerulli weekly for a month following his discharge. During this time he gradually resumes full weight bearing. Mr. Cerulli expresses pleasure with the relief of his hip pain and says he has no fear of having his left hip replaced in the future.

Clinical Reasoning in Patient Care

1. Patients rarely enter the healthcare system with a single diagnosis; Mr. Cerulli has Parkinson's disease in addition to his osteoarthritis. Should Ms. Phlaugh develop nursing diagnoses and plan interventions related to this diagnosis and its current treatment?
2. What postoperative assessment findings should be anticipated related to Mr. Cerulli's diagnosis of Parkinson's disease?
3. Does Parkinson's disease or its management increase Mr. Cerulli's risk for intra- or postoperative complications? If so, what complications could be anticipated?
4. Mr. Cerulli's preoperative laboratory work showed a modest elevation in his serum creatinine and BUN. What do these studies indicate? How might these changes affect nursing responsibilities related to medication administration for Mr. Cerulli?
5. Mr. Cerulli became confused postoperatively. What factors in his history might have alerted the nurses to this possibility? How might anesthesia and postoperative analgesics have contributed to his confusion?
6. Develop a care plan for Mr. Cerulli using the nursing diagnosis *Acute Confusion*.

See Evaluating Your Response in Appendix B.

- Emphasize the importance of proper posture and good body mechanics for walking, sitting, lifting, and moving. *Good body mechanics and posture reduce stress on affected joints.*
- Encourage the overweight patient to reduce weight. *Excess weight places abnormal stress on joints, particularly the knees.*
- Encourage the use of nonpharmacologic pain relief measures such as progressive relaxation, meditation, visualization, and distraction. *These adjunctive pain relief measures can reduce the patient's reliance on analgesics and increase comfort.*

Impaired Physical Mobility

As intra-articular cartilage degenerates and joint structures are altered, the patient with OA experiences pain, stiffness, and decreased ROM in affected joints. When the spine, large weight-bearing joints of the hips and knees, or the ankles and feet are affected, physical mobility can be significantly reduced.

Expected Outcome: Patient will maintain physical mobility and ability to perform desired and daily living activities.

- Assess the ROM of affected joints. *Assessing joint mobility is important as a basis for planning appropriate interventions.*
- Perform a functional mobility assessment, evaluating gait, ability to sit and rise from sitting position, ability to step into and out of the tub or shower, and negotiation of stairs. *The functional assessment provides vital data about the patient's ability to maintain ADLs.*
- Teach active and passive ROM exercises as well as isometric, progressive resistance, and low-impact aerobic exercises. *Active ROM exercises help maintain muscle tone and mobility of affected joints and prevent contractures. Isometric and progressive resistance exercises improve muscle tone and strength; aerobic exercise improves endurance and cardiovascular fitness.*
- Collaborate with physical and/or occupational therapists to recommend braces or mobility aids as appropriate. *Use of braces to support unstable joints or mobility aids such as a cane reduce the pressure on and risk of injury to joints affected by OA (Luke & Ma, 2012).*

Readiness for Enhanced Self-Care

Just as OA of the lower extremities can reduce the patient's mobility, OA of the upper extremities (the wrist, hand, and finger joints in particular) can significantly interfere with performance of ADLs such as cooking and brushing the hair. When the lower extremities are affected, bathing and toileting can be difficult.

- Perform a functional assessment of the upper and lower extremities. For upper extremities, assess the ability to touch the back of the head, and to hold and use small items such as eating utensils. *The functional assessment provides important data about the patient's ability to provide self-care.*
- Assess the home setting to determine the need for assistive devices such as handrails, grab bars, walk-in shower stall, or shower chair and handheld showerhead. *Many assistive devices are relatively easy and inexpensive to obtain and can significantly improve the patient's independence.*
- Assist in obtaining other assistive devices such as long-handled shoehorns, zipper grabbers, long-handled tongs or grippers for retrieving items from the floor, jar openers, and special eating utensils. *These devices can prolong independence in performing ADLs.*

Delegating Nursing Care Activities

As appropriate and allowed by the designated duties and responsibilities of unlicensed assistive personnel, the nurse may delegate nursing care activities such as assisting with ambulation, hygiene, and ADLs for the patient with osteoarthritis. With appropriate training and supervision, assistive personnel may assist with heat and cold application to affected joints as ordered.

Continuity of Care

Because of the chronicity of OA, patients and their families need appropriate teaching to manage the disease and its consequences effectively. Much of the teaching focus is on preservation of joint function and mobility. Discuss the following topics:

- Safeguard against hazards to safe mobility, such as scatter rugs. Encourage installation of safety devices such as handrails and grab bars.
- Understand the disease process and its chronic degenerative nature.
- Learn exercise techniques, including ROM, isometric, postural, stretching, and strengthening to maintain healthy cartilage, preserve ROM, and develop supportive muscles and tendons. A walking program is beneficial for patients with OA of the knee. Older adults may be more willing to exercise as part of a group or organized activity.
- Do not overuse or stress affected joints with heavy lifting, excessive stair climbing or bending, or other repetitive actions.
- Sit in a straight chair without slumping, avoid soft chairs or recliners, and sleep on a firm mattress or use a bed board.
- Use pain relief measures including prescribed or OTC analgesic medications and nonpharmacologic pain relief measures such as heat, rest, massage, relaxation, and meditation.

For the patient who has had a total joint replacement, discuss the following:

- Use and weight bearing of the affected limb
- Appropriate environmental modifications, such as an overhead trapeze for getting out of bed, elevated toilet seats, and types of chairs to use and avoid when sitting
- Prescribed exercises
- Use of assistive devices for ambulation, such as crutches or a walker
- Possible complications, including signs of infection or dislocation, and the need to notify the physician promptly if these occur.

Make referrals to home care, physical or occupational therapy, or other community agencies as indicated, and suggest the following resources:

- National Institute of Arthritis and Musculoskeletal and Skin Diseases
- Arthritis Foundation
- American College of Rheumatology
- Moss Rehab Resource Net.

THE PATIENT WITH MUSCULAR DYSTROPHY

Muscular dystrophy (MD) is a group of inherited muscle diseases that cause progressive muscle degeneration and wasting. The differences in the types of MD relate to the genetic pattern of transmission, the age at onset, the gender affected, the muscles involved, and the rate at which the disease progresses. These factors are summarized in Table 40–3. In the majority of cases of MD, there is a positive family history.

The most common form of MD, Duchenne muscular dystrophy (DMD), is inherited as a recessive single-gene defect on the X chromosome (a sex-linked recessive disorder), and is transmitted from the mother to male children. This disorder predominantly affects males and occurs in 1 of 3500 live male births. Although rare, spontaneous mutation may cause the disorder in girls (Grossman & Porth, 2014). It can be recognized as early as the 12th week of pregnancy by DNA analysis of a chorionic villi sample. DNA analysis also can be used to identify female relatives who may carry the defective gene. Manifestations of DMD appear in early childhood, with progressive muscle weakness ultimately leading to death from respiratory and cardiac muscle involvement by the late teens or early adulthood. Other types of MD have an onset at any age, and a slow progression with a normal life span.

Pathophysiology

Although the underlying genetic defect and cellular pathology differ among the muscular dystrophies, all are primary diseases characterized by progressive necrosis of muscle tissue. Fat and connective tissue replace muscle fibers, increasing size of the muscle while causing progressive weakness. Muscle weakness has an insidious onset but is relentlessly progressive. DMD, the best understood of the muscular dystrophies, results from mutation of the gene that codes for dystrophin, a protein necessary for stability of the sarcolemma. Instability leads to membrane tears, muscle necrosis, and a continuous process of repair, regeneration, and muscle fibrosis. Ultimately, there is almost complete loss of muscle fibers (Grossman & Porth, 2014).

Manifestations

All forms of MD exhibit manifestations of muscle weakness. The specific muscles involved depend on the type of MD. As the disease progresses, the person develops difficulty with ambulation and eventually becomes wheelchair-bound and finally bed-bound. Cardiac abnormalities, endocrine abnormalities, and mental retardation may also occur.

●○● INTERPROFESSIONAL CARE

Because there is no cure or specific treatment for MD, care focuses on preserving and promoting mobility. An interprofessional approach involving many members of the healthcare team is necessary to meet the physical and psychologic needs of these patients and their families. Diagnosis and classification of the muscular dystrophies are most often based on the manifestations and the pattern of muscle involvement. Biochemical examination, muscle biopsy, and electromyography confirm the diagnosis.

Tests include measuring creatine kinase (CK-MM, the isoenzyme found in skeletal muscle), which is elevated in the patient with suspected MD; performing a muscle biopsy to identify fibrous connective tissue and fatty deposits that displace functional muscle fibers; and conducting an electromyogram (EMG), which will show a decrease in amplitude in MD. Genetic testing may be done to identify the specific defect. Muscle biopsy may be performed to establish the diagnosis.

●○● NURSING CARE

Nursing care for a patient with MD focuses on promoting independence and mobility and providing psychologic support for both the

TABLE 40–3 Types of Muscular Dystrophy

Type	Sex and Age at Onset	Clinical Manifestations	Progression
Duchenne	Males Ages 3–5	Weakness of pelvic and shoulder girdles Waddling gait Toe walking Lordosis Cardiac abnormalities Low IQ in 50% of cases	Rapid; patient usually confined to wheelchair by age 15; death occurs by age 20
Myotonic	Males and females Any age	Weakness and atrophy of facial muscles Muscle weakness of distal extremities Cardiac abnormalities Endocrine abnormalities Mental retardation (common)	Slow; death usually occurs in early 50s
Becker	Males Ages 5–20	Weakness of pelvic and shoulder girdles Cardiac involvement, possible heart failure	Slow; patient usually confined to wheelchair at 25 years after onset; life span into 30s to 50s
Facioscapulohumeral	Males and females Ages 10–20	Weakness of face and shoulder girdles Eventual involvement of abdominal, feet, and pelvic muscles	Slow; normal life span
Limb-girdle	Males and females Ages 15–40	Weakness of shoulder and pelvic girdles	Extremely variable; usually slow

patient and family. A holistic approach is essential in planning and implementing care.

Diagnoses, Outcomes, and Interventions

Self-Care Deficit

The progressive muscle weakness that is associated with MD impairs the patient's ability to perform self-care.

Expected Outcome: Patient will accept assistance or total care from caregivers as needed.

- Provide patients and family with supportive care during the progress of the disease. *The goal of treatment is to prolong each functional stage and delay or prevent deformity. When transition from ambulation to a wheelchair occurs, depression and grief may occur.*
- Promote independence. Encourage tasks that can be accomplished rather than letting the patient struggle with tasks that may prove frustrating. *All forms of MD result in progressive muscle weakness. Management of the disease is directed toward keeping the patient as functional as possible while preventing any deformities.*

Continuity of Care

Teaching the patient with MD focuses on maintaining function and independence and preventing deformities. Teach prescribed exercises such as stretching and counterposturing exercises. For the patient with braces, discuss skin care and ways to prevent irritation under the brace. Because the patient may have weakness involving muscles of respiration, teach the patient how to prevent respiratory infections, such as avoiding crowds during flu season and being immunized against pneumococcal pneumonia and influenza. Provide information about support services and organizations such as the Muscular Dystrophy Association.

Autoimmune and Inflammatory Disorders

Autoimmune and inflammatory disorders of the musculoskeletal system are characterized by diffuse inflammatory lesions and degenerative changes in connective tissues. The disorders have similar clinical features and may affect many of the same structures and organs.

THE PATIENT WITH RHEUMATOID ARTHRITIS

Rheumatoid arthritis (RA) is a chronic systemic autoimmune disease that causes inflammation of connective tissue, primarily in the joints. Its course and severity are variable, and the range of manifestations is broad. Manifestations of RA may be minimal, with mild inflammation of only a few joints and little structural damage, or relentlessly progressive, with multiple inflamed joints and marked deformity. Most patients exhibit a pattern of symmetric involvement of multiple peripheral joints and periods of remission and exacerbation.

FAST FACTS

- RA is found worldwide, affecting 0.5% to 1% of the total population and all races.
- RA affects two to three times as many women as men.
- The onset of RA occurs most frequently between the ages of 25 and 55 years.

Source: (CDC, 2011c; Shah & St. Clair, 2012).

RA is less common than osteoarthritis: An estimated 27 million adults in the United States are affected by OA, whereas about 1.3 million have RA. It is important to establish an accurate diagnosis because the management of these disorders differs significantly. Clinical features distinguishing RA from OA are listed in Table 40–4.

The cause of RA is unknown. Genetic factors have been found to play a role in its development, likely in combination with environmental factors. The role of estrogens in the immune response may account for the significantly higher incidence of RA among women when compared to men (Shah & St. Clair, 2012). It is speculated that an infectious agent, such as mycoplasma, Epstein-Barr virus, or another virus, may play a role in initiating the abnormal immune responses present in RA. Several studies have found that cigarette smoking increases the risk for developing RA.

The course of RA is variable and fluctuating. Remissions are most likely to occur in the first year of the disease. Some people with RA have a single episode that resolves within 2 to 5 years after its onset, whereas others may have fluctuating disease activity. In the most severe disease course, RA is progressive and unremitting (CDC, 2011c). Life expectancy is shortened in people with RA, with cardiovascular disease and infection being the leading causes of death (Shah & St. Clair, 2012).

Pathophysiology

It is believed that exposure to an unidentified antigen (e.g., a virus) causes an aberrant immune response in a genetically susceptible host. As a result, normal antibodies (immunoglobulins) become autoantibodies and attack host tissues. These transformed antibodies, usually present in people with RA, include *rheumatoid factors (RFs)* and *anti-CCP antibodies*. The self-produced antibodies bind with their target antigens in blood, collagen, cartilage, and other proteins and tissues, forming immune complexes. Complement is activated by the immune complexes, prompting an inflammatory response in synovial and other involved tissues.

Leukocytes from the circulation are attracted to the synovial membrane of involved joints, where neutrophils and macrophages ingest the immune complexes and release enzymes that degrade synovial tissue and articular cartilage. Activation of B and T lymphocytes results in increased production of rheumatoid factors, anti-CCP antibodies, and enzymes that increase and continue the inflammatory process.

The inflammatory and immune processes damage the synovial membrane. It swells from infiltration of the leukocytes and thickens as cells proliferate and abnormally enlarge. Prostaglandins promote vasodilation, and synovial cells and tissue become hyperactive. New blood vessels grow to support synovial hyperplasia, forming a vascular granulation tissue called *pannus*.

TABLE 40–4 Comparison of the Manifestations of Rheumatoid Arthritis and Osteoarthritis

Feature	Rheumatoid Arthritis	Osteoarthritis
Onset	Usually insidious, may be abrupt	Insidious
Course	Generally progressive, characterized by remissions and exacerbations	Slowly progressive
Pain and stiffness	Predominant on arising, lasting >1 h; also occurs after prolonged inactivity	Pain with activity; stiffness following periods of immobility generally relieved within minutes
Affected joints	• Appear red, hot, swollen; "boggy" and tender to palpation; decreased ROM, weakness • Multiple joints affected in symmetric pattern; PIP, MCP, wrists, knees, ankles, and toes often involved	• Affected joints may appear swollen; cool and bony hard on palpation; decreased ROM • One or several joints affected including hips, knees, lumbar and cervical spine, PIP and DIP, and first MTP joint
Systemic manifestations	Fatigue, weakness, anorexia, weight loss, fever; rheumatoid nodules; anemia	Fatigue

The joint damage that occurs in RA is the result of at least three processes:

- Inflammatory pannus spreads to cover joint cartilage and produces enzymes such as collagenase and other proteases that promote tissue damage (Figure 40–7 ■).
- Cytokines, especially interleukin 1 (IL-1) and tumor necrosis factor alpha (TNF-α), activate chondrocytes to attack joint cartilage.
- These cytokines, along with IL-6, also activate osteoclasts, leading to resorption and demineralization of underlying bone.

Circulating immune complexes and the cytokines IL-1, TNF-α, and IL-6 account for the systemic features of RA as well, including malaise, fatigue, and vasculitis.

Joint Manifestations

The onset of RA is typically insidious, although it may be acute, precipitated by a stressor such as infection, surgery, or trauma. Joint manifestations are often preceded by systemic manifestations of inflammation, including fatigue, anorexia, weight loss, and nonspecific aching and stiffness. Patients report joint swelling with associated stiffness, warmth, tenderness, and pain. The pattern of joint involvement is typically polyarticular (involving multiple joints) and symmetric. The proximal interphalangeal (PIP) and metacarpophalangeal (MCP) joints of the fingers, the wrists, the knees, the ankles, and the toes are most frequently involved, although RA can affect any joint. Stiffness is most pronounced in the morning, lasting more than 1 hour. It may also occur with prolonged rest during the day and may be more severe following strenuous activity. Swollen, inflamed joints feel "boggy" or sponge-like on palpation because of synovial edema (Figure 40–8 ■). ROM is limited in affected joints, and weakness may be evident.

Without effective treatment, the persistent inflammation of RA causes deformities of the joint itself and supporting structures such as ligaments, tendons, and muscles. As the joint is destroyed, ligaments, tendons, and the joint capsule are weakened or destroyed. Joint cartilage and bone are also destroyed. Weakening or destruction of these supporting structures results in lack of opposition to muscle pull, causing deformity.

Characteristic changes in the hands and fingers include ulnar deviation of the fingers and subluxation at the MCP joints. *Swan-neck deformity* is characterized by hyperextension of the PIP joint with compensatory flexion of the distal interphalangeal (DIP) joints (Figure 40–9 ■). A flexion deformity of the PIP joints with extension of the DIP joint is called a *boutonnière deformity*. The ability to effect

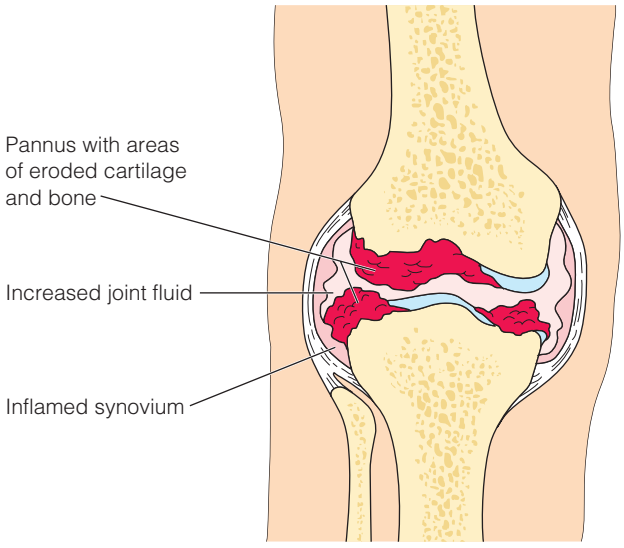

Figure 40–7 ■ Joint inflammation and destruction in rheumatoid arthritis. Note synovial inflammation with pannus formation and the erosion of cartilage and underlying bone.

Figure 40–8 ■ Swelling and inflammation of the second and third PIP joints of the hand in a patient with rheumatoid arthritis.

Figure 40–9 ■ Typical hand deformities associated with rheumatoid arthritis.

a pinch is limited by hyperextension of the interphalangeal joint and flexion of the MCP joint of the thumb.

Wrist involvement is nearly universal, leading to limited movement, deformity, and carpal tunnel syndrome. Inflammation of the elbows often causes flexion contracture.

The knees are frequently affected in RA, with visible swelling often obliterating normal contours. Instability of the knee joint along with quadriceps atrophy, contractures, and valgus (knock-knee) deformities can lead to significant disability. Ambulation may be limited by pain and deformities when the ankles and feet are involved. Typical deformities of the feet and toes include subluxation, hallux valgus (deviation of the great toe toward the other digits of the foot), lateral deviation of the toes, and cock-up toes (interphalangeal joint hyperextension).

Spinal involvement is usually limited to the cervical vertebrae. Neck pain is common, and neurologic complications can occur.

Extra-Articular Manifestations

RA is a systemic disease with a variety of extra-articular manifestations. These are seen particularly in patients with high levels of circulating autoantibodies. Fatigue, weakness, anorexia, weight loss, and low-grade fever are common when the disease is active. Anemia resistant to iron therapy frequently affects patients with RA. Skeletal muscle atrophy is common, usually most apparent in the musculature around affected joints.

Rheumatoid nodules may develop, usually in subcutaneous tissue in areas subject to pressure: on the forearm, olecranon bursa, over the MCP joints, and on the toes. Rheumatoid nodules are granulomatous lesions that are firm and either movable or fixed. They may also be found in viscera, including the heart, lungs, intestinal tract, and dura.

Other possible extra-articular manifestations of RA include pleural effusion, vasculitis, pericarditis, and splenomegaly (enlargement of the spleen). See the Multisystem Effects of Rheumatoid Arthritis feature.

Complications

People with rheumatoid arthritis have an increased risk of developing cardiovascular disease (CVD). In turn, CVD increases the risk of myocardial infarction, stroke, and death; in fact, RA is associated with a 30% increase in cardiovascular mortality. This increased risk for CVD in patients with RA is likely due to the systemic inflammation of RA. The systemic effects of RA also are thought to be responsible, at least in part, for an increased risk for infection and for developing lymphoma (Bergman, 2009). The chronic inflammation, use of corticosteroids in disease management, and reduced mobility associated with RA are thought to be contributing factors to an increased risk for osteoporosis in people with RA (Shah & St. Clair, 2012).

RHEUMATOID ARTHRITIS IN THE OLDER ADULT

Older adults are not immune from developing RA; its incidence continues to increase after age 60. Although some older adults may develop relatively mild, self-limited RA, those with elevated RA titers may experience a more aggressive disease course, with persistent disease activity, more systemic manifestations, and more rapid joint destruction.

●○● INTERPROFESSIONAL CARE

The diagnosis of RA is based on the patient's history, physical assessment, and diagnostic tests. Classification criteria developed by the American College of Rheumatology (2010) are used to help identify patients early in the course of the disease (Box 40–5). These criteria are applied to patients who present with synovitis involving at least one joint that is not better explained by another disease.

Once the diagnosis of RA has been established, the goals of therapy are to prevent joint damage and disability and to improve well-being and ability to function. No cure currently exists for RA; however, current treatment regimens can often significantly limit joint damage and preserve function. A multidisciplinary approach is used, with a balance of rest, exercise, physical therapy, and suppression of the inflammatory processes.

Because a cure is not available and traditional therapies are not always fully effective, the patient with RA is vulnerable to quackery. Many nontraditional treatments, including diets, topical preparations, vaccines, hormones, plant extracts, and copper bracelets, have been put forth. These treatments are often costly, and none has been shown to be effective.

DIAGNOSIS

Diagnostic tests are used to help establish the diagnosis of RA. Testing is also used to rule out other forms of arthritis and connective tissue disorders.

Laboratory tests are used to measure levels of autoantibodies, C-reactive protein levels, and the ESR, which is typically elevated. The anti-CCP blood test, which detects antibodies to cyclic citrullinated peptide (CCP), provides a more specific marker for RA. Anti-CCP and rheumatoid factor may be present in only about 50% of patients with early disease, however. A CBC is done to identify anemia.

BOX 40–5 Classification Criteria for Rheumatoid Arthritis

- Joint involvement: number of large and small joints involved
- Serology testing: presence of RF and/or anti-CCP antibodies
- Markers of acute inflammation: abnormal levels of C-reactive protein (CRP) or erythrocyte sedimentation rate (ESR)
- Duration of symptoms: 6 weeks or longer

Synovial fluid examination will demonstrate changes associated with inflammation, including increased turbidity (cloudiness), decreased viscosity, and increased protein and WBC levels. X-rays of affected joints are the most specific test for diagnosis of RA. Early in the disease, few changes may be evident other than soft tissue swelling and joint effusions. As the disease progresses, joint space narrowing and erosions are seen.

MEDICATIONS

Several different drug classifications are used in the pharmacologic management of patients with RA:

- NSAIDs and mild analgesics are used to help manage manifestations of the disease. Although these drugs may relieve symptoms of RA, they appear to have little effect on disease progression.
- Low-dose oral corticosteroids are used to rapidly reduce pain and inflammation. Recent studies suggest that low-dose oral corticosteroids also may slow the development and progression of bone erosions associated with RA. These drugs may be used early in the disease, before disease-modifying antirheumatic drugs have achieved full effect, and for acute disease flares. Intra-articular corticosteroids may be used to provide temporary relief in patients with one or a limited number of affected joints.
- A diverse group of drugs classified as disease-modifying antirheumatic drugs (DMARDs) is employed to slow or prevent the progression of joint damage. These drugs, which include synthetic (or nonbiologic) DMARDs such as methotrexate, sulfasalazine, and antimalarial agents, and biologic DMARDs such as anti–TNF-α, abatacept, and rituximab, appear to alter the course of the disease, reducing its destruction of joints. Current guidelines from the American College of Rheumatology (Hochberg et al., 2012) advocate early use of DMARDs, particularly for patients with high disease activity, functional limitation, or extra-articular disease.

NONSTEROIDAL ANTI-INFLAMMATORY DRUGS A number of NSAIDs are available for use in the management of RA. All NSAIDs act by inhibiting prostaglandin synthesis. Although the efficacy of all NSAIDs, including aspirin, is equivalent, patient responses are individual. Several trials of different NSAIDs may be necessary to find the most effective drug.

Gastric irritation, ulceration, and bleeding are the most common toxic effects of NSAIDs. They can also affect the lower intestinal tract, leading to perforation or aggravation of inflammatory bowel disorders. All NSAIDs can also be toxic to the kidneys. With the exception of the COX-2 inhibitor celecoxib, most NSAIDs also inhibit platelet function, increasing the risk for bleeding. Aspirin is the only drug in this group that has been found to lower the risk of cardiovascular disease; all others actually increase cardiovascular risk.

NSAIDs commonly prescribed for patients with RA are listed in Table 40–5.

CORTICOSTEROIDS Systemic corticosteroids can dramatically relieve the symptoms of RA and appear to slow the progression of joint destruction. The long-term use of corticosteroids is associated with multiple side effects, such as poor wound healing, increased risk of infection, osteoporosis, and GI bleeding. Severe rebound manifestations can occur when these medications are discontinued. For these reasons, the use of systemic corticosteroids is limited to acute disease flares, or, when necessary, low dosages daily.

DISEASE-MODIFYING ANTIRHEUMATIC DRUGS Disease-modifying antirheumatic drugs are the treatment of choice for RA with the goal of achieving remission or significantly lower disease activity (Singh et al., 2012). DMARDs are a diverse group of medications including drugs that modify immune and inflammatory responses (Table 40–6). They share characteristics that make them useful in the treatment of RA. The DMARDs may be used individually (monotherapy) or in combination. Although beneficial effects are not apparent for several weeks or months following the initiation of therapy, they can produce not only clinical improvement but also evidence of decreased disease activity. Because the desired effects of DMARDs are delayed, NSAIDs often are continued

TABLE 40–5 Selected Nonsteroidal Anti-Inflammatory Drugs Used in Rheumatoid Arthritis

Drug	Average Dose	Comments and Precautions
aspirin	600–900 mg 4–6 times daily	Least expensive NSAID; associated with risk of GI ulceration, bleeding, and possible hemorrhage; may cause hepatotoxicity
etodolac (Lodine)	200–400 mg q6h	Expensive; may have less GI toxicity
ibuprofen (Motrin, Advil, others)	300 mg qid; 400–800 mg tid or qid	Available in prescription and OTC forms; less gastric distress reported than with aspirin or indomethacin; discontinue if visual disturbances develop
indomethacin (Indocin)	25–50 mg bid or tid	A potent NSAID used for moderate to severe RA and acute episodes of chronic disease; higher incidence of adverse GI effects and CNS effects such as headache, dizziness, and depression
meloxicam (Mobic)	7.5–15 mg/day	Daily dosing and rare adverse effects are advantages
nabumetone (Relafen)	1000–2000 mg/day	Most common adverse effects include diarrhea, dyspepsia, and abdominal pain
naproxen (Aleve, Anaprox, Naprosyn)	250–500 mg bid	Available in prescription and OTC preparations
piroxicam (Feldene)	20 mg/day in a single or divided dose	Expensive; GI side effects including stomatitis, anorexia, and gastric distress may occur more frequently than with other NSAIDs
sulindac (Clinoril)	150–200 mg bid	May be safer for use than other NSAIDs in patients with chronic renal disease; rare fatal hypersensitivity reaction with fever, liver function abnormalities, and severe skin reaction

Note: Drugs identified in *italics* are among the 200 most commonly prescribed medications in the U.S.

MULTISYSTEM EFFECTS OF
Rheumatoid Arthritis

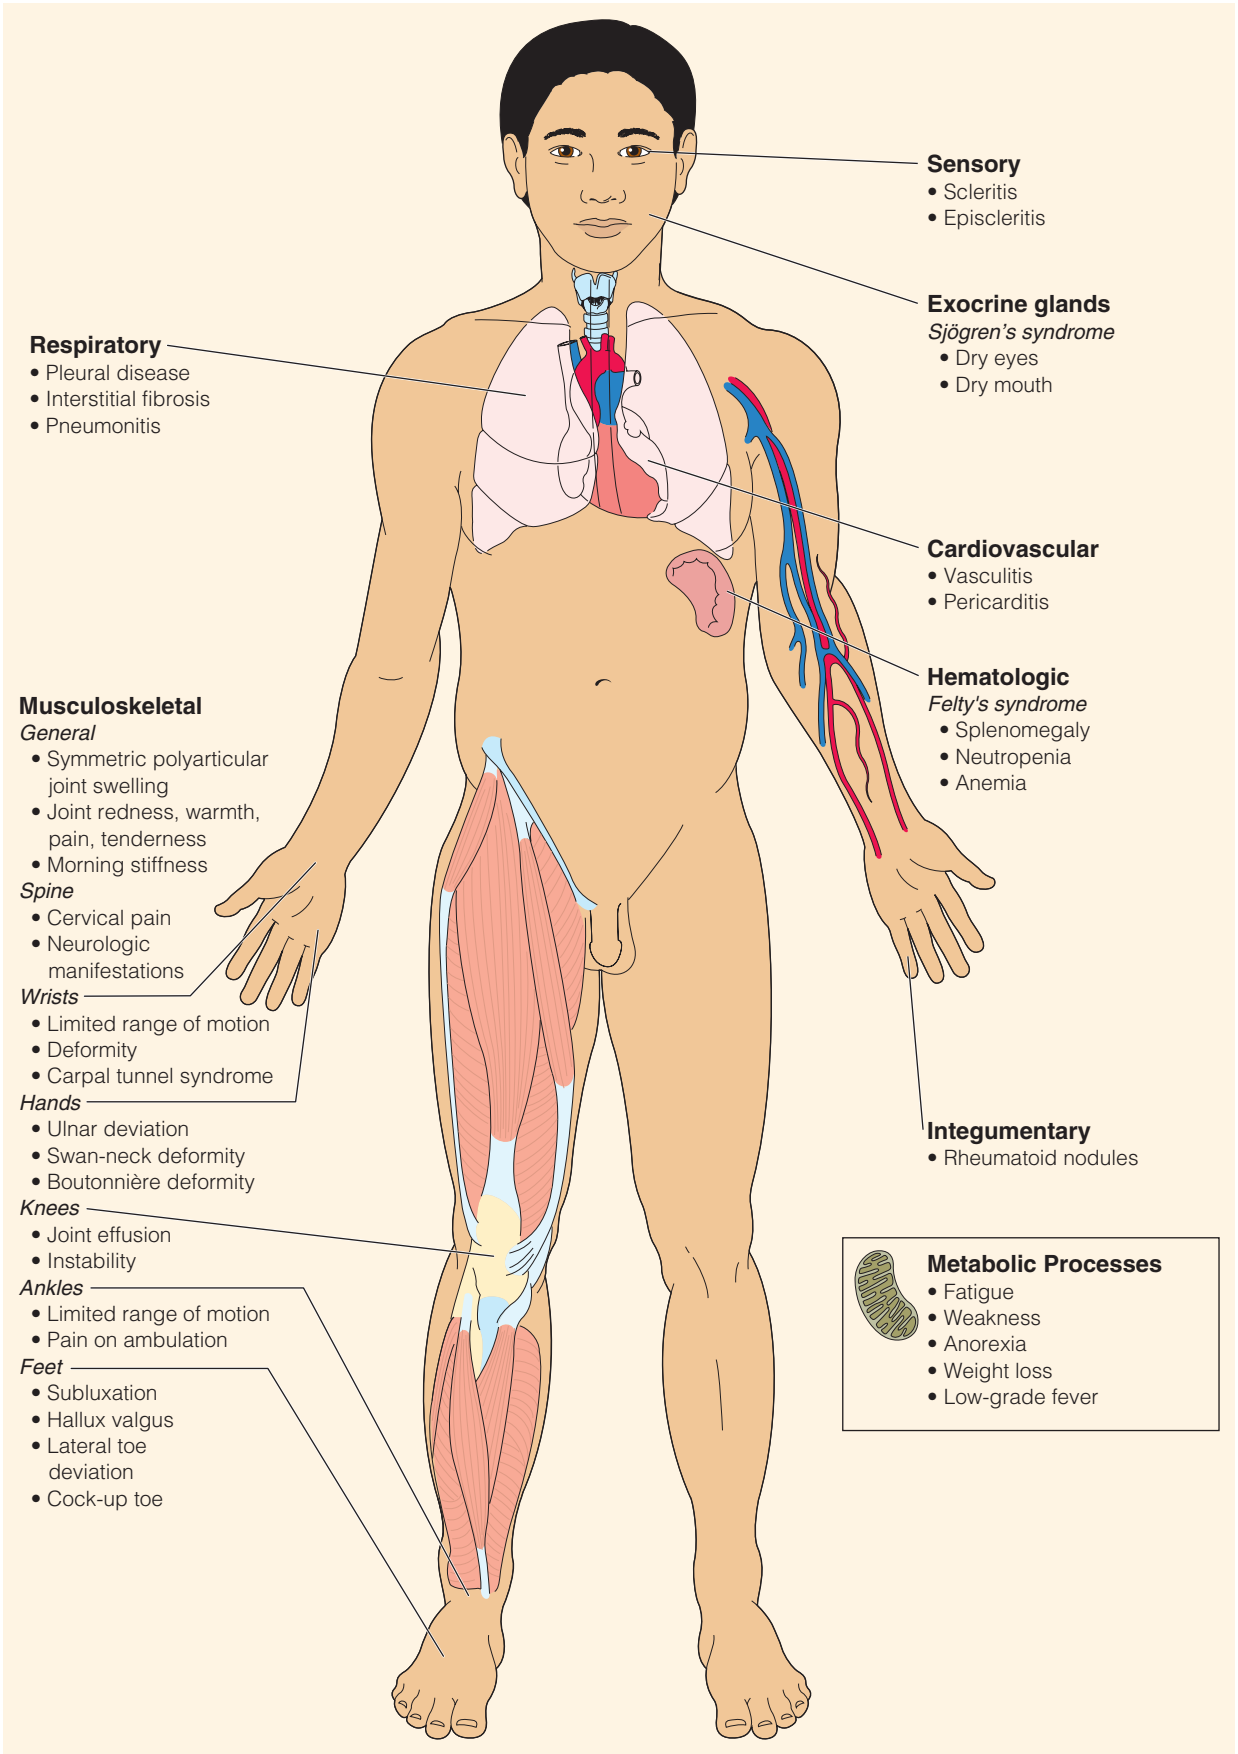

TABLE 40–6 Disease-Modifying Antirheumatic Drugs Used to Treat Rheumatoid Arthritis

Class/Medications	Usual Dose	Adverse Effects	Comments/Nursing Responsibilities
NONBIOLOGIC DMARDS			
hydroxychloroquine (Plaquenil)	200–600 mg/day with meals	• CNS reactions including irritability, nightmares, psychoses • Retinopathy • Alopecia, pruritus • Blood dyscrasias • GI disturbances	• Should not be used during pregnancy. • Regular ophthalmologic examinations are required.
leflunomide (Arava)	100 mg for 3 days, then 10–20 mg daily	• Diarrhea • Rash • Alopecia • Liver toxicity • Weight loss	• Is contraindicated for patients with hepatitis B or C. • Instruct to use reliable contraception. • Instruct to stop taking the drug and promptly report infection.
methotrexate	7.5–15 mg orally once per week	• Stomatitis, gastric distress • Blood dyscrasias • Liver toxicity, cirrhosis • Interstitial pneumonitis, pulmonary fibrosis	• Maintain high fluid intake. • Inspect mouth daily; report ulcerations, necrotic areas, bleeding or discomfort. • Monitor liver and kidney function tests, CBC, chest x-rays, reporting abnormal or unexpected results. • Instruct to avoid alcohol and exposure to sunlight or ultraviolet light. • Instruct to practice effective contraception during treatment.
sulfasalazine (Azulfidine)	2 g/day in divided doses with meals	• Anorexia, nausea, vomiting, gastric distress • Decreased sperm count • Headache • Rash • Blood dyscrasias • Hypersensitivity responses including Stevens-Johnson syndrome • CNS, liver, and renal toxicity	• Administer in evenly divided doses. • Maintain high fluid intake. • May cause yellow-orange skin or urine discoloration. • Regular CBCs necessary.
BIOLOGIC DMARDS			
abatacept (Orencia)	500–1000 mg per IV infusion every 2 weeks for two doses, then every month	• Headache • Nausea • Upper respiratory tract infection	• Screen for tuberculosis prior to initiating treatment. • Stop infusion and notify physician if hypotension, urticaria, or dyspnea develops. • Instruct to promptly report signs of allergic response or infection. • Advise to avoid live-virus vaccines while taking abatacept and for 3 months after discontinuing the drug.
anakinra (Kineret)	100 mg/day subcutaneously	• Bacterial infections (URI, sinusitis) • Injection-site reactions (erythema, inflammation, pain)	• Monitor for and report manifestations of infection. • Monitor blood counts and renal function studies. • Assess for injection-site reactions.
rituximab (Rituxan)	1000 mg per IV infusion on days 1 and 15	• Flu-like symptoms (fatigue, fever, chills, nausea) • Infusion reactions: fever, chills, pruritus, urticaria, flushing, dyspnea	• Monitor BP and ECG during infusion; promptly report hypersensitivity responses. • Instruct to use effective contraception during and for 12 months after treatment.
tocilizumab (Actemra)	4 mg/kg per IV infusion every 4 weeks	• Serious infections including opportunistic infections • Elevated ALT and AST levels	• Monitor for allergic responses during and immediately following infusion. • Monitor for and report manifestations of infection. • Monitor CBC and liver function studies.

TABLE 40–6 Disease-Modifying Antirheumatic Drugs Used to Treat Rheumatoid Arthritis (*continued*)

Class/Medications	Usual Dose	Adverse Effects	Comments/Nursing Responsibilities
Tumor necrosis factor inhibitors:		• Injection-site reactions • Increased risk for infection • Possible flu-like symptoms (headache, malaise)	• Obtain tuberculin test results before treatment is started. • Instruct to promptly report signs of infection. • Stop infusion of infliximab and promptly notify physician if signs of anaphylaxis develop.
• adalimumab (Humira)	40 mg subcutaneously every other week		
• etanercept (Enbrel)	25 mg subcutaneously twice weekly		
• infliximab (Remicade)	3 mg/kg IV infusion weeks 0, 2, 6, then every 8 wks		
• certolizumab (Cimzia, Pegol)	400 mg subcutaneously weeks 0, 2, 4; then 200 mg every other week		
• golimumab (Simponi)	50 mg subcutaneously monthly		

Note: Drugs identified in *italics* are among the 200 most commonly prescribed medications in the U.S.

during initial therapy. All of these drugs are fairly toxic, and close monitoring is necessary during the course of therapy. Treatment for active infections such as hepatitis B or C or known latent tuberculosis infection should be started prior to initiation of DMARD therapies (Singh et al., 2012).

NONBIOLOGIC DMARDS Commonly used nonbiologic DMARDs include methotrexate, sulfasalazine, leflunomide (Arava), and hydroxychloroquine.

Methotrexate is considered to be the DMARD of choice, used in both monotherapy and in combination with other DMARDs (Shah & St. Clair, 2012). A weekly dose can produce a beneficial effect in as few as 2 to 4 weeks. Gastric irritation and stomatitis are the most frequent side effects associated with methotrexate, but side effects may be better controlled if folic acid is taken at the same time. Alcoholism, diabetes, obesity, advanced age, and renal disease increase the risk of toxic effects (hepatotoxicity, bone marrow suppression, interstitial pneumonitis).

Sulfasalazine, a drug regularly prescribed for chronic inflammatory bowel disease, may also be prescribed for RA. Adverse effects such as neutropenia and thrombocytopenia are relatively common with sulfasalazine, necessitating frequent CBCs to monitor its effects. Leflunomide reversibly inhibits an enzyme involved in the autoimmune process. Because this drug is teratogenic, it is contraindicated for premenopausal women and for men who desire children. Hydroxychloroquine (Plaquenil) is an antimalarial agent sometimes employed in the treatment of RA. Three to 6 months of therapy is required to achieve the desired response, and many patients do not experience significant benefit. Although hydroxychloroquine has a relatively low toxicity, it can cause pigmentary retinitis and vision loss. Patients receiving this drug require a thorough vision examination every 6 months.

Drugs such as penicillamine or gold salts, used in the past to treat RA, rarely are prescribed. Although these agents may be effective for some patients, toxic reactions are common and can be severe, including bone marrow suppression, proteinuria, and nephrosis.

BIOLOGIC DMARDS Biologic DMARDs may be used alone, but often are prescribed in combination with methotrexate to reduce disease activity and induce remission (Shah & St. Clair, 2012; Singh et al., 2012). These drugs act by inhibiting components of the immune or inflammatory response, such as TNF-α or IL-1. They control the manifestations of RA in most patients, slow the progression of joint damage, and reduce disability. Biologic DMARDs increase the risk for infection and have been associated with an increased risk for reactivation tuberculosis. Patients are screened for tuberculosis prior to treatment.

Several biologic DMARDs act by inhibiting tumor necrosis factor, thus interrupting the inflammatory cascade of RA. Etanercept (Enbrel) inhibits the binding of tumor necrosis factor to receptor sites. Infliximab (Remicade) is a biologic response modifier and TNF-α receptor antagonist. Given by intravenous infusion, the drug is administered to reduce infiltration of inflammatory cells and TNF-α production. Adalimumab (Humira), given by subcutaneous injection, binds with TNF receptor sites.

Abatacept (Orencia) and rituximab (Rituxan) generally are reserved for patients with high levels of disease activity. Abatacept acts by interfering with the formation of T cells, whereas rituximab is a monoclonal antibody that depletes B cells. Tocilizumab (Actemra) and Anakinra (Kineret) work by inhibiting IL-1 and IL-6 receptors. Like other biologic DMARDs, these drugs are given parenterally, most by intravenous infusion.

TREATMENTS

The primary objectives in treating RA are to prevent joint damage and disability, reduce pain and inflammation, and minimize side effects of treatment.

REST AND EXERCISE A balanced program of rest and exercise is an important component in the management of patients with RA. Physical and occupational therapists can design and monitor individualized activity and rest programs.

Regular rest periods during the day may be beneficial to reduce manifestations of the disease. Additionally, splinting of inflamed joints reduces unwanted motion and provides local joint rest. A variety of orthotic devices are available to reduce joint strain and help maintain function.

A balanced program of physical therapy and exercise is critical to maintain muscle strength and joint mobility. Dynamic strength training (e.g., isometric exercises, use of resistance bands) is used to improve muscle strength without increasing joint stress. Low-impact aerobic exercises, such as swimming and walking, have been shown to benefit patients with RA without adversely affecting joint inflammation or prompting acute episodes. A program that includes 30 minutes of moderately intense activity most days of the week has been shown to improve both muscle strength and perceived health in patients with RA (Shah & St. Clair, 2012).

HEAT AND COLD Heat and cold are used for their analgesic and muscle-relaxing effects. Moist heat is generally the most effective, and can be provided by a tub bath or shower. Joint pain is relieved in some patients through the application of cold.

ASSISTIVE DEVICES AND SPLINTS Assistive devices, such as a cane, walker, or raised toilet seat, are most useful for patients with significant hip or knee arthritis. Splints provide joint rest and prevent contractures. Night splints for the hands and/or wrists should maintain the extremity in a position of maximum function. The best "splint" for the hip is lying prone for several hours a day on a firm bed. In general, splints should be applied for the shortest period needed, should be made of lightweight materials, and should be easily removed to perform ROM exercises once or twice a day.

NUTRITION For most patients with RA, an ordinary, well-balanced diet is recommended. Some patients may benefit from substitution of usual dietary fat with omega-3 fatty acids found in certain fish oils.

SURGERY Surgical intervention may be employed for the patient with RA when medical management has failed to prevent joint damage. Arthrodesis (joint fusion) may be used to stabilize joints such as cervical vertebrae, wrists, and ankles. Arthroplasty, or total joint replacement, may be necessary in cases of gross deformity and joint destruction. Total joint replacement and nursing care of patients undergoing this surgery are discussed in the preceding section on OA.

●○● NURSING CARE

Patients with chronic, progressive, systemic disorders such as RA have multiple nursing care needs involving many functional health patterns. Physical manifestations of the disease often result in acute and chronic pain, fatigue, impaired mobility, and difficulty performing routine tasks. Treatments to reduce disease activity or prompt remission can have significant side effects and often increase the patient's risk of infection. The disease also has many psychosocial effects. The patient has an incurable chronic disease and may be facing a lifetime of therapy. Pain and fatigue can interfere with the patient's ability to perform expected roles, such as home maintenance or job responsibilities. Even though the patient's hands may appear swollen or deformed, other people may not understand the systemic nature of the disease or realize the difference between RA and OA. See the Case Study & Nursing Care Plan for a patient with RA.

Health Promotion

People with RA can maintain control of their lives by becoming arthritis self-managers. They can help prevent deformities and the effects of arthritis by following prescriptions for exercise, rest, weight management, posture, and positioning. The MossRehab Resource Net (2010) outlines the following suggestions:

- Never attempt an activity that cannot be stopped immediately if it proves to be beyond your power to complete it.
- Respect pain as a warning signal. When you experience pain, change your method of doing things, use equipment or tools if necessary, and take intermittent rest periods.
- Use the strongest joints available for an activity. For example, use the palm of your hand or the crook of your elbow instead of fingers for grasping while carrying.
- Avoid stress toward a position of deformity, such as when the fingers drift toward the little finger. For example, open a jar with your right hand and close a jar with your left hand.
- Avoid activities that need a tight grip, such as writing, wringing, and unscrewing.

Assessment

Collect the following data through the health history and physical examination:

- *Health history:* pain; duration of morning stiffness; fatigue; joint inflammation: number, location, duration, onset, effect on function; fever; sleep patterns; current RA treatment; past illnesses (including tuberculosis or hepatitis) or surgery; ability to carry out ADLs and self-care activities
- *Physical assessment:* height/weight; gait; joints: symmetry, size, shape, color, appearance, temperature, range of motion, pain; skin: nodules, purpura; respiratory: cough, crackles; cardiovascular: pericardial friction rub, apical impulse, S_3.

Priorities of Care

Nursing care priorities for the patient with RA will vary depending on the circumstances of the nurse–patient interaction. The newly diagnosed patient who is just starting treatment to reduce disease activity with the goal of achieving remission has very different care needs than the patient experiencing a treatment complication such as infection or gastrointestinal bleeding, or the patient who has undergone a total joint arthroplasty.

Diagnoses, Outcomes, and Interventions

Many nursing diagnoses may be appropriate for the patient with RA. This section focuses on those related to its predominant manifestations and their effect on the patient's life.

Readiness for Enhanced Self-Health Management

Patients newly diagnosed with RA need to become actively involved in managing their disease. To do so, the patient needs to understand his or her condition, the prescribed therapeutic regimen and treatment goals, and how to manage both treatment and manifestations of RA. Disease manifestations such as fatigue, pain, and weakness, and medication effects such as increased risk for infection can interfere with the patient's ability to maintain health. Psychosocial issues such as denial, poor coping, lack of financial and other resources, and inadequate support can also be significant for the patient with RA.

Expected Outcome: Patient will demonstrate willingness and the ability to effectively manage prescribed therapeutic regimen.

- Assess the patient's understanding of RA, its manifestations and effects, and the anticipated course of the disease. Reinforce and clarify information as needed, providing written material at the patient's level. *Newly diagnosed patients need understandable information that is readily available to develop an understanding of their disease and its treatment, and their role in managing RA (Walker, 2012).*
- Initiate an interprofessional care conference with the patient and family. *Patients and families need opportunities to discuss management strategies and their concerns and perceptions to develop a better understanding of interprofessional team member roles and services (Firth, 2011).*
- Encourage the patient and family members to discuss the effect of the disease on their lives. *Open discussion helps identify the need for practical skills to manage pain, fatigue, and physical limitations of the disease, as well as psychosocial and emotional challenges associated with RA and its treatment (Firth, 2011).*
- Refer the patient and family to community and social service agencies, and local support groups. *These groups and agencies are valuable resources for the patient and family.*

Chronic Pain

Pain is a constant feature of RA when the disease is active. Some patients say the pain in joints and surrounding tissue is like a deep, constant toothache. Pain can significantly affect the patient's ability to provide self-care and maintain daily activities. It also contributes to the patient's fatigue.

Expected Outcome: Patient will report minimal joint pain (2 or lower as measured on a standard pain scale of 0 to 10).

- Monitor the level of pain and duration of morning stiffness. *Pain and morning stiffness are indicators of disease activity (Oliver, 2010). Increased pain may necessitate changes in the therapeutic treatment plan.*
- Teach the use of heat and cold applications to provide pain relief. The patient may apply heat by showering or taking tub baths, or by using local applications such as warm compresses or paraffin dips. During periods of acute inflammation, cold packs may relieve pain more effectively. *Both heat and cold have analgesic effects and can help relieve associated muscle spasms.*
- Teach about the use of prescribed anti-inflammatory medications and the relationship of pain and disease activity. *Anti-inflammatory agents reduce chemical mediators of inflammation and swelling, relieving pain. Increasing pain (level, duration, number of painful joints) is an indicator of increased disease activity and may necessitate a change in the therapeutic regimen.*

Evidence for Nursing Care

The Patient with Rheumatoid Arthritis

Selected resources that nurses may find helpful when planning evidence-based nursing care follow.

- Oliver, S. (2010). Improving long-term outcomes for rheumatoid arthritis: Evidence-based care. *Primary Health Care, 20*(9), 30–38.
- Scottish Intercollegiate Guidelines Network (SIGN). (2011). *Management of early rheumatoid arthritis. A national clinical guideline.* Edinburgh, Scotland: Scottish Intercollegiate Guidelines Network.
- Singh, J., Furst, D., Bharat, A., Curtis, J., Kavanaugh, A., Kremer, J., . . . Saag, K. (2012). 2012 update of the 2008 American College of Rheumatology recommendations for the use of disease-modifying antirheumatic drugs and biologic agents in the treatment of rheumatoid arthritis. *Arthritis Care & Research, 64*(5), 625–639.

Fatigue

The pain and chronic inflammatory processes associated with RA lead to fatigue. Other factors such as disrupted sleep, anemia, and muscle weakness contribute as well.

Expected Outcome: Patient will demonstrate reduced fatigue with increased ability and desire to participate in daily activities.

- Encourage a balance of periods of activity with periods of rest. *Both joint and whole-body rest are important, while regular activity is important to maintain muscle strength and reduce fatigue (Shah & St. Clair, 2012).*
- Help patient to prioritize activities, performing the most important ones early in the day. *Assigning priorities helps the patient avoid performing relatively unimportant activities at the expense of more meaningful and important ones.*
- Encourage dynamic (aerobic) physical activity in addition to prescribed ROM exercises. *Aerobic exercise promotes a sense of well-being and restful sleep patterns.*
- Refer to counseling or support groups. *Counseling and support groups can help the patient develop effective coping strategies and deal with depression and hopelessness.*

Ineffective Role Performance

RA can interfere with the patient's ability to pursue a career and fill other life roles, such as parent, spouse, or homemaker. As the patient's role changes, so must the roles of other family members. This can contribute to changes in family processes, increased stress, and further difficulty coping with the effects of RA.

Expected Outcome: Patient will acknowledge impact of disease on roles and relationships and express willingness to use available resources.

- Discuss the effects of the disease on the patient's career and other life roles. Encourage the patient to identify changes brought on by the disease. *Discussion helps the patient to accept the changes and begin to identify strategies for coping with them.*
- Encourage the patient and family to discuss their feelings about role changes and grieve lost roles or abilities. *Verbalization allows family members to validate and accept feelings about losses and changes, thus helping them to move into new roles.*
- Listen actively to concerns expressed by the patient and family members; acknowledge the validity of concerns about the disease, prescribed treatment, and the prognosis. *Demonstrating acceptance of these feelings and concerns promotes trust and validates their reality.*
- Help the patient and family identify strengths they can use to cope with role changes. *Identifying strengths helps the patient and family to consider role changes that maintain self-esteem and dignity.*
- Encourage the patient to make decisions and assume personal responsibility for disease management. *Patients who assume a personal and active role in managing their disease maintain a greater sense of self-control and self-esteem, which is associated with an improved quality of life (Furfaro & Mease, 2011).*

CASE STUDY & NURSING CARE PLAN A Patient with Rheumatoid Arthritis

Janice James is a 40-year-old high school science teacher who began noticing vague joint pain, fatigue, poor appetite, and general malaise about 3 months ago. Her symptoms have continued, and she reports feeling very stiff in the mornings, often taking until 10:00 or 11:00 a.m. to begin to feel normal. She initially attributed aching pain in her hands and wrists to the quilting she loves to do in the evenings, but made an appointment with her family physician when she noticed that her knuckles and finger joints were not just achy but also swollen and hot. Noting that Mrs. James has a significantly elevated ESR, the physician refers her to the rheumatology clinic for further evaluation. Following examination, laboratory and radiologic testing, the rheumatologist establishes a diagnosis of rheumatoid arthritis and initiates an interprofessional team conference to plan its management.

ASSESSMENT

Cathy Greenstein, RN, completes an assessment of Mrs. James. She notes that Mrs. James appears fatigued and ill, and states that she feels unable to keep up with all her responsibilities as a teacher and a parent due to her fatigue.

Mrs. James's past medical history reveals only the usual childhood diseases and three uncomplicated pregnancies. Physical assessment findings include BP 124/78 mmHg, P 82 bpm and regular, R 18/min, T 37.8°C (100.2°F) PO. Hands: swelling of the proximal interphalangeal (PIP) and metacarpophalangeal (MCP) joints of both hands; second and third PIP and second MCP joints on right hand are red, shiny, hot, spongy, and tender to palpation; able to extend fingers to 180 degrees but cannot make a complete fist with either hand, with flexion limited to less than 90 degrees; grip strength is weak bilaterally; wrist ROM is limited in all directions. Knees are swollen, and flexion is slightly limited; positive bulge sign in the right knee. Diagnostic findings are an ESR of 52 mm/h, elevated CRP, and positive for rheumatoid factor and anti-CCP antibodies. Few changes other than soft tissue swelling are evident on hand and wrist x-rays.

DIAGNOSES

- *Chronic Pain* related to joint inflammation
- *Impaired Home Maintenance* related to fatigue
- *Activity Intolerance* related to the effects of inflammation
- *Readiness for Enhanced Knowledge: Therapeutic Regimen*

EXPECTED OUTCOMES

- Patient will verbalize effective pain management strategies:
  - Use of assistive devices to minimize joint stress with ADLs
  - A plan to reduce responsibilities for home maintenance
  - An understanding of appropriate use of prescribed NSAID to relieve pain and reduce inflammation.
- Patient will demonstrate understanding of the prescribed therapeutic regimen and its importance for both short- and long-term benefit.

PLANNING AND IMPLEMENTATION

- Teach techniques for relieving pain and morning stiffness, including the following:
  - Schedule NSAIDs at equal intervals throughout the day.
  - Take morning NSAID dose with milk and crackers approximately 30 minutes before rising.
  - Perform ROM exercises in shower or bathtub.
  - Apply local heat with paraffin dip or compress, use cold packs as needed.
  - Teach techniques to minimize joint stress while performing ADLs.
- Provide Arthritis Foundation literature and information.
- Discuss ways to delegate household tasks to other family members.
- Explore ways to incorporate 30-minute rest breaks into work schedule.
- Provide information about the disease process and its manifestations, prescribed medications with desired and adverse effects, and the importance of balancing rest and activity.

EVALUATION

The initial treatment regimen of NSAIDs, methotrexate, rest, exercise, and physical therapy succeeded in reducing Mrs. James's disease activity. However, complete remission has not been achieved. She has had difficulty scheduling rest periods at work and has had to struggle to delegate household tasks. "I don't look sick to the kids, and they seem to think housecleaning is a terrible imposition on their time. It's often easier to just do it myself than to fight about it. Besides, that way it gets done right." Mrs. James has faithfully followed the prescribed medication regimen and exercise routines, and she has kept her scheduled appointments and maintained contact with the treatment team.

Clinical Reasoning in Patient Care

1. Review the diagnostic criteria for rheumatoid arthritis. What laboratory and radiologic tests are used to help establish the diagnosis of RA?
2. Are these tests specific for RA or might abnormal results occur with other diseases or in other circumstances?
3. Do these tests require any specific patient preparation or teaching? If so, what teaching does Mrs. James require?
4. Mrs. James is 40 years old. Would your nursing interventions differ if she were 72 years old? If so, how?
5. Rheumatoid arthritis is a chronic illness. What are the physical, emotional, and economic implications of a chronic illness that results in chronic pain and deformity?
6. Develop a nursing care plan for Mrs. James using the nursing diagnosis *Ineffective Role Performance*.

See Evaluating Your Response in Appendix B.

Delegating Nursing Care Activities

As appropriate and allowed within the designated duties and responsibilities of unlicensed assistive personnel, the nurse may delegate nursing care activities such as assisting with daily living activities and ROM exercises for the patient with rheumatoid arthritis.

Continuity of Care

RA is typically a chronic, progressive disease. As with most diseases of this nature, involvement of the patient and family in its management is vital. Education is an important nursing role in caring for patients with RA and their families, improving quality of life and motivation to adhere to the prescribed therapeutic regimen (Furfaro & Mease, 2011). Address the following topics for home care of the patient and for family members:

- Disease process and treatments, including rest and exercise
- Medications, including their desired effects and anticipated onset of action, common adverse effects, and precautions specific to each medication
- Management of stiffness and pain
- Energy conservation
- Use of assistive devices to maintain independence, including self-care aids such as handheld showers, long-handled brushes

and shoehorns, and eating utensils with oversized or special handles
- How to apply splints and take care of skin
- Home and equipment modifications, such as a raised toilet seat, grab bars in the bathroom, a bath chair, or adapted counter heights for patients in a wheelchair
- Physical therapy, occupational therapy, home health and homemaker services

THE PATIENT WITH ANKYLOSING SPONDYLITIS

Ankylosing spondylitis (AS), also known as *axial spondyloarthritis*, is a chronic inflammatory arthritis that primarily affects the axial skeleton, leading to pain and progressive stiffening and fusion of the spine. The typical age of onset is between 17 and 35, with an estimated 2.7 million adults affected in the United States (Reveille et al., 2012; Spondylitis Association of America, 2012a). The incidence is greater in men than women, and men have more severe disease. AS is difficult to diagnose in the early stages, but may be a major cause of persistent back pain in young adults.

The cause of ankylosing spondylitis is unknown. As with the other forms of arthritis primarily affecting the spine, there is a strong genetic component. Approximately 90% of people with ankylosing spondylitis have the HLA-B27 antigen; about 8% of the general population has this antigen (Grossman & Porth, 2014). Evidence indicates an immune component to disease development. Although a specific trigger for AS has not been identified, evidence suggests that enteric bacteria may play a role in its development (Taurog, 2012).

Pathophysiology

The inflammation of ankylosing spondylitis initially affects sites where tendons and ligaments attach to the bone. Early inflammatory changes often are first noted in the sacroiliac joints. As the cartilage erodes, joint margins ossify and are replaced by scar tissue. The joints of the spine are also affected, with inflammation of the cartilaginous joints and gradual calcification and ossification that leads to ankylosis, or joint consolidation and immobility. Other organ systems may be affected as well, including the eyes, lungs, heart, and kidneys.

Manifestations

The onset of ankylosing spondylitis is usually gradual and insidious. Patients may have persistent or intermittent bouts of low back pain. The pain is worse at night, followed by morning stiffness that is relieved by activity. Pain may radiate to the buttocks, hips, or down the legs. As the disease progresses, back motion becomes limited, the lumbar curve is lost, and the thoracic curvature is accentuated. In severe cases, the entire spine becomes fused, preventing any motion. Patients with ankylosing spondylitis may experience peripheral arthritis, primarily affecting the hip, shoulders, and knee joints. Systemic manifestations include anorexia, weight loss, fever, and fatigue. Many patients develop uveitis (inflammation of the iris and the middle, vascular layer of the eye). Extra-articular manifestations of the disease also may include inflammatory bowel disease, psoriasis, and, uncommonly, pulmonary or cardiac dysfunction (Taurog, 2012).

For most patients with ankylosing spondylitis, the disease is intermittent with mild to moderate acute episodes. These patients have a good prognosis with little risk of severe disability.

●○● INTERPROFESSIONAL CARE

Diagnostic testing shows an elevated ESR and CRP during periods of active disease and typically a positive HLA-B27 antigen. The diagnosis of ankylosing spondylitis is usually confirmed with x-ray examination of the sacroiliac joints and spine. The sacroiliac joint becomes blurred and gradually obliterated. As the disease progresses, vertebrae become squared, and disk spaces narrow. MRI allows earlier identification of active sacroiliitis, and may be used for diagnosis.

As with other forms of arthritis, the management of ankylosing spondylitis is multidimensional. Physical therapy and daily exercises are important to maintain posture and joint ROM. NSAIDs relieve pain and stiffness and allow the patient to perform necessary exercises. Patients who fail to respond to treatment with NSAIDs may be treated with a biologic DMARD that targets TNF-α. These drugs, including infliximab (Remicade), etanercept (Enbrel), and adalimumab (Humira) or golimumab (Simponi), significantly reduce disease activity and improve manifestations and function for patients with AS. Refer to Table 40–6 for nursing implications of these drugs. Severe hip joint arthritis may necessitate total hip arthroplasty.

●○● NURSING CARE

The primary nursing role in ankylosing spondylitis is to provide supportive care and education. To promote mobility, teach the patient to take NSAIDs at regular intervals throughout the day with food, milk, or antacid. If the patient is receiving a DMARD, provide information about possible adverse effects and when to contact the physician. Encourage the patient to maintain a fluid intake of 2500 mL or more per day. Suggest that the patient perform exercises in the shower because warm, moist heat prompts mobility. Stress the importance of following the prescribed physical therapy and exercise program to maintain mobility.

Teach the patient that proper positioning and posture are important. When sleeping, a bed board may be used to provide firmness, and the person should sleep in the supine position using either no pillow or only one small pillow. Other important self-care activities include losing weight if applicable, avoiding smoking, and using muscle-strengthening exercises. Suggest occupational counseling if pain and deformity are severe enough to cause work-related problems.

THE PATIENT WITH REACTIVE ARTHRITIS

Reactive arthritis (ReA) (Reiter's syndrome) is an acute, nonpurulent inflammatory arthritis that is believed to be a response to an exposure or infection with certain types of bacteria, including *Chlamydia*

(a bacterium contracted during sexual activity) or *Salmonella*, *Shigella*, *Yersinia*, or *Campylobacter* (which cause dysentery from contaminated or spoiled food). Like ankylosing spondylitis, this type of arthritis often affects people who have an inherited HLA-B27 antigen. Reactive arthritis is often found in patients with HIV infection, although the reason for the association is not clear. Reactive arthritis is typically self-limited, although it can be recurrent or progressive. About 15% to 20% of people with ReA develop a chronic arthritis or spondylitis (Spondylitis Association of America, 2012b).

Manifestations

Nonbacterial urethritis may be the initial manifestation of ReA in men. In women, urethritis and cervicitis may be asymptomatic. Fatigue, malaise, fever, and weight loss are common. Conjunctivitis and acute inflammatory arthritis follow. The arthritis is usually asymmetric, affecting weight-bearing joints of the lower extremities, such as the knees, ankles, metatarsal, and toe joints. The wrists and fingers may also be involved. Tendinitis, fasciitis, and back pain are common. Mouth ulcers, inflammation of the glans penis, and skin lesions may occur. The heart and aorta may also be affected.

●○● INTERPROFESSIONAL CARE

The diagnosis of reactive arthritis is based on the patient's history and presenting symptoms. Manifestations of ReA typically occur 2 to 4 weeks after the infection, and subside in 3 to 12 months. The condition has a tendency to recur. No test is specific for the disorder. Urethral or cervical cultures are obtained to rule out gonococcal infection. When *Chlamydia* is suspected, the patient may be treated with erythromycin or a 6-month course of rifampin plus azithromycin or doxycycline. Reactive arthritis is treated symptomatically, usually with NSAIDs. Patients with persistent ReA may respond to treatment with a DMARD such as sulfasalazine or an immunosuppressive agent such as azathioprine (Imuran) or methotrexate. In severe chronic ReA, a biologic TNF inhibitor such as adalimumab (Humira) or etanercept (Embrel) may be used (Taurog, 2012).

●○● NURSING CARE

Patients with reactive arthritis usually are seen in primary care settings such as a clinic or physician's office, making the nursing role primarily one of education. Teach the patient about the association of the arthritis with the precipitating infection (if identified). Stress the importance of treating the infection effectively if it is still present. Use this opportunity to provide information about sexually transmitted infections and protective measures to prevent their transmission. Discuss the usual self-limited nature of reactive arthritis, the appropriate use of prescribed NSAID preparations, and symptomatic relief measures such as application of heat and rest.

THE PATIENT WITH SYSTEMIC LUPUS ERYTHEMATOSUS

Systemic lupus erythematosus (SLE) is a chronic inflammatory autoimmune disease that affects almost all body systems, including the musculoskeletal system. The manifestations of SLE are widely variable and are thought to result from cell and tissue damage caused by deposition of antigen–antibody complexes in connective tissues. SLE can range from a mild, episodic disorder to a rapidly fatal disease process.

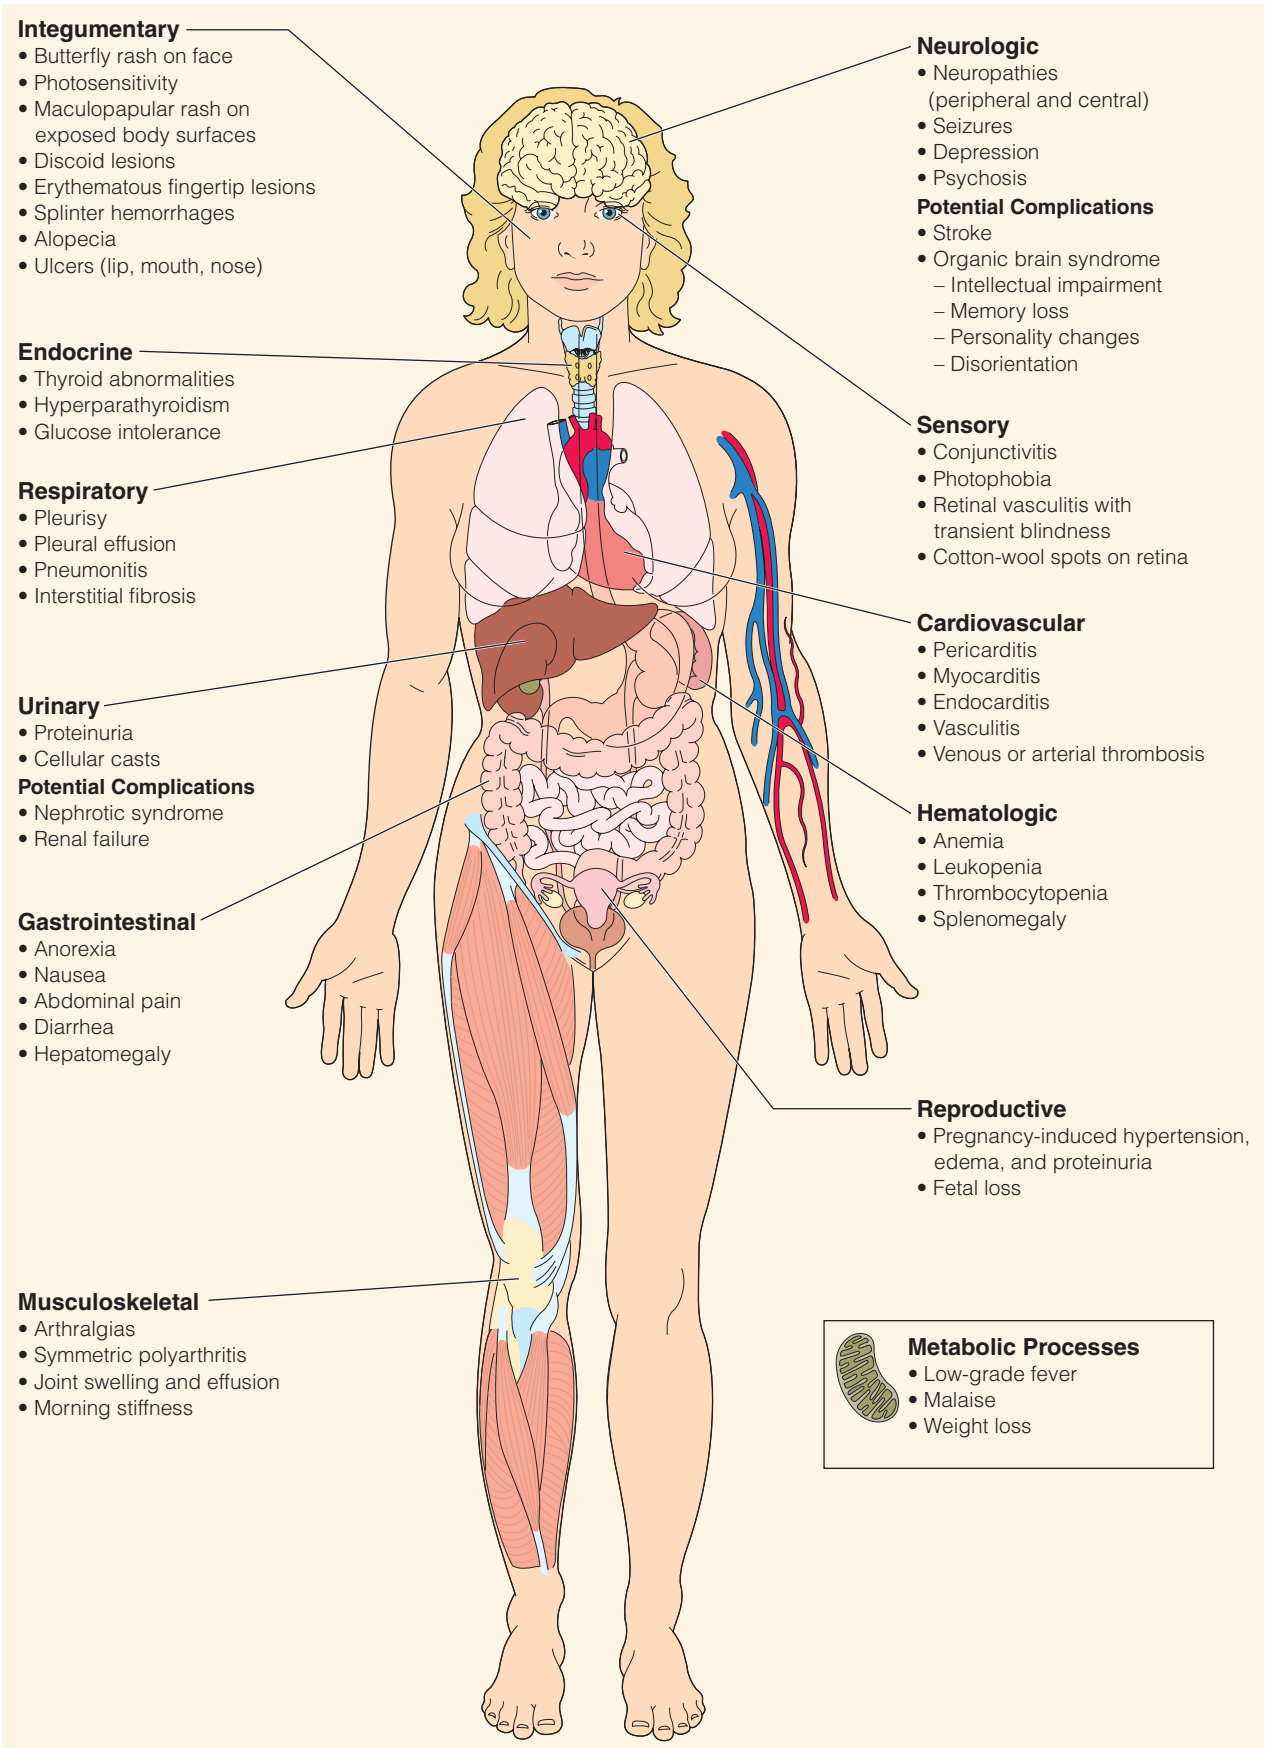
FAST FACTS

SLE

- Approximately 1 person in 2000 is affected by SLE (about 500,000 in the United States), with women predominating by a ratio of 10:1 over men.
- SLE usually affects women of childbearing age (when the incidence is 30 times greater than in men) but it can occur at any age, affect either gender, and is found in all ethnic groups.
- African American women have the highest prevalence of SLE; it also is more common in Hispanics, Native Americans, and Asians than it is in Caucasians (CDC, 2012). Lupus prevalence is lowest in Caucasian men (Hahn, 2012).
- Multiple etiologic factors contribute to SLE, including genetic, gender, and environmental factors.

Although the exact etiology of SLE is unknown, genetic, environmental, and hormonal factors play a role in its development. Twin studies and a familial pattern of the disease point to a genetic component, as does an increased incidence of other connective tissue diseases in relatives of people with SLE. Certain human leukocyte antigen (HLA) genes are seen more frequently in people with SLE. Environmental factors such as viruses (e.g., Epstein-Barr virus), occupational exposure to silica dust, ultraviolet light, and cigarette smoking may play a role in activation of the pathologic mechanisms of the disease. In addition, an imbalance of sex hormones may contribute to the development of SLE. Women who use estrogen-containing oral contraceptives or hormone replacement have a higher risk of developing SLE (Hahn, 2012).

The course of SLE is mild in most patients, with periods of remission and exacerbation. The number and severity of exacerbations tend to decrease with time. In some patients, however, SLE is a virulent disease with significant organ system involvement. Systemic disease, kidney failure, and infections are leading causes of death in patients with SLE, as are thromboembolic events (e.g., cardiovascular disease, stroke) (Hahn, 2012).



See the Multisystem Effects of SLE feature.

Pathophysiology

The pathophysiology of SLE involves the production of a large variety of autoantibodies against normal body components such as nucleic acids, erythrocytes, coagulation proteins, lymphocytes, and platelets. Autoantibody production results from hyperreactivity of B cells (humoral response) because of disordered T-cell function (cellular immune response). The most characteristic autoantibodies in SLE are produced in response to nucleic acids, including DNA, histones, ribonucleoproteins, and other components of the cell nucleus.

SLE autoantibodies bind with their target tissue to form immune complexes, which are then deposited in the connective tissue of blood vessels, lymphatic vessels, and other tissues. The deposits trigger an inflammatory response with release of chemotaxins, cytokines, vasoactive peptides, and destructive enzymes, which results in local tissue damage. The kidneys are a frequent site of complex deposition and damage; other tissues affected include the musculoskeletal system, brain, heart, spleen, lung, GI tract, skin, and peritoneum. The autoantibodies produced and their target tissue determine the manifestations of SLE.

MULTISYSTEM EFFECTS OF
Systemic Lupus Erythematosus

A number of drugs can cause a syndrome that mimics lupus in patients with no other risk factors for the disease. Procainamide (e.g., Procan-SR, Pronestyl) and hydralazine (Apresoline, Hydralyn) are the most common drugs implicated, along with isoniazid (INH).

Renal and CNS manifestations of SLE rarely occur with drug-induced lupus, but arthritic and other systemic symptoms are common. Manifestations of drug-induced lupus usually resolve when the medication is discontinued.

Manifestations

Typical early manifestations of SLE mimic those of rheumatoid arthritis, including systemic manifestations of fever, anorexia, malaise, and weight loss, and musculoskeletal manifestations of multiple arthralgias and symmetric polyarthritis. Joint symptoms affect more than 90% of patients with SLE. Although synovitis may be present, the arthritis associated with SLE is rarely deforming.

Most people affected by SLE have skin manifestations at some point during their disease. In fact, SLE was originally described as a skin disorder and named for the characteristic red butterfly rash across the cheeks and bridge of the nose (Figure 40–10 ■). Many patients with SLE are photosensitive; a diffuse maculopapular rash on skin exposed to the sun is common. Other cutaneous manifestations include discoid lesions (raised, scaly, circular lesions with an erythematous rim), hives, erythematous fingertip lesions, and splinter hemorrhages. Alopecia is common in patients with SLE, although the hair usually grows back. Painless mucous membrane ulcerations may occur on the lips or in the mouth or nose. Common manifestations of SLE are listed in an accompanying box.

Approximately 50% of people with SLE experience renal manifestations of the disease, including proteinuria, cellular casts, and nephrotic syndrome. Up to 10% develop renal failure as a result of the disease.

Figure 40–10 ■ The butterfly rash of systemic lupus erythematosus.

MANIFESTATIONS OF SLE

- Painful or swollen joints and muscle pain
- Unexplained fever
- Red rash, especially on the face
- Alopecia
- Pale, cyanotic fingers or toes
- Sensitivity to the sun
- Edema in legs and around eyes
- Ulcers in the mouth
- Enlarged lymph nodes
- Extreme fatigue

Hematologic abnormalities such as anemia, leukopenia, and thrombocytopenia are common with SLE. Up to 40% of patients with SLE develop pericarditis. Myocarditis is less common, but may develop. Vascular disorders such as vasculitis and Raynaud's phenomenon often occur. Patients with SLE have an increased risk for acute thrombotic events such as transient ischemic attack (TIA), stroke, and myocardial infarction. Pleuritis, pleural effusions, and lupus pneumonitis are common pulmonary manifestations of SLE.

Nervous system effects of the disease are common, including cognitive dysfunction with a decline in intellect, memory loss, and disorientation. Other possible neurologic manifestations include headache, psychosis, and seizures. Ocular manifestations of SLE include conjunctivitis, photophobia, and transient blindness due to retinal vasculitis.

GI manifestations of SLE, such as anorexia, nausea, abdominal pain, and diarrhea, may affect up to 45% of patients with the disease. The liver may be enlarged, and liver function tests may yield abnormal results.

●○● INTERPROFESSIONAL CARE

Because of the diversity of organ system involvement and manifestations of SLE, diagnosis can be difficult. No one specific test is available to confirm the presence of this disease in all people suspected of having it. Instead, the diagnosis is based on the patient's history and physical assessment, as well as laboratory studies.

As with RA, effective management of SLE requires teamwork, with active participation by both the patient and members of the healthcare team. Although there is no cure for SLE, the 10-year survival rate is approximately 90% among patients with this disease, which was once considered fatal in most cases.

DIAGNOSIS

The multiple autoantibodies produced in SLE cause a number of abnormalities in laboratory tests.

- *Antinuclear antibody (ANA) testing* is positive in more than 98% of patients with SLE.
- *Anti-DNA antibody testing* is a more specific indicator of SLE, because these antibodies are rarely found in any other disorder.
- *ESR* is typically elevated, occasionally to >100 mm/h.
- *Serum complement levels* are usually decreased as complement is consumed or "used up" by the development of antigen–antibody complexes.
- *CBC* abnormalities include moderate to severe anemia, leukopenia and lymphocytopenia, and possible thrombocytopenia.
- *Urinalysis* shows mild proteinuria, hematuria, and blood cell casts during exacerbations of the disease when the kidneys are

involved. Renal function tests including *serum creatinine*, *blood urea nitrogen (BUN)*, and *eGFR* may also be obtained to evaluate the extent of renal disease.
- *Kidney biopsy* may be performed to assess the severity of renal lesions and guide therapy.

MEDICATIONS

The patient with mild or remittent SLE may need little or no therapy other than supportive care. Arthralgias, arthritis, fever, and fatigue can often be managed with acetaminophen, aspirin, or NSAIDs. Aspirin is particularly beneficial for patients with SLE because its antiplatelet effects help prevent thrombosis. It may, however, cause liver toxicity and hepatitis. NSAIDs are used with caution because they may increase the risk of renal dysfunction or myocardial infarction.

Skin and arthritic manifestations of SLE may be treated with antimalarial drugs such as hydroxychloroquine (Plaquenil). Hydroxychloroquine has also been shown to be effective in reducing the frequency of acute episodes of SLE in people with mild or inactive disease. Retinal toxicity and possibly irreversible blindness are the primary concerns with this drug. For this reason, the patient taking hydroxychloroquine undergoes ophthalmologic exam every 6 months.

Patients with severe and life-threatening manifestations of SLE (such as nephritis, hemolytic anemia, myocarditis, pericarditis, or CNS lupus) require corticosteroid therapy in high doses. Such patients may require 40 to 60 mg of prednisone per day initially. The dosage is tapered as rapidly as the patient's disease allows, although lowering the dosage may precipitate an acute episode. Some patients with SLE require long-term corticosteroid therapy to manage symptoms and prevent major organ damage. These patients are at increased risk for corticosteroid side effects, such as cushingoid effects, weight gain, hypertension, infection, accelerated osteoporosis, and hypokalemia.

Immunosuppressive agents such as cyclophosphamide (Cytoxan), mycophenolate (CellCept), or azathioprine (Imuran) may be used, alone or in combination with corticosteroids, to treat patients with active SLE or lupus nephritis (see the accompanying Medication Administration box). When these agents are used in combination, lower, less toxic doses of each drug can be used. The patient receiving immunosuppressive agents is at increased risk for infection, malignancy, bone marrow depression, and toxic effects specific to the drug prescribed. Studies involving use of biologic therapies targeted at T or B lymphocytes are ongoing.

TREATMENTS

Because exposure to ultraviolet light can trigger a disease flare, the patient with SLE should be cautioned to avoid sun exposure. Patients should use sunscreens with a sun protection factor (SPF) rating of 15 or higher when out of doors. Topical corticosteroids may be used to treat skin lesions. Some physicians recommend avoiding the use of oral contraceptives because estrogen can trigger an acute episode.

Patients with lupus nephritis who progress to develop end-stage renal disease are treated with dialysis (hemodialysis or peritoneal dialysis) and kidney transplantation.

●○● NURSING CARE

Nursing care for the patient with mild SLE may be limited to teaching about the disease and strategies to maintain remission or low disease activity. The patient with severe disease, however, has many diverse nursing needs, which vary according to the organ systems involved. Because of the close link between RA and SLE, many of the nursing diagnoses and interventions identified for the patient with arthritis may be appropriate for the patient with lupus. The nursing care needs of the patient with lupus nephritis or end-stage renal disease are outlined in Chapter 28. This section focuses on the needs

MEDICATION ADMINISTRATION

Immunosuppressive Agents for SLE

CYTOTOXIC AGENTS

azathioprine (Imuran)

cyclophosphamide (Cytoxan)

cyclosporine (Sandimmune)

mycophenolate mofetil (CellCept)

Certain cytotoxic or antineoplastic drugs are effective as immunosuppressive agents. They act by decreasing the proliferation of cells within the immune system and are widely used to prevent rejection following a tissue or organ transplant. They are usually administered concurrently with corticosteroid therapy, allowing lower doses of both preparations, and resulting in fewer side effects.

Nursing Responsibilities
- Monitor blood count, with particular attention to the WBC and platelet counts. Notify the physician if WBCs fall below 4000 or platelets below 75,000.
- Monitor renal and liver function studies including creatinine, BUN, eGFR, and liver enzyme levels. Report any abnormal levels to the physician.
- Oral preparations should be administered with food to minimize GI effects. Antacids may be ordered.
- Increase fluids to maintain good hydration and urinary output.
- Monitor intake and output.
- Monitor for signs of abnormal bleeding: bleeding gums, bruising, petechiae, joint pain, hematuria, and black or tarry stools.
- Use meticulous hand hygiene and other appropriate measures to protect the patient from infection. Assess for signs of infection.
- Pulmonary fibrosis is a potential adverse effect of cyclophosphamide. Therefore, monitor the results of pulmonary function studies and be alert to clinical signs of dyspnea or cough.

Health Education for the Patient and Family
- Avoid large crowds and situations where you might be exposed to infections.
- Report signs of infection such as chills, fever, sore throat, fatigue, or malaise to the physician.
- Use contraceptive measures to prevent pregnancy while you are taking these drugs, because they cause birth defects.
- Avoid the use of aspirin or ibuprofen while taking these drugs. Report any signs of bleeding to the physician.
- You may stop menstruating while you are taking cyclophosphamide. The menses will resume after the drug is discontinued.
- If you are taking cyclophosphamide, be sure to report difficulty breathing or a cough to the physician.

of the patient related to the dermatologic manifestations of lupus, an increased risk for infection, and health maintenance.

Diagnoses, Outcomes, and Interventions

The priority nursing interventions for the patient with SLE are focused on problems with impaired skin integrity, ineffective protection, and impaired health maintenance.

Impaired Skin Integrity

Skin lesions are a common manifestation of SLE. A rash or discoid lesion interrupts the integrity of the skin, which is the first line of protection against infection, increasing the patient's already high risk of infection. These lesions, which usually appear on exposed parts of the skin, can also be disfiguring and cause the patient emotional distress.

Expected Outcome: Patient will verbalize understanding of and willingness to employ measures to reduce risk for epidermal manifestations of SLE.

- Assess knowledge of SLE and its possible effects on the skin. *Assessment allows the nurse to base teaching and information on the patient's existing knowledge, improving learning and retention.*
- Discuss the relationship between sun exposure and disease activity, both dermatologic and systemic. *It is important for the patient to understand that sun exposure may not only cause dermatologic manifestations but also trigger an acute episode.*
- Suggest the following strategies to limit sun exposure:
  - Avoid being out of doors during hours of greatest sun intensity (10:00 a.m. to 3:00 p.m.).
  - Use sunscreen with an SPF of 15 or higher when sun exposure cannot be avoided. Apply it 30 minutes before going out into the sun.
  - Reapply sunscreen after swimming, exercising, or bathing.
  - Wear loose clothing with long sleeves and wide-brimmed hats when out of doors.

  These strategies can help the patient maintain a normal lifestyle while helping to prevent acute episodes.
- Keep skin clean and dry; apply therapeutic creams or ointments to lesions as prescribed. *These measures promote healing and reduce the risk of infection.*

Ineffective Protection

Ineffective protection can be a problem for the patient with SLE, who is at increased risk for infection and multiple organ system problems because of the disease. In addition, treatment with corticosteroids or immunosuppressive agents further impairs immune responses and the ability to fight infection. The following interventions are for the patient who is hospitalized.

Expected Outcome: Patient will remain free of infection.

- Wash hands before and after providing direct care. *Hand hygiene removes transient organisms from the skin, reducing the risk of transmission to the patient.*

SAFETY ALERT

Hands must be washed before and after providing direct care, even if gloves are worn. A decrease in this type of medical asepsis is contributing to the increasing number of healthcare-associated infections that are resistant to antibiotics.

- Use strict aseptic technique in caring for intravenous lines and indwelling urinary catheters or performing any wound care. *Aseptic technique offers protection against external and resident host microorganisms.*
- Assess frequently for infection. Monitor temperature and vital signs every 4 hours. Assess for signs of cellulitis, including tenderness, redness, swelling, and warmth. Report signs of infection to the physician promptly. *Therapy can suppress usual responses, such as elevated temperature and inflammation. The fever of infection may be mistaken for the fever commonly associated with lupus. The patient receiving immunosuppressive therapy for the disease has an even higher risk for infection.*
- Monitor laboratory values, including CBC and tests of organ function; report changes to the physician. *An elevation in the WBC count with a shift to the left (increased numbers of immature leukocytes in the blood) may be an early indication of infection. Changes in liver function studies, renal function studies, myocardial enzymes, or other laboratory values may indicate organ system involvement.*
- Initiate reverse or protective isolation procedures as indicated by the patient's immune status. *These procedures provide further protection from infection for the severely immunocompromised patient.*
- Ensure an adequate nutrient intake, offering supplementary feedings as indicated or maintaining parenteral nutrition if necessary. *Adequate nutrition is important for healing and immune system function.*
- Teach the patient the importance of good hand hygiene after using the bathroom and before eating. *Hand hygiene reduces the risk of infection with endogenous organisms.*
- Monitor for potential adverse effects of medications including thrombocytopenia and possible bleeding, fluid retention with edema and possible hypertension, loss of bone density, osteoporosis, and possible pathologic fractures, renal or hepatic toxicity, and cardiac effects, particularly in the patient with fluid retention and hypervolemia. *Medications used to treat SLE have many potential adverse effects that can impair normal protective and homeostatic mechanisms.*

Readiness for Enhanced Self-Health Management

As with other chronic diseases, much of the responsibility for maintaining optimal health rests with the patient. Disease manifestations such as fatigue, arthralgias, arthritis, and increased risk for infection can interfere with the patient's ability to maintain health. Psychosocial issues can also be a significant factor in health maintenance for the patient with lupus. These issues may include denial of the significance of the disease, poor coping, lack of financial and other resources, and an inadequate support system.

Expected Outcome: Patient will demonstrate an understanding of and ability to manage prescribed therapeutic regimen.

- Assess the ability to maintain optimal health, identifying physical and psychosocial factors that may affect health maintenance. *Before intervening to improve the patient's health maintenance, the nurse must identify and understand factors affecting it.*
- Provide care and teaching in a nonjudgmental manner. *To intervene effectively, the nurse must accept the patient and family as they are.*

- Encourage the patient and family members to discuss the effect of the disease on their lives. *Open discussion helps the patient and the nurse identify barriers to health maintenance and begin exploring alternative strategies.*
- Initiate an interprofessional care conference with the patient and family. *In this care conference, a number of perspectives can be expressed, improving the planning of strategies for health maintenance activities.*
- Refer the patient and family to counseling as needed. *Counseling may help the patient and family develop the necessary coping skills to accept and deal with the disease.*
- Refer the patient and family to community and social service agencies, and local support groups. *These groups and agencies are valuable resources for the patient and family.*

Continuity of Care

Teaching is a critical factor in preparing patients with SLE to manage their chronic disease. Address the following topics:

- The disease and its potential effects. Promote an optimistic outlook, stressing that the majority of patients do not require long-term corticosteroid therapy and that the disease may improve over time.
- The importance of skin care.
- The importance of avoiding exposure to infection.
- The need to follow the prescribed treatment plan, including rest and exercise, medications, and follow-up appointments. Discuss manifestations of an acute episode (often called a *flare*) and stress the importance of contacting the physician promptly if any of these manifestations occur.

PRACTICE ALERT!

Warning Signs of a Flare

- Increased fatigue
- Pain, abdominal discomfort
- Rash
- Headache
- Fever
- Dizziness

- The importance of wearing a medical alert tag identifying the condition and therapy such as corticosteroids or immunosuppressives.
- Family planning with the patient and spouse. The use of oral contraceptives may be contraindicated for the patient; if appropriate, provide information about alternative means of birth control. Pregnancy is not contraindicated for most women with lupus. However, the pregnant patient requires close monitoring because acute episodes sometimes accompany pregnancy.
- The need for preventive healthcare for both men and women with SLE. Women should have gynecologic and breast examinations and men should have prostate examinations each year. Both men and women should have regular screenings for cholesterol and blood pressure. Annual influenza vaccinations are important, as is pneumococcal vaccination for older patients. If patients are taking corticosteroids or antimalarial medications, annual eye examinations should be conducted to screen for and treat any eye problems.

THE PATIENT WITH SYSTEMIC SCLEROSIS (SCLERODERMA)

Systemic sclerosis, also known as *scleroderma* (hardening of the skin), is a chronic disease characterized by deposition of excess collagen tissue in the skin and internal organs. The cause of systemic sclerosis is unknown, but genetic, immune, and environmental factors are thought to play a role. Although this uncommon disease is distributed worldwide, a higher incidence is noted in miners exposed to silica and in people exposed to certain chemicals such as polyvinyl chloride, epoxy resins, and aromatic hydrocarbons.

FAST FACTS

Systemic Sclerosis

- Systemic sclerosis affects approximately 300,000 people in the United States, with about one-third having the systemic form and the rest the localized form.
- Systemic sclerosis affects women more often than men by a ratio of approximately 3:1.
- The incidence is higher in African Americans than in Caucasians, and it tends to develop at an earlier age (Varga, 2012).
- Although it can occur at any age from infants to older adults, the onset of systemic sclerosis typically occurs between the ages of 30 and 50 years.

Pathophysiology

Early systemic sclerosis is characterized by functional and structural abnormalities of the small arteries and arterioles that lead to progressive vessel obstruction, increased permeability, and fibrosis. Blood flow to surrounding tissues and organs is reduced; inflammatory changes may be noted in affected tissues prior to the development of fibrosis. Autoimmunity and vascular damage are believed to lead to fibrosis in systemic sclerosis. This process is characterized by progressive replacement of normal tissue with dense connective tissue (Varga, 2012). Abnormal proliferation of fibrous connective tissue occurs in the skin, blood vessels, lungs, GI tract, and other organs. Nearly all patients with systemic sclerosis develop Raynaud's phenomenon, a vascular disorder characterized by reversible arterial vasospasm.

Scleroderma may be either limited, with limited visceral organ involvement, or diffuse, with both skin and visceral organ involvement. Limited cutaneous systemic sclerosis (lcSSc) affects the fingers, distal extremities, and face. Involvement of visceral organs tends to be slow and insidious, and the long-term prognosis is better than that for patients with diffuse sclerosis, with a 75% 10-year survival rate (Varga, 2012). In diffuse cutaneous systemic sclerosis (dcSSc), skin involvement is progressive, beginning at the distal extremities and progressing to involve the face and trunk. These patients tend to develop pulmonary fibrosis and renal involvement early in the disease. This disease is usually progressive; complete remission is rare. Infections and diseases of the cardiovascular, renal, pulmonary, and CNS are the most common causes of death in people with systemic sclerosis.

Manifestations

The initial manifestations of systemic sclerosis are usually noted in the skin, which thickens markedly. Diffuse, nonpitting swelling also

Figure 40–11 ■ Characteristic skin changes of scleroderma.
Source: Logical Images/Custom Medical Stock Photo.

is noted. As the disease progresses, the skin begins to atrophy, becoming taut, shiny, and hyperpigmented (Figure 40–11 ■). Facial skin tightening leads to loss of skin lines and a pursed-lip appearance. Skin tightness may limit mobility, particularly of the face and hands. Other skin manifestations include *telangiectasias* (flat, red areas caused by dilation of small blood vessels, usually noted on the face, hands, and in the mouth) and calcium deposits, usually noted around joints.

Arthralgias and Raynaud's phenomenon are common early manifestations of systemic sclerosis. Raynaud's phenomenon (intermittent attacks of small artery vasospasm) is characterized by pallor of the fingers followed by cyanosis, and then reactive hyperemia with redness. Attacks are usually triggered by cold temperatures.

The patient with visceral organ involvement may have varied symptoms. Dysphagia is common because the motility of the esophagus is affected. Pulmonary involvement can lead to exertional dyspnea due to impaired gas exchange and right-sided heart failure due to pulmonary hypertension. Involvement of the heart may cause manifestations of pericarditis and dysrhythmias. Diarrhea or constipation, abdominal cramping, and malabsorption can occur when the GI tract is affected. Renal effects can lead to proteinuria, hematuria, hypertension, and renal failure.

●○● INTERPROFESSIONAL CARE

The manifestations of systemic sclerosis often allow diagnosis with little or no testing. No cure is currently available; treatment is symptomatic and supportive.

DIAGNOSIS

No single diagnostic test is specific for systemic sclerosis, although a titer of 1:40 or higher for antinuclear antibody (ANA) is the most sensitive for diagnosis. Other laboratory studies that are done include an ESR, which is typically elevated from the chronic inflammatory process and a CBC, which will demonstrate anemia. A skin biopsy may be done to confirm the diagnosis.

MEDICATIONS

Medications to treat systemic sclerosis are chosen based on the patient's symptoms. Immunosuppressive agents and corticosteroids are of limited benefit, but may be used to slow or prevent pulmonary fibrosis and in life-threatening disease. Cyclophosphamide (Cytoxan) or methotrexate may slow disease progression. Sildenafil (Viagra) may be prescribed to treat symptomatic pulmonary hypertension. Calcium channel blockers such as nifedipine (Procardia) or alpha-adrenergic blockers such as prazosin (Minipress) may be prescribed for patients with Raynaud's phenomenon. When manifestations of esophagitis accompany systemic sclerosis, H_2-receptor blockers such as cimetidine (Tagamet) or ranitidine (Zantac), antacids, or omeprazole (Prilosec), which blocks all gastric secretion, may be ordered. Tetracycline or another broad-spectrum antibiotic may be prescribed to suppress intestinal flora and relieve symptoms of malabsorption. Patients with kidney disease are usually treated with angiotensin-converting enzyme (ACE) inhibitors such as captopril (Capoten) to control hypertension and preserve renal function. End-stage kidney disease is managed with dialysis and transplantation.

PHYSICAL THERAPY

Physical therapy is an important part of the management of systemic sclerosis to maintain mobility of affected tissues, the hands and face in particular. Because the mouth opening, if involved, becomes increasingly smaller as the disease progresses, stretching and strengthening of facial muscles can be vital to maintaining oral food intake.

●○● NURSING CARE

Nursing care needs of patients with systemic sclerosis are individualized to the effects and manifestations of the disease.

Skin manifestations are present to some degree in nearly all patients with systemic sclerosis. Nursing care related to the skin focuses on maintaining skin integrity and flexibility. Measures to maintain supple skin are important, because elasticity cannot be regained once it is lost. Apply moisturizers to prevent dryness and cracking. Protect the skin where it is stretched taut over joints or bony prominences. Perform ROM exercises to help prevent joint contractures due to increasingly tight skin.

Difficulty swallowing and recurrent esophagitis may interfere with the patient's nutritional status. Provide small, frequent meals. Consult with the dietitian and the patient to determine which foods are easy to swallow. Keep the patient in a sitting or Fowler's position after meals and elevate the head of the bed at night to minimize esophageal reflux.

The dermatologic and systemic effects of the disease may have significant psychologic effects on the patient, leading to feelings of helplessness and hopelessness, and self-esteem disturbance. Establish an atmosphere of trust with the patient. Listen actively and acknowledge concerns about the disease and its effects on the patient's life and appearance. Encourage the patient to share these concerns with family members and significant others. Provide referral to social services or counseling as appropriate.

The patient with predominant pulmonary disease has nursing care needs similar to those of other patients with restrictive respiratory disorders. If the patient with systemic sclerosis has impaired renal function, nursing care is similar to that for patients with chronic kidney disease.

Continuity of Care

Teach the patient with systemic sclerosis about the disease and introduce measures to help manage its effects. Stress the importance of good skin care and physical therapy exercises to maintain mobility,

particularly of the hands and face. Discuss the need to avoid chilling (local and whole body) to prevent episodes of Raynaud's phenomenon. Teach the role of proper dress in the winter: loose, warm clothing, gloves, and warm stockings. If needed, stress the need to stop smoking because of the vasoconstrictive effect of nicotine and the respiratory effects of the disease. Provide the patient with information about manifestations of disease progression and organ involvement. Teach the patient to report new or worsening symptoms to the physician. In addition, suggest the following resources:

- National Institute of Arthritis and Musculoskeletal and Skin Diseases
- Scleroderma Foundation
- Scleroderma Research Foundation
- International Scleroderma Network.

THE PATIENT WITH SJÖGREN'S SYNDROME

Sjögren's syndrome is a chronic, progressive autoimmune disorder that causes inflammation and dysfunction of exocrine glands throughout the body. Sjögren's syndrome primarily affects women, with a ratio of women to men at 9:1. The highest incidence is between the ages of 40 and 60 years. Although it can occur as a primary disorder, Sjögren's syndrome is often associated with other rheumatic disease, including rheumatoid arthritis, SLE, primary biliary cirrhosis, systemic sclerosis, Hashimoto's thyroiditis, and interstitial pulmonary fibrosis.

Pathophysiology

In this disease, exocrine glands in many areas of the body are destroyed by infiltration of lymphocytes and deposits of immune complexes. The salivary and lacrimal glands are particularly affected, leading to the characteristic manifestations of *xerophthalmia* (dry eyes) and *xerostomia* (dry mouth). Patients often experience dry, gritty-feeling eyes and may develop corneal ulcerations. Mucosal dryness affects taste, smell, chewing, and swallowing and leads to increased dental caries. Parotid gland enlargement is common. Excess dryness can also affect the nose, throat, larynx, bronchi, vagina, and skin. Systemic effects of Sjögren's syndrome include arthritis, dysphagia, pancreatitis, pleuritis, neurologic manifestations including migraine, and vasculitis. Nephritis may occur, but renal failure rarely results. Patients with Sjögren's syndrome have a greatly increased risk of developing malignant lymphoma.

●○● INTERPROFESSIONAL CARE

The diagnosis of Sjögren's syndrome is often based on the patient's history and clinical presentation. Schirmer's test, which measures the quantity of tears secreted in a 5-minute period in response to irritation; ocular staining; and slit-lamp examination of the eye may be performed. A definitive diagnosis can be made by biopsy of a salivary gland for evidence of lymphoid foci.

Treatment is supportive. Artificial tears are used to decrease eye irritation and dryness. The patient can keep the mouth moist by drinking fluids, using a saliva substitute, and chewing sugarless gum. Medications that increase mouth dryness, such as atropine and decongestants, should be avoided.

●○● NURSING CARE

Nurses caring for patients with Sjögren's syndrome need to teach measures to protect the patient's eyes and oral mucosa. Instill artificial tears as needed. Encourage the patient to sip fluids throughout the day. Provide frequent oral hygiene, particularly before and after meals. Ensure that the patient has sufficient fluids to drink during meals, because fluids help with chewing and swallowing.

THE PATIENT WITH INFLAMMATORY MYOPATHY

The inflammatory myopathies include polymyositis and dermatomyositis. Polymyositis is a systemic connective tissue disorder characterized by inflammation of connective tissue and muscle fibers leading to muscle weakness and atrophy. When muscle fiber inflammation is accompanied by skin lesions, the disease is known as dermatomyositis. Inflammatory myopathies are rare, affecting people of all ages and ethnic groups. Women are about twice as likely to be affected as men (Miller, 2012).

The immune mechanism causing the inflammatory response is not clear, but autoantibodies can be identified in the majority of people with the disease. The activation of complement is thought to contribute to the inflammatory process. Inflammation leads to muscle fiber necrosis and degeneration.

Manifestations

Initial manifestations of polymyositis include muscle pain, tenderness, and weakness; rash; arthralgias; fatigue; fever; and weight loss. Skeletal muscle weakness is the predominant manifestation. Its onset may be either insidious or abrupt. Muscle weakness tends to progress over weeks to months. Muscles of the shoulder and pelvic girdles are particularly affected, making it difficult for the patient to get out of chairs, climb stairs, and reach overhead. Weakness of neck flexor muscles may make it difficult to raise the head from a pillow. Affected muscles may also be tender and painful. A characteristic dusky red rash may be present on the face and upper trunk. Other manifestations include Raynaud's phenomenon, dysphagia, dyspnea, and cough (due to interstitial pneumonitis). The risk of malignancy is increased, particularly in patients with dermatomyositis.

●○● INTERPROFESSIONAL CARE

There is no specific test to diagnose inflammatory myopathy. Autoantibodies may be identified in blood serum. Serum levels of muscle enzymes are elevated, particularly creatine kinase (CK) and aldolase levels. Biopsy of involved muscle shows patchy muscle fiber necrosis and the presence of inflammatory cells.

A combination of rest and corticosteroid therapy is prescribed to reduce the inflammatory response. Long-term corticosteroid therapy may be necessary to manage the disease. Immunosuppressive agents such as methotrexate, cyclophosphamide, and azathioprine may be used in combination with corticosteroids to induce remission.

●○● NURSING CARE

The nursing role in caring for the patient with an inflammatory myopathy is supportive. Measures to promote comfort are important. Muscle weakness may interfere with the patient's ability to provide

self-care and manage health and home. The patient may have difficulty with speech because of pharyngeal muscle weakness. Provide alternate means of communication as needed, and use patience in listening. Observe closely while the patient eats, because aspiration is a potential problem. Modify the patient's diet as needed to maintain nutrition and safety.

Education of the patient and family is an important component of care. Emphasize the need to balance periods of rest and activity. Discuss skin care to prevent dryness and infection. Teach the patient about prescribed medications and their short- and long-term side effects. Provide information about safety measures while eating. Encourage family members to become trained in performance of the Heimlich maneuver and CPR. Discuss signs of respiratory infection and other possible complications of inflammatory myopathy, including renal failure and malignancy.

THE PATIENT WITH LYME DISEASE

Lyme disease is an inflammatory disorder caused by the spirochete *Borrelia burgdorferi*, which is transmitted primarily by ticks. It is the most commonly reported tick-borne illness in the United States. Geographically, Lyme disease is more prevalent in the areas where the ticks are found: in the Northeast and Middle Atlantic States, the upper Midwest, and Northern California and the Pacific Northwest regions of the United States (Kalish, 2012). It has also been reported throughout Europe, Asia, and Australia. Ticks that act as vectors for Lyme disease, primarily *Ixodes dammini*, *I. pacificus*, and *I. scapularis* in the United States, are usually carried by mice or deer, although other animals may be infected. The most frequent time of onset is the summer months.

FAST FACTS

Lyme Disease

- Lyme disease is the most common tick-transmitted disease in the United States.
- In 2012, 95% of reported Lyme disease cases occurred in 13 states: Connecticut, Delaware, Maine, Maryland, Massachusetts, Minnesota, New Hampshire, New Jersey, New York, Pennsylvania, Vermont, Virginia, and Wisconsin (CDC, 2013).
- Lyme disease occurs most often in children and adults living in rural areas.
- All stages of Lyme disease can be cured by antibiotics, but some people with late neurologic or arthritic involvement may not improve.

Pathophysiology

Borrelia burgdorferi enters the skin at the site of the tick bite. After an incubation period of up to 30 days, it migrates outward in the skin, forming a characteristic lesion called erythema migrans. It may also spread via lymph or blood to other skin sites, nodes, or organs. The inflammatory joint changes associated with Lyme disease closely resemble those of rheumatoid arthritis (vascular congestion, tissue infiltration by inflammatory cells, possible pannus formation, and erosion of cartilage and bone).

Manifestations

Manifestations often are seen in the skin, musculoskeletal system, and CNS. Lyme disease begins with flu-like manifestations and a skin rash, followed weeks or months later by neurologic symptoms, including facial nerve palsy and meningitis, and months to years later, by arthritis. This progression is highly individualized.

Figure 40–12 ■ The characteristic erythema migrans (bull's-eye) lesion of Lyme disease on a patient's arm.
Source: Centers for Disease Control and Prevention.

Erythema migrans is the initial manifestation of Lyme disease (Figure 40–12 ■). This flat or slightly raised red lesion at the site of the tick bite expands over several days (up to a diameter of 50 cm [20 in.]), with the central area clearing as it expands. Systemic symptoms such as fatigue, malaise, fever, chills, and myalgias often accompany the initial lesion. As the disease spreads, secondary skin lesions develop, as do migratory musculoskeletal symptoms, including arthralgias, myalgias, and tendinitis. Persistent fatigue is common during this stage of the disease. Headache and stiff neck are characteristic neurologic manifestations.

Complications

With untreated infection, complications can develop months to years after the initial infection. Chronic recurrent arthritis, primarily affecting large joints (especially the knee), is common. Permanent disability may result. Other effects that may be seen weeks to months after the initial infection include meningitis, encephalitis, and neuropathies, as well as cardiac complications including myocarditis and heart block.

●○● INTERPROFESSIONAL CARE

Both manifestations and laboratory studies are used to establish the diagnosis of Lyme disease. Culture of the organism from tissues and body fluids is difficult and slow. Antibodies to *B. burgdorferi* can be

detected by either enzyme-linked immunosorbent assay (ELISA) or Western blot methods within 2 to 4 weeks of the initial skin lesion.

The early diagnosis and proper antibiotic treatment of Lyme disease are important to preventing the complications of infection. A number of antibiotics may be used to treat Lyme disease, including doxycycline (Doxy-Caps, Vibramycin), amoxicillin (Amoxil), cefuroxime axetil (Ceftin), or erythromycin. Therapy may be continued for up to 1 month to ensure eradication of the organism from affected tissues. In addition to antibiotic treatment, aspirin or an NSAID may be prescribed for relief of arthritic symptoms. The affected joint may be splinted to rest the joint. When the knee is involved, weight bearing may be restricted and the use of crutches indicated.

●○● NURSING CARE

Nursing care focuses on prevention of the disease. Many people do not protect themselves from tick bites. This protection is becoming increasingly important with a higher incidence of Lyme disease, due in part to an overpopulation of deer and the encroachment of the suburbs on once rural areas. Simple measures that can help prevent tick bites are as follows:

- Avoid tick-infested areas, especially in spring and summer, such as woods and rural areas with brush and tall weeds.
- Cover exposed skin with long-sleeved shirts and tuck pants into socks. Wearing high rubber boots may provide additional protection.
- Use insect repellents that contain DEET on clothing and exposed skin and apply permethrin to clothing prior to exposure.
- Inspect skin, especially in areas of tight-fitting clothing, after exposure.
- Remove attached ticks with fine-tipped tweezers. Grasp the tick firmly as close to the skin as possible and pull the tick's body away from the skin. If the tick's head remains in the skin, it will not cause Lyme disease (the bacteria are in the tick's midgut). Most cases occur when the tick has been feeding for at least 24 hours. Clean the area with an antiseptic.

Infectious Disorders

THE PATIENT WITH OSTEOMYELITIS

Osteomyelitis is an infection of the bone. Osteomyelitis may occur as an acute, subacute, or chronic process. It occurs as a consequence of a penetrating wound, bacteremia (hematogenous osteomyelitis), invasion from a contiguous locus of infection, or skin breakdown in the presence of vascular insufficiency. Prosthetic joint implants and devices used to stabilize fractures are increasingly associated with complex infections (Tice, 2012). Hemodialysis and injection drug use also are risk factors for osteomyelitis.

Osteomyelitis can occur at any age, but adults over age 50 are more commonly affected. The older adult is at risk for osteomyelitis for several reasons. Immune function tends to decline with aging; the older adult also is more likely to have a chronic disease process such as diabetes mellitus that affects immune function. Circulatory status in older adults often is compromised by atherosclerotic processes, impairing blood flow to the bone. Older adults have a higher risk of pressure ulcers because of circulatory, skin, sensation, and mobility changes associated with aging. Pressure ulcers that cannot be staged and treated because of eschar formation pose a particular risk. In addition, the older adult may not demonstrate the typical signs of infection and inflammation, which allows an infectious process to become well established before it is detected.

Pathophysiology and Manifestations

The cause of osteomyelitis is usually bacterial; however, fungi, parasites, and viruses can also cause bone infection. *Staphylococcus aureus* is the most common infecting organism. Other organisms include *Escherichia coli*, *Pseudomonas*, *Serratia*, *Salmonella*, and *M. tuberculosis*.

After entry, bacteria lodge and multiply in the bone, resulting in the inflammatory and immune system response. Phagocytes attempt to contain the infection, releasing enzymes in the process that destroy bone tissue. Pus forms, followed by edema and vascular congestion. The Haversian canals in the medullary (marrow) cavity of the bone allow the infection to travel to other segments of the bone. If the infection reaches the outer margin of the bone (Figure 40–13 ■), it raises the periosteum of the bone, spreading along the surface. Lifting of the periosteum from the cortex disrupts the blood vessels that enter the bone. Pressure increases, further compromising the vascular

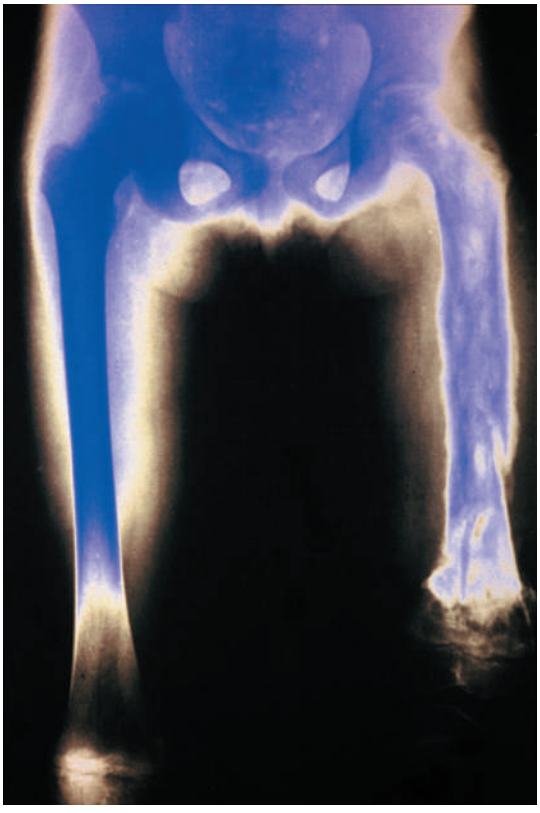

Figure 40–13 ■ X-ray of osteomyelitis caused by *Staphylococcus aureus*. Note how the right femur has been deformed by the infection.

supply and leading to ischemia and eventual necrosis of the bone. Blood and antibiotics cannot reach the bone tissue once the pressure compromises the vascular and arteriolar systems. In addition, bacteria adhere to damaged bone, coating the underlying bone with a protective film that further impedes host defenses.

Manifestations of osteomyelitis vary according to the age of the patient, the cause and site of involvement, and whether the infection is acute, subacute, or chronic (see the accompanying box).

HEMATOGENOUS OSTEOMYELITIS

Hematogenous infections are caused by pathogens that are carried in the blood from sites of infection elsewhere in the body. Hematogenous osteomyelitis primarily affects older adults, people with sickle cell disease, and intravenous drug users. The spine is the usual site of infection in adults. Pathogens enter the well-perfused vertebral bodies of adults via the spinal arteries. From there, the infection spreads into the disk space. The lumbar spine is involved more frequently than the thoracic or cervical spine. Urinary tract infections, soft tissue infection, endocarditis, and infected intravenous sites are sources of pathogens.

Patients with acute hematogenous osteomyelitis experience an acute onset of pain, tenderness, and fever. Soft tissue swelling over the affected bone may be noted. The course of vertebral osteomyelitis in intravenous drug users often is subacute, with vague, dull pain in the affected region and a normal or low-grade fever. The pain intensifies over 2 to 3 months, and is accompanied by tenderness, muscle spasm, and limited ROM.

OSTEOMYELITIS FROM A CONTIGUOUS INFECTION

Infections caused by an extension of infection from adjacent soft tissues fall into this category of osteomyelitis. The infection is a result of, or complication of, direct penetrating wounds, joint replacements, decubitus ulcers, and neurosurgery. This is the most common cause of osteomyelitis in adults.

The diagnosis of osteomyelitis often is not made until the infection has become chronic, because the signs of acute infection may be masked by local tissue inflammation. Failure to heal a surgical wound or fracture or a developing sinus tract may be initial indicators of a bone infection.

OSTEOMYELITIS ASSOCIATED WITH VASCULAR INSUFFICIENCY

People with diabetes and peripheral vascular disease are at risk for developing osteomyelitis involving the feet. Diabetic neuropathy exposes the foot to trauma and pressure ulcers. The patient may be unaware of the infection as it spreads into the bone. When tissue perfusion is poor, normal inflammatory responses and wound healing are impaired. The infection often is diagnosed when the patient seeks treatment for a nonhealing sore, swollen toe, or acute cellulitis.

MANIFESTATIONS OF OSTEOMYELITIS

LOCAL EFFECTS

- Acute or chronic bone pain of increasing intensity
- Low back pain
- Drainage and ulceration at involved site
- Swelling, erythema, and warmth at involved site
- Localized tenderness

SYSTEMIC EFFECTS

- Lymph node involvement, especially in the involved extremity
- High temperature with chills
- Malaise
- Tachycardia
- Nausea and vomiting
- Anorexia

●○● INTERPROFESSIONAL CARE

Care of the patient with osteomyelitis focuses on relieving pain, eliminating the infection, and preventing or minimizing complications. Early diagnosis is important to prevent bone necrosis by early administration of the appropriate antibiotic. A thorough history and physical examination are important to identify risk factors and possible causes of the infection.

DIAGNOSIS

The diagnosis of osteomyelitis is based on standard x-rays, bone scans, MRI, blood tests, and biopsy. An MRI, CT scan, and bone scan may be conducted to identify abscesses, sinus tracts, and bone changes. An ultrasound can detect subperiosteal fluid collections, abscesses, and periosteal thickening and elevation associated with osteomyelitis. During an acute infection, ESR and WBC are elevated. Blood and tissue cultures (from affected bone or soft tissue) are obtained to identify the infecting organism and direct antibiotic therapy.

MEDICATIONS

Antibiotic therapy is mandatory to prevent acute osteomyelitis from progressing to the chronic phase. Parenteral antibiotic therapy begins as soon as cultures (blood and/or wound) are obtained. A penicillinase-resistant semisynthetic penicillin (e.g., nafcillin, oxacillin) or a cephalosporin such as cefazolin (Ancef) or ceftriaxone (Rocephin) may be given until the culture and sensitivity results are known. These antibiotics are used initially because many cases of osteomyelitis are caused by *Staphylococcus aureus*. When the detailed sensitivity report is obtained from the cultures, more definitive antibiotics are prescribed.

For the patient with acute or chronic osteomyelitis, antibiotics are continued for 4 to 6 weeks. Intravenous antibiotic administration or oral therapy is common. Oral therapy with twice-daily ciprofloxacin has been shown to be as effective as parenteral therapy for treating adult patients with chronic osteomyelitis caused by susceptible organisms.

SURGERY

Surgical debridement may be performed early in the course of the infection to remove necrotic tissue and identify the infecting organism. Debridement is the primary treatment for the patient with chronic osteomyelitis. The periosteum is excised and the cortex is drilled to release the pressure from accumulated pus. During this procedure, cultures may be obtained and sent to the laboratory for analysis. The wound holes are irrigated, and the wound is then closed. The cavity may be kept clean by inserting drainage tubes that are connected to an irrigation and suction system. Postoperatively, the nurse is responsible for instilling and removing dilute antibiotic solutions through the drainage tubes. See the accompanying box for related nursing care.

A musculocutaneous (myocutaneous) flap is another approach used for the treatment of the dead space caused by extensive debridement of the infected site. The procedure involves moving or rotating

NURSING CARE OF THE PATIENT

Undergoing Surgical Debridement for Osteomyelitis

PREOPERATIVE CARE

- Discuss the impending surgery, the patient's concerns regarding surgery and its risks, and what steps will be taken if surgery is ineffective. *Open discussion and active listening are important means of gaining the patient's trust and encouraging the patient to express concerns about the outcome of the surgery.*
- Patients may need extensive antimicrobial treatment postoperatively if an irrigation system is surgically implanted. Before the procedure, explain to the patient that bed rest and an extended period of treatment in the hospital are imperative. *Patients who understand the events that may occur postoperatively may be more accepting of the required restrictions*.

POSTOPERATIVE CARE

- Provide meticulous care of the dressing and/or irrigation setup. *Frequently, the irrigation tubes are connected to a three-way stopcock, which allows irrigation and drainage of the debrided area without separating the tube from the collection device. Nurses need to be extremely cautious and adhere to strict sterile technique*.
- Assess the patient for manifestations of further infection. *Although the patient will receive antimicrobial agents, it is important to monitor him or her continually for sudden spikes in temperature, pain at the involved site, and other indications of superinfection*.

Health Education for the Patient and Family

- While receiving antimicrobial agents, be sure to drink adequate amounts of fluid and eat a high-calorie diet to minimize the risks for damage to the kidneys, yeast infection, and adverse GI effects.

a muscle and the section of skin fed by the arteries from that muscle into the cavity created by the surgery. A skin graft is performed later.

●○● NURSING CARE

The patient with chronic osteomyelitis faces frequent and lengthy hospitalizations and/or treatment modalities. The prognosis is uncertain, and functional deficits and amputation are a constant concern. The ongoing expenses, loss of financial support, and role changes within the family are also patient concerns.

Diagnoses, Outcomes, and Interventions

Nursing diagnoses associated with acute osteomyelitis focus on preventing the transmission of infection and problems due to immobility. Providing comfort and patient teaching are also very important.

Infection

The patient who has undergone surgical debridement of infected bone has an increased risk for infection due to disruption of the skin barrier. Aggressive antibiotic therapy also disrupts the patient's usual body flora, an important factor in preventing pathogenic organisms from establishing infection. Infection is a hypermetabolic state that increases the patient's kilocalorie needs.

Expected Outcome: Patient will experience no adverse consequences of surgical or antibiotic therapy.

- Maintain strict hand hygiene practices. *Meticulous hand hygiene helps prevent the spread of infection by minimizing the entry of organisms into susceptible patients.*

SAFETY ALERT

Careful hand hygiene before and after direct care is essential even if gloves are worn.

- Administer antimicrobial therapy at specified time intervals. *Optimal blood levels of antibiotic therapy are mandatory in patients with infectious processes.*
- Monitor site of infection, surgical wound, and systemic manifestations for evidence of desired therapeutic effect (reduced inflammation, evidence of healing, improving overall physical status). Promptly report deviations from expected course, as well as manifestations of superinfection or complications of therapy. *Monitoring patient responses to therapy is an important nursing responsibility in acute care settings, extended care or rehabilitation facilities, and in the patient's home.*
- Maintain the patient's optimal dietary kilocalorie and protein intake. *High kilocalorie and protein intake provide the patient with sufficient nutritional support for the body's needs during the stressful event of the inflammatory process.*

Hyperthermia

The infection and associated inflammatory process can cause fever in the patient with osteomyelitis.

Expected Outcome: Patient's body temperature will be within normal range.

- Monitor temperature every 4 hours and when patient reports chills and/or fever. Blood cultures are frequently ordered when an acute elevation of temperature occurs. *A sudden rise in temperature in patients with either acute or chronic osteomyelitis may indicate inadequate antimicrobial management.*
- Maintain a cool environment and provide light clothing and bedding during temperature elevation. *Proper environmental conditions and clothing enhance the evaporative process during acute temperature elevation and promote comfort.*
- Ensure a daily fluid intake of 2000 to 3000 mL. *Dehydration may result from evaporative fluid losses during acute temperature elevations. Furthermore, patients taking large doses of antibiotic therapy may experience fluid loss through excessive diarrhea as a side effect of the therapy.*

Impaired Physical Mobility

Pain, infection, inflammation, and the use of immobilizers can all impair the mobility of the patient with osteomyelitis.

Expected Outcome: Patient will experience no adverse effects of required immobilization.

- Maintain the affected limb in functional position when immobilized. *The patient may hesitate to move the involved extremity*

because of continuous pain; therefore, the extremity must be maintained in functional position to avoid flexion contracture.

- Maintain rest, and avoid subjecting the affected extremity to weight-bearing activities. *The involved extremity must be immobilized to avoid pathologic fractures caused by stress on the weakened bone.*
- Ensure active or passive ROM exercises every 4 hours. *Flexion contracture occurs when the patient remains immobile or when there is only minimal joint movement. Consult a physical therapist for a plan of exercises to avoid contracture.*

Acute Pain

The patient with osteomyelitis experiences pain due to swelling.

Expected Outcome: Patient will verbalize an acceptable level of comfort.

- Use a splint or immobilizer when the patient experiences acute pain from swelling. *Splinting or immobilizing the involved extremity provides support and reduces pain caused by movement.*
- Ask the physician to order scheduled administration of narcotic and nonnarcotic analgesics on a 24-hour basis rather than as needed. *The use of 24-hour administration allows blood levels of pain-relieving medications to remain constant.*
- Use nonpharmacologic strategies (e.g., heat, distraction, relaxation techniques) for adjunctive pain management. *Pain of the muscles and joints may be controlled through nonpharmacologic interventions. Warm moist packs, warm baths, or heating pads to the involved extremity provide comfort due to vasodilation.*
- Avoid excessive manipulation of the involved area; handle the area gently. Carefully assess the patient for guarding, limping, or unwillingness to move the affected part. Communicate to other healthcare professionals the patient's preferences for assistive devices and means of manipulating the involved area. *Gentle handling and minimal manipulation help reduce pain.*

Continuity of Care

Although patients may be hospitalized for acute treatment and surgery, most care is provided at home. Home health services can provide intravenous medications, if prescribed. Discuss the following topics for home care:

- The importance of careful hand hygiene, especially after toileting and dressing changes.
- The importance of taking all antibiotics as prescribed. Include information about helping prevent the yeast infections (of the mouth or vagina) and diarrhea often associated with prolonged antibiotic therapy by eating 8 oz of live-culture yogurt each day.
- The need to take pain medications on a regular basis to prevent pain from becoming severe. Provide information about how to deal with side effects, such as constipation, by increasing fluid and fiber intake.
- How to perform wound care and sources for needed equipment and supplies.
- Rest or limited weight bearing for the affected extremity or body part. Teach how to avoid complications associated with prolonged immobilization, such as frequently shifting position, keeping skin and linens clean and dry, and doing active ROM exercises for unaffected joints.
- The importance of maintaining good nutrition. An adequate supply of kilocalories, protein, and other nutrients is necessary for immune function and healing. Suggest frequent small meals and using nutritional supplements such as Ensure to help maintain nutritional intake.

THE PATIENT WITH SEPTIC ARTHRITIS

Septic arthritis can develop if a joint space is invaded by a pathogen. The primary risk factors for septic arthritis are persistent bacteremia (bacteria in the blood) (e.g., due to use of injectable drugs, endocarditis), previous joint damage (e.g., due to trauma or rheumatoid arthritis), impaired immunity (e.g., diabetes, renal failure, alcoholism), and loss of skin integrity. Arthroscopic surgery and total joint replacements that allow potential direct contamination of the joint are additional risk factors.

Pathophysiology

The most common bacteria implicated in septic arthritis include gonococci and *S. aureus*. Methicillin-resistant *S. aureus* (MRSA) and group B streptococci infections are increasingly seen. Infections by gram-negative bacteria such as *E. coli* and *Pseudomonas* more commonly affect people who inject recreational drugs or are immunocompromised.

Infection of the joint leads to inflammation with resulting synovitis and joint effusion. Abscesses may form in synovial tissues or bone underlying joint cartilage. If not treated promptly and effectively, septic arthritis can lead to destruction of the affected joint. A single joint, often the knee, is usually affected. Septic arthritis may also affect joints such as the shoulder, wrist, hip, fingers, or elbow.

Manifestations

The onset of septic arthritis is typically abrupt, marked by pain and stiffness of the infected joint. The joint appears red and swollen, and is hot and tender to the touch. Effusion (increased fluid within the joint space) is usually present. Systemic manifestations of infection, such as chills and fever, often accompany local manifestations, although these may be muted if the patient is immunocompromised or taking anti-inflammatory medications.

●○● INTERPROFESSIONAL CARE

Septic arthritis is a medical emergency requiring prompt treatment to preserve joint function. When it is suspected, fluid from the affected joint is aspirated and sent for Gram stain and culture. Cultures also are obtained from all likely sources of the infection, including blood, sputum, or wounds. The synovial fluid culture is always positive in nongonococcal septic arthritis, but often is negative for bacteria in early gonococcal arthritis. Infected synovial fluid usually is cloudy, with a high WBC count and a low glucose level. Joint x-ray films are often normal in the initial stages, but soon show demineralization, bony erosions, and joint space narrowing.

The infected joint is treated with drainage of infected pus and debris, rest, and systemic antibiotics. Needle aspiration of the infected joint may be effective to remove infected synovial fluid, although in some cases arthroscopy or arthrotomy are necessary. Repeated joint aspirations may be necessary. Treatment with a

broad-spectrum parenteral antibiotic is initiated before the results of culture are obtained. The medication may be changed or adjusted once the organism has been identified. Antibiotic therapy is continued for at least 2 weeks after inflammatory manifestations have abated. Joint rest with no weight bearing is prescribed, but immobilization of the joint is not generally required. Physical therapy is implemented during the recovery period to ensure maintenance of optimal joint function.

●○● NURSING CARE

Septic arthritis can be frightening to the patient who experiences a sudden onset of joint pain and swelling and is faced with the possibility of rapid functional loss of movement. Nursing care is both supportive and educative. Patients may be hospitalized for initial treatment with intravenous antibiotics. It is important to monitor the patient's response to therapy, including systemic manifestations such as fever. Position the affected joint appropriately, using pillows to elevate it as needed. Warm compresses may be ordered for comfort. Active ROM exercises preserve joint mobility and should be initiated as soon as the physician allows.

The patient with septic arthritis needs information about the disorder, its etiology, and its treatment. Teach the patient how organisms may gain entry into the joint space. Discuss the role that the use of injected drugs and sexually transmitted infections play in septic arthritis and means to prevent infection as appropriate (e.g., using clean "works," practicing safer sex). Refer the patient to a drug treatment program if necessary. Emphasize the importance of complying with all aspects of the treatment plan to prevent joint destruction and disability.

Neoplastic Disorders

Bone tumors may be either primary (arising in the bone itself) or metastatic (seeded from a tumor elsewhere in the body). Like other tumors, bone tumors can be either benign or malignant. Virtually every malignant tumor can metastasize to bone. However, the most common metastatic bone tumors originate from primary tumors of the prostate, breast, kidney, thyroid, and lung. The focus for discussion in this section is care of the patient with a primary bone tumor.

MEMORY CUE

Tumors That Metastasize to Bone

"**P**articular **T**umors **L**ove **K**illing **B**one"
Prostate
Thyroid
Lung
Kidney
Breast

THE PATIENT WITH A BONE TUMOR

Benign bone tumors, which are far more common than malignant bone tumors, tend to grow slowly and do not often destroy surrounding tissues. Primary malignant tumors of the bone, known as sarcomas, are rare, accounting for less than 0.2% of all adult cancers (American Cancer Society [ACS], 2011). Malignant tumors grow rapidly and metastasize.

Primary bone tumors arise from bone tissue itself, that is, cartilage (chondrogenic), bone (osteogenic), collagen (collagenic), and bone marrow cells (myelogenic). The tissue type, neoplasm classification, sites, and incidence of the most common primary bone tumors are summarized in Table 40–7.

Pathophysiology

The etiology of bone tumors is unknown, but there is a connection between increased bone activity and the development of primary bone tumors. Bone tumors frequently occur when primary bone

TABLE 40–7 Common Primary Bone Tumors

Tumor	Tissue Origin	Site	Population Affected
BENIGN BONE TUMORS			
Osteochondroma	Cartilage	On bone surface near growth plate; long bones	Most common benign tumor; children and adolescents
Enchondroma	Cartilage	Medullary bone; hands, feet, humerus, femur	Adolescents and young adults
Osteoid osteoma	Bone	Long bones; may also affect hands, fingers, or spine	Children to young adults; 3:1 males to females
MALIGNANT BONE TUMORS			
Osteosarcoma	Bone	Long bones around the knee (distal femur, proximal tibia), other long bones (proximal humerus)	Most common malignant bone tumor after multiple myeloma, 45% of bone sarcomas; adolescents and young adults; males more frequently than females
Ewing's sarcoma	Bone	Shaft of long bones; flat bones	Adolescents and young adults
Chondrosarcoma	Cartilage	Flat bones (pelvis, scapula), diaphysis (shaft) of long bones	Adults and older adults; accounts for 20%–25% of sarcomas
Multiple myeloma	Bone marrow (plasma cells)		Most common malignant bone tumor; considered a hematologic cancer

growth is at its peak in adolescence or is overstimulated during disease, such as Paget's disease. Exposure to radiation (for example, cancer radiation therapy) and bone marrow transplant are known to increase the risk for developing bone cancer, as are certain rare genetic disorders (ACS, 2011).

Primary tumors cause bone breakdown, called *osteolysis*, which weakens the bone, resulting in bone fractures. Normal bone adjacent to the tumor responds to tumor pressure by altering its normal pattern of remodeling. The bone's surface becomes altered, and the contours enlarge in the area of the tumor growth.

Malignant bone tumors invade and destroy adjacent bone tissue by producing substances that promote bone resorption or by interfering with a bone's blood supply. Benign bone tumors, unlike malignant ones, have a symmetric, controlled growth pattern. As they grow, they push against neighboring bone tissue. This weakens the bone's structure until it becomes unable to withstand the stress of ordinary use, frequently resulting in pathologic fracture.

Manifestations

The three main manifestations of bone tumors are pain, a mass, and impaired function. Bone pain usually comes on slowly and lasts for as long as a week, is constant or intermittent, and may be worse at night. The mass is described as a swelling or lump on the bone that is firm, slightly tender, and may be felt through the skin. The mass may interfere with normal movement and/or cause the bone to break. The manifestations of bone tumors are often associated with a history of a fall or blow to the extremity that brings the mass to the patient's attention. The injury, rather than the growth itself, usually causes the patient to seek medical attention. Manifestations of bone tumors are listed in an accompanying box.

●○● INTERPROFESSIONAL CARE

Treatment and care of the patient with a bone tumor focuses on prompt diagnosis, removal of the tumor, prevention of complications, and patient education.

DIAGNOSIS

The diagnosis of bone tumors is critical to the survival of the patient and possible preservation of the affected limb.

Radiologic studies include x-rays, CT scans, and MRI. X-rays show the location of the tumors and the extent of bone involvement. Benign tumors are characterized by sharp margins that are clearly separate from the surrounding normal bone. Malignant bone destruction has a characteristic "moth-eaten" pattern in which the growth has a less-defined margin that cannot be separated from the normal bone. CT scan and MRI are useful in evaluating the extent of tumor invasion into bone, soft tissues, and neurovascular structures. Percutaneous needle biopsy or needle biopsy at the time of surgery is used to determine the exact type of bone tumor.

Laboratory tests include an alkaline phosphatase (elevated with malignant bone tumor) and a calcium level (increased with massive bone destruction).

TREATMENTS

As with other malignant tumors, bone tumors are treated with chemotherapy, radiation therapy, and surgery.

CHEMOTHERAPY Chemotherapeutic agents are administered to shrink the malignant tumor before surgery, to control recurrence of tumor growth after surgery, or to treat metastasis of the tumor. Chemotherapeutic agents used to treat bone tumors are listed in Box 40–6. See Chapter 14 for further discussion of chemotherapy and its nursing implications.

RADIATION THERAPY Radiation therapy may be used in combination with chemotherapy for tumors sensitive to its effects. Most primary malignant bone tumors in adults are resistant to radiation, so its role generally is adjunctive. Radiation therapy is frequently applied to metastatic bone carcinomas as a method of pain control. It is also used to eliminate bony tumors or to eliminate any remaining tumor after a surgical procedure.

MANIFESTATIONS OF BONE TUMORS

BONY SARCOMAS

Site	Manifestations
Upper or lower extremity and pelvis	• Worsening deep bony pain • Pain at night or during rest that may radiate and become severe • Muscular weakness or atrophy
Metaphysis of distal femur, proximal tibia, proximal humerus, and pelvis	• Soft tissue mass extending from bone with erythematous or warm skin over tissue mass • Change in ability to perform ADLs • Fever

SOFT TISSUE SARCOMAS

Site	Manifestations
Upper or lower extremity and pelvis	• Enlarging firm mass with irregular borders, which causes pain in surrounding soft tissue structures
Thigh; shoulder and pelvis	• Erythema or warmth and venous dilation over skin • Muscular weakness and atrophy with limited range of motion, change in ability to perform ADLs and change in gait • Paresthesias with neurologic involvement and distal swelling • Palpable local lymph nodes
Pelvis	• Altered bowel and bladder habits or pain with intercourse

BOX 40–6 Chemotherapeutic Agents Used for Bone Tumors

ALKYLATING AGENTS
Ifosfamide
Cyclophosphamide

ANTIBIOTICS
Doxorubicin
Dactinomycin

ANTIMETABOLITES
Methotrexate

MITOSIS INHIBITORS
Etoposide

PLANT ALKALOIDS
Vincristine

SYNTHETIC AGENTS
Cisplatin

SURGERY The goal of surgery for the treatment of primary bone tumors is to eliminate the tumor completely. Tumors are removed either by excising the tumor itself or by amputating the affected limb. Wide excision of the tumor involves removing the tumor along with a small margin of normal tissue surrounding the tumor. In limb-sparing (or limb-salvage) surgery, cadaver allografts or metal prostheses are used to replace missing bone, avoiding amputation.

●○● NURSING CARE

Nursing care for the patient with a bone tumor requires innovative interventions from the time of diagnosis through the rehabilitation phase. In the acute phase, problems associated with pain, lack of knowledge, immobility, coping, and anxiety are foremost. If the patient develops complications from treatment or if a malignancy metastasizes, problems related to health management, home maintenance, self-concept, and prevention of further complications take priority.

Diagnoses, Outcomes, and Interventions

The patient with a bone tumor requires nursing care to address many health problems, including prevention of injury, relief of pain, assistance with mobility, and teaching about the disease process and treatment.

Risk for Injury

In the patient with a bone tumor, changes in bone tissue can cause pathologic fractures.

Expected Outcome: Patient will remain free of injury related to effects of bone tumor or treatment.

- Teach how to avoid falls or injury to the tumor site, such as by using assistive devices when walking and ensuring the home environment is safe (for example, remove throw rugs and use nightlights). *Pathologic fractures may occur at the tumor site because bone destruction can weaken the area.*
- Provide referral to physical or occupational therapy for fitting of and teaching about assistive devices for ambulating, such as a cane, crutches, or a walker. *Assistive devices can reduce the risk of falling when the patient has significant weakness of an extremity or when balance has been affected by treatment of the disease.*

Acute Pain, Chronic Pain

In the patient with a bone tumor, pain may be related to direct invasion of the tumor or to pathologic fractures. Patients may experience both acute and chronic pain.

Expected Outcome: Patient will be able to verbalize strategies to effectively manage pain.

- Develop strategies for controlling both acute pain (from surgery, fracture, or inflammation) and chronic pain (from progression of the disease). *Analgesics combined with nonpharmacologic methods of pain control provide optimum relief of pain. Chronic pain, when mild in nature, is best managed with NSAIDs or aspirin. Moderate pain is best managed with a combination of narcotic analgesics and NSAIDs. Severe pain is best relieved with long-acting or sustained-relief narcotic analgesics.*
- Provide assistive devices (e.g., canes, walkers, crutches) when the patient ambulates. *Assistive devices lessen the pain by supporting weight bearing during ambulation.*

Impaired Physical Mobility

Pain, muscle wasting, or surgical procedures can impair the physical mobility of the patient with a bone tumor.

Expected Outcome: Patient will participate in exercises and rehabilitation activities to regain physical mobility.

- Begin muscle strengthening and active and passive ROM exercises immediately after surgery. A continuous passive motion (CPM) machine may be used after surgical procedures to either upper or lower extremities. *Muscle strengthening exercises must be encouraged as soon as possible to prevent muscle wasting and shorten the rehabilitation period.*
- Encourage exercises that help strengthen the triceps muscles. *The triceps are the major muscles in the arms and must be strengthened to assist in use of crutches or other assistive devices.*
- For the patient who has undergone an amputation of a lower extremity, encourage quadriceps and gluteal setting exercises and leg raises. *These exercises will benefit the patient when the rehabilitation period begins.*

Continuity of Care

The patient with a primary bone tumor needs information about the disease, its potential consequences, and treatment options. Present information in a matter-of-fact manner, taking time to listen to and address the patient's and family's concerns. Discuss expected effects and potential side effects of surgery, chemotherapy, and radiation therapy. Provide information about how to minimize side effects. Teach the postsurgical patient about wound care, demonstrating dressing changes and stump care (if amputation has occurred). Provide the patient with a list of local resources for obtaining supplies. Discuss activity and weight-bearing restrictions. Refer the patient to physical therapy for teaching about ambulation and appropriate muscle-group strengthening exercises. Ensure that the patient who has experienced an amputation is working with or has a referral to a prosthetic specialist. For the patient with metastatic disease, discuss hospice services and support groups for patients with cancer.

Other Musculoskeletal Disorders

Other musculoskeletal disorders include low back pain, fibromyalgia, and disorders affecting the back and feet. Herniated intervertebral disk, a common back disorder, is discussed in Chapter 43.

THE PATIENT WITH LOW BACK PAIN

Acute or chronic low back pain involves the lumbar, lumbosacral, or sacroiliac areas of the back. In most cases, low back pain is nonspecific, without an identifiable anatomic explanation (Institute for Clinical Systems Improvement [ICSI], 2012). Back pain is a major health issue and frequent reason for physician visits in the United States, with an annual cost exceeding $100 billion. Back pain is the leading cause of disability among adults under age 45 years (Engstrom & Deyo, 2012). Low back pain caused by degenerative disk disease and herniated vertebral disks is discussed in Chapter 43.

Pathophysiology

The pathophysiology of back pain varies with its many causes (Box 40–7). In general, the five causes and types of back pain are as follows:

- Local pain is caused by compression or irritation of sensory nerves. Fractures, strains, and sprains are common causes of local pain.
- Referred pain may originate from abdominal or pelvic viscera. This type of pain is generally not affected by posture or movement.
- Pain of spinal origin, that is, pain associated with pathology of the spine such as disk disease or arthritis, may be referred to other structures such as the buttocks, groin, or legs.
- Radicular back pain is sharp, radiating from the back to the leg along a nerve root. This pain may be aggravated by movements such as coughing, sneezing, or sitting.
- Muscle spasm pain is associated with many spine disorders, although its origin may be unclear. This type of back pain is dull and may be accompanied by abnormal posture and taut spinal muscles.

There is increasing evidence that low back pain is often multifactorial in origin. Although an injury may account for initiation of the pain, factors such as deconditioning, psychologic issues, other chronic illnesses, genetics, and culture may be responsible for symptoms that extend past the normal healing time for damaged tissues (ICSI, 2012). Risk factors and pain characteristics that may indicate an important structural cause for low back pain are listed in Box 40–8.

Manifestations

Patients with low back pain report pain ranging from mild discomfort lasting a few hours to chronic debilitating pain. Acute low back pain is defined by a symptom duration of 6 weeks or less, subacute as having lasted 7 to 12 weeks, and chronic low back pain by a duration of more than 12 weeks (ICSI, 2012). Acute pain is usually thought to be injury related; however, most patients with acute low back pain are unable to identify a specific event associated with its onset.

Back pain may be localized, near the affected part of the back, or more generalized. Back pain may be referred to the buttocks, groin, or thighs. Radicular pain is generally sharp, radiating to a leg along a nerve pathway, and aggravated by coughing, sneezing, or contracting the abdominal muscles (for example, to lift a heavy object). Muscle spasm pain may be accompanied by abnormal posture and tense muscles along the spine.

BOX 40–7 Factors Associated with Back Pain

MECHANICAL INJURY OR TRAUMA
- Muscle strain or spasm
- Compression fracture
- Lumbar disk disease

DEGENERATIVE DISORDERS
- Spondylosis
- Spinal stenosis
- Osteoarthritis

SYSTEMIC DISORDERS
- Osteomyelitis
- Osteoporosis or osteomalacia
- Neoplasms, primary or metastatic

REFERRED PAIN
- Gastrointestinal disorders
- Genitourinary disorders
- Gynecologic disorders
- Abdominal aortic aneurysm
- Hip pathology

OTHER
- Fibromyalgia
- Psychiatric syndromes
- Chronic anxiety
- Depression

●○● INTERPROFESSIONAL CARE

Care of the patient with low back pain focuses on evaluating the cause of the pain (when identifiable), relieving pain, correcting the condition if possible, preventing complications, and educating the patient. A collaborative decision-making process is emphasized

BOX 40–8 Risk Factors and Indicators for Further Evaluation of Low Back Pain

- Unrelenting pain at night or at rest
- Risk factors for cancer, including older age, prior history of cancer, unexplained weight loss
- Risk factors for infection, such as immunosuppression, injection drug use, urinary tract infection, fever, or a history of tuberculosis
- Evidence of neurologic deficit, including new onset of urinary incontinence or retention, sensory and motor deficits
- Risk factors for a fragility fracture such as osteoporosis, chronic corticosteroid use, serious accident or injury, alcohol or drug abuse
- Evidence of other potential causes of back pain, such as pelvic organ disease, kidney disease, aortic aneurysm, gastrointestinal, pancreatic, or liver disease

to allow patients to make better-informed decisions regarding care (ICSI, 2012).

DIAGNOSIS

The choice of diagnostic tests for the patient with low back pain depends on the suspected diagnoses, clinical findings, and history. Current guidelines for care recommend that radiography, CT scans, and MRI be used only with clinical signs of a potentially serious underlying condition. Diagnostic testing may be considered if pain and other manifestations continue to limit the patient after 4 to 6 weeks of conservative treatment.

MEDICATIONS

The medications of choice for low back pain include nonprescription NSAIDs and analgesics (e.g., acetaminophen). NSAIDs block prostaglandin production and reduce inflammation, thus relieving the pain. Muscle relaxants, such as cyclobenzaprine (Flexeril), methocarbamol (Robaxin), or carisoprodol (Soma), may be used, but little evidence supports their efficacy. These drugs, as well as opioid analgesics, have a high abuse potential, so generally they are avoided unless necessary to allow sleep at night.

CONSERVATIVE TREATMENT

The majority of patients with acute low back pain need only a short-term treatment regimen. Limited rest, with early resumption of normal physical activity and education, is often the primary method of treatment. There is no evidence that activity is harmful or aggravating to the source of pain. In fact, activity promotes bone and muscle strength and may increase endorphin levels. Therefore, active rehabilitation helps to restore function and reduce pain.

Pain may be relieved by application of heat to the back. Exercise programs are helpful provided that the patient begins gradually and increases activity over time as the recovery process continues. Physical therapy procedures include diathermy (deep heat therapy), ultrasonography, hydrotherapy, and transcutaneous electrical nerve stimulation (TENS) units. These therapies reduce the muscle spasms and pain temporarily. They are frequently used in combination with exercise to provide early mobilization for the patient.

Complementary and alternative medicine strategies for low back pain include chiropractic, acupuncture, and massage. Evidence supports the use of spinal manipulation (chiropractic) for treating acute low back pain, finding its effectiveness to be equivalent to conservative medical management (Engstrom & Deyo, 2012).

●○● NURSING CARE

Nursing care of the patient with low back pain focuses on educating the patient. Most patients have very little understanding of the anatomy of the spine, the reasons for the pain, the choices for treatment, and the importance of self-management. Therefore, education is an essential aspect of treating low back pain.

Health Promotion

Recommendations for preventing back pain from the National Institute of Neurological Disorders and Stroke include the following:

- Have a regular exercise program.
- Stretch before working in the yard, jogging, and playing sports.
- Quit smoking.
- Lose weight, if needed.
- Maintain a correct posture.
- Use supportive seats when driving.
- Lift by bending at the knees rather than at the waist.
- Reduce emotional stress that causes muscle tension.

In industrial and work settings, nurses should be alert for situations that increase the risk of back pain and injury. Office workers should have chairs with appropriate seat height and length and back support. Modifications of work space or machinery may be necessary for industrial workers to avoid excess stresses on back muscles. Finally, it is important to remember that back pain is a leading cause of lost work time for nurses themselves. Remind coworkers to use good body mechanics and to seek help when lifting or moving patients.

Assessment

Collect the following data through the health history and physical examination:

- *Health history:* location, type (description), intensity, duration, aggravating and relieving factors; identifiable precipitating event, if known; previous episodes; current general health; ability to carry out ADLs and self-care activities; use of prescription, nonprescription, or recreational drugs or alcohol
- *Physical assessment:* appearance; posture and gait; height and weight; tenderness; lumbar spine ROM; lower extremity movement and sensation.

Priorities of Care

Educating the patient to become an active collaborator in treating his or her back pain is a priority for nurses and the whole interprofessional team.

Diagnoses, Outcomes, and Interventions

Readiness for Enhanced Self-Health Management

The patient with low back pain requires information regarding treatment, rehabilitation, and preventing injury.

Expected Outcome: Patient will become an active partner in managing back pain.

- Teach appropriate comfort measures, such as use of nonprescription analgesics or NSAIDs. Ensure the patient has a clear understanding of the appropriate use of muscle relaxants or opioid analgesics if prescribed or the rationale for not using these drugs to treat acute back pain. *Patients who have a clear understanding of appropriate treatment of their back pain and who participate in the plan of care have greater satisfaction with their treatment outcomes.*
- Discuss use of nonprescription analgesics and NSAIDs for low back pain. Instruct the patient to initially take analgesics or NSAIDs on a routine schedule. *Mild analgesics or NSAIDs may help the patient remain active, preventing muscle deconditioning that can occur with prolonged rest. Maintaining a constant blood level of the NSAIDs or analgesics reduces inflammation and provides continuous pain relief.*
- Encourage patients to stay active and continue daily living activities as allowed by symptoms. *There is little scientific evidence to show that bed rest is beneficial, but there is ample evidence about*

Evidence for Nursing Care

The Patient with Low Back Pain

Selected resources that nurses may find helpful when planning evidence-based nursing care follow.

- Crowe, M., Whitehead, L., Gagan, M., Baxter, D., & Panckhurst, A. (2010). Self-management and chronic low back pain: A qualitative study. *Journal of Advanced Nursing, 66*(7), 1478–1486.
- Institute for Clinical Systems Improvement (ICSI). (2012). *Adult acute and subacute low back pain.* Bloomington, MN: Author.

the adverse effects of bed rest. Staying in bed for more than 1 to 2 days can actually increase pain, and cause joint stiffness and muscle weakness.

- Instruct about appropriate use of heat to relieve back pain. Teach about the "rebound phenomenon" of prolonged heat or ice therapy. *Applying heat longer than 30 minutes causes a reverse effect known as the rebound phenomenon. Heat produces maximum vasodilation in 20 to 30 minutes. Continuation of the application beyond 30 to 45 minutes causes tissue congestion, and the blood vessels constrict. Although cold (e.g., an ice pack or massage with ice) may be used, evidence for its effectiveness in relieving back pain is lacking.*
- Teach the use of appropriate body mechanics in lifting and reaching. The patient should be instructed to plan the lift, keep the object being lifted close to the body, and avoid twisting when lifting. Encourage the patient to obtain help when lifting. *An item is considered excessively heavy if it equals 35% of the lifter's body weight.*
- Instruct the patient to modify the workplace or environment to minimize stress to the lower back. *Lumbar supports in chairs, adjustment of chair or table height, and rubber floor mats help prevent back strain or injury.*
- Encourage patients who are obese to lose weight. *The trunk of the body must carry excess weight when the patient is obese. People who are obese are farther away from the objects they lift because of their greater abdominal girth. They may also have more difficulty squatting to lift. The greater the distance between an object and the patient's center of gravity, the higher the risk for straining the lower back.*
- Discuss the use of complementary and alternative therapies in treating acute low back pain. *Spinal manipulation (chiropractic) has been shown to be equally effective to conventional medicine for treating low back pain.*

Continuity of Care

Back pain is a common problem in the United States and other industrialized countries. Nurses can have an effect on this significant problem by teaching health practices to prevent back injury to patients of all ages. Teach patients how to safely lift, bend, and turn when engaging in physical activity. Stress the importance of using large muscle groups of the legs to lift rather than bending and lifting with the smaller muscles of the back. Teach other aspects of good body mechanics, including posture, sleeping on a firm mattress, and sitting in chairs that provide good support. Discuss the positive effect of maintaining optimal body weight and good physical fitness.

THE PATIENT WITH FIBROMYALGIA

Fibromyalgia is a common rheumatic syndrome characterized by chronic widespread musculoskeletal pain, stiffness, and tenderness. Fibromyalgia is estimated to affect 2% to 3% of the world's population. It is found in most countries, among most ethnic groups, and across socioeconomic classes. Women are affected nine times more frequently than men. Although fibromyalgia can develop at any age, it is most prevalent in older women. The cause is unknown, but a combination of genetic and environmental factors is thought to contribute. Many patients with fibromyalgia relate its onset to physical or emotional trauma (Crofford, 2012a). It closely resembles chronic fatigue syndrome, except that musculoskeletal pain is predominant in fibromyalgia, whereas fatigue is a more significant feature of chronic fatigue syndrome.

Pathophysiology

The pathogenesis of fibromyalgia appears to be complex, involving several levels of the central nervous system, as well as the autonomic and somatic peripheral nervous systems and the endocrine system. Disordered central pain processing, with abnormal CSF levels of neurotransmitters (substance P, serotonin, and norepinephrine) and abnormal hypothalamic–pituitary–adrenal (HPA) axis responses, is increasingly shown to be central to fibromyalgia. As a result, patients with fibromyalgia perceive pain at a lower level of stimulation than people who are unaffected by the disorder.

Manifestations

A gradual onset of chronic, achy muscle pain is typical, although the onset may be sudden. The pain may be localized or involve the entire body, and may be exacerbated by changes in weather, disrupted sleep, exercise, or stress. The neck, spine, shoulders, and hips are often affected. Pain is produced by palpating localized "tender points" (Figure 40–14 ■). Local tightness or muscle spasm may also occur.

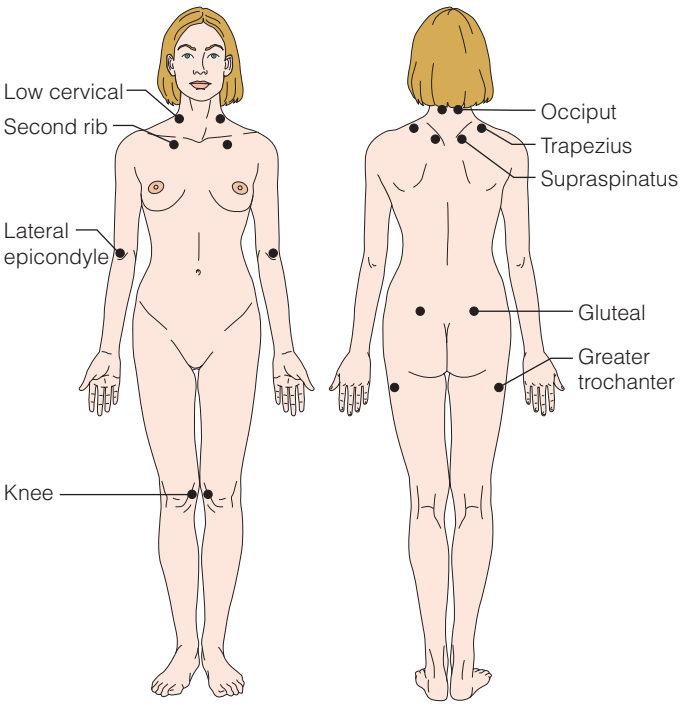

Figure 40–14 ■ Location of "tender points" in fibromyalgia.

Systemic manifestations of fibromyalgia include fatigue, sleep disruptions, headaches, morning stiffness, painful menstrual periods, and problems with thinking and memory (called *fibro fog*). Pain and fatigue are aggravated by exertion.

●○● INTERPROFESSIONAL CARE

The diagnosis of fibromyalgia is based on the history and physical assessment. The American College of Rheumatology criteria used for diagnosis are a history of widespread pain and symptoms of fatigue, waking unrefreshed, and cognitive symptoms (such as thinking or remembering difficulties) that have been present for at least 3 months (Wolfe et al., 2010). There are no laboratory or diagnostic tests for the disorder.

Acknowledgment of the patient's symptoms and the chronic but treatable nature of this disease is important. Treatment focuses on improving function and quality of life rather than on eliminating pain. Therapeutic measures include a program of structured aerobic exercise for conditioning, as well as stretching exercises. Heated pool treatments with or without exercise have been shown to be beneficial. Evidence to support other treatments such as cognitive behavioral therapy, hypnotherapy, biofeedback, and acupuncture is mixed.

Tricyclic antidepressants (e.g., amitriptyline, nortriptyline, or doxepin) have been shown to promote better sleep and relieve manifestations of fibromyalgia. Selective serotonin reuptake inhibitor (SSRI) antidepressants (e.g., fluoxetine [Prozac] and paroxetine [Paxil]) may be ordered. Only three medications are approved by the U.S. Food and Drug Administration for treating fibromyalgia. Two of these drugs, duloxetine (Cymbalta) and milnacipran (Savella), are mixed reuptake inhibitors that increase both serotonin and norepinephrine levels. The third approved drug, pregabalin (Lyrica), was developed to treat neuropathic pain. An NSAID analgesic may be recommended for pain relief.

●○● NURSING CARE

Nursing care for patients with fibromyalgia is supportive and educational, provided in community settings such as clinics and other primary care settings. Acknowledgment of the patient's symptoms and the chronic but treatable nature of this disease is important. Teach patients about the disorder, and reassure them that its course is not progressive and it does not cause crippling or deformity. Provide verbal and written instructions about the use of heat, exercise, stress reduction techniques, and prescribed medications to relieve manifestations. In addition, suggest the following resources:

- Fibromyalgia Network
- National Fibromyalgia Association
- Arthritis Foundation
- National Institute of Arthritis and Musculoskeletal and Skin Diseases.

THE PATIENT WITH SPINAL DEFORMITY

Scoliosis and kyphosis are the two most common deformities of the spinal column. *Scoliosis* is a lateral curvature of the spine. *Kyphosis* is excessive angulation of the normal posterior curve of the thoracic spine (Figure 40–15 ■).

An estimated 600,000 people in the United States are affected by scoliosis. It usually is diagnosed in adolescence. Although the incidence is equal between genders, females are eight times more likely to

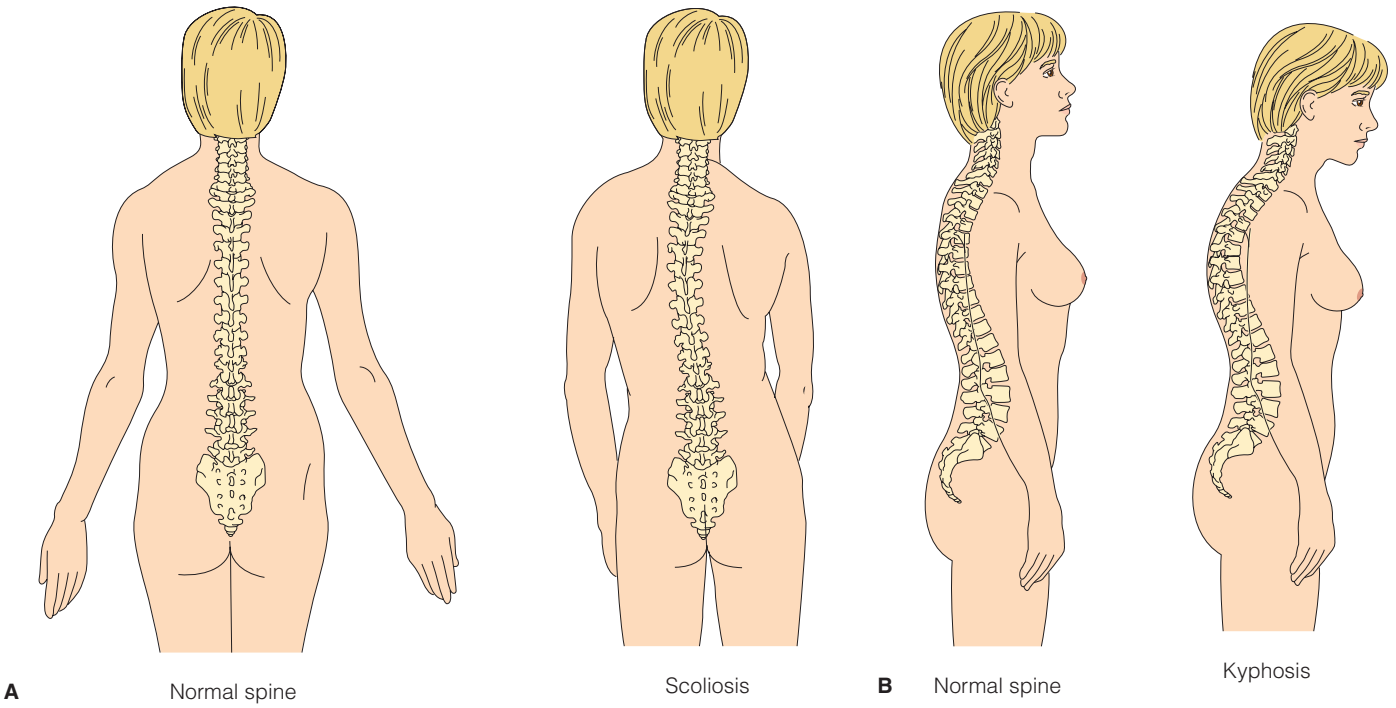

Figure 40–15 ■ Common deformities of the spinal column: A, Scoliosis is a lateral curvature of the spine. B, Kyphosis is an exaggerated posterior curvature of the thoracic spine.

MANIFESTATIONS OF SCOLIOSIS AND KYPHOSIS

SCOLIOSIS
- Asymmetry of shoulders, scapulae, waist creases
- Prominence of the thoracic ribs or paravertebral muscles on forward bend
- Lateral curvature and vertebral rotation on posteroanterior x-ray

SEVERE SCOLIOSIS
- Back pain
- Shortness of breath
- Anorexia, nausea

KYPHOSIS
- Posterior rounding at the thoracic level
- Kyphotic curve of over 45 degrees on x-ray

require treatment for significant curvature (National Scoliosis Foundation, n.d.). Idiopathic scoliosis is the most common form of the disorder, accounting for approximately 85% of cases. Congenital and neuromuscular disorders such as cerebral palsy, poliomyelitis, and MD account for the rest (Grossman & Porth, 2014).

Pathophysiology

SCOLIOSIS

Scoliosis is classified as *postural* when the small curve corrects with bending, and *structural* when the curve does not correct with bending. Most patients requiring treatment have structural scoliosis, a curve caused by a fixed deformity.

The lateral curve that occurs in scoliosis is usually evident in the thoracic, lumbar, or thoracolumbar regions of the spine. A right thoracic curve is the most common. The vertebral bodies in these spinal regions can be rotated as well as curved to one side or the other. Curves greater than 40 degrees are considered severe and require treatment.

As scoliosis emerges, the soft tissues (muscles and ligaments) shorten on the concave side of the curvature. Over time, progressive deformities of the vertebral column and ribs develop, causing one-sided compression of the vertebral bodies. The degree of compression and twisting varies according to the location of each vertebra within the curved portion of the spine.

Scoliosis is usually first noted by the deformity it causes, such as one shoulder that is higher than the other, a prominent hip, or a projecting scapula. Pain is present in severe cases, usually in the lumbar region. Pain also may be caused by pressure on the ribs or the crest of the ilium. Shortness of breath may result from diminished chest expansion, and GI disturbances may occur because of crowding of the abdominal organs. The manifestations of scoliosis and kyphosis are listed in an accompanying box.

KYPHOSIS

Like scoliosis, kyphosis is classified as postural or structural. Postural kyphosis is caused by a slumping posture. Structural kyphosis may result from congenital malformations or pediatric disorders such as rickets or poliomyelitis. However, kyphosis also may occur during adulthood as a result of vertebral tuberculosis and Paget's disease or metabolic disorders such as osteoporosis and osteomalacia. The condition can also result from the surgical removal or radiation of intervertebral disks for the treatment of spinal cord tumors or cysts.

The manifestations of kyphosis include moderate back pain and increased curvature of the thoracic spine as viewed from the side (*hunchback*). Impaired mobility and respiratory problems may occur in cases of severe curvature.

●○● INTERPROFESSIONAL CARE

Diagnosis of scoliosis and kyphosis is important to prevent severe spinal deformity and back pain in the adult. The patient stands with the arms relaxed and hanging freely at the sides while the examiner evaluates him or her from both the back and the front for symmetry of the shoulders, scapulae, waist creases, and the length of the arms. The patient then bends forward, and the examiner observes for prominence of the thoracic ribs or vertebral muscles. The patient is then viewed from the side while the screener looks for increased thoracic rounding or lumbar swayback.

DIAGNOSIS

Upright posteroanterior and lateral x-rays are used to confirm the diagnosis of curvature of the spine. For the patient with scoliosis, the degree of curvature is measured by determining the amount of lateral deviation to the left or right. For the patient with kyphosis, anteroposterior and lateral views typically reveal wedging of the vertebrae.

TREATMENTS

Scoliosis and kyphosis may be treated conservatively or with surgery.

CONSERVATIVE TREATMENT Braces can be used to prevent progression of scoliosis and kyphosis in younger patients whose skeletons have not yet matured. Bracing is the treatment of choice for adolescents with curves of 25 to 40 degrees. Unfortunately, this approach is ineffective in the adult patient. Conservative treatment for adults with scoliosis and kyphosis may include weight reduction, active and passive exercises, and the use of braces for support.

SURGERY The decision to surgically correct spinal deformities depends on factors such as the degree of curvature and the patient's overall physical, emotional, and neurologic status. Even with surgery, it is not possible to correct the abnormal curvature completely. The surgical procedure involves attaching metal reinforcing rods to the vertebrae, and is usually performed using an anterior approach, although more severe curvature may require both an anterior and a posterior approach. The types of straightening devices used most frequently use bilateral rods with wire hooks or screws that stabilize the spine and correct the deformity.

●○● NURSING CARE

Nursing interventions for patients with scoliosis or kyphosis focus on minimizing the risk for injury and neurologic impairment and educating the patient and family about the condition. See the section on herniated disk in Chapter 43 for nursing care of the patient undergoing back surgery.

Assess the environment for safety hazards. Some braces do not allow the patient to flex or hyperextend the spinal column. The older adult with kyphosis or a fixed curvature may also have limited spinal movement and difficulty seeing environmental hazards. Advise the patient to use handrails on stairways and take precautions when walking on slippery surfaces or areas with throw rugs.

Teach the patient for whom a brace is prescribed how to apply the brace, and ways to reduce skin irritation beneath the brace: wearing a smooth cotton t-shirt or cotton tube under the brace at all times, changing undergarments at least once daily, and washing them with a mild soap. Undergarments should be changed more frequently in warmer weather. Advise the patient to avoid lotion and body powders; they may irritate the skin. Suggest loosening the brace during meals and for the first 30 minutes after each meal to promote comfort and allow adequate nutritional intake.

Continuity of Care

Patients with structural scoliosis or kyphosis need reassurance that the condition was not caused by poor posture. If a brace is prescribed to relieve pain and other symptoms associated with the disorder, provide verbal and written instructions for wearing the brace, such as the number of hours per day it is to be worn and activity restrictions to follow when wearing or not wearing the brace. Teach the patient how to protect and care for skin under the brace.

Surgical patients need postoperative teaching regarding site care and activities. Patients who have spinal surgery often are allowed to ambulate soon after surgery, but sitting may be restricted because of the stresses it places on the spine. Instruct the patient to notify the physician if numbness, tingling, pain, or weakness of an extremity develops after surgery.

Discuss the importance of not smoking and of avoiding respiratory infections for patients with scoliosis or kyphosis that restricts respiratory excursion. Encourage these patients to obtain pneumococcal pneumonia and influenza immunizations.

THE PATIENT WITH A COMMON FOOT DISORDER

Foot disorders often cause pain or difficulty in walking. These disorders may be congenital; related to a systemic disorder; caused by wearing poorly fitting, confining, or high-heeled shoes; or due to physical stress on the foot. These disorders are more prevalent among women. Common foot disorders are summarized in Table 40–8.

●○● INTERPROFESSIONAL CARE

Care of the patient with a foot disorder focuses on relieving pain, correcting any structural deformity, and preventing reoccurrence. In most cases, foot disorders are diagnosed by the patient's history and by inspection. X-rays of the affected foot are taken if the need for surgery arises.

Conservative treatment usually involves the use of corrective shoes or orthotic devices that support the arch or cushion and stretch the affected joints. For Morton's neuroma, metatarsal pads are used to spread the patient's toes and decompress the affected nerve. Exercises that stretch the plantar fascia and calf muscles are beneficial in plantar fasciitis. Analgesics may be prescribed to relieve pain and inflammation. In severe cases, corticosteroid drugs may be injected into the affected joints or surrounding tissue to relieve acute inflammation.

Surgery is reserved for patients with intractable toe deformities or pain. Hallux valgus is treated with bunionectomy; ligaments are lengthened or shortened as needed, and pins are drilled into place so the toe remains in position. Similarly, the correction of hammertoe also involves straightening the affected toe and inserting pins to retain the correction. A cast may be applied over the foot following surgery to correct toe deformities. Surgery for Morton's neuroma causes loss of sensation to a portion of the foot because removing the neuroma involves cutting out a portion of the plantar nerve.

●○● NURSING CARE

Pain relief, prevention of infection, and patient education are important priorities for the nursing care of patients with foot disorders.

Instruct patients to wear appropriate or corrective footwear to assist in the conservative treatment of foot problems. Pain related to foot problems can result from footwear that does not provide proper toe room; in addition, heels higher than 1 inch can cause constant flexion and hyperextension problems. In some instances, the patient must purchase special shoes or orthotics to ensure correct fit and relief of symptoms.

Suggest purchasing protective pads to wear over painful bunions, calluses/corns, and the ball of the foot. Instruct to remove pads and inspect the skin every other day. Patients who have difficulty reaching or observing the involved foot should ask another person to do the inspection for them. It is especially important to emphasize the need for inspection to patients who have experienced loss of sensation of the feet due to such disorders as diabetes and chronic peripheral vascular disease.

Teach patients who have undergone surgery proper care and cleaning of exposed pins implanted during the surgical procedure. Instruct how to keep pins and casts dry while bathing or ambulating in inclement weather; for example, wearing a plastic bag over the cast or pins when bathing or walking in rain or snow.

Continuity of Care

For patients in all age groups, teach the importance of well-fitting footwear. Discuss the long-term effects of wearing high-heeled shoes with constricting toes with women. Suggest alternatives for stylish footwear, and encourage patients to wear supportive and nonrestrictive footwear at all times. Discuss the possible effects of bunions on balance, and talk about safety measures to prevent falls and injury. Teach patients techniques to relieve pressure on affected joints.

TABLE 40–8 Common Foot Disorders

Disorder	Description	Manifestations
Hallux valgus (bunion)	Enlargement and lateral displacement of the first metatarsal (great toe) (Figure 40–16 ■) with gradual loss of stabilizing action of the great toe	• Lateral deviation of the great toe with MTP joint enlargement • Joint pain • Calluses • Limited joint ROM, possible crepitus
Hammertoe	Dorsiflexion of the first phalanx with accompanying plantar flexion of the second and third phalanges; the second toe most commonly affected	• Pain • Inability to straighten toe • Callus on sole of the foot; corn on dorsiflexed joint
Morton's neuroma	Tumor-like mass within the neurovascular bundle of the intermetatarsal spaces (Figure 40–17 ■); usually unilateral, affecting the third web space	• Burning pain at the web space of the affected foot; radiates into the tips of involved toes • Symptoms aggravated by weight bearing, may be relieved by foot massage • Possible tender, palpable mass between the affected toes
Plantar fasciitis	Inflammation of the plantar fascia (connects the heel bone to the toes and creates the arch of the foot)	• Severe foot pain with first steps on arising in the morning or after a period of inactivity • Aggravated by walking barefoot, climbing stairs

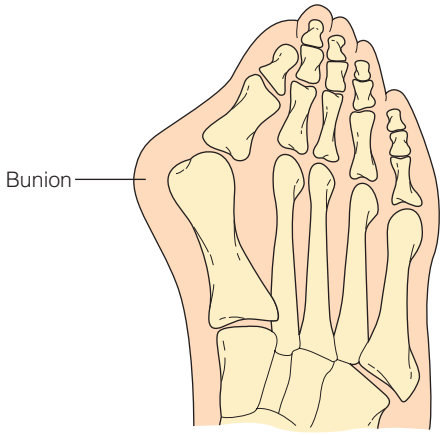

Figure 40–16 ■ Hallux valgus (bunion).

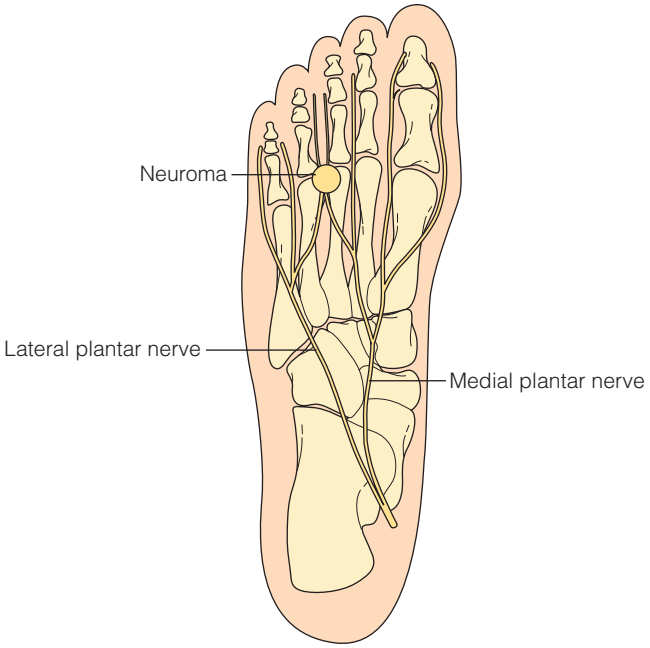

Figure 40–17 ■ Morton's neuroma.

CHAPTER HIGHLIGHTS

- **Disorders of the musculoskeletal system can have significant physical, psychosocial, and financial consequences. Patients with musculoskeletal disorders experience a variety of individualized responses to their altered health status. Nurses are responsible for coordinating interprofessional care, providing education, and ensuring psychologic support for the patient and family, as well as providing physical care.**
- **Metabolic bone and joint disorders arise from disrupted processes or impaired elimination of wastes. As a result, bones may be weak and easily fractured, leaving the patient at risk for fractures. Metabolic wastes such as urate crystals may accumulate, damaging joints and other tissues and causing acute pain.**
- Metabolic bone disorders, including osteoporosis, Paget's disease, and osteomalacia, begin in the bone remodeling process. Aging, calcium and phosphate imbalances, genetics, and changes in hormone levels contribute to these disorders.
- Osteoporosis is a major health problem in the United States, with fractures being the most common complication. Health promotion activities to prevent osteoporosis include a calcium-rich diet, weight-bearing exercise, and a healthy lifestyle.
- Gout is characterized by hyperuricemia and urate crystal formation in the joint synovium. Attacks of the disease typically begin with an acutely painful inflammation of the first joint of the great toe, although other joints such as the knee or elbow may be affected.
- **Degenerative disorders of the joints and muscles can lead to impaired mobility and chronic pain. These problems may in turn cause disability, especially in the performance of daily living activities.**
- Osteoarthritis (OA) is the most commonly occurring of all forms of arthritis, and a leading cause of pain and disability in older adults. The disease is characterized by loss of cartilage in articulating joints and hypertrophy of bone at the articular margins. Pain and inflammation are most often conservatively managed with mild analgesics and NSAIDs.
- Significant pain and disability not controlled with analgesics, NSAIDs, exercise, and physical therapy may necessitate total joint replacement.
- **Autoimmune and inflammatory disorders of the musculoskeletal system are systemic in nature and often chronic, potentially leading to significant disability. Care is multidimensional, involving pharmacologic and nonpharmacologic strategies to maintain optimal function.**
- Autoimmune and inflammatory musculoskeletal disorders include rheumatoid arthritis (RA), ankylosing spondylitis (AS), reactive arthritis (ReA), systemic lupus erythematosus (SLE), inflammatory myopathy, and Lyme disease.
- Although the cause of RA is unknown, it is believed to involve a combination of genetic and environmental factors. RA is a systemic disease, affecting one or many joints, and also causing fatigue, weakness, anorexia, weight loss, and fever. The primary objectives of treatment and care are to reduce pain and inflammation, preserve function, and prevent deformity.
- **Connective tissue is the most abundant and widely distributed body tissue. It connects body parts and provides support; forms bones, cartilage, and the walls of blood vessels; and attaches muscles to bones. Disorders that affect connective tissue have diverse manifestations, and patients need interprofessional team support for effective disease management.**
- SLE is a chronic inflammatory connective tissue disease, affecting almost all body systems, including the musculoskeletal system. Skin lesions are a common manifestation, exhibited by a characteristic rash on the face. The patient with SLE is at increased risk for infection.
- Systemic sclerosis is a chronic disease characterized by the formation of excess connective tissue and diffuse fibrosis of the skin and internal organs. It may be either localized or generalized.
- Lyme disease is caused by the spirochete *Borrelia burgdorferi*, carried and transmitted primarily by ticks. The disease can be treated effectively with antibiotics.
- **Infectious disorders of bone and joints are caused by a pathogen, and are often difficult to treat. Effective treatment is vital, however, to prevent chronic pain, deformity, and disability. The nurse coordinates, provides, and monitors treatment measures and responses in acute care and the home, and provides patient, family, and caregiver education.**
- Osteomyelitis and septic arthritis are infectious musculoskeletal disorders. Osteomyelitis may be the result of a bloodborne pathogen, a contiguous infection, or a complication of vascular insufficiency. Septic arthritis is a medical emergency, requiring immediate treatment to preserve joint function.
- **Bone tumors may be benign or malignant, primary or metastatic. The primary manifestations of a bone tumor are pain, a mass, and impaired function. Nursing care is directed toward teaching to prevent injury and interventions to relieve pain.**
- **Musculoskeletal disorders characterized by chronic pain and discomfort can have significant physical and psychosocial effects on the patient. The nursing role in caring for these patients focuses on providing support and educating the patient about his or her condition so the patient can be an active partner in managing the condition.**
- Low back pain is among the most common problems causing adults to seek medical care. Unless risk factors or manifestations indicating a secondary origin (e.g., a tumor or infection) are present, this condition is appropriate for conservative management with mild analgesics, NSAIDs, or chiropractic. Patients are encouraged to stay active, avoiding only strenuous lifting or activity.
- Fibromyalgia is characterized by chronic widespread musculoskeletal pain and tenderness that has a significant negative impact on physical and psychosocial functioning. A combination of physical conditioning, cognitive-behavioral strategies, and pharmacologic treatment is commonly employed to treat fibromyalgia.
- Structural musculoskeletal disorders include scoliosis, kyphosis, hallux valgus, hammertoe, and Morton's neuroma. Plantar fasciitis is a common cause of foot pain in adults.

TEST YOURSELF NCLEX-RN® REVIEW

1. A patient with osteoporosis is prescribed the bisphosphonate alendronate (Fosamax). What should the nurse include when teaching the patient about this medication? (Select all that apply.)
   1. Take the medication as directed with clear water only.
   2. Avoid lying down for 30 to 60 minutes after taking the drug.
   3. Consume no food or fluids for 30 minutes after taking the drug.
   4. Take calcium and vitamin D supplements as instructed by your healthcare provider.
   5. Tingling around the mouth or numbness and tingling of the fingers or toes are expected effects.
2. The nurse is preparing teaching for a patient with mild osteoarthritis of the knees. Which medication treatments should the nurse include in these instructions? (Select all that apply.)
   1. opioids
   2. NSAIDs
   3. hormones
   4. antibiotics
   5. hyaluronic acid
3. The nurse is reviewing laboratory values for a patient with an acute attack of gout. Which laboratory value should the nurse expect to be increased?
   1. uric acid
   2. creatinine
   3. hematocrit
   4. alkaline phosphatase
4. The nurse is preparing a teaching session for community members on osteoporosis and osteomalacia. What should the nurse include as a potential complication for both of these health problems?
   1. infection
   2. fractures
   3. blood clots
   4. contractures
5. During an assessment the nurse determines that a patient with knee pain is at risk for osteoarthritis. What did the nurse assess in this patient?
   1. having a history of falls
   2. eating a diet high in calcium
   3. walking 30 minutes each day
   4. being overweight by 30 pounds
6. The nurse monitors vital signs and laboratory values for a patient recovering from a total knee replacement. For which reason is the nurse implementing these actions?
   1. Prevent the progression of infection.
   2. Teach the patient the importance of these assessments.
   3. Ensure adequate circulation to the involved extremity.
   4. Promote rapport between the patient and the healthcare providers.
7. The nurse is determining the type of arthritis a patient is experiencing. Which assessment finding would be present if the patient has rheumatoid arthritis?
   1. Stiffness is relieved by activity.
   2. Health history includes weight loss and fever.
   3. Abnormal joint findings are limited to the hands.
   4. Heberden's nodes are located on the finger joints.
8. The nurse identifies the diagnosis of *Ineffective Protection* as appropriate for a patient with systemic lupus erythematosus. Which intervention should the nurse include when planning this patient's care?
   1. Monitor laboratory findings.
   2. Provide appropriate skin care.
   3. Practice careful hand hygiene.
   4. Administer prescribed medications.
9. The community nurse is preparing a presentation on Lyme disease for community members. What should the nurse explain about the spread of the organism for this disease?
   1. the bite of an infected mosquito
   2. brief contact with an infected tick
   3. an infected tick embedded for > 24 hours
   4. primarily by droplets from infected people
10. After assessing a patient in the emergency department, the nurse determines that the patient has a form of arthritis that is a medical emergency. For which type of arthritis should the nurse plan care for this patient?
    1. osteoarthritis
    2. septic arthritis
    3. gouty arthritis
    4. reactive arthritis

UNIT

10 Building Clinical Competencies

Responses to Altered Musculoskeletal Function

CLINICAL SCENARIO

Directions: *Read the following clinical scenarios and answer the questions that follow. To complete this exercise successfully, you will not only use knowledge of the content in this unit, but also principles related to priority setting and maintaining patient safety.*

You have been assigned to work with the following four patients for the 0700 shift on an orthopedic unit. Significant data obtained during report is as follows:

- Jesse Drummond is a 70-year-old African American patient with diabetes who is 3 days postoperative with bilateral below-the-knee amputations. Vital signs are temperature 37°C (99°F), pulse 88 bpm, respirations 24/min, and blood pressure 150/92 mmHg. He is complaining of feeling pain in his feet.
- Joyce Stevens is an 84-year-old who is 2 days postoperative ORIF of the right femur after a fall. Her vital signs are temperature 37.6°C (99.6°F), pulse 100 bpm, respirations 30/min and shallow, blood pressure 110/86 mmHg. She is confused when spoken to. Petechiae are noted on her arms and legs. She is complaining of difficulty breathing.
- José Rivera, a 21-year-old, was admitted with osteomyelitis of the upper right leg following a gunshot wound to the leg. Vital signs are temperature 39.2°C (102.6°F), pulse 98 bpm, respirations 22/min, blood pressure 138/80 mmHg. He is scheduled for surgical debridement of the wound this morning. He is complaining of pain and requesting pain medication.
- Kim Wong is a 30-year-old who is admitted with symptoms of painful and swollen joints, muscle pain, pale and cyanotic fingers and toes, and edema of the legs and periorbital areas. Her vital signs are temperature 38.1°C (100.6°F), pulse 78 bpm, respirations 16/min, blood pressure 108/72 mmHg. She is complaining of extreme fatigue. She is to have blood drawn for complete blood count (CBC), anti-DNA antibody testing, and serum complement levels.

CLINICAL REASONING

1. What clinical data suggest that Ms. Stevens is experiencing an acute event?

Priority Setting

2. In what order would you visit these patients after report?

A. _____
B. _____
C. _____
D. _____

Health Promotion

3. When Ms. Stevens is ready for discharge, what foods will you recommend she eat to promote healing?

Nursing Process

4. The nurse is performing a neurovascular assessment on Mr. Rivera's right lower extremity prior to sending him to the operating room for wound debridement. Which of the following does the nurse include in the focused assessment of the right lower extremity? (Select all that apply.)

A. pain
B. paroxysm
C. pallor
D. pulses
E. paresis
F. pallesthesia
G. paresthesia

5. After the amputation wound is redressed by the nurse, which of the following should Mr. Drummond be taught to toughen the stump?

A. Dangle the stump for 20 minutes every hour while awake.
B. Push the stump into soft and then harder surfaces.
C. Elevate the stump on two pillows, keeping the knee straight.
D. Apply the prosthesis over the compression dressing.

Communication

6. Mr. Drummond states, "If I knew my legs would hurt so bad after they were cut off, I would not have had the surgery. Will they ever quit hurting?" How will you answer his question?

7. Ms. Wong states, "If I have lupus, how will the doctor cure it?" How will you answer her question?

Delegation

8. What interventions can be delegated to the unlicensed assistive personnel (UAP) for each patient?

A. _____
B. _____
C. _____
D. _____

Interprofessional Care

9. What type of interprofessional care is essential for Mr. Drummond status post-bilateral lower extremity amputations?

Continuity of Care

10. Since teaching is critical for the patient diagnosed with systemic lupus erythematosus, what should be included to provide for continuity of care?

Safety

11. Which of the following measures is mostly clearly focused on prevention of deep venous thrombosis in Ms. Stevens?

A. forcing fluids
B. keeping the operative leg elevated
C. wearing sequential compression devices
D. turning side to side every 3 to 4 hours

Quality Improvement

12. The nurse manager on an orthopedic unit notes an increase in incidence of deep venous thrombosis in the patient population on the unit. What should the manager look for when performing a retrospective chart review?

Informatics

13. Part of the nursing care planning for Mr. Drummond, the patient who underwent bilateral below-the-knee amputations, would include detailed instructions regarding transfers. In an electronic medical record, where would the nurse expect to find detailed, individualized information regarding safe transfer technique for this patient?

A. admission note
B. nursing care plan (Kardex)
C. flow sheet
D. electronic order entry _____.

Responses to Altered Neurologic Function

 **41** Assessing the Nervous System 1331

 **42** Nursing Care of Patients with Intracranial Disorders 1352

 **43** Nursing Care of Patients with Spinal Cord Disorders and CNS Infections 1399

 **44** Nursing Care of Patients with Neurologic Disorders 1428

Cognitive–Perceptual Pattern

The neurologic system regulates and integrates body functions, mental abilities, and emotions; injury or disorders may affect communication, mobility, memory, decision-making, and sensation.

41 Assessing the Nervous System

LEARNING OUTCOMES

1. Describe the anatomy, physiology, and functions of the nervous system.
2. Explain manifestations of impairment of neurologic function.
3. Give examples of genetic disorders of the nervous system.
4. Describe normal variations in assessment findings for the older adult.
5. Identify specific topics for consideration during a health history assessment interview of the patient with neurologic disorders.
6. Explain techniques for assessment of neurologic function.
7. Identify abnormal findings that may indicate alterations in nervous system function.

CLINICAL COMPETENCIES

1. Conduct and document a health history for patients having or at risk for alterations in the neurologic system.
2. Conduct and document a physical assessment of neurologic structures and functions demonstrating sensitivity and respect for the diversity of the human experience.
3. Monitor the results of diagnostic tests and communicate abnormal findings within the interprofessional team.
4. Perform specific neurologic assessments for patients with suspected meningeal irritation and for patients who are disoriented or comatose.

MAJOR CHAPTER CONCEPTS

- Correct structure and function of the nervous system are vital to enervate, regulate, and integrate all of the body's functions.
- Manifestations of dysfunction, injury, and disorders affecting the nervous system may be detected during a general health assessment as well as during a focused nervous system assessment.

- Tuning fork
- Reflex hammer
- Pencil and paper
- Penlight
- Printed materials
- Substances to test the senses of smell and taste

The nervous system regulates and integrates all body functions, muscle movements, senses, mental abilities, and emotions. It collects information from the internal and external environments as sensory input, processes and interprets the input, and initiates and coordinates responses that are manifested as motor or sensory output. Alterations in structure and/or function of the nervous system have the potential to affect a wide variety of human functions, including activity and exercise, comfort, cardiovascular and respiratory function, elimination, and sexuality. Changes in appearance and abilities for self-care further increase the risk for alterations in self-concept and relationships.

Anatomy, Physiology, and Functions of the Nervous System

The nervous system is divided into two regions: the central nervous system (CNS), which consists of the brain and spinal cord, and the peripheral nervous system (PNS), which consists of the cranial nerves, the spinal nerves, and the autonomic nervous system.

Nerve Cells, Action Potentials, and Neurotransmitters

The highly integrated CNS and PNS consist of just two types of cells: neurons, which receive impulses and send them on to other cells, and neuroglia, which protect and nourish the neurons. This section focuses on the neurons.

NEURONS

Each neuron consists of a dendrite, a cell body, and an axon (Figure 41–1 ■). The dendrite is a short projection from the cell body that conducts impulses toward the cell body. Cell bodies, most of which are located within the CNS, are clustered in ganglia or nuclei. The cell bodies and dendrites comprise what is often called the *gray matter of the CNS*. The axon, a long process, conducts impulses away from the cell body. Many axons are covered with a myelin sheath, a white lipid substance. It is interrupted at intervals in unmyelinated areas called *nodes of Ranvier*, which allow movement of ions between the axon and the extracellular fluid. The myelin sheath serves to increase the speed of nerve impulse conduction in axons and is essential for the survival of larger nerve processes. Myelinated nerve fibers comprise the white matter of the brain and spinal cord.

ACTION POTENTIALS

Action potentials are impulses (movements of electrical charge along an axon membrane) that allow neurons to communicate with other neurons and body cells. They are initiated by stimuli and propagated by the rapid movement of charged ions through the cell membrane. When a neuron reaches a certain level of stimulation, an electrical impulse is generated and conducted along the length of its axon. The movement of impulses to and from the CNS is made possible by afferent and efferent neurons. Afferent, or sensory, neurons have receptors in skin, muscles, and other organs and relay impulses to the CNS. Efferent, or motor, neurons transmit impulses from the CNS to cause some type of action.

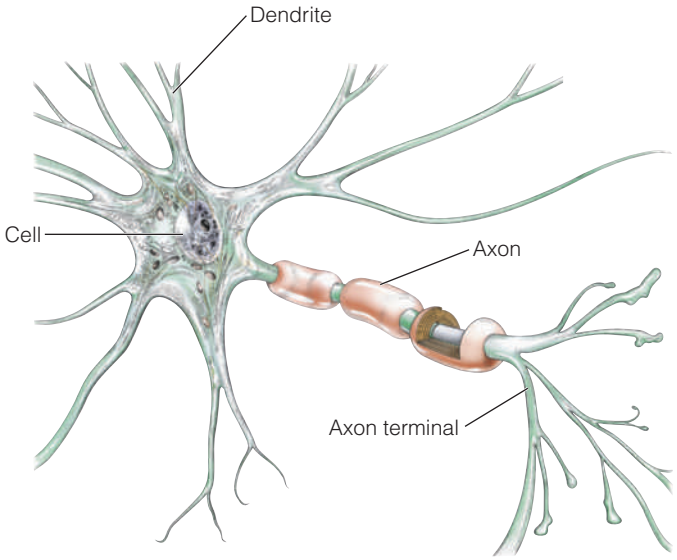

Figure 41–1 ■ A typical neuron.

Nerve impulses occur when a stimulus reaches a point great enough to generate a change in electrical charge across the cell membrane of a neuron. A neuron that is not involved in impulse conduction is in a resting, or polarized, state, in which the number of positive ions in the fluid outside of the cell membrane is greater than in the fluid within the cell. The chief regulators of membrane potential are sodium and potassium: Sodium is the major positive ion in the extracellular fluid, and potassium is the major positive ion in the intracellular fluid. In response to an electrical stimulus, the cell membrane becomes permeable to sodium, which moves into the cell. This changes the polarity of the cell membrane, and the neuron is said to depolarize. This event stimulates an action potential (a nerve impulse) to travel down the axon. When the charges and ions return to their original resting state, the neuron is repolarized. The events in an action potential are as follows:

1. Initially, sodium permeability increases. As the membrane is depolarized, sodium channels open and sodium rushes into the cell to a point of depolarization (the inside of the cell becomes less negative in comparison to the outside of the cell).
2. This is followed by a decrease in sodium permeability, lasting only about 1 millisecond. The sodium gates close and the sodium influx stops.
3. The final event is an increase in potassium permeability. The potassium gates open, potassium rushes out of the cell, and the cell interior becomes progressively less positive. The membrane potential moves back to its resting state and is repolarized.

The action potential is generated only at the point of the stimulus; but once generated, it is propagated along the entire length of the axon regardless of whether the stimulus continues. Conduction of the impulse is rapid in myelinated fibers, with the action potential "jumping" from one node of Ranvier to the next. The conduction of the impulse is slower in unmyelinated fibers.

NEUROTRANSMITTERS

Neurotransmitters are the chemical messengers of the nervous system. When the action potential reaches the end of the axon at the presynaptic terminal, a neurotransmitter is released and travels across the synaptic cleft to bind with receptors in the postsynaptic neuron dendrite or cell body. The neurotransmitter may either be inhibitory or excitatory. The excitatory neurotransmitter is almost always acetylcholine (ACh), which is rapidly degraded by the enzyme acetylcholinesterase. Nerves that transmit impulses through the release of ACh are called *cholinergic.* Receptors that bind ACh are found in the viscera, skeletal muscle cells, and the adrenal medulla (where they stimulate the release of epinephrine). The effect of ACh binding may be either to stimulate or to inhibit a response.

Norepinephrine (NE), which may be either excitatory or inhibitory, is another major neurotransmitter. Nerves that transmit impulses through the release of NE are called *adrenergic.* Receptors

that bind NE are found in the heart, lungs, kidneys, blood vessels, and all target organs stimulated by the sympathetic division except the heart. Adrenergic receptors are further divided into alpha and beta types. Alpha-adrenergic receptors help control such varied functions as arterial vasoconstriction and pupil dilation. Beta-adrenergic fibers may be either $beta_1$- or $beta_2$- receptors. $Beta_1$-receptors are found in the heart, where they regulate the rate and force of contraction. $Beta_2$-receptors are found in receptor cells of the lungs, arteries, liver, and uterus; they help regulate bronchial diameter, arterial diameter, and glycogenesis. Generally, binding of NE to alpha-receptors stimulates a response, whereas binding to beta-receptors inhibits a response.

Other neurotransmitters include gamma aminobutyric acid (GABA), which inhibits CNS function; dopamine, which may be inhibitory or excitatory and helps control fine movement and emotions; and serotonin, which is usually inhibitory and controls sleep, hunger, and behavior and also affects consciousness.

The Central Nervous System

The central nervous system (CNS) consists of the brain and spinal cord, highly evolved clusters of neurons that act to accept, interconnect, interpret, and generate a response to nerve impulses originating throughout the body.

THE BRAIN

The brain is the control center of the nervous system and also generates thoughts, emotions, and speech. The brain has four major regions: the cerebrum, the diencephalon, the brainstem, and the cerebellum (Figure 41–2 ■). The general functions of these regions are summarized in Table 41–1.

The two hemispheres of the cerebrum account for almost 60% of brain weight. The surface of the cerebrum is folded into elevated ridges of tissue called *gyri*, which are separated by shallow grooves (sulci) and deep grooves (fissures). The longitudinal fissure separates the hemispheres, and the transverse fissure separates the cerebrum from the cerebellum. In addition, each cerebral

TABLE 41–1 General Functions of the Four Regions of the Brain

Region	Functions
Cerebrum	Interprets sensory input. Controls skeletal muscle activity. Processes intellect and emotions. Contains skills memory.
Diencephalon	Conducts sensory and motor impulses. Regulates autonomic nervous system. Regulates and produces hormones. Mediates emotional responses.
Brainstem	Serves as conduction pathway. Serves as site of decussation of tracts. Contains respiratory nuclei. Helps regulate skeletal muscles.
Cerebellum	Processes information. Provides information necessary for balance, posture, and coordinated muscle movement.

hemisphere is divided into frontal, parietal, temporal, and occipital lobes (Figure 41–3 ■). The cerebral hemispheres are connected by a thick band of nerve fibers called the *corpus callosum*, which allows communication between the two hemispheres. Each hemisphere receives sensory and motor impulses from the opposite side of the body. Most people have a more highly developed left hemisphere, which is responsible for the control of language. The right hemisphere has greater control over nonverbal perceptual functions.

The cerebral cortex is the outer surface of the cerebrum. It consists of neuron cell bodies, unmyelinated fibers, neuroglia, and blood vessels. The functions of the different lobes of the cerebrum and the specific areas of the cerebral cortex are shown in Figure 41–3 and listed in Table 41–2.

The diencephalon is embedded in the cerebrum superior to the brainstem. It consists of the thalamus, hypothalamus, and epithalamus. The thalamus begins to process sensory impulses before

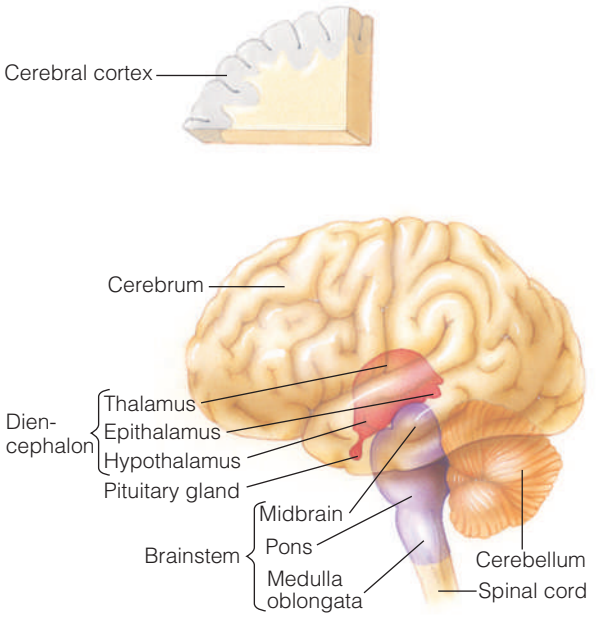

Figure 41–2 ■ The four major regions of the brain.

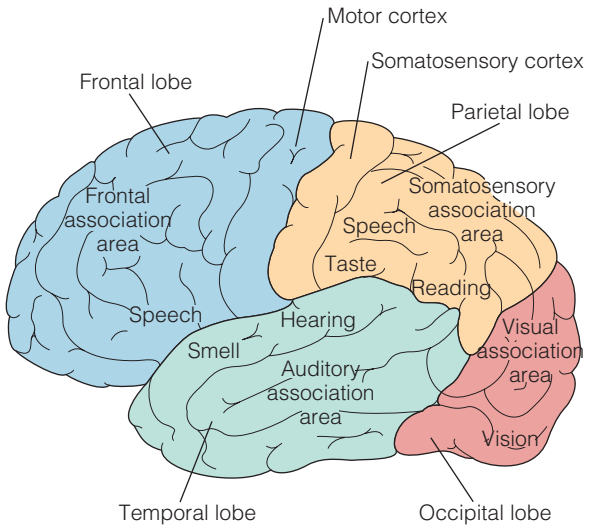

Figure 41–3 ■ Lobes of the cerebrum and functional areas of the cerebral cortex.

TABLE 41–2 Functions of Lobes of the Cerebrum and Areas of the Cerebral Cortex

Area	Functions
Parietal lobe (somatosensory area of cerebral cortex)	Promotes recognition of pain, coldness, and light touch. The left side receives input from the right side of the body, and vice versa.
Occipital lobe	Receives and interprets visual stimuli.
Temporal lobe	Receives and interprets olfactory and auditory stimuli.
Frontal lobe	Controls movements of voluntary muscles.
Primary motor area	Facilitates voluntary movement of skeletal muscles.
Speech area	Promotes understanding of spoken and written words.
Motor speech area (Broca's area)	Promotes vocalization of words.

they ascend to the cerebral cortex. It serves as a sorting, processing, and relay station for input into the cortical region. The hypothalamus, located inferior to the thalamus, regulates temperature, water metabolism, appetite, emotional expressions, part of the sleep–wake cycle, and thirst. The epithalamus forms the dorsal part of the diencephalon and includes the pineal body, which is part of the endocrine system that affects growth and development.

BRAINSTEM The brainstem consists of the midbrain, pons, and medulla oblongata. The midbrain is a center for auditory and visual reflexes and functions as a nerve pathway between the cerebral hemispheres and lower brain. The pons is located just below the midbrain. It consists mostly of fiber tracts, but it also contains nuclei that control respiration. The medulla oblongata, located at the base of the brainstem, is continuous with the superior portion of the spinal cord. Nuclei of the medulla oblongata play an important role in controlling cardiac rate, blood pressure, respiration, and swallowing.

The cerebellum is connected to the midbrain, pons, and medulla. Its functions include coordinating skeletal muscle activity, maintaining balance, and controlling fine movements.

VENTRICLES The brain contains four ventricles, which are chambers filled with cerebrospinal fluid (CSF). They are linked by ducts that allow the CSF to circulate. One lateral ventricle is located within each hemisphere. These communicate with the third ventricle through the foramen of Monro. The third ventricle communicates with the fourth ventricle through the cerebral aqueduct that runs through the midbrain. The cerebral aqueduct is continuous with the central canal of the spinal cord.

CEREBROSPINAL FLUID Cerebrospinal fluid, a clear and colorless liquid, is formed by the choroid plexus, which is made up of groups of specialized capillaries located in the brain ventricles. Derived from blood plasma, CSF consists of 99% water and contains protein, sodium, chloride, potassium, bicarbonate, and glucose (see Table 41–3 for normal laboratory values for CSF). The usual amount of CSF ranges from 80 to 200 mL and is replaced several times each day. CSF is normally produced and absorbed in equal amounts. CSF circulates from the lateral ventricles of the cerebral hemispheres into the third ventricle, through the midbrain, and into the fourth ventricle. Some CSF flows down the center of the spinal cord as the rest of it circulates into the subarachnoid space and returns to the blood through the arachnoid villi. CSF forms a cushion for the brain tissue, protects the brain and spinal cord from trauma, helps provide nourishment for the brain, and removes waste products of cerebrospinal cellular metabolism.

TABLE 41–3 Normal Laboratory Values for Cerebrospinal Fluid

Component	Normal Value
Appearance	Clear and colorless
pH	7.35
Specific gravity	1.007
WBCs	0–8 mm^3
Protein	40 mg/dL
Glucose	40–70 mg/dL
Chloride	118–132 mmol/L
Pressure	70–180 mmH_2O

MENINGES The brain and spinal cord are covered and protected by three connective tissue membranes called *meninges*. The meninges form divisions within the skull, enclose venous sinuses, and contain CSF. The meninges have three layers (Figure 41–4 ■). The outermost double layer, the dura mater, is attached to the inner surface of the skull. The middle layer is the arachnoid mater, which encloses the entire CNS and forms the subarachnoid space that contains CSF. The innermost layer, the pia mater, clings to the brain, spinal cord, and segmental nerves and is filled with small blood vessels.

CEREBRAL CIRCULATION AND THE BLOOD–BRAIN BARRIER The brain receives about 750 mL of blood each minute and uses 20% of the body's total oxygen uptake. The large amount

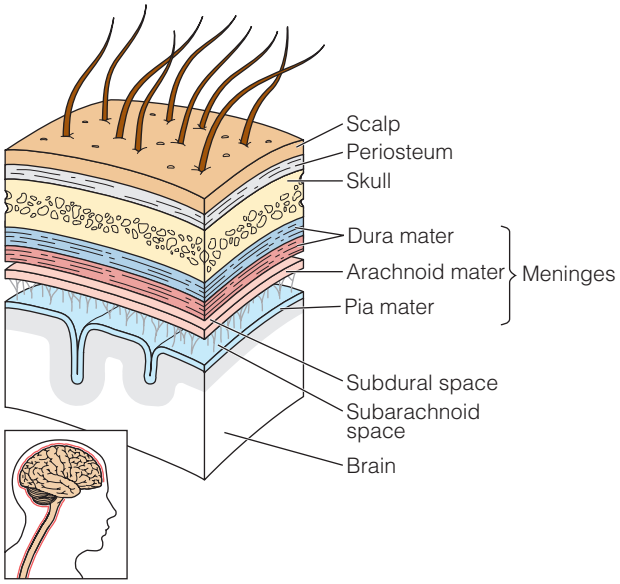

Figure 41–4 ■ Anatomy of the meninges.

of oxygen is necessary for metabolism of glucose, which is the brain's sole source of energy. Blood flow to the brain is mostly controlled by autoregulatory or local mechanisms that respond to the brain's metabolic needs. Autoregulation is the ability of the brain to maintain constant cerebral blood flow despite changes in systemic blood pressure. At least three metabolic factors affect cerebral blood flow: carbon dioxide, hydrogen ion, and oxygen concentrations. Of these, increased carbon dioxide is the major stimulus for vasodilation with resultant increased cerebral blood flow.

The anterior part of the brain is supplied with blood by the two internal carotid arteries, and the posterior part of the brain is supplied with blood by the vertebral arteries. The internal carotid artery branches into further arteries: the ophthalmic, posterior communicating, anterior choroidal, anterior cerebral, and middle cerebral. The brainstem and cerebellum receive their blood supply from the basilar artery. These major arteries are connected by small anterior and posterior communicating arteries, which form a circle of connected blood vessels called *the circle of Willis* (Figure 41–5 ■). This circle serves as a protective device, providing alternative routes for brain tissues to receive their blood supply.

The capillaries in the brain have low permeability because the cells that compose their walls join at very tight junctions and are surrounded by a basement membrane and by the processes of astrocytes in the brain. This blood–brain barrier allows lipids, glucose, some amino acids, water, carbon dioxide, and oxygen to pass through it, thus maintaining a controlled environment. Substances such as urea, creatinine, proteins, some toxins, and most antibiotics cannot pass this barrier and enter brain tissue. However, injury to or infection of the brain may cause increased permeability of the blood–brain barrier, altering concentrations of proteins, water, and electrolytes.

THE LIMBIC SYSTEM AND THE RETICULAR FORMATION

The limbic system and the reticular formation are functional brain systems. These systems, made of networks of neurons, communicate across areas of the brain.

The limbic system consists of structures that form a ring of tissue in the medial side of each hemisphere, surrounding the upper portion of the brainstem and corpus callosum. The limbic system integrates and modulates input to make up the affective part of the brain, providing emotional and behavioral responses to environmental stimuli.

The reticular formation is located through the central core of the medulla oblongata, pons, and midbrain. This system has widespread connections throughout the brain and relays sensory input from all body systems to all levels of the brain. The reticular formation includes the reticular activating system (RAS). The RAS is a stimulating system for the cerebral cortex, keeping it alert and responsive to incoming sensory stimuli while filtering out repetitive or unwanted stimuli. The sleep center inhibits activity of the RAS, and drugs and alcohol may depress it. Other parts of the reticular formation include motor nuclei that help maintain muscle tone and coordinated movements through interconnections with spinal nerves, and the vasomotor and cardiovascular regulatory centers, which are part of autonomic regulation of the cardiovascular system.

THE SPINAL CORD

The spinal cord, protected by the vertebrae, the meninges, and CSF, extends from the medulla to the level of the first lumbar vertebra (Figure 41–6 ■). It serves as a center for conducting messages to and from the brain and as a reflex center. The spinal cord is about 42 cm (17 in.) long and 1.8 cm (0.75 in.) thick. The gray matter of the cord is on the inside, and the white matter is on the outside (the reverse of the arrangement in the brain).

The spinal cord is surrounded by 33 vertebrae: 8 cervical, 12 thoracic, 5 lumbar, 5 sacral, and 4 fused vertebrae that form the coccyx. Each vertebra consists of a body and a vertebral arch formed by projections from the body. This arch encloses a space called the *vertebral foramen*. The vertebral foramina of all the vertebrae form the vertebral canal through which the spinal cord passes. Intervertebral foramina are spaces between the vertebrae through which spinal nerve roots pass as they exit the vertebral column. Intervertebral disks are located between each of the movable vertebrae. Each disk is made of a thick capsule surrounding a gelatinous core called the *nucleus pulposus*. Ligaments that provide mobility and protection surround the vertebral column.

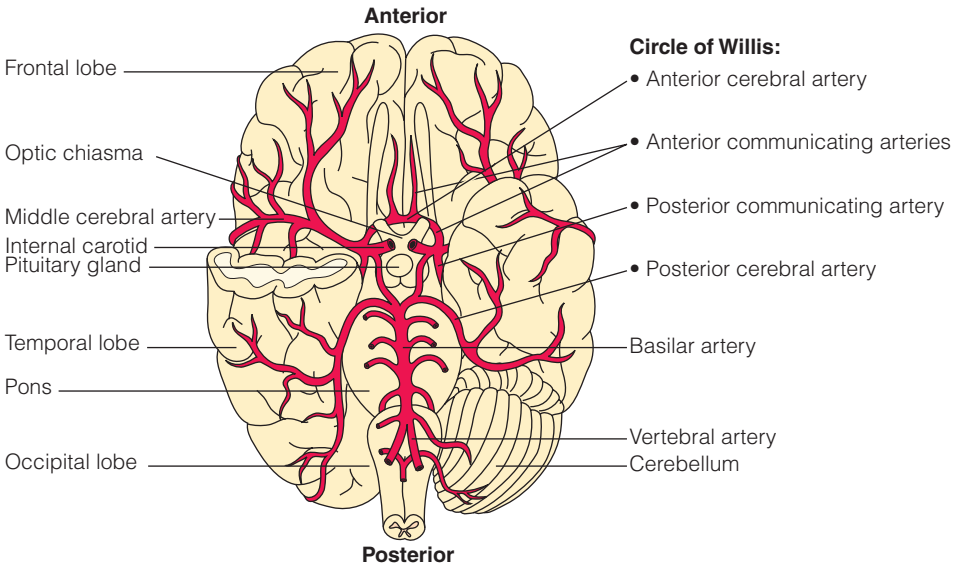

Figure 41–5 ■ Major arteries serving the brain and the circle of Willis.

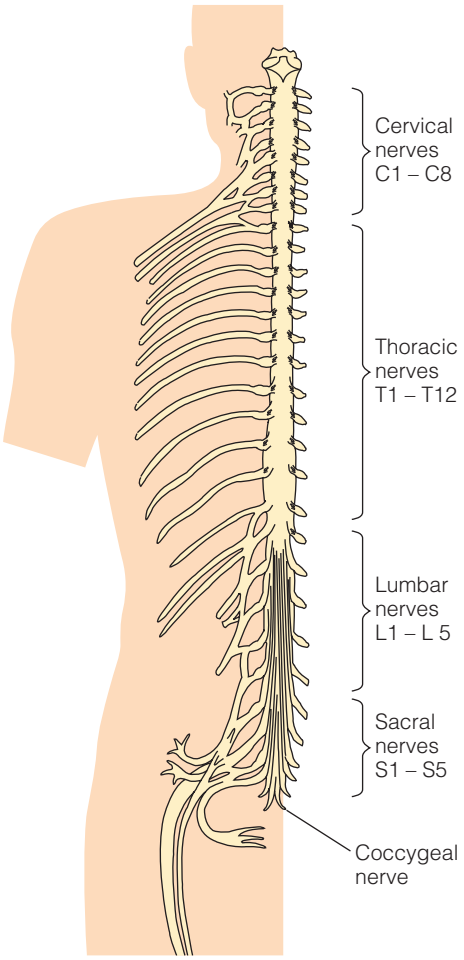

Figure 41–6 ■ Distribution of spinal nerves.

FUNCTIONS OF THE SPINAL CORD AND SPINAL ROOTS Messages to and from the brain are conducted via pathways called either *ascending* (sensory) or *descending* (motor) (Figure 41–7 ■). The major ascending tracts are the lateral and anterior spinothalamic tracts, which carry sensations for pain, temperature, and crude touch; and the posterior tracts, which carry sensations for fine touch, position, and vibration. The pyramidal tracts are descending tracts consisting of fibers that originate in the motor cortex of the brain and travel to the brainstem and then down the spinal cord. They mediate voluntary purposeful movements and stimulate certain muscular actions while inhibiting others. They carry fibers that inhibit muscle tone. The extrapyramidal tracts include the pathways between the cerebral cortex, basal ganglia, brainstem, and spinal cord outside the pyramidal tract. They maintain muscle tone and gross body movements.

UPPER AND LOWER MOTOR NEURONS Upper motor neurons carry impulses from the cerebral cortex to the anterior gray column of the spinal cord. Damage to upper motor neurons results in increased muscle tone, decreased muscle strength, decreased coordination, and hyperactive reflexes. Lower motor neurons begin in the anterior gray column of the spinal cord and end in the muscle. Damage to lower motor neurons results in decreased muscle tone, muscle atrophy, fasciculations, and loss of reflexes.

The Peripheral Nervous System

The peripheral nervous system (PNS) links the CNS with the rest of the body. It is responsible for receiving and transmitting information from and about the external environment. The PNS consists of nerves, ganglia (groups of nerve cells), and sensory receptors located outside—or peripheral to—the brain and spinal cord. The PNS is divided into a sensory (afferent) division and a motor (efferent) division. Most nerves of the PNS contain fibers for both divisions and all are classified regionally as either spinal nerves or cranial nerves.

SPINAL NERVES

The 31 pairs of spinal nerves (refer to Figure 41–6) are named by their location: cervical 8 pairs, thoracic 12 pairs, lumbar 5 pairs, sacral 5 pairs, and coccygeal 1 pair. Spinal nerves exit the vertebral column through intervertebral foramina to travel to the body regions they serve. The spinal cord does not reach the end of the vertebral column; as a result, the lumbar and sacral nerve roots travel inferiorly through the vertebral canal for some distance before exiting the vertebral column through their associated intervertebral foramina. This collection of descending nerve roots is called the *cauda equina*.

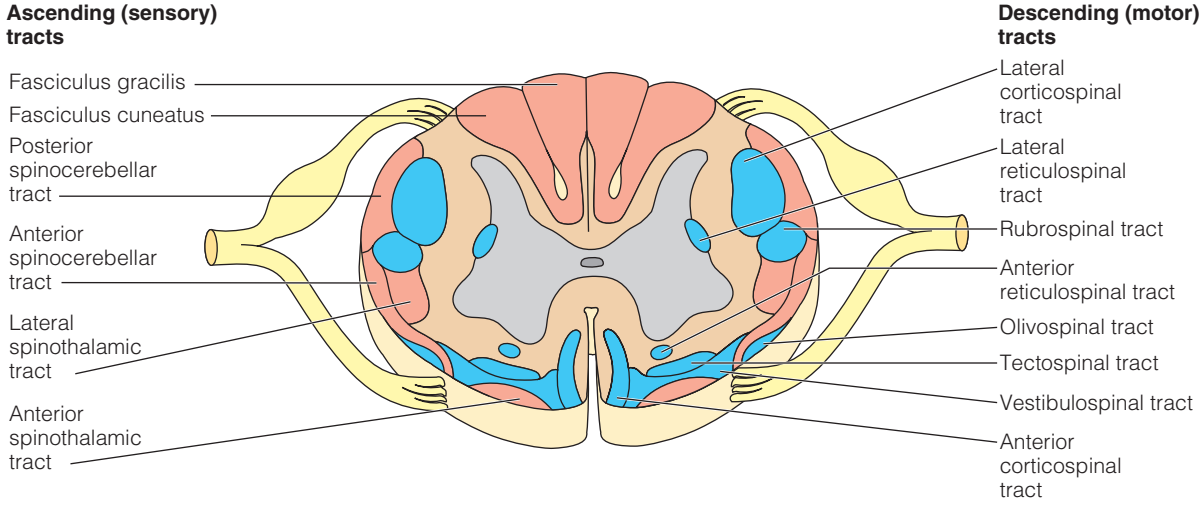

Figure 41–7 ■ Ascending and descending tracts of the spinal cord.

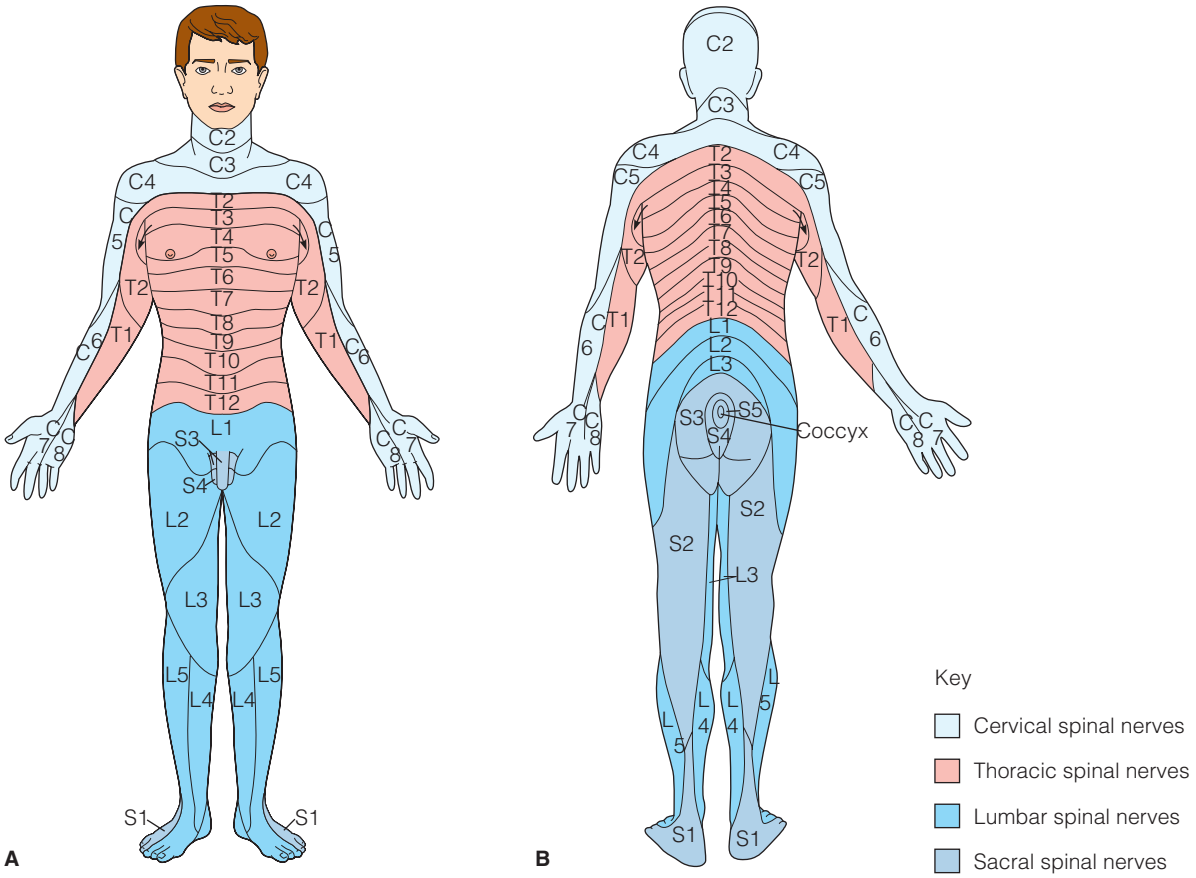

Figure 41–8 ■ A, Anterior and B, posterior dermatomes of the body.

Each spinal nerve contains both sensory and motor fibers. The sensory fibers are located in the dorsal root, and their cell bodies are located within the dorsal root ganglion. The motor fibers are located in the ventral root, and their cell bodies are located within the spinal cord. The dorsal and ventral roots merge outside the vertebral canal just past the dorsal root ganglion, forming a spinal nerve. Each spinal nerve further divides into branches called *rami*. An area of skin innervated by cutaneous branches of a single spinal nerve is called a *dermatome*. The dorsal roots of the spinal nerves carry sensations from these specific dermatomes. Dermatomes provide anatomic landmarks that are useful for locating neurologic lesions (Figure 41–8 ■).

CRANIAL NERVES

Twelve pairs of cranial nerves (CNs) originate in the forebrain and brainstem (Figure 41–9 ■). The vagus nerve extends into the ventral body cavity, but the other 11 pairs innervate only head and neck regions. Although most are mixed nerves, three pairs (olfactory, optic, and acoustic) are solely sensory. The cranial nerves and their related functions are listed in Table 41–4.

REFLEXES

A reflex is a rapid, involuntary, predictable motor response to a stimulus. Reflexes are categorized as either somatic or autonomic. Somatic reflexes result in skeletal muscle contraction. Autonomic reflexes activate cardiac muscle, smooth muscle, and glands. A reflex occurs over a pathway called a *reflex arc*.

The essential components of a reflex arc are a receptor, a sensory neuron to carry afferent impulses to the CNS, an integration center in the spinal cord or brain, a motor neuron to carry efferent impulses, and an effector (the tissue that responds by contracting or secreting) (Figure 41–10 ■).

Somatic reflexes mediated by the spinal cord are called *spinal reflexes*. Many spinal reflexes occur without impulses traveling to and from the brain, with the cord serving as the integration center. Deep tendon reflexes (DTRs) occur in response to muscle contraction and cause muscle relaxation and lengthening. DTRs depend on intact sensory and motor nerve roots, functional synapses in the spinal cord, a functional neuromuscular junction, and a competent muscle. Thus, an abnormal DTR could indicate a variety of health problems, including a lesion of a spinal nerve. Flexor, or withdrawal, reflexes are caused by actual or perceived painful stimuli and result in withdrawal of the part of the body that is threatened. Superficial responses result from gentle stimulation of the skin. These responses depend on functional upper motor pathways and an intact reflex arc.

The Autonomic Nervous System

The autonomic nervous system (ANS) is a division of the PNS that regulates the internal environment of the body. It is also called the *general visceral motor system*, because it consists of motor neurons that innervate the body's viscera. Whereas skeletal muscle activity and reflexes are regulated by a division of the PNS called the *somatic nervous system*, the ANS regulates the activity of cardiac muscle, smooth muscle, and glands. The ANS is primarily controlled by the reticular formation in the brainstem. Stimulation of centers in the medulla initiates reflexes that regulate cardiac rate, blood vessel diameter, and gastrointestinal function.

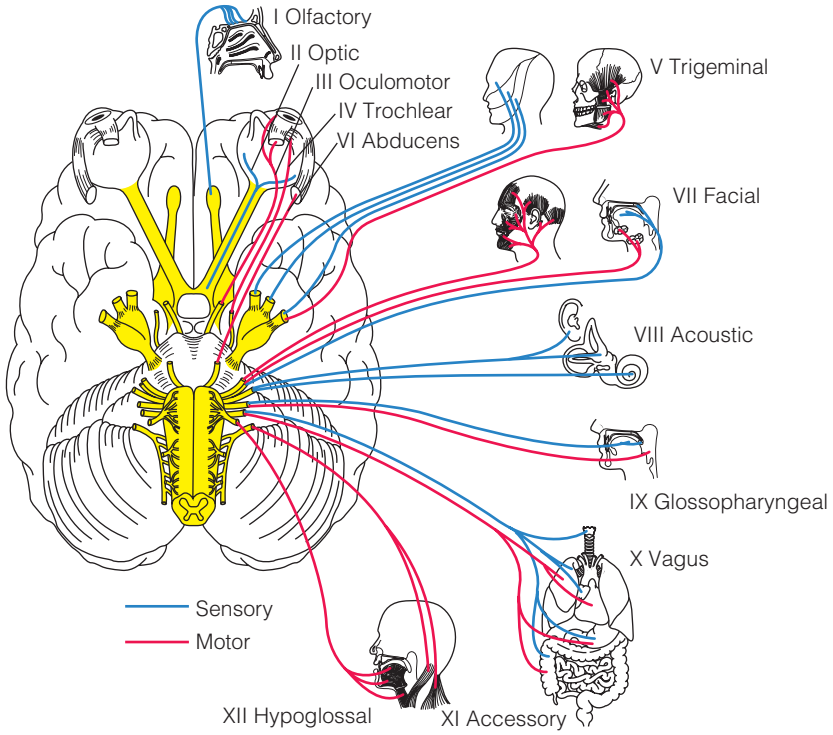

Figure 41–9 ■ Cranial nerves.

The ANS has sympathetic and parasympathetic divisions. Although fibers from both divisions affect the same structures, the actions of the two divisions are opposite in effect, and they serve to counterbalance each other. The major neurotransmitters for impulse transmission in the ANS are norepinephrine and acetylcholine.

SYMPATHETIC DIVISION

Norepinephrine is the primary neurotransmitter of the sympathetic division. The sympathetic division of the ANS prepares the body to handle situations that are perceived as harmful or stressful and to participate in strenuous activity. Cell bodies for this division arise in the lateral horns of the spinal cord in the area from T_1 through L_2. The fibers separate after leaving the cord and form a chain of ganglia that extends from the neck to the pelvis. Long fibers then extend to the organs that are supplied by the sympathetic division. Stimulation of the sympathetic division can exert the following effects on target organs or tissues:

- Dilated pupils
- Inhibited secretions
- Copious production of sweat (**diaphoresis**)
- Increased rate and force of heartbeat
- Vasodilation of the coronary arteries
- Dilation of the bronchioles
- Decreased digestion
- Increased release of glucose by the liver
- Decreased urine output
- Vasoconstriction of arteries
- Vasoconstriction of abdominal and skin blood vessels
- Increased blood clotting
- Increased metabolic rate
- Increased mental alertness.

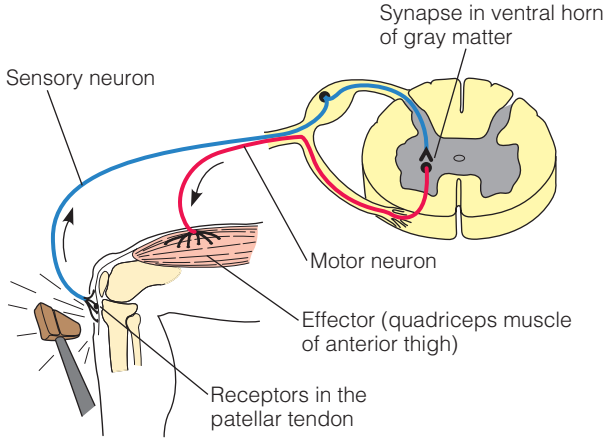

Figure 41–10 ■ A typical reflex arc of a spinal nerve. In the two-neuron reflex arc, the stimulus is transferred from the sensory neuron directly to the motor neuron at the point of synapse in the spinal cord.

PARASYMPATHETIC DIVISION

Acetylcholine is the primary neurotransmitter of the parasympathetic division. The parasympathetic division of the ANS operates during nonstressful situations. Cell bodies for this division are located in the brainstem (for the cranial nerves) and in the lateral gray matter of S_2 through S_4. Other than the fibers supplying cranial nerves III, VII, IX, and X, the fibers are carried by the vagus nerve to body tissues, thoracic organs, and visceral organs. Stimulation of the parasympathetic division of the ANS produces the following effects:

- Constriction of pupils
- Stimulation of glandular secretions
- Decreased heart rate

TABLE 41–4 Cranial Nerves

Name	Function
I Olfactory	Sense of smell
II Optic	Vision
III Oculomotor	Eyeball movement Raising of upper eyelid Constriction of pupil Proprioception
IV Trochlear	Eyeball movement
V Trigeminal	Sensation of the upper scalp, upper eyelid, nose, nasal cavity, cornea, and lacrimal gland Sensation of the palate, upper teeth, cheek, top lip, lower eyelid, and scalp Sensation of the tongue, lower teeth, chin, and temporal scalp Chewing
VI Abducens	Lateral movement of the eyeball
VII Facial	Movement of facial muscles Secretions of lacrimal, nasal, submandibular, and sublingual glands Sensation of taste
VIII Acoustic	Sense of equilibrium Sense of hearing
IX Glossopharyngeal	Swallowing Gag reflex Secretions of parotid salivary gland Sense of taste Touch, pressure, and pain from pharynx and posterior tongue Pressure from carotid arteries Receptors to regulate blood pressure
X Vagus	Swallowing Regulation of cardiac rate Regulation of respirations Digestion Sensation from thoracic and abdominal organs Proprioception Sense of taste
XI Accessory	Movement of head and neck Proprioception
XII Hypoglossal	Movement of tongue for speech and swallowing

- Vasoconstriction of coronary arteries
- Constriction of the bronchioles
- Increased peristalsis and secretion of gastrointestinal fluid.

ASSESSING NEUROLOGIC FUNCTION

Structures and functions of the neurologic system are assessed by findings from diagnostic tests, a health assessment interview to collect subjective data, and a physical assessment to collect objective data.

Diagnostic Tests

The results of diagnostic tests of neurologic structure and function are used to support the diagnosis of a specific injury or disease, to provide information to identify or modify the appropriate medications or therapy used to treat the disease, and to help nurses monitor the patient's responses to treatment and nursing care interventions. Diagnostic tests to assess the structures and functions of the neurologic system are described in the table beginning on page 1340. More information is included in the discussion of specific injuries or diseases in Chapters 42, 43, and 44.

Regardless of the type of diagnostic test, the nurse is responsible for explaining the procedure and any special preparation needed, assessing for medication use that may affect the outcome of the tests, ensuring the consent form is signed (if necessary), supporting the patient during the examination as necessary, documenting the procedures as appropriate, and monitoring the results of the tests. The nurse is also responsible for postprocedure care and patient teaching for self-care at home.

Genetic Considerations

When conducting a health assessment interview and a physical assessment, it is important to consider genetic influences on the health of the adult. Several neurologic diseases that directly affect the nervous system have a genetic component; some are due to mutation of a single gene, and others have a more complex method of inheritance. During the health assessment interview, ask about family members with health problems affecting neurologic structure or function. In addition, ask about a family history of problems with muscular coordination, Parkinson's disease, narcolepsy, tremor, seizures, Alzheimer's disease, multiple sclerosis, or amyotrophic lateral sclerosis (ALS). During the physical assessment, assess for any manifestations that might indicate a genetic disorder (see the accompanying box). If data are found to indicate genetic risk factors or alterations, ask about genetic testing and refer for appropriate genetic counseling and evaluation. Chapter 8 provides further information about genetics in medical-surgical nursing.

Health Assessment Interview

A health assessment to determine problems with neurologic structure and/or function may be conducted during a health screening, may focus on a chief complaint (such as headaches), or may be part of a total health assessment. Health problems affecting the neurologic system may manifest as problems with musculoskeletal function and an assessment of both systems may be necessary. If the patient's level of consciousness is altered, the nurse may need to rely on family members for information. The patient's level of consciousness may be assessed by using the Glasgow Coma Scale (Table 41–5 later in this chapter).

If the patient has problems with neurologic structure or function, analyze its onset, characteristics, course, severity, precipitating and relieving factors, and any associated symptoms, noting the time and circumstances. For example, ask the patient the following:

- Describe the location and intensity of the pain you have experienced in your left leg. Is it made worse by coughing, sneezing, or walking?
- When did you first notice that you were having numbness in your fingers?
- Describe the difficulty you have when you try to walk.

Questions about present health status include information about numbness, tingling sensations, tremors, problems with coordination or balance, or loss of movement in any part of the body. Ask

DIAGNOSTIC TESTS of the Neurologic System

Name of Test	Purpose and Description	Related Nursing Interventions
Carotid duplex study Transcranial Doppler study	A carotid duplex study evaluates the velocity of blood flow through the carotid arteries and identifies occlusive disease. Sound waves produced by the blood flow are used to produce an image. A transcranial Doppler study follows the same procedure, but is used to evaluate intracranial blood vessels.	No special preparation is needed.
Cerebral angiogram	A cerebral angiogram is the definitive diagnostic procedure for aneurysms, arteriovenous malformations, blood vessel patency and stenosis, thrombosis, vasospasm, aneurysm, and space-occupying lesions (such as tumors or hematomas). It may be performed either as part of a surgical procedure or with local anesthesia. In radiology, a contrast medium is injected and films are taken at various time intervals.	Tell the patient not to eat or drink fluids 8 hours prior to the procedure. Assess for history of allergy to iodine, seafood, or previous contrast dye; if present, notify physician. After the procedure, vital signs are monitored, and fluids are forced to clear the contrast medium. Bed rest is maintained for 12–24 h. Monitor for manifestations of a transient ischemic attack (weakness or numbness in an extremity, confusion, slurred speech) and delayed allergic reaction to the contrast dye (itching, rash, tachycardia, dyspnea, hypotension).
Computed tomography (CT) scan—brain, spine	A CT scan of the brain is used to identify intracerebral hemorrhage, tumors, cysts, aneurysms, edema, ischemia, atrophy, and tissue necrosis. It may also be used to evaluate a shift in intracranial contents and differentiate type of stroke. CT scans of the spine are primarily done to assess bony abnormalities. The tests involve computer assisted x-rays of several levels of cross sections of the body part being examined; they may be done with or without contrast.	If a contrast dye is used, tell the patient to not eat or drink liquids for 8 hours prior to the test, or if the test is in the afternoon to not eat or drink fluids after a liquid breakfast. Assess medications; if an iodinated contrast is used, oral hypoglycemic agents are contraindicated. Ask the patient to remove hairpins, clips, jewelry, and dentures if contrast dye is used. Explain to the patient that when a brain scan is done, the head is positioned in a cradle and a strap is applied snugly around the head during the test (the test lasts from 5–10 min). After a scan with contrast, monitor for and report signs of a delayed allergic reaction, such as rash, itching, headache, or vomiting.
Electroencephalogram (EEG) Magnetoencephalogram (MEG)	An EEG is used to measure the electrical activity of the brain to diagnose brain disease and brain death. Electrodes are applied to the scalp with skin clips and a graphic picture is obtained (similar to an ECG of the heart). An MEG detects magnetic fields generated by activity of neurons and can identify the area of the brain affected by a stroke, brain disorders or trauma, or seizures.	Assess medications and tell the patient not to take prescribed medications or liquids that may stimulate or depress brain waves as ordered (usually for 24–48 h) before the test. These include anticonvulsants, tranquilizers, depressants, and caffeine-containing foods and beverages (e.g., coffee, tea, colas, alcohol, and chocolate). Instruct the patient to wash his or her hair the night before the procedure, but to not use oil or hair spray on the hair. After the test, acetone may be used to remove the paste from the patient's head.
Electromyogram (EMG)	An EMG measures the electrical activity of skeletal muscles at rest and during contraction; and so is useful in diagnosing neuromuscular diseases. Needle electrodes are inserted into skeletal muscle (as on the legs) and electrical activity can be heard, viewed on an oscilloscope, and recorded on graph paper. Normally, there is no electrical activity at rest.	Tell patient not to drink fluids containing caffeine or to smoke for 3 h before the test. Assess medications: If approved by healthcare provider, patient should not take medications such as muscle relaxants, anticholinergics, and cholinergics. If serum enzymes are ordered (such as SGOT, CPK, or LDH), the specimen should be drawn before an EMG or 5–10 days after the test.
Evoked potentials	This test measures nerve conduction along pathways to evaluate the evoked potential of muscle contractions. It is used to diagnose and evaluate neuromuscular diseases and identify nerve damage. Transcutaneous or percutaneous electrodes are applied to the skin and provide recordings.	No special preparation is needed.

DIAGNOSTIC TESTS of the Neurologic System (*continued*)

Name of Test	Purpose and Description	Related Nursing Interventions
Lumbar puncture (LP)	An LP is used to measure CSF pressure and to obtain a sample of CSF to use in diagnosis of multiple sclerosis, or increased intracranial pressure from meningitis, subarachnoid hemorrhage, brain tumor, brain abscess, encephalitis, and viral infections. A needle is inserted in L_3–L_4 or L_4–L_5 and fluid is aspirated.	Ask the patient to void. Assess and document vital signs. Collect sterile lumbar puncture tray, an antiseptic solution, a local anesthetic, sterile gloves, and tape. Label the test tubes 1, 2, and 3. Place the patient on his or her side in the fetal position with back bowed, head flexed on the chest, and the knees drawn up to the abdomen. Assist the healthcare provider with the procedure. Following the LP, assess and document vital signs at specified intervals. Monitor for changes in neurologic status (fever, hypertension, irritability, lower extremity numbness or tingling, nonreactive pupils). Administer ordered analgesic for headache. Instruct the patient to lie flat in bed in the prone or supine position for 4–8 h. Monitor the puncture site for leakage of cerebrospinal fluid or hematoma formation. Encourage increased intake of fluids (up to 3000 mL in 24 h).
Magnetic resonance imaging (MRI) Functional MRI Magnetic resonance angiography (MRA) Magnetic resonance spectroscopy (MRS)	An MRI is done to identify and monitor conditions of the brain and spinal cord, including stroke, tumors, trauma, seizures, and multiple sclerosis. It uses magnetic energy to provide images, and a gadolinium contrast media may be used to enhance visualization. An MRI is more sensitive than a CT scan to the subtle vascular changes seen in Alzheimer's disease. A functional MRI is done to evaluate metabolic or blood flow responses of the brain to specific tasks, such as activity and rest. An MRA can provide information about the blood vessels of the brain and identify vascular lesions. It uses the signals from blood vessels to reconstruct only those vessels with blood flow. An MRS uses a scanner to confirm the presence of Alzheimer's disease, determine the extent of head injury from trauma or stroke, and identify the causes of coma.	Assess for any metallic implants (such as clips on brain aneurysms, pacemaker, body piercing, tattoos, and shrapnel). If present, notify physician. Remove transdermal medication patches (both OTC and prescribed) unless otherwise ordered. Replace the patch following the procedure. Tell the patient to inform the staff about the patch when making the appointment and when completing the admission information. Ask if patient is pregnant; if so, the test is not performed. Ask about claustrophobia; if a problem exists, request patient to ask the referring physician for a relaxing medication prior to the MRI. If the patient is very claustrophobic, obese, or confused, an open MRI may be used.
Myelogram	A myelogram is used to identify lesions of the spinal cord, such as tumors or a herniated intervertebral disk. A lumbar puncture is done, a contrast medium is injected into the subarachnoid space, and x-rays are taken.	Instruct the patient to drink additional fluids the day before the test, and then to stop all food and fluids for 4 h prior to the test. Assess medications; antipsychotics, antidepressants, and anticoagulants may be withheld for several days before the procedure, depending on physician orders. Tell the patient not to smoke the day before the test. Assess for history of allergy to iodine, seafood, or previous contrast dye; if present, notify physician. Ask the patient to void immediately before the test. After the procedure, position the patient in a supine position with the head slightly elevated for several hours. Encourage oral fluid intake. Monitor for and notify the physician of a fever, excessive nausea and vomiting, a severe headache, or a stiff neck. Take and record vital signs as specified. Monitor lumbar insertion site for CSF leakage or hematoma. Monitor neurologic status and ensure patient voids within 8 h. Encourage increased oral fluids. Administer prescribed analgesic for headache.
Positron emission tomography (PET) Single-photon emission computed tomography (SPECT)	When used to study the brain, a PET can assess normal brain function and cerebral blood flow and volume; it can differentiate different types of dementia; and it can identify stages of brain tumors. A substance containing a radionuclide is given by gas or by injection and cross sections of tissue are detected and displayed by computer. A SPECT is similar to a PET, but uses different substances. It can be used to diagnose strokes, brain tumors, and seizure disorders.	Tell the patient not to drink coffee or alcohol or smoke for 24 h before the test. Assess glucose levels pretest. Post-test, encourage oral fluids to facilitate excretion of the radioactive substance.
X-rays of skull and spine	Standard x-rays of the skull and spine are done to identify fractures, displacement of vertebrae, spinal curves, and tissue displacement (as by tumors).	No special preparation is needed.

GENETIC CONSIDERATIONS

Examples of Neurologic Disorders

- One risk factor for Parkinson's disease is a positive family history of the disease. This neurodegenerative disease is manifested by tremor, muscular stiffness, and difficulty with balance and walking.
- Although multiple sclerosis (MS) is not directly inherited, genetic factors may influence a predisposition to MS within families as well as the severity and course of the disease.
- Narcolepsy, a sleep disorder, has a familial connection.
- Huntington's disease (HD) is an inherited degenerative disorder that results in degeneration of neurons in certain areas of the brain. A child of a parent with HD has a 50–50 chance of inheriting the gene for the disease.
- Friedreich's ataxia is a rare inherited disease that causes a progressive loss of voluntary muscle coordination and enlargement of the heart.
- Essential tremor, as a primary disorder, affects as many as 3 to 4 million people. In more than half of cases, essential tremor is inherited as an autosomal dominant trait, meaning that children of an individual with the disease have a 50% chance of also developing the disorder.
- Epilepsy is one of the most common neurologic diseases, characterized by abnormal cell firing in the brain that causes recurring seizures. A genetic predisposition is found in many cases.
- Charcot-Marie-Tooth syndrome is the most common inherited peripheral neuropathy in the world, characterized by a slowly progressive degeneration of the muscles of the foot, lower leg, hand, and forearm.
- Alzheimer's disease (AD) is a leading cause of death in adults, increasing in incidence with age and more common in women. AD tends to run in families, with mutations in four genes believed to be responsible for the disease.
- Amyotrophic lateral sclerosis (ALS) is a neurologic disease that causes progressive degeneration of motor neurons in the brain and spinal cord, resulting in paralysis and death. Chromosome abnormalities have been linked to familial ALS.
- Although Tay-Sachs disease is most often considered a disease of children, there is a chronic adult form that causes neuron dysfunction and psychosis.

the patient about difficulty with speaking, seeing, hearing, tasting, or detecting odors. In addition, elicit information about memory, feeling state (such as anxiety or depression), recent changes in sleep patterns, ability to perform self-care and activities of daily living, sexual activity, and weight. If the patient is taking prescribed medications, over-the-counter medications, or herbal supplements, ask about the type and purpose, as well as the frequency and duration of use.

Ask about any past history of seizures, fainting, dizziness, headaches, and any trauma, tumors, or surgery of the brain, spinal cord, or nerves. Discuss illnesses that may cause neurologic manifestations, including cardiac disease, strokes, pernicious anemia, sinus infections, liver disease, and/or renal failure. Also ask the patient about family history of neurologic health problems, diabetes mellitus, hypertension, seizures, or mental health problems.

Question the patient about occupational hazards, such as exposure to toxic chemicals or materials, use of protective headgear, and the amount of time spent performing repetitive motions (e.g., data entry and assembly). Ask questions about self-care to assess the patient's diet and use of tobacco, drugs, or alcohol, and ask whether the patient wears a helmet when riding a bike or motorcycle or participating in contact sports or if seat belts are used when driving a vehicle.

Physical Assessment

Physical assessment begins when the nurse first meets the patient and makes an overall evaluation of the patient's mental and physical status. The mental status examination is conducted with both the nurse and the patient seated. The rest of the neurologic examination may be performed with the patient either sitting or standing. A thorough neurologic examination is discussed here, but in most instances, the nurse will conduct a focused assessment specific to the patient's health status.

The neurologic system is assessed through inspection, palpation, and percussion (with a reflex hammer). When conducting the mental status and cognitive portions of the examination, be aware that fatigue or illness may alter findings. Provide rest periods for the patient as needed. When interpreting findings, consider the patient's age, educational background, and cultural orientation. Normal age-related findings for the older adult are summarized in the Nursing Care of the Older Adult box.

NURSING CARE OF THE OLDER ADULT

Age-Related Changes in the Neurologic System

Age-related Change	Significance
• ↓ number of brain cells, cerebral blood flow, and metabolism. • Slower nerve conduction velocity.	Delayed response to multiple stimuli and slower reflexes; may need additional time to process and respond to verbal stimuli.
• Slower retrieval of information from long-term memory.	There is some age-related forgetfulness, which can be improved by using memory aids such as making lists.
• Slower response to changes in balance.	May contribute to increased risk for falls.
• May exhibit less readiness to learn and depend on prior experiences to solve problems. • Is more easily distracted and has a decrease in the ability to maintain attention.	Learning new skills or knowledge is improved when they are related to previously learned information and when limits are set on times for learning (for example, no more than 30 minutes at one time).

The assessment should take place in a private, comfortable setting. Ask the patient to remove outer clothing, shoes, and stockings. Provide a gown for the patient to wear. It is important to explain that the neurologic examination is lengthy and may consist of questions and requests that seem strange to the patient. Explain the rationale for each part of the examination.

A brief version of this physical assessment, often referred to as a *neuro check*, may be performed in a shorter time period when a patient requires frequent ongoing assessments of neurologic status (Box 41–1).

BOX 41–1 Abbreviated Neurologic Assessment (Neuro Check)

1. Assess level of consciousness (response to auditory and/or tactile stimulus).
2. Obtain vital signs (BP, P, R).
3. Check pupillary response to light.
4. Assess strength of hand grip and movement of extremities bilaterally.
5. Determine ability to sense touch/pain in extremities.

Neurologic Assessments

Technique/Normal Findings	Abnormal Findings
Mental Status Assessment	
Assess appearance, including dress, hygiene, grooming, gait, and posture. *The patient should be appropriately dressed and clean, with normal gait and posture.*	• Unilateral neglect (inattention to one side of body) may occur with some strokes. Poor hygiene and grooming may be seen in patients with dementing disorders. • Abnormal gait and posture may be seen in transient ischemic attacks (TIAs), strokes, and Parkinson's disease.
Assess behavior, including actions and affect, content and quality of speech, and level of consciousness (LOC). Use the Glasgow Coma Scale (see Table 41–5) to document findings. *A score of 15 on the Glasgow Coma Scale indicates the patient is alert and oriented.*	• Emotional swings or changes in personality may be observed in patients who have had a stroke. • The face appears masklike (very little expressive movement of facial muscles) in patients with Parkinson's disease. • Apathy is seen in dementing disorders. • **Aphasia** (defective or absent language function) may occur in TIAs and strokes. Aphasias are seen with damage to the left cerebral cortex. Aphasias are more often seen with strokes of the left hemisphere than the right hemisphere. • **Dysphonia** (change in the tone of the voice) is common in strokes. Dysphonia is seen with paralysis of the vocal cords (cranial nerve X). • **Dysarthria** (difficulty speaking) is seen with lesions of upper and lower motor neurons, the cerebellum, and the extrapyramidal tract. • Damage to the brainstem and/or cerebral cortex may alter LOC. • Drowsiness and decreased LOC may be associated with brain trauma, infections, TIAs, strokes, and brain tumors. • Level of consciousness, ranging from confusion to coma, is usually altered with a stroke.

TABLE 41–5 Glasgow Coma Scale

Assessment	Response	Score
Eyes Open (Record *C* if eyes are closed by swelling.)	Spontaneously	4
	To speech	3
	To pain	2
	No response	1
Best Motor Response (Record best upper arm response.)	Obeys commands	6
	Localizes pain	5
	Flexion-withdrawal	4
	Abnormal flexion	3
	Abnormal extension	2
	No response	1
Best Verbal Response (Record *T* if an endotracheal or tracheostomy tube is in place.)	Oriented	5
	Confused	4
	Inappropriate words	3
	Incomprehensible sounds	2
	No response	1
Total Score:		*

Note: *A higher score indicates a higher level of functioning.

(*continued*)

Neurologic Assessments (*continued*)

Technique/Normal Findings	Abnormal Findings
Assess cognitive function. Note orientation to time, place, and person. Note attention span and recent and remote memory. Ask the patient to do the following: **1.** Repeat five to seven numbers. **2.** Recall three items after 5 min. **3.** Recall his or her address, breakfast, or birthday. Assess thought processes (both content and perceptions) by noting responses to questions. Note ability to understand what is said and to express thoughts. Note ability to make logical and safe judgments. *The patient should be oriented to time, place, and person; demonstrate attention and ability to remember recent and past events; respond appropriately to questions; and be able to make judgments.*	• Disorientation to time and place may occur in patients with stroke of the right cerebral hemisphere. • Memory deficits are often seen in patients with a stroke. • Perceptual deficits may be seen in strokes. These same deficits may occur following brain trauma and in dementing disorders. • Impaired cognition is often noted with strokes, cerebral trauma, and brain tumors.
Cranial Nerve Assessments	
Test CN I (olfactory). Note patient's ability to smell scents (e.g., soap, coffee) with each nostril. This test is usually done only if a problem with the ability to smell is reported. *Sense of smell should be equal in both nostrils.*	• **Anosmia** (an inability to smell) may be seen with lesions of the frontal lobe and may also occur with impaired blood flow to the middle cerebral artery.
Test CN II (optic). Assess vision in each eye with Snellen chart (see Chapter 45 for guidelines). *Based on previous ability to see and use of visual aids, patient should be able to see with both eyes.*	• Blindness in one eye may be seen with strokes or with TIAs. Impaired vision or blindness in one side of both eyes (homonymous hemianopia) is associated with stroke. • Impaired vision may be seen with strokes and brain tumors. • Blindness or double vision may be noted with stroke and TIAs. • Diplopia (double vision) may occur in multiple sclerosis.
Test CNs III, IV, and VI (oculomotor, trochlear, and abducens). Assess extraocular movements by asking the patient to follow your finger as you write an *H* in the air (see Chapter 45). Assess PERRL ("pupils equally round and reactive to light") by covering one eye at a time and shining a bright light directly into the uncovered eye (use a penlight or the ophthalmoscope). See Chapter 45 for detailed assessment guidelines. *Extraocular movements should be present bilaterally, and pupils should be equally round and reactive to light.*	• **Nystagmus** (involuntary eye movement) may be seen with strokes. • Constricted pupils are associated with impaired blood flow from a stroke, or medication/drug use.
Assess for **ptosis** (drooping eyelids). *Eyelids should not droop.*	• Ptosis (also called *Horner syndrome*) occurs with strokes, myasthenia gravis, and palsy of CN III.

Neurologic Assessments (*continued*)

Technique/Normal Findings	Abnormal Findings
Test CN V (trigeminal). Assess ability to feel light, dull, and sharp sensations on the face. With the patient's eyes closed, check whether sensation is the same on both sides of the face. Stroke the cheek with a wisp of cotton for light touch, with a closed safety pin for dull touch, and with a tongue depressor for sharp touch. If the sharp point of a safety pin is used to assess sharp touch, be sure to avoid scratching the surface of the skin, and discard the pin after it is used. Assess the corneal reflex by touching the corneal surface with a wisp of cotton. The reflex may be absent or decreased in patients who wear contact lenses. *Ability to feel light, dull, and sharp sensations should be intact. Normally the patient blinks.*	• Changes in facial sensations are noted with impaired blood flow to the carotid artery. • Decreased sensations to the face and cornea on the same side of the body, as well as numbness of the lip and mouth, occur with strokes. • Loss of facial sensation or contraction of the masseter and temporal muscles is seen with lesions of CN V. • Severe facial pain is seen with trigeminal neuralgia (tic douloureux). • The corneal reflex may be impaired with lesions of CN V or VII.
Test CN VII (facial). Assess ability to taste sweet, sour, and salt on the anterior two-thirds of the tongue by asking the patient to stick out the tongue and applying a salty, sweet, or sour substance. Assess ability to frown, show teeth, blow out cheeks, raise eyebrows, smile, and close eyes tightly. *Patient should be able to taste sweet, sour, and salt substances. Should be able to frown, show teeth, blow out cheeks, raise eyebrows, smile, and close eyes tightly. Muscle movement should be equal bilaterally.*	• Loss of ability to taste may occur with brain tumors or with nerve impairment. • Asymmetry or decreased movement of facial muscles is noted with lesions of the upper and lower motor neurons. • Paralysis of the lower motor neurons from injury to CN VII results in the inability to close eyes, a flat nasolabial fold, paralysis of lower face, and inability to wrinkle forehead. • Paralysis of the upper motor neurons from a stroke results in weakness of eyelids and paralysis of lower face. • Pain, paralysis, and sagging of facial muscles are seen on the affected side in Bell's palsy.
Test CN VIII (acoustic). Assess ability to hear the ticking of a watch and whispered and spoken words (see Chapter 45). *Patient should be able to hear with both ears.*	• Decreased hearing or deafness may occur with strokes and/or tumors of CN VIII.
Test CN IX and X (glossopharyngeal and vagus). If gag reflex is intact, observe patient swallowing a small drink of water. Observe for a symmetrical rise of the soft palate and uvula as the patient says "ah." Assess gag reflex by touching back of patient's throat with tongue depressor. *Patient should have intact gag reflex*. Assess ability to taste salty, sweet, and sour substances on the posterior third of the tongue (see previous description). *Patient should be able to swallow without difficulty, have symmetrical rise of the soft palate, and taste appropriately.*	• **Dysphagia** (difficulty swallowing) is common with impaired blood flow to the brain. • Unilateral loss of the gag reflex occurs with lesions of CN IX and X.

(*continued*)

Neurologic Assessments (*continued*)

Technique/Normal Findings	Abnormal Findings
Test CN XI (spinal accessory). Assess the patient's ability to shrug the shoulders and turn head against resistance: Ask the patient to turn the head to one side against the resistance of your hand; ask the patient to shrug the shoulders while you exert downward pressure. Observe symmetry, strength, and size of muscles. *Patient should be able to shrug shoulders and turn head against resistance.*	• Muscle weakness is noted with lower motor neuron disease. Contralateral hemiparesis is seen with strokes.
Test CN XII (hypoglossal). Assess the patient's ability to stick out the tongue and move the tongue from side to side against resistance of a tongue depressor. *Patient should be able to stick out tongue, and move it from side to side against resistance.*	• Atrophy and **fasciculations** (twitches) of the tongue are seen in lower motor neuron disease. The tongue may deviate toward involved side of body.
Sensory Function Assessments	
Assess ability to feel touch. Touch both sides of various parts of the body (the chest, abdomen, arms, and legs) with one or more of the following: • Cotton wisp • Sharp object • Dull object • Vibrating tuning fork placed on bony prominences. *Patient can differentiate between soft and sharp, and can feel vibrations appropriately.*	• Decreased sensation of pain occurs with injury to the spinothalamic tract. • Decreased vibratory sensations are seen with injuries to the posterior column tract. • Transient numbness of face, arm, or hand is seen with TIAs. • Sensory loss on one side of the body is seen with lesions of higher pathways to the spinal cord. • Bilateral sensory loss is seen in polyneuropathy (a disease in which multiple peripheral nerves are affected, such as Guillain-Barré syndrome or diabetes mellitus). Sensations are impaired with strokes, brain tumors, and spinal cord trauma or compression.
Assess sense of position (**kinesthesia**). Move the patient's finger or big toe up or down. Ask the patient to describe the movement. *Patient can accurately describe position of finger or toe when moved up or down.*	• Lesions of the posterior column of the spinal cord may affect sense of position.
Assess ability to discriminate fine touch. Ask the patient to identify the following: 1. Object in hand, such as a coin or key (tests stereognosis) 2. Number written on hand (tests graphesthesia) (Figure 41–11 ■) 3. Two points of simultaneous pinpricks on the hand (tests two-point discrimination) (Figure 41–12 ■) 4. Where he or she is being touched (tests localization) 5. How many sensations are felt when touched simultaneously on both sides of the body (tests extinction). *Patient can identify and discriminate fine touch.*	• Inability to discriminate fine touch (stereognosis, graphesthesia, two points, point localization, and extinction) may occur with injury to the posterior columns or sensory cortex.

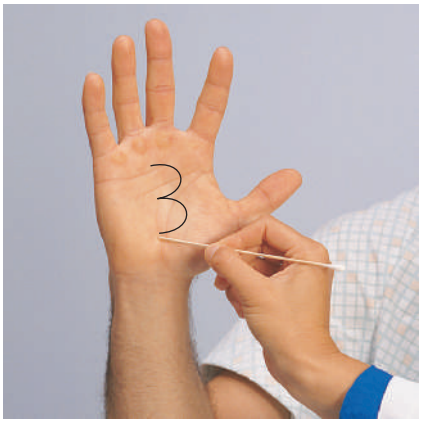

Figure 41–11 ■ Testing graphesthesia.

Figure 41–12 ■ Testing two-point discrimination.

Neurologic Assessments (*continued*)

Technique/Normal Findings	Abnormal Findings
Motor Function Assessments	
Assess bilateral symmetry and size of muscles. Assess for **tremors** (rhythmic movements) and fasciculations (irregular movements). Observe movements as patient is at rest (not making a purposeful movement) and with activity (making a purposeful movement, such as reaching for a glass of water). *Muscles are bilaterally symmetrical and of equal size. Tremors or fasciculations are not present.*	• Atrophy of muscles is seen with disease of the lower motor neurons. • Tremors that occur with activity are seen in multiple sclerosis and diseases of the cerebellar system. • Tremors that occur at rest and disappear with movement are common in Parkinson's disease. • Fasciculations occur in disease or trauma to the lower motor neurons, as a side effect of medications, in fever, in sodium deficiency, and in uremia.
Assess muscle tone. *Muscle tone is appropriate.*	• Muscle tone is decreased (**flaccidity**) in disease or trauma of the lower motor neurons and early stroke. • Muscle tone is increased (**spasticity**) in disease of the corticospinal motor tract. • Muscles are rigid in disease of the extrapyramidal motor tract. • Muscles move in small, regular jerky movements (cogwheel rigidity) in Parkinson's disease.
Assess bilateral muscle strength and movement. Ask the patient to do the following: **1.** Squeeze your hands. **2.** Push feet against the resistance of your hands. **3.** Raise both legs off the bed. *See Chapter 38 for a scale to grade muscle strength. Muscle strength and movement are bilaterally equal and strong.*	• Weakness of the arms, legs, or hands is often seen with TIAs. • Hemiplegia (paralysis of one-half of the body vertically) is noted with strokes. • Flaccid paralysis is noted with strokes. • Paralysis or decreased movement is seen in multiple sclerosis and myasthenia gravis. • There is total loss of motor function below the level of injury in complete spinal cord transection and in injuries to the anterior portion of the spinal cord. • Spasticity of muscles may occur as a result of incomplete spinal cord injuries.
Cerebellar Function Assessments	
Assess the gait. Ask the patient to walk normally, then in a heel-to-toe fashion, then on toes, and finally on heels. *Patient has appropriate gait, and can walk heel-to-toe, on toes, and on heels.* Perform Romberg's test: Ask the patient to stand with the feet together and eyes closed. (Stand close to patient to prevent falling). *There should be minimal swaying for up to 20 seconds.*	• **Ataxia** is a lack of coordination and a clumsiness of movements, with staggering, wide-based, and unbalanced gait. Ataxia is often seen with strokes and cerebellar tumors. Swaying and falling are seen in cerebellar ataxia. Inability to walk on toes, then heels, may indicate disease of the upper motor neurons. • Spastic hemiparesis is often associated with strokes or upper motor neuron disease. The patient walks with one leg stiffly dragging while the other leg circles out and forward. One arm is held flexed and close to the side. • Steppage gait is noted with disease of the lower motor neurons. The patient drags or lifts the foot high, then slaps the foot onto the floor. The patient cannot walk on the heels. • Sensory ataxia may be associated with polyneuropathy or damage to the posterior columns. The patient walks on the heels before bringing down the toes and the feet are held wide apart. Gait worsens with the eyes closed. • Parkinsonian gait is often seen in Parkinson's disease. The patient stoops over while walking and shuffles the feet. The arms are held close to the side. • A positive Romberg's test may be seen in cerebellar ataxia.
Assess coordination. Observe ability to pat knees, alternating front and back of hands and increasing speed. Observe ability to touch each finger of one hand to the thumb. Observe ability to touch the nose, then one of your fingers, then the nose again. Observe ability to run each heel down each shin, while in a supine position (Figure 41–13 ■). *Patient demonstrates coordinated movements.*	• Ataxic movements are apparent in cerebellar disease.

Figure 41–13 ■ Heel-to-shin test.

Reflex Assessments

A reflex hammer is used to strike the tendon of various reflex sites. To test deep tendon reflexes, ask the patient to lock the fingers of both hands together and then pull; this encourages relaxation and promotes reflexes of lower extremities. Superficial reflexes are assessed by lightly stroking the area with the end of a tongue depressor. Criteria often used to record reflexes are listed in the right-hand column.

0 = absent or no response
1 = hypoactive; weaker than normal (+)
2 = normal (++)
3 = stronger than normal (+++)
4 = hyperactive, sustained clonus (++++)
A score of 2 is considered normal.

Technique/Normal Findings	Abnormal Findings
Assess the patellar, biceps, brachioradialis, triceps, and Achilles deep tendon reflexes (Figure 41–14 ■). *Average responses are normal (neither hyperactive or no response).*	• Hyperactive reflexes are present with lesions of upper motor neurons. • Decreased reflexes are present with lower motor neuron involvement.
Assess for clonus by dorsiflexing the patient's foot. *No rhythmic oscillations are observed between dorsiflexion and plantar flexion.*	• Clonus, a hyperactive, rhythmic dorsiflexion and plantar flexion, is noted with upper motor neuron disease.

Figure 41–14 ■ Deep-tendon reflexes. A, Using reinforcement technique to test the patellar reflex. B, Biceps reflex. C, Brachioradialis reflex. D, Triceps reflex. E, Achilles reflex.

Assess the superficial abdominal and cremasteric reflexes. *Abdominal reflex:* Lightly stroke the abdomen with a tongue depressor from the side to the midline. *Normally the side of the abdomen being stroked will contract toward the umbilicus* (Figure 41–15 ■). *Cremasteric reflex:* Lightly stroke the inner thigh of the male patient with a tongue depressor. *Normally, the testicle on the side being stroked will rise.*	• Superficial reflexes may be absent with disease of the lower and upper motor neurons.

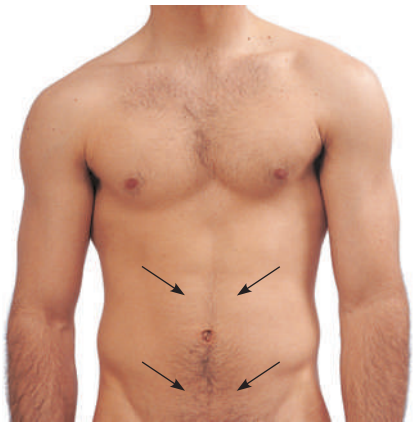

Figure 41–15 ■ Location of superficial abdominal reflexes.

Assess the Babinski (plantar response) reflex (Figure 41–16 ■). *Normally, the toes curl inward.*	• Dorsiflexion of the big toe and fanning of the other toes is seen with upper motor neuron disease of the pyramidal tract.

Figure 41–16 ■ Assessing Babinski reflex.

Special Neurologic Assessments

Technique/Normal Findings	Abnormal Findings
Assess for Brudzinski sign. With the patient supine, flex the head to the chest (Figure 41–17 ■). *There should be no pain, resistance, or flexion of the hips or knees.*	• Pain, resistance, and flexion of hips and knees occur with meningeal irritation. • Excessive pain and/or resistance occurs with meningeal irritation.
Assess for Kernig's sign. With the patient supine, flex the knees and hips, then straighten the knee (Figure 41–18 ■). *There should be no pain or resistance.*	• Resistance and pain may occur in a patient with multiple sclerosis.

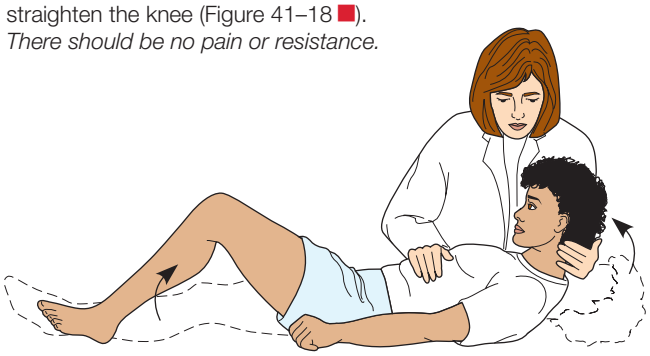

Figure 41–17 ■ Assessing Brudzinski sign.

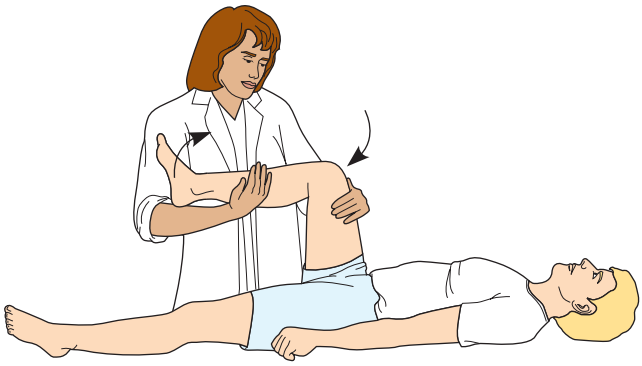

Figure 41–18 ■ Assessing Kernig's sign.

Assess for abnormal postures in patients who are unconscious. *There should be no abnormal posturing.*	Observe for **decorticate posturing**, in which the upper arms are close to the sides; the elbows, wrists, and fingers are flexed; the legs are extended with internal rotation; and the feet are plantar flexed (Figure 41–19 ■). • Decorticate posturing occurs with lesions of the corticospinal tracts. Observe for **decerebrate posturing**, in which the neck is extended, with the jaw clenched; the arms are pronated, extended, and close to the sides; the legs are extended straight out; and the feet are plantar flexed (Figure 41–20 ■). • Decerebrate posturing occurs with lesions of the midbrain, pons, or diencephalon.	

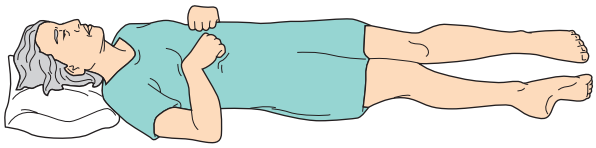

Figure 41–19 ■ Decorticate posturing.

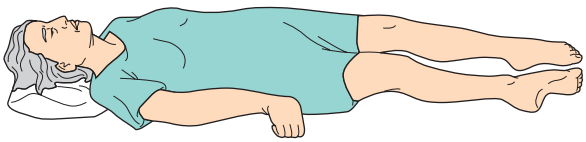

Figure 41–20 ■ Decerebrate posturing.

SAMPLE DOCUMENTATION

Assessment of the Neurologic System

45-year-old male having annual physical examination. No history of injury or infection involving the head or spine. No history of seizures, dizziness, headaches, memory loss, or problems with speaking or swallowing. Alert, oriented to person, place, and time. Able to follow directions, explain simple proverbs, and compare unlike objects. Cranial nerve testing results:

I = Identifies scents correctly.
II = Vision 40/20 in both eyes. Has full visual fields bilaterally.
III, IV, VI = Bilateral full extraocular movements, pupils are equally round, react to light and accommodation. No ptosis present in either eye.
V = Able to identify sharp, dull, and light touch to forehead, cheek, and chin. Corneal reflex present bilaterally, but decreased (wears contact lenses).
VII = Able to smile, frown, wrinkle forehead, show teeth, puff out cheek, purse lips, raise eyebrows, and close eyes against resistance.
VIII = Heard whispered words with both ears.
IX, X = Gag reflex present. Swallows without difficulty.
XI = Equal strength when shrugging both shoulders.
XII = Able to protrude tongue midline without tremors.

All extremities have full range of motion without tremors, tics, or weakness. No atrophy of muscles noted. Can perform repetitive alternating movements without difficulty. Gait is steady. Negative Romberg test. All reflexes are 2+ bilaterally. Abdominal reflex present. No Babinski's present.

CHAPTER HIGHLIGHTS

- **Correct structure and function of the nervous system are vital to enervate, regulate, and integrate all of the body's functions.**
- **Manifestations of dysfunction, injury, and disorders affecting the nervous system may be detected during a general health assessment as well as during a focused nervous system assessment.**

TEST YOURSELF NCLEX-RN® REVIEW

1. The nurse notes that a patient with a systemic illness is not demonstrating signs of neurologic involvement. Which physiologic mechanism should the nurse recall that protects the brain from harmful substances?
   1. blood–brain barrier
   2. structure of neurons
   3. large oxygen demand
   4. circulation of cerebrospinal fluid
2. The nurse is assessing a patient with damage to the lower motor neurons. Which findings should the nurse expect to assess in this patient? (Select all that apply.)
   1. loss of reflexes
   2. increased muscle tone
   3. decreased coordination
   4. decreased muscle strength
   5. muscle atrophy and fasciculations
3. The nurse is preparing a teaching session on the neurologic system for a group of nursing students. What should the nurse include about the purpose and function of cerebrospinal fluid? (Select all that apply.)
   1. Cushions the brain.
   2. Helps nourish the brain.
   3. Prevents glucose from entering brain cells.
   4. Protects the brain and spinal cord from trauma.
   5. Removes waste products of cellular metabolism.
4. Following a motorcycle crash, a patient is diagnosed with damage to the posterior spinal roots. What should the nurse expect to assess in this patient?
   1. flaccid paralysis of the legs
   2. loss of sensation to dull and sharp
   3. decreased sense of smell and taste
   4. changes in peripheral vision in both eyes

5. A patient reports narrowly missing having an automobile crash while merging onto the freeway while driving to see the healthcare provider for a routine appointment. Which division of the autonomic nervous system should the nurse recall as causing body responses to stress?
   1. adrenergic
   2. cholinergic
   3. sympathetic
   4. parasympathetic
6. The nurse is preparing to assess a patient's neurologic system. Which assessment technique is *not* a part of this physical assessment?
   1. palpation
   2. percussion
   3. inspection
   4. auscultation
7. The nurse is assessing a patient's cranial nerve function. What equipment should the nurse use to assess function of cranial nerve V, the trigeminal nerve?
   1. cotton ball and safety pin
   2. measuring tape and pencil
   3. scents such as coffee and vanilla
   4. stethoscope with bell and diaphragm
8. The nurse is determining which patients should have corneal reflex assessments completed during morning care. For which patients would assessing this reflex be appropriate? (Select all that apply.)
   1. an unconscious patient
   2. anyone over the age of 50
   3. a patient with a head injury
   4. a patient who wears contact lenses
   5. a patient with spinal cord trauma
9. The nurse is planning to assess a patient's gag reflex. What equipment should the nurse use to test this reflex?
   1. safety pin
   2. cotton ball
   3. stethoscope
   4. tongue depressor
10. The nurse is documenting that a patient is demonstrating decorticate posturing. What does this statement indicate about the patient's physical posture?
    1. in supine position, spine extended, legs extended
    2. in prone position with arms and knees sharply flexed
    3. arms close to sides, elbows and wrists flexed, legs extended
    4. neck extended, arms extended and pronated, feet plantar flexed

See Test Yourself answers in Appendix B.

42 Nursing Care of Patients with Intracranial Disorders

LEARNING OUTCOMES

1. Compare and contrast the pathophysiology, manifestations, interprofessional care, and nursing care of patients with alterations in level of consciousness and increased intracranial pressure (IICP).
2. Describe criteria for diagnosing persistent vegetative state and brain death.
3. Explain the pathophysiology, manifestations, complications, interprofessional care, and nursing care of intracranial disorders, including seizures, stroke, aneurysms, arteriovenous malformation, traumatic brain injury, tumors, and headaches.
4. Discuss the purposes, nursing implications, and health education for the patient and family for medications used to treat intracranial disorders.
5. Discuss surgical options for the treatment of IICP, epilepsy, traumatic brain injury, and brain tumors.

CLINICAL COMPETENCIES

1. Assess functional status of patients with intracranial disorders and monitor, document, and report abnormal manifestations.
2. Use assessed data, individual and cultural patient values and variations, expressed patient needs and preferences, clinical expertise, and evidence to determine priority nursing diagnoses and select and implement individualized nursing interventions for patients with intracranial disorders.
3. Administer medications used to treat intracranial disorders knowledgeably and safely.
4. Provide appropriate interventions to patients having intracranial pressure monitoring, tonic–clonic seizures, and intracranial surgery.
5. Effectively communicate with and function within the interprofessional team to plan and provide care for patients with intracranial disorders.
6. Use evidence-based practice to provide care for patients undergoing awake craniotomy.
7. Provide appropriate teaching to facilitate safety and to provide information and support necessary for long-term care of patients with intracranial disorders.
8. Revise plan of care as needed to provide effective interventions to promote, maintain, or restore functional health status to patients with intracranial disorders.

MAJOR CHAPTER CONCEPTS

- Increased intracranial pressure (IICP) is a sustained elevated pressure (greater than 10 mmHg) within the cranial cavity. IICP may result from cerebral edema, hydrocephalus, head trauma, tumors, abscesses, inflammation, hemorrhage, or stroke.
- A seizure is a single event of abnormal electrical discharge. Epilepsy is a chronic seizure disorder of abnormal, recurring, excessive, and self-terminating electrical discharges from neurons.
- A stroke is a condition in which neurologic deficits result from a sudden decrease in blood flow to a localized area of the brain. Strokes may be ischemic or hemorrhagic.
- Intracerebral hemorrhage may follow rupture of an intracranial aneurysm or arteriovenous malformation.
- Traumatic brain injury (TBI) refers to any injury of the scalp, skull, or brain, and is a leading cause of death and disability.
- Brain tumors are growths within the cranium, including on or in brain tissue, the meninges, the pituitary gland, or blood vessels.

transient ischemic attack (TIA), *1371*

The patient with an intracranial disorder presents a unique nursing challenge. Problems the patient experiences in the acute stage of the disorder are often a prelude to long-term problems requiring ongoing management. These long-term problems range from alterations in the body's basic functions to dysfunctions in the complex processes of the human mind. Systemic problems may accompany or develop secondary to an intracranial disorder. Intracranial disorders may affect both the patient's quality of life and that of the patient's family.

The manifestations of altered cerebral function discussed in this chapter occur as a result of illness or injury. Assessing the patterns of these manifestations helps determine the extent of the cerebral dysfunction and improvement or deterioration of cerebral function. Except in the case of direct damage to the brainstem and reticular activating system (RAS), brain function deterioration usually follows a predictable progression, that is, a pattern in which higher levels of function are impaired initially, progressing to impairment of more primitive functions. Altered level of consciousness (LOC) and behavior changes are early manifestations of the deterioration of the function of the cerebral hemispheres. Structures in the midbrain and brainstem are affected sequentially, with characteristic changes in LOC; patterns of respiration, pupillary, and oculomotor responses; and motor function. Manifestations of progressive deterioration of cerebral function are outlined in Table 42–1.

THE PATIENT WITH ALTERED LEVEL OF CONSCIOUSNESS

Consciousness is a condition in which the individual is aware of self and environment and is able to respond appropriately to stimuli. Full consciousness requires both normal arousal and full cognition. Arousal, or alertness, depends on the RAS, a diffuse system of neurons in the thalamus and upper brainstem. Cognition is a complex process involving all mental activities controlled by the cerebral hemispheres, including thought processes, memory, perception, problem solving, and emotion. These two components of consciousness depend on the normal physiologic functions of and connections between the arousal mechanisms of the reticular formation and the cognitive functions of the cerebral hemispheres. Because arousal and cognition are independent components of consciousness, each can act separately on stimuli. For example, the RAS reacts to the discomfort caused by a full bladder by waking the person in the middle of the night. Once awake, however, the frontal cortex alerts the person that the bladder is full and prompts the person to go to the bathroom and empty it.

Conditions that affect either the RAS or the function of the cerebral hemispheres can interfere with the normal level of consciousness. Terms commonly used to describe altered LOC are listed and defined in Table 42–2. A patient may pass from full consciousness to coma within hours or experience a slow diminishment of consciousness that does not become evident for weeks or months. The nurse can help provide effective care for a patient with an altered LOC by looking beyond the diagnostic labels of consciousness and accurately assessing the patient's behavior and response to stimuli.

MEMORY CUE

To help remember the major causes of altered consciousness, use the following:

A-E-I-O-U = Alcohol, Epilepsy, Insulin, Opium, Uremia
TIPSS = Tumor, Injury, Psychiatric, Stroke, Sepsis

TABLE 42–1 Progression of Deteriorating Brain Function

Level of Consciousness	Pupillary Response	Oculomotor Responses	Motor Responses	Breathing
Alert; oriented to time, place, and person	Brisk and equal; pupils regular	Eyes move as head turns Caloric testing (ear irrigation) produces nystagmus	Purposeful movement; responds to commands	Regular pattern with normal rate and depth
Responds to verbal stimuli; decreased concentration; agitation, confusion, lethargy; disoriented	Small and reactive	Roving eye movements; doll's eyes positive, with gaze fixed straight ahead; eye deviation away from cold caloric stimulus and toward warm stimulus	Purposeful movement in response to pain stimulus	Yawning, sighing respirations
Requires continuous stimulation to rouse			Decorticate posturing with upper extremity flexion	Cheyne-Stokes respirations with crescendo–decrescendo pattern in rate and depth followed by period of apnea
Reflexive positioning to pain stimulus	Pupils fixed (nonreactive) in midposition	Caloric testing produces nystagmus	Decerebrate posturing with adduction and rigid extension of upper and lower extremities	Central neurogenic hyperventilation with rapid, regular, and deep respirations; apneustic breathing with prolonged inspiration and pauses at full inspiration and following expiration
No response to stimuli	Pupils fixed in midposition	No spontaneous eye movement or nystagmus	Extension of upper extremities with flexion of lower extremities; flaccidity (lack of muscle tone)	Cluster or ataxic breathing with irregular pattern and depth of respirations; gasping respirations or apnea

TABLE 42–2 Terms Used to Describe Level of Consciousness

Term	Characteristics of the Patient
Full consciousness	Alert; oriented to time, place, and person; comprehends spoken and written words
Confusion	Unable to think rapidly and clearly; easily bewildered, with poor memory and short attention span; misinterprets stimuli; judgment is impaired
Disorientation	Not aware of or not oriented to time, place, or person
Obtundation	Lethargic, somnolent; responsive to verbal or tactile stimuli but quickly drifts back to sleep
Stupor	Generally unresponsive; may be briefly aroused by vigorous, repeated, or painful stimuli; may shrink away from or grab at the source of stimuli
Semicomatose	Does not move spontaneously; unresponsive to stimuli, although vigorous or painful stimuli may result in stirring, moaning, or withdrawal from the stimuli, without actual arousal
Coma	Unarousable; will not stir or moan in response to any stimulus; may exhibit nonpurposeful response (slight movement) of area stimulated but makes no attempt to withdraw
Deep coma	Completely unarousable and unresponsive to any kind of stimulus, including pain; absence of brainstem reflexes; corneal, papillary, and pharyngeal reflexes; and tendon and plantar reflexes

Pathophysiology

Level of consciousness may be altered by processes that affect the arousal functions of the brainstem, the cognitive functions of the cerebral hemispheres, or both.

AROUSAL AND COGNITION

The physiologic seat of consciousness, the reticular formation, is a mass of nerve cells and fibers that make up the core of the brainstem, extending from the medulla to the midbrain. The axons of reticular neurons are exceptionally long and branch outward to cells in the hypothalamus, thalamus, cerebellum, and spinal cord. A system of reticular neurons within the RAS passes steady streams of impulses through thalamic relays in order to stimulate the cerebral cortex into wakefulness. The body's sensory tracts interact with RAS neurons; this interrelationship helps control the strength of the rousing effect on the cerebrum.

Damage to the RAS impairs an individual's ability to maintain wakefulness and arousal. Stroke is the most common cause of RAS destruction. Other causes include demyelinating diseases such as multiple sclerosis, tumors, abscesses, and head injury. Function of the RAS may be suppressed by compression of the brainstem with edema and ischemia. Pressure and compression of the brainstem may be due to tumors, edema, IICP, hematomas or hemorrhage, or aneurysm. Although it is possible to assess LOC or arousal in the patient with RAS damage, an impairment in arousal may make it impossible to assess cognitive function.

The function of the cerebral hemispheres depends on continuous blood flow with unimpeded supplies of oxygen and glucose. Processes that disrupt this flow of blood and nutrients may cause widespread damage, impairing arousal and cognition. Bilateral hemispheric lesions (such as global ischemia) and metabolic disorders (such as hypoglycemia) are the most common causes of altered LOC related to cerebral dysfunction of the hemispheres. Localized masses, such as a hematoma or cerebral edema, that displace normal structures and cause direct or indirect pressure on the opposite hemisphere or brainstem can also affect LOC. The patient who has widespread damage to the cerebral hemispheres but an intact RAS has sleep–wake cycles and may rouse in response to stimuli; the patient cannot be said to be alert, however, because cognition is impaired.

Any systemic condition that affects the delivery of blood, oxygen, and glucose to the brain or alters cell membranes may also alter LOC. If cerebral blood flow is impaired or the patient becomes hypoxic or hypoglycemic, cerebral metabolism is impaired and level of consciousness declines rapidly. Severe hypoxia quickly leads to ischemia. Ischemia may be focal (for example, following a stroke) or global (as from cardiac arrest or hypovolemic shock). Patients at particular risk include those with poorly controlled diabetes and those with cardiac or respiratory failure. Other metabolic alterations that can affect LOC include fluid and electrolyte imbalances, such as hyponatremia or hyperosmolality, and acid–base alterations, such as hypercapnia (an elevated arterial carbon dioxide level) (refer to Chapter 10). Accumulated waste products and toxins from liver or renal failure can affect neuronal and neurotransmitter function, altering LOC. Drugs that depress the central nervous system (e.g., alcohol, analgesics, anesthetics) suppress metabolic and membrane activities in the RAS and cerebral hemispheres, thereby affecting LOC. Glutamate, the main excitatory neurotransmitter in the brain, may accumulate during prolonged ischemia, resulting in acute glutamate toxicity and cell death.

Seizure activity, with abnormal electrical discharges from a local area of the brain or from the entire brain, commonly affects LOC. It appears that the spontaneous, disordered discharge of activity that occurs during a seizure exhausts energy metabolites or produces locally toxic molecules, altering LOC for a time after the seizure. Consciousness returns when the metabolic balance of the neurons is restored. (Seizures are discussed later in this chapter.)

As impairment of brain function progresses, higher intensity stimuli are required to elicit a response from the patient. Initially, the patient may rouse to verbal stimuli and respond appropriately to questions, remaining oriented to time, place, and person. With deterioration of neurologic function, the patient becomes more difficult to rouse and may become agitated and confused when awakened. Orientation to time is lost initially, followed by orientation to place and then to person. Continuous stimulation or vigorous shaking is required to maintain wakefulness as LOC decreases.

Eventually, the patient does not respond, even with deep painful stimuli.

PATTERNS OF RESPIRATIONS

Progressive impairment of neural function also causes predictable changes in respiratory patterns as respiratory centers are affected. In normal respirations, a rhythmic pattern is maintained by neural centers in the pons and medulla that respond to changes in arterial levels of oxygen (PaO_2) and carbon dioxide ($PaCO_2$). When there is damage to the RAS or cerebral hemispheres, neural control of these centers is lost, and lower brainstem centers regulate breathing patterns by responding only to changes in $PaCO_2$, resulting in irregular respiratory patterns. The initial manifestations of deteriorating brain function are yawning and sighing. As outlined earlier in Table 42–1, progressive deterioration in brain function is accompanied by decreasing LOC and changes in breathing patterns. The types of respirations, by area of cerebral damage, are as follows:

- *Diencephalon:* Cheyne-Stokes respirations (alternating periods of deep, rapid breathing followed by periods of apnea)
- *Midbrain:* neurogenic hyperventilation (may exceed 40 breaths per minute), the result of uninhibited stimulation of the respiratory centers
- *Pons:* apneustic respirations, characterized by sighing on midinspiration or prolonged inhalation and exhalation; results from excessive stimulation of the respiratory centers
- *Medulla:* ataxic/apneic respirations (totally uncoordinated and irregular), probably as a result of the loss of responsiveness to CO_2.

PUPILLARY AND OCULOMOTOR RESPONSES

The areas of the brainstem that control arousal are adjacent to areas that control the pupils. A predictable progression of pupillary and oculomotor responses occurs as level of consciousness deteriorates toward coma (refer to Table 42–1). If the lesion or process affecting neurologic function is localized, effects may initially be seen in the ipsilateral pupil (the pupil on the same side as the lesion). With generalized or systemic processes, pupils are affected equally. If the pupils are small and equally reactive, metabolic processes affecting LOC may be present. With compression of cranial nerve III at the midbrain, the pupils may become oval or eccentric (off center). As the level of functional impairment progresses, the pupils become fixed (unresponsive to light) and dilated. The sudden appearance of fixed and dilated pupils may be described in an informal medical term as *blown pupils.*

In deteriorating LOC and coma, spontaneous eye movement is lost and reflexive ocular movements are altered. Normally, both eyes move simultaneously in the same direction; injury to the cranial nerve nuclei in the midbrain and pons can impair normal movement. Doll's-eye movements are reflexive movements of the eyes in the opposite direction of head rotation; they are an indicator of brainstem function (Figure 42–1 ■). As a result of the oculocephalic reflex, the eyes move upward with passive flexion of the neck and downward with passive neck extension. As brainstem function deteriorates, this reflex is lost. The eyes fail to turn together and, eventually, remain fixed in the midposition as the head is turned.

MOTOR RESPONSES

The level of brain dysfunction and the side of the brain affected may be assessed by motor responses. These responses are the most accurate identifier of changes in mental status. In altered LOC, motor responses to stimuli range from an appropriate response to a command (e.g., "squeeze my hand") to flaccidity (refer to Table 42–1). Initially, the patient may be able to move purposefully away from a noxious stimulus, for example, to brush the examiner's hand away from the face. As function declines, movements become more generalized (withdrawal, grimacing) and less purposeful. Reflexive motor responses may occur, including decorticate posturing with flexion of the upper extremities accompanied by extension of the lower extremities. With further decline, decerebrate posturing is seen, with adduction and rigid extension of the upper and lower extremities. Without intervention, the patient eventually becomes flaccid, with little or no motor response to stimuli.

COMA STATES AND BRAIN DEATH

Possible outcomes of altered LOC and coma include full recovery with no long-term residual effects, recovery with residual damage (such as learning deficits, emotional difficulties, or impaired judgment), or more severe consequences such as persistent vegetative state (cerebral death) or brain death.

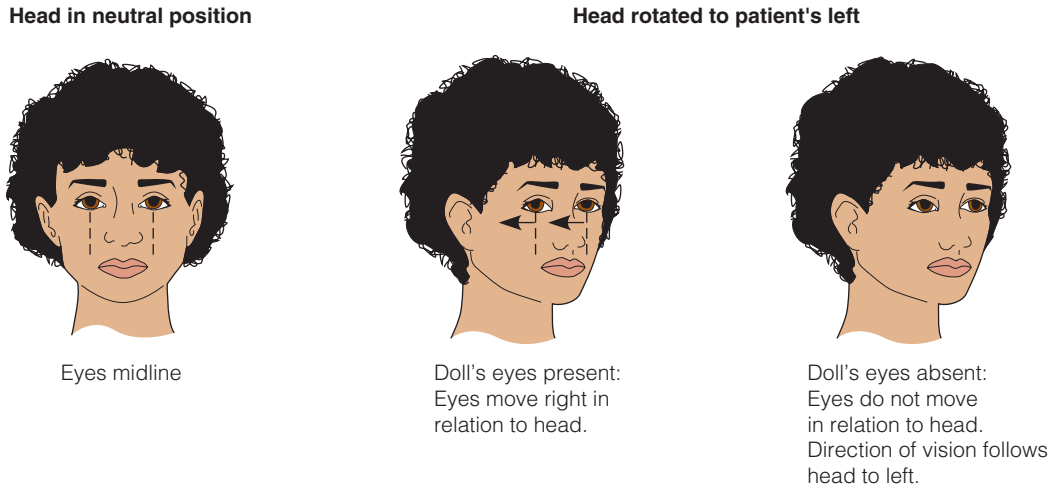

Figure 42–1 ■ Doll's-eye movements characteristic of altered level of consciousness.

PERSISTENT VEGETATIVE STATE **Persistent vegetative state (PVS)** is a permanent condition of complete unawareness of self and the environment and loss of all cognitive functions. Usually the result of severe brain trauma or global ischemia, this condition results from death of the cerebral hemispheres with continued function of the brainstem and cerebellum. While the homeostatic regulatory functions of the brain continue, the ability to respond meaningfully to the environment is lost. The patient has sleep–wake cycles and retains the ability to chew, swallow, and cough but cannot interact with the environment. When awake, the eyes may wander back and forth across the room, but they cannot track an object or person. In a minimally conscious state, the patient is aware of the environment and can follow simple commands, manipulate objects, gesture or verbalize to indicate yes/no responses, and make meaningful movements (such as blinking or smiling) in response to a stimulus. The diagnosis of PVS requires that the condition be present at 1 month after acute brain injury and present for at least 1 month in degenerative/metabolic disorders or developmental malformations (Huether & McCance, 2011). PVS presents difficult ethical, moral, and legal issues.

LOCKED-IN SYNDROME **Locked-in syndrome** is distinctly different from persistent vegetative state in that the patient is alert and fully aware of the environment and has intact cognitive abilities, but is unable to communicate through speech or movement because of blocked efferent pathways from the brain. Motor paralysis affects all voluntary muscles, although the upper cranial nerves (I through IV) may remain intact, allowing the patient to communicate through eye movements and blinking. In essence, the patient is locked inside a paralyzed body while remaining fully conscious of self and environment. Infarction or hemorrhage of the pons that disrupts outgoing nerve tracts but spares the RAS is the usual cause of locked-in syndrome. This condition may also result when the corticospinal tracts between the midbrain and pons are interrupted. Disorders of the lower motor neurons or muscles, such as poliomyelitis, myasthenia gravis, or amyotrophic lateral sclerosis (ALS), may also paralyze motor responses, leading to locked-in syndrome.

BRAIN DEATH **Brain death** is the cessation and irreversibility of all brain functions, including the brainstem. Although the exact criteria for establishing brain death may vary somewhat from state to state, it is generally agreed that brain death has occurred when there is no evidence of cerebral or brainstem function for an extended period (usually 6 to 24 hours) in a patient who has a normal body temperature and is not affected by a depressant drug or alcohol poisoning. Generally recognized criteria are the following:

- Unresponsive coma with absent motor and reflex movements
- No spontaneous respiration (apnea)
- Pupils fixed (unresponsive to light) and dilated
- Absent ocular responses to head turning and caloric stimulation (Caloric stimulation is performed by irrigating the ear with ice-cold water to test the oculovestibular reflex, a reflex controlled by the brainstem. Normally, the cold causes the eyes to first move toward the irrigated side, followed by a return to midline.)
- Flat electroencephalogram (EEG) and no cerebral blood circulation present on angiography (if performed)
- Persistence of these manifestations for 30 minutes to 1 hour and for 6 hours after onset of coma and apnea.

Apnea in the comatose patient is determined by the apnea test. The ventilator is removed while maintaining oxygenation by tracheal cannula and allowing the PCO_2 to increase to 60 mmHg or higher. This level of carbon dioxide is high enough to stimulate respiration if the brainstem is functional. The EEG may be used to establish the absence of brain activity when brain death is suspected. A flat EEG over a period of 6 to 12 hours in a patient who is not hypothermic or under the influence of drugs that depress the central nervous system (CNS) is generally accepted as an indicator of brain death.

Prognosis

The prognosis for patients with altered LOC and coma varies according to the underlying cause and pathologic process. Age and general medical condition also play a role in determining outcome. Young adults may fully recover following deep coma from, for example, head injury or drug overdose. Recovery of consciousness within 2 weeks is associated with a favorable outcome. In general, the prognosis is poor for patients who lack pupillary reaction or reflex eye movements 6 hours after the onset of coma.

●○● INTERPROFESSIONAL CARE

Management of the patient with an altered LOC or coma must begin immediately. The focus of management is to identify the underlying cause, preserve function, and prevent deterioration if possible. Airway and breathing must be maintained during the initial acute stage until the diagnosis and prognosis can be established. Intravenous fluids are used to support circulation and to correct fluid, electrolyte, and acid–base imbalances. Treatment protocols to reduce IICP or control seizure activity (discussed later in this chapter) may be initiated. Changes in LOC associated with craniocerebral trauma often require immediate surgical intervention.

DIAGNOSIS

Although the patient's history and physical examination findings often indicate the cause of alterations in LOC, several diagnostic tests may be useful in establishing the diagnosis. The tests used to evaluate possible metabolic, toxic, or drug-induced disorders include both radiologic and laboratory tests.

CT and MRI scanning are done to detect neurologic damage due to hemorrhage, tumor, cyst, edema, myocardial infarction, or brain atrophy. These tests may also identify displacement of brain structures by large or expanding lesions. Radioisotope brain scan is performed to identify abnormal lesions in the brain and evaluate cerebral blood flow. Cerebral angiography allows radiographic visualization of the cerebral vascular system. This exam can identify lesions such as aneurysms, occluded vessels, or tumors, and may also be used to determine cessation of cerebral blood flow and brain death. Transcranial Doppler studies are used to assess cerebral blood flow. Lumbar puncture with cerebrospinal fluid (CSF) analysis is performed when infection and possible meningitis are suspected as a cause of altered LOC. EEG is used to evaluate the electrical activity of the brain.

Laboratory tests are used to identify and monitor altered LOC. These may include any or all of the following:

- *Blood glucose* is measured immediately when coma is of unknown origin and hypoglycemia is suspected or possible. When the

blood glucose falls to less than 40 to 50 mg/dL, cerebral function declines rapidly.

- *Serum electrolytes*—sodium, potassium, bicarbonate, chloride, and calcium in particular—are measured to assess for metabolic disturbances and guide intravenous therapy. Hyponatremia, in which serum sodium levels are below 115 mEq/L (normal level: 135 to 145 mEq/L), is associated with coma and convulsions, especially if it develops rapidly.
- *Serum osmolality* is evaluated. Both hyperosmolar and hypoosmolar states may be associated with coma. Hyperosmolality (above 320 mOsm/kg H_2O) causes cellular dehydration of brain tissue as fluid is drawn into the vascular system by osmosis. Hypoosmolality (less than 250 mOsm/kg H_2O), by contrast, leads to cerebral edema and swelling, impairing consciousness.
- *Arterial blood gases* (ABGs) are drawn to evaluate arterial oxygen and carbon dioxide levels as well as acid–base balance. Hypoxemia is a frequent cause of altered LOC; increased levels of carbon dioxide are also toxic to the brain and can induce coma, particularly when the onset of hypercapnia is acute.
- *Liver function tests*, including bilirubin, AST, ALT, LDH, serum albumin, and serum ammonia levels, are determined to evaluate hepatic function. High ammonia levels seen in hepatic failure interfere with cerebral metabolism and neurotransmitters, affecting LOC.
- *Toxicology screening* of blood and urine is done to determine if altered LOC is the result of acute drug or alcohol toxicity. Serum alcohol levels are measured and the blood is assessed for the presence of substances such as barbiturates, carbon monoxide, or lead.

MEDICATIONS

Medications are used to support homeostasis and normal function for the patient with altered LOC, as well as to treat specific underlying disorders. An intravenous catheter is inserted, and fluid balance is maintained using isotonic or slightly hypertonic solutions, such as normal saline or lactated Ringer's solution. The patient's response to fluid administration is monitored carefully for evidence of increased cerebral edema.

If hypoglycemia is present, 50% glucose is administered intravenously to rapidly restore cerebral metabolism. Conversely, insulin is administered to the patient with hyperglycemia to reduce the blood glucose level and thus the serum osmolality. With narcotic overdose, naloxone is administered. Naloxone is a narcotic antagonist that competes for narcotic receptor sites, effectively blocking the depressant effect of the narcotic. Thiamine may be administered with glucose, particularly if the patient is malnourished or known to abuse alcohol, to prevent exacerbation of Wernicke's encephalopathy, a hemorrhagic encephalopathy due to thiamine deficiency that is associated with chronic alcoholism.

Any underlying fluid and electrolyte imbalance is corrected by administering medications or appropriate electrolytes. For the patient who is hyponatremic and has a low serum osmolality, furosemide (Lasix) or an osmotic diuretic such as mannitol may be administered to promote water excretion. Appropriate antibiotics are administered intravenously to the patient with suspected or confirmed meningitis.

SURGERY

Although surgery is not indicated for most patients with altered LOC, it may be necessary if the cause of coma is an intracerebral tumor, hemorrhage, or hematoma. When there is a risk of IICP, the patient is monitored continuously. Intracranial monitoring is discussed in the following section.

OTHER TREATMENTS

Support of the airway and respirations is vital in the patient with an altered LOC. The patient who is drowsy but rousable may need little more than an oral pharyngeal airway. With more severe alterations in consciousness, the patient may need endotracheal intubation to maintain airway patency, particularly if the cough and gag reflexes are absent. Mechanical ventilation is indicated when hypoventilation or apnea is present. Unless a do-not-resuscitate (DNR) order is in effect, mechanical ventilation should be initiated even if it has not been established that the disorder is reversible; without ventilatory support, cerebral anoxia develops rapidly, and brain death may ensue. ABGs are monitored frequently to determine the adequacy of ventilation. Cautious hyperventilation may be used to reduce $PaCO_2$ and promote cerebral vasoconstriction to reduce cerebral edema.

NUTRITION

In patients with long-term alterations in consciousness, such as PVS or locked-in syndrome, measures to maintain nutritional status are initiated. Enteral feedings with a gastrostomy tube are preferred if the patient is unable to take enough food by mouth without aspirating. In some cases, total parenteral nutrition (TPN) may be used.

●○● NURSING CARE

Nursing care of the patient with an altered LOC is planned and implemented for a variety of responses of both the patient and the family of the patient.

Support of the Family

Family members of a patient with an altered level of consciousness are often very anxious. It is difficult for the family to deal with the patient's uncertain prognosis. They may experience various conflicting emotions, such as guilt and anger. Reinforce information provided by the physician, and encourage the family to talk to the patient as though he or she were able to understand. Explain that this communication may initially seem awkward, but in time it will feel appropriate. The presence of many tubes (e.g., intravenous line, urinary catheter, ventilator) may be overwhelming to the family. They may not perceive the seriousness of the situation if a thorough explanation is not given. Include family members in the patient's care as much as they wish to be involved.

Allow significant others to stay with the patient when possible. Reinforce the need for family members to care for themselves by encouraging adequate meals and rest. Offer to contact support services such as friends, neighbors, and social services that the hospital may provide. Ask family members to leave a telephone number where they can be reached, and assure them that they will be called if any significant changes occur. Encourage family members to call if they have questions or concerns.

Assessment

See the Manifestations and Interprofessional Care sections for the assessment of the patient with altered LOC.

Priorities of Care

Collaborating with the interprofessional team to ensure adequate treatment of the underlying process while providing care that supports the physical and psychologic responses to the disorder is a priority of nursing care.

Diagnoses, Outcomes, and Interventions

Diagnoses, outcomes, and interventions discussed in this section are directed toward the unconscious patient and focus on problems with airway maintenance, skin integrity, contractures, and nutrition.

Ineffective Airway Clearance

Ineffective airway clearance related to loss of the cough reflex and the inability to expectorate is a major problem for the unconscious patient. The cough reflex may be absent or impaired when conditions that produce coma depress the function of the medullary centers.

Expected Outcome: Adequate airway clearance will be maintained by the nurse through safety measures and appropriate suctioning.

- Assess ability to clear secretions. Monitor breath sounds, rate and depth of respirations, dyspnea, pulse oximeter, and the presence of cyanosis. *The patient's ability to clear secretions serves as the initial assessment base for developing further interventions.*
- In unconscious patients or those without an intact cough reflex, maintain an open airway by periodic suctioning, limiting the time of suctioning to 10 seconds (Wagner et al., 2006). Periodic suctioning may be necessary to clear the airway of mucus, blood, or other drainage. *Suctioning for more than 10 seconds in the patient with IICP may cause hypercapnia, which in turn vasodilates cerebral vessels, increases cerebral blood volume, and increases ICP.*

SAFETY ALERT

If the patient has a basilar skull fracture or CSF draining from the ears or nose, never suction nasally.

- Turn from side to side every 2 hours, and maintain a side-lying position with the head of the bed elevated approximately 30 degrees. Do not position the unconscious patient on the back. *Turning the patient from side to side facilitates respirations, prevents the tongue from obstructing the airway, and helps prevent pooling of secretions in one area of the lungs (thus decreasing the risk of pneumonia).*
- Monitor the results of arterial blood gas analysis and pulse oximetry. Maintain records of trends. *ABGs and pulse oximetry directly measure the oxygen content of blood and are good indicators of the lungs' ability to oxygenate the blood.*

Risk for Aspiration

The unconscious patient with a depressed or absent gag and swallowing reflex is at high risk for aspiration. Drainage, mucus, or blood may obstruct the airway and interfere with oxygenation. Pooling of aspiration secretions in the lungs also increases the risk of pneumonia.

Expected Outcome: Patent airway and clear lung sounds will be maintained.

- Assess swallowing and gag reflexes every shift as appropriate to the patient's level of consciousness. *Deepening levels of unconsciousness may cause a loss of the swallow and gag reflexes.*
- Monitor for and report manifestations of aspiration: crackles and wheezes, dullness to percussion over an area of the lungs, dyspnea, tachypnea, and cyanosis. *Early recognition facilitates prompt intervention.*
- Provide interventions to prevent aspiration: Maintain NPO status, position on the side, and provide suctioning as needed. *The side-lying position allows secretions to drain from the mouth rather than into the pharynx. Oral hygiene and suctioning remove secretions that might otherwise be aspirated.*

SAFETY ALERT

Never give unconscious patients oral food and fluids because of the risk of aspiration.

Risk for Impaired Skin Integrity

On average, healthy people change positions during sleep every 11 minutes; the unconscious patient often cannot maintain the movement needed to prevent pressure on the skin, especially over bony prominences. As a result, the skin and subcutaneous tissues may become ischemic and prone to develop pressure ulcers. Perspiration and incontinence of urine and stool may exacerbate the problem. Nursing interventions are directed to maintaining the integrity not only of the skin, but also of the lips and mucous membranes. Nursing care to prevent pressure ulcer development is discussed in Chapter 16.

Expected Outcome: Patient will experience effective wound healing and infection management as evidenced by skin integrity and body temperature within normal range.

Impaired Physical Mobility

Patients who are unconscious are unable to maintain normal musculoskeletal movement and are at high risk for contractures related to decreased movement. Because the flexor and adductor muscles are stronger than the extensors and abductors, flexor and adductor contractures develop quickly without preventive measures. Passive range-of-motion (ROM) exercises must be performed routinely to maintain muscle tone and function, to prevent additional disability, and to help restore impaired motor function.

Expected Outcome: Patient's joint range of motion will be maintained with progression to transfers and ambulation as LOC alteration resolves.

- Maintain extremities in functional positions by providing proper support devices. Remove support devices every 4 hours for skin care and passive ROM exercises. Provide pillows for the axillary region; rolled washcloths may be placed in elevated hands; use splints to prevent plantar flexion (foot drop). *Pillows in the axillary region help prevent adduction of the shoulder. Rolled washcloths help decrease edema and flexion contracture of the fingers. Splints are useful in preventing plantar flexion.*
- Collaborate with a physical therapist to develop and implement passive ROM exercises (unless contraindicated, e.g., for the patient with IICP) at least four times a day. *ROM exercises help prevent contractures by stretching muscles and tendons and maintaining joint mobility.*

Risk for Imbalanced Nutrition: Less Than Body Requirements

The unconscious patient is at risk for an alteration in nutrition related to a reduced or complete inability to eat. This is especially true for the

patient who is unconscious as the result of an infection or trauma, both of which increase metabolic requirements.

Expected Outcome: Patient's nutritional intake will be adequate to meet physiologic processes as evidenced by oral or enteral intake of high-protein, high-nutrient diet.

- Monitor nutritional status through daily weights (on bed scales) and laboratory data. For accuracy, weigh the patient at the same time each day, wearing the same clothing, and using the same scales. *Changes in laboratory data with decreased nutrition include a decrease in the levels of serum prealbumin and serum transferrin.*
- Assess the need for alternative methods of nutritional support (tube feeding or total parenteral nutrition) through collaboration with dietitian. *Patients unable to take oral food require parenteral nutrition or liquid feedings through a nasogastric, gastrostomy, or jejunostomy tube. Protein, calorie, zinc, and vitamin C needs increase during wound healing.*

THE PATIENT WITH INCREASED INTRACRANIAL PRESSURE

In the adult, the rigid cranial cavity created by the skull is normally filled to capacity with three essentially noncompressible elements: the brain (80%), cerebrospinal fluid (8%), and blood (12%). A state of dynamic equilibrium exists: If the volume of any of the three components increases, the volume of the others must decrease to maintain normal pressures within the cranial cavity. This is known as the Monro-Kellie hypothesis. The normal intracranial pressure is 5 to 10 mmHg (measured intracranially with a pressure transducer while the patient is lying with the head elevated 30 degrees) or 60 to 180 cm H_2O (measured with a water manometer while the patient is lying in a lateral recumbent position).

Increased intracranial pressure (IICP), also labeled *intracranial hypertension*, is sustained elevated pressure (greater than 10 mmHg) within the cranial cavity. Sustained IICP can result in significant tissue ischemia and damage to delicate neural tissue. Cerebral edema is the most frequent cause of sustained increases in ICP. Other causes include head trauma, tumors, abscesses, stroke, inflammation, and hemorrhage.

Pathophysiology

Cerebral blood flow and perfusion are important concepts for understanding the development and effects of IICP. Whereas blood and CSF contribute an equal percentage to normal intracranial volume, vascular factors account for twice the amount of increase in ICP that CSF does. The brain requires a constant supply of oxygen and glucose to meet its metabolic demands; 15% to 20% of the resting cardiac output goes to the brain to meet its metabolic needs. Interruption of the cerebral blood flow leads to ischemia and disruption of the cerebral metabolism.

Pressure and chemical autoregulation are compensatory mechanisms in which cerebral arterioles change diameter to maintain cerebral blood flow when ICP increases. In pressure autoregulation, stretch receptors within small blood vessels of the brain cause smooth muscle of the arterioles to contract. Increased arterial pressure stimulates these receptors, leading to vasoconstriction; when arterial pressure is low, stimulation of these receptors decreases, causing relaxation and vasodilation. Chemical, or metabolic, autoregulation works in much the same way as pressure autoregulation. In this case, the stimulus is a buildup of metabolic by-products of cell metabolism, including lactic acid, pyruvic acid, carbonic acid, and carbon dioxide. Carbon dioxide and increased hydrogen ion concentration are potent cerebral vasodilators that may act locally or systemically to increase cerebral blood flow. Conversely, a fall in $PaCO_2$ causes cerebral vasoconstriction. Arterial oxygen tension (PaO_2) also affects cerebral blood flow, although it is a less powerful mechanism than that exerted by carbon dioxide and hydrogen ions.

IICP may result from an increase in intracranial contents from a space-occupying lesion, hydrocephalus, cerebral edema, excess cerebrospinal fluid, or intracranial hemorrhage. Displacement of some CSF to the spinal subarachnoid space and increased CSF absorption are early compensatory mechanisms. The low-pressure venous system is also compressed, and cerebral arteries constrict to reduce blood flow. Brain tissue's ability to accommodate change is relatively restricted. The relationship between the volume of the intracranial components and intracranial pressure is known as *compliance*. When the capacity to compensate for IICP is exceeded, increased intracranial pressure (hypertension) develops. Intracranial hypertension is a sustained state of IICP and is potentially life threatening.

Autoregulatory mechanisms have a limited ability to maintain cerebral blood flow. When autoregulation fails, cerebrovascular tone is reduced and cerebral blood flow becomes dependent on changes in blood pressure. Autoregulation may be lost either locally or globally because of several factors, including IICP, local or diffuse cerebral tissue ischemia or inflammation, prolonged hypotension, and hypercapnia or hypoxia.

Cerebral Edema

Cerebral edema is an increase in the volume of brain tissue due to abnormal accumulation of fluid. Cerebral edema is associated with IICP; it may occur as a local process in the area of a tumor or injury, or it may affect the entire brain. Two types of cerebral edema are vasogenic edema and cytotoxic edema. Both types may occur at the same time (Huether & McCance, 2011):

- Vasogenic edema, an extracellular edema of the white matter, results from an increase in the capillary permeability of cerebral vessels. Localized cerebral edema occurs around brain tumors and globally around cerebral trauma and meningitis.
- Cytotoxic edema is an increase in fluid in neurons, glia, and endothelial cells as a result of failure of the sodium-potassium pump with accumulation of water and sodium in the cells. Diffuse brain swelling results. Both white and gray matter can be involved. Cytotoxic edema is associated with an event causing anoxia or hypoxia, such as a cardiac arrest. It may also occur with hypo-osmolar conditions such as hyponatremia or the syndrome of inappropriate secretion of antidiuretic hormone (SIADH).

Hydrocephalus

Hydrocephalus in adults refers to a syndrome in which abnormal overproduction, circulation, or reabsorption of CSF occurs. It is classified as either noncommunicating or communicating hydrocephalus. Noncommunicating hydrocephalus occurs when CSF drainage from the ventricular system is obstructed. It may develop when a mass or tumor, inflammation or hemorrhage, or congenital malformation obstructs the ventricular system. Communicating hydrocephalus is

a condition in which CSF is not effectively reabsorbed through the arachnoid villi. It may occur secondarily to subarachnoid hemorrhage or scarring from infection. In normal pressure hydrocephalus, seen most often in adults age 60 or older, ventricular enlargement causes cerebral tissue compression but the CSF pressure on lumbar puncture is normal. This condition may follow cerebral trauma or surgery, or the cause may not be known.

Brain Herniation

If IICP is not treated, cerebral tissue is displaced toward a more compliant area. This can result in brain herniation, the displacement of brain tissue from its normal compartment under dural folds of the falx cerebri or through the tentorial notch or incisura of the tentorium cerebelli (Huether & McCance, 2011). Herniation of the cerebellum through the tentorium exerts pressure on the brainstem, with subsequent herniation through the foramen magnum. This is a lethal complication of IICP because it puts pressure on the vital centers of the medulla.

Brain herniation syndromes are generally categorized as supratentorial or infratentorial, depending on their location above or below the tentorium cerebelli (Figure 42–2 ■). Supratentorial herniation syndromes include cingulate herniation, central or transtentorial herniation, uncal or lateral transtentorial herniation, and infratentorial.

- Cingulate herniation (Figure 42–2A) occurs when the cingulate gyrus is displaced under the falx cerebri. Local blood supply and cerebral tissue are compressed, resulting in ischemia and further increases in intracranial pressure.
- Central or transtentorial herniation is the downward displacement of brain structures, including the cerebral hemispheres, basal ganglia, diencephalon, and midbrain through the tentorial incisura (Figure 42–2B). The patient's neurologic signs may deteriorate rapidly, with decreased LOC progressing to coma, Cheyne-Stokes respirations progressing to central neurogenic hyperventilation, and pupils progressing from small and reactive to midsize and fixed. The patient may demonstrate abnormal motor responses with unilateral decorticate posturing.
- Uncal or lateral transtentorial herniation occurs when a lateral mass displaces cerebral tissue centrally, forcing the medial aspect of the temporal lobe under the edge of the tentorial incisura (Figure 42–2C). The oculomotor nerve (cranial nerve III) often becomes trapped between the uncus and the tentorium, causing ipsilateral pupillary dilation. Other manifestations include alterations in LOC, motor deficits (which may occur on the same side as the herniation because of compression of the cerebral peduncle on the opposite side), decreased sensation, respiratory changes, abnormal positioning, and eventual respiratory arrest.
- Infratentorial herniation results from increased pressure within the infratentorial compartment. Herniation may occur either upward, with structures displaced through the tentorial incisura, or downward, with displacement through the foramen magnum (Figure 42–2D). Downward displacement compresses the medulla, including its centers for controlling vital functions. Manifestations associated with medullary compression include coma, altered respiratory patterns, fixed pupils, and decorticate or decerebrate posturing. Respiratory or cardiac arrest may occur.

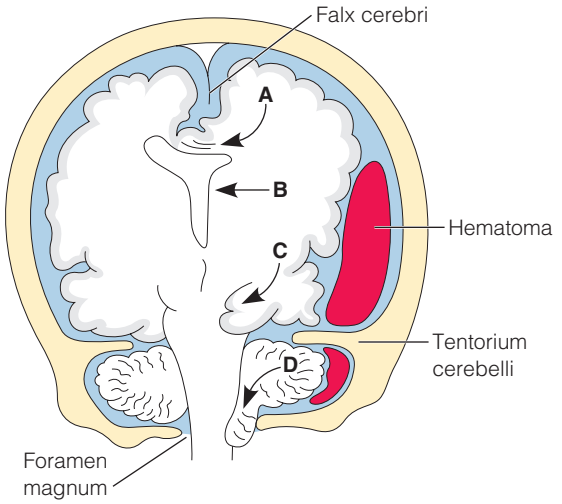

Figure 42–2 ■ Forms of brain herniation due to IICP. A, Cingulate herniation occurs when the cingulate gyrus is compressed under the falx cerebri. B, Central herniation occurs when a centrally located lesion compresses central and midbrain structures. C, Lateral herniation occurs when a lesion at the side of the brain compresses the uncus or hippocampal gyrus. D, Infratentorial herniation occurs when the cerebellar tonsils are forced downward, compressing the medulla and top of the spinal cord.

Manifestations

With loss of autoregulation, intracranial pressure continues to rise and cerebral perfusion falls. Cerebral tissue becomes hypoxic, and manifestations of cellular ischemia appear. The manifestations and related pathophysiology of IICP are listed in the Pathophysiology Linkage box and further described next.

LEVEL OF CONSCIOUSNESS

Because the neurons of the cerebral cortex are most sensitive to oxygen deficit, changes in cortical function are the most sensitive indicator of neurologic change (Huether & McCance, 2011). Behavior and personality changes occur; the patient may become irritable and agitated. Memory and judgment are impaired, and speech pattern changes may be noted. The patient's LOC decreases. As cerebral hypertension and hypoxia progress, the LOC continues to decrease in a predictable pattern to coma and unresponsiveness.

MOTOR RESPONSES

Pressure on the pyramidal tract often causes weakness (hemiparesis) on the contralateral side early in IICP. As ICP continues to increase, hemiplegia and abnormal motor responses, such as decorticate or decerebrate posturing, develop.

VISION AND PUPILS

Altered vision is an early manifestation of IICP; it is caused by pressure on the visual pathways and cranial nerves. Blurred vision, decreased visual acuity, and diplopia are common. Pupillary and oculomotor responses are affected as well. Because the cause of IICP is often localized at first, pupillary changes, including gradual dilation and sluggish response to light, may initially be limited to the ipsilateral side.

VITAL SIGNS

Ischemia of the vasomotor center in the brainstem triggers the CNS ischemic response, a late sign of IICP. Neuronal ischemia in the

PATHOPHYSIOLOGY LINKAGE

Increased Intracranial Pressure

Manifestations	Related Pathophysiology
Decreasing level of consciousness: Early there is confusion, restlessness, lethargy, disorientation that progresses first to time, then to place and person. Higher levels of function (mental processing) are affected first; as pressure increases, midbrain and deeper, more primitive functions are affected. Late in the process there is coma without response even to painful stimuli.	Pressure on the cerebral cortex from an increase in cerebral contents and cerebral hypertension causes decreased oxygenation (hypoxia) of neurons.
Pupillary dysfunction, sluggish response to light progresses to dilated and fixed pupils. Vision becomes blurred and diplopia (double vision) is common. There may be an inability to move the eyes upward and drooping (ptosis) of the eyelids.	Increased intracerebral pressure on cranial nerves and the visual pathways.
Papilledema (edema of the optic disc).	With increased pressure and interference with CSF circulation, capillary permeability increases and fluid leaks into the optic papilla (point where the central retinal artery enters the eye in the center of the optic nerve).
Abnormal motor responses, including weakness of the contralateral (opposite) side (hemiparesis) early; followed by hemiplegia, decorticate or decerebrate posturing.	Pressure on pyramidal (corticospinal) tracts, which control function on the opposite side of the body.
Increase in MAP, with a significant increase in systolic blood pressure and pulse pressure.	Pressure on cerebral vessels results in ischemia of the vasomotor center in the brainstem.
Decreased pulse rate.	Increase in MAP in turn causes reflexive slowing of the cardiac rate.
Dramatic increase in body temperature.	Increased intracerebral pressure impairs hypothalamic function and compensatory mechanisms fail.
Altered respirations.	Increased pressure impairs hypothalamic function and respiratory centers, with loss of responsiveness to CO_2.
Headache, worse on rising to an upright position and when changing positions.	Pressure on pain-sensitive structures, such as the middle meningeal arteries, the venous sinuses, and the dura at the base of the brain. The intracranial pressure increases during position changes.
Nausea with projectile vomiting.	Compression of the brainstem and direct stimulation of the vomiting center.

vasomotor center causes a marked increase in the mean arterial pressure (MAP), with a significant increase in systolic blood pressure and increased pulse pressure. The increased MAP causes reflexive slowing of the cardiac rate. This trio of manifestations (rising systolic blood pressure, widening pulse pressure, bradycardia) is known as Cushing's response and represents a compensatory response to try to maintain cerebral perfusion pressure. The loss of compensatory mechanisms and brainstem function is a late sign indicated by hypertension, bradycardia, and respiratory abnormalities, and is called *Cushing's triad* (Huether & McCance, 2011). Although the temperature is usually normal in early stages, as ICP continues to increase, hypothalamic function is impaired and the temperature may rise dramatically.

MEMORY CUE

The blood pressure and pulse assessments in IICP (systolic BP ↑ with widening pulse pressure and pulse ↓) are the opposite of those found in hypovolemic shock (both systolic and diastolic BP ↓ and P ↑).

OTHER MANIFESTATIONS

Additional manifestations of IICP include headache, particularly on rising, that worsens with position changes. Headache is more common with slowly developing IICP and occurs because of pressure on pain-sensitive structures, such as the middle meningeal arteries, the venous sinuses, and the dura at the base of the skull. Papilledema (edema and swelling of the optic disc) may be noted on funduscopic examination. Vomiting, often projectile and occurring without warning, may develop.

●○● INTERPROFESSIONAL CARE

Management of the patient with IICP is directed toward identifying and treating the underlying cause of the disorder and controlling ICP to prevent herniation syndrome. IICP is a medical emergency, and there is little time to complete lengthy diagnostic tests. The diagnosis must be made on the basis of observation and neurologic assessment; even subtle changes may be clinically significant.

DIAGNOSIS

Diagnostic tests focus on identifying the presence of IICP and its underlying cause. A CT scan or MRI is generally the initial test used to identify the possible causes of IICP (such as space-occupying lesions or hydrocephalus) and to evaluate therapeutic options. In general, a lumbar puncture is not performed when IICP is suspected

because the sudden release of the pressure in the skull may cause cerebral herniation.

In addition to the diagnostic tests listed in the previous section for altered LOC, the following specific tests are usually ordered and their results closely monitored:

- *Serum osmolality* is an indicator of hydration status in the patient with IICP. The test measures the number of dissolved particles (electrolytes, urea, glucose) in the serum. The normal range for the adult is 280 to 300 mOsm/kg H_2O. In addition to the restriction of fluids in the patient with IICP, serum osmolality is maintained at a slightly elevated level (325 mOsm/kg H_2O) to draw excess intracellular fluid into the vascular system.
- *ABGs* are monitored frequently to assess pH and levels of oxygen and carbon dioxide. Hydrogen ions and carbon dioxide are both potent vasodilators; hypoxemia also causes vasodilation, although to a lesser degree.

MEDICATIONS

Medications play an important role in the management of IICP. These medications with nursing implications are described in the accompanying Medication Administration box.

In addition, sedation and paralysis are used as chemical restraints to control restlessness and agitation, because these movements increase blood pressure, ICP, and cerebral metabolism. Paralysis with neuromuscular blockage is most often accomplished with pancuronium. Patients must be closely monitored during treatment for residual muscle weakness and signs of respiratory distress.

SURGERY

Patients with IICP may undergo various intracranial surgical techniques to treat the underlying cause (see the discussion in the later section on brain tumors). In addition, infarcted or necrotic tissue may be resected to reduce brain mass. A drainage catheter or shunt may be inserted laterally via a burr hole into a ventricle to drain excess cerebrospinal fluid and reduce hydrocephalus. The removal of even a small amount of CSF may dramatically reduce IICP and restore cerebral perfusion pressure.

ICP MONITORING

Critical to preserving brain function and preventing secondary brain damage from IICP are careful assessments and monitoring with ICP monitors, measuring cerebral blood flow and cerebral perfusion pressure, and measuring oxygen levels of brain tissue. Intracranial

MEDICATION ADMINISTRATION

Increased Intracranial Pressure

OSMOTIC DIURETICS

mannitol (Osmitrol)

urea

glucose

Osmotic diuretics (hyperosmotic agents) draw fluid out of brain cells by increasing the osmolality of the blood. The effects of these drugs vary with the type of injury. Mannitol therapy is often initiated if the patient's ICP has exceeded 15 to 20 mmHg for at least 10 minutes. Both IV bolus and continuous infusion techniques are used. Repeated use of mannitol can lead to continual elevations in serum osmolality, with attendant risk of seizures and a serious fluid and electrolyte imbalance. Urea is seldom administered IV because a severe local reaction may result if leakage occurs at the injection site. Mannitol and urea are used cautiously if renal disease is present.

Nursing Responsibilities

- Monitor vital signs, urinary output, central venous pressure (CVP), and pulmonary artery pressures (PAP) before and every hour throughout administration.
- Assess for manifestations of dehydration.
- Assess for muscle weakness, numbness, tingling, paresthesia, confusion, and excessive thirst.
- Assess for pulmonary edema while administering the medication.
- Monitor neurologic status and intracranial pressure readings.
- Monitor renal function and serum electrolytes throughout therapy.
- Do not administer the medication if crystals are present in solution. Administer with an inline filter. Observe infusion site frequently for infiltration.
- Do not administer mannitol solution with blood.

LOOP DIURETICS

furosemide (Lasix)

ethacrynic acid (Edecrin)

Loop diuretics such as furosemide and ethacrynic acid inhibit sodium and chloride reabsorption at the ascending loop of Henle. They cause a reduction in the rate of CSF production, thus reducing the ICP.

Nursing Responsibilities

- Monitor vital signs and electrolyte values closely.
- Assess fluid status throughout therapy.
- Monitor blood pressure and pulse before and during administration.
- Monitor renal laboratory studies closely.
- Use infusion pump to ensure accurate dosage.

INTRAVENOUS FLUIDS

Keeping the patient moderately dehydrated to maintain serum osmolality can be effective in reducing cerebral edema. When giving IV fluids, closely monitor the osmolality of the solutions; if patients with IICP are given hypo-osmolar solutions, increased cerebral edema can occur. Preferred solutions include 0.45% to 0.9% sodium chloride solutions.

Nursing Responsibilities

- Monitor fluid status closely.
- Monitor neurologic status closely.
- Avoid administering solutions that become hypo-osmolar, such as 5% dextrose in water.

OTHER PHARMACOLOGIC INTERVENTIONS FOR ICP

- Antipyretics, such as acetaminophen, are used in conjunction with a hypothermia blanket to reduce hyperthermia, thereby decreasing the high cerebral metabolism that contributes to IICP.
- Antiulcer drugs, such as histamine H_2 antagonists (for example, ranitidine [Zantac]) or sucralfate (Carafate), are used in patients with ICP to decrease the development of stress ulcers.
- Antihypertensive agents, such as beta-adrenergic blocking agents, may be used if the mean arterial pressure is high.
- Vasopressors may be used if the mean arterial pressure is low.
- Anticonvulsants may be given to prevent or treat seizures.

Note: Because the patient with IICP often has an altered level of consciousness, patient and family teaching are not discussed in this box.

pressure monitors facilitate continual assessment of ICP and the effects of medical therapy and nursing interventions. In addition, cerebral perfusion pressure (the difference between MAP and ICP) can be readily calculated, allowing more precise manipulation of therapeutic measures to maintain cerebral perfusion and thereby prevent ischemia. The criteria for ICP monitoring depends on the patient, but in general, patients who are comatose and have a Glasgow Coma Scale score of 8 or less should be monitored. (The Glasgow Coma Scale is illustrated in Table 41–5.)

Basic monitoring systems include an epidural probe, subarachnoid bolt or screw, and intraventricular catheter (Figure 42–3 ■). Intraventricular fluid-filled catheters are placed in the anterior horn of the lateral ventricle (most often in the right side). Ventricular catheters can both drain CSF and measure ICP. The ICP value is measured deep in the brain and is considered the most reflective of the whole brain pressure. Subarachnoid devices are placed in the subarachnoid space. A fiberoptic transducer-tipped catheter can be placed in the epidural, subdural, or parenchymal space, with ICP values considered very accurate. Once the intracranial sensor is implanted, it is connected to a transducer that converts the impulses to a signal that the recording device can translate into an oscilloscope tracing, digital value, or graphic recording.

Transcranial blood flow is monitored with transcranial Doppler (TCD) studies to measure the velocity of blood flow in the cerebral vessels. Cerebral perfusion pressure (CPP) is the pressure it takes for the heart to provide the brain with blood, calculated by subtracting the ICP from mean arterial pressure (normal CPP is 70 to 95 mmHg). Brain oxygenation monitoring may be conducted by using a jugular bulb oxygen saturation (SjO_2) monitor connected to a small fiberoptic catheter inserted into the jugular vein (normal SjO_2 is 50% to 75%). Another device used to monitor brain tissue oxygenation is the LICOX system, which includes information about oxygen status and temperature status within the brain tissue itself. In addition, cerebral microdialysis catheters can provide information about the nature of the cerebral interstitial fluid.

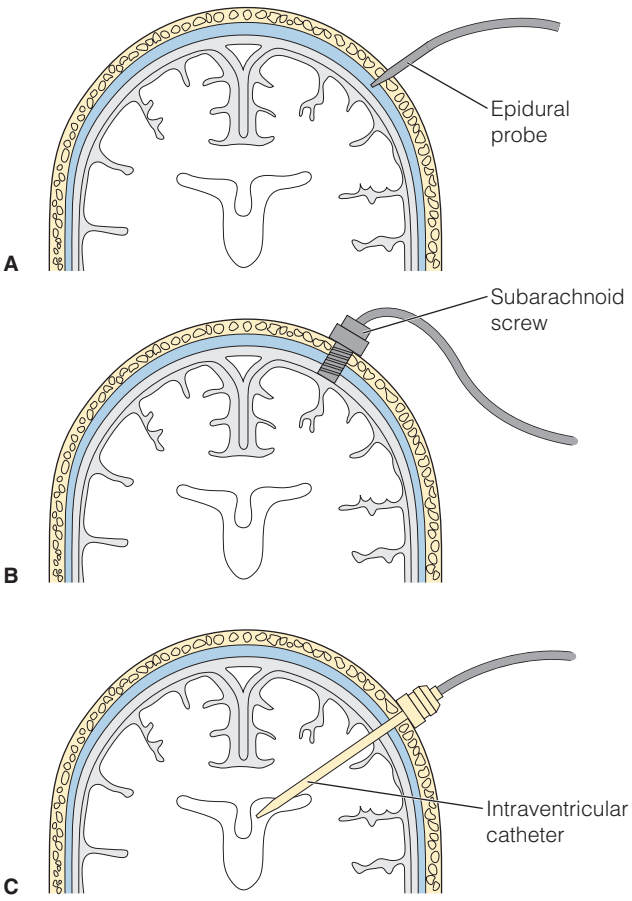

Figure 42–3 ■ Types of intracranial pressure monitoring. A, Epidural probe. B, Subarachnoid screw. C, Intraventricular catheter.

MECHANICAL VENTILATION

Patients with ICP often require intubation and are placed on a ventilator for respiratory management. Mechanical ventilation may be used to maintain partial pressure of oxygen and carbon dioxide, thus preventing hypoxemia and hypercapnia, both of which can increase intracranial pressure. It is important to maintain adequate oxygenation with a partial pressure of arterial oxygen at about 100 mmHg and a partial pressure of arterial carbon dioxide of about 35 mmHg. The patient with IICP and signs of impending herniation may be carefully hyperventilated to cause cerebral vasoconstriction; however, this also increases cerebral ischemia.

●○● NURSING CARE

The nursing care of patients with IICP involves identifying those at risk and managing factors known to increase intracranial pressure. A major focus is protecting the patient from sudden increases in ICP or a decrease in cerebral blood flow.

Assessment

See the Manifestations and Interprofessional Care sections for the assessment of the patient with IICP.

Priorities of Care

Collaborating with the interprofessional team to ensure adequate treatment of the underlying process while providing care that supports the physical and psychologic responses to the disorder is a priority of nursing care.

Diagnoses, Outcomes, and Interventions

Nursing interventions include monitoring neurologic status, maintaining airway patency, ensuring adequate ventilation, positioning and moving, instituting seizure precautions (described later in this chapter), and monitoring fluids and electrolytes. Additionally, both patient and family need emotional support during this period.

Ineffective Tissue Perfusion: Cerebral

A number of disorders may lead to IICP, including cerebral edema, hydrocephalus, tumors, hematoma and hemorrhage, herniation syndromes, trauma, and changes in carbon dioxide concentrations. IICP alters cerebral perfusion and oxygenation of brain cells. The patient with IICP requires intensive care, and often needs ventilator assistance.

Expected Outcome: Patient's ICP will be maintained within normal range as evidenced by motor/sensory functions, papillary size and reaction, and behaviors.

- Assess for and report manifestations of IICP every 15 minutes to 1 hour and as necessary. Assessment areas include LOC, behavior, motor/sensory functions, pupillary size and reaction to light, and vital signs, including temperature. Look for trends, because vital signs alone do not correlate well with early deterioration. *Assessment of neurologic status establishes the patient's clinical condition and provides a baseline for measuring changes. Sudden changes in neurologic signs often indicate deterioration. An elevated temperature with increased oxygen consumption further increases intracranial pressure. Pupillary responses mirror the status of the midbrain and pons. Pressure on the brainstem may compromise the function of cranial nerves IX and X and protective mechanisms, such as the gag and cough reflexes.*

SAFETY ALERT

Often, the earliest manifestations of a change in intracranial pressure are alterations in the level of consciousness and respirations.

- For the patient on a ventilator: Maintain patency of the airway; preoxygenate with 100% oxygen before suctioning; limit suctioning to 10 seconds; suction gently. *Preoxygenation helps maintain oxygen levels during suctioning. Suctioning stimulates the cough reflex and Valsalva maneuver. Correct suctioning minimizes the risk of hypoxemia.*
- Monitor ABGs. *ABGs provide a reliable indicator of oxygen and carbon dioxide levels. If oxygen concentration is low, oxygen may be given or increased.*
- Elevate head of the bed to 30 degrees or keep flat, as prescribed; maintain the alignment of the head and neck to avoid hyperextension or exaggerated neck flexion; avoid prone position. *Keeping the head of the bed elevated facilitates venous drainage from the cerebrum. Obstruction of jugular veins can impede venous drainage from the brain.*
- Teach the patient at risk for or experiencing IICP (and able to follow instructions) to avoid coughing, blowing the nose, straining to have a bowel movement, pushing against the bed rails, or performing isometric (muscle contracting) exercises. *These actions increase ICP.*
- Monitor bladder distention and bowel constipation. Administer stool softeners and use the Credé technique (applying pressure to the suprapubic region with the fingers of one or both hands) to empty the bladder (if ordered). If the Credé technique is not effective, discuss with the physician urinary catheterization if the bladder remains distended. *Constipation and bladder distention increase intrathoracic or intra-abdominal pressure and place the patient at risk for impaired venous drainage from the brain.*
- If alert, assist in moving up in bed. Do not ask to push with heels or arms or push against a footboard. Avoid a footboard and restraints. *Moving up in bed requires pushing. Helping the patient move prevents initiation of the Valsalva maneuver, which increases intracranial pressure.*
- Plan nursing care so that activities are not clustered together; avoid turning the patient, getting the patient on the bedpan, or suctioning within the same time period. Schedule nursing care to provide rest periods between procedures. *Multiple procedures, including certain nursing care activities, can increase ICP. Constant stimulation tends to increase ICP. Individualized nursing care ensures optimal spacing of activities and rest.*
- Provide a quiet environment, limiting noxious stimuli. Avoid jarring the bed. Try to limit situations that cause emotional upset; maintain a calm, reassuring manner; caution family members to refrain from unpleasant conversations or conversations that may be emotionally stimulating to the patient. *Noxious stimuli and emotional upsets cause an elevation in ICP.*
- Maintain fluid limitations, if prescribed. *Restricting fluids helps decrease cerebral edema by reducing total body water.*

Risk for Infection

Although any patient with an open head wound is at risk for infection, the interventions discussed here are for the patient with an intracranial monitoring device. Most clinical units have written protocols for managing these systems. The following nursing actions serve only as a general guide.

Expected Outcome: Infection management and control will be maintained as evidenced by freedom from symptoms of infection, maintenance of white blood cell count and differential, and vital signs within normal limits

- Keep dressings over the catheter dry, and change dressings on a prescribed basis (usually every 24 to 48 hours). *Wet dressings are conducive to bacterial growth.*
- Monitor the insertion site for leaking CSF, drainage, or infection. Monitor for manifestations of infection, including changes in vital signs, chills, increased WBC counts, and positive cultures of drainage. *Close monitoring helps detect the earliest signs of infection and helps prevent major complications. Fever is usually considered the key assessment. However, fever in a patient with a neurologic disorder may be due to damage to the hypothalamus. Headache, generalized muscle aches, shivering, and chills may also be seen in the patient with infection.*
- Use strict aseptic technique when in contact with the device. Check drainage system for loose connections. *The use of aseptic technique and monitoring drainage systems for loose connections help prevent nosocomial infections. Most nosocomial infections are transmitted by healthcare workers who fail to wash their hands properly, to change gloves between patients, or to follow aseptic technique protocols. Invasive procedures provide an excellent opportunity for microbes to enter the body.*

Patient and Family Education

Encourage the family to talk to the patient, but maintain a quiet environment with a minimum of stimuli. Inform family members that upsetting the patient may increase intracranial pressure and that they should avoid discussions that may distress the patient. For patients unable to make decisions about treatment and to sign informed consent, the family must carry out these functions.

THE PATIENT WITH SEIZURES

A **seizure** is "a single event of abnormal electrical discharge in the brain resulting in an abrupt and temporary altered state of cerebral function" (Hickey, 2013). This abnormal neuronal activity, which may involve all or part of the brain, disturbs skeletal motor function, sensation, autonomic function of the viscera, behavior, and/or consciousness. Although many of the disorders discussed in this chapter may cause seizures, this section focuses on **epilepsy** (seizure

disorder), a chronic disorder of abnormal, recurring, excessive, and self-terminating electrical discharge from neurons. All people with epilepsy have seizures, but not all people who have a seizure have epilepsy. Only after an individual has two or more seizures is the diagnosis of epilepsy made (National Institute of Neurological Disorders and Stroke [NINDS], 2012a). Epilepsy is characterized by recurring seizures accompanied by some type of change in behavior. The time period between seizures may range from minutes to years.

Incidence and Prevalence

Seizures and epilepsy are estimated to affect more than 3 million people of all ages in the United States. There is a strong genetic component. Although people of any age may be affected, the prevalence and incidence of epilepsy increases in older adults (see the Nursing Care of the Older Adult box.)

FAST FACTS

Epilepsy

- Epilepsy affects people of all ages, races, and ethnic backgrounds.
- Epilepsy is the fourth most common neurologic disorder in the United States.
- About 2.2 million Americans have epilepsy.

Source: Epilepsy Foundation, 2012.

Although some precipitating factors for seizures are known (such as birth defects, trauma, brain tumors, IICP, metabolic disorders, Alzheimer's disease, and cardiovascular diseases), the cause is unknown in 70% of all cases (Huether & McCance, 2011). Isolated seizure episodes may occur in otherwise healthy people for a variety of reasons, including fever, infection, metabolic or endocrine disorder (such as hypoglycemia), or exposure to toxins.

Pathophysiology

Seizures occur when there is an excessive imbalance in excitation and inhibition in either focal areas of the cerebral cortex (causing focal seizures) or over the entire cerebral cortex (causing generalized seizures). Either a focal or a generalized increase in the excitability of neurons may result from energy failure of neurons, producing either transient depolarization or lack of local inhibition. Seizures may also result from alterations in membrane potentials that increase the risk of hypersensitive neurons responding abnormally to changes in the cellular environment.

All people have a seizure threshold; when this threshold is exceeded, a seizure may occur. In some people, the seizure threshold may be abnormally low, increasing their risk for seizure activity; in other people pathologic processes may alter the seizure threshold. The hypersensitive neurons that initiate seizure activity are called the epileptogenic focus. The epileptogenic focus generates a large number of discharges that are either enhanced or minimized, depending on the active neurotransmitter present on the postsynaptic membrane. Secondary epileptogenic foci may be induced in the same hemisphere through synapses or may spread to involve the opposite hemisphere through connecting pathways (Huether & McCance, 2011).

People who have epilepsy often experience triggers that provoke a seizure. Triggers may be individualized, such as specific music or odors, and flashing lights. General triggers include fatigue, hypoglycemia, fever, alcohol consumption, constipation, hyperventilation, and menstruation.

NURSING CARE OF THE OLDER ADULT

Epilepsy in Older Adults

For years, epilepsy was believed to be a disease that only affected children. However, by age 75, 3% of the population will have been diagnosed with epilepsy and 10% will have experienced a seizure (Epilepsy Foundation, 2012). Having a seizure disorder at this age increases the risk of falls and fractures and threatens independence. These data have important implications for nursing assessments and care.

- The most common cause of epilepsy in older adults is arteriosclerosis of the cerebrovascular system and stroke.
- The most common type of seizure in older adults is a complex partial seizure.
- Older adults tend to have longer post-seizure manifestations than do younger adults.
- Epilepsy that begins in older adults is often easier to control with antiepileptic drugs (AEDs) than that in younger people. However, some AEDs decrease the effect of statins used to treat elevated cholesterol levels.

Manifestations

Although seizures may be categorized in several different ways, the classification developed by the International League Against Epilepsy is the most useful clinically (Rudzinski & Shih, 2011). In this classification, seizures are divided into those that are partial (affect only part of the brain) and those that are generalized (affect all of the brain). An individual may have more than one type, in what are called mixed seizures.

PARTIAL SEIZURES

Partial seizures involve the activation of only a restricted part of one cerebral hemisphere. A partial seizure in which consciousness is not altered is called a simple partial seizure; one in which consciousness is impaired is called a complex partial seizure.

SIMPLE PARTIAL SEIZURES The manifestations of simple partial seizures depend on the involved area of the brain. Manifestations may include alterations in motor function, sensory signs, or autonomic or psychic symptoms. Typically, the motor portion of the cortex is affected, causing recurrent muscle contractions of the face or a contralateral part of the body, such as a finger or hand. This motor activity may stay confined to one area or spread sequentially to adjacent parts, a phenomenon known as a Jacksonian march or Jacksonian seizure. Manifestations of a simple partial seizure involving the sensory portion of the brain may include abnormal sensations or hallucinations. Disruptions in the function of the autonomic nervous system, with resulting tachycardia, flushing, hypotension, and hypertension, or psychic manifestations, such as a sense of déjà vu (a feeling that "this has happened before") or inappropriate fear or anger, may also be experienced during a simple partial seizure.

COMPLEX PARTIAL SEIZURES During a complex partial seizure, consciousness is impaired and the person may engage in repetitive, nonpurposeful activity, such as lip smacking, aimless walking, or picking at clothing. These behaviors are known as

automatisms. During the seizure, the person loses conscious contact with the environment; amnesia is common after the seizure, and several hours may elapse before the patient regains full consciousness. Complex partial seizures usually originate in the temporal lobe and may be preceded by an **aura**, a warning sign of an impending seizure, such as an unusual smell, a sense of déjà vu, or a sudden intense emotion.

GENERALIZED SEIZURES

Generalized seizures involve both hemispheres of the brain as well as deeper brain structures, such as the thalamus, basal ganglia, and upper brainstem. Consciousness is always impaired with generalized seizures. Absence and tonic–clonic seizures are the common forms of generalized seizure activity.

ABSENCE SEIZURES Absence (petit mal) seizures are characterized by a sudden brief cessation of all motor activity accompanied by a blank stare and unresponsiveness. Absence seizures are more common in children but also occur in adults. The seizure typically lasts only 5 to 10 seconds, although some may last for 30 seconds or more. Movements such as eyelid fluttering or automatisms such as lip smacking may occur during an absence seizure. Seizure activity may vary from occasional episodes to several hundred per day.

TONIC–CLONIC SEIZURES Tonic–clonic seizures (grand mal) are the most common type of seizure activity in adults. This type of seizure activity follows a typical pattern. A warning aura may precede generalized seizure activity. The aura may be a vague sense of uneasiness or an abnormal gustatory, visual, auditory, or visceral sensation (such as a metallic taste in the mouth, a smell of burning rubber, or seeing a bright light). Often, however, the seizure occurs without warning.

The seizure begins with a sudden loss of consciousness and sharp tonic muscle contractions (the tonic phase of the seizure). With the muscle contraction, air is forced out of the lungs, and the patient may cry out. Postural control is lost, and the patient falls to the floor in the opisthotonic posture (Figure 42–4A ■). Muscles are rigid, with the arms and legs extended and the jaw clenched. Urinary incontinence is common; bowel incontinence may also occur. Breathing ceases and cyanosis develops during the tonic phase of a seizure. The pupils are fixed and dilated. The tonic phase lasts an average of 15 seconds, although it may persist for up to a minute.

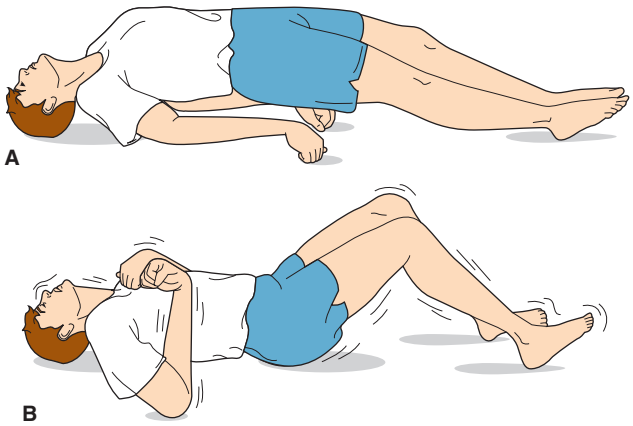

Figure 42–4 ■ Tonic–clonic seizures in grand mal seizures. A, Tonic phase. B, Clonic phase.

The clonic phase, which follows the tonic phase, is characterized by alternating contraction and relaxation of the muscles in all the extremities along with hyperventilation (Figure 42–4B). The eyes roll back, and the patient froths at the mouth. The clonic phase varies in duration and subsides gradually. The entire tonic–clonic portion of the seizure generally lasts no more than 60 to 90 seconds.

Following the clonic phase of seizure activity, the person remains unconscious and unresponsive to stimuli. This period is known as the postictal period or phase. The person is relaxed and breathes quietly; he or she regains consciousness gradually and may be confused and disoriented on waking. Headache, muscle aches, and fatigue often follow the seizure, and the person may sleep for several hours. Amnesia of the seizure is usual; the person also may not recall events just prior to the seizure activity.

Because of the lack of warning with tonic–clonic seizures, head injury, fractures, burns, or motor vehicle crashes may occur secondarily to seizure activity.

STATUS EPILEPTICUS

Status epilepticus can develop during seizure activity. In this case, the seizure activity becomes continuous, with only very short periods of calm between intense and persistent seizures. The repetitive seizures may be of any type, although they are usually generalized tonic–clonic (Huether & McCance, 2011). Repeated seizures have a cumulative effect, producing muscular contractions that can interfere with respirations. Hypoxia, acidosis, hypoglycemia, hyperthermia, and exhaustion may occur if the convulsive activity is not halted.

Status epilepticus requires immediate intervention to preserve life. Establishing and maintaining the airway is a priority. A solution of 50% dextrose is administered IV to prevent hypoglycemia. Diazepam (Valium) or lorazepam (Ativan) is given intravenously, and the dose repeated in 10 minutes if necessary to stop seizure activity. Phenytoin (Dilantin) is administered IV for longer term control of seizures. Phenobarbital may also be administered to patients in status epilepticus.

●○● INTERPROFESSIONAL CARE

Initial treatment focuses on controlling the seizure; the long-term goal is to determine the cause and prevent future seizures. Interprofessional care includes diagnostic testing, medications, and, in some cases, surgery.

DIAGNOSIS

Diagnostic testing is performed to confirm the diagnosis and to determine any treatable causes and precipitating factors. Radiologic examinations include an MRI or CT scan to determine abnormalities in the brain and a skull x-ray to identify any bony abnormalities. An electroencephalogram (EEG) helps localize any brain lesions and confirm the diagnosis. A lumbar puncture may be performed to assess spinal fluid for CNS infections (increased WBCs) or tumors (increased protein levels). Blood studies are used to assess blood count, electrolytes, blood urea, and blood glucose.

MEDICATIONS

Antiepileptic drugs (AEDs) do not cure epilepsy, but they can reduce or control most seizure activity. More than 20 drugs are available for use in the treatment of epilepsy. AEDs generally act in one of two

ways: by raising the seizure threshold or by limiting the spread of abnormal activity within the brain.

The goals of medications for epilepsy are to protect the patient from harm and to reduce or prevent seizure activity without impairing cognitive function or producing undesirable side effects. Ideally, the lowest possible dose of a single medication that will control the patient's seizures is prescribed; however, several medications must be tried before the most effective is identified, and a combination of drugs may be needed to manage the patient's seizures. Therapy is individualized, based on the type of seizure activity and the patient's response to the medication. In most patients with seizures of a single type, satisfactory control can be established with a single AED. Drugs that may be used with adults having either partial or mixed seizures include gabapentin (Neurontin), lamotrigine (Lamictal), oxcarbazepine (Trileptal), and topiramate (Topamax) (Vallerand & Sanoski, 2012). AEDs have been associated with suicidal thoughts and behavior; as a result, the U.S. Food and Drug Administration has issued a list of the warning signs. Nurses should assess for these manifestations and instruct the family to call the healthcare provider to report any unusual changes in the patient's mood or behavior. Examples of and nursing implications for AEDs are described in the accompanying Medication Administration box. Examples of drug interactions with AEDs are listed in Box 42–1.

If the patient has been seizure free for at least 3 years, withdrawal of medications may be considered, with the dose of one drug at a time reduced over weeks or months. There is no way to predict which patients can remain seizure free without medication, but if seizures reoccur, the same medications usually provide good control.

BOX 42–1 Drug Interactions with AEDs

- *Valproic acid (Depakene) and phenobarbital.* Blood levels of phenobarbital may rise significantly when valproic acid is added to the patient's medication regimen.
- *Phenobarbital and digoxin.* This combination may increase the metabolism of digoxin, resulting in decreased digoxin levels.
- *Phenobarbital and sodium warfarin (Coumadin).* Phenobarbital may decrease the absorption of sodium warfarin from the gastrointestinal tract and decrease the drug's anticoagulant response.
- *Disulfiram (Antabuse) and phenobarbital.* This combination may inhibit the metabolism of the anticonvulsant drug and increase the incidence of side effects associated with the AED.
- *Carbamazepine and oral contraceptives.* Carbamazepine decreases the effectiveness of oral contraceptives.
- *Other drugs.* Other drugs reported to interact with anticonvulsant drugs include aspirin, certain antibiotics, isoniazid, acetazolamide (Diamox), antacids, folic acid, and narcotics.

SURGERY

Resective surgery, with removal of the epileptogenic focus, is an option for patients whose seizures are not well controlled with AEDs. Candidates for this type of surgery include those who are unresponsive

MEDICATION ADMINISTRATION

Seizures

ANTIEPILEPTIC DRUGS (AEDS)

phenytoin (Dilantin)
phenobarbital
primidone (Mysoline)
carbamazepine (Tegretol)
valproic acid (Depakene)
ethosuximide (Zarontin)
clonazepam (Klonopin)
gabapentin (Neurontin)
lamotrigine (Lamictal)
tiagabine HCl (Gabitril)

AEDs are used to control chronic seizures and involuntary muscle spasms or movements characteristic of certain neurologic diseases. These drugs act in the motor cortex of the brain to reduce the spread of electrical discharges from the rapidly firing epileptic foci in this area. These agents control seizures without impairing the normal functions of the CNS. Drugs effective against one type of seizure may not be effective against another; anticonvulsant therapy must be individualized.

Nursing Responsibilities

- Monitor blood pressure, pulse, and respirations.
- Note evidence of CNS side effects, such as blurred vision, dimmed vision, slurred speech, nystagmus, or confusion. Gingival hyperplasia may be noted in patients taking phenytoin.
- Recognize that if patients are to be on prolonged therapy, they may need a diet rich in vitamin D.
- Monitor the serum calcium level as ordered; phenytoin can contribute to demineralization of bone.
- When administering anticonvulsants intravenously, monitor closely for respiratory depression and cardiovascular collapse.
- Administer gabapentin 2 hours after antacids.
- Administer tiagabine HCl with food.

Health Education for the Patient and Family

- Take the exact dosage prescribed. Do not increase, decrease, or discontinue the dosage without obtaining the primary care provider's approval; doing so may lead to convulsions.
- Avoid hazardous tasks until the drug has been regulated. AEDs may at first decrease mental alertness and cause drowsiness, headache, dizziness, and uncoordination of muscles. These effects are usually dose related and may disappear with a change of dosage or continued therapy. See Box 42–1 for drug interactions with AEDs.
- If you are taking phenytoin (Dilantin), maintain good oral hygiene: Use a soft toothbrush, massage the gums, and floss daily.
- It is very important to obtain liver function studies regularly as ordered by the primary care provider. This will help detect early signs of hepatitis and other liver problems. Report for all scheduled laboratory studies, including complete blood count, kidney and liver function studies, and drug levels.
- Carry identification indicating the type of seizures for which you are being treated.
- Do not take gabapentin 1 hour before or less than 2 hours after an antacid.
- If you are taking lamotrigine and develop a rash, tell your healthcare provider.
- Take tiagabine HCl (Gabitril) with food.

Note: Drugs identified in *italics* are among the 200 most commonly prescribed medications in the U.S.

to medical management, who have a unilateral focus, and who have impaired quality of life from seizures. The goal of surgery is to reduce the patient's uncontrollable seizures. General postoperative care for the patient with intracranial surgery follows the nursing management guidelines outlined later in the chapter. Another surgical option in clinical trials, the Responsive Neurostimulator System, uses electrodes implanted in the brain that are stimulated by low-level electrical current to suppress a seizure.

VAGAL NERVE STIMULATION THERAPY

This therapy is designed to send regular small pulses of electrical energy to the brain via the vagus nerve. A flat, round battery (about the size of a silver dollar) is implanted in the chest wall, and electrodes are threaded under the skin and wound around the vagus nerve in the neck. The battery is programmed to deliver a few seconds of electrical energy every few seconds. The therapy does not stop the seizures, but rather reduces the number and improves the patient's quality of life.

●○● NURSING CARE

Nursing care is described for patients with a seizure disorder, but the care of the person during a seizure is the same regardless of the cause. See the Case Study & Nursing Care Plan for a patient with seizures on page 1370.

Health Promotion

Health promotion activities for the patient with seizures focus on teaching to reduce the incidence of seizure activity and to promote safety. Stress the following:

- Stress the importance of follow-up care, of keeping medical appointments, and of continuing to take AEDs as prescribed even when no seizures are experienced.
- Review any state and local laws that apply to people with seizure disorders. Driving a motor vehicle is usually prohibited for 6 months to 2 years after a seizure episode. Usually, a driver's license can be reinstated or obtained after a seizure-free period and a letter from the healthcare provider.
- Know drug interactions with other prescribed drugs, over-the-counter (OTC) drugs, street drugs, and alcohol.
- Teach family members first aid for a seizure: Cushion the head, loosen anything tight around the neck, turn on the side, do not hold down.
- Teach family members to call for medical assistance if the seizures lasts for more than 5 minutes, recovery is slow, a second seizure occurs, there is difficulty breathing after recovery, or if there are signs of injury (such as bleeding from the mouth).

Assessment

See the Manifestations and Interprofessional Care sections for the assessment of the patient with seizures.

Collect the following data through the health history and physical examination:

- *Health history:* Past seizures; age when the first seizure occurred, most recent seizure; factors precipitating a seizure, any warning signs (aura); prophylactic anticonvulsant therapy; and specific concerns the patient may have about the seizures.
- *Physical assessment:* Important data used in determining an accurate diagnosis describes manifestations obtained from nursing assessments before, during, and after a seizure. (Table 42–3 lists nursing assessments with rationale.)

Priorities of Care

Collaborating with the interprofessional team to ensure adequate treatment of the underlying process while providing care that

TABLE 42–3 Nursing Assessments Before, During, and After a Seizure

Assessment	Rationale
What was the patient's level of consciousness? If consciousness was lost, at what point?	Indicates area of brain involved and type of seizure.
What was the patient doing just before the attack?	May suggest precipitating factors.
In what part of the body did the seizure start?	May indicate the site of seizure activity in the brain tissue; for example, if jerking movements were first observed in the right hand, the seizure focus may be in the left motor cortex.
Was there an epileptic cry?	Usually indicates the tonic stage of a generalized tonic–clonic seizure.
Were any automatisms such as eyelid fluttering, chewing, lip smacking, or swallowing observed?	Often seen in complex, partial, and absence seizures.
How long did movements last? Did the location or character change (tonic to clonic)? Did movements involve both sides of the body or just one?	Indicates areas in which focal activity originated.
Did the head and/or eyes turn to one side and, if so, which side?	Helps localize the focus of the seizure. During the seizure, the head and eyes typically will turn away from the side of the epileptogenic focus.
Were there changes in pupillary reactions?	Indicates involvement of the autonomic nervous system.
If the patient fell, was the head hit?	Skull x-ray studies may be needed to rule out subdural hematoma or fracture.
Was there foaming or frothing from the mouth?	Usually indicates a tonic–clonic seizure.
Was there urinary or bowel incontinence?	Usually indicates a tonic–clonic seizure.

Evidence for Nursing Care

The Patient with Seizures

Selected resources that nurses may find helpful when planning evidence-based nursing care follow.

- Bingham, E. (2011). Care of older people with epilepsy. *Nursing Older People, 23*(1), 24–28.
- Queally, C., & Lailey, C. (2012). Care of the person with epilepsy in the hospital environment—getting it right. *British Journal of Neuroscience Nursing, 8*(1), 14–20.

supports the physical and psychologic responses to the disorder is a priority of nursing care.

Diagnoses, Outcomes, and Interventions

Nursing care of patients with seizures focuses on providing care during and immediately after the seizure and on patient/family teaching. The patient with seizures has a wide variety of responses to actual or potential changes in health status; interventions discussed in this section focus on facilitating physical and psychologic comfort and safety.

Risk for Ineffective Airway Clearance

During a seizure, the tongue may fall back and obstruct the airway, the gag reflex may be depressed, and secretions may pool at the back of the throat. These may put the patient at risk for an obstructed airway. Most seizures occur in the home or community; therefore, teach these interventions to the patient's family:

Expected Outcome: Adequate airway clearance will be maintained through the use of protective interventions to maintain patent airway.

- Provide interventions to maintain a patent airway:
  - Loosen clothing around the neck.
  - Turn on the side.
  - Do not force anything into the mouth.
  - If prescribed and available, administer oxygen by mask.

  Although it was at one time believed that it was necessary to place a padded tongue blade in the patient's mouth during a seizure, this is no longer recommended; an improperly placed tongue blade can obstruct the airway. Turning the patient on the side allows secretions to drain from the mouth.
- Teach family members or significant others how to care for the patient during a seizure to prevent airway obstruction. *Family members are often the only people present to provide this emergency intervention.*

Anxiety

The patient with a seizure disorder is understandably anxious about the future, with questions about ability to go to school, work, have a family, and drive a car. Feelings of embarrassment about having a seizure in public and rejection by others are common and also increase the patient's anxiety.

Expected Outcome: Patient will be able to control anxiety as evidenced by verbalized decrease in subjective distress.

CASE STUDY & NURSING CARE PLAN A Patient with a Seizure Disorder

Janet Carlson is a 19-year-old college student who lives with her parents and one younger sister. Although Janet had seizures while she was in grade school, they have been controlled with medication. However, she had a tonic–clonic seizure yesterday and immediately made an appointment with her family physician. She is currently taking phenytoin (Dilantin) 300 mg/day as a maintenance medication to prevent seizures.

ASSESSMENT

Evita Farias, RN, completes a health history for Ms. Carlson. During the history, she tells Ms. Farias that she has been under stress because of difficulties in completing her course requirements this semester. She has not been sleeping as many hours per night, and sometimes she forgets to take her medication. Janet's serum phenytoin level is 8 mg/mL. Therapeutic level is 10 to 20 mg/mL.

DIAGNOSES

- *Risk for Injury* related to recurrence of generalized tonic–clonic seizure activity and low serum phenytoin levels
- *Deficient Knowledge* of activities that may trigger seizure occurrence, the effect of stress on seizures, and medication information

EXPECTED OUTCOMES

- Patient will verbalize precipitating and triggering factors related to the onset of seizures.
- Patient will verbalize the relationship between emotional and physical stress and seizures.
- Patient will verbalize the importance of taking AEDs.

PLANNING AND IMPLEMENTATION

- Teach patient and her family the following:
  - Current information about seizures
  - Care during and after a seizure
  - Medication protocols
  - Factors and activities that can trigger seizures
  - The importance of follow-up care.
- Refer patient and her family to a local epilepsy support group.
- Recommend that she purchase and wear a medical alert bracelet.

EVALUATION

Ms. Carlson is instructed to continue taking Dilantin 300 mg/day. She states the importance of nutrition, rest, and measures to reduce stress. She also discusses the importance of maintaining the proper blood levels of her medication, stating that too little or too much of the medication could cause problems. Ms. Carlson recognizes that the seizures had recurred during a busy time in school during which she had forgotten to take her medication. She is now wearing a medical alert bracelet. Ms. Farias provides the Carlsons with the telephone number of the Epilepsy Foundation of America.

Clinical Reasoning in Patient Care

1. If you were Ms. Carlson's nurse, would your teaching differ if she were living alone? If so, how?
2. Ms. Carlson tells you that although she knows she should not drive a car, she often drives her friend to work. How would you approach this problem?
3. Ms. Carlson states "it's embarrassing to wear a medical alert bracelet." How would you respond, and what recommendation(s) would you make?

See Evaluating Your Response in Appendix B.

- Provide support by explaining that concerns are normal. *It is important to be sensitive to the effect of seizures on the patient's self-concept and body image; alterations in these areas not only increase anxiety but also cause withdrawal from socialization with others. Demonstrating acceptance of the patient's concerns allows further discussion.*
- Help identify safe leisure activities. *Worrying about being hurt if a seizure occurs may cause withdrawal from social activities that are pleasurable.*
- Provide information about sources and support groups. *Sharing information with other people with similar health problems allows for a more realistic viewpoint; accurate information can clear up misconceptions that cause anxiety.*
- Provide accurate information about hiring practices and legal limitations on driving or operating heavy or dangerous machinery. *Accurate information decreases anxiety about the unknown. The Americans with Disabilities Act prohibits discrimination; however, there are legal limitations on driving until the person is proven free of seizures.*

Readiness for Enhanced Knowledge

Women with epilepsy require specific knowledge related to their menstrual cycle, contraception, and childbearing.

Expected Outcome: Patient will explain how to incorporate new health regimen into lifestyle.

- Encourage discussion with the woman's healthcare provider about the increased probability of seizures at the time of menses. *Medications to prevent seizures may require dosage adjustments, and avoidance of other triggers is important.*
- Discuss the effects of AEDS. *AEDs decrease the effectiveness of oral contraceptives (decreased effectiveness is indicated by breakthrough bleeding); other forms of birth control (such as intrauterine devices) may be necessary. In addition, some AEDs can cause birth defects if pregnancy does occur.*

Continuity of Care

Teaching follows a systematic assessment of the needs of both the patient and family. Include family members so that they can learn seizure management, including the care and observations necessary before and during a seizure. Stress the importance of safety and keeping the airway patent during a seizure.

Help both the patient and family adjust to a diagnosis of epilepsy. Address the following topics:

- The importance of wearing a medical alert band or carrying a medical alert card at all times
- Avoiding alcoholic beverages and limiting coffee intake
- Taking showers versus tub baths, because of safety issues during a generalized seizure
- Factors that may trigger a seizure, and paying attention to an aura if one occurs
- Helpful resources, including the American Epilepsy Society and the Epilepsy Foundation.

THE PATIENT WITH A STROKE

A **stroke** (cerebral vascular accident [CVA], or brain attack) is an emergency condition in which neurologic deficits result from a sudden decrease in blood flow to a localized area of the brain. Strokes may be ischemic (when blood supply to a part of the brain is suddenly interrupted by a thrombus, embolus, or blood vessel stenosis) or hemorrhagic (when a blood vessel ruptures, spilling blood into spaces surrounding neurons). The neurologic deficits caused by ischemia and the resultant necrosis of cells in the brain vary according to the area of the brain involved, the size of the affected area, and the length of time blood flow is decreased or stopped. A major loss of blood supply to the brain can cause severe disability or death. When the duration of decreased blood flow is short and the anatomic area involved is small, the person may not be aware that damage has been done.

Incidence and Prevalence

On average, someone in the United States has a stroke every 40 seconds and dies of a stroke every 4 minutes. Stroke is the fourth leading cause of death and the leading cause of adult disability in North America, where 795,000 people suffer a stroke each year. Of those, 160,000 die and many patients who survive are left with some type of functional impairment (American Heart Association [AHA], 2012). The risk doubles for every decade after age 55, and two-thirds of all strokes occur in people over the age of 65. As the population of baby boomers reaches and exceeds this age, stroke will be even more significant to healthcare providers.

Risk Factors

Certain diseases, lifestyle habits, and ethnic backgrounds increase the risk of a stroke. Risk factors include hypertension, sickle cell disease, atrial fibrillation, diabetes mellitus, hyperlipidemia, sleep apnea, smoking, and substance and alcohol abuse. Other risk factors include a previous stroke or transient ischemic attack (TIA or *little stroke*), family history of stroke, obesity, a sedentary lifestyle, and recent viral and bacterial infections. Risk factors specific to women are oral contraceptive use, pregnancy, childbirth, menopause, migraine headaches with aura, autoimmune disorders (such as diabetes and lupus), hormone replacement therapy, and clotting disorders. Blacks have about a one-third higher risk of having a stroke as do Whites. Hispanics have a higher incidence of ischemic stroke at an earlier age and also have a higher incidence of intracerebral hemorrhage and subarachnoid hemorrhage (AHA, 2012).

Risk factors are classified as unmodifiable (age, gender, race, and heredity) and modifiable (all disease and lifestyle risks). Modifiable risk factors can be altered by prevention. The National Institute of Neurological Disorders and Stroke (2012a) recommends the following preventive measures for the most important treatable conditions that increase the risk of stroke:

- Hypertension: *Treat it*. Eat a balanced diet, maintain a healthy weight, and exercise to reduce blood pressure.
- Cigarette smoking: *Quit it*. Medical help is available.
- Heart disease: *Manage it*. Healthcare providers can treat heart disease and prescribe medications to help prevent the formation of clots. For those over the age of 50, discuss aspirin therapy with your provider.
- Diabetes: *Control it*. Treatment can delay complications that increase the risk of stroke.
- TIAs: *Seek help.* TIAs should never be ignored and can be treated.

Pathophysiology

The brain, which makes up only 2% of total body weight, receives approximately 20% of the cardiac output each minute (about 750 mL) and accounts for 20% of the body's oxygen consumption. Cerebral blood flow, especially in the deep cerebral vessels, is largely self-regulated by the brain to meet metabolic needs. This self-regulation (also called *autoregulation*) allows the brain to maintain a constant blood flow despite changes in systemic blood pressure. However, autoregulation is not effective when systemic blood pressure falls below 50 mmHg or rises above 160 mmHg. In the latter case, the increased systemic pressure causes an increase in cerebral blood flow with resultant overdistention of cerebral vessels. Cerebral blood flow also increases in response to increased carbon dioxide concentrations, increased hydrogen ion concentrations, and decreased oxygen concentrations.

When blood flow to and oxygenation of cerebral neurons are decreased or interrupted from a stroke, pathophysiologic changes at the cellular level take place in 4 to 5 minutes. Each minute during a stroke, 2 million brain cells die. The changes that take place are the result of a chain of chemical reactions called the ischemic cascade (Huether & McCance, 2011). This process occurs in three stages: primary cell death, secondary cell death, and inflammation and immune response.

Primary cell death begins as blood supply is cut off to a part of the brain, resulting in ischemia in the core area of involved brain tissue. Anoxia and lack of nutrients to the cells affect the mitochondria of the cells, essentially depriving the cells of their energy source. As the mitochondria break down, they release oxygen-free radicals (such as glutamate) into the cytoplasm, destroying other intercellular structures. Cell membrane channels open, allowing calcium, sodium, and potassium to enter the cells. At the same time, the affected cells release excitatory amino acids into the intracellular spaces. Homeostasis is lost and water enters the cell (called *cytoxic edema*) to the point that the cells burst and quickly become infarcted and necrotic. This process begins in 4 to 5 minutes and may last as long as 2 to 3 hours.

Secondary cell death ensues from exposure to excessive amounts of glutamate, nitric oxide, free radicals, and excitatory amino acids released from necrotic cells. These cells, surrounding the area of initial damage, have only enough blood supply to remain alive for a few hours. If blood supply is restored to these cells within 2 to 3 hours, some cells can live and become functional. The area of living cells in and around the area of dead and necrotic cells is called the penumbra.

As secondary cell death is taking place, the body's immune system does further damage through an inflammatory reaction mediated by the vascular system. The initial damage attracts leukocytes to the damaged area; these white cells penetrate the endothelial wall, move through the blood–brain barrier, and invade the substance of the brain, causing further injury and cell death. Monocytes and macrophages release inflammatory chemicals (cytokines, interleukins, and tissue necrosis factor) at the site of injury to inhibit the release of natural tissue plasminogen activator and inactivate anticlotting factors. These effects make it more difficult for the body to dissolve a clot.

A stroke is characterized by a gradual or rapid onset of neurologic deficits due to compromised cerebral blood flow. The neurologic deficits that occur as a result of a stroke can often be used to identify its location. Because the motor pathways cross at the junction of the medulla and spinal cord (decussation), strokes lead to loss or impairment of sensorimotor functions on the side of the body *opposite* the side of the brain that is damaged. This effect, known as a **contralateral deficit**, means that a stroke in the right hemisphere of the brain is manifested by deficits in the left side of the body (and vice versa).

ISCHEMIC STROKE

Ischemic strokes account for 87% of all strokes (Hickey, 2013). The blockage may result from a blood clot (either as a thrombus or an emboli) or from stenosis of a vessel resulting from a buildup of plaque. Plaque may cause stenosis in large blood vessels or small blood vessels. Large vessel blockage usually is the result of thrombi. Small vessel strokes are small to very small infarcts in the deep, noncortical areas of the brain or the brainstem. Cardiogenic embolic strokes are caused by a blood clot (most commonly from atrial fibrillation) moving through cerebral blood vessels until the vessel is too small to allow further movement.

TRANSIENT ISCHEMIC ATTACK A **transient ischemic attack (TIA)**, sometimes called a mini-stroke, is a brief period of localized cerebral ischemia that causes neurologic deficits lasting for less than 24 hours (Hickey, 2013). TIAs are often warning signals of an ischemic thrombotic stroke. One or many TIAs may precede a stroke, with the time between the TIA and a stroke ranging from hours to months. The etiology of TIA includes inflammatory artery disorders, sickle cell disease, atherosclerotic changes in carotid and cerebral arteries, thrombosis, and emboli. Neurologic manifestations of a TIA vary according to the location and size of the cerebral vessel involved and have a sudden onset. Commonly occurring deficits include contralateral numbness or weakness of the leg, hand, forearm, and corner of the mouth; aphasia; and visual disturbances such as blurring. The patient may also experience a visual disturbance called amaurosis fugax (a fleeting blindness of one eye, described as a shade coming down over vision in the affected eye).

LARGE VESSEL (THROMBOTIC) STROKE A thrombotic stroke is caused by occlusion of a large cerebral vessel by a thrombus (blood clot). Thrombotic strokes most often occur in older people who are resting or sleeping. The blood pressure is lower during sleep, so there is less pressure to push the blood through an already narrowed arterial lumen, and ischemia may result.

Thrombi tend to form in large arteries that bifurcate and have narrowed lumens as a result of deposits of atherosclerotic plaque. The plaque involves the intima of the arteries, causing the internal elastic lamina to become thin and frayed with exposure of underlying connective tissue. This structural change causes platelets to adhere to the rough surface and release the enzyme adenosine diphosphate. This enzyme initiates the clotting sequence, and a thrombus forms. A thrombus may remain in place and continue to enlarge, completely occluding the lumen of the vessel, or a part of it may break off and become an embolus. These strokes commonly affect a single cerebral artery supplying the cerebral cortex, causing aphasia, neglect syndrome, and/or visual field defects.

SMALL VESSEL STROKE (LACUNAR INFARCT) Thrombotic strokes affecting the smaller cerebral vessels are called lacunar (small vessel) strokes, because the infarcted areas slough off, leaving a small cavity or "lake" in the brain tissue. They occur in the deeper parts of the brain or the brainstem from occlusion of small branches of

large cerebral arteries, most often the middle cerebral and posterior cerebral arteries. Manifestations include motor hemiplegia, sensory hemiplegia, and dysarthria.

CARDIOGENIC EMBOLIC STROKE A cardiogenic embolic stroke results when a blood clot from atrial fibrillation, ventricular thrombi, myocardial infarction, congestive heart disease, or atherosclerotic plaque (and other sources) enters the circulatory system and becomes lodged in a cerebral vessel too narrow to permit further movement. The blood vessel is then occluded. The most frequent sites of cerebral emboli are at bifurcations of vessels, particularly those of the middle cerebral artery.

HEMORRHAGIC STROKE

A hemorrhagic stroke, or intracranial hemorrhage, occurs when a cerebral blood vessel ruptures. There are two types of hemorrhagic strokes: intracerebral hemorrhage and subarachnoid hemorrhage. An intracerebral hemorrhage often occurs in older adults with sustained increase in systolic-diastolic blood pressure. A subarachnoid hemorrhage is commonly seen in younger people. Intracranial hemorrhage usually occurs suddenly, often when the affected person is engaged in some activity. Although hypertension is the most common cause, a variety of factors may contribute to a hemorrhagic stroke, including rupture of a brittle plaque-encrusted artery wall, ruptured intracranial aneurysms, trauma, erosion of blood vessels by tumors, arteriovenous malformations, anticoagulant therapy, and blood disorders. Of all forms of stroke, this form is most often fatal. (Hemorrhagic strokes that result from ruptured cerebral aneurysm or an arteriovenous malformation are discussed in the next sections of the chapter.)

As a result of rupture of the blood vessel, blood enters the brain tissue, the cerebral ventricles, or the subarachnoid space, compressing adjacent tissues and causing blood vessel spasm and cerebral edema. Blood in the ventricles or subarachnoid space irritates the meninges and brain tissue, causing an inflammatory reaction and impairing absorption and circulation of cerebrospinal fluid (CSF). The onset of manifestations from a hemorrhagic stroke is rapid. Manifestations depend on the location of the hemorrhage, but may include vomiting, headache, seizures, hemiplegia, and loss of consciousness. Pressure on brain tissue from IICP may cause coma and death.

Manifestations

Manifestations of a stroke vary according to the cerebral artery involved and the area of the brain affected. Women with stroke are more likely to report nontraditional manifestations (especially disorientation, confusion, or loss of consciousness) than men. Manifestations are always sudden in onset, focal, and usually one sided. The various deficits associated with involvement of a specific cerebral artery are collectively referred to as stroke syndromes, although the deficits often overlap, as shown in the accompanying Manifestations box.

Complications

Typical complications include sensory-perceptual deficits, cognitive and behavioral changes, communication disorders, motor deficits, and elimination disorders. These may be transient or permanent, depending on the degree of ischemia and necrosis as well as time of treatment. As a result of the neurologic deficits, the patient with a stroke has complications that involve many different body systems (see the accompanying Manifestations and Complications box). The disabilities resulting from a stroke often cause serious alterations in functional health status.

MANIFESTATIONS OF A STROKE BY INVOLVED CEREBRAL VESSEL

INTERNAL CAROTID ARTERY
- Contralateral paralysis of the arm, leg, and face
- Contralateral sensory deficits of the arm, leg, and face
- If the dominant hemisphere is involved: aphasia
- If the nondominant hemisphere is involved: apraxia, agnosia, unilateral neglect
- Homonymous hemianopia (see Figure 42–5 ■)

MIDDLE CEREBRAL ARTERY
- Drowsiness, stupor, coma
- Contralateral hemiplegia of the arm and face
- Contralateral sensory deficits of the arm and face
- Global aphasia (if dominant hemisphere involved)
- Homonymous hemianopia

ANTERIOR CEREBRAL ARTERY
- Contralateral weakness or paralysis of the foot and leg
- Contralateral sensory loss of the toes, foot, and leg
- Loss of ability to make decisions or act voluntarily
- Urinary incontinence

VERTEBRAL ARTERY
- Pain in face, nose, or eye
- Numbness and weakness of the face on involved side
- Problems with gait
- Dysphagia

SENSORY-PERCEPTUAL DEFICITS

A stroke may involve pathologic changes in neurologic pathways that alter the ability to integrate, interpret, and attend to sensory data. The patient may experience deficits in vision, hearing, equilibrium, taste, and sense of smell. The ability to perceive vibration, pain, warmth, cold, and pressure may be impaired, as may proprioception

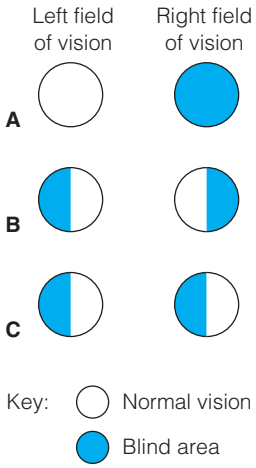

Figure 42–5 ■ Abnormal visual fields. A, Normal left field of vision with loss of vision in right field. B, Loss of vision in temporal half of both fields (bitemporal hemianopia). C, Loss of vision in nasal field of right eye and temporal field of left eye (homonymous hemianopia).

MANIFESTATIONS AND COMPLICATIONS OF STROKE BY BODY SYSTEM

INTEGUMENT
- Decubitus ulcers

NEUROLOGIC
- Hyperthermia
- Neglect syndrome
- Seizures
- Agnosia
- Communication deficits: expressive aphasia, receptive aphasia, global aphasia, agraphia
- Visual deficits: homonymous hemianopia, diplopia, decreased acuity
- Cognitive changes: memory loss, short attention span, distractibility, poor judgment, poor problem solving, disorientation
- Behavioral changes: emotional lability, loss of social inhibitions, fear, hostility, anger, depression
- IICP
- Alterations in consciousness
- Sensory loss to touch, pain, heat, cold, pressure

RESPIRATORY
- Respiratory center damage
- Airway obstruction
- Decreased ability to cough

GASTROINTESTINAL
- Dysphagia
- Constipation, stool impaction

GENITOURINARY
- Incontinence, frequency, urgency
- Urinary retention
- Renal calculi

MUSCULOSKELETAL
- Hemiplegia
- Contractures
- Bony ankylosis
- Disuse atrophy
- Dysarthria

(the body's sense of its position). The loss of these sensory abilities increases the risk for injury. Deficits may include the following:

- **Hemianopia**: The loss of half of the visual field of one or both eyes; when the same half is missing in each eye, the condition is called homonymous hemianopia (refer to Figure 42–5C).
- **Agnosia**: The inability to recognize one or more subjects that were previously familiar; agnosia may be visual, tactile, or auditory.
- **Apraxia**: The inability to carry out some motor pattern (e.g., drawing a figure, getting dressed) even when strength and coordination are adequate.

Another form of sensory-perceptual deficit is the **neglect syndrome** (or unilateral neglect), in which the patient has a disorder of attention. In this syndrome, the person cannot integrate and use perceptions from the affected side of the body or from the environment on the affected side, and ignores that part. In severe cases, the patient may even deny the paralysis. This deficit is more common following a stroke of the right hemisphere where damage to the parietal lobe (a center for mediation of directed attention) results in perceptual deficits.

Pain and discomfort may accompany a stroke, with the patient experiencing acute pain, numbness, or strange sensations. Although not common, damage to the thalamus may cause central stroke pain or central pain syndrome (CPS). The pain in this syndrome includes hot and cold, burning, tingling, and sharp stabbing pain, most often in the extremities. It is worsened by movement and temperature changes. The painful sensations are not relieved by pain medications, nor are there any specific treatments.

COGNITIVE AND BEHAVIORAL CHANGES

A change in consciousness, ranging from mild confusion to coma, is a common manifestation of a stroke. It may result from tissue damage following ischemia or hemorrhage involving either the carotid or vertebral arteries. Altered consciousness may also be the result of cerebral edema or IICP.

Behavioral changes include emotional lability (in which the patient may laugh or cry inappropriately), loss of self-control (manifested by behavior such as swearing or refusing to wear clothing), and decreased tolerance for stress (resulting in anger or depression). Intellectual changes may include memory loss, decreased attention span, poor judgment, and an inability to think abstractly.

COMMUNICATION DISORDERS

Communication is a complex process, involving motor functions, speech, language, memory, reasoning, and emotions. Communication disorders are usually the result of a stroke affecting the dominant hemisphere. The left hemisphere is dominant in about 95% of right-handed people and 70% of left-handed people (Huether & McCance, 2011). Many different impairments may occur, and most are partial. Disorders of communication affect both speech (the mechanical act of articulating language through the spoken word) and language (the vocal or written formulation of ideas to communicate thoughts and feelings). Language involves oral and written expression and auditory and reading comprehension. Among these disorders are the following:

- **Aphasia**: The inability to use or understand language; aphasia may be expressive, receptive, or mixed (global).
- *Expressive aphasia:* A motor speech problem in which one can understand what is being said but can respond verbally only in short phrases; also called Broca's aphasia.
- *Receptive aphasia:* A sensory speech problem in which one cannot understand the spoken (and often written) word. Speech may be fluent but with inappropriate content; also called Wernicke's aphasia.
- *Mixed or global aphasia:* Language dysfunction in both understanding and expression.
- *Dysarthria:* Any disturbance in muscular control of speech.

MOTOR DEFICITS

Body movement results from a complex interaction between the brain, spinal cord, and peripheral nerves. The motor areas of the cerebral cortex, the basal ganglia, and the cerebellum initiate voluntary movement by sending messages to the spinal cord, which then transmits the messages to the peripheral nerves. A stroke may interrupt the CNS component of this relay system and produce effects in the contralateral side ranging from mild weakness to severe limitation of any kind of movement.

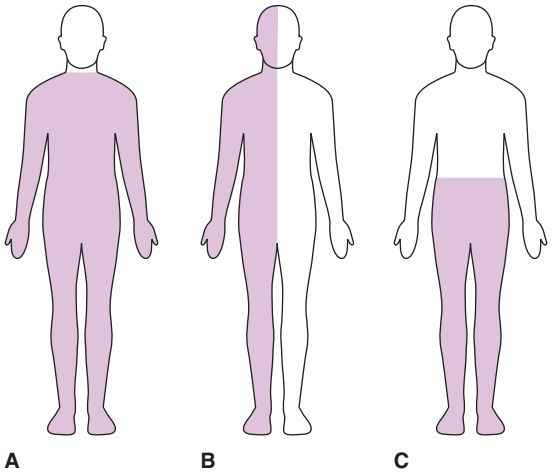

Figure 42–6 ■ Types of paralysis. A, Quadriplegia is complete or partial paralysis of the upper extremities and complete paralysis of the lower part of the body. B, Hemiplegia is paralysis of one-half of the body when it is divided along the median sagittal plane. C, Paraplegia is paralysis of the lower part of the body.

Depending on the area of the brain involved, strokes may cause weakness, paralysis, and/or spasticity. The deficits include the following:

- **Hemiplegia**: Paralysis of the left or right half of the body (Figure 42–6 ■).
- **Hemiparesis**: Weakness of the left or right half of the body.
- *Flaccidity:* Absence of muscle tone (hypotonia).
- *Spasticity:* Increased muscle tone (hypertonia), usually with some degree of weakness. The flexor muscles are usually more strongly affected in the upper extremities, and the extensor muscles are more strongly affected in the lower extremities.

When the corticospinal tract is involved, the affected arm and leg almost always are initially flaccid and then become spastic within 6 to 8 weeks. Spasticity often causes characteristic body positioning: adduction of the shoulder, pronation of the forearm, flexion of the fingers, and extension of the hip and knee. There is often foot drop, outward rotation of the leg, and dependent edema in the involved extremities.

The motor deficits may result in altered mobility, further impairing body function. The complications of immobility involve multiple body systems and include orthostatic hypotension, increased thrombus formation, decreased cardiac output, impaired respiratory function, osteoporosis, formation of renal calculi, contractures, and decubitus ulcer formation.

ELIMINATION DISORDERS

Disorders of bladder and bowel elimination are common. A stroke may cause partial loss of the sensations that trigger bladder elimination, resulting in urinary frequency, urgency, or incontinence. Control of urination may be altered as a result of cognitive deficits. Changes in bowel elimination are common, resulting from changes in LOC, immobility, and dehydration.

●○● INTERPROFESSIONAL CARE

The type of treatment a patient with a stroke receives depends on the stage of the disease. In general there are three treatment stages: stroke prevention, acute care immediately after a stroke, and rehabilitation after a stroke. The patient with an acute stroke may receive medical and/or surgical treatment. The focus in the acute care phase is on diagnosing the type and cause of the stroke, supporting cerebral circulation, and controlling or preventing further deficits. The goals of stroke care are to minimize brain injury and maximize patient recovery. The focus of acute care has shifted from the nearest hospital to certified stroke centers (if possible) where patients with a stroke can be provided appropriate care from entrance to the emergency department to discharge following rehabilitation.

DIAGNOSIS

Diagnosis begins with a complete history and careful physical assessment, including a thorough neurologic examination. The time of the onset of stroke manifestations is a critical part of assessment. The National Institutes of Health (NIH) Stroke Scale (2003) is a clinical evaluation tool widely used to assess neurologic outcome and degree of recovery. Part of the scale is illustrated in Table 42–4. The tool measures LOC, vision, facial paralysis, motor abilities, ataxia, sensation, language, and attention. The entire scale may be accessed at the website for the National Institute of Neurological Disorders and Stroke.

Imaging tests are used to identify an increased risk for a stroke or to identify pathophysiologic changes after a stroke has occurred. Computed tomography (CT) is the first imaging technique used to demonstrate the presence of hemorrhage, tumors, aneurysm, ischemia, edema, and tissue necrosis. A CT scan can also demonstrate a shift in intracranial contents and is useful in distinguishing the type of stroke (e.g., a hemorrhagic stroke results in an increase in density). Cerebral infarctions usually are visible with a CT scan 6 to 8 hours after a stroke; hemorrhage is visible immediately. Other imaging tests that may be used for diagnosis include a cerebral arteriogram, a transcranial ultrasound Doppler, an MRI, an MRA, a PET, and a SPECT. A perfusion- and diffusion-weighted imaging (DWI) test can be used to identify cerebral ischemia immediately after onset of the stroke and also identify areas of possibly reversible damage (the penumbra). In addition to imaging tests, a blood test has recently been approved to screen for recurrent stroke risk. The PLAC test scans the blood for high levels of lipoprotein-associated phospholipase A2 (Lp-Pla2), found to be more common in people who have had strokes.

A lumbar puncture may be performed to obtain CSF for examination if there is no danger of IICP. An ischemic stroke may elevate CSF pressure; after a hemorrhagic stroke blood may be seen in the CSF.

MEDICATIONS

Medications are administered to prevent a stroke in patients with TIAs or a previous stroke, and to treat the patient during the acute phase of a stroke. Treatment for IICP was discussed in a previous section of the chapter.

PREVENTION Antiplatelet agents are often used to treat patients with TIAs or who have had a previous stroke. Platelets are concentrated in high blood flow arteries, where they adhere to endothelial tissue damaged by atherosclerosis and occlude the vessel. The drugs used to prevent clot formation and blood vessel occlusion include aspirin, clopidogrel (Plavix), dipyridamole (Persantine), and ticlopidine (Ticlid). Daily low-dose aspirin reduces TIA occurrence and stroke risk by interfering with platelet aggregation.

TABLE 42–4 NIH Stroke Scale: Assessment of Level of Consciousness

Instructions	Scale Definition	Score*
1a. Level of Consciousness: The investigator must choose a response, even if a full evaluation is prevented by such obstacles as an endotracheal tube, language barrier, orotracheal trauma/bandages. A 3 is scored only if the patient makes no movement (other than reflexive posturing) in response to noxious stimulation.	0 = Alert, keenly responsive. 1 = Not alert, but arousable by minor stimulation to obey, answer, or respond. 2 = Not alert, requires repeated stimulation to attend, or is obtunded and requires strong or painful stimulation to make movements (not stereotyped). 3 = Responds only with reflex motor or autonomic effects or totally unresponsive, flaccid, movements are dysreflexic.	_____
1b. LOC Questions: The patient is asked the month and his or her age. The answer must be correct. There is no partial credit for being close. Aphasic and stuporous patients who do not comprehend the questions will score 2. Patients unable to speak because of endotracheal intubation, orotracheal trauma, severe dysarthria from any cause, language barrier, or any other problem not secondary to aphasia are given a 1. It is important that only the initial answer be graded and that the examiner not help the patient with verbal or nonverbal cues.	0 = Answers both questions correctly. 1 = Answers one question correctly. 2 = Answers neither question correctly.	_____
1c. LOC Commands: The patient is asked to open and close the eyes and then to grip and release the nonparetic hand. Substitute another one-step command if the hands cannot be used. Credit is given if an unequivocal attempt is made but not completed due to weakness. If the patient does not respond to command, the task should be demonstrated to him or her (pantomime) and score the results (i.e., follows none, one, or two commands). Patients with trauma, amputation, or other physical impediments should be given suitable one-step commands. Only the first attempt is scored.	0 = Performs both tasks correctly. 1 = Performs one task correctly. 2 = Performs neither task correctly.	_____

**Note:* A lower score indicates better function.

Ticlopidine (Ticlid) is a platelet-aggregation inhibitor that has shown reduction in thrombotic stroke risk.

ACUTE STROKE Medications are used to treat the patient during the acute phase of an ischemic stroke to prevent further thrombosis formation, increase cerebral blood flow, and protect cerebral neurons. The type of medication used varies according to the type of stroke.

Fibrinolytic therapy, using a tissue plasminogen activator such as recombinant tissue-type plasminogen activator alteplase (tPA), sometimes given concurrently with an anticoagulant, is used to treat ischemic stroke. The drug converts plasminogen to plasmin, resulting in fibrinolysis of the clot. To be effective, it must be given IV within 3 hours of the onset of manifestations, after confirming (with a CT scan) that the patient has not had a hemorrhagic stroke. However, a European study found that tPA administered between 3 and 4.5 hours after the onset of manifestations significantly improved clinical outcomes, although it also increased the risk of intracranial hemorrhage. Antithrombotic drugs, which inhibit the platelet phase of clot formation, have been used as a preventive measure for patients at risk for ischemic stroke. Both aspirin and dipyridamole have been used for this purpose. These drugs are sometimes also used in combination with other drugs during acute treatment. Antiplatelet agents are contraindicated in patients with a hemorrhagic stroke.

Anticoagulant drug therapy (refer to Chapter 30) may be ordered for an ischemic stroke. The most commonly used anticoagulants are warfarin (Coumadin), heparin, and enoxaparin (Lovenox). Anticoagulants do not dissolve an existing clot but rather prevent further extension of the clot and formation of new clots. Sodium heparin may be given subcutaneously or by continuous IV drip, or warfarin sodium (Coumadin) may be given orally. It is recommended that the use of antifactor Xa be used to monitor blood coagulation (Hickey, 2013).

SAFETY ALERT

Anticoagulants are never administered to a patient with a hemorrhagic stroke.

Management of hypertension is controversial but if the patient is eligible for fibrinolytic therapy, blood pressure control is essential to decrease the risk of bleeding. If the blood pressure is sustained at systolic levels >185 mmHg systolic or diastolic levels >110 mmHg diastolic, the patient cannot be treated with IV tPA.

TREATMENTS

The treatments used in the management of a stroke include surgery and rehabilitation.

SURGERY Surgery may be performed to prevent the occurrence of a stroke, to restore blood flow when a stroke has already occurred, or to repair vascular damage or malformations. In people who have had TIAs or are in danger of having another stroke, a carotid endarterectomy at the carotid artery bifurcation may be performed

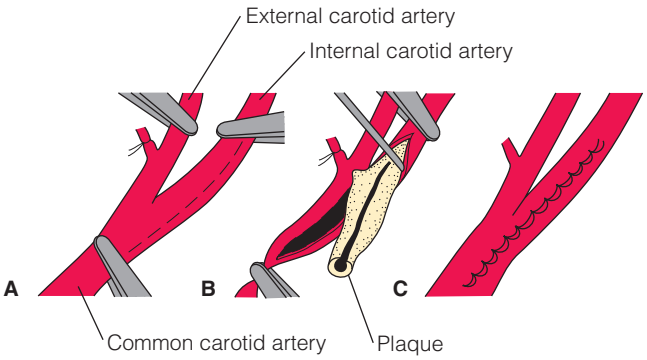

Figure 42–7 ■ Carotid endarterectomy. A, The occluded area is clamped off and an incision is made in the artery. B, Plaque is removed from the inner layer of the artery. C, To restore blood flow through the artery, the artery is sutured, or a graft is completed.

to remove atherosclerotic plaque (Figure 42–7 ■). Nursing care for the patient in the initial postoperative period following a carotid endarterectomy is described in the accompanying box.

When an occluded or stenotic vessel is not directly accessible, an extracranial-intracranial bypass may be performed through bypass of the internal carotid, middle cerebral, or vertebral arteries. The procedure reestablishes blood flow to the affected area of the brain. A carotid angioplasty with stenting is an option for treating cerebral stenosis. During the procedure an angioplasty balloon catheter is inserted through an artery in the patient's arm or leg. Under fluoroscopy, the catheter is advanced to the area of carotid artery stenosis and a small filter is inserted to catch any clots or pieces of debris that might break loose. The balloon is then inflated to widen the artery, followed by insertion of a permanent stent in the area of the angioplasty.

Other treatments include suctioning the clot out of the artery or threading a wire through the clot and pulling it out. A noninvasive method of improving recovery from a stroke, called noninvasive transcranial direct current stimulation (TDCS), has been shown to improve motor outcomes and is under study.

REHABILITATION Various types of interprofessional therapy are necessary for post-stroke rehabilitation. These are most often provided in a setting dedicated to rehabilitation. Patients are frequently transferred to these settings for post-stroke care for several weeks before being discharged to home. Listed next are the types and goals of therapies used:

- Physical therapy may help prevent contractures and improve muscle strength and coordination. Physical therapists teach exercises to enable the patient to relearn how to walk, sit, lie down, and change from one type of movement to another.
- Occupational therapy provides assistive devices and a plan for regaining lost motor skills that greatly improve quality of life after a stroke. These skills include eating, drinking, bathing, cooking, reading, writing, and toileting.
- Speech therapy is provided to help the patient improve swallowing as well as how to relearn language and communication skills.

●○● NURSING CARE

Even though many people who have a stroke have full recovery, a substantial number are left with disabilities that affect their physical, emotional, interpersonal, and family status. The required nursing care is often complex and multidimensional, requiring consideration of continuity of care for patients in acute care settings, long-term care settings, rehabilitation centers, and the home.

Nurses caring for patients who have had a stroke require knowledge and skill to meet patient and family needs during both the acute and the rehabilitative phases of care. The patient may have multiple losses: loss of mobility, ability to provide self-care, communications, concept of self, and interpersonal or intimate relationships with others. Holistic, individualized nursing care is essential in all settings and

NURSING CARE OF THE PATIENT

Having a Carotid Endarterectomy

POSTOPERATIVE CARE

- Position on the unoperated side and either maintain a flat position or elevate the head of the bed 30 degrees as prescribed. Maintain head and neck alignment and avoid rotating, flexing, or hyperextending head. *Pressure on the wound is undesirable. Elevating the head decreases edema in the operative site. Maintaining head and neck alignment prevents additional tension or pressure on the operative side.*
- Support the head when changing position. Teach to support the head with the hands when able to move about. *Supporting the head helps prevent stress on the operative site (which may cause bleeding and hematoma formation); it also helps reduce stress on the suture line.*
- Assess respirations and oxygen saturation.
  a. *Hemorrhage.* Assess the dressing and the area under the neck and shoulders for drainage. Assess for increased pulse and decreased blood pressure. *The most common cause of respiratory problems is pressure on the trachea from a hematoma formation.*
  b. *Respiratory distress.* Assess respiratory rate, rhythm, depth, and effort. Observe for restlessness. Keep a tracheostomy tray at the bedside. *Respiratory distress may result from edema and hematoma formation, which may compress the trachea.*
  c. *Cranial nerve impairment.* Observe and record any facial drooping, tongue deviation, hoarseness, dysphagia, or loss of facial sensation. *Cranial nerves may be stretched during surgery, leading to temporary deficits in cranial nerve function.*
  d. *Hypertension or hypotension.* Take and record blood pressure at least hourly. Report any changes immediately and implement orders for medications to treat hypertension or hypotension. *About one-half of all patients having a carotid endarterectomy develop unstable blood pressure related to surgical denervation of the carotid sinus. Uncontrolled hypertension may precipitate a stroke. The most common problem is hypotension, possibly related to stimulation of the carotid body baroreceptors, which are exposed during surgery. Hypotension may result in myocardial ischemia.*

focuses on promoting the achievement of maximum potential and quality of life.

The patient's family is often faced with many changes. The young to middle-age adult with a family member who has had a stroke may be faced with economic difficulties and social isolation. The middle-age adult family member may become the caretaker for an older parent. An older adult may not be able to care for a spouse and may have to accept long-term care placement. In addition, the older adult who has no family may have to struggle alone to regain the ability to function independently. Although not all of these problems are amenable to nursing solutions, the nurse is most often the healthcare provider who assesses and identifies the needs of each individual and provides information and referrals to patients and families to help meet those needs.

Because a stroke has the potential to cause many different health problems, a wide variety of nursing diagnoses may be appropriate. It is important to remember that each person will be affected differently, depending on the degree of ischemia and the area of the brain involved. Nursing diagnoses discussed in this section focus on problems with cerebral tissue perfusion (specific to nursing care during the acute phase), physical mobility, self-care, communication, sensory-perceptual deficits, bowel and urine elimination, and swallowing (specific to prevention of complications and rehabilitation). In addition, many of the diagnoses, outcomes, and interventions provided for the patient with alterations in consciousness, IICP, and seizures may be appropriate. See the Case Study & Nursing Care Plan for a patient with a stroke on page 1381.

Health Promotion

Health promotion activities focus on stroke prevention, especially for those people with known risk factors. More lives are saved by preventing strokes than by treating them. It is important to discuss, as appropriate, the importance of stopping smoking and drug use with patients of all ages. Maintaining a normal weight through diet and exercise can help reduce obesity, which increases the risk of hypertension and type 2 diabetes mellitus (both in turn increase the risk of a stroke). Cholesterol levels should be screened regularly to monitor for hyperlipidemia. Regular healthcare to monitor for and treat cardiovascular disorders and to detect and treat infections such as infective endocarditis is important.

It is also important to increase public awareness of the signs of a TIA or stroke and of the need to call 911 or to seek care immediately if warning signs or symptoms occur. There are several public awareness campaigns that are useful. The symptoms listed next are those publicized by NINDS (2012a). The Fast Facts box provides clues to recognizing a stroke from the National Stroke Association. In addition, The Stroke Collaborative (2012) describes five warning signs of stroke as follows:

- *Weakness:* sudden loss of strength or sudden numbness in the face, arm, or leg, even if temporary
- *Trouble speaking:* sudden difficulty speaking or understanding or sudden confusion, even if temporary
- *Vision problems:* sudden trouble with vision, even if temporary
- *Headache:* sudden severe and unusual headache
- *Dizziness:* sudden loss of balance, especially with any of the above signs.

FAST FACTS

How to Detect Stroke Symptoms and Act F.A.S.T.

F = Face	Ask the person to smile. Does one side of the face droop?
A = Arm	Ask the person to raise both arms. Does one arm drift downward?
S = Speech	Ask the person to repeat a simple sentence. Does the speech sound blurred or strange?
T = Time	If you observe any of these symptoms, it is time to call 911 or get to the nearest stroke center or hospital.

(National Stroke Association, 2012).

Assessment

See the Manifestations and Interprofessional Care sections for the assessment of the patient with stroke.

The following data are collected through the health history and physical examination. Further focused assessments are described with nursing interventions. If the patient is a woman, she has risks for stroke that are different than those of a man and should be asked questions specific to her gender (see the accompanying Meeting Individualized Needs box).

- *Health history:* risk factors, previous stroke, drug use (prescribed, OTC, and street drugs), smoking history, when manifestations began, severity of manifestations, presence of incontinence, family support system, advance directives or medical power of attorney
- *Physical assessment:* stroke scale, level of consciousness, vital signs, motor strength, coordination, communication, cranial nerves, sensory function, skin integrity, mobility status.

Priorities of Care

Collaborating with the interprofessional team to ensure adequate treatment of the underlying process while providing care that supports the physical and psychologic responses to the disorder is a priority of nursing care.

Diagnoses, Outcomes, and Interventions

Depending on the severity of the stroke, the patient may be admitted to the intensive care unit. Regardless of the hospital setting, the nurse provides interventions to maintain functional status and prevent complications.

Risk for Ineffective Tissue Perfusion: Cerebral

The initial assessment and care of the patient admitted for intensive care focuses on identifying changes that may indicate altered cerebral perfusion. The patient's airway, breathing, circulation, and neurologic status are monitored and interventions are provided to maintain cerebral perfusion.

Expected Outcome: Patient will demonstrate appropriate orientation to person, place, time and situation as indicated. Patient's cerebral perfusion will be adequate as evidenced by motor/sensory functions, pupillary size and reaction, and behaviors.

- Monitor respiratory status, oxygen saturation, and airway patency. Auscultate pulmonary sounds and monitor respiratory rate and results of studies of arterial blood gases.

Evidence for Nursing Care

The Patient with a Stroke

Selected resources that nurses may find helpful when planning evidence-based nursing care follow.

- Miller, E. L., Murray, L., Richards, L., Zorowitz, R. D., Bakas, T., Clark, P., & Billinger, S. A. (2010). Comprehensive overview of nursing and interprofessional rehabilitation care of the stroke patient: A scientific statement from the American Heart Association. *Stroke, 41*(10), 2401–2448.
- Mink, J., & Miller, J. (2011). Stroke, part I: Opening the window of opportunity for treating acute ischemic stroke. *Nursing 2011, 41*(1), 25–33.
- Mink, J., & Miller, J. (2011). Stroke, part 2: Respond aggressively to hemorrhagic stroke. *Nursing 2011, 41*(3), 36–43.

- Suction as necessary, using care to suction no longer than 10 seconds at any one time, using sterile technique.
- Administer oxygen as prescribed.
  The patient may be unconscious and breathing may be impaired. Suctioning removes secretions that obstruct air flow, but also decreases O_2, increases CO_2, and partially obstructs the airway. Suctioning for longer than 10 seconds at a time may increase intracranial pressure (Hickey, 2013). Respiratory complications develop rapidly, as manifested by crackles and wheezes, rapid respirations, and respiratory acidosis. The administration of oxygen decreases the risk for hypoxia and hypercapnia, which can increase cerebral ischemia and intracranial pressure.
- Position the patient on the side. *Side positioning allows secretions to drain out of the mouth, helping to prevent aspiration.*
- Monitor mental status and LOC: restlessness, drowsiness, lethargy, inability to follow commands, unresponsiveness. *Changes in mental status and LOC are often initial manifestations of IICP.*
- Assess for pain, headache, decreased muscle strength, sluggish pupillary reflexes, absent gag or swallowing reflexes, hemiplegia, Babinski's sign, and decerebrate or decorticate posturing. *Frequent monitoring of neurologic status is necessary to detect changes. Alterations in mental status, LOC, movement, strength, and reflexes indicate IICP, the major cause of death in the acute phase of a stroke.*
- Continuously monitor cardiac status, observing for dysrhythmias. *A stroke may cause cardiac dysrhythmias, including bradycardia, PVCs, tachycardia, and AV block. Characteristic ECG changes include a shortened PR interval, peaked T waves, and a depressed ST segment.*
- Monitor body temperature and maintain temperature at less than 37°C (98.6°F) at all times during acute care. *In a large meta-analysis, fever was consistently found to be associated with worse outcomes in patients with stroke.*
- Maintain accurate intake and output records. Measure urinary output via a Foley catheter. *A stroke may damage the pituitary gland, resulting in diabetes insipidus and the possibility of dehydration from greatly increased urinary output. If a Foley catheter is inserted, follow strict guidelines to prevent infection and for securing the catheter.*
- Monitor for diabetes insipidus and dehydration. *Diabetes insipidus is indicated by a large output of dilute urine; dehydration is indicated by scanty amounts of dark, concentrated urine. Clarification of the difference in symptoms promotes appropriate intervention delivery.*

Meeting Individualized Needs

Risk Factors for Stroke in Women

Some risk factors for stroke apply only to women, most specifically pregnancy, childbirth, and menopause. These risks are the result of fluctuations in hormones that occur at different stages of life. However, other risks are also more common for women, and information should be collected during a health history. For accurate assessment, ask the following questions, depending on the woman's age:

- How many pregnancies have you had?
- Have you had a miscarriage? If so, how many?
- How many births have you had? When was your last delivery?
- When was your last menstrual period?
- Do you take any type of hormone replacement therapy?
- Do you take birth control pills?
- Do you have migraine headaches? If so, do you have an aura?
- Have you ever been diagnosed with diabetes or lupus?
- Have you ever been diagnosed with a clotting disorder? Have you ever had a clot in your leg?

- Monitor for seizures. Pad the side rails, and administer prescribed AEDs. *Seizures may be the result of cerebral tissue damage or IICP. Padded side rails prevent injury if a seizure occurs. AEDs prevent or treat seizures.*

Impaired Physical Mobility

The goals of care for patients with impaired mobility are to maintain and improve functional abilities (by maintaining normal function and alignment, preventing edema of extremities, and reducing spasticity) and to prevent complications.

Expected Outcome: Patient's joint range of motion will be maintained with progression to transfers and ambulation as tolerated and appropriate for condition.

- Encourage active ROM exercises for unaffected extremities and perform passive ROM exercises for affected extremities every 4 hours during day and evening shifts and once during the night shift. Support the joint during passive ROM exercises. *Active ROM exercises maintain or improve muscle strength and endurance, and help to maintain cardiopulmonary function. Passive ROM exercises do not strengthen muscles but do help maintain joint flexibility.*
- Turn every 2 hours around the clock, following a posted schedule for side-to-side and supine-to-prone position changes (verify prone positioning with the physician). Maintain body alignment and support extremities in proper position with pillows. *Turning on a regular basis, accompanied by proper positioning, maintains joint function, alleviates pressure on bony prominences that can lead to skin breakdown, decreases dependent edema in hands and feet, and lessens the risk of complications resulting from immobility.*

SAFETY ALERT

Both active and passive exercises increase venous return, decreasing the risk of thrombophlebitis.

PRACTICE ALERT!

When lying on the affected side, patients may be restless because they do not have normal sensation and may feel as if they are going to fall.

- Monitor the lower extremities each shift for manifestations of thrombophlebitis. Assess for increased warmth and redness in calves; measure the circumference of the calves and thighs. Provide care for sequential compression stockings (per agency protocol), if prescribed. *Patients on bed rest (especially those with loss of muscle strength and tone) are particularly prone to the development of deep venous thrombosis. Promptly report manifestations of thrombophlebitis.*
- Collaborate with the physical therapist as the patient gains mobility, using consistent techniques to move the patient from the bed to the wheelchair and to help the patient ambulate. *The use of consistent techniques facilitates rehabilitation.*

Self-Care Deficit

The patient who has had a stroke may have a self-care deficit (bathing, dressing, feeding, and/or toileting) as a result of impaired mobility or mental confusion. It is important for patients to perform as much of their own physical care and grooming as possible to promote functional ability, increase independence, decrease feelings of powerlessness, and improve self-esteem. Before establishing a plan to increase self-care, determine which hand was dominant before the stroke. If the patient's dominant side is affected, self-care will be more difficult.

Expected Outcome: Patient will be able to complete self-care activities to optimal potential.

- Screen for executive cognitive dysfunction (abstract thought, actions planned and taken toward a goal, adaptation to the unexpected). *Executive cognitive dysfunction can more reliably predict loss of autonomy than memory impairment can. This assessment is essential to helping a patient remain as safe and independent as possible.*
- Encourage use of the unaffected arm to bathe, brush teeth, comb hair, dress, and eat. *Use of the unaffected arm promotes functional ability and independence.*
- Teach the patient to put on clothing by first dressing the affected extremities and then dressing the unaffected extremities. *This technique facilitates self-dressing with minimal assistance.*
- Collaborate with the occupational therapist in scheduling times for training for upper extremity functioning necessary for activities of daily living (ADLs). Encourage the use of assistive devices (if required) for eating, physical hygiene, and dressing. *Following a regular schedule in daily routines promotes learning. The use of assistive devices promotes independence and decreases feelings of powerlessness. Optimal grooming facilitates positive self-concept.*

Impaired Verbal Communication

The patient who loses communication abilities requires intensive speech therapy and emotional support. It is important to determine the specific nature of the impairment when planning interventions and helping family members understand specific problems. Although the speech therapist is usually most involved with speech rehabilitation, nurses must plan interventions to meet communication needs during all phases of care.

Expected Outcome: Patient will be able to use alternative methods of communication effectively.

- Approach and treat the patient as an adult.
- Do not assume that the patient who does not respond verbally cannot hear. Do not use a raised voice when addressing the patient.
- Allow adequate time for the patient to respond.
- Face the patient and speak slowly.
- When you do not understand the patient's speech, be honest and say so.
- Use short, simple statements and questions.
  Accepting the patient and providing dignity and respect enhances the nurse–patient relationship. Allowing adequate response time and using short verbal statements or questions while facing the patient motivates the patient to communicate and decreases frustration.
- Accept frustration and anger as a normal reaction to the loss of function. *Anger represents the patient's frustration at the inability to control the loss of function.*
- Try alternate methods of communication, including writing tablets, flash cards, and computerized talking boards. *Patients unable to communicate verbally may use other methods effectively.*

Impaired Urinary Elimination and Risk for Constipation

Both urinary and bowel elimination may be altered because of neurologic deficits, impaired mobility, cognitive impairment, communication deficits, or preexisting problems (especially if the patient is an older adult). Other causes include changes in food and fluid intake and side effects of medications. Urinary incontinence or retention and constipation, fecal incontinence, and fecal impaction are the usual manifestations.

Expected Outcome: Patient will be able to perceive and recognize cues for toileting and independently conduct toileting activities to their optimal function.

- Assess for urinary frequency, urgency, incontinence, nocturia, and voiding in small amounts. In addition, assess the patient's ability to respond to the need to void, the ability to use the call light, and the ability to use toileting equipment. Use established guidelines to assess and manage patients with urinary incontinence. *Assessment needed for early detection of bladder dysfunction.*
- Assess for a distended bladder. *Voiding small amounts of urine frequently may be a manifestation of a bladder dysfunction.*
- Encourage bladder training by having patient void on schedule, such as every 2 hours, rather than in response to the urge to void.
- Teach Kegel exercises. To perform Kegel exercises, the patient contracts the perineal muscles as though stopping urination, holds the contraction for 5 seconds, and then releases.
- Use positive reinforcement (verbal praise) for successful management of urinary elimination.
  Voiding every 2 hours or on schedule promotes bladder tone and urine storage. Kegel exercises increase pubococcygeal muscle tone and bladder control, decreasing incontinence. Positive reinforcement can be a useful part of the teaching program.
- Discuss prestroke bowel habits, as well as the pattern of bowel elimination since the stroke.
- If the patient is able to swallow without difficulty, encourage fluids (up to 2000 mL/day) and a high-fiber diet.
- Increase physical activity as tolerated.
- Assist in using the toilet facilities at the same time each day (based on usual patterns of bowel elimination), ensuring privacy and having the patient sit in an upright position if at all possible.
- Administer prescribed stool softeners if the patient is following a bowel elimination routine or is not drinking sufficient fluids.

Increased fluids, fiber, and activity stimulate intestinal motility. Establishing a regular daily time for bowel movements in the upright position and in privacy promotes normal bowel elimination. Stool softeners help prevent the formation of hard stool that is more difficult to expel.

Impaired Swallowing

A stroke may impair the ability to swallow. Weakness or lack of coordination of the tongue, attention deficits, and deficits involving the swallowing reflex all play a role. Dysphagia (difficulty swallowing) may result in choking, drooling, aspiration, or regurgitation. Nursing care focuses on maintaining safety by preventing aspiration and on ensuring adequate nutrition.

Expected Outcome: Patient will remain free from aspiration as evidenced by clear lung sounds and temperature within normal range.

- Monitor results of swallowing studies (often conducted by a physical therapist) prior to providing oral food and fluids.
- When eating, do the following to avoid aspiration and ensure safety:
  - Position in upright sitting position with neck slightly flexed.
  - Order puréed or soft food. Liquids should be of the same consistency as honey.
  - Feed or teach patient to eat by putting food behind the front teeth on the unaffected side of the mouth and tilting the head slightly backward. Teach to swallow one bite at a time.
  - Assess for coughing with eating or drinking.
  - Have suction equipment available at the bedside in case of choking or aspiration.

    Sitting upright with the head and neck first slightly flexed and then tilted back helps the patient swallow. The patient can usually swallow puréed or soft foods more easily than liquid or solid foods. Using the unaffected side of the mouth helps prevent food from collecting in the mouth and makes swallowing safer; in addition, food is less likely to fall out of the mouth.

SAFETY ALERT

After eating, check the mouth for "pocketing" of food, especially in the affected cheek.

- Monitor lung sounds. *Coarse lung sounds heard in the right upper and/or lower lobes may indicate aspiration because the right bronchus is the first division of the bronchi and where the majority of aspirations occur.*
- Minimize distractions and, if necessary, give step-by-step instructions for eating. *Distractions increase the risk of aspiration. Complex activities are easier to perform when broken down into small steps.*

Continuity of Care

Throughout the rehabilitation process, it is important not only to encourage self-care as much as possible but also to involve family members in the plan of care. Stress that ADLs may take twice as long as they did before the stroke. Emphasize that physical function may continue to improve for up to 3 months, and speech may continue to improve for even longer. Address the following topics in preparing the patient and family for continuity of care:

- Physical care, medications, physical therapy, occupational therapy, speech therapy.
- Home environment conducive to using equipment (such as a wheelchair or walker) and equipment modifications (e.g., a raised toilet seat, grab bars in the bathroom, a bath chair, a vise lid opener, a long-handled shoehorn).
- Home health services.
- Community resources, such as Meals-on-Wheels, senior centers, older adult care, large-print telephone dials, stroke clubs, and an emergency alerting system. Financial assistance may be available within the community for housekeeping and personal care assistance.
- Helpful organizational resources include the American Heart Association, the National Stroke Association, Stroke Clubs International, and the National Institute of Neurological Disorders and Stroke.

THE PATIENT WITH AN INTRACRANIAL ANEURYSM

An *intracranial aneurysm* is a saccular outpouching of a cerebral artery that occurs at the site of a weakness in the vessel wall. It is believed to be the result of a congenital defect in a cerebral vessel wall. A ruptured cerebral aneurysm is the most common cause of a hemorrhagic stroke. Seen most often in adults over age 50, a ruptured intracranial aneurysm often results in death or severe disability in those who survive (Huether & McCance, 2011).

Pathophysiology

Intracranial aneurysms tend to occur at the bifurcations in the circle of Willis. Intracranial aneurysms often enlarge over time, making the vessel wall thin and increasing the probability of rupture. There are several types, but most are small saccular aneurysms called berry aneurysms (because of their small berry-like projections). Rupture of these aneurysms results in bleeding into the subarachnoid space (causing a subarachnoid hemorrhage).

Manifestations

The manifestations of a ruptured intracranial aneurysm (and subsequent subarachnoid hemorrhage) include a sudden, explosive headache and neck pain; nausea and vomiting; a stiff neck and photophobia (due to meningeal irritation); cranial nerve deficits; and stroke syndrome. Hypertension and cardiac dysrhythmias may occur from the massive release of catecholamines triggered by the subarachnoid hemorrhage. Fibrin and platelets seal off the bleeding point, but the escaped blood forms a clot that irritates the brain tissue. The resulting inflammatory response causes cerebral edema, and both the edema and the hemorrhage increase intracranial pressure. The pituitary gland is in proximity to the circle of Willis and is often affected secondary to edema and irritation, with resulting diabetes insipidus and hyponatremia.

Complications

The major complications of a ruptured intracranial aneurysm are rebleeding and vasospasm. Hypothalamic dysfunction, hydrocephalus, and seizures are also potential complications. The greatest risk for rebleeding is within the first 2 weeks after the initial

CASE STUDY & NURSING CARE PLAN A Patient with a Stroke

Orville Boren is a 63-year-old African American who had a stroke due to a right cerebral thrombosis 1 week ago. He is a history instructor at the local community college. His hobbies are wood carving and gardening. Mr. Boren is also an active member of his church. For the past 2 years, Mr. Boren has been taking medication for hypertension, but his wife Emily reports that he often forgets to take it and that his blood pressure was high at his last physical examination. Mrs. Boren tells the staff that she has never had to worry about her husband's health before and that she wants to learn everything she can to care for him at home. However, she says that her husband was always the one to make the decisions and pay the bills. Mrs. Boren adds that all the children, grandchildren, neighbors, and family pastor want to see Mr. Boren back at home as soon as possible.

ASSESSMENT

Carol Merck, RN, the nurse assigned to Mr. Boren, completes a health history and physical assessment, with Mrs. Boren providing information for the history. Mrs. Boren reports that her husband did have several spells of dizziness and blurred vision the week before his stroke, but they lasted only a few minutes and he believed them to be due to "old age and working out in the sun." On the morning of admission, Mr. Boren woke up and could not move his left arm or leg; he also could not speak sensibly. Mrs. Boren called 911, and an ambulance took her husband to the hospital.

Physical assessment findings include the following: Mr. Boren is drowsy but responds to verbal stimuli. Although he does not respond verbally, he can nod his head to indicate "yes" when asked questions. Flaccid paralysis is present in his left arm and left leg, with no response noted to touch in those extremities (he is left handed). Visual fields are decreased in a pattern consistent with homonymous hemianopia. A CT scan, negative on admission, is repeated on the day after admission and confirms the medical diagnosis of a right-brain stroke due to a thrombus of the middle cerebral artery.

Mr. Boren's medical treatment includes heparin sodium administered by continuous intravenous drip, with clotting studies to be performed every 4 hours and the dose adjusted accordingly.

DIAGNOSES

- *Feeding Self-Care Deficit* related to loss of the ability to use the left hand and arm
- *Impaired Physical Mobility* related to neurologic deficits causing left hemiplegia
- *Risk for Impaired Skin Integrity* related to inability to change position
- *Sensory Perception Disturbed: Visual* related to changes in visual fields
- *Impaired Verbal Communication* related to cerebral injury

EXPECTED OUTCOMES

- Patient will learn to use his right hand to feed himself.
- Patient will participate in exercises necessary to maintain muscle strength and tone.
- Patient will maintain skin integrity.
- Patient will indicate understanding that visual fields may improve in a few weeks.
- Patient will practice and implement speech therapy activities while at the same time using alternative methods of communication.

PLANNING AND IMPLEMENTATION

- Arrange mealtimes so that he is sitting up by the window in a clean and private environment.
- Provide adaptive devices (silverware with thick handles and nonslip plates).
- Encourage Mrs. Boren to visit at mealtimes, to assist with meals, and periodically to bring a favorite food from home.
- Provide passive ROM exercises for his left arm and leg; schedule active ROM exercises for his right extremities as well as quadriceps and gluteal sets every 4 hours during waking hours.
- Keep his skin clean and dry at all times.
- Establish and maintain a regular schedule for turning when he is in bed.
- Place objects (e.g., call bell, tissues) on unaffected side and approach him from that side.
- Support attempts to communicate verbally; when he is not understood, he prefers to use a large marker and tablet.

EVALUATION

Mr. Boren is discharged to his home with home health visits ordered for physical therapy, occupational therapy, speech therapy, and skilled nursing care. During the first 2 months after discharge, Martha Grimes, RN, the home health nurse, visits Mr. and Mrs. Boren at home. At the end of 2 months, Mr. Boren is using his right hand to feed himself. He has regained partial use of his left arm and leg and is using a walker to move around the house and yard; he is even able to work in his flower garden. His skin has remained intact, and his vision is back to normal. He is slowly relearning speech; this has been the most difficult change for him to accept. Once he writes on his tablet, "I think God has forgotten me."

Clinical Reasoning in Patient Care

1. Hypertension is sometimes referred to as "the silent killer." Provide justifications for this statement.
2. The functional changes Mr. Boren has experienced may make a return to teaching difficult. What other uses of his knowledge and abilities might you suggest?
3. If after you had completed passive ROM on Mr. Boren's left arm, he wrote, "I just ignore that part of my body—it doesn't work anyway," what would be your reply?

See Evaluating Your Response in Appendix B.

rupture, although it may occur at any time following the initial occurrence. Approximately 70% of patients who have rebleeding will die (Hickey, 2013). Cerebral vasospasm is a common but dangerous complication that is associated with a large number of deaths and disability. A cerebral vasospasm narrows the lumen of one or more cerebral vessels, causing ischemia and infarction of brain tissue supplied by the affected vessels. It occurs in blood vessels surrounded by thick blood clots, and is thought to be the result of the release of ET-1, a potent vasoconstrictor of cerebral arteries (Hickey, 2013). The manifestations vary according to the degree of spasm and the area of brain affected. Regional alterations may cause focal deficits (such as hemiplegia), whereas global alterations cause loss of consciousness.

●○● INTERPROFESSIONAL CARE

The care of the patient with a ruptured intracranial aneurysm includes determining the location of the aneurysm, treating the manifestations of the hemorrhage, and preventing rebleeding and vasospasm. Interventions using radiology, angiography, and a variety of procedures may be used to prevent aneurysm rupture or to stop the bleeding. Surgery is usually the treatment of choice to repair the bleeding artery.

DIAGNOSIS

The diagnostic tests conducted to identify the site and extent of a ruptured intracranial aneurysm, as well as rebleeding, are a CT scan, a spiral computed tomography angiogram (CTA), and bilateral carotid and vertebral cerebral angiograms. A CT is used to initially detect the hemorrhage, and a CTA can rapidly identify the arterial anatomy. Angiograms provide visualization of all four major cerebral vessels and their branches, providing early diagnosis and treatment. A lumbar puncture will reveal blood-tinged spinal fluid.

MEDICATIONS

Calcium channel blockers, such as nimodipine (Nimotop), are used to improve neurologic deficits due to vasospasm following subarachnoid hemorrhage from ruptured intracranial aneurysms. Administered orally or by feeding tube (never IV), it has been found to enhance collateral blood flow and improve outcomes (Hickey, 2013).

Other medications that may be prescribed include anticonvulsants, such as phenytoin (Dilantin), to prevent seizures if the patient has IICP; analgesics for headache; antacids and H_2-receptor antagonists (such as ranitidine [Xanax]) to prevent gastric irritation; and stool softeners to prevent constipation and straining with a bowel movement (which increases intracranial pressure and blood pressure and may cause rebleeding).

PROCEDURES USED TO TREAT ANEURYSM

Treatments for an intracranial aneurysm are performed either to prevent rupture or to isolate the vessel to prevent further bleeding. Patients with good neurologic status may have surgery soon after the rupture. In patients with significant neurologic deficits, surgery may be delayed until they are more stable and less at risk for vasospasm; however, the trend is toward surgery as soon as possible.

Several different types of procedures are used to repair a ruptured intracranial aneurysm or to prevent the rupture of an existing large aneurysm. The neck of the aneurysm may be clipped with a metal clip to prevent entry of blood into the aneurysm. Endovascular techniques that may be used include balloon embolization and platinum coil electrothrombosis.

●○● NURSING CARE

Nursing care is planned and implemented for the patient with a ruptured intracranial aneurysm to prevent rebleeding as well as to meet needs resulting from neurologic deficits. Appropriate diagnoses, outcomes, and interventions are described earlier in the chapter in the discussion of nursing care for the patient with a stroke. The priority interventions in the acute care stage of a ruptured intracranial aneurysm focus on treating ineffective cerebral tissue perfusion.

THE PATIENT WITH AN ARTERIOVENOUS MALFORMATION

An arteriovenous (AV) malformation is a congenital intracranial lesion, formed by a tangled collection of dilated arteries and veins that allows blood to flow directly from the arterial into the venous system, bypassing the normal capillary network. Most AV malformations (90%) are located in the cerebral hemispheres; the remainder are found in the cerebellum and brainstem.

Rupture of vessels in AV malformations account for 2% of all strokes. Patients with this condition develop manifestations before 40 years of age; it affects men and women equally (Huether & McCance, 2011). The manifestations are the result of spontaneous bleeding from the lesion into the subarachnoid space or brain tissue.

Pathophysiology

AV malformations, believed to arise from failure of development of the capillary network in the embryo, displace rather than encompass normal brain tissue. The pathophysiologic effects of an AV malformation are the result of the shunting of blood from the arterial to the venous system and of altered perfusion of cerebral tissue near the malformation. The shunting of arterial blood directly into the venous system within the malformation transfers the higher arterial pressure directly into the lower pressure venous system. This increased pressure is likely to cause spontaneous bleeding or progressive expansion and rupture of a blood vessel. Altered cerebral perfusion results when blood flow through a large, high-flow malformation is diverted from the normal cerebral circulation, causing tissue ischemia of the area surrounding the malformation. This is sometimes called a *vascular steal phenomenon*.

AV malformations range in size from very small to very large. Large malformations are usually initially manifested by seizure activity. In contrast, the manifestations of a small malformation are more often due to a hemorrhage that causes neurologic deficits. In both instances, the patient may have recurrent headaches that do not respond to treatment.

●○● INTERPROFESSIONAL CARE

AV malformations are diagnosed with the same diagnostic tests used to diagnose an intracranial aneurysm. Treatment is by surgical excision, vascular occlusion, and radiosurgery. When the malformation is excised or obstructed, blood flow is no longer shunted, and cerebral perfusion improves.

●○● NURSING CARE

Nursing care depends on the condition of the malformation. If hemorrhage has not occurred, teach the patient to avoid activities that raise blood pressure or could cause injury. The patient is usually given medications to control blood pressure and prevent seizures. If the malformation ruptures and causes an intracranial hemorrhage, nursing care is the same as that provided to a patient who has had a stroke.

THE PATIENT WITH A TRAUMATIC BRAIN INJURY

Traumatic brain injury (TBI; also called *craniocerebral trauma*) refers to any injury of the scalp, skull (cranium or facial bones), or brain. TBI is a leading cause of death and disability in the United States. The Centers for Disease Control (2014) define TBI as "caused by a bump, blow, or jolt to the head or a penetrating head injury that disrupts the normal function of the brain.". A TBI may be classified as a penetrating (or open) head injury (when an object pierces the skull and enters the brain) or a closed head injury (the head suddenly and violently hits an object but the object does not break through the skull). Damage to the brain may be focal (confined to one area) or diffuse (involving more than one area of the brain). TBI may cause

problems with cognition, movement, sensation, and emotions. Even mild brain injuries, if repeated over an extended period of time, can result in cumulative neurologic and cognitive deficits. TBI is a major public health problem, especially among males ages 15 to 24 and among both men and women 75 years of age or older (NINDS, 2012b). People ages 75 and older have the highest rates of TBI-related hospitalizations and death (Brain Trauma Foundation [BTF], 2012).

FAST FACTS

TBI

- Each year, 1.6 million people have a TBI; of those, 230,000 are hospitalized and survive.
- Each year, 52,000 people die of TBI.
- An estimated 5.3 million Americans are living with disabilities from TBI.
- Blasts are the leading cause of TBI among military personnel in war zones; veterans' advocates believe 150,000 to 300,000 Iraq veterans have suffered TBI.

(BTF, 2012; NINDS, 2012b).

According to the NINDS (2012b), more than 50% of all TBIs in adults under the age of 75 are the result of crashes involving cars, motorcycles, bicycles, and pedestrians. TBIs in adults over the age of 75 are the result of falls. Other causes include violence and sports injuries. At least half of all TBIs involve alcohol or other drug use. The cause often determines the outcome; 91% of TBI from firearms (two-thirds of which may involve suicides) result in death, while 11% of TBIs from falls result in death.

Specific damage following craniocerebral injuries is related to the mechanism of the injury (how it occurs), the nature of the injury (type), and the location of the injury (where it occurs).

Head injuries may occur through several mechanisms:

- Contact phenomena injury is sustained when the head is struck by a moving object, such as a swinging bat. It includes local effects such as scalp lacerations and/or skull fractures and intracerebral contusions, lacerations, hematoma, and hemorrhage.
- Acceleration–deceleration injury (linear injury) occurs when the head hits an object and the brain rebounds within the skull (Figure 42–8 ■). The brain is injured at the point of impact (the *coup*) and on the opposite side of the impact (the *contrecoup*). Strain on cerebral tissue produces injury by compression, tension, or shearing. This type of injury is responsible for acute subdural hematoma and diffuse axonal injury.
- Rotational injury occurs when the brain rotates within the skull and hits bony buttresses in the cranial vault; these injuries are more severe than those from linear injuries.

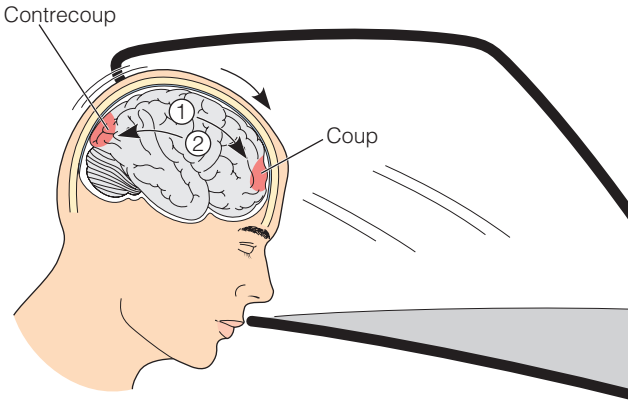

Figure 42–8 ■ Coup–contrecoup head injury. Following the initial injury (coup), the brain rebounds within the skull and sustains additional injury (contrecoup) in the opposite part of the brain.

Types of craniocerebral trauma include injuries to the skull, injuries to the brain (including concussion and contusion), and intracranial hematomas and hemorrhage. Brain injury can result either from the direct effects of the trauma on brain tissue or from secondary responses to trauma, such as cerebral edema, hematoma, or IICP.

FOCAL OR DIFFUSE TRAUMATIC BRAIN INJURY

The brain is protected from injury by enclosure in the bones of the skull and the cushioning effects of cerebrospinal fluid. Metabolic stability is maintained by a variety of mechanisms, including the blood–brain barrier and autoregulation of blood supply. However, damage to the brain can occur from the direct effects of trauma as well as from injury from ischemia, cerebral edema, IICP, hypoxia, and infection. These mechanisms of injury are often interrelated.

Pathophysiology

Brain injury results from both primary and secondary mechanisms. Primary injury results from the impact. A blow to the head, even with no break in the skull, can cause serious and diffuse brain injury. Injury to axons disrupts oligodendroglia, and direct mechanical disruption is caused by debris and leakage.

Secondary injury is the progression of the initial injury resulting from events that affect perfusion and oxygenation of brain cells. The theories of cause and mechanisms of secondary injury are summarized here. They include the effects of hypoxia, ischemia, and inflammation. Hypoxia interferes with the delivery of oxygen; ischemia interferes with the delivery of oxygen and glucose and with the removal of metabolic wastes. The consequences of cerebral ischemia include increased cellular permeability to sodium (cytotoxic edema) and release of free fatty acids and lactic acidosis. The release of excitatory amino acids (such as glutamate and aspartate) causes an influx of calcium with changes in electrophysiology. The inflammatory process begins immediately, resulting in the release of cytokines. It is unknown if these cytokines are protective or injurious, but it is known that inflammatory mediators such as tumor necrosis factor increase with TBI and are associated with cerebral edema, disruption of the blood–brain barrier, and death of neurons (Hickey, 2013; Huether & McCance, 2011).

Acute brain injury affects all body systems as well as the central nervous system. Systemic effects of acute brain injury are listed in Table 42–5.

FOCAL BRAIN INJURIES

Focal brain injuries are specific brain lesions confined to one area of the brain. They include contusions and hemorrhage/hematomas. The force of an impact produces contusions from direct contact with the inside of the skull that in turn may cause epidural hemorrhage and subdural and intracerebral hematomas. The mechanisms of injury are damage to the brain at the point of the impact and the rebound effect. The damaged area is surrounded by edema, contributing to

TABLE 42–5 Systemic Effects of Acute Brain Injury

Cause	Effect
• Stimulation of the sympathetic nervous system (SNS), which stimulates the adrenal cortex and medulla to increase glucocorticoid and mineralocorticoid levels	• Increased metabolism of carbohydrates, fats, and proteins • Retention of sodium and water
• Stimulation of the SNS, increasing the serum catecholamine levels	• Hypertension • EEG changes • Dysrhythmias (bradycardia, sinus tachycardia)
• Altered release of antidiuretic hormone (ADH) from the posterior pituitary	• Retention of water or diuresis and diabetes insipidus
• Neurogenic pulmonary dysfunction	• Abnormal respiratory patterns • Reduced residual capacity with retention of CO_2, vasodilation, and increased ICP • Pulmonary edema
• Stress response to trauma	• Hyperglycemia
• Increased platelet, plasma fibrinogen, and thromboplastin levels	• Decreased clotting and prothrombin times • Vascular occlusion • Disseminated intravascular coagulation • Anemia
• Immunosuppression	• Infection
• Decreased gastric motility and increased gastric acidity	• Gastritis • Gastric ulcers

IICP. Infarction and necrosis, multiple hemorrhages, and edema are found within the contused areas.

Intracranial hemorrhage can result directly from the trauma or from the shearing forces on cerebral arteries and veins that occur with acceleration–deceleration. Depending on the site and rate of bleeding, manifestations may appear immediately or may not become evident for hours or even weeks. Intracranial hemorrhages and the hematomas they cause place pressure on surrounding structures, causing manifestations of an expanding focal lesion. They also cause IICP, leading to altered levels of consciousness and potential herniation syndromes. Intracranial hematomas are classified by their location as epidural, subdural, or intracerebral. Table 42–6 compares the frequency, locations, common sites, precipitating factors, and manifestations of intracranial hematomas; Figure 42–9 ■ illustrates their locations.

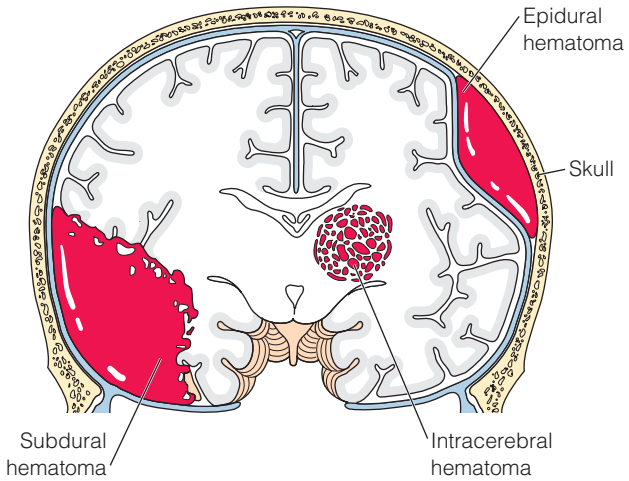

Figure 42–9 ■ Three types of hematomas: epidural hematoma, subdural hematoma, and intracerebral hematoma.

CONTUSION A cerebral contusion is a bruise of the surface of the brain, typically accompanied by small, diffuse venous hemorrhages. Both white and gray matter may have a bruised, discolored appearance. Contusions (and other focal brain injuries) occur when the brain strikes the inner skull, often with a coup (point of impact) lesion and a contrecoup lesion on the opposite side of the brain. Contusions occur most frequently near bony prominences of the skull. Cerebral edema can follow contusion, resulting in IICP. Contusions; small, diffuse venous hemorrhages; and brain swelling are at their peak 12 to 24 hours after injury.

Manifestations of the contusion depend on the size and location of the brain injury. An initial loss of consciousness occurs; LOC may remain altered, and behavior changes such as combativeness may persist for an extended period. Full consciousness may be regained extremely slowly, and residual deficits may persist; in some patients, full LOC never really returns. Focal effects of the contusion may cause loss of reflexes, hemiparesis (muscular weakness of one-half of the body), or abnormal posturing. Manifestations of IICP may occur if cerebral edema develops. Regaining full LOC may take an extended period of time and residual deficits may persist.

EPIDURAL HEMATOMA An **epidural hematoma** (also called an *extradural hematoma*) develops in the potential space between the dura and the skull, which normally adhere to one another. As the blood collects, the expanding hematoma pulls the dura away from the skull. Epidural hematomas affect young to middle-age adults more frequently than older adults, because the dura becomes more tightly attached to the skull with aging.

Epidural hematomas usually result from a skull fracture that tears an artery, often the middle meningeal artery. Because epidural hematomas are arterial in origin, they tend to develop rapidly. The patient may lose consciousness with the initial injury and then have a brief lucid period before the LOC rapidly declines from drowsiness to coma as the hematoma expands, compressing brain tissue. Other

TABLE 42–6 Comparison of Intracranial Hematomas

Type/Frequency	Location/Common Site	Precipitating Factors	Manifestations
EPIDURAL HEMATOMA 2%–6% of all types of head injuries	Located in the space between the skull and the dura mater Common site: the temporal bone (over the middle meningeal artery)	Skull fractures Contusion	Momentary loss of consciousness followed by a lucid period lasting from a few hours to 1–2 days Rapid deterioration in level of consciousness (drowsiness to confusion to coma) Seizures Headache Hemiparesis (may be ipsilateral or contralateral) Fixed dilated ipsilateral pupil Rise in blood pressure with decreases in pulse and respirations indicates a rapidly increasing hematoma
SUBDURAL HEMATOMA Approximately 29% of all types of head injuries	Located in the space below the dural surface (between the dura and arachnoid and pia mater layers of meninges) Common site: may occur any place in cranium	Closed head injury Acceleration–deceleration injury Cerebral atrophy (seen in older adults) Chronic alcoholism Use of anticoagulants Contusion	Acute: • Headache • Drowsiness • Agitation • Slowed thinking • Confusion Subacute: • Same as those of acute subdural hematoma but develop more slowly Chronic: • Manifestations may not appear until weeks to months after injury • Confusion, slowed thinking, drowsiness
INTRACEREBRAL HEMATOMA 14%–15% of all types of head injuries	Located directly in the brain tissue Common site: frontal or temporal region	Gunshot wounds Depressed bone fractures Stab injury Long history of systemic hypertension Contusions	Headache Deteriorating consciousness to deep coma Hemiplegia on contralateral side Dilated pupil on the side of the clot

manifestations include headache; vomiting; a fixed, dilated pupil on the same side (ipsilateral) as the hematoma; contralateral (opposite side) hemiparesis or hemiplegia; and possible seizures. Because epidural hematomas usually develop rapidly, timely intervention is vital to prevent significant increases in ICP and herniation.

SUBDURAL HEMATOMA **Subdural hematomas**, in which a localized mass of blood collects between the dura mater and the arachnoid mater, are more common than epidural hematomas. Acute subdural hematomas are usually located at the top of the head, and develop within 48 hours of the initial head injury. Although a lucid period may occur, the patient commonly develops drowsiness, confusion, and enlargement of the ipsilateral pupil within minutes or hours of the injury. If responsive, the patient may complain of a unilateral headache. Hemiparesis and respiratory pattern changes may occur.

Chronic subdural hematomas develop over weeks or months. The chronic type is seen most often in older adults and people who have some brain atrophy with subsequent enlarged epidural space. Chronic subdural hematomas are often associated with relatively minor trauma such as a fall or may occur spontaneously in the older adult or in patients with bleeding disorders. Manifestations of the hematoma develop slowly and may be mistaken for the onset of dementia in the older adult. Slowed thinking, confusion, drowsiness, and lethargy are common early manifestations. Other manifestations include headache, dilation and sluggishness of the ipsilateral pupil, and possible seizures.

INTRACEREBRAL HEMATOMA Intracerebral hematomas may be single or multiple, and are associated with contusions. They may occur in any location but usually are found in the frontal or temporal lobes. They may result from closed head trauma, particularly contusion or shearing of small blood vessels deep within the hemispheres. Intracerebral hematomas can also accompany other types of head trauma such as lacerations. Older adults are particularly vulnerable to intracerebral hemorrhage because cerebral blood vessels are more fragile and easily torn. The manifestations of intracerebral hematoma vary according to the location of the hematoma. Headache may develop, along with decreasing LOC, hemiplegia, and dilation of the ipsilateral pupil. The expanding clot increases intracranial pressure, and herniation may occur.

DIFFUSE CEREBRAL INJURY

A diffuse cerebral injury (concussion and diffuse axonal injury) affects the entire brain and is caused by a shaking motion, with twisting movement (rotational injury) as the primary mechanism of injury. Shearing stresses on brain tissue cause axonal damage from shearing, tearing, or stretching of nerve fibers. The most serious axonal injuries are located farthest from the brainstem, with the frontal and temporal axonal tracts being most vulnerable to injury. Physical deficits include spastic paralysis, peripheral nerve injury, swallowing disorders, visual and hearing impairments, and taste and smell disorders. Damage to axons decreases the speed of information processing and responding and disrupts attention, resulting in serious cognitive and affective impairments. Cognitive deficits that may result include disorientation and

confusion, short attention span, problems with memory and learning, perceptual problems, and poor judgment. Possible behavioral deficits include agitation, impulsivity, depression, and social withdrawal.

Initially, the damage involves tearing of axons, blood vessels, and brain tissue (visible only by electron microscope). The number of damaged axons progressively increases, with pathology involving the nuclei and axons. The damaged axons, which resemble sausage links, regress into round balls called retraction balls (visible with light microscopy). After several weeks, the retraction balls are replaced by clusters of microglia. In the final phase, astrocytosis (equivalent to scarring) occurs at the site of axonal damage, accompanied by demyelination of long axon tracts.

MILD CONCUSSION The word **concussion** means violent shaking. A concussion involves temporary axonal disturbances. It is defined as a momentary interruption of brain function. A concussion is associated with an immediate, brief loss of consciousness on impact. Altered consciousness may last only seconds or persist for several hours. Amnesia for events immediately preceding (antegrade amnesia) and following (retrograde amnesia) the injury is common. Other manifestations of concussion are listed in the accompanying box.

CLASSIC CEREBRAL CONCUSSION A classic cerebral concussion involves diffuse cerebral disconnection from the brainstem RAS. An immediate loss of consciousness occurs, lasting less than 6 hours. Both retrograde and antegrade amnesia occur, and cerebral contusions may be present. In a severe concussion, a brief seizure and respiratory arrest may occur; transient pallor, bradycardia, and hypotension may accompany loss of consciousness. Patients may develop postconcussion syndrome with persistent headache, dizziness, irritability, insomnia, impaired memory and concentration, and learning problems. Postconcussion syndrome may last for several weeks or, rarely, up to a year.

DIFFUSE AXONAL INJURY Diffuse axonal injury (DAI) is a brain injury in which a high-speed acceleration–deceleration injury, typically associated with motor vehicle crashes, causes widespread disruption of axons in the white matter. Focal lesions may be found in the corpus callosum, midbrain, and brainstem. An immediate loss of consciousness occurs. DAI accounts for approximately 50% of primary brain injuries and accounts for 35% of deaths from all TBIs (Hickey, 2013).

DAIs may range from mild to severe. In mild DAI, coma lasts 6 to 24 hours, and cognitive, psychologic, and sensorimotor deficits may persist. In moderate DAI, injury and impairment is spread throughout the cerebral cortex and diencephalon. There is axonal tearing, coma lasting more than 24 hours, and often incomplete recovery. In severe DAI, axonal injury occurs in both cerebral hemispheres, the diencephalon, and the brainstem. Immediate autonomic dysfunction occurs, and IICP is manifested. Profound cognitive and sensorimotor deficits occur, involving movement, verbal and written communication, ability to learn and reason, and ability to modulate behavior.

MANIFESTATIONS OF CONCUSSION

- Immediate loss of consciousness (lasting usually no longer than 5 minutes)
- Amnesia for events surrounding injury
- Headache
- Drowsiness, confusion, dizziness
- Visual disturbances (diplopia, blurred vision)
- Possible brief seizure activity with transient apnea, bradycardia, pallor, and hypotension

POSTCONCUSSION SYNDROME

- Persistent headache
- Dizziness
- Irritability and insomnia
- Impaired memory and concentration, learning problems

●○● INTERPROFESSIONAL CARE

The patient with a brain injury may receive medical and/or surgical treatment. Although patients with a mild concussion may be assessed and sent home for recovery, most people who have a TBI require intensive care at a trauma center. Evidence-based guidelines for medical care have been established by the Brain Trauma Foundation in the document *Guidelines for the Management of Severe Traumatic Brain Injury* (2007) and are updated periodically. A summary of the immediate care of the patient with a TBI follows:

- *Concussion:* Following a concussion, the patient may be observed for 1 to 2 hours in the emergency department (ED), and then discharged home with instructions for further observation to detect manifestations of secondary injury. If the loss of consciousness extended more than 2 minutes, the patient may be admitted to the hospital for observation.
- *Acute TBI:* Recognition and management of acute TBI with transport to an ED is essential to patient outcomes. Morbidity and mortality increase with hypotension (systolic pressure less than 90 mmHg) and hypoxia (PaO_2 less than 60 mmHg), so fluids are given to support a mean systolic arterial blood pressure at more than 90 mmHg. The fluid of choice for IV fluids is hypertonic saline because it reduces IICP (Hickey, 2013). Assessment of the patient's airway, breathing, and circulation (ABCs), with management of dysfunction, is necessary to decrease the secondary effects of the brain injury. An intracranial pressure monitor probe may be inserted to assess ICP and monitor therapy to reduce cerebral edema and maintain cerebral perfusion. Osmotic diuretics such as mannitol also may be administered to reduce cerebral edema. Adequate oxygenation is vital to maintain cerebral metabolism; carbon dioxide is a potent vasodilator, and increased levels may contribute to cerebral edema and IICP.

On admission to the ICU from the ED, the patient may be placed on a special bed and connected to various monitoring devices. Invasive lines are inserted, including a central venous pressure (CVP) catheter, arterial line, pulmonary catheter, ventriculostomy, ICP monitor, and perhaps a retrograde jugular catheter. In most instances, an endotracheal tube is inserted and connected to a mechanical ventilator, cardiac monitoring is initiated, bilateral sequential pressure boots are applied, pulse oximetry is started, and a rectal temperature probe is inserted. Laboratory values are monitored for changes to ensure early detection of cerebral hypoxia and impending ischemia to prevent secondary brain injury.

DIAGNOSIS

Diagnostic testing may be done to monitor hemodynamic status and detect conditions that may contribute to cerebral edema. Radiologic

examinations include skull x-rays (to identify skull fractures and assess penetrating objects) and CT scan or MRI to detect contusions and lacerations associated with diffuse axonal injury. ABGs are analyzed, with particular attention to oxygen and carbon dioxide levels.

MANAGING IICP

IICP is managed to reestablish equilibrium of the intracranial contents and prevent secondary brain damage. Treatments include airway management, hyperventilation (used if signs of herniation appear), fluid resuscitation, positioning, temperature regulation, and medications. Medications other than those previously discussed include a category of drugs called neuroprotectants. These drugs are used to treat or alter some of the pathologic pathways that occur in ischemia, and must be administered within a short time of the injury to be effective. Classifications of the drugs include lipid peroxidase inhibitors, free radical scavengers, receptor antagonists, calcium channel blockers, and gangliosides.

SURGERY

Small subdural hematomas can frequently be reabsorbed and may be treated conservatively with close observation and supportive care. However, the treatment of choice for epidural hematomas and large acute subdural hematomas is surgical evacuation of the clot. This can often be performed through burr holes made into the skull (Figure 42–10 ■). In an epidural hematoma, the bleeding vessel can also be ligated during this procedure, preventing further bleeding. Rebleeding may occur following evacuation of an acute subdural hematoma in older adults and patients with chronic alcoholism. A craniotomy is necessary to evacuate chronic subdural hematomas because the hematoma tends to solidify, making it difficult or impossible to remove through burr holes. Surgery is less successful in treating intracerebral hematomas because of widespread tissue damage. Supportive care to manage intracranial pressure and prevent complications is provided.

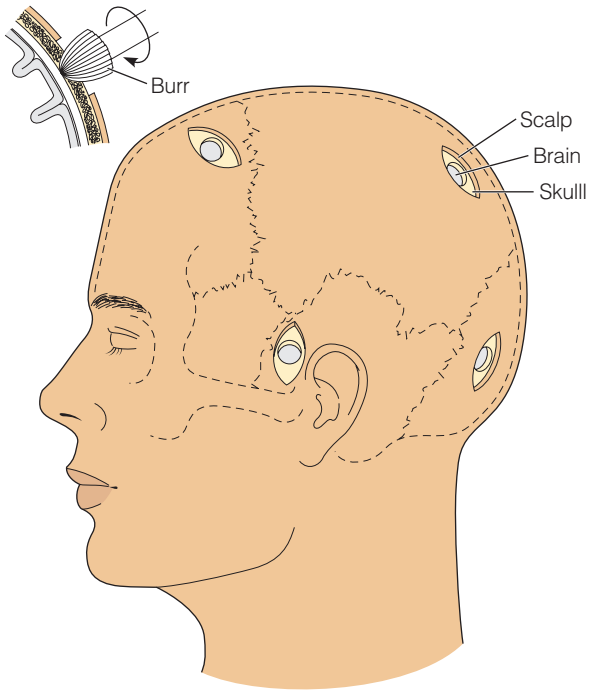

Figure 42–10 ■ Possible location of Burr holes.

●○● NURSING CARE

In addition to the nursing care discussed in this section, see the Case Study & Nursing Care Plan for a patient with a subdural hematoma on page 1388.

Health Promotion

The best way to treat any injury is to prevent it from happening. Public education must continue to stress the importance of safe driving, the dangers of driving under the influence of alcohol or drugs, and the necessity of wearing seat belts and cycle helmets. Legislation has mandated such motor vehicle changes as seat belts, child safety seats, air bags, use of headsets with cell phones, and prohibition of texting while driving. Other behaviors that can reduce the morbidity and mortality associated with TBI are following gun safety rules, promoting farm safety, and teaching older adults about safety (such as preventing falls) in the home.

Assessment

See the Manifestations and Interprofessional Care sections for the assessment of the patient with subdural hematoma.

Collect the following data through the health history and physical examination:

- *Health history:* A history of the injury is helpful in understanding the nature of the craniocerebral trauma; knowledge about loss of consciousness assists the nurse in planning care. However, most patients with severe TBI will not be able to communicate (either from the injury itself or from intubation).
- *Physical assessment:* Neurologic assessment, including pupils, LOC, Glasgow Coma Scale (a finding of 3 to 8 denotes severe TBI as defined by the Brain Trauma Foundation), brainstem reflexes (cornea, cough, gag, extraocular movements), spontaneous movement; response to pain; vital signs; skull and face (deformity, lacerations, bruising, bleeding); movement of extremities, other injuries.

Priorities of Care

Collaborating with the interprofessional team to ensure adequate treatment of the underlying process while providing care that supports the physical and psychologic responses to the disorder is a priority of nursing care.

Diagnoses, Outcomes, and Interventions

Nursing care of the patient in the acute care phase initially focuses on maintaining an effective airway and breathing pattern. Nursing care is also directed toward continuous assessment and monitoring of neurologic function as well as other body systems. This close monitoring provides early recognition and treatment of problems and complications, and initiation of aggressive forms of therapy that may be needed.

Many nursing diagnoses associated with traumatic brain injury correspond with those outlined previously for the patient with altered LOC, IICP, and seizures. Specific nursing diagnoses discussed in this section focus on problems with intracranial adaptive capacity, airway clearance, and breathing patterns.

SAFETY ALERT

Overhydration from rapid infusion of IV fluids may cause or further increase IICP.

CASE STUDY & NURSING CARE PLAN A Patient with a Subdural Hematoma

Wong Lee is a 50-year-old tug boat mechanic who is married and has three sons. Although Mr. Lee has been through rehabilitation twice for alcoholism, he has not been able to quit drinking. His physician has explained the physical consequences and the possible interaction between alcohol and the anticoagulant Mr. Lee is taking for chronic atrial fibrillation. While attending a family reunion, during which he eats a large meal and drinks several beers, Mr. Lee joins a game of softball. Mrs. Lee is concerned that Mr. Lee has consumed too much alcohol to play ball in the heat, but Mr. Lee is adamant and states that he wants to pitch. During the end of the second inning, the batter hits a ball that strikes Mr. Lee in the head. Mr. Lee stumbles and drops to the ground, holding his head. He does not lose consciousness and gets up on his own. His sons and wife try to persuade him to go to the hospital, but Mr. Lee insists he feels fine.

Two weeks later, after an evening of consuming several mixed drinks, Mr. Lee develops a headache. He attributes the headache to a hangover, but instead of improving the next day, the headache becomes steadily worse. He becomes confused and disoriented. His wife, concerned that his drinking is increasing again, calls the physician, who admits Mr. Lee to the detoxification center at the local hospital. A CT scan is performed. The diagnosis of a subdural hematoma is made, and Mr. Lee is transferred to the neurosurgical unit.

ASSESSMENT

When Saundra Knight, the nurse on the neurosurgical unit, enters the room, she notices that Mr. Lee is sitting in bed, laughing and giddy. As she begins to talk to Mr. Lee, he states, "Don't ask me anything—I can't think. My headache is getting worse." Over the next few hours, the giddiness subsides, and Mr. Lee becomes drowsy. Ms. Knight reports a Glasgow Coma Scale score of 11. An ICP monitor is inserted and reveals IICP. Mr. Lee is scheduled to have burr holes and hematoma evacuation that afternoon.

DIAGNOSES

- *Risk for Ineffective Breathing Pattern* related to pressure on respiratory center by intracranial hematoma
- *Ineffective Cerebral Tissue Perfusion* related to IICP secondary to cerebral edema

EXPECTED OUTCOMES

- Patient will maintain a respiratory rate and rhythm within normal limits.
- Patient will maintain adequate cerebral perfusion, as evidenced by stable vital signs, stable neurologic status, and no decrease in level of consciousness.

PLANNING AND IMPLEMENTATION

- Perform neurologic assessment every 2 hours or as needed.
- Monitor vital signs every 2 hours or as needed.
- Explain to the family the procedure for intracranial surgery.

EVALUATION

The first day postoperatively, Mr. Lee begins breathing on his own without ventilatory support. His respiratory rate and rhythm are within normal limits, with no signs of abnormal breath sounds. The ICP monitor readings are appropriate, and Mr. Lee shows significant improvement in level of consciousness, with a Glasgow Coma Scale score of 15. Mr. Lee continues to improve and is discharged to home 5 days after surgery.

Clinical Reasoning in Patient Care

1. Describe the similarities and differences between Mr. Lee's disorder and the manifestations of other types of intracranial hematomas.
2. Mr. Lee kept trying to pull out his ICP line. You know he should not be restrained, because pulling against restraints increases restlessness and increases intracranial pressure. What would you do?
3. Write a care plan for Mr. Lee for the nursing diagnosis *Acute Confusion*.

See Evaluating Your Response in Appendix B.

Decreased Intracranial Adaptive Capacity

The patient with a traumatic brain injury has or is at high risk for IICP. Because the mechanisms that normally compensate for changes in intracranial pressure are compromised, intracranial pressure increases in disproportion to a variety of stimuli. (See the discussion earlier in the chapter for other diagnoses, outcomes, and interventions for the patient with IICP.)

Expected Outcome: Patient will experience fewer than five episodes of disproportionate increases in intracranial pressure in 24 hours.

- Monitor for manifestations of IICP, including eye opening response, motor response, and verbal response. *These responses evaluate the ability to integrate commands with conscious and involuntary movement.*
- Monitor for changes in vital signs: bradycardia or tachycardia, varying breathing patterns, hypertension, and/or widening pulse pressure. Vital signs vary depending on the site of impairment. *Cushing's triad (bradycardia, increased systolic blood pressure, and increased pulse pressure) indicates brainstem ischemia leading to cerebral herniation.*
- Monitor for vomiting, headache, lethargy, restlessness, purposeless movements, and changes in mentation. *These manifestations may be early indicators of intracranial pressure changes.*
- Monitor temperature and initiate hypothermia treatment as prescribed. *Impaired hypothalamic function can interfere with temperature regulation. Hyperthermia may increase ICP.*
- Monitor fluid status: Regularly compare intake and output (a urinary catheter is inserted to assess renal perfusion), review serum osmolality, and use an infusion pump to administer IV fluids (if prescribed). *Osmotic diuretics, if used to treat cerebral edema, may cause hypotension and decreased cardiac output.*

Evidence for Nursing Care

The Patient with Traumatic Brain Injury

Selected resources that nurses may find helpful when planning evidence-based nursing care follow.

- Jett, S. (2010). Combat-related blast-induced neurotrauma: A public health problem. *Nursing Forum, 45*(4), 237–245.
- Lefebvre, H., & Levert, M.-J. (2012). The close relatives of people who have had a traumatic brain injury and their special needs. *Brain Injury, 26*(9), 1084–1097.
- Watts, D. D., Gibbons, S., & Kurzweil, D. (2011). Mild traumatic brain injury: A survey of perceived knowledge and learning preferences of military and civilian nurses. *Journal of Neuroscience Nursing, 43*(3), 122–131.

Ineffective Airway Clearance

The primary objective in the care of any trauma patient is maintaining a patent airway to prevent hypoxia. However, in the initial acute care phase, the risk of cervical vertebral fractures and spinal cord injury may complicate the process of establishing a patent airway. In addition, other multisystem injuries may complicate the interpretation of vital signs. In general, all unconscious people with a head injury should be intubated with an endotracheal tube to prevent aspiration. Patients with head trauma may also require a tracheostomy to provide an airway and be placed on a ventilator.

Expected Outcome: Adequate airway clearance will be maintained by use of protective interventions to maintain airway patency and suctioning as indicated.

- Monitor neurologic manifestations on a regular schedule. *Changes in neurologic manifestations may indicate IICP, with the risk of further depression of the respiratory system and respiratory arrest.*
- Maintain head and neck in neutral alignment, immobilized until injury is determined. *Head rotation and neck flexion are associated with IICP, decreased jugular venous outflow, and localized changes in cerebral blood flow. Immobilization prevents spinal cord injury in suspected or actual fractures of the cervical spine; spinal cord injury at this level would further impair respiratory function.*
- Clear the nose and mouth of mucus and blood. *This helps maintain patency of the upper airway.*
- Suction the airway as needed, limiting suctioning time to no more than 10 seconds at one time. Do not suction the nasal passages until a dural tear has been ruled out. *Suctioning is usually necessary to maintain a patent airway.*

Ineffective Breathing Pattern

The patient with a traumatic brain injury and hematoma is at high risk for ineffective breathing pattern related to IICP. If ICP increases dramatically, tentorial herniation may occur, leading to sudden respiratory arrest.

Expected Outcome: Patient will utilize techniques to promote adequate ventilation such as deep breathing and slowing respirations.

- Monitor the respiratory pattern for rate, depth, and rhythm every 2 hours or as needed if the patient is not on a ventilator. Assess breath sounds, presence of cyanosis, restlessness, and use of accessory respiratory muscles. Monitor pulse oximetry and blood gas levels. *Head injuries may cause alterations in respirations. An increased respiratory rate may indicate hypoxia. A decrease in respiratory rate may be the result of depression of the medullary respiratory center.*

SAFETY ALERT

In general, an initial increase in intracranial pressure causes respirations to slow; as the pressure continues to increase, respirations become rapid.

- Monitor ICP readings. Continuous measurement of ICP is used to diagnose and monitor IICP. *As ICP increases, herniation may occur, leading to respiratory arrest and death.*
- If the patient is not intubated, prepare for oxygen administration and/or tracheal intubation if respiratory distress occurs. *Supplying oxygen prevents hypoxia until a hematoma can be evacuated, relieving pressure on the respiratory center.*
- Prepare for cranial surgery if deteriorating respiratory pattern and neurologic changes are noted. *Surgical intervention usually consists of placing several burr holes in the skull or performing a craniotomy to remove the hematoma. (Intracranial surgery is discussed later in the chapter.) However, the cerebral edema and IICP may cause death even if surgery is performed.*

Continuity of Care

Inform the patient and family that a postconcussion syndrome sometimes occurs. If the patient experiences persistent headaches and dizziness, is uncharacteristically emotional, seems overly tired, or has difficulty paying attention or remembering, the healthcare provider should be notified. Explain that these manifestations may persist for some time. Rehabilitation may help the patient compensate for memory impairment and attention deficits.

Patients who survive an acute brain injury will require long-term physical care and rehabilitation. Although recovery is highly individualized, many patients who regain consciousness require lifelong care; others remain in a coma or vegetative state. The family members often expect the patient to recover fully after the coma subsides, and they need information about the real possibility of residual deficits in self-care, emotional responses, cognition, communication, and movement. Topics that should be addressed for home care include the following:

- The need to encourage self-care and independence as much as possible
- Information to enhance recovery (CDC, 2010):
  - Get lots of rest. Don't rush back to work or school.
  - Avoid anything that could cause another blow or jolt to the head.
  - Consult with physician about when it will be safe to drive a car, ride a bike, or use heavy equipment (reaction time is often slower after a TBI).
  - Take only prescribed drugs and don't drink alcohol.
  - Write things down if you are having problems remembering.
  - If the injury was severe, therapy may be needed to learn lost skills, such as speaking, walking, or reading.
- Safety issues
- Equipment needs, such as a wheelchair and hospital bed
- Vocational counseling and services
- Referral to community resources and support groups
- Helpful resources: National Head Injury Foundation, Brain Injury Association of America, Brain Trauma Foundation, and the International Center for Individuals with Disabilities.

THE PATIENT WITH A BRAIN TUMOR

Brain tumors are growths of abnormal cells in brain tissue, meninges, the pituitary gland, or blood vessels. Brain tumors may be benign or malignant, primary or secondary (metastatic), and intracerebral or extracerebral. Regardless of type or location, brain tumors are potentially lethal because they grow within a closed cranial vault and displace or impinge on CNS structures. Chapter 14 provides information about cancer in adults.

Incidence and Prevalence

It is estimated that 24,620 new cases of primary malignant brain tumors are diagnosed annually in the United States, and approximately 13,000 people die each year (American Brain Tumor Association [ABTA], 2012). Even more brain tumors are the result of metastasis of cancer in other parts of the body (ABTA, 2012).

The cause of many brain tumors is largely unknown. The brain itself is relatively protected from cancer-causing chemicals that are inhaled or eaten, including cigarette smoke. DNA mutations may affect oncogenes (speed up cell division) or tumor suppressor genes (slow cell division or cause cell death) so that the risk for or actual abnormal cell growth occurs. These mutations may be genetic or may occur as cells continually divide, die, and are replaced. Research is ongoing in this area.

Pathophysiology

Brain tumors may be classified as benign or malignant, based on the tissue type and characteristics of the cells. The use of the term *benign* may be misleading. A tumor that is benign by histologic examination but is surgically inaccessible may continue to grow and expand, increasing intracranial pressure and causing neurologic deficits, herniation, and finally death. In discussions of brain tumors, the term *malignant* is used to describe the lack of cell differentiation and the invasive nature of the tumor.

Brain tumors also may be classified as primary or metastatic, depending on their origin (Table 42–7). Primary tumors of CNS tissue arise from the cells and structures that are found within the brain, for example, neurons and neuroglia. The primary intracranial tumors that originate in the skull cavity but not from brain tissue itself arise

TABLE 42–7 Classification of Primary Brain Tumors

Tumor Type	Tumor Name	Characteristics
PRIMARY TUMORS		
Intracerebral tumors Originate from neuroglia and invade brain tissue Most common type of brain tumor	Glioma • Astrocytoma • Glioblastoma multiforme • Ependymoma • Oligodendroglioma • Astroblastoma	Most common glioma (30% of all brain tumors; 80% of all malignant brain tumors) Most malignant form Fast growing Tumor that develops from lining of ventricles Slow growing Rare, slow growing May be encapsulated Benign
EXTRACEREBRAL TUMORS		
Tumors arising from the supporting structures of the nervous system	Medulloblastoma	Rare (1% of all brain tumors) Fast growing and malignant Found in cerebellum
	Meningioma	Most common primary brain tumor (34%) Slow growing Develops in meninges (especially dura) Firm and encapsulated
	Acoustic neuroma (neurofibromatosis)	About 9% of all brain tumors Slow growing Benign Originates from Schwann cells of cranial nerve XIII May also affect cranial nerves V, VII, IX, and X Genetic origin due to autosomal dominant Mendelian trait Firm, encapsulated lesions attached to nerve
CONGENITAL (DEVELOPMENTAL) TUMORS	Hemangioblastoma	Vascular tumor Slow growing
	Craniopharyngioma	Solid or cystic tumor Compresses pituitary gland Presses on the third ventricle and may cause blockage of CSF
PITUITARY ADENOMAS	Chromophobic	About 13% of all brain tumors Account for most pituitary tumors Nonsecreting tumor Slow growing
	Eosinophilic	Secreting tumors that produce growth hormone
	Basophilic	Secreting tumors that produce adrenocorticotropic hormone Fast growing

from the supporting structures, including the meninges, pituitary gland, and pineal gland. Primary brain tumors rarely metastasize outside the CNS. Metastatic brain tumors originate from structures outside the brain, such as the lungs (most common origination), breasts, and prostate gland.

Focal disturbances from both primary and metastatic tumors take place when there is compression of brain tissue, tumor infiltration, or direct invasion of brain parenchyma with destruction of neural tissue, altered blood flow, and brain edema. Vasogenic edema occurs as the tumor grows and compresses adjacent tissue. Increased capillary permeability allows plasma to seep into the extracellular space and between the layers of the myelin sheath, altering electrical potential and impairing cell activity. Venous obstruction and edema due to breakdown of the blood–brain barrier by substances released by the tumor cells increase intracranial volume and intracranial pressure.

Manifestations

Manifestations can develop as a result of the growth of the tumor, while others are related to the location of the lesion (see the accompanying box). Some of the more common manifestations include changes in cognition or consciousness, a headache that is usually worse in the morning, seizures, and vomiting. Compression of brain tissue and the invasion of the brain tumor into the cerebral tissue may lead to changes typically seen with cerebral edema and IICP (described earlier in the chapter). Cerebral blood supply may diminish as the tumor compresses blood vessels. Shifts in brain tissue can occur, leading to brain herniation syndromes and, if untreated, death.

●○● INTERPROFESSIONAL CARE

Treatment for a brain tumor may involve chemotherapy, radiation therapy, surgery, or any combination of these as discussed in Chapter 14. Several variables are considered when selecting the appropriate treatment modality: the size and location of the tumor, the type of tumor, related symptoms (such as neurologic deficits), and the patient's overall condition.

DIAGNOSIS

A thorough history and physical examination are conducted, with abnormal findings from an examination of the fundus of the eye, visual fields, neurologic assessment, and EEG used to identify a possible tumor. An MRI with gadolinium enhancement, the test of choice, can locate the tumor and define its size, shape, extent to which normal anatomy is distorted, and the degree of any associated cerebral edema. Arteriograms may show stretching or displacement of cerebral vessels by the tumor, as well as the presence of tumor vascularity. Endocrine studies are conducted if a pituitary tumor is suspected. (Refer to Chapters 18 and 41 for further information about diagnostic tests of the endocrine and neurologic systems.)

CHEMOTHERAPY

The use of chemotherapy to treat brain tumors has been limited by the blood–brain barrier. Various methods are used to overcome the barrier. An intraventricular method of medication administration uses an Ommaya reservoir that is surgically implanted into a lateral ventricle of the brain (Figure 42–11 ■). Convection-enhanced delivery (CED) is the continuous injection of chemotherapy (as a fluid) directly to the tumor site through a catheter with positive pressure (in this case, the blood–brain barrier keeps the chemotherapy inside the brain). Biodegradable anhydrous wafers, which are impregnated with a chemotherapeutic drug, may be implanted into the tumor at the time of surgery as another option.

An oral chemotherapeutic medication, temozolomide (Temodar), is used for palliative therapy for glioblastoma. Research is ongoing to develop agents that will specifically target the genetic features and molecular profiles of a tumor (Huether & McCance, 2011).

MANIFESTATIONS OF BRAIN TUMORS BY LOCATION

Lobe	Manifestations
Frontal lobe tumors	• Inappropriate behavior • Recent memory loss • Personality changes • Headache • Inability to concentrate • Expressive aphasia • Impaired judgment • Motor dysfunctions
Parietal lobe tumors	• Sensory deficits: paresthesia, loss of two-point discrimination, visual field deficits
Temporal lobe tumors	• Psychomotor seizures
Occipital lobe tumors	• Visual disturbances
Cerebellum tumors	• Disturbances in coordination and equilibrium
Pituitary tumors	• Endocrine dysfunction • Visual deficits • Headache

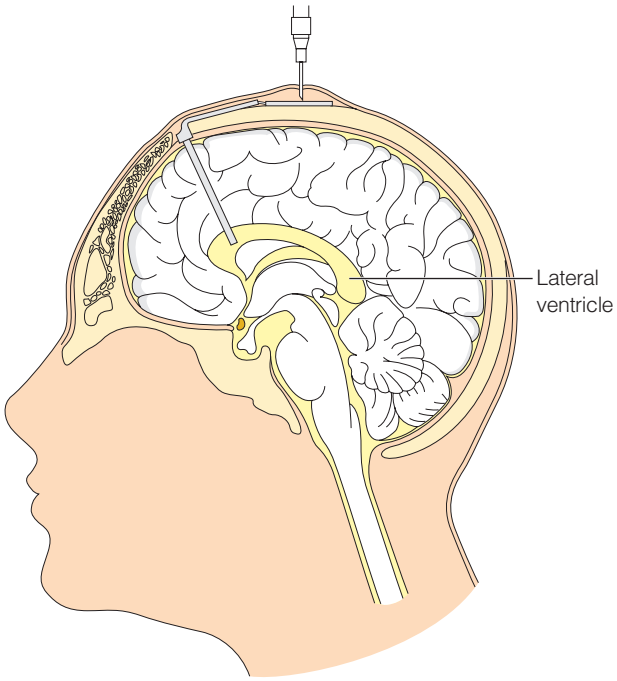

Figure 42–11 ■ Ommaya reservoir for medication administration.

SURGERY

Surgery is the preferred treatment of primary tumors. The goal is to remove the tumor if possible, reduce the size of the tumor, or provide symptom relief (palliation). The type of procedure, the surgical approach, and the timing of surgery (emergency versus planned procedure) influence the overall nursing management of the patient having intracranial surgery.

Some of the more common intracranial neurosurgical procedures follow:

- *Burr hole:* a hole made in the skull with a special drill. The hole may facilitate the evacuation of an extracerebral clot, or a series of holes may be made in preparation for craniotomy (refer to Figure 42–10).
- *Craniotomy:* a surgical opening into the cranial cavity (Figure 42–12 ■). A series of burr holes is made and the bone between the holes is cut with a special saw called a craniotome. The tumor is excised, and the bone flap is returned to the opening. A craniotomy may also be performed to repair defects associated with traumatic head injuries or to repair a cerebral aneurysm. In some cases, the patient is awake during the surgery, as described in the Moving Evidence into Action box on page 1393.
- *Craniectomy:* An excision of a portion of the skull and complete removal of the bone flap. This procedure may be done to provide decompression after cerebral edema. Pressure on the brain structures is reduced by providing space for expansion.
- *Cranioplasty:* Plastic repair to the skull in which synthetic material is inserted to replace the cranial bone that was removed. This procedure may be performed after a large craniectomy. The plastic repair restores the contour and integrity of the cranium.

RADIATION THERAPY

Radiation therapy may be administered alone or as adjunctive therapy with surgery. Radiation is often the treatment of choice for surgically inaccessible tumors; it may also be used to decrease the size of a tumor prior to surgery. Tumors that were not completely excised by surgery may also be treated with radiation.

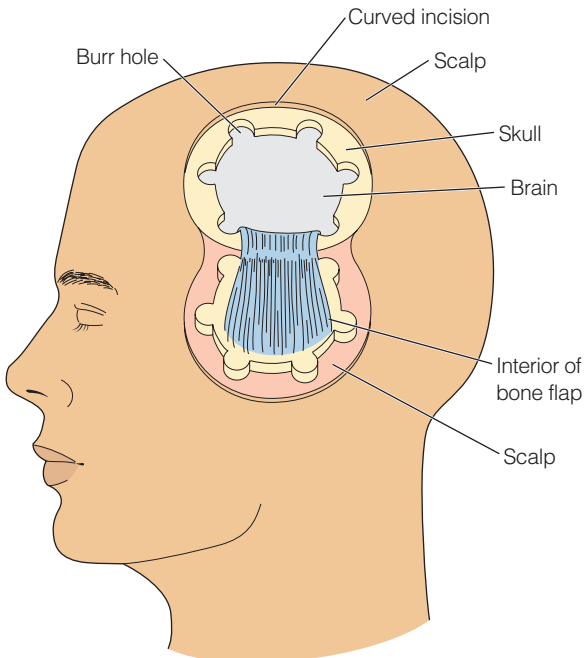

Figure 42–12 ■ In a craniotomy, a portion of the skull and overlying scalp is removed to allow access to the brain.

SPECIALTY PROCEDURES

Technologic advances—including the development of special instruments, the use of stereotaxic techniques for localizing a specific target, and the use of the laser beam—have greatly advanced neurosurgical practice. Microsurgery involves an operating microscope with microinstruments and supportive illumination equipment. Using stereotaxic techniques to precisely locate a specific target point allows for location of discrete areas of the brain that control specific functions and exact locations of deep brain lesions. The use of a laser beam for excision of a tumor results in less damage to surrounding tissue and less postoperative swelling. The gamma knife, which is not actually a knife but a heavily shielded helmet, is capable of destroying deep and otherwise inaccessible lesions in a single treatment session (Huether & McCance, 2011). Research is being conducted on other methods of treating brain tumors, including hyperthermia and duplicating the immune response.

●○● NURSING CARE

The nursing care of the patient with a brain tumor includes support during the diagnostic period and specific management as directed by the selected treatment. The foundation for care is data from the health history and physical assessment, which includes identifying neurologic deficits. Many of the alterations in health commonly experienced by the patient with a brain tumor have been discussed throughout this chapter, including altered level of consciousness, IICP, and seizures. The patient will require intensive care in the immediate postoperative period. In addition to the nursing care described in this section, see the Case Study & Nursing Care Plan for a patient with a brain tumor on page 1395.

Assessment

See the Manifestations and Interprofessional Care sections for the assessment of the patient with a brain tumor.

Priorities of Care

Collaborating with the interprofessional team to ensure adequate treatment of the underlying process while providing care that supports the physical and psychologic responses to the disorder is a priority of nursing care.

Diagnoses, Outcomes, and Interventions

This section of the chapter focuses on nursing interventions for the patient who has intracranial surgery. The nursing diagnoses discussed are anxiety, risk for infection, ineffective protection, acute pain, and low self-esteem.

Anxiety

The diagnosis of a brain tumor brings anxiety and feelings of uncertainty about the future. Both the patient and family members are likely to be apprehensive and require education and emotional support.

Expected Outcome: Patient will be able to control anxiety as evidenced by verbalized decrease in subjective distress.

- Explain routine medical procedures, including blood work and radiologic studies. *Baseline laboratory and radiologic studies are*

Moving Evidence into Action

Patients Undergoing an Awake Craniotomy

Brain mapping is a procedure conducted to identify the functional areas of the brain that control language and motor abilities. The patient is awake during the surgery, and a handheld probe is used to stimulate areas of the brain. The areas stimulated become temporarily inactivated (as evidenced by asking the patient to speak or move), so that the surgeon knows which areas to avoid when removing a brain tumor. This study (Manchella et al., 2011) examined the experiences of patients in term of their feelings, what they think about, and how they approach this type of surgery without an anesthetic.

Findings from the study illustrated the complexity of the experience and the effect on the patient. Preoperatively, the patients felt a part of the decision making about being awake during the surgery, needed strong emotional support, kept busy to remain distracted, and avoided thinking about how they would handle the surgery itself. During the surgery, patients concentrated on doing what they were asked to do and having their senses (especially hearing) play the strongest role. After the surgery, the patients tested their ability to speak and move to ensure they had returned to normal, felt tired, and were surprised that no typical postoperative complications (e.g., nausea, pain) occurred.

Implications for Nursing

There is very little in the literature about nursing care of patients who are awake during surgery. This study identified information about the experience, updating the base for guidelines for preoperative, intraoperative, and postoperative nursing interventions. Certainly, having surgery for a brain tumor, having a malignancy, and knowing one will be awake during the procedure are each traumatic, but when combined they can easily be overwhelming. Nursing care before the surgery must focus on meeting the emotional needs of the patient as well as providing interventions (such as active listening and focused discussions) to relieve anxiety and fear. Because hearing the surgeon explain what was being done was very important to the patients, it is important that the nurse discuss this aspect with the physician.

Moving Knowledge into Action

1. Provide examples of leading statements you might use to discuss awake surgery with a patient.
2. In this study, patients wanted to see their family members immediately after surgery to reassure themselves that they were back to normal. Very few hospitals allow visitors in the recovery area. What process would you use to change this general rule? How would you handle the same request from other patients if the rule were changed for this population?
3. Considering the surgery, describe the immediate postoperative care necessary. What would be the priority assessments?

needed to ensure that the patient has no other preexisting medical condition. Explaining the procedures and assisting the patient through this process help decrease anxiety.

- Reinforce, clarify, and repeat information. *Both patient and family may have limited understanding of the scheduled diagnostic tests, procedures, and treatment modalities. The patient may be confused or have altered thought processes as a result of the tumor. Information may need to be repeated or reexplained.*
- Encourage patient and family to verbalize feelings, questions, and fears. Provide realistic information appropriate to their level of understanding. *Verbalization helps reduce anxiety and fear.*
- Review patient and family strengths and effective coping skills. *Personal strengths, support systems, and coping skills can aid in the development of appropriate strategies to reduce anxiety.*
- Arrange for a member of the clergy to visit if desired. *Faith in a higher being is often a strong source of strength and support.*
- Provide preoperative teaching, including the following information:
  - Type of anesthesia and surgery
  - Time surgery will begin and expected length of procedure and recovery room stay
  - Where the patient will be taken after surgery (CCU, ICU) (If possible, show the patient and family the CCU or ICU and introduce them to the nurse who will be in charge of care after the surgery.)
  - Where family can wait during and following surgery
  - Appearance of the patient after surgery, which may include swollen, bruised eyelids and other facial features; a large dressing covering the head; a partially or fully shaved head; and a tracheostomy or endotracheal tube
  - Behavior of the patient after surgery, which will differ depending on the site of surgery, although cognitive and behavioral changes are common

  Information about what to expect reduces anxiety.
- Allow time for patient and family to be together. *Patients and families need quiet time together to support each other and prepare emotionally for surgery.*

Risk for Infection

The patient who has had intracranial surgery is at risk for infection from multiple invasive lines, the scalp wound, and the risk of introduction of bacteria into the operative area. The nurse provides interventions to monitor for and prevent infection.

Expected Outcome: Infection management and control will be maintained as evidenced by freedom from symptoms of infection, maintenance of white blood cell count and differential, and vital signs within normal limits.

- Monitor for leakage of CSF: presence of glucose in clear drainage from ears, nose, or wound; constant swallowing; statements of "something dripping down the back of my throat." *These manifestations indicate an opening in the dura, which provides an avenue for an ascending infection.*
- Provide interventions to prevent contamination of the area leaking CSF, if appropriate:
  - If leaking from the nose: Keep head of bed elevated 20 degrees unless contraindicated; do not suction nasally; do not clean nose; tell patient not to put finger in nose; do not insert packing.
  - If leaking from the ear: Position patient on side of leakage unless contraindicated; do not clean ear; tell patient not to put finger in ear; do not insert packing.
  - Place a sterile dressing over the area of drainage and change as soon as it becomes damp.

  Leakage of CSF indicates a break in the dura and increases the risk of an ascending infection. Surgery may be necessary to repair the break; however, the leak usually heals spontaneously in about 1 week.
- Monitor for and report manifestations of infection:
  - Take and record temperature on a regular basis.

- Assess IV insertion sites for redness, swelling, drainage, and pain.
- Assess scalp wound for redness, swelling, bulging, drainage, and pain.
- Assess for manifestations of meningitis: fever and chills, increasing headache, neck stiffness, positive Kernig's or Brudzinski sign, photophobia.
- Monitor laboratory reports for increased WBC count.
  Intact skin is the first line of defense against infection. Any break in the skin increases the risk of infection. Intracranial surgery increases the risk of meningitis, with infectious agents ascending into the brain.

- Implement interventions to prevent infection:
  - Use strict aseptic technique when changing dressings and when caring for wound drains and ICP monitor lines.
  - Keep the patient's hands away from drains and dressings; use mitten restraints if necessary.
  - Administer prescribed antibiotics.
    Sterile technique decreases the risk of introducing infection into a wound. Antibiotics are usually prescribed prophylactically to prevent infection.

Ineffective Protection

The patient who has intracranial surgery does not have normal human defenses against changes in intracranial pressure and is also at risk from cerebral edema, IICP (with seizures), and a shift of intracerebral contents. In addition, the surgery may cause cerebral bleeding or hematoma formation. Assessments and interventions for IICP and seizures were described earlier in the chapter.

Expected Outcome: Patient will remain free of any evidence of new increased intracranial pressure or bleeding.

If a shunt has been inserted, the following applies:

- *For internal shunts:* Avoid pressure on the shunt, reservoir, or tubing. Pump the shunt only if prescribed.
- *For external shunts:* Avoid kinks in tubing, and maintain the drainage collecting device and patient's head at the prescribed levels.

Acute Pain

The patient who has intracranial surgery has a headache as a result of either compression or displacement of brain tissue or from IICP.

Expected Outcome: Patient will achieve adequate pain control as evidenced by rest and sleep behaviors and reduced pain-related behaviors.

- Assess the location, duration, and intensity of the pain, using a scale of 0 (no pain) to 10 (worst pain) in the patient who can communicate verbally. *The patient is the best source of information about pain.*
- Implement interventions to reduce the pain:
  - Raise the head of the bed slightly.
  - Reduce noise and bright lights in the room.
  - If allowed, loosen head dressing.
  - Administer narcotic analgesics with caution.
    Nonpharmacologic measures and medications may be used to reduce IICP and headache.

SAFETY ALERT

Narcotic analgesics mask changes in eye signs and depress respirations.

Situational Low Self-Esteem

The patient who has intracranial surgery has many alterations that affect self-esteem and body image. Physical changes include a loss of hair on the scalp, swelling and bruising in the eyelids and face, and perhaps an indentation in the skull. The patient must depend on others to meet basic needs. There are often long-term neurologic deficits, affecting areas such as speech, vision, and motor abilities, which require changes in roles and relationships.

Expected Outcome: Patient will demonstrate that self-perceptions are accurate given their physical capabilities.

- Assess for verbal and nonverbal manifestations of negative self-esteem: denial of changes, preoccupation with changes, refusal to look in the mirror, withdrawal from family and friends, expressions of grief and loss. *Low self-esteem can be initiated by stressful situations and changes in body image.*
- Provide interventions to improve self-concept:
  - Limit negative self-assessment.
  - Help focus on positive areas of life.
  - Help identify sources of support and strength.
  - Help identify and use helpful coping methods.
  - Encourage significant others to visit.
  - Encourage independence in self-care.
    Self-esteem is derived from one's own perceptions of competence and from the responses of others. When one's self-concept and self-ideal are congruent, self-esteem is enhanced.

Continuity of Care

The effect of the possible outcomes following the surgery often produces fear in both patient and family, interfering with their ability to retain information. The patient may have cognitive or neurologic deficits that interfere with learning. Family members must be assessed for their ability to cope with the stress of the surgery. Information may have to be repeated several times.

Patients and their families who have experienced intracranial surgery require emotional support. The process of recovery is often extended and may involve adaptation to changes in body image and management of any motor or sensory deficits. If family members are willing, they may begin to assist with ADLs while the patient is in the hospital, such as assisting with personal hygiene and meals. Patients should also be encouraged to take an active role in their own care. Discharge planning includes a discussion of the following topics: medication information; wound care; the use of wigs, turbans, hats, or colorful scarves; and the importance of follow-up visits. In addition, emphasize the importance of reporting manifestations such as stiff neck, increasing headache, elevated temperature, new motor or sensory deficits, vision changes, or seizures.

Provide information about the overall treatment plan, management of deficits and/or disabilities, and future needs. Specific teaching topics are as follows:

- Safety measures for motor deficits, sensory deficits, lack of coordination, seizures, and cognitive deficits
- Comfort measures for nausea, vomiting, and pain
- Measures for communication if aphasia is present
- Measures to improve vision if visual deficits are present
- How to buy wigs and hairpieces
- Referrals to support groups and community resources

CASE STUDY & NURSING CARE PLAN A Patient with a Brain Tumor

Claire Lange is a 42-year-old television announcer. During one night's broadcast, she confuses several major news items so badly that her co-anchor tries to correct her. Ms. Lange responds angrily that she does not need any help and then rises and storms off the set. As she leaves the camera area, she limps noticeably and appears to drag her left leg. The show's producer asks her what is wrong; she screams that nothing is wrong—she simply has another headache. He follows her to her dressing room and inquires about her headaches. She tells him that they come and go but have been getting worse lately. He then asks her if she has injured her left leg; she responds that the leg was weak because she was tired. As the producer leaves the dressing room, Ms. Lange begins to shake and collapses on the floor. The producer recognizes that she is having a seizure and calls for an ambulance.

Ms. Lange is admitted to the neurology floor of the local hospital for evaluation. A CT scan, MRI, and EEG are completed and identify an intracranial mass. A biopsy of the mass is positive for malignant cells. A glioma in the frontal lobe is identified, and surgery is scheduled for that week.

ASSESSMENT

When Clara Rosetti, RN, enters Ms. Lange's room, she sees Ms. Lange looking at her shoulder-length hair in the mirror. Ms. Lange tells Ms. Rosetti that she has never in her life worn her hair any shorter, and "Now you're going to cut it all off!" She paces the room and makes the statement, "I guess the hair isn't really important if I survive this situation." She also says that she has a headache.

DIAGNOSES

- *Acute Pain* (headache) related to tumor and increase in intracranial pressure
- *Disturbed Body Image* related to upcoming hair loss and cranial incision
- *Anxiety* related to unknown future following surgery

EXPECTED OUTCOMES

- Patient will verbalize the causes of pain.
- Patient will verbalize an understanding of the changes in body appearance that are associated with the scheduled intracranial surgery (e.g., shaving of the head prior to surgery, cranial incision, facial swelling postoperatively).
- Patient will identify measures that will help minimize the effect of the hair loss.
- Patient will verbalize a reduction in anxiety.

PLANNING AND IMPLEMENTATION

- Assess level of discomfort using a rating scale of 0 to 10.
- Provide a quiet, nonstimulating environment.
- Position the patient for comfort, keeping the head of the bed elevated to promote venous drainage.
- Assess level of consciousness for potential increases in ICP.
- Encourage to verbalize feelings about the surgery.
- Suggest measures that may help minimize the hair loss, such as the use of turbans, scarves, hats, and wigs.
- Suggest relaxation techniques to decrease anxiety.

EVALUATION

By the time of surgery, Ms. Lange has recognized the relationship between the brain tumor and the headache. She states that lying in a flat position and coughing increase the headache. The head of the bed is kept at a 30- to 42-degree angle. Daily activities are spaced to provide periods of rest. Ms. Lange demonstrates no significant changes in level of consciousness. She has talked about the effect of the loss of her hair and television responsibilities. Ms. Lange has learned that the hair preparation would be done in surgery and that the hair would be saved for her. She states she has already consulted her hair stylist and that "scarves and turbans are on the way."

Clinical Reasoning in Patient Care

1. Outline interventions to decrease intracranial pressure both before and after surgery.
2. When making your initial assessments on the morning of surgery, you find that Ms. Lange has a decreased pulse and increased blood pressure. She tells you her headache is worse and suddenly vomits. What do you do now?
3. Ms. Lange asks you to be sure that she has absolutely no visitors after surgery, because she knows how ugly she will look. How would you respond?
4. Design a plan of care for Ms. Lange for the nursing diagnosis of *Powerlessness*.

See Evaluating Your Response in Appendix B.

THE PATIENT WITH A HEADACHE

Headache, one of the most frequent manifestations of a health problem, is pain within the cranial vault. Headaches may occur as a result of benign or pathologic conditions, intracranial or extracranial conditions, diseases of other body systems, stress, musculoskeletal tension, or a combination of these factors. Most tension headaches are mild, transient, and relieved by a mild analgesic. However, some headaches are chronic, intense, and recurrent. Manifestations of headache vary according to the cause, type, and precipitating symptoms,

Pathophysiology

The bones of the skull and the brain tissue lack pain-sensitive nerve fibers, but selected structures within and surrounding the cranial vault are sensitive to pain. There are many different types of headaches, and headaches may be primary or secondary to many other illnesses and injuries. This discussion focuses on migraine headache and cluster headache.

MIGRAINE HEADACHE

Migraine headache is a recurring primary headache, often initiated by a triggering event and usually accompanied by a neurologic dysfunction. It affects about 20 million people in the United States and is more common in women than in men. The headaches have a familial association, and are thought to be inherited as an autosomal dominant trait. Migraine headaches may occur daily or as infrequently as once a year.

The two most common types of migraine headaches are migraine without an aura (occurring in about 85% of cases) and classic migraine with aura (Huether & McCance, 2011). In a migraine with aura, some type of sensory manifestation (such as visual disturbances) occurs prior to the manifestations. The manifestations, except for the aura, are the same for both types. The exact causes of migraine are not fully understood, but there is a relationship between serotonin and migraine headaches. It is thought that cerebral blood vessels narrow and reduce blood flow, followed by vasodilation, swelling, and pain.

A variety of factors are believed to trigger the onset of a migraine headache. Rapid changes in blood glucose levels, stress, emotional excitement, fatigue, alcohol intake, stimuli such as bright lights, and food high in tyramine or other vasoactive substances (e.g., aged cheese, nuts, chocolate, and alcoholic beverages) have been associated with migraine attacks. Hypertension and fever may make the disorder worse. The menstrual cycle is a trigger for many women.

In a migraine headache, the pain is unilateral and throbbing, but can become bilateral as the headache continues. Physical activity or even moving the head can intensify pain. Chills, nausea and vomiting, fatigue, and sensitivity to light, sound, or odor are often present. Other manifestations may include blurred vision, anorexia, hunger, diarrhea, abdominal cramping, facial pallor, sweating, and stiffness or tenderness of the neck. The headache lasts 4 to 72 hours and then gradually subsides. The patient may be acutely ill and is often extremely irritable. The sensory organs often become hypersensitive, and the patient withdraws from sound and light. The scalp is tender. After the headache, the headache area is sensitive to touch, and a deep aching is present. The patient is exhausted.

CLUSTER HEADACHE

A cluster headache is an extremely severe, unilateral, burning pain located behind or around the eyes; predominantly experienced by men between 20 and 40 years of age. The headaches occur in groups or "clusters" of one to eight each day for several weeks or months, followed by remission lasting months to years (Hickey, 2013). The physiologic mechanism underlying cluster headaches is not well understood, but involves a vascular disorder, a disturbance of serotonergic mechanisms, a sympathetic defect, or dysregulation of the hypothalamus. The headaches often occur in the spring and fall and then disappear for an extended period. Triggers for cluster headaches are individualized and include alcohol intake, certain foods, smoking, high altitude, and sleep cycle disturbances.

Although the headache may occur at any time, it typically begins 2 to 3 hours after falling asleep, awakens the person, and then lasts from 15 minutes to 3 hours. Intense unilateral pain around or behind one eye is accompanied by rhinorrhea, lacrimation, flushing, sweating, facial edema, and possible miosis or ptosis on the affected side. The same side of the head is involved in each cluster of attacks.

●○● INTERPROFESSIONAL CARE

Therapeutic management of migraine and cluster headache includes a combination of patient teaching, medications, and measures to control contributing factors.

DIAGNOSIS

Diagnosis and treatment are based on history, identifying triggering or precipitating events, and the type of headache. A thorough history and physical examination are integral parts of the assessment. Neurodiagnostic testing may be done to rule out a structural disease process. Testing may include a brain scan, MRI, x-ray studies of the skull and cervical spine, EEG, or lumbar puncture for CSF if inflammation is suspected. Serum metabolic screens and hypersensitivity testing also may be performed if systemic problems are suspected.

MEDICATIONS

The management of migraine and cluster headaches includes administering medications to prevent pain (prophylactic therapy) as well as drugs to stop (or abort) a headache in progress. The patient with frequent migraine headaches is a candidate for prophylactic therapy. When the manifestations of migraine are recognized early, medications may be used to abort or limit the severity and duration of the headache. Drug categories used to treat migraine headaches, followed by examples, include beta-blockers (*propranolol*, [Inderal]), tricyclic antidepressants (*amitriptyline* [Endep]), ergot alkaloids (methysergide [Sansert]), selective serotonin reuptake inhibitors (SSRIs) (*paroxetine* [Paxil]), and calcium channel antagonists (*verapamil* [Calan]).

Sumatriptan (Imitrex) is available in oral, nasal spray, or subcutaneous injection forms. It binds with serotonin$_1$ receptors and is rapidly effective. Zolmitriptan (Zomig), a serotonin 5-HT$_1$- receptor agonist, is administered orally or by nasal spray and is effective in the treatment of acute headache. Once a migraine is in progress, a narcotic analgesic such as codeine may be required. Antiemetics may be prescribed to control nausea and vomiting.

Note: Drugs identified in *italics* are among the 200 most commonly prescribed medications in the United States.

Many of the same medications used to treat migraine headaches are used to treat cluster headaches. Medications such as ergotamine tartrate may be given in suppository form at bedtime to prevent headache during the episodic attacks. Patients may find that inhaling 100% oxygen at 7 L/min for 15 minutes at the onset of an attack relieves their headache. Preventive treatment includes calcium channel blockers, lithium carbonate, topiramate, and baclofen. Intranasal lidocaine may be effective. Deep-brain surgical neurostimulation is an experimental approach that is having some success in eliminating cluster headaches (Huether & McCance, 2011).

●○● NURSING CARE

The primary response of the patient requiring nursing interventions is teaching for self-care at home. Provide suggestions for strategies to control the pain (see Box 42–2). In addition, suggest the patient keep a diary of duration, onset, location, relation to menstruation or food intake, and precipitating triggers. Referrals for methods of stress reduction may be necessary for patients with long-term or migraine headaches.

BOX 42–2 Suggestions to Decrease Incidence of Migraine Headaches

- Wake up at the same time every morning.
- Eat your meals and exercise on a regular schedule.
- No smoking or caffeine after 3 p.m.
- No artificial sweeteners or MSG.
- Reduce or eliminate red wine, cheese, alcohol, chocolate, and caffeine.
- Practice relaxation techniques, such as yoga, meditation, or biofeedback.

CHAPTER HIGHLIGHTS

- Altered level of consciousness (LOC) is a common response to intracranial disorders, and is an early manifestation of deterioration of the function of the cerebral hemispheres. The alteration in cerebral function occurs in a sequential pattern, with characteristic changes in LOC, respiratory patterns, pupillary and oculomotor responses, and motor function. Coma states include persistent vegetative state and locked-in syndrome.
- **Increased intracranial pressure (IICP) is a sustained elevated pressure (greater than 10 mmHg) within the cranial cavity. IICP may result from cerebral edema, hydrocephalus, head trauma, tumors, abscesses, inflammation, hemorrhage, or stroke.**
- The manifestations of IICP include a decreasing LOC, abnormal motor weakness and responses, altered vision, altered vital signs, headache, papilledema, and projectile vomiting. If untreated, IICP causes a displacement (herniation) of cerebral tissue, and herniation of the cerebellum through the tentorium, followed by herniation of the brainstem through the foramen magnum. This is a lethal complication of IICP because it puts pressure on the vital centers in the medulla. IICP is primarily managed with osmotic diuretics and monitored with continuous intracranial pressure monitors.
- **A seizure is a single event of abnormal electrical discharge. Epilepsy is a chronic seizure disorder of abnormal, recurring, excessive, and self-terminating electrical discharges from neurons. Seizures are categorized into those that affect only a part of the brain (partial seizures) and those that affect all of the brain (generalized). The most common type of seizure in adults is a tonic–clonic generalized seizure.**
- **A stroke is a condition in which neurologic deficits result from a sudden decrease in blood flow to a localized area of the brain. Strokes may be ischemic or hemorrhagic. Ischemic strokes result from a blockage of a cerebral artery by formation of a blood clot or by a clot or foreign substance lodging in a blood vessel; they include transient ischemic attacks, thrombotic strokes, or embolic strokes. Hemorrhagic strokes occur when a cerebral blood vessel ruptures.**
- Depending on the size and location of cerebral tissue damage, strokes may cause cognitive and behavior changes, sensory-perceptual deficits, language disorders, and motor deficits. Treatment of an ischemic stroke with fibrinolytic therapy within 3 hours of the onset of manifestations may reverse damage to cerebral neurons.
- Nursing care is directed toward both prevention of a stroke through community-based educational programs and interventions to promote recovery and decrease complications.
- **Intracerebral hemorrhage may follow rupture of an intracranial aneurysm or arteriovenous malformation. Intracranial aneurysms occur at the site of a weakness in a cerebral blood vessel, while AV malformations are a tangled collection of dilated arteries and veins.**
- **Traumatic brain injury (TBI) refers to any injury of the scalp, skull, or brain, and is a leading cause of death and disability. TBIs include focal or diffuse brain injury. An acute brain injury affects all body systems, and carries the risk of secondary injury to the brain from hypoxia and ischemia.**
- An epidural hematoma develops in the potential space between the dura and the skull. A subdural hematoma collects between the dura mater and the arachnoid mater. Diffuse brain injuries include contusions, concussions, and diffuse axonal injury. Patients with an acute TBI must have immediate transport and treatment in an ED, followed by care in an ICU. They will require long-term physical care and rehabilitation.
- **Brain tumors are growths within the cranium, including on or in brain tissue, the meninges, the pituitary gland, or blood vessels. Brain tumors may be benign or malignant, primary or metastatic, and intracerebral or extracerebral. Regardless of the type or location, brain tumors are potentially lethal because they displace or impinge on CNS structures within a closed bony system.**
- Headaches, a common type of intracranial pain, are categorized as tension, migraine, and cluster. A classic migraine is characterized by an aura; a common migraine does not have an aura.

TEST YOURSELF NCLEX-RN® REVIEW

1. The nurse is assessing the breathing pattern of a patient with a head injury who has a change in level of consciousness. Which pathophysiologic event causes an irregular respiratory pattern as level of consciousness decreases?
   1. Pressure on the meninges
   2. Reflexive motor responses
   3. Loss of the oculocephalic reflex
   4. Brainstem responses to changes in $PaCO_2$

2. The nurse assesses a depressed gag reflex in an unconscious patient. Which nursing diagnosis should the nurse use to guide this patient's care?
   1. *Risk for Aspiration*
   2. *Ineffective Breathing Pattern*
   3. *Decreased Intracranial Adaptive Capacity*
   4. *Imbalanced Nutrition: Less Than Body Requirements*

3. The nurse is caring for a patient with increased intracranial pressure. Why should the nurse expect osmotic diuretics to be prescribed for this patient?
   1. To treat hyperthermia.
   2. To prevent the onset of seizures.
   3. To reduce the risk for gastrointestinal hemorrhage.
   4. To draw edematous fluid into the vascular system.

4. The nurse is monitoring the neurologic status of a patient in a coma. Which command should the nurse use to accurately identify changes in mental status?
   1. "Squeeze my hand."
   2. "Tell me your name."
   3. "Are you having trouble breathing?"
   4. "Look at this light when I shine it in your eyes."

5. Laboratory tests are being prescribed for a patient with altered level of consciousness. Which tests should the nurse expect to be prescribed for this patient? (Select all that apply.)
   1. Blood glucose
   2. Urine for WBCs
   3. Serum electrolytes
   4. Spinal fluid osmolarity
   5. Blood and urine toxicology
6. The nurse is caring for a patient with altered level of consciousness. On which laboratory value should the nurse focus as the most accurate indicator of hydration status in the patient?
   1. CBC
   2. Urinalysis
   3. Blood culture
   4. Serum osmolality
7. The nurse is concerned that a patient is experiencing a transient ischemic attack. What did the nurse most likely assess in this patient? (Select all that apply.)
   1. Sudden severe pain over the left eye
   2. Visual disturbance of one or both eyes
   3. Loss of sensation and reflexes in both legs
   4. Complete paralysis of the right arm and leg
   5. Numbness and tingling in the corner of the mouth
8. The nurse is instructing a patient on ways to prevent a stroke. What should the nurse emphasize as being the greatest risks for a stroke? (Select all that apply.)
   1. Diabetes
   2. Head trauma
   3. Heart disease
   4. Hypertension
   5. High cholesterol levels
9. The nurse is providing care for a patient who has had an acute ischemic stroke of a left cerebral vessel. The medical record includes information that the patient has contralateral deficits. What does this information suggest to the nurse?
   1. Both sides of the body are involved.
   2. Deficits will be present below the level of the stroke.
   3. The patient will have neurologic deficits on the left side of the body.
   4. The patient will have neurologic deficits on the right side of the body.
10. A patient with a thrombotic stroke is prescribed to receive tissue plasminogen activator. Why should the nurse ensure this medication is provided within the first 3 hours after the thrombotic stroke?
    1. To increase platelet aggregation.
    2. To cause fibrinolysis of the clot.
    3. To reduce the risk of vasospasm.
    4. To decrease the risk of infection.

See Test Yourself answers in Appendix B.

43 Nursing Care of Patients with Spinal Cord Disorders and CNS Infections

LEARNING OUTCOMES

1. Explain the pathophysiology, manifestations, complications, interprofessional care, and nursing care of patients with spinal cord injury, herniated intervertebral disk, spinal cord tumor, and central nervous system (CNS) infections.
2. Compare and contrast the pathophysiologic effects of injuries and tumors of the spinal cord.
3. Discuss the purposes, nursing implications, and health education of the patient and family for medications used to treat spinal cord injuries, tumors, and CNS infections.
4. Explain the surgical procedures and methods used to stabilize, immobilize, and treat spinal cord injuries.

CLINICAL COMPETENCIES

1. Assess and monitor the functional health status of patients with spinal cord disorders and CNS infections, communicating findings to appropriate interprofessional team members.
2. Demonstrate effective use of individualized and patient-centered strategies as well as evidence-based practice to prioritize care and implement interventions for patients with spinal cord disorders and CNS infections.
3. Adapt individual and cultural values and variations as well as expressed needs and preferences into the plan of care for patients with spinal cord disorders and CNS infections.
4. Administer oral and injectable medications used to treat spinal cord disorders and CNS infections knowledgeably and safely.
5. Provide appropriate and safe care to patients having a carotid endarterectomy, halo fixation, and a posterior laminectomy.
6. Effectively communicate with and function within the interprofessional team to plan and provide care.
7. Utilize assessed data, patient values, and evidence to provide teaching to facilitate self-catheterization, self-care of a ruptured intervertebral disk, and community-based self-care of disabilities resulting from spinal cord disorders and CNS infections.
8. Use evidence-based research to prevent ventilator-associated pneumonia in patients in the neurologic ICU.
9. Revise plan of care as needed to provide effective interventions to promote, maintain, or restore functional health status to patients with spinal cord disorders and CNS infections.
10. Document care in the electronic medical record and use information management tools to monitor outcomes of care.
11. Participate in studies and projects to improve the quality and safety of care for patients with spinal cord disorders and CNS infections.

MAJOR CHAPTER CONCEPTS

- Spinal cord injuries (SCIs) are typically related to trauma, with the major risk factors being age (young adults), gender (male), and alcohol or drug abuse. The causes of SCIs include direct trauma, fractures, torn ligaments, circulatory impairment, contusions, lacerations, or transections of the cord. Complete or incomplete SCIs are determined by the degree of interruption in motor and sensory pathways. Movement, perception, sensation, sexual function, and elimination are potentially affected by these injuries.
- Complications of SCIs include spinal shock, which is the temporary loss of all reflexes (areflexia) below the level of injury. Manifestations of spinal shock include bradycardia, hypotension, and flaccid paralysis. Autonomic dysreflexia (AD) is an exaggerated sympathetic response when SCI injuries are at or above T_6. AD is triggered by noxious stimuli and results in severe and life-threatening hypertension.
- Rehabilitation of the patient with an SCI is an ongoing process from intensive care to home care. Nursing interventions are necessary in all settings to promote independence in self-care.
- A herniated intervertebral disk is a rupture of the cartilage surrounding the intervertebral disk with protrusion of the nucleus pulposus. The major manifestation of lumbar disks is lower back and sciatic pain on the affected side. Medications, treatments, and surgeries are available.
- Spinal cord tumors may be benign or malignant, primary or metastatic. Depending on their size and location, pathologic changes in spinal cord function can result from compression, invasion, or ischemia.
- CNS infections may be caused by bacteria, bacterial toxins, viruses, fungi, protozoans, and rickettsiae. Organisms may enter the CNS through the bloodstream or by direct invasion. The major CNS infections are meningitis and encephalitis, and treatments include broad-spectrum antibiotics or antifungal agents. Community-based health education can provide information to prevent illness in the case of rabies, tetanus, and botulism.

The health problems discussed in this chapter result from disorders of the spinal cord and infections of the central nervous system (CNS). Patients with these disorders experience a wide variety of neurologic deficits that affect functional health patterns. They often also require treatment and care for both acute and long-term health problems.

Nursing care for patients with these disorders is tailored to meet the needs of the patient and is individualized by the patient's responses to alterations in structure and function. The disabilities and long-term effects from spinal cord disorders, spinal cord injuries, and CNS infections have the potential to cause feelings of loss and grief for patient and families.

THE PATIENT WITH A SPINAL CORD INJURY

Nursing care of patients with a spinal cord injury takes place from acute care through ongoing rehabilitation in a variety of settings. Although priorities may change depending on the patient and setting, care focuses on maximizing functional health status to preserve quality of life. The nurse provides care and collaborates with other members of the interprofessional team in meeting this goal.

A **spinal cord injury (SCI)** involves damage to the neural elements of the spinal cord. Because the spinal cord contains the tracts that connect sensory afferent neurons and lower motor neurons with centers in the brain, both sensory and motor functions are often involved. The major causes of SCI are contusion, compression, laceration, transection, hemorrhage, damage to blood vessels that supply the spinal cord, and damage to blood vessels in the spinal cord, resulting in ischemia and possible necrosis (Nayduch, 2010).

If vertebrae are fractured and ligaments are torn, both fractures and tears can damage the cord and spinal nerves and make the spinal column unstable. Injury to blood vessels supplying the cord can cause permanent damage. This discussion focuses on traumatic injuries, but the information is also applicable to congenital deformities, primary or metastatic tumors, ischemia and infarction, and bone disease with pathologic fractures of the vertebrae.

FAST FACTS

SCI

- Approximately 12,000 people suffer an SCI each year.
- An estimated 89.8% of all people with SCIs live in a private, non-institutional setting. Only 6.2% of these individuals go to nursing homes.
- The majority (80.7%) of SCIs occur in young males, and the majority of injuries are caused by motor vehicle crashes (40%). The second most common cause is falls, followed by acts of violence (most commonly gunshot wounds)
- The average age of victims is currently 28.7, and that number is slowly increasing.
- Pneumonia and septicemia are the most common causes of death in those who survive SCIs.

Source: National Spinal Cord Injury Statistical Center, 2013.

Pathophysiology

The spinal cord provides a two-way pathway for the conduction of impulses and information to and from the brain and the body, serves as a major reflex center, and (through its attached spinal nerves) is involved in the sensory and motor innervation of the entire body below the head. It consists of an outer region of white matter and an inner region of gray matter. The gray matter comprises the central canal of the cord, the posterior horns, the anterior horns, and the lateral horns. It is divided into a sensory half (dorsally) and a motor half (ventrally) and innervates somatic and visceral regions of the body. The white matter consists of tracts or pathways that convey information. The ascending (sensory) pathways carry information about proprioception, fine touch, discrimination, pain, temperature, deep pressure, and touch. The descending (motor) pathways carry information about movement. The pyramidal tracts control skilled voluntary movements (such as writing). The extrapyramidal tracts (all tracts other than the pyramidal tracts) bring about all other body movements.

Most spinal cord injuries involve damage to the vertebrae and supporting ligaments as well as the spinal cord itself. Damage to these structures may in turn damage the spinal cord. The pathophysiology of SCI involves primary and secondary injury. When the spinal cord is injured, the irreversible neurologic primary injury causes microscopic hemorrhages in the gray matter of the cord and edema of the white matter of the cord that leads to necrosis of neural tissue. These initial pathologic changes are followed by the secondary injury, with mechanisms that increase the area of injury. Neuronal injury leads to loss of reflexes below the level of injury. The hemorrhages extend, eventually involving the entire gray matter. Microcirculation to the cord is impaired by edema and hemorrhage, causing the release of norepinephrine, serotonin, dopamine, and histamine. Vasospasms occur due to the vasoactive effects and further decrease microcirculation, causing ischemia. Proteolytic and lipolytic enzymes from injured neurons are released, causing further swelling, demyelination, and necrosis in spinal cord neurons (Wagner, Johnson & Kidd, 2013).

When ischemia is prolonged, necrosis of both gray and white matter begins within a few hours, and within 24 hours the function of nerves passing through the injured area is lost. Although circulation returns to the white matter of the cord in about 24 hours, decreased circulation in the gray matter continues. Because edema extends the

level of injury for two cord segments above and below the affected level, the extent of injury cannot be determined for up to 1 week.

Tissue repair occurs over a period of 3 to 4 weeks. Phagocytes enter the area in 36 to 48 hours after the initial injury. Neurons degenerate and are removed by microphages in the first 10 days after the injury. Red blood cells (RBCs) disintegrate, and the hemorrhages are reabsorbed. Eventually the area of injury is replaced by acellular collagenous tissue, and the meninges thicken.

FORCES RESULTING IN SCI

SCIs are the result of the application of excessive force to the spinal column. The most common causes of abnormal spinal column movements are acceleration and deceleration (forces that are applied to the body, for example, in automobile crashes and falls). Acceleration occurs when external force is applied in a rear-end collision; the upper torso and head are forced backward and then forward. Deceleration occurs in a head-on collision; the external force is applied from the front. The head and body move forward until they meet a stationary object and then are forced backward. The alteration of the spinal cord and soft tissues caused by these abnormal movements is called **deformation**. The following forces and movements (Figure 43–1 ■) may cause a variety of spinal cord injuries, with the extent of injury depending on the amount and direction of motion, and the rate of application of force:

- *Hyperflexion*, or forcible forward bending, may compress vertebral bodies and disrupt ligaments and intervertebral disks.
- *Hyperextension*, or forcible backward bending, often disrupts ligaments and causes vertebral fractures. A whiplash injury is a less severe form of hyperextension, with injury to soft tissues but no vertebral or spinal cord damage.
- *Axial loading*, a form of compression, is the application of vertical force to the spinal column (for instance, by falling and landing on the feet or buttocks, or by diving into shallow water).
- *Excessive rotation*, in which the head is excessively turned, may tear ligaments, fracture articular surfaces, and cause compression fractures.

The spinal cord may be penetrated by bullets and other foreign objects (e.g., knife wounds, shrapnel from explosions). Penetrating injuries may cause vertebral fractures or blood vessel damage, tear ligaments and muscles, or cut through part or all of the spinal cord. Complete severing of the cord is rare.

SITES OF PATHOLOGY

The injury is identified by vertebral level. For example, a C_6 spinal cord injury is at the sixth cervical vertebra. The most frequent sites of injury of the cord are at the first, second, and fourth to sixth cervical vertebrae (C_1, C_2, C_4 to C_6); and the eleventh thoracic to second lumbar vertebrae (T_{11} to L_2). Because the cervical spine has a wider range of movement than the rest of the spine, the cervical portion is more likely to be affected by externally applied forces. In addition, the cord fills most of the vertebral canal in the cervical and lumbar regions and thus is more easily injured. Damage to vertebrae and ligaments causes the spinal column to become unstable, increasing the possibility of compression or stretching of the cord with any further movement.

CLASSIFICATION OF SCI

SCIs are further classified according to the amount of cord involvement. **Quadriplegia** (also called *tetraplegia*) occurs with damage to the neural structures in the cervical area of the cord, resulting in loss or impairment of motor and/or sensory function in the arms, trunk, legs, and pelvic organs. **Paraplegia** occurs with damage to the neural structures in the thoracic, lumbar, or sacral area of the cord, resulting in loss or impairment of motor and/or sensory function in the trunk,

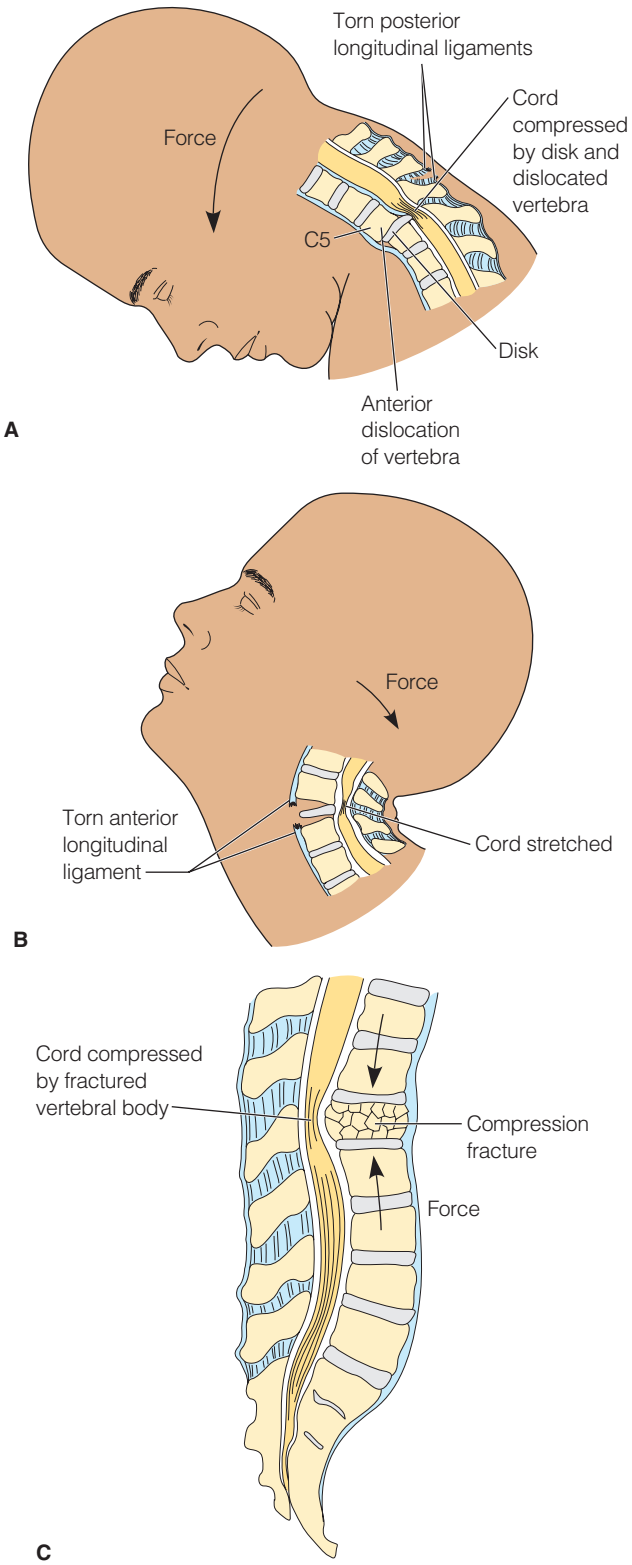

Figure 43–1 ■ Spinal cord injury mechanisms. A, Hyperflexion. B, Hyperextension. C, Axial loading, a form of compression.

TABLE 43–1 Incomplete Spinal Cord Injury Syndromes

Type	Cause	Location	Deficits
Central cord syndrome	Cord transection Hyperextension	Cervical	Spastic paralysis of the upper extremities Variable paralysis of the lower extremities Variable effects on the bowel, the bladder, and sexual function
Anterior syndrome	Damage to the anterior spinal artery Infarction of the anterior spinal artery Hyperflexion	Anterior two-thirds of the cord	Paralysis below the level of injury Loss of temperature and pain sensation below the level of injury
Posterior syndrome	Vertebral dislocation Herniated disk Compression	Nerve roots	Weakness in isolated muscle groups Tingling, pain Decreased or absent reflexes in the involved area Bowel or bladder dysfunction
Brown-Séquard syndrome	Penetrating trauma	Hemisection of the anterior and posterior cord	Paralysis below the level of injury on the ipsilateral (same) side of the body Contralateral loss of temperature and pain sensation below the level of injury Ipsilateral loss of proprioception below the level of injury
Homer's syndrome	Incomplete cord transection	Cervical sympathetic nerves	Ipsilateral ptosis of the eyelid, constricted pupil, and facial anhidrosis (inability to perspire)

legs, and pelvic organs. Function of the arms is spared; the other losses depend on the level of injury. Complete SCIs involve complete interruption of the motor and sensory neural pathways. This results in a total loss of motor and sensory function below the level of the injury, although complete does not necessarily mean the spinal cord has been severed. An incomplete SCI is a partial interruption of the motor and sensory pathways, with variable loss of function below the level of injury. Incomplete SCIs are further classified into syndromes as outlined in Table 43–1. Both complete and incomplete injuries can occur in paraplegia and quadriplegia. Alterations in function that occur as the result of spinal cord injury vary depending on the amount of tissue damage and level of injury.

Manifestations

The spinal cord, vertebrae, intervertebral disks, spinal nerves, ligaments, and surrounding soft tissue structures are in such close anatomic proximity that any condition or injury affecting one structure may affect any one or all surrounding structures. Injuries of the spinal cord have the potential to affect movement, perception, sensation, sexual function, and elimination. Manifestations and complications of SCI by body system are listed in an accompanying box.

SPINAL SHOCK

Spinal shock is the response of the cord itself to injury. It involves temporary loss of reflex function (*areflexia*) below the level of injury at the cervical and upper thoracic spinal cord. As a result of the injury, sympathetic function is interrupted and parasympathetic function is unopposed. This condition is characterized by flaccid paralysis, loss of skin reflexes and deep tendon reflexes, and loss of all sensations below the level of injury. There is loss of urinary bladder tone, intestinal peristalsis, perspiration, and vasomotor tone. Additionally, the autonomic dysfunction results in hypotension, bradycardia (50 to 70 bpm), warm skin, and body temperature that responds to the immediate environment (Nayduch, 2010). The pathophysiology of the characteristic manifestations of spinal shock is described in the Pathophysiology Linkage box on page 1403.

Spinal shock begins immediately after complete transection of the spinal cord, when connections between the brain and the spinal cord are interrupted and the cord does not function at all. The response also occurs (although in varying degrees) after partial transection as well as after spinal cord contusions, compression, and ischemia. Return of function includes bladder tone, hyperreflexia, and sacral reflexes. Flaccid paralysis is then followed by spasticity-hypertonicity (Nayduch, 2010).

An individual with a cervical or upper thoracic SCI may also have **neurogenic shock**, resulting in cardiovascular changes. These changes are due to the inability of higher centers in the brainstem to modulate reflexes. As a result, vascular beds below the level of injury dilate, and the cardiac accelerator reflex is suppressed. The patient experiences hypotension and bradycardia. Other manifestations may include respiratory insufficiency due to loss of innervation of the diaphragm in C_1 to C_4 injuries, hypothermia, paralytic ileus, urinary retention, and oliguria. See the Manifestations box for a list of effects by body system.

It is difficult initially to differentiate spinal shock from neurogenic shock. Recovery from spinal shock is a gradual process, usually lasting from 4 to 6 weeks. Weakness and sensory loss lasting longer than 6 weeks are likely due to the injury. Loss of autonomic tone may last days to months, depending on the severity and level of the SCI. A full neurologic assessment should be done regularly to detect changes signaling the onset of spinal or neurogenic shock (Wagner et al., 2013).

Complications

The complications of an SCI involve many different body systems and often result in permanent disability and loss of functional health status. The complications include but are not limited to upper and lower motor neuron deficits, paraplegia and quadriplegia, and autonomic

MANIFESTATIONS AND COMPLICATIONS OF SPINAL CORD INJURY BY BODY SYSTEM

INTEGUMENT
- Decubitus (pressure) ulcers

NEUROLOGIC
- Pain
- Areflexia
- Hypotonia
- Autonomic dysreflexia

CARDIOVASCULAR
- Spinal shock
- Paroxysmal hypertension
- Orthostatic hypotension
- Cardiac dysrhythmias
- Decreased venous return
- Hypercalcemia

RESPIRATORY
- Limited chest expansion
- Decreased cough reflex
- Decreased vital capacity

GASTROINTESTINAL
- Stress ulcers
- Paralytic ileus
- Stool impaction
- Stool incontinence

GENITOURINARY
- Urinary retention
- Urinary incontinence
- Neurogenic bladder
- Impotence
- Testicular atrophy
- Inability to ejaculate
- Decreased vaginal lubrication

MUSCULOSKELETAL
- Joint contractures
- Bone demineralization
- Osteoporosis
- Muscle spasms
- Muscle atrophy
- Pathologic fractures
- Paraplegia
- Quadriplegia

dysreflexia. Other complications, depending on the level and severity of the injury, are ineffective respirations; altered skin integrity; increased risk of thrombosis; and alterations in bowel elimination, urinary elimination, and sexual patterns.

UPPER AND LOWER MOTOR NEURON DEFICITS

Motor neurons are functional units that carry motor impulses. Injuries to the spinal cord are often classified as either upper motor neuron lesions or lower motor neuron lesions. The upper motor neurons (located in the cerebral cortex, thalamus, brainstem, and corticospinal and corticobulbar tracts) are responsible for voluntary movement. When these motor pathways are interrupted, the patient experiences spastic paralysis and hyperreflexia and may be unable to carry out skilled movement.

Lower motor neurons (located in the anterior horn of the spinal cord, the motor nuclei of the brainstem, and the axons that reach the motor end plate of skeletal muscles) are responsible for innervation and contraction of skeletal muscles. Interruption of lower motor neurons results in muscle flaccidity and extensive muscle atrophy, with loss of both voluntary and involuntary movement. If only some of the motor neurons supplying a muscle are affected, the patient experiences partial paralysis; if all motor neurons to a muscle are affected, the patient experiences complete paralysis and hyporeflexia.

PARAPLEGIA AND QUADRIPLEGIA

Two common neurologic deficits resulting from an SCI are paraplegia and quadriplegia, described earlier and illustrated in the previous chapter (refer to Figure 42–6 on page 1374).

PATHOPHYSIOLOGY LINKAGE

Spinal Shock

Manifestations	Related Pathophysiology
Decreased peripheral vascular resistance with decreased peripheral vascular tone and vasodilatation	Loss of sympathetic input to the blood vessels of the peripheral system and the heart; unopposed vagal tone
Bradycardia	Suppression of the cardiac accelerator reflex and vasodilation.
Hypotension	Loss of autonomic vasoconstrictor reflexes and vascular tone.
Flaccid paralysis	Lower motor neuron injury at or below T_{12}.
Bowel and bladder dysfunction	Lower motor neuron injury at or below T_{12}.
Inability to regulate body temperature and lack of perspiration	Communication between thermoregulatory center in the hypothalamus and sympathetic effector responses below the level of injury is lost, causing loss of ability to conserve or dissipate heat (as by perspiring).
Loss of sensation	Interrupted impulses to the brain.

AUTONOMIC DYSREFLEXIA

Autonomic dysreflexia (also called *autonomic hyperreflexia* or AD) is an exaggerated sympathetic response that occurs in patients with SCIs at or above the T_6 level. This response is seen only after recovery from spinal shock and occurs due to a lack of control of the autonomic nervous system by higher centers. When stimuli are unable to ascend the cord, mass reflex stimulation of the sympathetic nerves below the level of the injured cord area occurs, triggering massive vasoconstriction. The vagus nerve then causes bradycardia and vasodilation above the level of injury. Untreated autonomic dysreflexia is potentially fatal.

Autonomic dysreflexia is triggered by stimuli that would normally cause abdominal discomfort, by stimulation of pain receptors, and by visceral contractions. Causes include a full bladder (the most common cause) resulting from a blocked urinary catheter, fecal impaction, bladder infections or stones, sexual intercourse, intrauterine contractions, pressure ulcers or ingrown toenails, dressing changes, and surgical procedures. Evidence of this syndrome may not occur until months after the injury so that nurses and families must be skilled at recognizing the signs (Nayduch, 2010). Symptoms include pounding headache, bradycardia, flushing, blurred vision, nausea, diaphoresis above the lesion, and hypertension (with readings as high as 240/120 mmHg). Autonomic dysreflexia is a neurologic emergency and requires immediate treatment.

●○● INTERPROFESSIONAL CARE

The patient with an acute SCI requires emergency assessment, immobilization, and possibly medications and surgery. The patient is first assessed and stabilized at the accident scene, transported for treatment to an emergency department, and then admitted to an intensive care unit. Management requires an interprofessional team for this complex multisystem injury.

EMERGENCY CARE

The danger of death from SCI is greatest when there is damage to or transection of the upper cervical region. When the injury is at the C_1 to C_4 level, respiratory paralysis is common, and the patient who survives requires ventilator assistance to breathe. Injuries below C_4 may increase the risk of respiratory failure if edema ascends the cord. It is of critical importance not to complicate the initial injury by allowing the fractured vertebrae to damage the cord further during transport to the hospital. Although at one time injuries to the high cervical cord were almost always fatal, advances in trauma care have greatly improved the survival rate.

All people who have sustained trauma to the head or spine, or who are unconscious, should be treated as though they have a spinal cord injury. Prehospital management includes rapid assessment of the ABCs (airway, breathing, circulation), immobilizing and stabilizing the head and neck, removing the individual from the site of injury, stabilizing other life-threatening injuries, and rapidly transporting the individual by ambulance or helicopter to the appropriate facility (a trauma center, if available). Guidelines for emergency care are as follows:

- Do not flex, extend, or rotate the neck.
- Immobilize the neck, using rolled towels or blankets, or apply a cervical collar before moving the patient onto a backboard.
- Secure the head by placing a belt or tape across the forehead and securing it to the stretcher.

BOX 43–1 Assessment Findings in Acute SCI

CERVICAL INJURY
- Paralysis or weakness of extremities
- Respiratory distress manifested by changes in ABG studies, cyanosis, flaring of the nostrils, use of accessory muscles of respiration, and restlessness
- Pulse rate below 60 bpm and systolic BP below 80 mmHg
- Decreased peristalsis

THORACIC AND LUMBAR INJURY
- Paralysis or weakness of extremities

- Maintain the patient in the supine position.
- Transfer directly from the stretcher with backboard still in place to the type of bed that will be used in the hospital.

Assessment findings at the scene of the accident or in the ED vary according to the level of injury. The assessment findings common to the level of injury are outlined in Box 43–1. Manifestations of spinal shock are also assessed.

The patient in the ED with a suspected or identified SCI is also treated for respiratory problems, paralytic ileus, atonic bladder, and cardiovascular alterations. Respiratory distress in the patient with a cervical-level injury is treated by placing the patient on a ventilator. Oxygen is administered to the patient with a thoracic-level injury. Paralytic ileus (obstruction of the intestines due to lack of peristalsis) is common in patients with an SCI and is treated by the insertion of a nasogastric tube hooked to wall suction. To prevent overdistention of an atonic bladder, an indwelling catheter is inserted and connected to gravity drainage. Cardiovascular status is assessed continuously using telemetry as well as invasive monitoring devices, such as a pulmonary artery catheter and/or arterial line. Steroid protocols are often instituted using methylprednisolone (Solu-Medrol) if the drug can be given within 8 hours of injury. Although there are risks associated with its use, evidence shows that methylprednisolone reduces cord compression resulting from edema, thereby avoiding a secondary injury (Hansebout & Kachur, 2012).

DIAGNOSIS

Diagnostic tests are ordered to identify the level and extent of injury, and to detect any complications. The tests include x-rays of the spine, CT or MRI of the spine, and somatosensory-evoked potential studies to locate the level of spinal cord injury by stimulating peripheral nerves and measuring response times. ABGs are measured to establish a baseline or to identify problems due to respiratory insufficiency. A trauma screen (blood type and cross-match, blood alcohol level, urine drug screen, and pregnancy test for women up to age 45) is conducted in the ED.

FLUIDS

Crystalloids such as D_5 45NS or Ringer's lactate solution are often administered. Potassium and multivitamins may be added to the IV fluids. If the patient becomes hypotensive in the early stage of treatment, IV fluids are administered to increase blood pressure.

MEDICATIONS

Pharmacologic treatment of the patient with SCI is primarily symptomatic. Medications focus on decreasing edema from the injury, treating hypotension and bradycardia, relieving pain, treating

spasticity, preventing immobility complications, and maintaining bowel function.

- Corticosteroids may be used to decrease or control inflammation and edema of the cord.
- Vasopressors are used in the immediate acute care phase to treat bradycardia or hypotension due to spinal and neurogenic shock. Examples of these drugs are dopamine (Intropin) to treat hypotension in neurogenic shock and dobutamine (Dobutrex) to support cardiac function. Atropine should be available at the bedside to treat bradycardia.
- Antispasmodics such as *baclofen* (Lioresal), *diazepam* (Valium), and dantrolene (Dantrium) may be used to treat spasticity in patients with spinal cord injury.
- Antiemetics may be administered to prevent vomiting.
- Analgesics such as nonsteroidal anti-inflammatory drugs (NSAIDs) and narcotics are administered to reduce pain.
- Proton pump inhibitors, such as *esomeprazole* (Nexium), *omeprazole* (Prilosec), rabeprazole (AcipHex), or pantoprazole (Protonix), are often administered to prevent stress-related gastric ulcers, a common complication in SCI.
- Unless contraindicated, anticoagulants including heparin or *warfarin* (Coumadin) may be given to prevent thrombophlebitis.
- Stool softeners such as docusate (Colace) may be administered as part of a bowel training program (Wilson et al., 2013).

TREATMENTS

The treatments used in the management of an SCI include surgery, stabilization, and immobilization.

SURGERY Early surgical treatment may be necessary if there is evidence of compression of the spinal cord by bone fragments or a hematoma. Surgery may also be done to stabilize and support the spine. However, many patients are treated with stabilization devices and do not require surgery. Surgeries that may be performed include a decompression laminectomy, a spinal fusion, and insertion of metal rods. Surgeries of the spine are discussed later in the chapter.

STABILIZATION AND IMMOBILIZATION As a result of one or more dislocations or fractures of the cervical vertebrae, the patient with an SCI may be immobilized in some type of traction or external fixation device to stabilize the vertebral column and prevent further damage to the cord (Figure 43–2 ■). Traction may also be used to stabilize the spinal column for patients who are not yet in a condition to have surgery or who have severe bleeding and edema of the injured cord. The physician applies the traction or fixation device; the nurse is responsible for assessments and interventions following the application.

Figure 43–2 ■ Traction device.

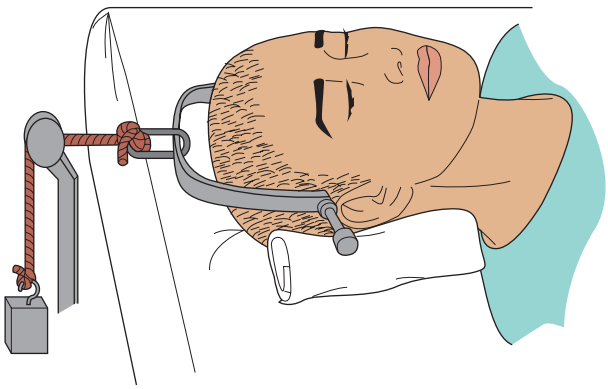

Figure 43–3 ■ Cervical traction may be applied by several methods, including Gardner-Wells tongs.

Although used less frequently today, various devices provide cervical traction. For example, Gardner-Wells tongs may be used (Figure 43–3 ■). In this type of traction, the physician applies pins to the skull, approximately 1 cm above each ear, and weights are attached to the device.

The halo external fixation device is often used to provide stabilization if there is no significant involvement of the ligaments (Figure 43–4 ■). It is most often used to provide stability for fractures

Moving Knowledge into Action

A 45-year-old female is admitted with a neck injury after falling off of her horse. The patient is fully immobilized with a cervical collar in place. She is alert, oriented, and complaining of shortness of breath. The patient is receiving 4 L/min of oxygen per nasal cannula and her pulse oximetry measures 89%.

1. What are the priorities when planning care for this patient?
2. What diagnostic tests should you prepare this patient for as you plan care?

of the cervical and high thoracic vertebrae without cord damage. This device allows greater mobility, self-care, and participation in rehabilitation programs. The device is secured with four pins inserted into the skull, two in the frontal bone and two in the occipital bone. The halo ring is then attached to a rigid plastic vest lined with sheepskin. Nursing interventions for the patient using a halo fixation device are described in an accompanying box.

RESEARCH TO IMPROVE SCI MANAGEMENT

An SCI is costly in terms of human life, human function, and healthcare costs. For the patient with a high cervical injury, improving the ability of even one spinal segment to function may make an enormous difference in quality of life. Research is currently being conducted on neurons of the spinal cord, stimulators to improve muscle function, and equipment to aid activities of daily living (ADLs) (National Institute of Neurologic Disorders and Stroke [NINDS], 2013b).

Scientists are focusing on methods of advancing our knowledge of spinal cord repair, including protecting surviving neurons from further damage, replacing damaged neurons, stimulating the regrowth of axons and correctly targeting their connections, and retraining neural circuits to restore body functions. Basic research is ongoing about areas such as decreasing or blocking the action of glutamate so that secondary nerve damage is minimized, controlling inflammation, preventing self-destruction of nerve cells, and promoting regeneration. These effects may possibly be initiated by medications, cooling the body to a state of mild hypothermia, transplanting cell grafts into the damaged area, using stem cells, and promoting axonal growth (Schira et al., 2012).

Clinical research to improve rehabilitation is ongoing. A functional electrical stimulation (FES) system uses electrical stimulators to encourage functional walking and gripping. The stimulators must be implanted and the computer interface system is still limited. Devices implanted in the brain might be used to send a signal to a computer that in turn signals a robotic arm to move. New technologies include improved, lighter-weight wheelchairs; some can climb stairs and lift an individual to eye-level. Voice-activated computers can be used for many self-care activities, including banking, dialing a phone, reading, and dressing (NINDS, 2013b).

●○● NURSING CARE

The patient with an SCI has complex needs during both the acute phase and the rehabilitative phase that involve a multidisciplinary approach to care. Patients are typically younger and will therefore require consideration of the lifelong effects on themselves and their families. The nurse coordinates and plans patient care, implementing interventions that are individualized. The focus of the plan is to prevent the secondary complications of immobility and altered body functions, to promote self-care, and to educate the patient and family. See the Case Study & Nursing Care Plan for a patient with an SCI on page 1410.

NURSING CARE OF THE PATIENT

Halo Fixation

- Maintain integrity of the halo external fixation device:
  a. Inspect pins and traction bars for tightness; report loosened pins to physician.
  b. Tape the appropriate wrench to the head of the bed for emergency intervention.
  c. Never use the halo ring to lift or reposition the patient.
  Loosening of the apparatus poses the risk of further damage to the cord. It is the responsibility of the nurse to maintain the integrity of the apparatus and the safety of the patient.
- Assess muscle function and skin sensation every 1 hour in the acute phase and every 4 hours thereafter:
  a. Assess motor function on a scale of 0 to 5, with 0 being no evidence of muscle contraction and 5 being normal muscle strength with full range of motion (ROM).
  b. Assess sensation by comparing touch and pain, moving from impaired to normal areas, and testing both the right and left sides of the body.
  Monitoring muscle function and skin sensation allows early identification of potential neurologic deficits.
- Monitor pin sites each shift and follow hospital policy for pin care daily for the first 48 to 72 hours, and then weekly. General guidelines include the following (Wagner et al., 2013):
  a. Assess pin sites for redness, edema, odor, and drainage.
  b. Clean each pin site with a sterile applicator dipped in a sterile solution (such as sterile chlorhexidine solution, 2 mg/mL) using one applicator per stroke in a circular motion, moving away from the pin. Remove crusts.
  c. Apply a topical antibiotic and cover with sterile 2-inch split gauze squares.
  Organisms can enter the body through the pin-insertion site and crusts; assessments and care are provided to detect signs of and prevent infection.
- Maintain skin integrity:
  a. Turn the immobile patient every 2 hours.
  b. Inspect the skin around edges of the vest every 4 hours.
  c. Change the sheepskin liner when it is soiled and at least once each week.
  These interventions prevent skin injury and irritation.

Health Promotion

Health promotion for SCI primarily involves preventing injuries. Nurses can provide valuable information in the community and in the workplace to prevent SCI. Programs that focus on wearing seat belts and using approved infant seats and child booster chairs in automobiles can do much to help decrease the number of SCIs each year. Educational programs that promote workplace safety and farm safety should include information about how to prevent falls and how to use heavy equipment safely.

Assessment

The following data are collected through the health history and physical examination (refer to Chapter 41). Further focused assessments are described with nursing interventions in the next section.

- *Health history:* time, location, and type of event causing injury; location, duration, quality, and intensity of pain; dyspnea; sensation; paresthesia
- *Physical assessment:* vital signs, motor strength, movement, spinal reflexes, bowel sounds, bladder distention, level of consciousness.

Priorities of Care

Nursing care priorities for the patient with SCI evolve over time. Interventions to preserve life and prevent or manage complications have priority during the initial period following the injury. As the acuity of the injury resolves, the focus moves to restoring functional capabilities to the greatest extent possible.

Diagnoses, Outcomes, and Interventions

Because an SCI has many possible effects, many nursing diagnoses may be appropriate. Nursing diagnoses discussed in this section focus on problems with physical mobility, respirations, dysreflexia, bowel and bladder elimination, sexual dysfunction, and self-esteem.

Impaired Physical Mobility

After the initial period of spinal shock and areflexia, the patient regains spinal reflex activity and muscle tone that is not under the control of higher centers. Patients with injuries above the level of T_{12} experience involuntary spastic movements of skeletal muscles. These movements reach a peak about 2 years after the injury and then gradually subside (Wagner et al., 2013). Spasms impair the ability to carry out ADLs and work. If present, paraplegia or quadriplegia increases the potential for impaired skin integrity, thrombophlebitis, and contractures.

The goals of care for patients with impaired mobility related to a spinal cord injury are to reduce the effects of spasticity and to prevent complications involving the skin, the cardiovascular system, and joint function.

Expected Outcome: Patient will demonstrate minimal spasticity and optimal motor functioning.

- Perform passive ROM exercises for all extremities at least twice a day. Identify stimuli that cause spastic movements and either avoid the stimuli (such as certain exercises) or teach the patient to expect the movements. *ROM exercises help prevent contractures and stretch spastic muscles, promoting rehabilitation.*
- Maintain skin integrity by turning every 2 hours, assessing pressure points at least once each shift, and using a special bed if necessary. The patient may be placed on a regular or special bed, such as a kinetic bed. *Immobility compresses soft tissues and promotes the development of decubitus ulcers. The lack of sensory warning mechanisms and of voluntary motor control of skin dermatomes further increases the risk for altered skin integrity. Special beds allow movement or turning while keeping the spinal column in alignment.*
- Assess the lower extremities each shift for manifestations of deep venous thrombosis (DVT). Observe for redness, swelling, and increased heat; measure thigh and calf circumference daily. If antiembolic stockings or sequential compression devices are ordered, remove for 30 to 60 minutes each shift and assess for skin impairment and provide skin care. *Patients with neurologic deficits are at high risk for DVT as a result of immobility, vasomotor dysfunction, and decreased venous return with venous stasis, especially during the first 2 to 3 weeks after injury. Thigh-high graduated compression stockings and/or sequential compression boots help prevent pooling of blood in the lower extremities and increase venous return, lessening the risk for venous stasis and thrombus formation. Nurses must ensure the stockings are properly sized and used.*

Impaired Gas Exchange

Injuries at the level of C_3 to C_5 affect the diaphragm and the phrenic nerve. An injury at level T_1 through T_7 impairs phrenic nerve innervation of the intercostal muscles, and at T_6 to T_{12}, the abdominal muscles are denervated, compromising exhalation and overall respiratory function. Patients will have an ineffective cough due to abdominal muscle paralysis, thereby increasing the risk of pneumonia. Patients with cord injuries at C_3 or above have paralysis of the respiratory muscles and cannot breathe without a ventilator (see the Moving Knowledge into Action box for related nursing care). Goals of care are to maintain a patent airway, promote oxygenation, and prevent respiratory complications.

Expected Outcome: Patient will demonstrate effective respiratory pattern and adequate gas exchange.

- Monitor vital capacity and respiratory effectiveness, assessing for tachycardia, restlessness, PaO_2 less than 60 mmHg, $PaCO_2$ greater than 50 mmHg, and vital capacity less than 1 L. *Patients with cervical cord injuries frequently require ventilatory support; injuries at other levels may reduce deep breathing, vital capacity, and effective coughing.*

SAFETY ALERT

Changes in ABGs and vital capacity signal respiratory insufficiency.

- Monitor for signs of ascending edema of the spinal cord, including difficulty swallowing or coughing, respiratory stridor, use of accessory muscles of respiration, bradycardia, and increasing motor and sensory loss. Report these manifestations immediately. *Hemorrhage and edema can further impair respiratory function. Patients with injuries above C_7 may need a tracheostomy in addition to mechanical ventilation.*

Ineffective Breathing Pattern

In patients with SCI injury at higher levels, assisted ventilation and a tracheostomy are often necessary; when the injury is at lower levels, the patient's ability to take a deep breath and cough is also diminished.

Evidence for Nursing Care

The Patient with Spinal Cord Injury

A resource that nurses may find helpful when planning evidence-based nursing care follows.

- Consortium for Spinal Cord Medicine. (2010). Sexuality and reproductive health in adults with spinal cord injury: A clinical practice guideline for health-care professionals. *Journal of Spinal Cord Medicine, 33*(3), 281–336.

Moving Evidence into Action

Reducing Incidence of Ventilator-Associated Pneumonia

Ventilator-associated pneumonia (VAP) is a preventable secondary complication from intubation and mechanical support. Mechanically intubated patients in the ICU are at increased risk of VAP from factors such as a decreased level of consciousness; dry, open mouth; and aspiration of secretions. A quality improvement project conducted by Hutchins and colleagues (2009) examined the use of oral care every 4 hours on these patients. The teeth were brushed with cetylpyridinium chloride using a suction toothbrush, the oral cavity was cleansed with suction swabs treated with hydrogen peroxide, a mouth moisturizer was applied, deep oropharyngeal suctioning was performed, and suction catheters were used to control secretions. The primary efficacy variable was a diagnosis of VAP in patients mechanically ventilated for ≥48 hours.

Results demonstrated that the use of an oral care protocol intervention and ventilator bundle led to an 89.7% reduction in the VAP rate in mechanically ventilated patients from 2004 to 2007 (Hutchins et al., 2009). This study improved nursing care and patient outcomes significantly.

Implications for Nursing

Although studies have been conducted to determine if oral care and preventing VAP are related, the role of tooth brushing largely has been ignored. This study demonstrated that timed, consistent oral care can almost totally reduce the incidence of VAP in ICU patients who are mechanically intubated. As such, the study provides evidence on which to base nursing practice to prevent complications, and also demonstrates the cost effectiveness of a simple nursing intervention.

Moving Knowledge into Action

1. What factors do you believe contribute to nursing compliance, or lack of it, with this type of oral care protocol?
2. This study was designed for a specific population. How do you think it could be adapted to prevent respiratory problems in patients who are not mechanically ventilated, but are comatose, demented, quadriplegic, or very old?

The goals of nursing interventions are to maintain normal respiratory rate (12 to 20 breaths per minute), maintain a patent airway, effective breathing patterns, and to prevent pulmonary complications such as atelectasis and pneumonia.

Expected Outcome: Patient will demonstrate effective respiratory patterns and an absence of infectious and mechanical complications.

- Assess respiratory rate, rhythm, and depth every 4 hours (or more frequently if needed). Auscultate breath sounds as a part of a respiratory assessment. *Injury to the cervical or thoracic cord can decrease respiratory function and increase the risk for respiratory problems.*
- Monitor results of oxygen saturation with pulse oximetry and arterial blood gas (ABG) studies. *ABG studies provide information about gas exchange; decreasing pH, oxygen, and oxygen saturation levels and increasing carbon dioxide levels signal respiratory acidosis.*
- Administer supplemental oxygen as prescribed. *Oxygen saturation must be maintained at 100% with supplemental oxygen to prevent hypoxemia and secondary SCI.*
- Assist the patient to turn, cough, and deep breathe at least every 2 hours. *Paralysis of intercostal or abdominal muscles decreases the ability to expectorate secretions by coughing; retained secretions increase the risk for pneumonia. The inability to breathe deeply may result in atelectasis.*
- Increase fluids given by mouth to 3000 mL per day (if oral intake is approved), according to patient preference for type of liquids and the patient's ability to swallow. *Increased fluid intake thins secretions and facilitates expectoration (Wagner et al., 2013).*

Autonomic Dysreflexia

Autonomic dysreflexia is an emergency that requires immediate assessment and intervention to prevent complications of extremely high blood pressure (loss of consciousness, seizure, and even death).

- Elevate the head of the patient's bed and remove compression stockings or boots. *These measures create a position that induces orthostatic hypotension, thereby causing pooling of blood in the lower extremities and decreased venous return, thus decreasing blood pressure.*
- Assess blood pressure every 2 to 3 minutes while at the same time assessing for stimuli that initiated the response (such as a full bladder, impacted stool, or skin pressure). *The most serious danger in dysreflexia is elevated blood pressure, which could precipitate a stroke, myocardial infarction, dysrhythmias, or seizures. If the patient has a Foley catheter, ensure that there are no kinks in the tubing. If there is no Foley catheter, drain the bladder with a straight catheter. If manifestations persist, assess for a fecal impaction and, if present, insert Nupercaine cream into the rectum, wait 10 minutes, and digitally remove the impaction.*
- If blood pressure remains dangerously elevated, the physician may prescribe intravenous administration of diazoxide (Hyperstat). Other medications that may be used include nifedipine (Procardia), hydralazine (Apresoline), or labetalol (Normodyne). *Diazoxide is an antihypertensive drug used in emergency situations to lower blood pressure in adults with dangerously high readings. Nifedipine and hydralazine are peripheral vasodilators that are administered to decrease the elevated blood pressure. Labetalol is a beta-blocker that results in vasodilation and thereby lowers BP.*

SAFETY ALERT

It is important to closely monitor for hypotension following administration of these medications, especially if the stimulus for the dysreflexia has been removed. If labetalol is ordered, the heart rate must be at least 60 for safe administration of this medication.

Impaired Urinary Elimination and Constipation

Depending on the level of the injury, the patient with an SCI may have alterations in bowel and bladder function. Patients with injuries to the cord at or above the S_2 to S_4 levels will have a neurogenic bladder, with deficits in control of micturition. Voluntary and involuntary bowel control are affected in the patient with a lower motor neuron injury. Bowel and bladder retraining are possible but if not, then assisted elimination is necessary. Although an indwelling catheter may be used in the acute phase of care, the goal is to reestablish a catheter-free state where intermittent self-catheterization is possible. Goals of care are to restore effective elimination patterns.

Expected Outcome: Patient will demonstrate normal bladder and bowel patterns.

- Monitor for manifestations of a full bladder. *Overdistention stretches the bladder and can lead to backflow of urine into the ureters and kidney. Stasis of urine in an incompletely emptied bladder increases the risk for infection.*
- Monitor for bowel sounds, bowel patterns, and stool consistency. *Good bowel function is imperative for effective elimination and to prevent complications.*

SAFETY ALERT

A distended bladder can be palpated over the lower abdomen above the symphysis pubis. Voiding frequently in small amounts may signal a neurogenic bladder.

- Teach how to use trigger voiding techniques prior to straight catheterization. These techniques include stroking the inner thigh, pulling the pubic hair, tapping on the abdomen over the bladder, and (in females) pouring warm water over the vulva. *These techniques stimulate parasympathetic reflexes and may facilitate voiding.*
- Teach self-catheterization to patients who will be able to carry out the procedure alone or with minimal assistance (Box 43–2). *Straight catheterization at regular intervals is part of bladder training because periodic distention and relaxation of bladder muscles promote reflex bladder activity. In addition, self-care fosters independence.*
- Monitor residual urine throughout the bladder retraining program. *A residual urine amount of less than 80 mL after a triggered voiding is considered satisfactory.*
- Monitor for elimination of frequent, small, liquid, foul-smelling stools. *Injuries to sacral cord elements or higher often result in loss of defecation reflex. Even if peristalsis is present, the ability to have a bowel movement is impaired by loss of this reflex. Fecal impactions are an ongoing problem and are manifested by this type of bowel elimination.*
- Institute a bowel retraining program as follows:
  - Assess patterns of bowel elimination to establish the best times for individualized program.
  - Maintain high-fluid, high-fiber diet.
  - Use stool softeners as prescribed; rectal suppositories and enemas may be used 30 minutes after meals to stimulate stronger peristalsis and facilitate evacuation.
  - Maintain upright position if at all possible and ensure privacy.
  - If patient is unable to evacuate, digital stimulation or manual removal on a regular basis may be the most effective long-term management.

  A bowel retraining program to regulate the bowel through reflex activity may be instituted in patients with upper motor neuron injuries. The patient with a lower motor neuron injury loses defecation reflex, and bowel retraining is more difficult.

Sexual Dysfunction

Sexual intercourse is often still possible for the SCI patient. In men, the general rule is that the higher the level of injury the greater the potential to have reflexogenic erections, although ejaculation or orgasm may not occur. Fertility is diminished due to a lack of temperature control of the testes. Ejaculation can be stimulated so that the patient's sperm can inseminate his partner, so that fatherhood is a possibility. Men who have sacral-level injuries do not have reflexogenic erections but may have psychogenic erections and are more likely to remain fertile.

Women with SCI generally do not have sensation during sexual intercourse, but pregnancy is possible. There is an increased risk of autonomic dysreflexia in pregnant females with SCI, particularly

BOX 43–2 Patient Teaching of Self-Catheterization

Self-catheterization on an intermittent basis (usually a part of self-care at home) is a clean rather than a sterile procedure. The hands should be washed before and after the procedure, and the urinary meatus should be gently cleansed with soap and water.

FEMALE SELF-CATHETERIZATION

- Attempt to void. If urine is not of sufficient quantity (at least 100 mL) or if you cannot void at all, do self-catheterization. *A large amount of residual urine means that more frequent catheterizations (every 4 to 6 hours) are necessary.*
- While sitting on the wheelchair or the commode, locate urethra. Visualize urethra by looking in a mirror, or palpate urethra with fingertip. *Visualization or palpation of the meatus is necessary for accurate catheter insertion.*
- Lubricate meatus with a water-soluble lubricant. *Lubrication facilitates insertion of catheter and reduces trauma to tissues.*
- Take a deep breath and insert the catheter tip 5 to 7.5 cm (2 to 3 in.) or until urine flows. *The catheter enters bladder more easily when sphincter is relaxed. The deep breath relaxes sphincter. The female urethra is 3.8 to 6.4 cm (1.5 to 2.5 in.) long.*
- Hold catheter securely and allow urine to drain until flow stops. *Withdrawing and reinserting catheter increase risk of infection.*
- Withdraw catheter and wash with soap and water. Store catheter in a clean airtight container. *The catheter can be reused until it is too soft or too hard to be directed into and through urinary meatus. Clean technique (not sterile) is sufficient for home self-catheterization.*

MALE SELF-CATHETERIZATION

- Attempt to void. If urine is not of sufficient quantity (e.g., less than 100 mL) or if you cannot void at all, do self-catheterization. *A large amount of residual urine means that more frequent catheterizations (every 4 to 6 hours) are necessary.*
- Sit either on the commode or in wheelchair. Hold penis with slight upward tension and extend it to its full length. *Extending the penis straightens the urethra.*
- Lubricate the catheter from tip to about 15 cm (6 in.) downward. *Lubrication is crucial to male catheterization because of length of urethra.*
- Take a deep breath and insert catheter 15 to 18 cm (6 to 7 in.) or until urine flows. *The catheter enters bladder more easily when sphincter is relaxed. The deep breath relaxes sphincter. The male urethra is about 15 cm (6 in.) long.*
- Hold catheter securely and allow urine to drain until flow has stopped. *Withdrawing and reinserting catheter increase risk of infection.*
- Withdraw catheter and wash with soap and water. Store catheter in a clean and airtight container. *The catheter can be reused until it is too soft or too hard to be directed into and through the urethra. Clean technique (not sterile) is used for home self-catheterization.*

during labor and delivery. Birth control options should be discussed on an ongoing basis.

A patient with an SCI may be deeply concerned about sexual dysfunctions, and these concerns may lead to lowered self-esteem, altered self-image, and/or changes in feelings about being an attractive and desirable person. The nurse must assess concerns and provide a climate that is receptive to discussion about sexuality. Examples of objectives for sexual counseling for the SCI patient are that the patient will understand how the injury has altered sexual functioning, will be aware of alternative ways of achieving sexual pleasure, and will have a positive self-concept and body image.

Patients with SCIs will be assessed in terms of their physical limitations and educated regarding the potential for sexual functioning and fertility.

Expected Outcome: Patient will experience optimal sexual functioning with minimal complications related to sexual interactions.

- Include data about sexuality when obtaining the nursing history and database. *Sexuality is a private matter for most people, and the patient may not discuss it unless the nurse introduces the topic.*
- Provide accurate information about the effect of the SCI on sexual function. *Accurate information gives the patient a realistic picture of how the injury will affect sexuality.*
- Initiate a discussion with the patient and partner of alternative means of gaining sexual satisfaction; these include the use of vibrators, and oral–genital and manual stimulation. *Alternatives to intercourse can meet sexual needs and help maintain the relationship with a significant other.*
- Refer for sexual counseling, if appropriate, or to local support groups where questions can be answered by others with similar experiences. *Knowing that others have had similar experiences can decrease social isolation and provide a means of learning alternative methods of sexual functioning.*

Situational and Chronic Low Self-Esteem

An SCI is the result of sudden trauma. Within moments, a formerly independent, fully functioning individual is suddenly unable to move and faces enormous adjustments in social, economic, and personal roles and relationships. Body image, self-esteem, and role performance are affected by the damage. Patients often demonstrate

CASE STUDY & NURSING CARE PLAN A Patient with an SCI

Jim Valdez, a 19-year-old college sophomore, is admitted to the hospital by ambulance following an automobile crash. His family (father, mother, and sister) lives 100 miles away and cannot visit often, although they are very concerned. On admission to the hospital, a CT scan of the spine shows a fracture and partial laceration of the cord at the C_7 level. Mr. Valdez is in halo traction. One night, he tells the nurse, "I wish I had just died when I got hurt. I don't think I can stand to live like this."

ASSESSMENT

When Mr. Valdez is admitted to the intensive care unit, he has flaccid paralysis involving all extremities. He has no sensation below the clavicle or in portions of his arms and legs. His bladder is distended and bowel sounds are absent. Other assessment findings include BP 90/56 mmHg, P 50 bpm, T 36.1°C (97°F), arterial blood gases pH 7.4, PaO_2 96, $PaCO_2$ 37, SaO_2 96%. Oxygen per nasal cannula is given at 2 L/min, and halo traction is applied. A Foley catheter is inserted into his bladder, and a nasogastric tube is inserted and attached to low-pressure continuous suction.

After 3 days, Mr. Valdez is moved from the intensive care unit to the neurosurgical unit for continuing care and planning for transfer to a rehabilitation hospital in his home town. His vital signs have stabilized and are normal for his age; respirations and oxygenation are normal. Other neurologic assessments remain the same.

DIAGNOSES

- *Impaired Physical Mobility* related to paralysis of lower and upper extremities
- *Bowel Incontinence* related to lack of voluntary sphincter control
- *Complicated Grieving* related to denial of loss

EXPECTED OUTCOMES

- Patient will be actively involved in exercise programs.
- Patient will have a soft, formed stool every second or third day.
- Patient will verbally express his grief to parents and staff.

PLANNING AND IMPLEMENTATION

- Conduct passive exercises on all extremities four times a day.
- Provide progressive mobilization by initially raising the head of the bed 90 degrees (repeat two to three times during the first day of movement); if blood pressure remains normal, dangle for 5 minutes before transferring him to a chair.
- His usual time for a bowel movement is after breakfast; schedule retraining program for that time.
- Encourage a diet high in fiber and fluids. Likes whole-wheat bread, orange juice, and cola; does not like water.
- Promote grief work by providing time to express feelings. Explain to the family that his denial and anger are part of the grieving process.
- Determine food likes and dislikes and order preferred foods from the menu. Encourage his friends to bring in his favorite foods periodically.
- Take and record weight every third day, using the bed scales.

EVALUATION

By the time Mr. Valdez is transferred to the rehabilitation hospital he is looking forward to learning how to use special equipment and getting his own motorized wheelchair. He is able to sit up in a chair without dizziness or hypotension. The use of ordered stool softeners combined with a high-fiber diet and fluid intake of 2000 to 3000 mL per day has maintained bowel elimination. Mr. Valdez and his parents have spent 3 hours talking about their feelings related to the accident and the future. Although the discussion is emotionally difficult, all three say they now feel much better. Mr. Valdez still has episodes of angry outbursts and tears, but he is more optimistic about what can be done and believes he can finish college. He selects foods from the menu each day and eats most of his meals, but he especially enjoys the times his friends bring in pizza or hamburgers.

Clinical Reasoning in Patient Care

1. Considering Mr. Valdez's age and developmental level, do you think his emotional responses to his injury are appropriate?
2. Issues of sexuality are obviously important for the patient with a spinal cord injury. How would you approach Mr. Valdez about this topic?
3. What would be your response if Mr. Valdez allows only male nurses to provide care?
4. Outline a teaching program to help Mr. Valdez meet long-term urinary elimination needs.

See Evaluating Your Response in Appendix B.

behaviors that may be difficult for the nurse to handle including depression, denial, and anger immediately after the injury. In addition to these responses, the young adult patient may act out by making sexually overt statements.

The goals of care for the SCI patient and family include acceptance of changes in biopsychosocial functioning while optimizing the patient's ability for self-care and independence.

Expected Outcome: Patient will demonstrate optimal self-esteem.

- Encourage talking about all aspects of physical function and care. *Talking provides a safe outlet for fears and frustrations and increases self-awareness. Acceptance of self facilitates rehabilitation.*
- Encourage self-care and independent decision making. *Participating in self-care can promote positive coping; making decisions decreases feelings of powerlessness.*
- Help identify strategies to increase independence in desired roles; include both short- and long-term goals. Discuss assistive devices (such as hand-operated automobiles). *Identifying strategies to increase independence fosters a positive self-concept and motivates the patient to achieve rehabilitation goals.*
- Include family members and important others in discussions. *The realization that others do care and will continue to provide support is important in fostering positive self-regard.*
- Refer the patient and family to support groups or for psychologic counseling. *Adjustment to change is more likely when the patient and family seek peer and professional assistance.*

Delegating Nursing Care Activities

As appropriate and allowed by the designated duties and responsibilities of unlicensed assistive personnel, the nurse may delegate nursing care activities such as measuring vital signs (including orthostatic vital signs), encouraging oral or enteral fluid intake, and providing skin care.

Continuity of Care

Rehabilitation of the patient with an SCI is an ongoing process that moves from intensive care through intermediate care to rehabilitation and then community-based and home care. Nursing interventions are necessary at all points in the process to prevent the complications of altered physical mobility and body functions and to teach the patient and family measures that promote independence in self-care.

Discharge planning should be addressed even in the initial plan of care while the patient is in the critical care setting. Advance planning ensures continuity of care when the patient leaves the hospital setting.

The following should be included in teaching the patient and family about care at home:

- Self-care activities (ADLs, exercises, bowel and bladder programs, skin care)
- Mobility (use of assistive devices: wheelchair, crutches, special automobiles)
- Preparation of the home environment:
  - If the patient is in a wheelchair, will steps, stairs, doors, or carpeted floors present physical barriers?
  - If a special bed is necessary, have arrangements been made to provide it?
- Psychologic support
- Independent activities
- Community resources, such as emergency alerting systems through a local hospital or agency, support groups, career centers for job retraining, counseling
- Coping skills for patient and caregiver
- Referral to a home health agency and physical therapist for the patient who is returning home
- Helpful resources:
  - American Spine Injury Association
  - National Spinal Cord Injury Association
  - American Paralysis Association
  - Christopher and Dana Reeve Paralysis Foundation

THE PATIENT WITH A HERNIATED INTERVERTEBRAL DISK

A *herniated intervertebral disk* (also called a *ruptured disk*, *herniated nucleus pulposus*, or *slipped disk*) is a rupture of cartilage surrounding the intervertebral disk with protrusion of the nucleus pulposus (Figure 43–5 ■). This disorder is the most common cause of low back pain and is estimated to affect as many as two-thirds of people at some point in their lifetimes (Huether & McCance, 2011).

FAST FACTS

Herniated Intervertebral Disks

- Herniated intervertebral disks are more common in men than women.
- Most patients are between the ages of 30 and 50.
- The majority of herniated disks occur in the lumbar region (L_4 or L_5 to S_1). Cervical **herniation** most often involves C_6 to C_7.
- Multiple herniations only occur in about 10% of all patients.

Source: Hickey, 2013.

Pathophysiology

The intervertebral disks, located between the vertebral bodies, are made of an inner nucleus pulposus and an outer collar (the annulus fibrosus). The disks allow the spine to absorb compression by acting

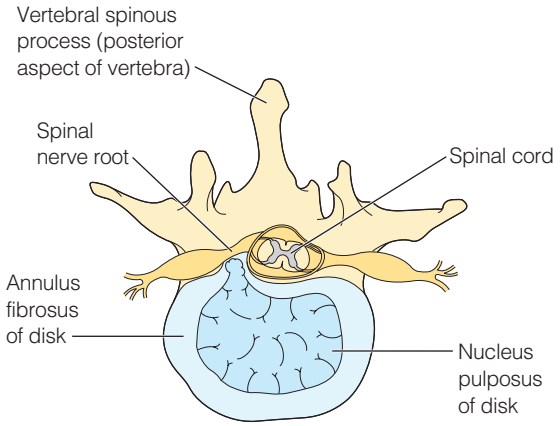

Figure 43–5 ■ A herniated intervertebral disk. The herniated nucleus pulposus is applying pressure against the nerve root.

as shock absorbers. A herniated intervertebral disk occurs when the nucleus pulposus protrudes through a weakened or torn annulus fibrosus of an intervertebral disk (refer to Figure 43–5). This protrusion may occur anywhere along the vertebral column, but herniation of thoracic disks is uncommon.

A herniated intervertebral disk may result from trauma, degenerative disorders of the spine, or aging. The protrusion may occur spontaneously or as a result of trauma, such as lifting heavy objects while in the flexed position, or falling on the buttocks or back. It may result from degenerative diseases, such as osteoarthritis, and aging. Aging causes degeneration in the annulus fibrosus and the posterior longitudinal ligaments, and the vertebrae and disks are less able to respond to movement and are more easily injured.

Rupture of the disk most often allows herniation of the nucleus pulposus in a posterolateral direction, with compression of the associated nerve root. The resulting pressure on adjacent spinal nerves causes characteristic manifestations, which vary with the location and the amount of protruding disk material. Occasionally the herniation is central rather than posterolateral, with pressure on the spinal cord.

The herniation may be abrupt or gradual. Lifting incorrectly or suddenly twisting the spine can cause rupture with immediate intense pain and muscle spasms. Gradual herniation is the result of degenerative changes, osteoarthritis, or ankylosis spondylitis. Patients with a gradual herniation have a slow onset of pain and neurologic deficits. Both motor and sensory manifestations occur, and are localized to the area of the body innervated by the nerve root. The manifestations may be described as **radiculopathy** (a condition in which one or more nerves, especially nerve roots, do not function normally), and/or **paresthesia** (an abnormal sensation of the skin, such as numbness, burning, or pricking).

Lumbar Disk Manifestations

The classic manifestation of a ruptured lumbar disk is recurrent episodes of pain in the lower back. The pain typically radiates across the buttock and down the posterior leg. **Sciatica** is a term used to describe lumbar back pain that radiates down the posterior leg to the ankle and is increased by sneezing or coughing (the result of pressure on nerve roots L_4, L_5, S_1, S_2, or S_3, which give rise to the sciatic nerve). The patient feels pain when lifting one leg while dorsiflexing the foot of that leg. Sciatica pain varies in intensity, ranging from mildly uncomfortable to excruciating. It is aggravated by a variety of positions and activities, including sitting, straining, coughing, sneezing, climbing stairs, walking, and riding in a car. Prolonged sitting and climbing of stairs are especially painful.

Other manifestations include postural deformity, motor deficits, sensory deficits, and changes in reflexes. When standing, the patient typically has a slight forward tilt to the trunk, scoliosis of the lumbar spine, slight flexion of the hip and knee on the affected side, and paravertebral muscle spasms. Motor deficits include weakness and some patients may experience problems with sexual function and urinary elimination. Sensory deficits include paresthesias and numbness. Knee and ankle reflexes are decreased or absent.

MANIFESTATIONS OF A HERNIATED INTERVERTEBRAL DISK

L_4 TO L_5 LEVEL (AFFECTS FIFTH LUMBAR NERVE ROOT)
- Pain in hip, lower back, posterolateral thigh, anterior leg, dorsal surface of foot, great toe
- Muscle spasms in affected areas
- Paresthesia over lateral leg and web of great toe
- Foot drop (rare)
- Decreased or absent ankle reflex
- Cauda equina syndrome (with complete nerve root compression): bowel and bladder incontinence, paralysis of lower extremities

L_5 TO S_1 LEVEL (AFFECTS FIRST SACRAL NERVE ROOT)
- Pain in midgluteal region, posterior thigh, calf to heel, plantar surface of the foot to the fourth and fifth toes
- Paresthesias in posterior calf and lateral heel, foot, and toes
- Difficulty walking on toes

C_5 TO C_6 LEVEL (AFFECTS SIXTH CERVICAL NERVE ROOT)
- Pain in neck, shoulder, anterior upper arm, radial area of forearm, thumb
- Paresthesia of forearm, thumb, forefinger, and lateral arm
- Decreased biceps and supinator reflex
- Triceps reflex normal to hyperactive

Cervical Disk Manifestations

A majority of cervical herniations are the result of degeneration; other causes include trauma, such as a whiplash injury (Isaac et al., 2012). Cervical disks that herniate laterally cause radicular pain in the shoulder, neck, and arm and paresthesias along the dermatome of the compressed nerve root. Other manifestations of lateral cervical herniation include muscle spasms and stiff neck and decreased or absent arm reflexes. Central cervical herniations result in a dull, intermittent pain; however, the patient may also experience lower extremity weakness, unsteady gait, muscle spasms, urinary elimination problems, altered sexual function, and hyperactive lower extremity reflexes. A cervical herniation due to acute trauma may be manifested by immediate weakness of the extremity, or if severe, by paralysis. Any suspected herniation due to trauma requires immobilization and immediate transport to an ED to prevent further injury (Isaac et al., 2012).

●○● INTERPROFESSIONAL CARE

Considerations for the patient with a **ruptured intervertebral disk** include identifying the location of herniation and determining whether conservative treatment or surgery is indicated. Diagnostic tests may also be performed to differentiate a herniated disk from other causes of acute back pain.

DIAGNOSIS

Diagnostic tests are ordered to differentiate the cause of back pain; for example, back and leg pain is also caused by spinal tumors, degenerative processes, or abdominal diseases. Assessing pain is an important part of diagnosis. The tests (refer to Chapter 41) include x-rays and CT scans of the lumbosacral or cervical area to identify skeletal deformities and narrowing of the disk spaces. Electromyography (EMG), which measures electrical activity of skeletal muscles at rest and during voluntary contraction, may be conducted to identify specific muscles affected by the pressure of the herniation on the nerve roots. A myelogram with contrast medium is performed to rule out tumors and illustrate areas of herniation, although it does not provide the detail found with CT or MRI.

Muscle strength and reflexes are tested, with the straight leg test being an important diagnostic test. It is conducted by placing the

patient in the supine position and passively raising the leg, or by having the patient sit on a table and slowly extending the knee with both hip and knee flexed at a 90-degree angle. This movement places traction on the nerve root, which increases the pain if the nerve root is inflamed.

MEDICATIONS

The patient with a ruptured intervertebral disk is treated with medications to relieve pain and reduce swelling and muscle spasms. Pain is usually managed with NSAIDs. Muscle spasms are treated with muscle relaxants.

TREATMENTS

A ruptured intervertebral disk may be treated conservatively or with surgery.

CONSERVATIVE TREATMENT A ruptured intervertebral disk is usually managed conservatively unless the patient is experiencing severe neurologic deficits. The goals of treatment are pain relief and healing of the involved disk by fibrosis. Conservative treatment is usually prescribed for 2 to 6 weeks. If the patient continues to have pain after that time, surgery may be considered. The treatment regimen depends on the severity of the manifestations. Decreasing activity level with bed rest is no longer recommended; in many cases, the patient is advised to continue with normal activities while taking prescribed medications for pain, inflammation, and muscle spasms.

SURGERY Surgery is indicated for patients with unrelenting pain, those who fail to respond to conservative management, or those with serious neurologic deficits (DiCecco, 2010). Several surgical interventions are used to treat a ruptured intervertebral disk. The type of surgery chosen depends on the location of the disk and the stability of the spinal column:

- A laminectomy, the type of surgery most often performed, is the removal of a part of the vertebral lamina (bony arch on dorsal surface). The surgery is done to relieve pressure on the nerves. It is often combined with removal of the protruding nucleus pulposus (nucleotomy). Nursing care for the patient having a laminectomy is discussed in an accompanying box. A **diskectomy** is the removal of the nucleus pulposus of an intervertebral disk. Diskectomy may be performed alone or in conjunction with a laminectomy (DiCecco, 2010).
- Spinal **fusion** is the insertion of a wedge-shaped piece of bone or bone chips (usually harvested from patient's ileac crest) between the vertebrae to stabilize them. A spinal fusion may also be performed through a spinal implant with a device called a BAK (a hollow titanium cylinder with holes), which is packed with grafted bone from a donor site and placed in the space where a disk is removed. Although not appropriate for all patients requiring a spinal fusion, this does facilitate a short hospital stay and convalescence.
- Foraminotomy is a surgical procedure to enlarge the space (passageway or neuroforamen) where a spinal nerve exits the spinal canal. The bone or tissue obstructing the passageway is removed. The posterior approach is taken for lumbar surgery while cervical disc surgery can be approached posteriorly or anteriorly (DiCecco, 2010).
- Intradiscal electrothermal therapy (IDET) uses thermal energy to treat pain from a bulging spinal disk. A special needle is inserted into the disk and heated to a high temperature. The heat thickens and seals the disk wall and decreases bulging of the disk.
- A microdiskectomy, in which microsurgical techniques are used, is performed through a very small incision. This type of surgery decreases the possibility of trauma to surrounding structures during surgery and allows early postoperative mobility and a short hospital stay.

●○● NURSING CARE

Nursing care for the patient with a ruptured intervertebral disk may be provided through information in community and work settings, during conservative treatment, and during pre- and postoperative treatment. The pain of the ruptured disk is often discouraging and debilitating, and may affect the patient's ability to work.

Health Promotion

Proper body mechanics may help prevent the occurrence of a ruptured intervertebral disk. Teaching body mechanics for lifting and moving heavy objects should begin when children enter school. This information should be provided to anyone (including nurses) who performs lifting on a regular basis. The guidelines for proper body mechanics are as follows:

- Begin activities by spreading feet apart to broaden base of support.
- Use large muscles of arms to lift and use legs to push if lifting
- Position body as close to object as possible before lifting or moving
- Slide, roll, push, or pull an object rather than lift it.
- When lifting, bend knees and lift up over own center of gravity.
- When lifting, use back support belt.

Assessment

The following data are collected through the health history and physical examination (refer to Chapter 41):

- *Health history:* type of employment, risk factors, pain (location, duration, intensity).
- *Physical assessment:* muscle strength and coordination, sensation, reflexes.

Priorities of Care

The goals of care are to maximize comfort, provide effective pain management techniques, promote correct body alignment, and prevent further injury.

Diagnosis, Outcomes, and Interventions

Nursing care for patients with a herniated intervertebral disk focuses largely on pain management, both during conservative management and after surgery.

Acute Pain

Patients with a ruptured intervertebral disk experience acute back and leg pain. Acute pain may be related to preoperative muscle spasms or nerve root compression. After surgery, the patient may have pain at the site of the incision and in the surgical area.

NURSING CARE OF THE PATIENT

Having a Posterior Laminectomy

PREOPERATIVE TEACHING

- Demonstrate and ask for a return demonstration of logrolling, explaining that the patient will be turned using this method for 1 to 2 days postoperatively and then allowed to do so without assistance. *To ensure healing, the spinal column must remain in alignment when turning and moving*.
- Explain the importance of taking pain medications regularly and of asking for them before the pain is severe. Inform the patient that pain may not improve for several days or weeks after surgery. *Pain is easier to control if medications are taken before the pain is severe. Pain may be prolonged in the post-op laminectomy patient because edema due to surgery irritates and compresses the nerve roots*.
- Demonstrate the use of a fracture bedpan and ask the patient to practice its use. *The patient usually must remain flat in bed for a period of time following surgery. A fracture bedpan is more comfortable for patients who must lie flat*.
- Explain the need to lay flat when eating. *This position prevents flexion of the spine*.
- Demonstrate and ask for a return demonstration of deep breathing, use of the incentive spirometer, and leg exercises. *These measures prevent respiratory and circulatory complications*.

POSTOPERATIVE CARE

- Maintain a position that minimizes stress on the surgical wound. For patients with cervical laminectomy, perform the following:
  a. Elevate the head of the bed slightly.
  b. Position a small pillow under the neck.
  c. Maintain the position of the cervical collar.

  For patients with lumbar laminectomy, perform the following:
  a. Keep the bed flat or elevate the head of the bed slightly.
  b. Place a small pillow under the head.
  c. Place a small pillow under the knees, or use a pillow to support the upper leg when the patient lies on one side.

  These positions minimize stress on the surgical wound and suture line. A cervical collar provides stability and prevents flexing or twisting of the neck.
- Turn every 2 hours, using the logrolling technique. Teach the patient not to use the side rails to change position. Maintain proper body alignment in all positions. *The patient's body is turned as a single unit (usually with a turning sheet) to avoid movement of the operative area. Pulling on the side rails puts stress on the operative area and may also cause misalignment of the vertebral column*.
- Monitor for signs of nerve root compression.
  a. Cervical laminectomy: Assess hand grips, arm strength, ability to move the fingers, and ability to detect touch.
  b. Lumbar laminectomy: Assess leg strength, ability to wiggle the toes, and ability to detect touch.

  Compare bilateral findings. Report muscle weakness or sensory impairment to the physician immediately. *Loss of motor and sensory function may indicate nerve root compression*.
- Assess for hematoma formation as manifested by severe incisional pain unrelieved by analgesics and a decrease in motor function. Report these findings immediately. *A hematoma may form at the surgical site. If untreated, it may cause irreversible neurologic deficits including paraplegia and bowel/bladder dysfunctions* (Dampeer, 2010).
- Assess for leakage of cerebrospinal fluid (CSF). Assess the dressing for increased moisture. Check the sheets for wetness when the patient is lying supine; check for clear liquid running down the back when the patient is sitting or standing. Gently palpate edges of wound to detect a bulge. Use a Dextrostix strip to assess leakage for the presence of glucose, which is a positive indicator of CSF. *Although uncommon, leakage of CSF greatly increases the risk for infection of the wound and of the meninges*.
- Assess for nerve root injury. Assess the ability to dorsiflex the foot (lumbar laminectomy) and the grip strength (cervical laminectomy). Assess the patient who has had a cervical laminectomy for hoarseness. Report hoarseness and further assess ability to swallow. *Nerve root compression may cause permanent damage, resulting in foot drop (in lumbar laminectomy patients) and hand weakness (in cervical laminectomy patients). Damage to the laryngeal nerve may cause permanent hoarseness. Impaired ability to swallow puts the patient at risk for aspiration*.
- Assess for urinary retention. The patient should void within 8 hours after surgery. If the physician allows, let males stand to void. Compare intake and output for each 8-hour period. Use a bladder scanner to identify urinary retention or residual urine. *All patients who have received a general anesthetic are at risk for urinary retention. The patient who has had a lumbar laminectomy may have even more difficulty voiding as a result of stimulation of sympathetic nerves during surgery*.
- Assess for pain using a scale from 0 (no pain) to 10 (severe pain). Administer prescribed analgesics on a regular basis, or teach patient to use patient-controlled analgesia (PCA) pump, if prescribed. Discuss concerns about pain that is unrelieved by surgery. *Compression of the nerve root over time results in edema and inflammation. Because of surgery-induced edema, the patient is likely to experience either the same pain or perhaps more severe pain in the period immediately after surgery. This pain usually persists for several weeks after surgery. In addition, many patients who have had a lumbar laminectomy have muscle spasms in the lower back, abdomen, and thighs for the first few days after surgery*.
- Assess for infection by taking and recording vital signs at least every 4 hours; report increased body temperature. Assess the wound and dressing for signs of infection including erythema, purulent drainage, and pain. Use sterile technique to change dressings. *The surgical patient is always at risk for infection; the patient with a laminectomy is also at risk for arachnoiditis. This inflammation of the arachnoid layer of the spinal meninges results from contamination during surgery and may cause painful adhesions*.
- Encourage deep breathing and the use of incentive spirometry every 2 hours; coughing may be discouraged. *Anesthesia and immobility depress respiratory function. Coughing may be discouraged because it can disrupt healing tissues, especially in patients having a cervical laminectomy*.
- Increase mobility as prescribed. (The time frame for ambulation is prescribed by the physician; the routine here is representative.) Patients often sit on the side of the bed and dangle their legs the evening after surgery or the first day thereafter. Most patients ambulate the first postoperative day. To help the patient out of bed, first elevate the head of the bed. Then bring the patient's legs over the side of the bed at the same time that the upper body moves into the upright position. Patients should only ambulate without assistance if there is no dizziness or weakness. *Early ambulation increases respiratory and circulatory function and decreases the risk of thrombophlebitis of the lower extremities. The vertebral column should remain in alignment while the patient sits and stands. Safety must be a priority during the postoperative period.*

Expected Outcome: Patient will be free of acute leg and back pain.

- Assess the degree of pain on a scale of 0 to 10 with 10 being greatest pain and identify contributing and relieving factors. *Pain is a subjective experience requiring a thorough nursing assessment prior to any interventions.*
- Use a firm mattress or place a board under the mattress. *A firm bed supports the spinal column and muscles.*
- Teach the patient to avoid turning or twisting the spinal column and to assume positions that decrease stress on the vertebral column (e.g., when in the supine position, flex the hips slightly). A small pillow may be placed under the knees (for patients with a herniated lumbar disk) or under the neck (for patients with a herniated cervical disk). *Correct body positions can decrease intradisk pressure.*
- Provide analgesic medications around the clock. *Intense pain can increase muscle spasms, making it crucial to maintain therapeutic levels of analgesics in the bloodstream.*

Chronic Pain

The patient with a ruptured intervertebral disk often has pain for an extended period of time. Despite conservative treatment or previous surgery, pain may be ongoing or intermittent. If previous surgery has not relieved the pain, the patient may be depressed or angry. Caring for a patient with chronic pain is frustrating, and the patient is often regarded as difficult.

Expected Outcome: Patient's pain will be managed effectively with optimal pain relief.

- Treat the patient's reports of pain with respect. *The patient is the person experiencing the pain and is thus the expert about it.*
- Do not refer to the patient as being addicted to pain medication. *All types of pain medications may be used legitimately to manage pain.*

SAFETY ALERT

Although the patient may develop tolerance to a narcotic analgesic, tolerance does not imply addiction. Pain is unique for each patient and must be assessed objectively. Using the pain scale and administering medications and treatments to reduce pain is essential in those with chronic pain.

- Monitor patient carefully for any changes in condition. *Significant changes in the patient's condition may go unrecognized when pain is present for a prolonged period of time.*
- Maintain written plans of care for pain management that are individualized and ensure continuity of care. *When the patient makes several visits (for instance, to an emergency department or a pain clinic), medical records provide a past history of effective pain management.*
- Teach alternative methods of pain management. Assess and consider *the patient's coping style when recommending methods. Patients who have a passive coping style are more likely to manage pain by depending on others, taking medications, and resting. Patients with an active coping style are more likely to manage pain by learning self-management methods and staying active.*
- Develop effective methods of improving rest and sleep. Problems with rest and sleep make pain management more difficult. *Sleeping poorly at night contributes to decreased motivation, confused thinking, depression, and muscle aches.*
- Refer patient to a physical therapist for an exercise program, if appropriate. *The patient needs to know exactly what exercises to do, how many repetitions are recommended, for how long, and how often. The patient should not exercise to the point of causing increased pain.*
- Assess need for referrals (and make them if necessary) for the patient who is depressed or anxious. *Anxiety and depression are often linked to long-term chronic pain, making pain management more difficult. Suggest that referrals for help with the frustration (rather than depression) may make a significant difference in the effectiveness of pain management strategies.*

Constipation

The patient with a ruptured intervertebral disk often has problems with constipation because of reduced mobility. Nursing interventions to alleviate and prevent constipation are important because straining to have a bowel movement can increase intradisk pressure, thus increasing pain. The goal of care is to prevent constipation and restore normal bowel elimination patterns.

Expected Outcome: Patient's bowel elimination patterns will be within normal limits.

SAFETY ALERT

People who use laxatives or enemas for long periods of time may be dependent on them to have a bowel movement. Accurate assessments of patterns and management techniques is essential to avoid bowel dysfunction

- Assess the patient's usual bowel routine, including diet, fluid intake, and the use of laxatives or enemas. *Effective interventions are based on individualized needs.*
- Encourage a fluid intake of 2500 to 3000 mL/day unless contraindicated by the presence of renal or cardiac disease. *Adequate fluid intake facilitates the passage of feces.*
- Increase fiber and bulk in the diet. If the patient is unable to tolerate increased fiber, consult with the physician about the use of stool softeners or bulk-forming agents. *Bulk and fiber promote regularity by retaining water in the large intestine.*

Delegating Nursing Care Activities

As appropriate and allowed by the designated duties and responsibilities of unlicensed assistive personnel, the nurse may delegate nursing care activities such as measuring fluid intake and output, collecting vital signs (including orthostatic vital signs), encouraging oral or enteral fluid intake, positioning the patient, and providing skin care.

Continuity of Care

It is the nurse's responsibility to teach the patient and family about chronic pain control, including specific interventions to alleviate pain. The nurse's role may be that of advocate and creative problem solver (see the Meeting Individualized Needs box). The following topics should be addressed:

- Often the goal is to control pain so that the patient can perform normal ADLs, rather than to reach a pain-free state.
- Nonpharmacologic methods of pain management include relaxation techniques, guided imagery, distraction, hypnosis, and

Meeting Individualized Needs

Teaching the Patient with a Ruptured Intervertebral Disk

- Sleep on a firm mattress; use a bed board if necessary.
- When lying in the supine position, flex the knees to approximately a 45-degree angle with a small pillow and use a small pillow under the head.
- Avoid any activities that flex the spine, such as bending or lifting, and do not twist the back.
- Follow a diet to maintain body weight or to lose weight if needed.
- Follow the prescribed exercise program; for example, do the following:
  a. Lie flat on your back on the floor. Tighten your abdominal and buttock muscles and tilt your pelvis forward so that your lower back is flat on the floor (this is called a *pelvic tilt*). Hold the position for 3 seconds and repeat for the prescribed number of times.
  b. Lying on the back on a firm surface, press the feet to the floor, tighten the abdominal muscles, and lift the upper half of the body off the floor. Hold the position for 3 seconds, and repeat as prescribed.
  c. Lying on your back on a firm surface, bring your knees up to the chest. Put your hands around your knees and raise the buttocks off the floor. Repeat as prescribed.
  d. Sit upright on the floor or a firm surface. Keep one leg straight and bend the other knee. Reach for the toes of the straightened leg. Switch legs. Repeat as prescribed.
  e. Stand upright. Squat down, flexing the hips and knees. Straighten your back. Stand upright by straightening the knees. Repeat as prescribed.
- Wear flat-heeled shoes that provide good support.
- Use proper lifting techniques. For instance, squat and use your thigh muscles to lift an object from the floor, and spread your feet to get a wide base of support when you lift while you are standing.

music. Joining a support group may be an effective intervention in coping with and managing pain.
- Patients may be referred to a physical therapist for education about body mechanics and back-strengthening exercises. Nurses should have the patient demonstrate the exercises to reinforce teaching.

THE PATIENT WITH A SPINAL CORD TUMOR

Spinal cord tumors may be benign or malignant, primary or metastatic. Tumors of the spinal cord are seen equally in men and in women, most often occur between the ages of 20 and 60 years, and are rare in older adults.

Classification

Tumors of the spinal cord are classified as either primary or secondary (metastatic). Primary tumors are rare and have an unknown cause. They may arise at any level of the spinal column, with the majority being thoracic. Most spinal cord tumors are metastatic. Metastatic tumors occur in approximately 20% of all patients with cancer (Hickey, 2013) and are most commonly the result of malignancies of the lung, breast, prostate, colon, kidney, or uterus.

Spinal cord tumors may also be classified by anatomic location as either intramedullary or extramedullary tumors. Intramedullary tumors arise from within the neural tissues of the spinal cord; those that occur most frequently are ependymomas and gliomas. Extramedullary tumors, the most common type, arise from tissues outside the spinal cord, with commonly occurring tumors including neurofibromas, meningiomas, sarcomas, chordomas, and vascular tumors. Extramedullary tumors are further categorized as intradural (arising from the nerve roots or meninges within the subarachnoid space) or extradural (arising from epidural tissue or the vertebrae outside the dura). Extradural tumors are the most common location for metastatic cancer. Both primary and metastatic intradural tumors can involve the cerebrospinal fluid, a condition known as *leptomeningeal disease* (LMD).

Pathophysiology

Depending on their anatomic location, spinal cord tumors lead to pathologic changes as a result of compression, invasion, or ischemia secondary to arterial or venous obstruction. Extramedullary tumors (whether benign or malignant) alter normal function through compression of the spinal cord, with destruction of white matter and eventual filling of the space around the spinal cord. Cord compression is a serious complication with symptoms ranging from minor sensory disturbance and autonomic changes to severe pain and irreversible paralysis (Kilbride et al., 2010). Compression of the cord interferes with normal blood flow and membrane potentials, altering afferent and efferent motor, sensory, and reflex impulses. Compression causes edema, which can ascend the cord and cause further neurologic deficits. Intramedullary tumors both compress and invade the cord, resulting in cord enlargement and distortion of the white matter.

The vertebral column is the most common site in the bony skeleton for cancer metastasis. Metastatic tumors can involve the vertebrae, grow through the vertebral foramina, or directly affect the dura, spinal fluid, or spinal cord. The lesion, as it grows, causes epidural compression of the cord or spinal nerves.

Manifestations

The manifestations of a spinal cord tumor depend on the anatomic location, level of occurrence, type of tumor, and spinal nerves involved. General manifestations of a spinal cord tumor include pain, motor and sensory deficits, changes in bowel and/or bladder elimination, and changes in sexual function. Specific manifestations by anatomic level are outlined in the accompanying box.

Pain is often the first manifestation of a spinal cord tumor. It is caused by compression of the spinal cord, tension on the spinal nerves, or tumor attachment to the proximal dura (the covering of the spinal cord). The pain may be either localized or radicular. Localized pain is felt when pressure is applied over the spinous process of the involved area and often accompanies metastatic vertebral tumors. Radicular pain is sensed along the path of a nerve as a result of compression, irritation, or tension of a nerve root, and is often made worse by any activity that causes intraspinal pressure, such as sneezing or coughing.

MANIFESTATIONS OF SPINAL CORD TUMORS

CERVICAL CORD TUMORS
- Ipsilateral arm motor involvement, followed by ipsilateral and contralateral leg involvement, followed by contralateral arm involvement
- Paresis of the arms and legs
- Stiffness of the neck
- Paraplegia
- Pain in the shoulders and arms
- Hyperactive reflexes

THORACIC CORD TUMORS
- Paresis and spasticity of one leg, followed by paresis and spasticity of the other leg
- Pain in the back and chest
- Positive Babinski reflex
- Bowel and bladder dysfunction
- Sexual dysfunction

LUMBOSACRAL CORD TUMORS
- Paresis and spasticity of one leg, followed by paresis and spasticity of the other leg
- Pain in the lower back, radiating to the legs and perineal area
- Loss of sensation in the legs
- Bowel and bladder dysfunction
- Sexual dysfunction
- Decreased or absent ankle and knee reflexes

Motor manifestations resulting from a spinal cord tumor include paresis and paralysis below the level of the tumor, spasticity, and hyperactive reflexes. The Babinski reflex may be positive. These deficits are the result of involvement of the corticospinal tracts.

Many different sensory manifestations may occur, depending on the location and level of the tumor. Lateral tumor growth and compression affect the lateral spinothalamic tracts, causing pain, numbness, tingling, and coldness. If the tumor involves the posterior columns, the senses of vibration and proprioception of body parts are affected.

Bladder and bowel elimination and sexual function are often affected. Bowel elimination deficits include constipation that may progress to paralytic ileus. Initial bladder elimination deficits include frequency, urgency, and difficulty voiding, and may progress to urinary retention and a neurogenic bladder. The male patient may be impotent.

Syringomyelia is a complication of spinal cord tumors involving formation of a fluid-filled cystic cavity in the central intramedullary gray matter and causing pain, motor weakness, and spasticity.

●○● INTERPROFESSIONAL CARE

The medical management of the patient with a spinal cord tumor focuses first on diagnosis. Treatment depends on the type of tumor, its location, and the patient's condition. Prognosis and quality of life are related to the patient's pretreatment ambulatory status, rapid diagnosis, and treatment (Kilbride et al., 2010).

DIAGNOSIS

The patient with a spinal cord tumor undergoes many of the same diagnostic tests as does the patient with a ruptured intervertebral disk including x-rays, CT scans, MRI, and myelogram (refer to Chapter 41). A lumbar puncture will demonstrate CSF with a xanthochromic appearance (having a yellow color), elevated protein, few to no cells, and immediate clotting. This cluster of findings is called *Froin's syndrome*. A biopsy may be done to identify the tumor type.

MEDICATIONS

The patient with a spinal cord tumor is prescribed medications (typically opioid analgesics) to control pain and edema. Severe pain can result from a metastatic tumor and may necessitate insertion of an epidural catheter for narcotic analgesia. Steroids such as dexamethasone (Decadron) are administered to control cord edema.

IMMOBILIZATION

Spinal stability must be determined before treatments can be planned, particularly because some treatments have the potential to destabilize the spine (radiotherapy, laminectomy). The biomechanics, anatomy, and flexibility of the spine are assessed to determine if the spine is unstable. External spinal support such as bracing may be used as a conservative therapy to immobilize the spine if instability is caused by a spinal tumor (Kilbride et al., 2010).

SURGERY

Intramedullary and intradural tumors are surgically excised when possible by performing a laminectomy. Advances in microsurgical techniques and laser surgery have increased the possibility that tumors can be removed. Metastatic tumors that cause cord compression require surgical decompression and/or partial removal to preserve motor, bowel, or bladder function. The patient with a tumor involving more than two vertebrae may have a spinal fusion and rod insertion to stabilize the spinal column (Warren, 2011).

RADIOSURGERY

An advanced device called the *CyberKnife* may be used for some patients. It provides a painless, noninvasive treatment that delivers high doses of precisely targeted radiation to destroy tumors while minimizing damage to healthy tissue. The device is controlled by a flexible robotic arm, making it possible to treat the spine and spinal cord (areas that cannot be treated with other radiosurgery techniques).

RADIATION THERAPY

Radiation therapy is used to treat metastatic spinal cord tumors for several different reasons. It may be used on an emergency basis to treat the patient with rapidly progressing neurologic deficits. It may be used to reduce pain, and it may be used following surgical excision of as much tumor mass as possible.

Radiation of the spinal cord may cause radiation-induced myelopathy to develop. This complication of radiation exposure occurs over time, with manifestations of *Brown-Séquard syndrome* (weakness or paralysis on one side of the body and loss of sensation on the opposite side) developing 12 to 15 months after therapy. The manifestations may progress to paraplegia, sensory loss, and loss of bowel and bladder control (Warren, 2011).

●○● NURSING CARE

Nursing care for the patient with a spinal cord tumor is individualized to the type of tumor and the type of treatment. The patient with a benign tumor that is removed by surgery has different healthcare needs than the patient with a metastatic tumor, even though they may

have similar neurologic deficits. The patient with a spinal cord tumor (regardless of type) requires nursing care to monitor for neurologic changes, to provide pain management, and to manage motor and sensory deficits in order to preserve quality of life.

The assessments and nursing interventions for the patient with a spinal cord tumor are much the same as those described for the patient with an SCI or the patient undergoing surgery for a ruptured intervertebral disk. Following surgical treatment, the patient may be transferred to a rehabilitation center or be discharged to home for the recovery period. Referrals for home care, occupational therapy, and physical therapy can restore functional abilities. Family members and caregivers must be taught how to position and transfer the patient from bed to chair. Teaching must also include methods for providing physical care, managing any devices (such as an indwelling catheter), and preventing or treating constipation (Warren, 2011).

THE PATIENT WITH A CENTRAL NERVOUS SYSTEM INFECTION

The CNS, including the brain, spinal cord, meninges, neural tissues, and blood vessels, may be directly affected by bacteria, viruses, fungi, protozoans, and rickettsiae. In general, organisms enter the brain in two ways: by bacteria that cross the blood–brain barrier due to infections of nearby structures (such as sinusitis, otitis media, or pneumonia) or by direct invasion through, for example, a skull fracture or bullet hole. The incidence of pathogenic CNS infections increases in the presence of HIV and AIDS because of the risk of opportunistic infections such as toxoplasmosis, cryptococcus, tuberculosis, herpes simplex, cytomegalovirus (CMV), or a polyoma virus.

Pathophysiology

When pathogens enter the CNS and the meninges, an infectious inflammatory process results. As edema occurs, intracranial pressure (ICP) increases. The pathogenic invasion and increased ICP (IICP) may result in brain damage and life-threatening complications.

MENINGITIS

Meningitis is a pyogenic (purulent) infection that involves the pia mater, the arachnoid, and the subarachnoid space, including the cerebrospinal fluid. The infection spreads rapidly throughout the CNS because of the circulation of CSF around the brain and spinal cord. Meningitis may be acute or chronic, and bacterial, viral, fungal, or parasitic in origin. The two types of acute infectious meningitis are acute purulent meningitis (usually bacterial) and acute lymphocytic meningitis (usually viral).

The causative organism must overcome nonspecific and specific host defense mechanisms to invade and replicate in the CSF. These defenses include the skin barrier, the blood–brain barrier, the nonspecific inflammatory response, and the immune response. The organisms that initiate the host response in meningitis initially colonize and invade the nasopharyngeal mucosa. Organisms invade the vascular system and then penetrate the CNS if the blood–brain barrier is damaged by surgery, the inflammatory response, or cerebral edema.

Infection of the CSF and meninges causes an inflammatory response in the pia, arachnoid, and CSF. Because the meninges and subarachnoid space are continuous around the brain, spinal cord, and optic nerves, the infection and inflammatory response are always cerebrospinal, involving both the brain and spinal cord. Increased capillary permeability causes leakage of fluids into the interstitial spaces while purulent exudate infiltrates cranial nerve sheaths and blocks the choroid plexus and subarachnoid villi. IICP causes decreased cerebral perfusion and a loss of cerebral autoregulation.

BACTERIAL MENINGITIS The causative organisms of bacterial meningitis include *Neisseria meningitis*, meningococcus, *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Escherichia coli*, but most are caused by pneumococcus or meningococcus. The incidence of meningitis from *H. influenzae* has been greatly reduced because of vaccination against the organism.

Epidemics of meningococcal meningitis occur in populations who live in close contact, such as military recruits and students living in college dormitories. Adolescents and young adults account for nearly 30% of cases of meningococcal meningitis in the United States, and vaccinations are now available to prevent meningococcal meningitis (Strunk & Rocchiccioli, 2010).

Risk factors for meningitis include otitis media, mastoiditis, sinusitis, neurosurgery, systemic sepsis, immunocompromise, basal skull fractures, or crowded living conditions. Pathogen entry into the CNS initiates the inflammatory response in the meninges, CSF, and ventricles. Meningeal vessels become engorged and permeability increases. Phagocytic white blood cells (WBCs) migrate into the subarachnoid space, forming a purulent exudate that thickens and clouds the CSF and impairs its flow. Rapid exudate formation causes further inflammation and edema of meningeal cells with resulting IICP.

MANIFESTATIONS The patient with bacterial meningitis typically presents with fever and chills, severe headache, back and abdominal pain, and nausea and vomiting. The older adult may not have a high fever, but may instead exhibit confusion. Meningeal irritation causes nuchal rigidity (stiff neck), a positive Brudzinski sign (neck flexion that causes hip and knee flexion; see Figure 43–6 ■), and a positive Kernig's sign (inability to extend knee while hip is flexed at a 90-degree angle). Photophobia and possibly diplopia are present.

In meningococcal meningitis, skin hemorrhages and ecchymosis occur related to the vasculitis caused by the rapidly replicating

Figure 43–6 ■ Positive Brudzinski sign.

pathogens. IICP may be present and cause decreased LOC, seizures, changes in vital signs and respiratory pattern, and papilledema. Bacterial meningitis manifestations are listed in the accompanying box.

COMPLICATIONS The arachnoid layer may have fibrotic changes and formation of scar tissue from the infection. Adhesions and effusions can develop, interfering with the normal circulation of CSF. Complications of bacterial meningitis include cranial nerve damage and hydrocephalus with cranial nerve VIII (auditory nerve) frequently affected and causing deafness.

VIRAL MENINGITIS Acute viral meningitis, also called *aseptic meningitis*, is less severe than bacterial meningitis. Numerous viruses, such as herpes simplex virus (HSV), herpes zoster, Epstein-Barr virus, cytomegalovirus (CMV), or West Nile virus, can cause viral meningitis. Although the inflammatory response is also provoked, this disease is typically benign, short lived, and with an uneventful recovery.

MANIFESTATIONS The manifestations of viral meningitis, although similar to bacterial meningitis, are milder. The patient may have mild flu-like symptoms that progress to an intense headache and malaise, nausea, vomiting, and lethargy. Photophobia and drowsiness can occur but the patient typically remains oriented. A mild fever, neck stiffness, positive Brudzinski sign, and positive Kernig's sign are usually present (Marchiondo, 2010).

ENCEPHALITIS

Encephalitis is a generalized infection of the parenchyma of the brain or spinal cord. It is typically caused by a virus, but can also be caused by bacteria, fungi, and other organisms. See Table 43–2 for a list of common causes.

MANIFESTATIONS OF BACTERIAL MENINGITIS

- Restlessness, agitation, and irritability
- Severe headache
- Signs of meningeal irritation:
  a. Nuchal rigidity
  b. Positive Brudzinski sign
  c. Positive Kernig's sign
- Chills and high fever
- Confusion, altered LOC
- Photophobia (aversion to light), diplopia (double vision)
- Seizures
- Signs of IICP (widened pulse pressure and bradycardia, respiratory irregularity, decreased LOC, headache, and vomiting)
- Skin hemorrhages, petechial rashes, or ecchymosis (in meningococcal meningitis)

VIRAL ENCEPHALITIS Viruses depend on living tissue for reproduction and become highly destructive when invading brain tissue. They gain access to the CNS via the bloodstream or via a preexisting case of meningitis. An inflammatory response extends over the cerebral cortex, white matter, and meninges. Degeneration of neurons occurs along with local necrotizing hemorrhage. Generalized hemorrhage, edema, and progressive degeneration of nerve cell bodies occur. Unlike meningitis, there is no exudate formation. Certain viruses show a propensity for specific areas of the brain (e.g., herpes simplex virus involves frontal and temporal lobes).

Manifestations of viral encephalitis vary depending on the organism and area of the brain affected, and are similar to those of meningitis. These include fever, headache, seizures, stiff neck, and

TABLE 43–2 Causes of Encephalitis

Cause	Comments
Arboviruses	Transmitted most often by bites from mosquitoes. Bites from mosquitoes occur in middle to late summer. Most common types are St. Louis, eastern and western equine encephalitis, and West Nile encephalitis. May destroy major parts of lobe or hemisphere. Two-thirds of patients who develop eastern equine encephalitis either die or develop severe residual disabilities (e.g., seizures, blindness, deafness, speech disorders, or mental retardation). Incubation is 5 to 15 days. Mortality rates associated with arboviruses are higher than those associated with enteroviruses.
Enteroviruses, such as echovirus, coxsackievirus, poliovirus, paramyxovirus (the virus that causes mumps), and varicella-zoster (the virus that causes chickenpox)	Infection occurs more frequently in summer (except infection by the mumps virus, which occurs more frequently in early winter). A degree of protection can be provided by immunization against measles, mumps, and poliomyelitis. Mortality rates are lower than those associated with herpes simplex type 1 virus.
Herpes simplex type 1 virus	Most common nonepidemic encephalitis in North America. Can occur any time of year and throughout the world. Has an affinity for frontal and temporal lobes. Prognosis is grave but not hopeless: Mortality rate can be as high as 40%, and patient may die within 2 weeks.
Amebic meningoencephalitis due to infection by *Naegleria* and *Acanthamoeba* protozoa	Both protozoa are found in warm freshwater and enter nasal mucosa of people swimming in ponds or lakes. May also be found in soil and decaying vegetation. Incidence of infection is increasing in North America.
Exogenous poisoning	May occur after ingestion of lead or arsenic or inhalation of carbon monoxide.

altered LOC. The patient may be disoriented, agitated, restless, lethargic, or drowsy. Disease progression can lead to coma.

ARBOVIRUS ENCEPHALITIS The arboviruses are arthropod-borne (mosquito and tick) agents that infect humans. They include many different types, including western equine encephalitis, St. Louis encephalitis, and West Nile encephalitis. Adults are most often infected with St. Louis encephalitis, with older adults affected more often. The most common arboviral encephalitis in the United States is West Nile encephalitis, which has become endemic in the United States.

The arthropod-borne agents cause widespread degeneration of nerve cells, resulting in edema, necrosis, and possible hemorrhage. IICP may develop. Manifestations include fever, malaise, sore throat, nausea, vomiting, stiff neck, tremors, paralysis, exaggerated deep tendon reflexes, seizures, and altered LOC.

BRAIN ABSCESS

A brain abscess is an infection with a collection of purulent material within the brain tissue. Approximately 80% are found in the cerebrum and 20% are cerebellar.

The causes of a brain abscess include open trauma and neurosurgery; infections of the mastoid, middle ear, nasal cavity, or nasal sinuses; metastatic spread from distant foci (such as heart, lungs, skin, abscessed teeth, and dirty needles); and arising from other associated areas of infection. Immunocompromise increases the risk for abscesses. The most common pathogens causing an abscess are streptococci, staphylococci, and bacteroids. Yeast and fungi may also cause brain abscesses.

A brain abscess results from the presence of microorganisms in the brain tissue. If the abscess is encapsulated, it may enlarge and behave as a space-occupying lesion within the cranium. This predisposes the patient to a systemic inflammatory process and to the serious consequences of IICP. Occasionally, the abscess does not become encapsulated but spreads through brain tissue to the subarachnoid space and ventricular system.

Initially, patients exhibit general symptoms of infection, such as chills, fever, malaise, and anorexia. Because a brain abscess generally forms after infection, the patient may think that he is having an exacerbation of that initial infection and may experience seizures, altered LOC, and manifestations of IICP. As the abscess enlarges, symptoms will reflect its location in the brain. For example, a frontal lobe abscess may cause contralateral hemiparesis, expressive aphasia, focal seizures, and frontal headache.

●○● INTERPROFESSIONAL CARE

Both meningitis and encephalitis can be fatal if they are not promptly diagnosed and treated. Even with treatment, CNS damage can cause serious neurologic deficits. Bacterial meningitis is a medical emergency and must be treated with appropriate antibiotics and supportive interventions. The treatments for viral meningitis and encephalitis are primarily symptomatic. Brain abscesses are treated with antibiotics; if this is not effective, the abscess may be drained or surgically removed (Clinical Digest, 2010).

DIAGNOSIS

The diagnosis of bacterial or viral meningitis is based on manifestations and diagnostic test results. Gram stain and culture of the CSF are used to determine if a bacterial infection is present and to identify the specific infectious agent. Counterimmunoelectrophoresis (CIE) is a laboratory test that may be ordered to determine the presence of viruses or protozoa. Polymerase chain reaction (PCR) techniques may be used to detect viral DNA or RNA in spinal fluid. CT scan will show an area of increased contrast surrounding a low-density core with brain abscess.

Lumbar puncture with examination of the CSF is utilized to diagnose bacterial meningitis. Data that indicate bacterial meningitis include turbid, cloudy CSF, markedly increased WBC counts and protein content, and a decreased glucose content. Opening pressures on the lumbar puncture are elevated. In contrast, encephalitis displays a normal CSF analysis and pressure. The patient with a brain abscess will have a markedly elevated pressure with elevated protein content and elevated WBC count. Glucose content is normal. (Because a lumbar puncture in the presence of a space-occupying lesion can result in brain herniation and death, a CT scan is performed first if neurologic findings support such a lesion.)

MEDICATIONS

Immediate intravenous administration of a broad-spectrum antibiotic that crosses the blood–brain barrier into the subarachnoid space is instituted in cases of bacterial meningitis. Once culture reports identify the causative organism, drug therapy with a high dose of one or more specific antibiotics IV is continued for 2 weeks. The penicillin (such as ampicillin) and cephalosporin (such as cefotaxime or ceftriaxone) antibiotics are preferred (van der Beek et al., 2012). If resistant strains of bacteria are identified, vancomycin (Vancocin) may be administered. However, as the bacteria are killed, the toxins they release increase production of inflammatory cytokines, which are potentially lethal. Steroids such as dexamethasone (Decadron) are often given with the antibiotics to suppress inflammation.

Treatment for encephalitis consists of administering specific medications and preventing complications. Fungal meningitis is treated with antifungal agents, such as amphotericin-B (Amphotec), flucytosine (Ancobon), and *fluconazole* (Diflucan). Viral encephalitis is treated with intravenous *acyclovir* (Zovirax) or vidarabine (Vira-A).

Antibiotic therapy is the primary treatment for brain abscess. A combination of broad-spectrum antibiotics is used if the infecting organism is unknown. Anticonvulsant medications such as *phenytoin* (Dilantin) and levetiracetam (Keppra) are often prescribed to prevent or control seizure activity. Antipyretic and analgesic medications may provide symptomatic relief; however, analgesics that have a depressant effect on the CNS (such as opiates) are avoided to prevent masking of early manifestations of deteriorating level of consciousness (LOC). The patient initially may require antiemetics to control nausea and vomiting. Fluid and electrolyte status is maintained through intravenous fluid replacement until the patient is able to resume oral intake.

SURGERY

Surgical drainage of an encapsulated abscess may be necessary. The decision to perform surgery is based on the patient's general condition, the stage of abscess development, and the site of the abscess.

●○● NURSING CARE

CNS infections are serious illnesses, with potentially life-threatening effects and complications. Nursing assessments and interventions are

critical in identifying changes in the patient's neurologic status and preventing complications from IICP. In addition to the nursing care described in this section, see the Case Study & Nursing Care Plan for a patient with bacterial meningitis on page 1422.

Health Promotion

As with many other intracranial injuries and disorders, educational activities to promote health by preventing meningitis and encephalitis are important nursing interventions. The following information to reduce risk should be provided:

- Vaccinations for meningococcal meningitis are recommended by the Centers for Disease Control (CDC) (2011c) and are often required for military recruits and college students. The CDC also recommends the vaccine for those traveling to an underdeveloped country where meningococcal disease is common (i.e., parts of Africa), those who are immunocompromised, or those with possible exposure to the infection. Two vaccines are available: meningococcal conjugate vaccine (MCV4) for adults ages 55 and under, and meningococcal polysaccharide vaccine (MPSV4) for adults over age 55.
- Adults over the age of 65 years should receive the pneumococcal vaccine.
- Wash hands with soap and water before and after contact with an individual who may be infected with meningitis or encephalitis and after using the bathroom.
- Do not share food, drinking glasses, eating utensils, tissues, towels, lipstick, or cigarettes.
- Control mosquitos with repellants, insecticides, and protective clothing. Community programs conduct spraying to destroy the insect larvae and eliminate breeding places, such as pools of stagnant water.
- Prompt diagnosis and treatment are crucial for infections of the head, neck, and respiratory system as well as for signs and symptoms of meningitis.

Assessment

Collect the following data through the health history and physical examination (refer to Chapter 41). Further focused assessments are described in the following interventions section.

- *Health history:* risk factors (place of residence, exposure to someone with meningitis or encephalitis, concurrent infections, other illnesses, travel), when manifestations began, severity of manifestations, current nausea, headache and stiff neck, seizures
- *Physical assessment:* Glasgow Coma Scale, LOC, vital signs, motor function, pupillary check, cranial nerves, neck ROM, Brudzinski sign, Kernig's sign, skin (rash, petechiae, purpura), muscle movement and strength, speech.

Priorities of Care

The goals of care for the patient with a CNS infection are an absence of infection, normal neurologic functioning, and normal vital signs.

Diagnoses, Outcomes, and Interventions

In planning and implementing nursing care for the patient with a CNS infection, the prognosis may depend on the supportive care given. The patient is often very ill, and the combination of fever, dehydration, and IICP may predispose him or her to seizures. Airway obstruction, respiratory arrest, or cardiac dysrhythmias may occur. Nursing diagnoses and interventions for the patient with an altered LOC, IICP, and seizures are also appropriate for the patient with a CNS infection. Nursing interventions in this section focus on ineffective protection and risk for fluid volume deficit.

Ineffective Protection

Patients with CNS infections are less able to protect themselves against insults from both internal and external sources. The effects of the infection, inflammation, and resulting pathophysiologic processes may include pain, fever, altered LOC, seizures, IICP, and cranial nerve dysfunction. In addition, pathophysiologic effects on the brain may lead to permanent neurologic deficits, such as loss of motor function or dementia.

Expected Outcome: Patient will be adequately protected against infection.

- Monitor neurologic status on a regular basis. *Many complications are evidenced by changes in neurologic manifestations.*
- Monitor vital signs, including temperature, on a regular basis. *The patient often has a high temperature throughout the illness, ranging from 38° to 40.5°C (101° to 105°F).*
- Monitor levels of consciousness. Assess levels of orientation, memory, attention span, and response to stimuli. *Early in the infection, the patient often has problems with memory and orientation. There may be problems with following commands, restlessness, irritability, and combativeness. As the illness progresses, the LOC decreases to lethargy and finally into deep coma*

SAFETY ALERT

Hyperthermia may result from IICP, while an increased temperature can also increase ICP. The presence of any fever must be recognized promptly and treated effectively to prevent further increases in ICP.

- Monitor for manifestations of seizure activity, and institute seizure precautions:
  - Monitor twitching of hands or face and tonic–clonic movements.
  - Have an oral airway and suction equipment readily available.
  - Pad side rails, maintain bed in low position, and keep side rails up. *Irritation of the cerebral cortex secondary to meningeal inflammation may cause seizures. Careful monitoring and seizure precautions are necessary to prevent injury.*
- Monitor for manifestations of cranial nerve damage; monitor extraocular movements, facial movement, dizziness, ability to hear, double vision, drooping upper eyelids (ptosis), and pupillary changes. *Cranial nerve dysfunction may result from inflammation or vascular changes in the brain.*
- Monitor for manifestations of IICP: decreased pulse, increased blood pressure, widening pulse pressure, respiratory changes, and vomiting. *IICP results from infectious or inflammatory exudate, cerebral edema, and hydrocephalus.*
- Administer prescribed medications and fluids. *Antiepileptics are prescribed to prevent or control seizures, and antibiotics are prescribed to eradicate the bacteria. Mannitol may be prescribed to reduce IICP. IV fluids are administered to replace fluids lost through vomiting and diaphoresis.*

CASE STUDY & NURSING CARE PLAN A Patient with Bacterial Meningitis

Monty Cook is a 22-year-old musician who plays in a local rock band. He is unmarried and lives with his parents. He is known by everyone in the community as a quiet, low-key, easygoing person and an excellent guitar player. During a performance 2 days ago, he had difficulty playing his guitar, complaining of bright stage lights blazing in his eyes. When he tried to keep his head down to prevent the lights from hurting his eyes, he noticed his neck was very stiff. After the performance, one of the newest members of the band remarked that it certainly was not their best performance. Monty responded angrily that maybe the new members of the group needed more practice. Then he stomped out and went home to bed.

He wakes at 4:00 a.m. with a severe headache, sweating, chills, and a temperature of 38.9°C (102°F). He is unable to bend his neck without severe pain. His mother is alarmed at his agitation and irritability and rushes him to the emergency department (ED). A lumbar puncture performed in the ED reveals turbid, cloudy fluid; Mr. Cook also has a markedly increased WBC count, increased protein, and a decreased glucose content. Bacterial meningitis is diagnosed and Mr. Cook is admitted.

ASSESSMENT

When the nurse, Agatha Aldi, enters the patient's room, Mr. Cook is thrashing in the bed and talking incoherently. On assessment, the nurse notes dry mucous membranes, cracked lips, and small petechiae over the upper torso and abdomen. Mr. Cook's temperature is now 40°C (104°F) and a positive Kernig's sign is present. Intravenous broad-spectrum antibiotics are prescribed and initiated. After 2 hours nurse Aldi notes that Mr. Cook's LOC has decreased significantly.

DIAGNOSES

- *Hyperthermia* related to infection and abnormal temperature regulation by hypothalamus
- *Disturbed Thought Processes* related to intracranial infection
- *Ineffective Protection* related to progression of illness

EXPECTED OUTCOMES

- Patient's body temperature will decrease.
- Patient will become less restless and agitated.
- Patient will remain free of injury.

PLANNING AND IMPLEMENTATION

- Monitor vital signs every 2 hours.
- Provide sponge baths if temperature continues to rise.
- Provide a quiet, nonstimulating environment with the shades drawn.
- Provide oral care every 4 hours.
- Measure and compare intake and output every 2 hours.
- Perform neurologic assessments every 2 to 4 hours.
- Monitor for and report seizure activity and decreasing level of consciousness.
- Keep bed in low position with side rails elevated.
- Administer prescribed intravenous antibiotics.

EVALUATION

After 4 days of antibiotic therapy, Mr. Cook's temperature has returned to near normal. Ms. Aldi notes that he has begun opening his eyes and visually tracking her as she moves about the room. Mr. Cook responds to a request to squeeze Ms. Aldi's fingers and after several hours asks her what has happened. On day 5, Mr. Cook states that he feels better and his headache is gone. He ask for sips of juice and begins urinating regularly. Seven days after admission, Mr. Cook is discharged and is able to go home with his mother. He has some weakness in his legs, but otherwise has no evidence of neurologic deficits.

Clinical Reasoning in Patient Care

1. What strategies should the nurse use to decrease the environmental stimuli for Mr. Cook, and what is the rationale for doing so?
2. If you were caring for Mr. Cook in the initial phase of the illness and he became combative, what would you do?
3. Develop a plan of care for Mr. Cook for the nursing diagnosis *Acute Pain*. Consider the effect of narcotics on respiratory function in designing the plan.

See Evaluating Your Response in Appendix B.

Risk for Imbalanced Fluid Volume

The patient is at risk for fluid volume deficit related to increased metabolic rate and diaphoresis. The goals of care are to provide hydration and maintain adequate intake and output.

Expected Outcome: Patient will be adequately hydrated.

- Monitor for presence, or worsening, of fluid volume deficit.
  - Measure and compare intake and output every 2 to 4 hours.
  - Monitor daily body weights.
  - Monitor skin turgor and condition of mucous membranes and tongue.
  - Monitor urine amount, color, and odor.
  - Monitor BUN:creatinine ratio.

  The elastic property of the skin depends partially on interstitial fluid volume. If the patient has a fluid volume deficit, skin flattens more slowly after a pinch is released. Mucous membranes and tongue are dry, urine output is decreased, urine is dark in color and concentrated with a strong odor, urine specific gravity is greater than 1.020, and BUN will rise out of proportion to serum creatinine.
- When administering fluids, either orally or parenterally, consider concurrent illnesses. *Patients with IICP or renal failure require complex management. Refer to Chapter 10 for a further discussion of fluid volume deficit.*

SAFETY ALERT

A weight loss of 0.5 kg (1 lb) represents a fluid loss of approximately 500 mL. Close monitoring of intake and output is essential for prompt recognition of fluid deficits. Renal function can be permanently impaired in states of dehydration

THE PATIENT WITH TETANUS

Tetanus, or lockjaw, is a disorder caused by the neurotoxin *Clostridium tetani*. This anaerobic bacillus lives in the soil, and spores enter the body through open wounds contaminated with dirt, street dust, or feces (animal or human). Incidence is highest among people who have never been immunized, older adults whose immunity has been lost, and women. Fatal outcomes are more likely in older adults and account for over 10% of all cases (CDC, 2013). Contaminated lesions of the head and face are linked to less favorable outcomes than those on other areas of the body.

When the spores of *C. tetani* enter a wound, they germinate and produce a toxin called tetanospasmin. Incubation occurs over an average of 8 to 12 days but can range from 5 days to 15 weeks (McPhee & Papadakis, 2014). Toxins are then absorbed by the peripheral nerves and carried to the spinal cord, where they block the

action of inhibitory enzymes at spinal synapses. This impairs transmission of neuromuscular impulses and even minor stimuli will cause uncontrolled muscle spasms.

Manifestations begin with pain at the infection site followed by neck and jaw stiffness and dysphagia. Profuse perspiration, increased salivation, and drooling can occur followed by hyperreflexia and spasms of the jaw muscles (trismus) or facial muscles. Rigidity and painful spasms of the abdomen, neck, and back then follow. Generalized tonic seizures may result from minor stimuli and the patient assumes a typical opisthotonic position during the seizures characterized by retraction of the head, arching of the back, and extension of the feet. Breathing may be impaired by spasms of the glottis and respiratory muscles. Throughout these changes, the patient retains normal mental status.

The complications of tetanus include urinary retention and airway obstruction from the spasms. Cardiac and respiratory failure are late, life-threatening complications.

●○● INTERPROFESSIONAL CARE

There are no specific diagnostic tests for tetanus; diagnosis is based on manifestations. Tetanus is completely preventable by active immunization. Immunization for children includes tetanus toxoid, administered as part of the diphtheria-tetanus-pertussis (DTaP) immunization series. In adults immunization is obtained by administering tetanus toxoid (Td) as two doses 4 to 6 weeks apart, with a third dose in 6 to 12 months. All individuals should have a booster dose every 10 years throughout life or at the time of a major injury if the last booster dose was given more than 5 years prior to the injury (CDC, 2013).

If a wound is contaminated or if the individual's immunization status is uncertain, passive immunization with tetanus immune globulin is administered. Active immunization with tetanus toxoid is begun at the same time. The wound is carefully and thoroughly debrided and antibiotics administered.

The patient with tetanus requires intensive care in an area of minimal stimulation. Penicillin is administered to help destroy the toxin-producing organism. Muscle spasms and seizures are controlled by chlorpromazine (Thorazine) or diazepam (Valium), often combined with a sedative. Anticoagulants may be prescribed to prevent venous thrombosis. In severe cases, seizures and spasms are controlled with paralysis by a curare-like medication, and airway obstruction is managed by mechanical ventilation.

●○● NURSING CARE

Nursing care for the patient with tetanus is intensive and focuses on assessments and interventions to promote safety, prevent injury, maintain nutrition, and maintain pulmonary and cardiovascular function. The patient usually requires in-hospital care for 2 to 5 weeks. The nursing care plan commonly includes the following:

- Place in a quiet, darkened room to decrease stimuli that cause muscle spasms and seizures.
- Provide only necessary physical care, and do so during periods of maximal sedation to decrease tactile stimulation that causes muscle spasms.
- Maintain oxygenation through mechanical ventilator and frequent suctioning of secretions.
- Maintain intravenous access for the administration of fluids and medications.
- Administer prescribed antibiotics, anticonvulsants, and sedatives. In the case of cardiovascular complications, administer prescribed beta-adrenergic blocking agents such as propranolol (Inderal).
- Provide adequate nutrition through prescribed nutritional support, such as total parenteral nutrition.
- Monitor respiratory and cardiovascular status and provide immediate interventions for respiratory or cardiovascular failure.
- Monitor fluid and electrolyte status. Ensure adequate fluid intake to maintain hydration and urinary output.
- Monitor urinary output, which should be maintained at 1.5 to 2 L/day.
- Monitor for the hazards of immobility, including constipation, pneumonia, deep venous thrombosis, and pressure ulcers.

Health Promotion

Tetanus is a preventable disorder, and nurses have a major role in promoting immunizations for all children and for educating adults about the need for booster doses. The older population is at risk if there is no history of immunization or a lapsed immunization. Community health fairs and programs targeting senior citizen groups can address this issue.

Wound care must be taught and must include the use of soap and water. All foreign material should be carefully flushed or removed from a wound, and medical care sought for wounds that are more extensive or contaminated.

THE PATIENT WITH CREUTZFELDT-JAKOB DISEASE

Classic **Creutzfeldt-Jakob disease (CJD)** (*spongiform encephalopathy*) is a rapidly progressive, degenerative, neurologic disease that causes brain degeneration without inflammation. The disease is not transmissible and is always fatal. The causative agent is believed to be an abnormal form of a cellular glycoprotein known as a *prion protein*. Transmission of the agent is by direct contamination with infected neural tissue, such as during eye and brain surgery. The disease occurs worldwide, but is more often found in England, Chile, and Italy, in adults over the age of 50 years.

A different form of the disease, called *new variant CJD* (vCJD), is a rare, degenerative, fatal brain disorder, but differs from the classic form of CJD. New variant CJD, referred to as "mad-cow disease," is believed to result from consumption of cattle products contaminated with bovine spongiform encephalopathy (BSE) and affects primarily young adults. Because the illness is fatal and is associated with infected cattle, severe restrictions have been placed on the importation of cattle, sheep, and goats as well as related animal products from countries in which BSE occurs.

Creutzfeldt-Jakob disease is characterized by degeneration of the gray matter of the brain. The spongiform degeneration (involving the formation of tiny holes and resembling a sponge) produces severe dementia, myoclonus (muscle contractions), and characteristic changes in brain waves. Biopsies of brain tissue after death show loss of neurons and proliferation of astrocytes (indicating destruction of nearby neurons).

The disease has characteristic stages and manifestations. Onset is rapidly progressive and is characterized by memory changes, an

exaggerated startle reflex, sleep disturbances, and nervousness. The individual then experiences deterioration in motor, sensory, and language function. Tremors, hyperreflexia, rigidity, and a positive Babinski reflex are often present, and confusion progresses to dementia in almost all cases. Patients in the terminal state are comatose and exhibit decorticate and decerebrate posturing. The median duration of illness for CJD is 4 to 5 months; the median duration of illness for vCJD is 13 to 14 months (CDC, 2010).

No specific treatment is available to stop or slow the progression of CJD. Collaborative interventions focus on the disease's manifestations. The disease is diagnosed by a thorough neurologic examination, specific EEG changes, and a CT scan. A final diagnosis can be made only by postmortem examination. It is often difficult to differentiate CJD from Alzheimer's disease, especially in the early stages.

The nurse may identify the manifestations of Creutzfeldt-Jakob disease when conducting a health history and total physical assessment by including questions about familial history, cultural and geographic risk, and high-risk occupations or procedures. Assessment of mental function, reflexes, and cranial nerve function may provide information to assist in diagnosis.

Nursing care focuses on maximizing comfort, preventing injury, preventing transmission, and providing support. The following guidelines are useful in designing the plan of care:

- Although comfort is difficult to assess in patients with impaired cognitive function, interventions that provide a quiet environment and analgesia are important.
- Communication is essential, even if patient is unable to respond.
- Institute seizure precautions, and pad side rails.
- Provide skin care, changes in position, and pressure-relief mattresses to decrease risk of pressure ulcers, venous stasis, and pneumonia.
- Maintain universal precautions when providing care. Disinfect surfaces with a solution of 5% bleach. Sterilize contaminated equipment by autoclave, or soak in 5% bleach solution for 1 hour. Label all specimens as biohazardous. Teach staff and family members guidelines for care, including careful hand hygiene. Patients do not require isolation.
- Provide time for family members to verbalize grief and loss, which may be manifested as anger and frustration with the healthcare system.
- Provide information to family members about the plan of care.
- Refer family members to sources of support, such as social services and clergy.

THE PATIENT WITH POSTPOLIOMYELITIS SYNDROME

Postpoliomyelitis syndrome is a complication of a previous infection by the poliomyelitis virus. Polio was an epidemic in the 1940s and 1950s, but has largely been eradicated through immunization with oral live trivalent virus vaccine. It is estimated that nearly 25% to 50% of the estimated 440,000 people in the United States who had contracted the disease are reexperiencing acute manifestations (NINDS, 2014). These people have struggled for years to rehabilitate themselves and lead productive lives but as they approach retirement age, they are again experiencing manifestations that may be physically and psychologically incapacitating. Symptoms of such a recurrence include weakness in both previously affected and unaffected muscles. The manifestations include progressive muscle weakness, fatigue, and pain, leading to muscle atrophy and scoliosis.

The cause of postpoliomyelitis syndrome is not known. The new weakness of muscles is believed to be due to degeneration of individual nerve terminals in the motor units that remain after the initial illness. Gradually, nerve terminals malfunction and permanent weakness occurs.

Postpoliomyelitis syndrome is diagnosed by a previous history of polio and manifestations that persist for at least 1 year. Diagnostic studies of nerve conduction, muscle strength, and pulmonary function determine current physical status. Treatment addresses the manifestations and often involves physical therapy and pulmonary rehabilitation programs.

The patient with postpoliomyelitis syndrome faces the challenge of unexpected physical changes. Patients are often anxious about how others will react or what the future holds. Respiratory dysfunction may result in the need for oxygen and muscle weakness and decreased pulmonary function may make walking difficult, if not impossible. ADLs, independent self-care, and careers are threatened.

Many former polio patients have not fully recovered psychologically and may respond to a recurrence of manifestations with denial and disbelief. Older patients may not know they had polio as children. Nurses are responsible for assessing and identifying the manifestations of the disease, and it is essential to question middle-age and older adults about a past history of polio when conducting the health history. The nurse individualizes teaching to meet the physical and psychosocial needs of the patient and family by providing candid explanations. Patients are taught how to prevent fatigue, promote optimal respiratory function, meet self-care needs, modify ADLs, and maintain safety. Follow-up care with nurses, physicians, physical therapists, respiratory therapists, and counselors is indicated. Referral to a support group can make a positive difference in the coping strategies of the patient and family.

THE PATIENT WITH RABIES

Rabies is a viral infection of the CNS most often transmitted through the bite of an infected rabid animal (CDC, 2011a). If untreated, rabies is fatal; however, the number of deaths from rabies is one to two per year. After an incubation period that usually lasts from 3 to 7 weeks, the virus travels to the brain of the infected animal via the nerves. It multiplies and migrates to the salivary glands. Saliva and brain tissue are considered infectious materials; blood, urine, and feces are not considered infectious and exposures do not require postexposure prophylaxis.

The patient with rabies usually has a history of an animal bite but may also become infected through an abrasion or open wound that is exposed to the infected saliva. The virus spreads from the wound to local muscle cells and then invades the peripheral nerves. It eventually travels to the CNS.

The manifestations occur in stages. During the initial, or prodromal, stage, the site of the wound is painful and exhibits various paresthesias. The infection causes anxiety, irritability and depression. General manifestations of infection (such as headache, loss of appetite, and sore throat) may appear. Patients may have increased sensitivity to light and sounds, and the skin is especially sensitive to changes in temperature. The prodromal stage is followed by an

excitement stage where periods of agitation alternate with periods of quiet. Attempts to drink cause painful laryngospasms that prevent the individual from drinking fluids (a phenomenon called *hydrophobia*). Large amounts of thick, tenacious mucus are present. The patient experiences convulsions, muscle spasms, and periods of apnea. Untreated cases lead to death within about 7 days and are typically due to respiratory failure.

Animals that bite are kept under observation for 7 to 10 days to detect rabies manifestations. Sick animals should be euthanized and the brain tissue examined for rabies, which is detected by fluorescent antibody testing. The blood of an infected person can be tested with the same diagnostic study to confirm the presence of rabies antibodies.

Nursing care for patients with rabies is provided in an intensive care unit, with the patient in a quiet, darkened room to decrease stimulation. Interventions are required to maintain the airway, maintain oxygenation, and control seizures. Universal precautions are vigilantly maintained as the rabies virus is present in the patient's saliva. If an open wound of a healthcare provider is contaminated with infected saliva, the provider must receive postexposure immunizations.

Patient and family teaching focuses on the importance of immunizing pets, providing proper care of wounds, and seeking immediate medical attention for animal bites. Because the untreated disease is almost always fatal, the best intervention is prevention. Preventive activities follow:

- Immunize household dogs and cats; immunize people who are bitten by animals.
- Local treatment of animal bites and scratches:
  - Carefully and thoroughly clean wounds with soap and water to remove saliva and dilute the viral exposure.
  - Immediately seek emergency treatment for person.
- Following exposure, rabies immune globulin (RIG) is administered once for passive immunization. Up to 50% of the globulin is infiltrated around the wound, and the rest is administered intramuscularly. At the same time, an inactivated human diploid cell vaccine (HDCV) is administered intramuscularly, beginning on the day of exposure and on days 3, 7, 14, and 28 after exposure (CDC, 2011a). RIG and HDCV should never be given in the same syringe or at the same site. Local and mild systemic reactions include itching, tenderness, headaches, muscle aches, and nausea.

THE PATIENT WITH BOTULISM

Botulism is food poisoning caused by ingestion of food contaminated with a toxin produced by the bacillus *Clostridium botulinum*. This anaerobic spore-forming bacillus is found in the soil. Infection occurs from eating improperly canned or cooked foods, especially home-canned vegetables and fruits, smoked meats, and vacuum-packed fish. Untreated cases can lead to death.

The toxins liberated by *C. botulinum* are absorbed by the gastrointestinal tract and bound to nerve tissues, blocking the release of acetylcholine from nerve endings and causing respiratory paralysis due to skeletal muscle paralysis.

Manifestations appear 12 to 36 hours after ingestion of contaminated food and begin with visual disturbances including diplopia; loss of accommodation; fixed, dilated pupils; and possible ptosis. Gastrointestinal manifestations include nausea and vomiting, diarrhea, dysphagia, and dry mouth. Impaired laryngeal muscle tone leads to dystonia. Paralysis of all muscle groups leads to respiratory paralysis and death.

Infection with the *Clostridium* toxin is verified by laboratory analysis of serum, stool, and suspected food if available. If botulism is suspected, the state health department and the CDC should be notified for assistance with laboratory assays and procuring botulism antitoxin. All people who may have eaten contaminated food must be monitored. Patients are hospitalized and monitored for respiratory failure, paralytic ileus, and urinary retention. Toxins in the GI tract are removed by cathartics, enemas, and gastric lavage. Respiratory paralysis is treated with mechanical ventilation and a possible tracheostomy. Botulism antitoxin is administered to eradicate toxins in the blood while nutritional support is provided with total parenteral nutrition. IV fluids are administered to prevent dehydration and renal failure The patient will be NPO until able to swallow and breathe.

During this time, the patient may need to modify ADLs and take rest periods throughout the day. If ventilation can be maintained adequately, the patient often recovers without further neurologic deficits, although fatigue and weakness may persist for up to a year (CDC, 2011b). Education of the public to prevent botulism is important.

Delegating Nursing Care Activities

As appropriate and allowed by the designated duties and responsibilities of unlicensed assistive personnel, the nurse may delegate nursing care activities such as assisting with bathing and other ADLs, measuring fluid intake and output, collecting vital signs (including orthostatic vital signs), encouraging oral or enteral fluid intake, and providing skin care and positioning.

Continuity of Care

Address the following topics at community health programs:

- Home-canned foods must be processed in a pressure cooker rather than in boiling water because the organism is difficult to kill.
- Do not eat home-processed foods that have a change in color, are soft, contain gas bubbles, or have a bad odor.
- Always heat both home-processed and commercial foods at temperatures over 120°C (248°F) or boil for 10 minutes before tasting or eating them.
- Discard home-processed or commercially canned or bottled foods with defective seals.
- Discard commercially prepared canned foods that are damaged or have bulging sides or leaking contents (CDC, 2011b).

CHAPTER HIGHLIGHTS

- **Spinal cord injuries are typically related to trauma, with the major risk factors being age (young adults), gender (male), and alcohol or drug abuse. The causes of SCIs include direct trauma, fractures, torn ligaments, circulatory impairment, contusions, lacerations, or transections of the cord. Complete or incomplete SCIs are determined by the degree of interruption in motor and sensory pathways. Movement, perception, sensation, sexual function, and elimination are potentially affected by these injuries.**
- **Complications of SCIs include spinal shock, which is the temporary loss of all reflexes (areflexia) below the level of injury. Manifestations of spinal shock include bradycardia, hypotension, and flaccid paralysis. Autonomic dysreflexia (AD) is an exaggerated sympathetic response when SCI injuries are at or above T_6. AD is triggered by noxious stimuli and results in severe and life-threatening hypertension.**
- **Rehabilitation of the SCI patient is an ongoing process from intensive care to home care. Nursing interventions are necessary in all settings to promote independence in self-care.**
- **A herniated intervertebral disk is a rupture of the cartilage surrounding the intervertebral disk with protrusion of the nucleus pulposus. The major manifestation of lumbar disks is lower back and sciatic pain on the affected side.**
- **Spinal cord tumors may be benign or malignant, primary or metastatic. Depending on tumor size and location, pathologic changes in function can result from compression, invasion, or ischemia.**
- **CNS infections are caused by bacteria, bacterial toxins, viruses, fungi, protozoans, and rickettsiae. Organisms enter the CNS through the bloodstream or by direct invasion. The major CNS infections are meningitis and encephalitis. Treatments include broad-spectrum antibiotics or antifungal agents. Community-based health education can provide important preventive information.**

TEST YOURSELF NCLEX-RN® REVIEW

1. A patient is admitted to the emergency department with a cervical SCI following an automobile crash. What should the nurse explain to the family as the reason for the patient being placed on mechanical ventilation?
   1. The accident injured the patient's lungs.
   2. The nerves that control lung function have been injured.
   3. The patient is unable to breathe because of being unconscious.
   4. The ventilator is temporary to ensure the patient receives adequate oxygen until recovery.

2. The nurse is planning care for a patient with an acute SCI. According to best practices, which medications should the nurse prepare to administer to this patient? (Select all that apply.)
   1. analgesics
   2. antibiotics
   3. vasopressors
   4. antihistamines
   5. corticosteroids

3. A patient with a thoracic spinal cord injury is experiencing spinal shock. How should the nurse explain this pathophysiologic process to the patient?
   1. There is damage to the lower motor neurons.
   2. There is an exaggerated sympathetic response.
   3. There is a loss of control of cardiovascular mechanisms.
   4. There is a temporary loss of reflex function below the level of injury.

4. A patient is demonstrating manifestations of autonomic dysreflexia. What will the nurse most likely assess as the reason for this health problem?
   1. diarrhea
   2. distended bladder
   3. elevated blood pressure
   4. respiratory wheezes and stridor

5. An industrial nurse is conducting a class for manufacturing plant employees on methods to prevent back pain. What should the nurse include in this teaching? (Select all that apply.)
   1. Use large leg muscles to push when lifting.
   2. Bend from the waist to lift articles from the floor.
   3. Spread the feet apart to broaden the base of support.
   4. Work as closely as possible to the object to be moved.
   5. Always lift articles rather than rolling or pushing them.

6. A nurse is assessing a patient recovering from a posterior cervical laminectomy for manifestations of spinal cord compression. How should this assessment be conducted?
   1. Ask the patient to wiggle his or her toes.
   2. Ask the patient to grip the nurse's hands.
   3. Use a stethoscope to auscultate heart sounds.
   4. Use a reflex hammer to assess Babinski's reflex.

7. A nurse is planning care for a patient with a lumbar metastatic spinal cord tumor. Which assessment finding indicates that pain control is needed?
   1. fever
   2. diarrhea
   3. increased heart rate
   4. urinary incontinence

8. A patient with meningitis is drowsy and confused. What should the nurse explain to the patient's family as being the cause for these mental status changes?
   1. decreased intracranial pressure
   2. bleeding in the central nervous system
   3. elevated serum white blood cell count
   4. sluggish flow of cerebrospinal fluid

9. A nurse is planning a seminar for city public health workers on ways to reduce the onset of central nervous system infections in the community. On which topic should the nurse focus in this seminar?
1. garbage pickup
2. sanitation services
3. mosquito spraying
4. washing fruits and vegetables

10. A patient with a spinal cord injury is prescribed pantoprazole (Protonix). According to best practices, why is this medication prescribed for the patient?
1. Prevents stress-related gastric ulcers.
2. Encourages healing of gastric nerves.
3. Promotes digestion of enteral feedings.
4. Supports healthy bacteria in the gastrointestinal tract.

44 Nursing Care of Patients with Neurologic Disorders

LEARNING OUTCOMES

1. Identify risk factors for degenerative neurologic, peripheral nervous system (PNS), and cranial nerve disorders.
2. Explain the pathophysiology, manifestations, complications, interprofessional care, and nursing care of patients with degenerative neurologic, PNS, and cranial nerve disorders.
3. Compare and contrast the manifestations of the progressive stages of Alzheimer's disease.
4. Discuss the purposes, nursing implications, and health education for the patient and family for medications used to treat Alzheimer's disease, multiple sclerosis, Parkinson's disease, and myasthenia gravis.
5. Describe the procedures (thymectomy, percutaneous rhizotomy, plasmapheresis) used to treat selected neurologic disorders.

CLINICAL COMPETENCIES

1. Assess and monitor functional status of patients with neurologic disorders, and communicate findings to appropriate interprofessional team members.
2. Demonstrate effective use of individualized and patient-centered strategies as well as evidence-based research to prioritize care and design nursing interventions that are specific to the needs of aging patients with multiple sclerosis.
3. Incorporate assessments, patient needs and preferences (including individual and cultural values), clinical expertise, and evidence-based practice into the formation of priorities and interventions for patients with neurologic disorders.
4. Safely and accurately administer oral and injectable medications used to treat Alzheimer's disease, multiple sclerosis, Parkinson's disease, and myasthenia gravis.
5. Provide competent care to patients having a thymectomy, percutaneous rhizotomy, or plasmapheresis.
6. Effectively communicate with and function within the interprofessional team to plan and provide care for patients with neurologic disorders.
7. Provide appropriate and effective teaching to facilitate safety, communication, and community-based self-care for patients with acute and chronic healthcare needs that result from neurologic disorders.
8. Revise plan of care as needed to provide effective interventions to promote, maintain, or restore functional health status to patients with neurologic disorders.
9. Document care in the electronic medical record and use information management tools to monitor outcomes of care.
10. Participate in studies and projects to improve the quality and safety of care for patients with neurologic disorders.

MAJOR CHAPTER CONCEPTS

- Dementia involves impairment in short- and long-term memory; impairment in language, motor activity, recognition, and/or abstract thinking; and a clinical course characterized by gradual onset and continuing cognitive decline.
- Alzheimer's disease (AD) is progressive and characterized by cognitive and functional decline with atrophy of brain tissue, loss of neurons, neurofibrillary tangles, and amyloid plaques. There are no effective treatments for preventing AD, although pharmacologic and nonpharmacologic therapies may slow its course. AD eventually leaves the individual unable to communicate, maintain continence, and recognize self or others. Education of caregivers addresses burdens and expectations, and provides instruction regarding community resources. The goal is to maximize the environment to the patient's functional abilities and safety needs.
- Multiple sclerosis (MS) is an autoimmune, demyelinating disease of the central nervous system. MS is multifactorial, with genetic and environmental factors linked to its incidence. Exposure to UVB light and exposure to the Epstein-Barr virus have been implicated as environmental factors that interact with genes to lead to the onset of MS. The loss of myelin leads to axon dysfunction, which slows and distorts nerve impulses. Medications are used to slow the progression of the disease, decrease the number of exacerbations, and treat manifestations.
- Parkinson's disease (PD) is a progressive degenerative neurologic disease characterized by tremor, muscle rigidity, and bradykinesia. The loss of voluntary motor control is the result of pathologic processes resulting in a decrease of dopamine (an inhibitory neurotransmitter) so that it can no longer inhibit acetylcholine (an excitatory neurotransmitter). Medications are used to treat manifestations and include monamine oxidase (MAO) inhibitors, dopaminergics, dopamine agonists, and anticholinergics.
- Huntington's disease (chorea) is a progressive, degenerative inherited neurologic disease characterized by increasing dementia and chorea. The presence of an excess of dopamine causes excessive, uncontrolled movement.
- Amyotrophic lateral sclerosis (ALS) is a rapidly progressive and fatal degenerative motor neuron disease characterized by weakness and wasting of voluntary control muscles, but without sensory or cognitive changes. The patient

eventually loses the ability to communicate and breathe. Riluzole, antiglutamate medication, is used to treat (but not cure) manifestations.

- Myasthenia gravis (MG) is a chronic autoimmune PNS disorder characterized by fatigue and severe skeletal muscle weakness. It results from a decreased number of acetylcholine receptors at the neuromuscular junction, so muscles are unable to contract. Life-threatening emergencies include myasthenic crisis (sudden increase in motor weakness) and cholinergic crisis.
- Guillain-Barré syndrome (GBS) is an acute inflammatory demyelinating disease of the PNS characterized by an acute onset of flaccid motor paralysis that begins in the lower extremities and ascends to involve the upper extremities, torso, and cranial nerves. Paralysis of intercostal and diaphragmatic muscles often necessitates ventilatory assistance. The acute phase lasts from 1 to 3 weeks, followed by recovery, which takes from 6 months to 2 years.
- Cranial nerve disorders include trigeminal neuralgia (TN) and Bell's palsy. TN is a chronic disorder of cranial nerve V and causes severe facial pain. Bell's palsy is an acute disorder of cranial nerve VII, characterized by unilateral paralysis of the facial muscles. Patients provide self-care at home and require teaching to help prevent complications.

KEY TERMS

Alzheimer's disease (AD), *1430*
amyotrophic lateral sclerosis (ALS), *1454*
basal ganglia, *1444*
Bell's palsy, *1466*
dementia, *1429*
dopaminergic, *1445*
Guillain-Barré syndrome (GBS), *1461*
Huntington's disease, *1451*
multiple sclerosis (MS), *1436*
myasthenia gravis (MG), *1457*
myelin sheaths, *1436*
neuralgia, *1464*
neurotransmitters, *1445*
Parkinson's disease (PD), *1444*
trigeminal neuralgia (TN), *1464*

This chapter discusses degenerative neurologic disorders, PNS disorders, and cranial nerve disorders. For many of the disorders, care is based on similar nursing diagnoses. To avoid repeating those diagnoses and interventions for each disorder, they have been divided among the nursing care discussions as appropriate.

Degenerative Neurologic Disorders

Degenerative neurologic disorders affect the central nervous system (CNS) and the peripheral nerves. By progressively disrupting cognitive processes or motor functions, disorders such as Alzheimer's disease, Parkinson's disease, and multiple sclerosis strike at the core of an individual's sense of personal autonomy and well-being and can be psychologically and emotionally devastating to family members and caregivers.

Ongoing medical research into degenerative neurologic disorders offers an increasing measure of hope to patients and their families. The discovery of genetic or biochemical markers associated with some of these disorders is leading to the development of effective screening and diagnostic methods. In addition, new drugs may halt the progression of the disorders in some patients, transforming the disorders into manageable conditions. The chapter begins with a discussion of dementia, which is not a specific disease, but rather a collection of manifestations that are caused by a variety of disorders that affect the brain.

DEMENTIA

Dementia (meaning *deprived of mind*) is cognitive decline caused by any disorder that permanently damages areas of the brain necessary for memory and learning. The hallmark of dementia is impairment of both short- and long-term memory, with resultant deficits in abstract thinking, impaired judgment, problem solving, and/or changes in personality (Wagner et al., 2013). Impairments of cognitive function are usually accompanied by deterioration in emotional control, social behavior, and motivation. People with dementia may have agitation, delusions, and hallucinations. All forms of dementia result from death of neurons and/or the loss of communication among the cells. Although the exact cause is not always known, many forms of dementia are characterized by abnormal structures in the brain called *inclusions*, and there is clearly a genetic component in the development of some types of dementia. It is important to remember that although the incidence of dementia increases with aging, it is not a normal component of aging.

To be diagnosed with dementia, the following criteria must be met:

- A decline in memory as well as deficits in at least one of the following cognitive abilities:
  1. Ability to generate coherent speech or understand spoken or written language
  2. Ability to recognize or identify objects, assuming intact sensory function
  3. Ability to execute motor activities, assuming intact motor abilities, sensory function, and comprehension of the required task
  4. Ability to think abstractly, make sound judgments, and carry out complex tasks.
- The decline in cognitive abilities must be severe enough to interfere with daily life (Alzheimer's Association, 2011b).

Although exact numbers are difficult to determine, it is estimated that in the United States as many as 4.5 million people have dementia, and of those 60% to 80% have Alzheimer's disease (AD) (Wagner et al., 2013). It is estimated that 24 million people worldwide

have dementia and that this figure will double every 20 years, with 42 million by the year 2020 (Hoe & Thompson, 2010). Many different diseases and conditions may cause dementia, including Alzheimer's disease, vascular dementia, Parkinson's disease, normal pressure hydrocephalus, Creutzfeldt-Jakob disease, metabolic disorders, medications, poisoning, and anoxia. Even though the actual cause of all dementias may not be known, factors that increase the risk of developing one or more kinds of dementia have been identified. These include aging, a family history of dementia, smoking and alcohol use, atherosclerosis, high cholesterol, elevated plasma homocysteine levels, diabetes mellitus, and Down syndrome.

THE PATIENT WITH ALZHEIMER'S DISEASE

Alzheimer's disease (AD) (*dementia of Alzheimer type [DAT]* or *senile disease complex*) is a form of dementia characterized by progressive, irreversible deterioration of general intellectual functioning. AD accounts for almost 80% of dementia diagnoses, and occurs in middle or late life (Davis et al., 2011). It affects almost twice as many women as men, but this is believed to be the result of women living relatively longer than men. People with AD die an average of 4 to 6 years after diagnosis, but the disease duration varies from 3 to 20 years (Alzheimer's Association, 2013).

Although the exact cause is unknown, it appears that AD develops from the interaction of multiple factors. Age is the major risk factor, but other risk factors include head trauma, inflammatory factors, and oxidative stress. Other risk factors to evaluate include low educational level, lack of mental stimulation, migraines, and heavy smoking and alcohol consumption. People who develop AD under age 65 are said to have early-onset AD; those who develop AD after age 65 have late-onset AD. A small percentage of AD is caused by a genetic variation and is characterized by an early onset—sometimes affecting people as young as 30. Research into the genetics of early-onset AD has identified mutations of at least three genes: the *APP* gene on chromosome 21, *PSI* gene on chromosome 14, and *PS2* gene on chromosome 1. The *ApoE* gene on chromosome 19 increases the risk for the development of late-onset AD and lowers the age of onset, but it is not yet known how this occurs.

Memory loss is usually the first sign of Alzheimer's disease. Memory deficits are initially subtle and family members and friends may not suspect a problem until the disease progresses and manifestations become more noticeable. Family members may deny the manifestations, and this denial often results in attempts to dismiss or hide the deficits from others, until the patient exhibits unsafe or extremely unusual behavior (Hoe & Thompson, 2010). Progression of the disease varies, but the course is one of deteriorating cognition and judgment with eventual physical decline and total inability to perform activities of daily living (ADLs). With the loss of the ability to perform even the most basic ADLs, the burden of meeting the patient's needs shifts to the caregiver.

FAST FACTS

Alzheimer's Disease

- Scientists estimate that more than 5.3 million people have AD.
- AD is the sixth leading cause of death in the United States.
- A new case of AD is diagnosed every 70 seconds, and the most significant risk factor for development of AD is rising age.
- The lifetime risk for AD for those living to age 55 is 17% in women and 9% in men.
- 9.9 million unpaid caregivers take care of people with AD.

Source: Alzheimer's Foundation, 2013; Davis et al., 2011.

Pathophysiology

Characteristic findings in the brains of patients with AD are loss of nerve cells and the presence of neuritic plaques, neurofibrillary tangles, and amyloid angiopathy (Figure 44–1 ■). Several theories are proposed for the cause of AD. The theories include the amyloid hypothesis (AD is the result of an accumulation of beta-amyloid in plaques), the tau hypothesis (AD is the result of tau protein dysfunction), and the vascular hypothesis (many AD patients also have vascular dementia, the result of cardiovascular and cerebrovascular disease causing endothelial damage). Making diagnosis more difficult is that some people have these same pathophysiologic changes, but do not develop AD.

Neuritic plaques are groups of nerve cells (and especially the terminal axons) that degenerate and clump around an amyloid core as plaques, found in the spaces between the neurons of the brain. These plaques, which develop first in areas used for memory and cognition, disrupt transmission of nerve impulses. The plaques consist primarily of insoluble deposits of beta-amyloid, a protein fragment from a larger protein called amyloid precursor protein, mixed with other neurons and nonnerve cells. Many scientists believe that beta-amyloid is the critical component in the development of AD (Wagner et al., 2013).

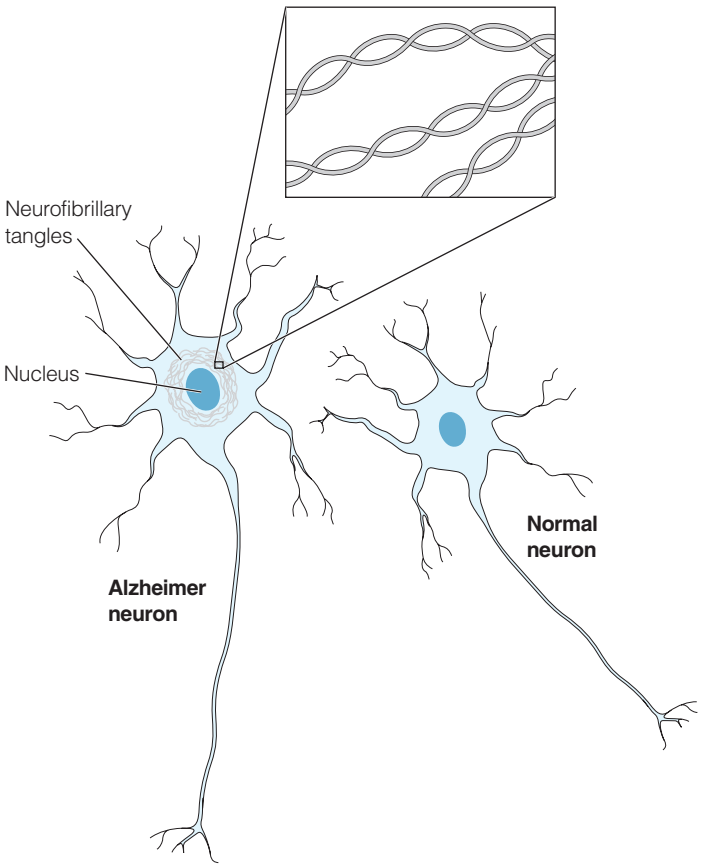

Figure 44–1 ■ Neuron with neurofibrillary tangles seen in Alzheimer's disease.

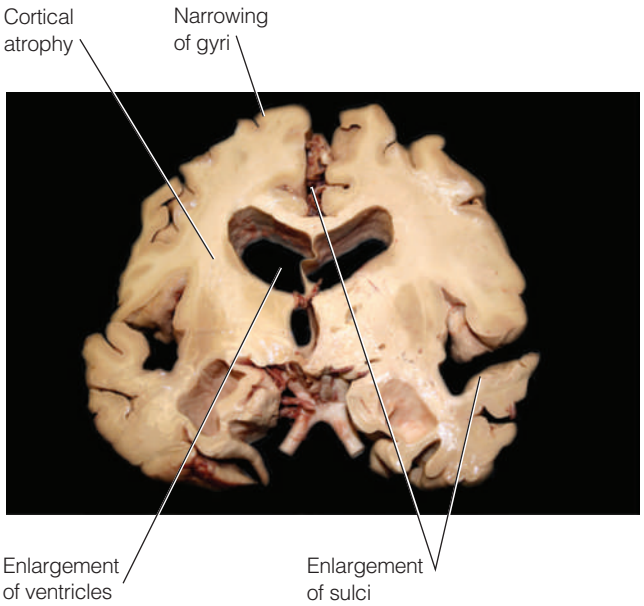

Figure 44–2 ■ Changes in neuroanatomy associated with Alzheimer's disease. Note areas of cortical atrophy, narrowing of the gyri, enlargement of sulci, and ventricular dilation.
Source: Living Art Enterprises/Science Source.

Neurofibrillary tangles, found in the cytoplasm of abnormal neurons, are composed of fibrous proteins wound around each other in a helical way. The fibrous proteins contain tau, also a protein. Tau normally holds together the microtubules, which guide nutrients and molecules to the end of the axon. Because tau no longer maintains the transport system, communication is lost between neurons. Death of neurons may follow, contributing to the development of dementia.

Blood flow to the affected areas of the brain is decreased. The brain atrophies, and corresponding enlargement of ventricles and sulci is evident (Figure 44–2 ■). As AD progresses, more areas of the brain are affected. Neuronal and neurotransmitter losses (especially of choline acetyltransferase, necessary for the synthesis of acetylcholine, a neurotransmitter associated with memory) are correlated with the number of neuritic plaques and the severity of AD.

AD is characterized by atrophy of the cortical area of the brain and loss of neurons, especially in the parietal and temporal lobes. With significant atrophy and loss of brain tissue, the ventricles enlarge (a form of hydrocephalus). Several structural and chemical changes in the brain occur with AD, especially in the hippocampus and the frontal and temporal lobes of the cerebral cortex. As AD destroys neurons in the hippocampus and related structures, short-term memory fails and the ability to perform easy and familiar tasks declines. The effect of AD on neurons in the cerebral cortex is loss of language skills and judgment. Emotional outbursts and behavior changes (such as wandering and agitation) begin to occur and become more frequent as the disease progresses. Eventually, other areas of the brain are affected; all affected areas begin to atrophy, and the person becomes totally helpless and unresponsive.

Stages and Manifestations

The Alzheimer's Association (2014b) classifies Alzheimer's disease into seven stages based on the patient's manifestations and abilities. The progression of AD varies for each individual and may not precisely follow these stages.

STAGE 1: NO COGNITIVE IMPAIRMENT

Memory problems are not experienced nor evident to others.

STAGE 2: VERY MILD DECLINE

People find themselves having memory lapses, forgetting familiar names, or losing everyday objects such as keys and glasses. These memory problems are not evident to others nor are they detectable during a medical examination.

STAGE 3: MILD COGNITIVE DECLINE

Early-stage AD may be diagnosed in some, but not all, people with AD in this stage. Family and friends begin to notice problems and the deficits may be measured or detected during a medical examination. Common problems include trouble finding words or names, decreased ability to remember names when introduced to new people, retaining little information when reading a passage, decreased ability to plan or organize, losing or misplacing valuable objects, and having performance issues in social and work settings that are noticeable to others.

STAGE 4: MODERATE COGNITIVE DECLINE

A careful medical interview will identify deficiencies in knowledge of recent events, impaired ability to perform challenging mental arithmetic (such as counting backward from 100 by 7s), decreased capacity to perform complex tasks (such as buying groceries or paying bills), and a reduced memory for personal history. The person often appears subdued and withdrawn, especially in social or mentally challenging situations.

STATE 5: MODERATELY SEVERE COGNITIVE DECLINE

In this stage major deficits in memory and a decline in cognitive function emerge. Some assistance with ADLs becomes essential, but the person can usually eat and use the toilet. People with AD in this stage do usually retain knowledge about themselves, and know their name and the names of family members. Problems include inability to recall current address or telephone number; confusion about where they are as well as the date, day of the week, or season; and trouble with less challenging mental arithmetic (such as counting backward by 4s from 40).

STAGE 6: SEVERE COGNITIVE DECLINE

This stage is characterized by worsening memory, emergence of personality changes, and the need for extensive help with ADLs. There is loss of most awareness of recent experiences and events as well as of the surroundings. The person generally knows his or her own name, but has problems recalling most personal history. People with AD in this stage do sometimes forget the names of family members, but they can usually distinguish familiar from unfamiliar faces. Without supervision they may, for example, put pajamas over daytime clothing or shoes on wrong feet. They need help with details of toileting (flushing, wiping, disposing of tissue) and are increasingly incontinent of urine or feces. There is disruption of their normal sleep/wake cycle. They tend to wander and get lost. Significant personality and behavior changes occur, such as suspiciousness and delusions, hallucinations, or compulsive/repetitive behavior (such as hand wringing or tissue shredding).

STAGE 7: VERY SEVERE COGNITIVE DECLINE

This is the final stage. The person loses the ability to respond to his or her environment, the ability to speak, and the ability to control

movement. Some words or phrases may be spoken, but they are not recognizable. Total care is needed for eating and toileting (there is general incontinence). The ability to walk without assistance is lost first, followed by the ability to sit without support, the ability to smile, and the ability to hold up the head. Reflexes become abnormal, muscles grow rigid, and swallowing is impaired. There are many possible causes of death as the person with AD reaches the final stage. The affected person is at increased risk for aspiration pneumonia from impaired swallowing. Loss of neurons impairs sensations such as hunger or thirst, leading to complications of malnutrition or dehydration. Infections can result in sepsis.

●○● INTERPROFESSIONAL CARE

There is no cure for AD, and the main objective of care is to provide an environment that matches the patient's functional abilities. Nurses, physicians, physical therapists, and social workers collaborate with the patient's family to provide the least restrictive environment in which the patient can safely function.

DIAGNOSIS

There is no specific diagnostic test for AD. The only definitive method of diagnosis is postmortem examination of brain tissue. As a result, AD is diagnosed by ruling out causes for the patient's manifestations. An extensive workup is especially important, because the dementia may be due to a reversible or treatable condition. For example, an older patient's misuse of medications can lead to overdosing and resulting confusion. Other conditions that may be considered are depression, infection, hypothyroidism, dehydration, heart disease, stroke, and chronic obstructive respiratory disease. Mental status is assessed with tests such as the Folstein Mini Mental State Examination (measures orientation, registration, attention, calculation, recall, and language) and the Alzheimer's Disease Assessment Scale (assesses memory, speech, language, depression, psychosis, and vegetative manifestations). A simple but valid test that is often used to track cognitive changes over time is the clock drawing test (Davis et al., 2011).

A diagnosis of AD requires the documented presence of dementia established by clinical examination and the results of a mental status test, onset between age 40 and 90 years (most often after age 65), and absence of systemic or brain disorders that could cause deficits in memory and cognition (Alzheimer's Association, 2011b).

MEDICATIONS

No drugs have demonstrated effectiveness in halting the AD process but those medications listed in the Medication Administration box are considered to slow the progression of cognitive decline. Other medications are prescribed for manifestations such as sleep disturbances and agitation. Guidelines for pharmacologic treatment of AD recommend that decisions should be based on a drug's potential adverse side effects, ease of use, and cost (Davis et al., 2011).

Depression often accompanies AD and is treated with the appropriate medication. Antihistamines and tricyclic antidepressants

MEDICATION ADMINISTRATION

The Patient with Alzheimer's Disease

ACETYLCHOLINESTERASE INHIBITORS (AChEIs)

tacrine hydrochloride (Cognex)

donepezil hydrochloride (Aricept)

galantamine (Razadyne)

rivastigmine tartrate (Exelon or Exelon patch)

In the early stages of AD, the pathologic changes in neurons result in a deficiency of acetylcholine (a key neurotransmitter involved in cognitive functioning). Cholinesterase inhibitors slow the breakdown of acetylcholine release by the remaining intact neurons. In addition, rivastigmine tartrate inhibits the G_1 form of acetylcholinesterase (found in higher levels in the brain of patients with AD), so less acetylcholine is degraded. The drugs are used to improve memory in mild to moderate AD dementia. In this group, donepezil is considered first-line therapy because of its once-daily dosing, narrower adverse effect profile, and efficacy. Tacrine is rarely used due to its inconvenient dosing schedule (four times daily) and risk of hepatotoxicity (Davis et al., 2011).

NMDA RECEPTOR ANTAGONIST (N-METHYL-D-ASPARTATE)

memantine hydrochloride (Namenda)

This drug binds to NMDA receptor-operated cation channels, slowing death of neurons. It temporarily delays more severe AD manifestations.

Nursing Responsibilities

- Monitor for nausea, vomiting, anorexia, and diarrhea.
- Monitor for bradycardia if AChEIs are being administered with beta-blockers, digoxin, or antiarrhythmic drugs.
- Administer donepezil hydrochloride at bedtime.
- Administer rivastigmine tartrate (both capsules and liquid) with food. Liquid form may be administered undiluted or mixed with water, juice, or soda. Stir to completely dissolve. The rivastigmine patch is applied once every 24 hours at the same time of day, using the upper chest, upper or lower back, or upper arm.
- Administer tacrine hydrochloride 1 hour before meals, if possible.
- Monitor for jaundice, increased bilirubin levels, and other signs of liver involvement, such as rising serum aminotransferase (AST, ALT) levels. Therapy is usually decreased when the enzyme level exceeds four times normal limits and is discontinued when the level reaches five times normal.
- Observe for GI bleeding and gastric pain.
- Monitor for cholinergic-related problems: bladder outlet obstruction, seizures, and slowed cardiac rate.
- Assist with ambulation because dizziness is a common side effect.
- Monitor glycemic control in patients with diabetes.
- Assess for improvement in AD symptoms, especially in reasoning, memory, and ADLs.

Health Education for the Patient and Family

- Notify the physician promptly if jaundice, seizures, slowed heart rate, GI bleeding, or difficulty urinating occurs.
- Follow directions for times and instructions for administration of specific medication.
- Follow healthcare provider's recommendation for periodic EEGs, blood tests, and urine tests.
- Medications do not cure AD, and eventually become ineffective as the disease progresses.

Note: Drugs identified in *italics* are among the 200 most commonly prescribed medications in the U.S.

that have high anticholinergic activity are usually avoided because they can increase AD manifestations. Occasionally patients with AD require tranquilizers such as thioridazine (Mellaril) or haloperidol (Haldol) to manage severe agitation, delusions, or aggression. When antipsychotic drugs are prescribed, concerns that need to be addressed include the risk of anticholinergic adverse effects, as well as drug cost (Davis et al., 2011).

ALTERNATIVE AND COMPLEMENTARY THERAPY

Alternative and complementary therapies have been used in treating the manifestations of AD and include the following:

- Huperzine A, a traditional Chinese medicine, which acts as an acetylcholinesterase inhibitor
- Coenzyme Q10, an antioxidant that naturally occurs in the body
- Supplements, such as zinc, selenium, and evening primrose oil
- Therapies involving massage, art, music, sound, dance, and pet therapy.

●○● NURSING CARE

Health Promotion

Patients with AD often require intensive, supportive nursing interventions directed at the physical and psychosocial responses to illness. Equally important, the nurse can facilitate the long-term support of these patients by providing teaching and referrals to follow-up care in the community. See the Case Study & Nursing Care Plan for a patient with AD on page 1437.

Health promotion for the patient with AD focuses on maintaining functional abilities and safety. If the patient will be cared for at home, address safety considerations as well as the caregivers' abilities to meet the patient's basic needs, such as maintaining hygiene and other ADLs. Adapt nursing interventions and teaching to the patient's stage of AD. Nurses promote caregiver health; information about caregiver support systems and respite care should be provided.

The public needs to be aware of the warning signs of AD, and seek medical care when they are observed. The 10 warning signs of AD are memory loss, difficulty performing familiar tasks, problems with language, disorientation to time and place, poor or decreased judgment, problems with abstract thinking, misplacing things, changes in mood or behavior, changes in personality, and loss of initiative (Alzheimer's Association, 2011b). Although there is no proven way to prevent AD, recommendations have been made to delay the onset of manifestations. These include staying active mentally, physically, and socially. Activities such as walking each day, reading the newspaper, visiting the library, or writing a letter are important in maintaining cognitive ability in old age. Other recommendations are generally beneficial for health including eating a healthy diet (with an emphasis on fruits, vegetables, and fiber), controlling cardiovascular and diabetes mellitus risk factors (weight, smoking, blood pressure, and cholesterol), and avoiding head injuries (by wearing seat belts and helmets and avoiding falls).

Assessment

Collect the following data through the health history and physical examination (refer to Chapter 41). Further focused assessments are described with nursing interventions that follow.

NURSING CARE OF THE OLDER ADULT

MEMORY

Many older adults experience mild problems with memory, but do not have AD. Careful evaluation of the older adult is done in order to avoid misdiagnosing dementia in these cases.

- *Health history:* family member/caregiver support, living arrangements, ability to carry out ADLs, drug use, work history (e.g., exposure to metals), previous history of multiple strokes, brain injury or brain infection, family history of dementia, sleep pattern, changes in cognition and memory, ability to communicate, changes in behavior
- *Physical assessment:* height/weight, orientation, abstract reasoning, mental status.

Priorities of Care

The goals of care for a patient with an impaired memory are to maintain a safe environment and to optimize that environment to the patient's functional level. Techniques to help with the memory loss should be included in teaching for both the patient and the caregiver.

- Suggest complementary therapies, such as meditation, massage, or exercise. *These activities can help reduce stress; stress can aggravate memory loss.*
- Suggest using a calendar, keeping lists of reminders, or asking someone else to remind of appointments and events. *Written or verbal reminders are helpful if memory is impaired.*

SAFETY ALERT

Risk for falls and medication errors are both factors in the care of patients with AD. Any change in the physical environment, or placement of household belongings, or increased stimulation can contribute to an increased risk for falls and to the possibility of medication errors. Patients with AD frequently require supervision with physical tasks, ambulation, and medication administration, particularly in an unfamiliar environment.

Diagnoses, Outcomes, and Interventions

During the early stage of AD, nursing care focuses on helping the patient make minor adaptations to his or her environment. As the patient becomes progressively unable to manage self-care tasks, more adaptations are required. Equally important, the caregiver needs much support—both physical and psychosocial—as the patient becomes increasingly dependent.

Evidence for Nursing Care

The Patient with Alzheimer's Disease

Selected resources that nurses may find helpful when planning evidence-based nursing care follow.

- Davis, N. J., Hendrix, C. C., & Superville, J. G. (2011). Supportive approaches for Alzheimer disease. *Nurse Practitioner*, *36*(8), 22–30. doi:10.1097/01.NPR.0000399724.54519.ae
- Hoe, J., & Thompson, R. (2010). Promoting positive approaches to dementia care in nursing. *Nursing Standard*, *25*(4), 47–56.

Impaired Memory

Expected Outcome: Patient with impaired memory will be in a safe environment where the risk for harm is eliminated.

- Recommend using a medication box labeled with days and times. *A medication box is a good way to remember to take medications.*
- If treatment or professional care of the individual with AD is necessary, provide information to the healthcare staff about the individual's memory problems. *Families provide much of the care and support of older adults living with dementia. Family caregivers are an important source of information and should be regarded as an integral part of the healthcare team.*
- Provide continuity in nursing staff. *This not only promotes consistency of care for the patient, but also allows the nurse to determine more accurately changes in the patient's condition.*
- Repeat explanations simply and as needed to decrease anxiety. *Loss of short-term memory leads to loss of a point of reference; eventually, AD patients think they are experiencing everything for the first time.*

SAFETY ALERT

It may be necessary to teach the caregiver how to refill the medication box, or to stress the importance of spot checking if the patient fills it.

Anxiety

Managing the AD patient's behaviors associated with anxiety, restlessness, and confusion is a major challenge confronting nurses and caregivers. Frequently, patients are relatively calm in the morning hours, only to experience increasing periods of agitation in the afternoon and evening hours. The AD patient may wake from the night's sleep with confusion, fearfulness, or panic attacks.

Expected Outcome: Patient's anxiety will be minimized/controlled so as to ensure patient safety and manageability, as well as patient comfort.

- Monitor for early behaviors of fatigue and agitation. *Early assessment of problems results in prompt intervention to promote rest or to remove the patient from the situation causing anxiety.*
- Remove from situations that are causing increased anxiety, such as noisy activities involving large groups. *High-stimulus situations may increase anxious feelings and agitation.*
- Keep daily routine as consistent as possible. *Providing a structured day enhances feelings of familiarity and decreases stress.*
- Schedule rest periods or quiet times throughout the day. *Fatigue contributes to anxiety and lowers the ability to tolerate stress.*
- Provide quiet activities, such as listening to favorite music, in the afternoon or early evening. *Quiet activities may help decrease sundowning.*
- If confusion and agitation persist or escalate, assess for physical causes such as decreased oxygenation, infections, fatigue, constipation, and electrolyte imbalance. *Physical factors can increase agitation in patients with AD.*
- Use therapeutic touch or gentle hand massage. *These activities induce relaxation and have a calming effect.*

Hopelessness

As the patient and family recognize the effect of AD on their lives, they may feel a sense of hopelessness. They may not have the coping skills to deal effectively with the diagnosis and anticipated problems. The increasingly degenerative, irreversible nature of the disorder tends to diminish hope; only the ability to adapt to the many problems can restore it.

Expected Outcome: Signs and symptoms of hopelessness will be minimized by use of coping skills and family/community resources.

- Assess the patient's and family's response to the diagnosis and understanding of AD; encourage expression of feelings. *Understanding the patient's and family's perspective enables the nurse to dispel myths about AD.*
- Provide realistic information about the disorder; provide information at the patient's and family's level of understanding. *Patient and family may need to have separate sessions. Factual information provides a foundation for decision making.*
- Avoid criticizing or judging expressed feelings. *An environment accepting of the expression of real feelings promotes both further expression of feelings and willingness to discuss other issues.*
- Support positive family bonds and enhance communication among family members; promote mutual positive regard. *Strong family relationships can provide direction for living and convey a willingness to share the burden.*
- Encourage the patient to make as many decisions as possible. *Self-determination enhances a feeling of control over a situation and may give a sense of hope.*
- Encourage the patient and family to seek spiritual guidance that previously inspired hope. *The patient's church is a legitimate support system. Faith and belief in a higher power can inspire hope beyond present circumstances.*

Caregiver Role Strain

Most caregivers of patients with AD are spouses or other family members. Because AD is a chronic and debilitating disorder, caregivers may feel overwhelmed by their responsibilities. The caregiving spouse faces not only the responsibility for the patient's multiple physical demands but also economic and psychosocial stressors. The patient may have to cease driving, and the loss of independence represented by this loss of the ability to drive may trigger anxiety and anger. Fear of the future, loss of income, loss of companionship and a mate—combined with fatigue—make the caregiver vulnerable. Caregivers may become physically and mentally exhausted and socially isolated because of the overwhelming responsibilities of providing total care to the incapacitated family member. Although most families prefer to keep the person with AD at home as long as possible, most people with the disease eventually need more assistance than family members can provide, and must move to a facility for professional care.

Expert workgroups spearheaded by the National Institute on Aging of the National Institutes of Health have developed new criteria and guidelines for the diagnosis of Alzheimer's disease. They are now available online through the Alzheimer Association's journal, *Alzheimer's & Dementia*. The new criteria and guidelines include recommendations for clinical office settings and research settings.

Expected Outcome: Caregivers will manage stress of role by acknowledging and accessing resources that reduce responsibilities and minimize stress/exhaustion/demands.

Meeting Individualized Needs

Safety Interventions for the Patient with Alzheimer's Disease

DECREASING THE RISK OF FALLS

The Hendrich II Fall Model my be used to evaluate for risk for falls in patients with AD (Hendrich, 2013). Although originally designed to be used with patients in the acute care setting, most of the information is equally as useful for home care or long-term care patients. The tool may be accessed online at the Hartford Institute for Geriatric Nursing or the ConsultGeriRN website. A video demonstrating its use is available at the Hartford website.

- Assess usual environment for hazards, such as throw rugs, electrical cords, and slick floors.
- Observe areas of special concern, such as the bathroom, kitchen, and stairs, and modify as needed; for example, provide skidproof surfaces, mark stairs to show depth, and equip toilet and shower areas with safety bars.
- Evaluate muscle strength and gait; consult a physical therapist to plan exercises to increase strength and balance.
- Check shoes for fit and support.
- Inquire about alcohol use and medications that affect balance or cause mobility problems; for example, antihypertensive agents can cause dizziness with position changes.
- Use night-lights and increase daytime lighting in dark areas, such as hallways.
- Keep traffic areas free from clutter.

DECREASING INJURIES RELATED TO COGNITIVE IMPAIRMENTS

- Secure items that may be mistakenly ingested, such as cleaning preparations and house plants.
- Modify potentially unsafe areas, such as unenclosed porches.
- Provide double lock systems to outside doors and doors to rooms that are off-limits.
- Protect from fire hazards; for example, make matches and cigarettes inaccessible.
- Fence the yard with a locked gate to prevent wandering. Although developed for patients with dementia in the acute care setting, much of the information is equally useful for home care and long-term care patients.
- Modify the controls on the oven and stove.
- Adjust the water heater to a safe temperature.

GENERAL SAFETY CONSIDERATIONS

- Plan a calling system for emergencies; have children or friends call at about the same time every day as a check.
- Ensure that the family member with a cognitive impairment has no access to dangerous objects in the home such as knives and guns.
- If safety is a concern (such as turning on the stove and forgetting it), suggest using alternatives such as a microwave. Program emergency numbers into the telephone. Ask patient to consider a Life-Line telephone program. *These measures can increase safety.*
- Suggest using cues, such as an alarm on a watch or a pocket computer, to trigger actions at designated times. *Cues are often helpful when memory loss is a problem.*

DECREASING INJURIES FROM CHRONIC CONFUSION

Patients with AD often have memory deficits that make functioning in a nonstructured environment difficult. Many of the nursing interventions for this diagnosis need to be modified over time as the patient continues to lose cognitive function.

- Label rooms, drawers, and other items as needed. *Visual cues promote the highest possible degree of independence for the patient.*
- Remove potential hazards (such as sharp knives or potentially harmful liquids or chemicals) from the environment. *Ensuring safety is a critical factor in providing care.*
- Keep environmental stimuli to a minimum: Decrease noise levels; speak in a calm, low voice; and take an unhurried approach. *Minimizing sensory input and maintaining a calm manner may decrease anxiety.*
- Begin each interaction by identifying self and calling patient by name. See Box 44–1 for other communication techniques. *These techniques provide information and a sense of security for the patient with memory loss.*
- Limit questions to those that require a simple yes or no response. *Questions need to be appropriate to the patient's ability as decision making and verbal skills decline.*
- Orient to the environment, person, and time as able; place large, easy-to-read calendars and clocks in the patient's line of vision. Make references to the season or day of the week when conversing with the patient. *Orient the patient according to his or her level of ability; orienting to precise time may not be possible in the later stages of AD.*
- The colors red and yellow are more easily seen by older adults. Provide boundaries by placing red or yellow tape on the floor to aid in visual cues of boundaries and therefore enhance safety. *Boundaries help the patient stay within safe areas.*

- Teach the caregivers self-care techniques, such as taking rest periods and avoiding fatigue. *Fatigue adds to stress and potentially leads to poor decision making.*
- Have the caregivers list and regularly take part in physical activities they enjoy, such as walking or swimming. *Regular physical exercise decreases stress.*
- Refer the caregivers to local AD support groups. Suggest books pertinent to the subject. *Providing explicit suggestions for locating support systems and providing specific information promote coping.*
- Refer the caregivers to Meals-on-Wheels, home health, respite care, and other community services. *Community agencies can relieve some of the daily care burdens, thus providing time for other activities. Programs that support caregivers have been shown to delay nursing home placement.*
- Ensure that the family knows that hospice care is available during the end stages of AD. *Hospice services can support the family during this difficult time.*

Delegating Nursing Care

As appropriate and allowed by the designated duties and responsibilities of unlicensed assistive personnel, the nurse may delegate nursing care activities such as close monitoring of environment for safe conditions (e.g., avoiding scatter rugs, moving furniture, and providing lighting so that patient can ambulate safely).

Continuity of Care

Family caregiving takes an enormous toll on mental, physical, emotional, and financial resources. Family members see a former fully functioning and independent loved one become progressively more impaired and dependent on others for total care. The patient with AD drains time and energy, leading to high rates of depression, symptoms of "burnout," and frequent illnesses in the caregiver. The stress may even cause them to become physically abusive to the patient (Wiglesworth et al., 2010).

BOX 44–1 Communicating with the Patient with Alzheimer's Disease

- Face the patient and talk directly to him or her; call the patient by name.
- When first approaching the patient, identify yourself.
- Use simple sentences and words with few syllables.
- Speak in a calm, low voice.
- Ask one question at a time. Use questions that require only a yes or no response.
- Keep nonverbal communication relaxed and parallel to the verbal communication.
- Avoid giving the impression of being in a hurry; try to have a relaxed approach.
- Observe for anxiety—wringing hands, pacing, darting eye movements—and alter your approach to decrease anxiety.
- Avoid arguing with patients; do not insist on orienting patient to reality; the patient's point of reference may not be based in reality.
- Give plenty of time for the patient with AD to process what you are trying to say; do not expect patients to perform skills beyond their abilities.
- Repeat explanations in simple terms.

Teaching for patients and families centers initially on explaining the disorder and exploring available support systems. Anticipate the need to reexplain the disorder and its consequences because patients and families may be in shock or denial during the initial period of the disease. In addition to explaining the anticipated changes with AD, suggest practical solutions to identified problems. It is important to evaluate both the patient and caregivers; interventions must be appropriate for the family's situation and resources. Maintaining the least restrictive environment that promotes safety for the patient is a major goal of teaching. Using memory cues, such as labeling drawers to indicate the specific types of clothing and labeling rooms, can help orient the patient and foster independence. Consistency in the environment and daily routine is an essential part of care. Emphasizing realistic expectations means adjusting care and communication techniques to the patient's level of ability.

Address the following topics for home care of the patient and for the caregiver:

- Support groups and peer counseling are helpful in handling caregiver stress.
- An individual with AD who is confused or agitated is not comfortable and is usually frightened.
- Plan care that matches the person's level of coping, using a consistent routine.
- Provide regular rest periods to decrease the patient's stress and fatigue (these do not increase nighttime wandering).
- Plan care for the caregiver. Periodic adult day care or respite care during the initial stages, with plans for increasing assistance to meet the patient's daily needs as the disease progresses, may be sufficient. Referrals to the appropriate agency for long-term care, including skilled nursing facilities, may be indicated. Family members may need help adjusting to the idea of extended care but may be relieved to relinquish the physical care needs.
- Suggest the following resources: Alzheimer's Association, Alzheimer's Disease and Related Disorders Association, Alzheimer's Disease Education and Referral Center, and the National Institute of Neurological Disorders and Stroke.

THE PATIENT WITH MULTIPLE SCLEROSIS

Multiple sclerosis (MS) is a chronic demyelinating disease of the CNS (brain, optic nerves, and spinal cord). The disease ranges from relatively mild to totally disabling. The manifestations of MS vary according to the area of the nervous system affected. The initial onset may be followed by a total remission, making diagnosis difficult. In many patients, MS is characterized by periods of exacerbation, when manifestations are highly pronounced, followed by periods of remission, when manifestations are not obvious. The end result is progression of the disease with increasing loss of function.

The onset of MS is usually between 20 and 40 years of age, but the disease has been diagnosed in individuals as young as 2 years and as old as 75 years. MS is the most prevalent CNS demyelinating disorder, and is a leading cause of neurologic disability in young adults. Although all races are affected, MS is primarily a disease of people of northern European ancestry. The risk of developing MS is 15-fold greater when MS is also present in a first-degree relative, and even higher in monozygotic twins. Those with the human leukocyte antigen HLA-DR2 haplotype are especially at risk, although the reason is unknown (Wagner et al., 2013).

FAST FACTS

Multiple Sclerosis

- Approximately 400,000 people in the United States have MS; the incidence is approximately 1 to 2 million worldwide.
- Women are affected two times more often than men.
- The disease is more prevalent in colder northern latitudes, such as the northern Atlantic states, the Great Lakes region, and the Pacific Northwest.

Source: National Multiple Sclerosis Society, 2011.

Pathophysiology

MS is believed to occur as a result of an autoimmune response in a genetically susceptible individual. The target antigen has not been identified, but is suggested to be an immune response to a protein in the CNS. As with other demyelinating disorders, MS is characterized by inflammation and selective destruction of CNS myelin (Wagner et al., 2013).

Myelin sheaths are fatty, segmented wrappings that normally protect and insulate nerve fibers and increase the speed of transmission of nerve impulses. In multiple sclerosis, these myelin sheaths of the white matter of the spinal cord, brain, and optic nerve are destroyed in patches, called plaques, along the axon (see Pathophysiology Illustrated on pages 1438 and 1439). The demyelination of nerve fibers slows and distorts the conduction of nerve impulses and sometimes results in the total absence or distortion of impulse transmission. The neurons affected by MS are located in the spinal cord, brainstem, cerebral and cerebellar areas, and the optic nerve. The peripheral nerves are not affected.

Plaques typically are scattered through the white matter of the CNS, although they may extend into adjacent gray matter. Early manifestations are the result of inflammatory edema in and around the plaque and partial demyelination. These manifestations typically disappear within weeks after the initial episode. With progression of the disease, the demyelination and plaque formation result in scarring of glia (gliosis) and degeneration of axons. MS develops in two stages. In the first stage small inflammatory lesions develop sequentially. During the second stage these lesions extend and consolidate as gliosis

CASE STUDY & NURSING CARE PLAN A Patient with Alzheimer's Disease

Arthur and Ruth Joste, both age 73, have been married for 47 years; he is a retired history teacher, she has been a homemaker. They have four children; two live in the same town, and two live out of state. Arthur has noticed that he is having problems remembering friends' names and phone numbers; his wife has been asking him if he is driving in the correct direction when they go shopping.

Mrs. Joste has severe osteoarthritis and is unable to lift heavy objects; she is only able to perform light housekeeping tasks. For about 18 months, Mrs. Joste has been aware of her husband's progressive cognitive decline, including forgetting current news from last night's newspaper, miscalculating checkbook balances, neglecting his hygiene needs, and confusing their children's and grandchildren's names. The Jostes are referred to a neurologist for evaluation.

ASSESSMENT

Martha Spital, RN, assesses Mr. Joste at the neurologist's office. She notes that he is unable to recall his home address without prompting, to name the correct date (although he does know the day of the week), to subtract serial 7s more than twice, and to recall two of three objects. He is alert to his surroundings. Mrs. Joste states that the problems seem to be getting worse with time. Mr. Joste seems easily agitated, and his wife reports that his sleep habits are "jumbled"; he has long periods of wakefulness in the nighttime hours.

Following a thorough evaluation and diagnostic testing to rule out other possible disorders, the neurologist tells the couple that Mr. Joste has probable dementia of the Alzheimer's type. Both have feared this diagnosis; they want to know how they can be sure that Mr. Joste has this disease and what they can do to prevent further decline. Both are obviously saddened, and they verbalize their feelings of being overwhelmed. The Jostes intend to remain in their home "for as long as we can."

DIAGNOSES

- *Chronic Confusion* related to deterioration of brain function and dementia
- *Self-Care Deficits* related to forgetfulness and declining physical abilities
- *Risk for Injury* related to decreased orientation
- *Disturbed Sleep Pattern* related to time disorientation
- *Caregiver Role Strain* (wife) related to need to care for self and husband

EXPECTED OUTCOMES

- Patient will remain free of injury.
- Patient will navigate home environment with modifications as needed.
- Patient will participate in grooming and hygiene activities with prompting and supervision.
- Patient will obtain a minimum of 7 uninterrupted hours of sleep a night.
- Mrs. Joste will participate in a minimum of two out-of-home activities a week.

PLANNING AND IMPLEMENTATION

The home health nurse, Erick Montane, RN, makes a home visit to evaluate the environment, assess available support, and determine needs. He meets two of the Jostes' children, Dawn and Jay, who live in the same community and are willing to participate as much as possible in providing care and modifying the home.

Mr. Montane discusses the importance of establishing and maintaining a consistent daily routine. He emphasizes the importance of matching activities to Mr. Joste's mental abilities to avoid frustration and increased agitation. Mr. Montane recommends labeling drawers with their contents, such as Mr. Joste's sock drawer. Labeling rooms may eventually be necessary.

Because his inability to comprehend and process information distresses and agitates Mr. Joste, Mr. Montane teaches the family to modify their communications to fit Mr. Joste's cognitive ability, such as using simple, direct statements and directions. Mr. Montane recommends that family members keep background noise to a minimum because this may be a source of confusion.

After assessing the home, Mr. Montane makes the following recommendations about safety:

- Remove throw rugs from hallways, and tack down any remaining carpets. Ensure that stairs are carpeted to protect Mr. Joste from injury.
- Secure the kitchen, bathroom, and workshop cabinets as well as the controls on the oven and stove.
- Modify the doors so that operating the locks requires a two-step system of unlocking, such as with a deadbolt and a key.
- Provide extra lighting in dark areas, especially a night-light in the hallway and bathroom.

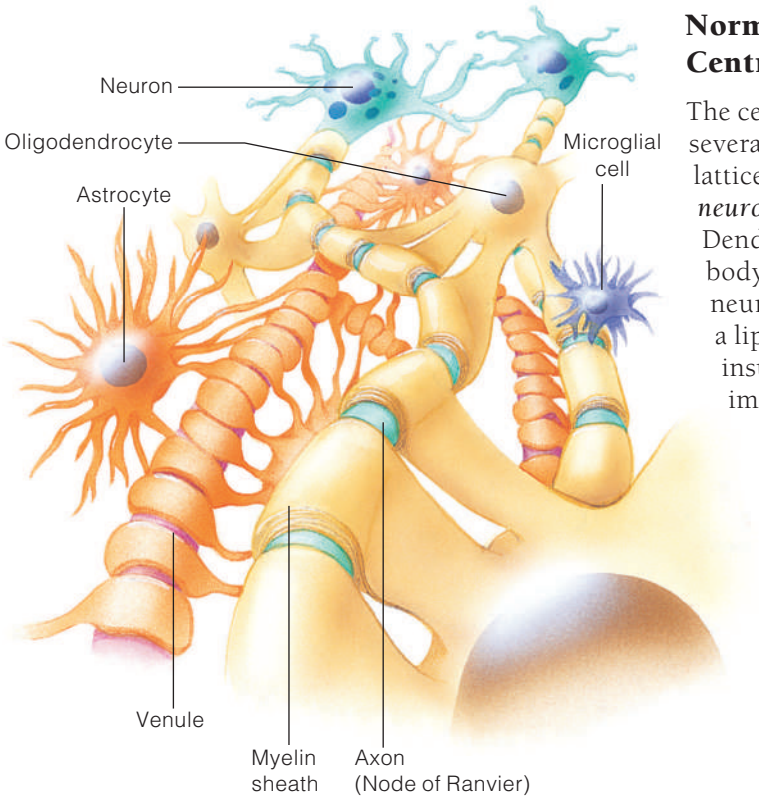
Mr. Montane explains that Mrs. Joste will need assistance with housekeeping as Mr. Joste continues to decline. Mr. Montane provides referrals to community services, including Meals-on-Wheels, which can supply a daily meal. He also suggests that the Jostes obtain the services of a home health aide to provide daily hygiene care. Most of the remaining home maintenance needs can be met with the children's help.

Mr. and Mrs. Joste and the two children attend the weekly local support group meetings for Alzheimer's disease and related disorders for approximately 3 months; thereafter, Mrs. Joste attends with her daughter.

EVALUATION

Six months after the initial home visit and family planning session, Mr. Joste assesses as follows:

- Has not had a fall, burn, or other injury.
- Has periods of confusion when outside his home, but 90% of the time is oriented to place when at home.
- Has attended several support group meetings until 3 months ago. Currently, his wife attends weekly, and a daughter occasionally accompanies her. She has continued to participate in their church and maintains contact with a few friends. She is finding it harder to leave her husband unattended for even a few minutes.
- Is able to clean and dress himself with prompting; he is not able to choose his own clothing. If hygiene articles are "set up" (e.g., if the toothpaste is placed on the toothbrush), he remembers to perform the hygiene activity. The children have been replacing buttons and zippers with Velcro closures on his clothing.
- Sleeps an average of 6 hours a night with a 30-minute nap in the afternoon; this pattern is consistent with his previous sleep pattern.
- Has seemed to be more easily agitated for the past month. He wanders from room to room, apparently looking for something. These behaviors are worse in the evening and on cloudy days. Mrs. Joste sadly acknowledges her progressive inability to care for her husband.



Clinical Reasoning in Patient Care

1. Develop a tool to teach safety needs for the patient with Alzheimer's disease and his family.
2. List five interventions to decrease agitation in older adults with cognitive impairment; give three additional examples of activities suited to an older adult with AD who has osteoarthritis.
3. You are caring for a patient in stage 5 Alzheimer's disease. She is 165 cm (65 in.) tall and weighs 59.9 kg (132 lb); she has lost 1.4 kg (3 lb) within the past month. The patient has difficulty focusing on eating and is easily agitated. Describe your plan for ensuring that she has adequate nutrition. (Refer to the Edinburgh Feeding Evaluation in Dementia Scale found at the Hartford Institute for Geriatric Nursing or the ConsultGeriRN website.)

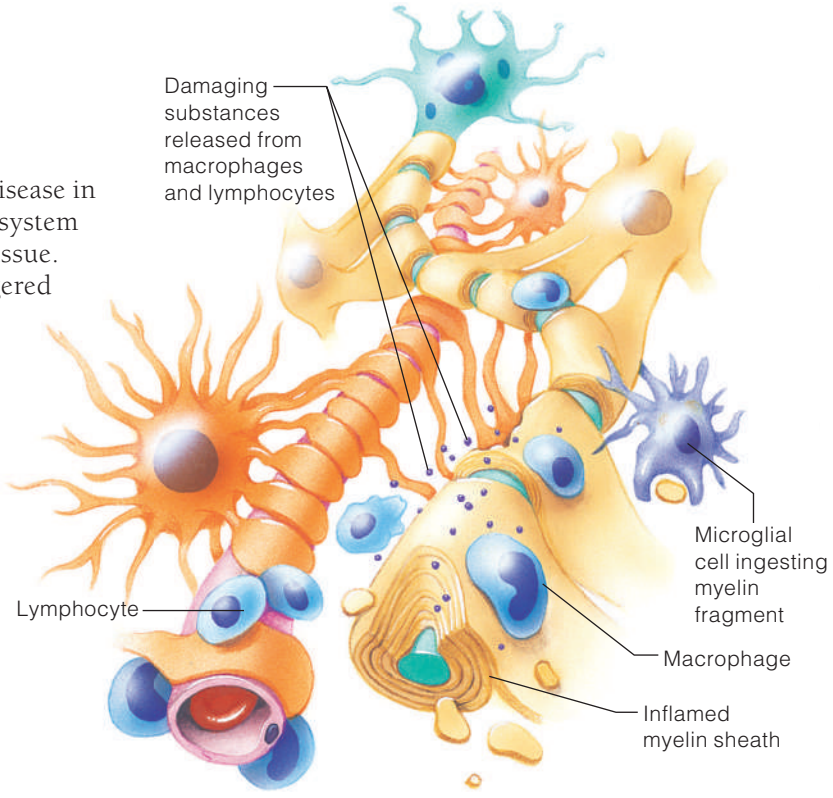
See Evaluating Your Response in Appendix B.

PATHOPHYSIOLOGY ILLUSTRATED

Multiple Sclerosis

Normal Anatomy of the Central Nervous System

The central nervous system (CNS) is composed of several cell types arranged in a dense, interconnected lattice. The basic functional cell of the CNS is the *neuron*, which transmits electrochemical impulses. Dendrites, thin projections extending from the neuron body, receive impulses that are passed down the neuronal axon for transmission to other cells. Myelin, a lipid-protein substance, surrounds the axons, insulating them and speeding nerve impulse transmission.

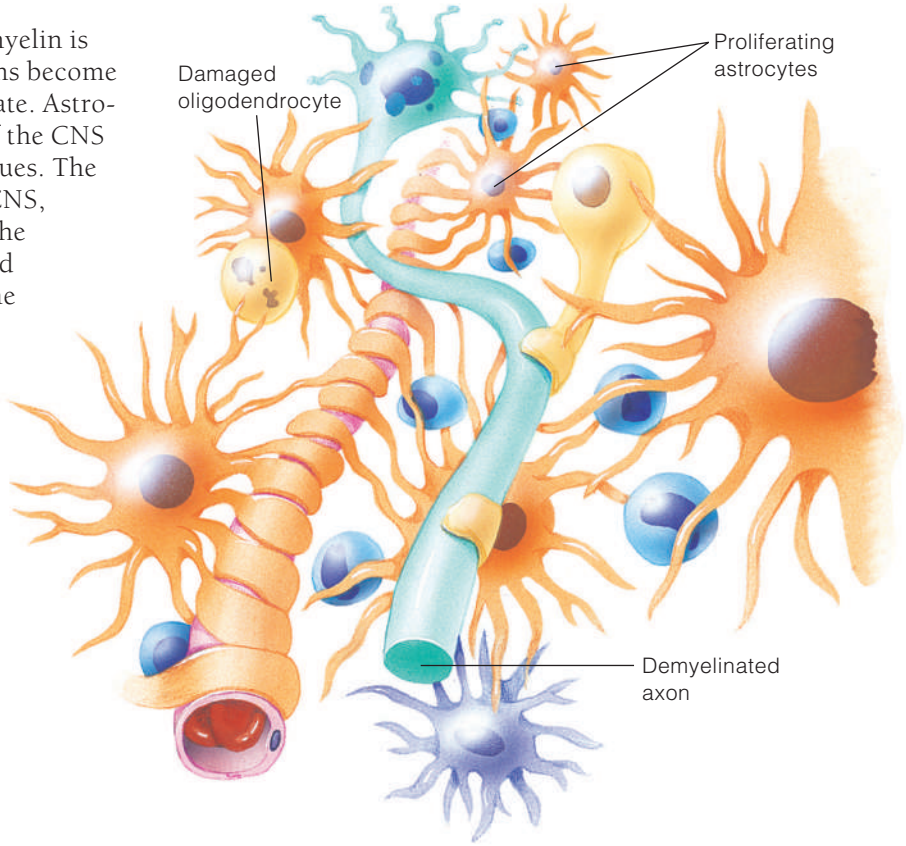


Neurons are surrounded by a network of cells:

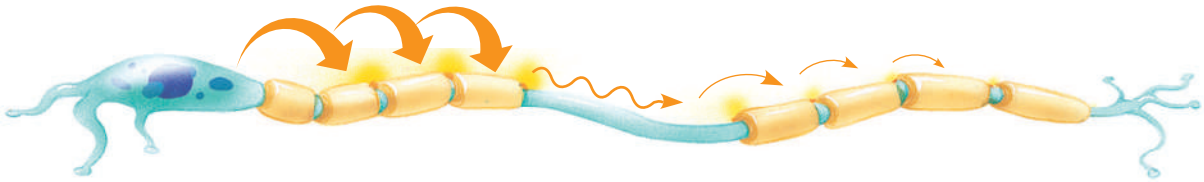
- *Astrocytes* support neurons and connnect them to surrounding capillaries and venules.
- *Microglia* are motile phagocytic cells.
- *Oligodendrocytes* wrap concentric layers of myelin around nearby axons.

Acute Attack

Multiple sclerosis (MS) is a demyelinating disease in which axonal myelin in the central nervous system is eroded, destroyed, and replaced by scar tissue.



An autoimmune process apparently triggered by genetic and environmental factors is believed to cause inflammation of venules in the CNS. This disrupts the blood–brain barrier, allowing lymphocytes to enter CNS tissue. These lymphocytes proliferate and produce IgG, an antibody that attacks and damages myelin and causes the release of inflammatory chemicals and edema. As the inflammation subsides, the myelin regenerates and manifestations of the disease subside.



PATHOPHYSIOLOGY ILLUSTRATED (*continued*)

Chronic Lesion

After repeated inflammatory attacks, myelin is irreparably damaged. Segments of axons become totally demyelinated and may degenerate. Astrocytes proliferate in damaged regions of the CNS (a process called *gliosis*), forming plaques. The plaques are scattered throughout the CNS, appearing as gray or pinkish lesions. The relapsing-remitting character of MS and the scattered areas of damage within the CNS account for the variable nature of MS manifestations.

Abnormal Nerve Impulse Transmission

In an undamaged neuron, nerve impulses travel down the axon by "leaping" from one node of Ranvier to the next, thus greatly increasing the speed of impulse transmission. When nerve impulses travel down an axon damaged by MS, they are significantly slowed and weakened as they pass across the surface of demyelinated areas. Impulses may be blocked entirely when axons degenerate. The weakening or interruption of the transmission of nerve impulses and plaque formation within the CNS cause the manifestations of MS, including extremity weakness, paresthesias, visual disturbances, bladder dysfunction, and vertigo.

and demyelination occurs. It is unknown whether the inflammatory process is directed against the myelin or against oligodendrocytes that produce myelin. Evidence suggests that remyelination can occur in the CNS if the disease process is stopped before the oligodendrocytes are destroyed (Wagner et al., 2013).

There are four possible courses of MS: relapsing-remitting (characterized by periodic remission and exacerbation of manifestations), primary progressive (almost continuous neurologic deterioration from onset of manifestations), secondary progressive (gradual deterioration with or without relapses), and progressive-relapsing (gradual progression of neurologic deterioration with superimposed relapses). Most individuals with MS present with the relapsing-remitting type.

Manifestations

The manifestations of MS (see the accompanying box) vary according to the areas destroyed by demyelination and the affected body system (see Multisystem Effects of Multiple Sclerosis on page 1441). The most common manifestations are sensory loss, visual deficits, weakness, paresthesias, ataxia, and vertigo. In many patients, the initial manifestation involves blurred or double vision (diplopia), red-green color distortion, or even blindness in one eye (National Institute of Neurological Disorders and Stroke [NINDS], 2013d). Fatigue is one of the most disabling manifestations, and affects almost all patients with MS. The manifestations (individualized to each patient) typically last for several days or weeks and then completely or partially resolve. After a period of relatively normal function, manifestations reappear.

●○● INTERPROFESSIONAL CARE

Management of the patient with MS varies according to the severity of the manifestations. The focus is on retaining the optimal level of functioning possible, given the degree of disability. Rehabilitation—physical, occupational/vocational, and psychosocial—is a cornerstone of an interprofessional approach to treatment. During exacerbations, the focus of interventions shifts to controlling manifestations and quickly returning to remission. Recent studies have focused on the concept of *neuroprotection*, which appears to limit the degeneration associated with MS. Neuroprotection combines specific brain imaging techniques, which measure the actual volume of the brain, with newer medications (Markowitz, 2010).

MANIFESTATIONS OF MULTIPLE SCLEROSIS

- Visual deficits, with visual blurring, fogginess, or haziness; diplopia, impaired color perception, decreased central visual acuity, area of diminished vision in the visual fields, acquired color vision deficit (especially to red and green), and an altered pupillary reaction to light
- Brainstem lesions (cranial nerves III to XII) with nystagmus, dysarthria, deafness, vertigo, vomiting, tinnitus, facial weakness, decreased sensation, diplopia, and eye pain; and cognitive dysfunctions involving concentration, short-term memory, word finding, and planning
- Mood alterations are manifested as depression more often than euphoria
- Weakness and/or numbness in one or both extremities (most often the legs)
- Upper motor neuron involvement is manifested by stiffness, slowness, weakness (spastic paresis)
- Bladder dysfunctions include urgency, hesitancy, and incontinence
- Bowel dysfunction is most often seen as constipation
- Sexual dysfunction

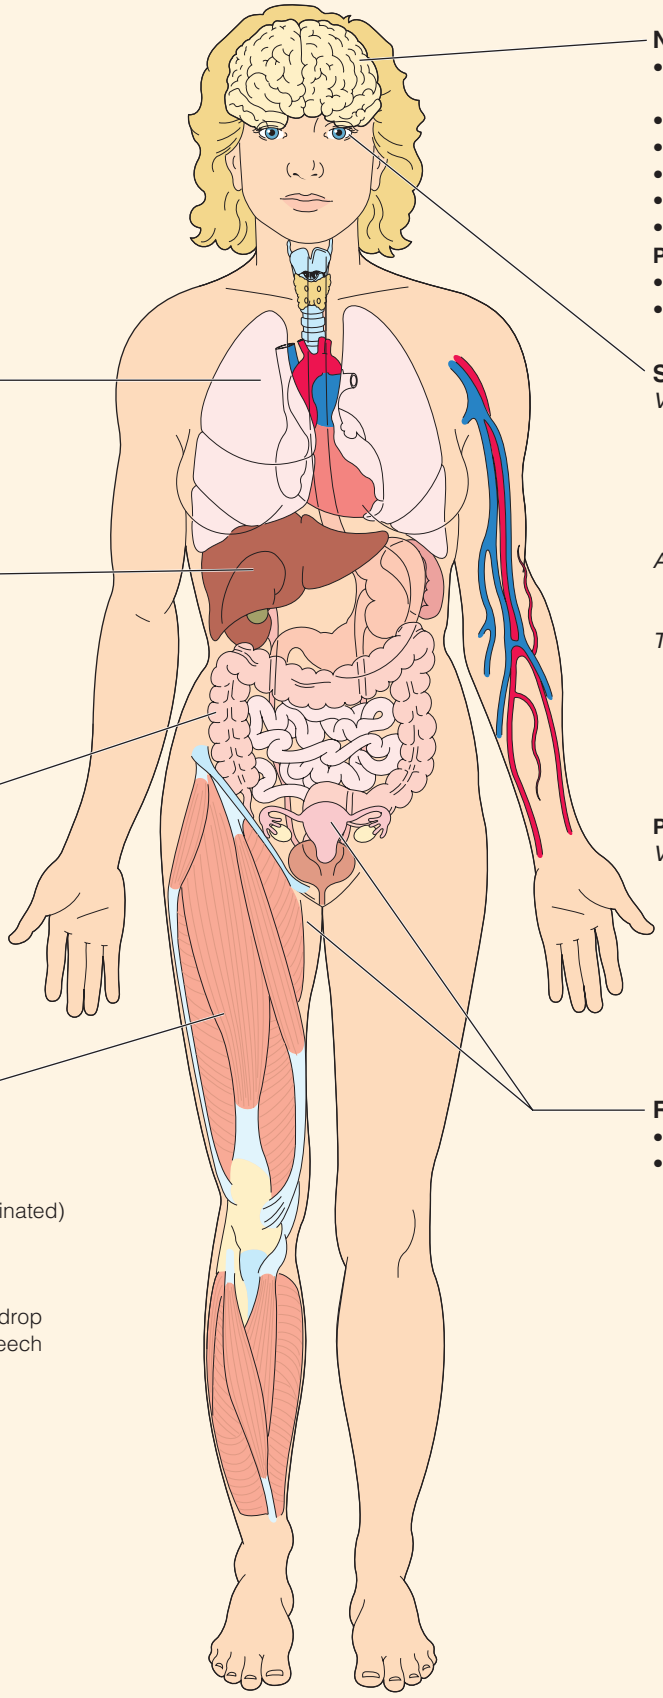
DIAGNOSIS

A diagnosis of MS requires that the patient have one of the following: (a) two or more exacerbations separated by 1 month or more and lasting more than 24 hours, followed by recovery; (b) a history of repeated exacerbations and remissions with or without complete recovery, followed by progressively more severe manifestations lasting for 6 months or more; or (c) slowly increasing manifestations for at least 6 months.

Diagnostic tests (refer to Chapter 41) vary with the presenting complaints. Magnetic resonance imaging (MRI) with findings of lesions is the most definitive test available; however, it is only one of several laboratory and diagnostic tests that may be performed when establishing the diagnosis. Cerebrospinal fluid (CSF) analysis reveals an increased number of T lymphocytes that are reactive with antigens, indicating the presence of an immune response. The majority of patients with MS have elevated levels of immunoglobulin G (IgG) in the CSF. A CT scan of the brain may reveal atrophy and white matter lesions.

MEDICATIONS

Medications slow the progression of MS and decrease the number of attacks. (See the Medication Administration box on page 1443.) Medications are used for a variety of reasons, including to treat manifestations, to modify the course of the disease, or to interrupt the progression of the disease.



The medications used during an exacerbation are aimed at decreasing inflammation to inhibit manifestations and induce remission. A combination of adrenal corticosteroid hormone (ACTH) and glucocorticoids is often used to decrease inflammation and suppress the immune system. Immunosuppressive agents, including azathioprine (Imuran), cyclophosphamide (Cytoxan), and mitoxantrone (Novantrone), are also used. Interferon and glatiramer acetate are used to reduce exacerbations in patients with relapsing-remitting MS. Interferon alpha, beta, and gamma (Roferon-A, Etavia, Intron A, Wellferon, Infergen, Avonex or Rebif, Betaseron, Actimmune) enhance immune function, while glatiramer acetate (Copaxone) stimulates parts of the myelin basic protein to reduce the relapse rate of MS. Both drugs are given by injection and are usually well tolerated. An oral medication given once daily, called fingolimod (Gilenya), is now available. It works to trap immune cells in lymph nodes. The first dose is monitored due to the risk of bradycardia, and other side effects include diarrhea, cough, and headache. Natalizumab (Tysabri) is given to patients with relapsing forms of MS to delay physical disability and reduce the frequency of exacerbations. A 2-year study found that 17% of patients relapsed on natalizumab, whereas 29% of patients relapsed on placebo (Markowitz, 2010). Teriflunomide (Aubagio) is an oral medication that reduces the lesions associated with MS, but may also cause serious liver damage as well as diarrhea and nausea (Mayo Clinic, 2012).

Medications may be used to treat the specific manifestations of MS. Anticholinergics are administered for bladder spasticity; cholinergics are given for bladder flaccidity. Fatigue may be treated with amantadine (Symmetrel), pemoline (Cylert), and an experimental drug, aminopyridine.

SURGERY

Surgery may be indicated for patients who experience severe spasticity and deformity. However, physical therapy can prevent most severe

MULTISYSTEM EFFECTS OF
Multiple Sclerosis

Neurologic
- Emotional lability (euphoria or depression)
- Forgetfulness
- Apathy
- Scanning speech
- Impaired judgment
- Irritability

Potential Complications
- Convulsive seizures
- Dementia

Sensory

Visual
- Blurred vision
- Diplopia
- Nystagmus
- Visual field defects (blind spots)
- Eye pain

Auditory
- Vertigo
- Nausea

Tactile (especially hands or legs)
- Numbness
- Paresthesias (tingling, burning sensation)
- Diminished sense of temperature
- Pain with spasms
- Loss of proprioception

Potential Complication

Visual
- Blindness

Respiratory
- Diminished cough reflex

Potential Complication
- Respiratory infections

Urinary
- Hesitancy
- Frequency
- Retention
- Reflex bladder emptying

Potential Complications
- Recurring UTIs
- Incontinence

Gastrointestinal

Oral/esophageal
- Difficulty chewing
- Dysphagia

Upper/lower GI
- Decreased or absent sphincter control
- Bowel incontinence
- Constipation

Musculoskeletal
- Fatigue
- Limb weakness
- Ataxic movements (shaky, irregular, uncoordinated)
- Intention tremors
- Spasticity
- Muscular atrophy
- Dragging of foot and foot drop
- Dysarthria with slurred speech

Reproductive
- Impotence (male)
- Loss of genital sensation

PATHOPHYSIOLOGY LINKAGE

Multiple Sclerosis

- Destruction of the myelin sheaths of the white matter of the spinal cord, brain, and optic nerve results in plaques that inhibit conduction of nerve impulses. This results in visual deficits such as blurring, fogginess, diplopia, impaired color perception, decreased central visual acuity, diminished visual fields, and an altered pupillary reaction to light.
- Brainstem lesions (cranial nerves III to XII) lead to nystagmus, dysarthria, deafness, vertigo, vomiting, tinnitus, facial weakness, decreased sensation, diplopia, and eye pain, and to cognitive dysfunctions involving concentration, short-term memory, word finding, and planning.
- Plaque formation causes changes in mood, typically manifested as depression more often than euphoria.
- Weakness and/or numbness in one or both extremities (most often the legs) results from plaque formation in the spinal cord.
- Upper motor neuron involvement is manifested by stiffness, slowness, and weakness (spastic paresis).
- Plaques on the spinal cord may cause bladder and bowel dysfunctions such as urgency, hesitancy, incontinence, and constipation.
- Sexual dysfunction may also result from destruction of myelin sheaths along the spinal cord.

problems. Foot drop from severe plantar flexion can be relieved with an Achilles tenotomy, a surgical procedure in which the Achilles tendon is transected.

NUTRITION AND FLUIDS

Patients with MS may be overweight because of their inability to ambulate; depression may contribute to the problem because people who are depressed tend to eat more. Ideally, the patient should maintain a weight as close as possible to that recommended for the patient's height and body type.

As MS progresses, the patient's ability to prepare food and eat may be compromised. Changes in muscle tone, tremor, weakness, and ataxia all contribute to nutritional problems. Dysphagia is a common problem. The diet is adapted to accommodate changes in the patient's ability to chew and swallow, and collaboration with a dietitian will be important.

REHABILITATION

Physical and rehabilitative therapies are tailored to the patient's level of functioning. The long-term goal is to enable the patient to retain as much independence as possible. One major intervention is to maintain and increase existing muscle strength.

Spasticity is managed with stretching exercises, gait training, and braces, splints, or other assistive devices. To maintain balance, the patient is encouraged to widen the base of support by standing with the feet slightly further apart. Walkers and canes may be weighted to provide support and balance for the ataxic patient.

An interprofessional approach to rehabilitation will provide supportive services: speech therapy for problems with phonation, occupational therapy to maintain strength in the upper extremities and carry out ADLs, and occupational counseling. Referrals to a urologist are indicated for problems with urinary incontinence, urinary tract infections, retention, and impotence. Consultation with a respiratory therapist may be needed if the patient develops chronic respiratory infections from inability to cough, move secretions, or breathe deeply, especially with increased debilitation.

●○● NURSING CARE

Because the disease most often affects young adults, the psychosocial and economic effect can be devastating. People with MS have to make adjustments to the body image changes while simultaneously adapting to the altered relationships and decreased earnings usually encountered with the disease. A once-healthy spouse may become wheelchair bound; an individual once independent may eventually become dependent for even the most basic ADLs. The unpredictable course of MS is a challenge for long-term planning. See the Case Study & Nursing Care Plan for the patient with MS on page 1445.

Health Promotion

Following an overview of the disorder, the patient needs to understand how to prevent fatigue and exacerbations. Teach the patient to avoid stress, extremes of cold and heat, high humidity, physical overexertion, and infections, because these may trigger a relapse of manifestations. Because the woman in the postpartum period has a 20% to 40% greater risk for relapse in the first 6 months, counseling about this risk is indicated. However, pregnancy itself seems to be protective against relapse. Also, address preventive measures to avoid risk of respiratory and urinary tract infections.

Assessment

Collect the following data through the health history and physical examination (see Chapter 41):

- *Health history:* History of childhood viral illnesses, geographic residence as a child, exposure to physical or emotional stressors (pregnancy/delivery, extremes of heat), medications, symptom onset, severity of manifestations.
- *Physical assessment:* Affect, mood, speech, eye movements, gait, tremors, vision and hearing, reflexes, muscle strength and movement, sensation. Assess for the Lhermitte's sign: an electrical shock-like tingling down the back, trunk, arms, and legs produced when the neck is flexed (the sign is positive in MS).

Diagnoses, Outcomes, and Interventions

Interventions for the patient with MS vary with the acuity of exacerbations and the presenting problems. Many nursing diagnoses relate to the inability to perform ADLs, such as *Self-Care Deficit* and *Impaired Home Maintenance.* Others reflect problems with musculoskeletal changes or altered nerve conduction such as *Impaired Physical Mobility*, *Ineffective Breathing Pattern*, *Constipation*, and *Functional Urinary Incontinence*. The nursing diagnoses discussed in this section are *Fatigue* and *Self-Care Deficit*.

Fatigue

Fatigue is experienced by almost all patients with MS. Fatigue in the patient with MS may be both primary and secondary. Primary fatigue is caused by the disease itself; secondary fatigue is the result of some of the pathophysiologic consequences of the disease. It is experienced both mentally and physically. Fatigue affects every aspect of the MS patient's life: the ability to remain independent and perform self-care, sexual function, mobility, airway clearance, and ultimately self-concept and coping. Fatigue will increase the MS patient's risk for falls. It is important to remember that the fatigue from chronic illnesses such as MS is very different from being tired, and that rest and sleep may not result in improvement.

MEDICATION ADMINISTRATION

The Patient with Multiple Sclerosis

IMMUNOMODULATORS

interferon beta-1a (Avonex) (administered IM one time a week)

interferon beta-1a (Rebif) (administered subcutaneously three times a week)

interferon beta-1b (Betaseron) (administered subcutaneously every other day)

glatiramer acetate (Copaxone, Copolymer-1) (administered subcutaneously daily)

natalizumab (Tysabri) (administered IV monthly)

mitoxantrone (Novantrone) (IV administration once every 3 months)

teriflunomide (Aubagio) (oral once a day tablet)

Interferon beta-la, interferon beta-1b, and glatiramer acetate are administered to patients with relapsing-remitting MS to prolong the time of onset to disability. Their use is based on the assumption that MS is an immunologically mediated disease. Interferon beta-1b produces a decrease in the MS lesions in some patients. Some patients, however, develop a decrease in the absolute neutrophil count and increases in the levels of liver enzymes. Anxiety, confusion, and depression with suicidal tendencies also have been reported. Other adverse reactions include pain, inflammation, hypersensitivity at the injection site, and generalized flu-like manifestations. Some women experience menstrual disorders. Pregnant women should not take these medications. Natalizumab has strict treatment guidelines, and can only be administered in infusion centers with monitoring by specially trained physicians. Liver enzymes are monitored closely for patients taking teriflunomide, and cardiac function must be assessed frequently with mitoxantrone (National MS Society, 2011).

Nursing Responsibilities

- Assess baseline parameters to evaluate drug side effects: psychologic profile, liver function tests, and CBC with differential.
- Monitor CBC and liver function tests every 3 months or as prescribed.
- Assess injection site and report ulceration promptly (pain and redness are common reactions).
- Evaluate patient's baseline neurologic, sensory, and motor function. Monitor changes in condition and function.
- Report if patient is pregnant or breast-feeding.

Health Education for the Patient and Family

- These drugs may cause depression and thoughts of suicide; report these feelings immediately to the physician.
- Administer medication within 3 hours of reconstitution. Rotate injection sites, and avoid any areas that are red or show other skin reactions.
- Seek follow-up care to monitor neurologic changes, CBC, and liver function.
- Avoid prolonged exposure to sunlight.
- Flu-like manifestations may occur within hours to days after an injection.

ADRENOCORTICOSTEROID THERAPY

adrenocorticotropic hormone (ACTH) (Acthar)

prednisone (Deltasone, Meticorten, Orasone)

methylprednisolone (Medrol, Solu-Medrol)

Adrenocorticosteroids are used both to sustain a remission and to treat exacerbations of MS. ACTH is usually given to induce a remission. It is administered intravenously for 1 week and may be followed by oral prednisone therapy. Another protocol involves administering ACTH intravenously for 3 days followed by intramuscular injections every 12 hours for 1 week (Wilson et al., 2013). The drugs are given to suppress the immune system, implicated in the etiology of MS. If the drug is used long term, the usual steroid precautions are indicated, such as monitoring for glucose intolerance, osteoporosis, and cataract formation. The drugs are used with caution in pregnant and lactating women.

MUSCLE RELAXANTS

baclofen (Lioresal)

dantrolene (Dantrium)

diazepam (Valium)

Muscle relaxants are given to patients with MS to relieve muscle spasms. Baclofen and diazepam act by suppressing CNS reflexes that regulate muscle activity; neither drug affects muscle strength. Baclofen therapy should be discontinued over 1 to 2 weeks; sudden withdrawal may cause seizures and paranoid ideation. In contrast to diazepam and baclofen, dantrolene acts directly on skeletal muscles, and it may affect muscle strength. Dantrolene may cause hepatotoxicity and should not be administered when hepatitis or cirrhosis is present.

Nursing Responsibilities

- Evaluate baseline muscle strength and spasticity, range of motion (ROM), and dexterity.
- Maintain safety or fall precautions; dizziness and drowsiness are common side effects.
- For the patient taking dantrolene, monitor liver function tests (enzymes and bilirubin) for signs of hepatotoxicity.

Health Education for the Patient and Family

- These drugs may cause sedative effects. Take appropriate safety measures (e.g., avoid driving).
- Avoid CNS depressants (antihistamines, alcohol); they can increase the sedative effects of the medication.
- Continue follow-up care; if you are taking dantrolene, for example, liver function will need to be monitored.
- If you are taking baclofen, do not suddenly stop the medication.
- Increase fiber and fluids in the diet to prevent constipation.
- Change positions slowly to minimize dizziness and other effects of orthostatic hypotension.

IMMUNOSUPPRESSANTS

azathioprine (Imuran)

cyclophosphamide (Cytoxan)

Immunosuppressants are given to patients with MS because of the autoimmune component of the disease. Both medications can cause bone marrow suppression and increase the risk of cancer. Azathioprine may produce hepatitis. Toxic effects of cyclophosphamide include hemorrhagic cystitis, sterility, and stomatitis.

Nursing Responsibilities

- Monitor baseline parameters: CBC with platelet count and differential, urinalysis, liver function tests, hepatitis profile.
- Assess for anemia: fatigue, lethargy, pallor.
- Watch for bleeding.
- Protect against and observe for subtle signs of infection.

Health Education for the Patient and Family

- Report infection, bleeding, and anemia immediately.
- Drink at least 2 L (2 quarts) of fluid a day, and observe urine for blood.
- Report jaundice immediately.
- Check oral cavity daily for changes or ulcers.
- Avoid becoming pregnant while taking these drugs.
- Obtain follow-up care, including frequent blood tests.

Note: Drugs identified in *italics* are among the 200 most commonly prescribed medications in the U.S.

A great deal of teaching is needed to help the patient and family understand fatigue and how to adapt. Patients and families need assistance managing fatigue in a society in which energy is highly valued.

Expected Outcomes: The patient will be free of fatigue as evidenced by ability to complete self-care activities and other ADLs. The patient will be able to optimize independence and self-care by demonstrating ADL abilities, taking frequent rest periods, and maintaining adequate nutrition.

- Assess degree of fatigue and identify contributing factors. The Fatigue Impact Scale may be used to assess the effect of fatigue on ADLs. *Fatigue is a subjective experience that needs to be evaluated thoroughly before planning can begin.*
- Arrange daily activities and ADLs to include rest periods. In this form of energy conservation, more strenuous activities are carried out in the morning, with regular rest periods between activities (Braley & Chervin, 2010). *Rest is essential to manage feelings of fatigue; periods of relaxation may help replenish energy reserves.*
- Ask the patient to consider which activities are really necessary and to set priorities. *Prioritizing activities promotes independence and self-control.*
- Suggest performing tasks in the morning hours. *Biorhythm studies indicate that people usually have greater energy reserves in the morning hours and diminished reserves in the afternoon.*
- Advise to avoid temperature extremes, such as hot showers or exposure to cold. *Maintaining a relatively constant body temperature may avoid exacerbation of the disorder. Heat can delay impulse transmission across demyelinated nerves, which contributes to fatigue.*
- Provide interventions to relieve pain (a fairly common manifestation of MS). *Pain can increase fatigue; fatigue can increase the experience of pain. In one study, women with relapsing-remitting MS were found to have more pain than healthy women (Newland, 2009).*
- Refer to the appropriate professionals to manage fatigue: stress management groups, support groups, occupational or physical therapist, as indicated. *Support groups and therapy can facilitate self-management and improve coping.*

Delegating Nursing Care Activities

As appropriate and allowed by the designated duties and responsibilities of unlicensed assistive personnel, the nurse may delegate nursing care activities such as measuring fluid intake and output, collecting vital signs (including orthostatic vital signs), encouraging oral or enteral intake, positioning the patient, and providing skin care.

Self-Care Deficit

Patients with MS may need assistance with bathing, toileting, dressing, grooming, and feeding. The help needed can range from minimal guidance to total dependence. The patient's ability to perform self-care activities is the gauge by which family members and caregivers need to adjust assistance. Self-care encompasses both the decisions about care and the provision of care; most patients are capable of making decisions even after physical limitations prevent physical self-care. The need to maintain self-determination cannot be overemphasized and must be incorporated into each intervention. As the patient with MS ages, there may be even more need for teaching to provide self-care.

- Assess the extent of the patient's self-care deficit; refer to other health team members for assessment as appropriate. For example, refer to a speech pathologist to assess swallowing and gag reflex, if indicated. *An accurate assessment is crucial to individualizing interventions.*
- Suggest adaptive devices, such as arm or wrist braces, as needed. *Meeting hygiene needs and feeding self are essential for positive self-concept, self-esteem, and socialization.*
- Teach to use assistive devices, such as plate guards, to modify consistency of foods, and to eat when energy level is better. If unable to buy and prepare meals, provide referral to Meals-on-Wheels. *Proper nutrition is basic to health; adapting utensils and foods can facilitate meeting nutritional needs.*
- Teach interventions related to altered bowel and bladder function: fluid intake of at least 2000 mL daily, bowel routine as indicated to prevent constipation, and self-catheterization skills as necessary. *Maintaining optimal bowel and bladder function decreases the risk of urinary tract infection and bowel impaction.*

Evidence for Nursing Care

The Patient with Multiple Sclerosis

A resource that nurses may find helpful when planning evidence-based nursing care follows.

- Markowitz, C. E. (2010). The current landscape and unmet needs in multiple sclerosis. *American Journal of Managed Care*, *16*(S21), 1–8.

Continuity of Care

The inconsistent and erratic nature of MS can make teaching for self-care difficult. Initial teaching focuses on a realistic explanation of MS. Referral to a support group early in the course of the disease is indicated. Social support can make a positive difference in a patient's and family's ability to cope with MS. Address the following topics in preparing the patient for home care:

- Various treatment options and their side effects
- Ongoing care from nurses, counselors, and physical, occupational, and speech therapists, as well as the physician and community health nurse
- Helpful resources: National MS Society and the National Institute of Neurological Disorders and Stroke (NINDS).

THE PATIENT WITH PARKINSON'S DISEASE

Parkinson's disease (PD) is a progressive, degenerative neurologic disorder of **basal ganglia** function characterized by tremor (shaking), muscle rigidity, bradykinesia (slowness of movement), and postural instability (Lindop, 2012). People with PD are faced with multiple problems involving independence in ADLs, emotional well-being, financial security, and relationships with others. Prognosis is poor, owing to the progressive degeneration that ultimately affects multiple physiologic systems and their function. Psychosocial effects are equally devastating, and the family needs more support as the patient's debilitation increases. Total disability is usually seen 10 to 20 years after diagnosis, and life expectancy may be decreased, especially in those with early-onset PD (Lindop, 2012). The leading cause of death is pneumonia.

PD is one of the most common neurologic disorders, affecting more than 1 million people in North America and more than 4 million people worldwide. It is estimated that approximately 50,000 new cases are identified each year in the United States.

The disorder usually develops after age 50 years (called late-onset PD), but does occur in younger adults (PD before age 50 is

CASE STUDY & NURSING CARE PLAN A Patient with Multiple Sclerosis

George McMurphy, a 45-year-old from northern Minnesota, was diagnosed with MS approximately 5 years ago. He states that he probably had mild symptoms as long ago as 10 years. He works as a manager for a large grocery store chain near his home. He lives at home with his wife and two children, ages 12 and 15. Recently, Mr. McMurphy has had increasing problems with urinary incontinence, lack of energy, weakness, extreme fatigue, and altered mobility from spasticity in his leg muscles. He has a fever, chest congestion, and a cough productive of green sputum. He is admitted to the hospital for evaluation and treatment of pneumonia and exacerbation of his MS.

Denise Miller, RN, primary care nurse, is assigned to care for Mr. McMurphy. His major complaint is the inability to "bring up all this sputum; I feel rotten from being so congested. I hate not being able to get to work and for my wife having to tend to my personal needs." Vital signs are as follows: BP 134/84 mmHg, P 94 bpm, R 30/min, T 38.8°C (102°F). Mr. McMurphy is admitted for an acute exacerbation of the disorder, probably triggered by pneumonia. He will be treated with ACTH and intravenous antibiotics during this admission.

Mr. McMurphy is discharged 3 days following admission. He states that he feels stronger; on discharge, he has no problem clearing his airway. Although he continues to pace his activities to avoid fatigue, his muscle strength and "tiredness" have improved. He is able to complete ADLs unassisted.

Pulmonary function has returned to normal prehospitalization levels: ABGs and pulse oximetry are within normal limits. Both Mr. McMurphy and his wife have listed several ways to modify their daily routine to allow more rest and decreased stress. Follow-up visits to his primary care physician have been arranged, and the couple has been provided with information about the local MS support group.

DIAGNOSES

- *Ineffective Airway Clearance* related to lung infection and thick mucus
- *Activity Intolerance* related to fatigue and spasticity
- *Self-Care Deficit: Toileting, Feeding, and Grooming* related to muscle weakness

EXPECTED OUTCOMES

- Patient will be able to clear airway, with clear lungs on auscultation and pulse oximetry readings above 95%.
- Patient will be able to ambulate using assistive devices, if needed, and to take frequent rest periods during episodes of mobility.
- Patient will be able to perform self-care activities such as bathing, dressing, and feeding oneself without becoming overly fatigued and tired.
- Patient will be able to verbalize methods to adapt daily routine to patient's level of tolerance.

PLANNING AND IMPLEMENTATION

- Initiate pulmonary hygiene measures (e.g., incentive spirometry, turning, deep breathing and coughing, breathing exercises, and postural drainage) at least every 2 hours. Assess lung sounds, oxygen saturation, and ability to clear airway.
- Teach the importance of maintaining an oral fluid intake of at least 2000 mL/day to prevent tenacious sputum and urinary tract infections. Teach signs and symptoms of urinary and respiratory infections.
- Encourage participation in decision making about care.
- Assist with ADLs only as needed, based on level of fatigue and muscle weakness.
- Plan self-care activities so that they are performed during periods of peak level of energy; intersperse rest periods throughout the day.
- Refer to an MS support group.
- Refer to physical and occupational therapists for counseling regarding control of spasticity and possible splinting of spastic muscles.
- Consult a urologist for assessment of bladder incontinence; teach intermittent catheterization. Alternatively, the use of an external condom catheter may be indicated.

Clinical Reasoning in Patient Care

1. Describe approaches the nurse could take to ensure that Mr. McMurphy does not exceed his activity tolerance.
2. Develop a teaching plan for Mr. McMurphy to help prevent future respiratory infections.
3. Develop a care plan for Mr. McMurphy for the nursing diagnosis *Risk for Injury* related to fatigue, muscle weakness, and spasticity.

See Evaluating Your Response in Appendix B.

called early-onset PD). Men and women are affected equally. There is a genetic link, with about 15% of PD having a family history of the disease. The cause of PD is still unknown, but is believed to be the result of environmental and genetic factors, with genetic mutations especially implicated in early-onset PD (Genetics Home Reference, 2013). See Meeting Individualized Needs: PD in Older Adults on page 1447.

Parkinson's-like manifestations, called secondary parkinsonism, may result from other disorders such as stroke, brain trauma, encephalitis, brain tumors, toxins, and drugs. Drug-induced parkinsonism, which is usually reversible, may occur in people taking neuroleptics, antiemetics, antihypertensives, and illegal designer drugs containing MPTP, a toxic chemical. Carbon monoxide or cyanide poisoning can also cause secondary parkinsonism. This discussion focuses on primary Parkinson's disease.

Pathophysiology

Coordinated, voluntary body movement is achieved through the actions of **neurotransmitters** in the basal ganglia of the brain. Some neurotransmitters facilitate the transmission of excitatory nerve impulses, while other neurotransmitters inhibit their transmission. Together, this system allows control of movement. A disturbed balance between excitatory and inhibitory neurotransmitters causes disorders of voluntary motor function, such as PD.

In PD, neurons in the cerebral cortex atrophy and are lost, the **dopaminergic** nigrostriatal (pigmented) pathway degenerates, and the number of specific dopamine receptors in the basal ganglia decreases. These pathologic processes cause a decrease in the production of dopamine (a neurotransmitter that helps regulate nerve impulses involved in motor function) from the substantia nigra. The usual balance of dopamine (an inhibitory neurotransmitter) and acetylcholine (an excitatory neurotransmitter) in the brain is disrupted, and dopamine no longer inhibits acetylcholine. The failure to inhibit acetylcholine is the underlying basis for the manifestations of the disorder.

In Parkinson's, up to 80% of the neurotransmitter dopamine may have been depleted before symptoms occur (Lindop, 2012). It is believed that the basal ganglia pathways are bypassed in Parkinson's and the frontal cortex is used instead, resulting in the symptoms of PD.

Manifestations

Parkinson's disease begins with subtle manifestations. Prompt recognition of symptoms and rapid treatment of those complaints improves

outcomes and maintains self-care abilities and independence (Lindop, 2012). Initially, patients complain of feeling tired and seem to move more slowly; a slight tremor may accompany the fatigue. Over time, the manifestations progressively increase in severity. Other manifestations, less often described, are an impaired sense of smell (which may be an early manifestation) and pain (Lindop, 2012). The manifestations of PD are presented in the box below.

TREMOR

Tremor at rest is usually the most visible manifestation, affecting the hands and feet, head, neck, face, lips and tongue, or jaw. The characteristic tremor is rhythmic, alternating flexion and contraction, and is initially unilateral. The tremor disappears with movement and sleep. As the disorder progresses, the tremor becomes bilateral. Patients have progressive impairment in performing skills that require dexterity and fine muscle control, such as writing and eating.

RIGIDITY AND BRADYKINESIA

Manifestations related to motor and postural effects include rigidity, bradykinesia, and uncoordinated movements. Rigidity (resulting from involuntary contraction of all skeletal muscles) makes both active and passive movement difficult. It is manifested as increased resistance to passive ROM. Although the extremity moves, it does so in a jerky motion, called cogwheel rigidity. The first manifestation of rigidity may be muscle cramps in the toes or hands, but most often the patient describes stiffness, heaviness, or aching in muscles. Rigidity, which may result in flexion contractures, begins on one side of the body and progresses to become bilateral.

Bradykinesia, experienced as difficulty in starting, continuing, or coordinating movements, is the most common and crippling manifestation. All striated muscles are affected, including those that involve walking, turning, chewing, swallowing, and speaking. Slowed or delayed movements affect the eyes, mouth, and voice, causing a masklike face and softened or muffled voice. Disorders of swallowing result in problems with eating and with drooling. Patients have a staring gaze with minimal change in expression (Figure 44–3 ■). Patients describe a sense of being frozen in place as voluntary movement is lost, and they stand, sit, or lie in one position without movement for long periods of time. Movement is interspersed with freezing, brought about by turning, increasing the effort to move, or making visual or touch contacts.

ABNORMAL POSTURE

The loss of normal postural reflexes results in postural abnormalities, including disorders of postural fixation, equilibrium, and righting. Involuntary flexion of the head and shoulders means the person with PD cannot maintain an upright position of the trunk when sitting or standing. This problem of postural fixation results in the characteristic stooped, leaning forward position. Disorders of equilibrium follow loss of postural fixation with an inability to make adjustments when leaning or falling, increasing the risk of injury from falls (forward or backward). The patient takes short, shuffling steps to try to maintain an upright position when walking.

AUTONOMIC AND NEUROENDOCRINE EFFECTS

Many manifestations result from the loss of functions controlled by the autonomic nervous system. Elimination problems include constipation and urinary hesitation or frequency. Patients may experience problems related to orthostatic hypotension, including dizziness

MANIFESTATIONS OF PARKINSON'S DISEASE

RELATED TO MOTOR DYSFUNCTION

- Nonintention tremor
- Bradykinesia or akinesia
  a. Slowed movements; inability to initiate voluntary movements
  b. Slowed speech, low amplitude
  c. Poor articulation
  d. Decreased eye movements (i.e., blinking)
  e. Masklike, expressionless face
- Rigidity
- Posture and gait disturbances
  a. Trunk tilted forward
  b. Shuffling gait, propulsive at times
  c. Retropulsion
- Complications: falls, fractures, impaired communication, social isolation

RELATED TO AUTONOMIC SYSTEM DYSFUNCTION

- Skin problems
  a. Seborrhea
  b. Excess sweating on face and neck, absence of sweating of trunk and extremities
  c. Mottled skin
- Heat intolerance
- Postural hypotension
- Constipation
- Complications: skin breakdown, dizziness, falls, constipation

RELATED TO COGNITIVE AND PSYCHOLOGIC DYSFUNCTION

- Dementia
  a. Memory loss
  b. Lack of insight and problem-solving ability
  c. Declining intellectual abilities
- Anxiety
- Depression
- Complications: loss of ability to function, social isolation

Figure 44–3 ■ In Parkinson's disease, the patient's face lacks expression or animation.
Source: Scott Houston/Corbis

with position change. Eczematous skin changes and seborrhea are related to the increase in sweat gland activity secondary to increased sebotrophic hormone production.

MOOD AND COGNITION

Both depression and dementia are pathologies associated with PD. Depression occurs in one-half of all patients and one-third have dementia. Dementia, resulting from loss of cholinergic cells, loss of neurons, senile plaques, neurofibrillary tangles, and amyloid changes in small blood vessels, occurs in 20% of patients with PD and develops later in the disease (Wagner et al., 2013). The patient has manifestations similar to the person with Alzheimer's disease, including confusion, disorientation, memory loss, distractibility, and changes in abstraction and judgment. Bradyphrenia may also occur, resulting in slow thinking and a decreased ability to form thoughts, to plan, or to make decisions.

SLEEP DISTURBANCES

Patients with PD commonly have sleep disturbances, although they may experience decreased manifestations during sleep in the early stages. The ability to fall and stay asleep is affected by acetylcholine. Muscle rigidity may compromise sleep because of the inability to change position. This lack of muscle movement causes the patient to awaken and consciously shift position.

INTERRELATED EFFECTS

Some of the manifestations that patients with PD experience have multiple contributing factors. For example, constipation is common because of decreased peristalsis. However, decreased peristalsis is not the only cause: Immobility, tremors (resulting in being unable to drink from a glass easily), and dietary changes from dysphagia all contribute to the problem of constipation.

Complications

The following complications are associated with Parkinson's disease:

- Oculogyric crisis, in which the eyes become fixed with a lateral and upward gaze
- Paranoia and hallucinations, which may accompany dementia
- Impaired communication due to changes in speech, handwriting, and expressiveness
- Falls from balance, posture, and motor changes
- Infections, such as pneumonia, related to immobility
- Malnutrition related to dysphagia and inability to prepare meals
- Altered sleep patterns due to loss of dopamine, L-dopa side effects (nightmares, dreams) or side effects of anticholinergics (hyperreflexia, muscle twitching), and depression
- Skin breakdown and pressure ulcers associated with urinary incontinence, malnutrition, and sweat reflex changes
- Depression and social isolation.

●○● INTERPROFESSIONAL CARE

At present there is no cure for PD, but medications bring dramatic improvement in manifestations. Diagnosis is based primarily on a thorough history and physical examination, and is made based on having two of the three cardinal manifestations: tremor at rest, bradykinesia, and rigidity. Interventions vary with the clinical stage of the disorder and include medication, surgery, and rehabilitation to retain the optimal level of functioning possible. An interprofessional approach is essential for these patients. Speech and swallowing problems can be addressed by a speech therapist, while a physical therapist teaches the patient an awareness of his environment and the cues that can be initiated to provoke or "unfreeze" physical abilities. This increases the odds that visual and auditory cues can enhance a PD patient's motor and cognitive functioning. An example of this is placing tape on the floor as a reminder of where the walking strides should fall, or a buzzing or ringing watchband to remind the patient to dress, shower, or eat. Pharmacy should be directly involved in the teaching related to medications, as should any community organizations that may enhance the patient's ability to remain independent. The interprofessional team of nurses, physicians, and psychiatrist can be closely involved in the patient's care, monitoring him for depression and hopelessness, which often accompany this diagnosis (Lindop, 2012). Evidence-based practice guidelines for the diagnosis and prognosis of new onset PD are available (National Guidelines Clearinghouse, 2012).

DIAGNOSIS

No diagnostic test differentiates Parkinson's disease from other neurologic disorders (Hickey, 2013).

MEDICATIONS

The goal of drug therapy is to control manifestations to the extent possible. Generally, medications vary with the stage of the disease; however, response is individualized and guides the selection of medications. Types of drugs used include monoamine oxidase B (MAO-B) inhibitors, dopaminergics, dopamine precursors, dopamine agonists, glutamate antagonists, and anticholinergics. Information about these drugs is presented in the accompanying Medication Administration box. It is important for patients and family members to know that each person must be individually evaluated, and if medications for PD become ineffective, others may be prescribed.

Other medications may be used to treat problems related to Parkinson's disease. Antidepressants may be prescribed. Propranolol (Inderal) may be used to treat tremors; it should be used cautiously when patients have orthostatic hypotension. Botulism toxin injections may be given to treat eyelid spasms and abnormal posturing (dystonia) involving the extremities.

Meeting Individualized Needs

PD in the Older Adult

Parkinson's disease is a common disorder in older adults, who are already at greater risk for falls resulting from orthostatic hypotension, osteoporosis, poor vision, and other problems that cause disorientation and confusion, such as Alzheimer's disease.

- Older adults are particularly susceptible to psychologic disturbances. For this reason, an environment of reduced stimulation as well as other pharmacologic and nonpharmacologic measures may be necessary. A priority is to protect the older adult from injury and maintain safety and supervision at all times if signs of psychologic dysfunction are present.
- Older adults are especially susceptible to heat stroke and psychologic side effects, including confusion, depression, delusions, and hallucinations. Anticholinergics should be tapered slowly when discontinued to avoid enhancing parkinsonian symptoms.

MEDICATION ADMINISTRATION

The Patient with Parkinson's Disease

DOPAMINE PRECURSORS

levodopa (Larodopa, Dopar)

carbidopa-levodopa (Sinemet)

GLUTAMATE ANTAGONIST

amantadine (Symmetrel)

These drugs have their major effect on the akinesia of Parkinson's disease, improving mobility while decreasing muscle rigidity and tremor. Levodopa is a metabolic precursor of dopamine, but unlike dopamine, it can cross the blood–brain barrier. Levodopa is converted to dopamine in the brain by decarboxylase, a catalytic enzyme, and stimulates dopamine receptors to balance the dopamine/acetylcholine concentrations. Carbidopa prevents decarboxylase from converting levodopa to dopamine in the peripheral tissues; therefore, carbidopa is frequently given in combination with levodopa. Amantadine, often used in the early stages of PD, is used to treat dyskinesia and also elevates mood.

Levodopa is avoided in patients with narrow-angle glaucoma, severe angina pectoris, transient ischemic attacks, or melanoma. The "on–off" phenomenon occurs after the patient takes levodopa for several years; this phenomenon is characterized by unexpected dyskinesias (abnormal movements) and lack of symptom control.

Common side effects are nausea and vomiting; darkening of urine and sweat; dyskinesias, especially in the first few months of therapy; dysrhythmias; orthostatic hypotension; and psychologic reactions, such as hallucinations and vivid dreams.

Nursing Responsibilities

- Establish the patient's baseline functional abilities in performing ADLs and administering the medication; assess motor control and coordination.
- To avoid adverse reactions, assess the patient's overall health status before initiating therapy.
- Monitor medications known to cause adverse drug interactions: anticholinergics, pyridoxine, and antipsychotic agents alter the effectiveness of levodopa; MAO-B inhibitors can cause severe hypertension because of their vasoconstrictive effects.
- Withhold levodopa for 8 hours prior to administering Sinemet to avoid potentiating the effects of the circulating levodopa.

Health Education for the Patient and Family

- Levodopa may not take effect for several weeks to months.
- Do not alter dosages of medications; taking more of a medication may not result in better symptom control and can cause severe side effects.
- Your protein intake should be divided into equal amounts for the day's meals. Avoid foods high in pyridoxine, such as pork, beef, ham, avocado, beans, and oatmeal.
- Levodopa may cause urine to darken, but this is harmless.
- To prevent side effects do the following:
  - Prevent nausea by taking medication with food.
  - Change position slowly to avoid a drop in blood pressure and risk of falling.
  - Prevent constipation by increasing fluid intake and exercising regularly.
- Notify practitioner if you begin to have difficulty making voluntary movements or if cardiac or psychologic symptoms develop.
- Watch for the "on–off" phenomenon, in which periods of symptom control alternate with periods when the drug fails to control symptoms.

MONOAMINE OXIDASE B INHIBITORS

selegiline (Eldepryl, Carbex)

rasagiline (Azilect)

Selegiline works by selectively inhibiting the enzyme that inactivates dopamine in the brain. It may be administered alone or as adjunct therapy with levodopa: Selegiline inhibits the enzyme system that would otherwise break down and destroy dopamine. This synergistic effect lasts approximately 1 to 2 years. The combination of selegiline and levodopa increases the adverse reactions of dopamine; nurses must be alert for orthostatic hypotension, changes in movement, hallucinations, and confusion. These responses can be modified by lowering the dose of levodopa. Because it is highly selective for the MAO-A enzyme, selegiline does not have antidepressant effects like the MAO-B inhibitors. The risk of severe hypertension is low. Rasagiline also inhibits MAO-B breakdown of dopamine in the brain; when given with levodopa, it may enhance the response.

Nursing Responsibilities

- Establish baseline functional abilities: motor control and movements, position changes, and mental status.
- Monitor problems with insomnia.
- Assess for orthostatic hypotension; look for unsteadiness with position change and complaints of dizziness.
- Assess for hypertension, which can occur with higher than usual doses.
- Do not administer selegiline with meperidine (Demerol) or fluoxetine (Prozac).

Health Education for the Patient and Family

- It is very important to take the medication as directed, especially dose and time of administration.
- Notify the practitioner if insomnia occurs.
- Report signs of dizziness when changing positions or standing, changes in ability to move, or psychologic changes.
- Change positions slowly, especially when moving from a sitting to a standing position.
- Keep follow-up appointments for evaluation of the medication's effectiveness.

DOPAMINE AGONISTS

apomorphine (Apokyn)

bromocriptine (Parlodel)

pergolide (Permax)

pramipexole (Mirapex)

ropinirole (Requip)

rotigotine transdermal system (Neupro)

Dopamine agonists act by mimicking the role of dopamine in the brain. They are frequently used in combination with levodopa therapy: When dopamine agonists are given with levodopa, they increase the therapeutic effects of levodopa and reduce fluctuations in motor symptoms. Adverse reactions are similar to those of levodopa: nausea, orthostatic hypotension, and psychologic disturbances are common. Nursing responsibilities and patient and family teaching information are similar to those that apply to the dopaminergics; however, family members should know that these drugs may cause compulsive behavior.

CATECHOL-*O*-METHYLTRANSFERASE (COMT) INHIBITORS

tolcapone (Tasmar)

entacapone (Comtan)

COMT inhibitors inhibit catechol-*O*-methyltransferase (COMT), which is responsible for metabolizing dopamine. The concurrent administration of a COMT inhibitor with levodopa increases the amount of levodopa available to the brain to control Parkinson's disease.

Nursing Responsibilities

- Monitor liver function test results and manifestations of liver impairment (dark urine, jaundice).
- Administer with food.
- If given concurrently with warfarin, monitor PT and INR.

MEDICATION ADMINISTRATION (*continued*)

Health Education for the Patient and Family

- Avoid using alcohol and sedatives.
- Rise slowly from a sitting or lying position to avoid falling.
- Nausea is common at the beginning of therapy.
- Do not abruptly stop taking the medication.
- Report increased loss of muscle control, yellow skin or eyes, dark urine, hallucinations, and severe diarrhea.

ANTICHOLINERGICS

trihexyphenidyl (Artane)

benztropine (Cogentin)

biperiden (Akineton)

ethopropazine (Parsidol)

Anticholinergics are effective in Parkinson's disease because they block the excitatory action of the neurotransmitter acetylcholine. They are frequently used during the early stages of the disease or when the patient can no longer take levodopa. They may be given in combination with carbidopa-levodopa therapy. These medications ease drooling, tremors, and rigidity; however, side effects are common and may include blurred vision, dry mouth, constipation, delayed gastric emptying, urinary retention, photophobia, and tachycardia.

Nursing Responsibilities

- Perform baseline assessment for presence of glaucoma, cardiac dysfunction, and prostatic hypertrophy.
- Note other medications, including OTC medications that have anticholinergic effects, such as antihistamines and tricyclic antidepressants.
- Monitor for side effects, especially changes in vision, urinary elimination, gastric emptying, and mentation.

Health Education for the Patient and Family

- Inform your practitioner if you begin taking any new medications or notice any new symptoms.
- Avoid overexposure to heat, and take precautions to avoid heat stroke: Drink fluids, keep cool, and avoid strenuous activity on hot days.
- Practice home safety to prevent falls associated with blurred vision.
- Avoid taking OTC antihistamines or sleeping aids; these have anticholinergic activity.
- Have the eyes examined annually to check for glaucoma; wear dark glasses if photophobia develops.
- Do not suddenly stop taking anticholinergics.

Note: Drugs identified in *italics* are among the 200 most commonly prescribed medications in the U.S.

SURGERY

Surgical treatment of PD may be used for patients who have had the disease for a long time and are no longer able to control manifestations with medications. The most commonly used procedure is deep brain stimulation (DBS). Treatment by DBS is used for carefully selected patients with advanced tremors. Those with cognitive impairments are not candidates for this type of surgery, because DBS can further impair cognitive function (Hickey, 2013).

In the surgery, an implanted pacemaker-like neurostimulator (about the size of a stopwatch) is implanted into the subthalamus area (a small structure deep in the subcortical area) of the brain. An insulated wire is then connected to an implanted pulse generator (similar to an advanced cardiac pacemaker) near the clavicle (NINDS, 2012b). The electrical impulses from the generator stimulate the targeted area of the brain to interfere with and block the brain's electrical signals that cause the manifestations of PD. Although most people with PD will need to continue medications after having DBS, many are able to reduce the dosage as well as side effects (such as dyskinesias from long-term levodopa use). Following surgery, the patient is closely monitored for neurologic complications (such as weakness, confusion, decreasing LOC, seizures or dysrhythmias), intracranial infections, and technology malfunction. Intracranial disorders are discussed in Chapter 42.

Stem cell transplantation is a surgical procedure limited to a few medical centers. In this investigational treatment, not approved by the FDA, stem cells are implanted into the brain in the hopes that the new cells will grow and produce enough dopamine to restore some lost mobility (Lindop, 2012).

●○● NURSING CARE

The chronic and eventually debilitating nature of PD poses many challenges to patients, families, and healthcare professionals. Dependence due to declining physical and mental abilities is of major concern. In the early stages, most patients are able to remain at home, with the family assisting with or providing many of the patient's ADL needs. As the disease progresses and the burden of care increases, the patient and family may prefer placement in a long-term care facility. See the Case Study & Nursing Care Plan for the patient with PD on page 1452.

Health Promotion

Teaching preventive measures is extremely important when caring for patients who have symptoms of Parkinson's disease. Preventing malnutrition, falls and other environmental accidents, constipation, skin breakdown from incontinence or immobility, and joint contracture requires teaching and reinforcement.

In addition to incorporating information about safety needs, teach ways to prevent orthostatic hypotension when the patient changes positions; some patients may benefit from wearing individually fitted compression hose. Address safety considerations for proper administration of medications.

Assessment

Collect the following data through the health history and physical examination (refer to Chapter 41). Further focused assessments are described with nursing interventions.

- *Health history:* brain trauma, stroke, infection, exposure to heavy metals or carbon monoxide, medication and drug use, incontinence, constipation, weight loss, sweating, sleep problems, muscle pain, mood
- *Physical assessment:* affect; appearance; speech; scalp, eyelashes, and skin; drooling; tremor; coordination; posture; gait; muscle rigidity; mental status.

Moving Knowledge into Action

The Patient with Parkinson's Disease

1. How can the family of the patient with Parkinson's disease most effectively be involved by the nurse in that patient's care?
2. What are the major nutritional challenges faced by the patient with Parkinson's disease and how would the nurse address them?

Diagnoses, Outcomes, and Interventions

Patients with PD have complex and, ultimately, multisystem needs. Deficits in mobility and self-care are common. Psychosocial needs may include problems related to *Ineffective Coping*, *Powerlessness*, and *Disturbed Body Image*. Refer to the nursing care sections throughout this chapter for discussions of *Fatigue, Self-Care Deficit, Ineffective Airway Clearance*, and other pertinent diagnoses. This section focuses on the nursing diagnoses related to impaired physical mobility, impaired verbal communication, imbalanced nutrition, and disturbed sleep pattern.

Impaired Physical Mobility

Patients with PD have impaired mobility for several reasons, including tremors, gait pattern disturbances, and alterations in body positioning, such as forward bending of the trunk. Poor self-esteem may contribute to the patient's lack of motivation and willingness to be mobile.

Expected Outcome: Patient's deficits in mobility and self-care will be eliminated or minimized as evidenced by the patient being able to perform ADLs independently or with minimal assistance.

- Suggest referral to a physical therapist to develop an individualized exercise program. *A program specific to the patient supplies motivation and also helps the patient maintain muscle tone, flexibility, and mobility.*
- Request the physical therapist teach caregivers how to do ROM exercises at least twice a day, emphasizing the trunk, neck, arms, hips, and legs. *Maintaining joint mobility promotes better function and strength, improving gait pattern. Consistent ROM exercises can prevent contractures.*
- Ask caregivers to ambulate the patient at least four times a day if possible. *Exercise fosters independence and self-esteem.*
- Recommend assistive devices, such as lift chairs, canes, splints, or braces, as indicated. *Adaptive equipment improves balance, protects joints, and promotes proper anatomic positioning.*
- To promote mobility and safety do the following:
  - Slightly elevate the back legs of chairs and raise the toilet seat to help rise from a sitting position to a standing position.
  - Wear shoes with Velcro closures.
  - Remove potential hazards, such as unanchored throw rugs.
  - Install handrails and nonskid surfaces in bath tubs and showers.
  - Ensure adequate lighting throughout the home and in outside areas, especially in areas where transfers are common.

Safety measures prevent potential complications that may result from falls or other accidents and promote self-esteem and quality of life through self-care. Although patients with PD are aware of the risk for falls, they often are unaware of common risk factors, especially medication use (*Gazewood et al., 2013*).

Evidence for Nursing Care

The Patient with Parkinson's Disease

Selected resources that nurses may find helpful when planning evidence-based nursing care follow.

- Gazewood, J., Richards, R., & Clebak, K. (2013). Parkinson disease: an update. *American Family Physician*, *87*(4), 267–273.
- Lindop, F. (2012). A multidisciplinary approach to Parkinson's disease. *British Journal of Neuroscience Nursing*, *8*(2), 61–64.

Impaired Verbal Communication

Diminished vocal amplitude and loss of muscular control can impair the patient's ability to speak. Both caregivers and family members must remember to give patients enough time for self-expression; an unhurried approach is recommended. Seek input from family members when determining alternative methods of communicating with the patient.

- Assess current communication abilities in speech, hearing, and writing. *Communication involves both sending and receiving messages.*
- Develop methods of communication appropriate to coordination abilities, such as a magic slate, flash cards with common phrases, and pointing to objects. *Individualizing a method of communication decreases anxiety and isolation.*
- Suggest referral to a speech pathologist to develop oral exercises and interventions that will facilitate speaking. *The muscles of speech and swallowing are affected by the Parkinson's disease process.*
- Remind patient to speak more loudly, if possible. *A low, monotonous voice is characteristic of the patient with Parkinson's disease.*

Imbalanced Nutrition: Less Than Body Requirements

Tremors, altered gait, and impaired chewing and swallowing can cause nutritional problems in the patient with PD. As the disorder progresses, interventions for ensuring optimal nutrition need to be adapted to the patient's functional abilities. Assess the patient's swallow reflex before starting any feeding program. During the initial stages of the disorder, some patients may have the nursing diagnosis *Imbalanced Nutrition: More Than Body Requirements* if kilocalorie intake exceeds energy expenditure.

- Assess nutritional status and self-feeding abilities; suggest referral to an occupational or speech therapist, if needed. *An initial assessment of abilities ensures that interventions are personalized to the patient's current functional abilities.*
- Teach caregivers how to prepare foods of proper consistency as determined by swallowing function. *The patient may aspirate food that is too liquid.*
- Weigh weekly. *Early recognition of weight loss allows for intervention.*
- Teach eating methods to decrease tremors, such as holding a piece of bread in the hand that is not holding an eating utensil. *Nonintention tremor may be reduced through purposeful activity.*
- Encourage diet that is high in bulk and fluids. *Several anti-Parkinson's medications and inactivity can cause constipation.*

Disturbed Sleep Pattern

Rigidity and weakness can cause patients with Parkinson's disease to lose the ability to move and change positions during sleep. The

resulting discomfort causes periods of wakefulness. Medications to treat Parkinson's disease contribute to sleep pattern disturbance; for example, levodopa can cause vivid dreams. Nurses can help accurately assess the sleep pattern disturbance and can plan interventions to improve or increase sleep time.

- Assess sleep pattern and existing conditions that may affect sleep, such as depression or pain. *Patients experiencing anxiety, depression, and dementia have a difficult time falling asleep and may wake up more often at night.*

SAFETY ALERT

Remember to assess pain status; lack of adequate pain control may interfere with sleep as well as with mobility/balance.

- Explain the disease process and the effects of decreased dopamine on the sleep–wake cycle. *Depending on the dosage, levodopa causes less REM sleep and deep sleep.*
- Review the patient's medication. *Bromocriptine and levodopa, especially if used with an anticholinergic, can cause vivid dreams. Other medications (diuretics, theophylline, hypnotics) also may interfere with sleep.*
- Teach how to modify lifestyle activities that affect sleep and mobility:
  - Institute a routine of activities with limited rest periods during the day; avoid napping close to bedtime. Avoid strenuous exercise in the evening. *Daytime sleeping may contribute to decreased nighttime sleeping. Vigorous exercise just before bedtime may act as a stimulant.*
  - Incorporate diet modifications, such as limiting caffeine and alcohol intake. *Caffeine is a stimulant, and alcohol may cause early morning awakenings, increased daytime sleepiness, and nightmares.*
  - Drink a glass of milk before bedtime. *Milk contains tryptophan, which produces sedative effects by shortening the time taken to fall asleep (sleep latency).*
  - Adapt the environment to aid in sleep (e.g., darken the room and decrease noises). *Reducing environmental stimuli decreases external sleep disturbances.*

Delegating Nursing Care Activities

As appropriate and allowed by the designated duties and responsibilities of unlicensed assistive personnel, the nurse may delegate nursing care activities such as monitoring diet intake and output to determine diet restrictions (limiting alcohol/caffeine, promoting milk at bedtime). Other activities to be delegated are promoting patient exercise during the day and restricting it at night and creating an optimal environment for sleep (darkened and quiet room).

Continuity of Care

It is important for both the patient and the family to maintain independence and self-care as long as possible. To maintain function and quality of life, the following topics should be addressed:

- Realistic expectations
- Equipment suppliers
- Home environment conducive to using equipment
- Referrals to speech therapist, occupational therapist, physical therapist, and dietitian
- Gait training and exercises for improving ambulation, speech, swallowing, and self-care
- Increased fluid intake of 3000 mL/day and increased fiber in every meal.
- Stool softeners or laxatives as needed for bowel elimination
- Swallowing during eating and taking medications (Have suction equipment available and know the Heimlich maneuver if choking occurs.)
- Foods that can be easily swallowed (such as pureed or soft) and feed six small meals a day if possible
- Helpful resources: American Parkinson's Disease Association; National Parkinson Foundation, Inc.; Parkinson's Disease Foundation; and the National Institute of Neurological Disorders and Stroke.

THE PATIENT WITH HUNTINGTON'S DISEASE

Huntington's disease (HD) is a progressive, degenerative, inherited neurologic disease characterized by increasing dementia and chorea (jerky, rapid, involuntary movements). It is an autosomal-dominant inherited disease that causes localized death of neurons of the basal ganglia (Wagner et al., 2013). The exact cause is unknown, but postmortem studies have demonstrated a decrease in gamma-aminobutyric acid (GABA), an inhibitory neurotransmitter in the basal ganglia. There is also a decrease in acetylcholine levels, suggesting that the manifestations are the result of an imbalance in dopamine and acetylcholine. HD is a familial disease; each child of an HD parent has a 50% chance of inheriting the HD gene and, if so, will eventually develop the disease (NINDS, 2013c). There is no cure for the disease.

Because the patient is usually asymptomatic until age 30 to 40, he or she may already have passed the gene to the next generation. The psychologic effect is devastating to patients and their families. The family not only experiences guilt from passing the disease from one generation to the next, but also is faced with the overwhelming long-term care needs of those affected. It is common for several family members to have the disease.

Pathophysiology

Huntington's disease causes destruction of cells in the caudate nucleus and putamen areas of the basal ganglia. Other areas of the brain, such as the frontal lobes, may selectively atrophy. Several neurotransmitters and their receptors are decreased, including GABA and acetylcholine. The neurotransmitter dopamine is not affected in Huntington's disease, but the decrease in acetylcholine results in a relative excess of dopamine in the basal ganglia. In Parkinson's disease a deficit of dopamine causes slow movement or lack of movement, whereas in Huntington's disease the opposite occurs resulting in a relative excess of dopamine that causes excessive, uncontrolled movement.

Manifestations

Manifestations and complications primarily involve abnormal movement and progressive dementia (see the accompanying Manifestations box). The progression and sequence of manifestations vary while the psychologic manifestations are more debilitating than the choreiform (rapid and jerky) movements.

CASE STUDY & NURSING CARE PLAN A Patient with Parkinson's Disease

Stanley Ralph, age 78, was diagnosed with PD at age 64. His wife died 5 years ago and he has no other family living. Mr. Ralph worked for more than 40 years as a mechanic in a large factory. He is a resident of a long-term care facility. During a clinic visit for a review of his medications, the following assessment was made.

ASSESSMENT

White male with history of PD for the past 14 years. Skin oily and damp. Tremors in both hands and the lips. Gait is slow and shuffling, with a forward leaning posture. Speech slow and slurred. Face expressionless. Has lost 4.5 kg (10 lb) since last visit 3 months ago. Has been on levodopa with carbidopa since diagnosis. States major problems are "eating problems, bowel problems, walking problems."

DIAGNOSES

- *Constipation* related to lack of exercise, decreased food intake, and effects of medications
- *Impaired Verbal Communication* related to lip tremors, slow/slurred speech, and facial muscle involvement of PD
- *Imbalanced Nutrition: Less Than Body Requirements* related to difficulty swallowing and chewing
- *Impaired Physical Mobility* related to rigidity and bradykinesia

EXPECTED OUTCOMES

- Patient will have a soft stool at least every other day.
- Patient will practice exercises provided by physical therapist twice a day.
- Patient will increase number of calories, fluids, and fiber in diet provided at long-term facility.
- Patient will improve joint mobility and ability to ambulate.

PLANNING AND IMPLEMENTATION

- Discuss problems with bowel elimination with staff at long-term facility; suggest increasing fluids to 3000 mL/day and also increasing fiber in the diet with oatmeal for breakfast, and more fruits and vegetables at meals.
- Encourage exercises provided by speech therapist to improve speech and swallowing. If these are not effective, make a referral for another evaluation.
- Discuss diet plan with dietitian at the long-term care facility, including consistency of foods and number of calories. Suggest dietitian be a part of swallowing evaluation conducted by the speech therapist.
- Refer for physical therapy and occupational therapy for a program to improve gait and joint mobility, and to decrease risk of falling.

EVALUATION

In a return visit 3 months later, Mr. Ralph reports that "my bowels are working better." He has gained 3.2 kg (7 lb), and the staff report that this is related to multiple factors, including practicing his swallowing exercises, getting more exercise that stimulated his appetite, and changing his diet to six small meals a day of soft or pureed foods. The staff is offering him liquids at meals and snack times, and he usually drinks all they give him. His speech is not much improved. His posture and gait are somewhat better, and he is doing the exercises provided by the physical therapist and occupational therapist. Mr. Ralph's functional abilities have improved so much that the staff is considering training sessions specific to care of residents with PD.

Clinical Reasoning in Patient Care

1. Although Mr. Ralph did not mention it, the staff reports that he is frustrated by not being able to dress himself. What suggestions could you make to facilitate his independence?
2. Mr. Ralph spends most of his time alone, although he enjoys the company of the other residents. List assessments and interventions to increase his diversional activity.
3. The loss of his wife and the debilitating effects of his disease increase Mr. Ralph's risk for the nursing diagnosis of *Chronic Sorrow*. What might you suggest the long-term staff do to reduce this risk? Are there other resources that might assist him with this problem?

See Evaluating Your Response in Appendix B.

Early manifestations of personality change include severe depression, memory loss with decreased ability to concentrate, emotional lability, and impulsiveness. The patient experiences frequent mood swings ranging from uncontrollable periods of anger to apathy. Eventually, signs of dementia, including disorientation, confusion, and lack of sense of time, become evident and interfere with self-care.

Motor manifestations usually parallel personality and mood changes. The motor manifestations worsen with environmental stimuli and emotional stress but are absent when the patient is sleeping. Initially, movement problems are described as fidgeting or restlessness, followed by progressive worsening of abnormal movements. The choreiform movements, which begin in the face and arms and then involve the entire body, are manifested by facial grimaces, tongue protrusion, jerky movement of the distal arms or legs, and a rhythmic, lurching gait that almost resembles a dance. (The term *chorea* comes from *choreia,* the Greek word meaning "dance.") Gait changes cause uncoordinated movements and contribute to frequent falls.

The muscles of swallowing, chewing, and speaking are affected, leading to dysphagia and dysarthria and associated problems with communication and nutrition. The patient's constant movement and difficulty in swallowing contribute to weight loss and eventual cachexia. Breathing is impaired because the diaphragm is unable to move effectively.

The manifestations slowly progress over approximately 15 to 20 years after initial manifestations appear. Prognosis is poor, with inevitable debilitation and total dependence. Death usually results from aspiration pneumonia or another infectious process.

●○● INTERPROFESSIONAL CARE

There is no cure for Huntington's disease, and treatment addresses the disease's manifestations. Nurses provide care to patients with Huntington's disease in a variety of community settings. Initially, patients and families can manage care needs at home, but as the disease progresses, the patient requires constant supervision, such as that provided in day care facilities. Eventually, skilled long-term care is needed. Patients who develop acute problems may be hospitalized until the crisis is managed. Because of the inevitable total multisystem debilitation of patients with Huntington's disease, nurses and other caregivers face many challenges.

MANIFESTATIONS OF HUNTINGTON'S DISEASE

MOTOR EFFECTS

Early

- Restlessness
- "Fidgety" feeling
- Minor gait changes—unsteady on feet
- Posture and positioning disturbances, frequent falls
- Inability to keep the tongue from protruding
- Slurred speech with poor articulation
- Complications: increasing problem with self-care activities, such as bathing, grooming, eating

Late

- Chorea—severely altered gait with irregular, uncontrollable movement; shoulders shrug arrhythmically
- Facial grimacing—raising of eyebrows, uncontrollable protrusion of the tongue
- Dysphagia
- Unintelligible speech
- Impaired diaphragmatic movement
- Complications: immobility, aspiration, choking, and, eventually, total dependence, poor oxygenation, emaciation, and cachexia

PSYCHOSOCIAL EFFECTS

Early

- Irritability
- Outbursts of rage alternating with euphoria
- Depression
- Complication: suicide

Late

- Decreasing memory
- Loss of cognitive skills
- Eventual dementia
- Complication: total dependence

DIAGNOSIS

Genetic testing (described in Chapter 8) is the only diagnostic means available for diagnosing patients suspected of having Huntington's disease. Both blood and amniotic fluid may be tested for the presence of a gene mutation on chromosome 4 using DNA analysis. The test can predict with 95% accuracy which offspring have the disease.

MEDICATIONS

The following medications are given for the manifestations of Huntington's disease:

- Medications with the highest level of evidence in favor of their use are tetrabenazine (Xenazine), amantadine, and riluzole (Rukovets, 2012). Tetrabenazine shows the most improvement in treating the chorea of Huntington's disease. The drug may cause depression and risk of suicide; patients and caregivers should immediately stop the drug and notify the healthcare provider if manifestations of depression are observed. It increases the effects of, and should not be taken in combination with, Levodopa (for Parkinson's disease). Riluzole is associated with the risk of elevated liver enzymes.
- Antipsychotics, specifically phenothiazines and butyrophenones, are effective in Huntington's disease because they block dopamine receptors in the brain. The therapeutic goal is to restore the balance among the neurotransmitters.
- Antidepressants are prescribed in the early stage of the disease; however, medications are no substitute for intense follow-up counseling for patients and families.

●○● NURSING CARE

Nurses are faced with a multitude of challenges when caring for patients and families who have Huntington's disease, including physiologic, psychosocial, and ethical problems. Physiologic problems are related to the progressive and eventually debilitating nature of the disease. Psychosocial concerns occur as a result of the patient's personality and mental changes, the family's responsibility for providing care, and the guilt implicit in a genetically transmitted disease. Ethical difficulties relate to the genetic nature of the disease: DNA testing for the marker on chromosome 4 can determine whether the person is a carrier of the disease before beginning to exhibit manifestations. Children of people with Huntington's disease are thus faced with the choice of finding out whether they will eventually be affected. If they choose not to be tested, they may pass the disease on to yet another generation; if a fetus is affected, they may face the decision of whether to undergo an abortion.

Diagnoses, Outcomes, and Interventions

Initially, much of the nursing care focuses on teaching about the disease, psychologic support, and genetic counseling. As manifestations become more severe, nursing considerations center on problems related not only to immobility and altered nutrition, but also to the increasing self-care deficits. Families and patients experiencing Huntington's disease face many psychosocial issues. Nurses listen actively to provide comfort and encouragement throughout the lengthy illness. Of the many possible nursing diagnoses for the patient with Huntington's disease, this section focuses on those related to aspiration, nutrition, skin integrity, and communication.

Risk for Aspiration

Uncoordinated movements and swallowing and chewing problems put the patient at high risk for aspiration.

- Maintain in an upright position while the patient eats; support the head. *Proper positioning may prevent aspiration during mealtime.*
- Teach the Heimlich maneuver to caregivers and family members. *Aspiration is a real possibility; caregivers must be prepared to reestablish the patient's airway.*
- Provide food that is thick enough to manage, such as thick soups, mashed potatoes, stews, or casseroles. *These foods are more readily tolerated and manipulated by the tongue than liquids.*
- Make sure food is swallowed before giving another spoonful of food. *The automatic phase of swallowing may be disrupted in the patient with Huntington's disease; providing adequate time and smaller bites may improve the ability to manipulate foods.*
- Provide a calm, relaxing eating environment. *Stress worsens choreiform movements and inappropriate behaviors.*

Imbalanced Nutrition: Less Than Body Requirements

Patients with Huntington's disease have unpredictable choreiform movements of the extremities and decreased ability to control muscles involved with chewing and swallowing. Families and caregivers are challenged to provide sufficient calories to maintain the patient in positive nitrogen balance.

- Evaluate current weight and nutritional status, including serum prealbumin and transferrin levels. *Establishing a baseline is crucial for meeting individual caloric, protein, vitamin, and mineral needs.*

- Assess ability to swallow and manipulate eating utensils. *Aspiration is an ever-present danger that must be avoided; utensils may need to be adapted to patient's abilities, if patient is able to assist at all.*
- Continue feeding even if the patient physically turns away from the meal. *Involuntary choreiform movements should not be interpreted as a refusal to eat.*
- Provide high-kilocalorie, nutritious foods and sufficient snacks; request input from a dietitian. *The constant movement of Huntington's disease increases caloric requirements.*
- Avoid milk; provide frequent oral hygiene. *Milk tends to thicken secretions. Decreasing thick secretions may improve ability to swallow and enable the patient to ingest more calories.*

Impaired Skin Integrity

Skin integrity is only one component of the patient's general need for protection and avoidance of injury. Several factors increase the risk for impaired skin integrity, including poor nutritional status, eventual total immobility, and incontinence.

- Evaluate the skin for actual and potential areas of breakdown. *Establishing a baseline is necessary to modify care and provide prophylactic protection of high-risk pressure areas.*
- Determine nutritional status, especially serum prealbumin level and vitamin, mineral, and kilocalorie intake. *Optimal nutritional status and positive nitrogen balance help prevent skin breakdown and formation of pressure ulcers.*
- Turn and inspect the skin at least every 2 hours, giving special consideration to areas that are most prone to breakdown, such as heels and coccyx. *Pressure points are particularly susceptible to skin breakdown.*
- Provide ROM exercises on a regular schedule in the daytime. *Movement stimulates circulation, which provides oxygenation and allows nutrients to reach muscles and skin.*
- Keep the skin clean and dry; pay particular attention to the perineal area if incontinent. *Skin in proximity to the perineal area, such as the sacral area, is highly susceptible to breakdown due to exposure to wet, acidic urine and fecal material.*
- Place on an alternating-pressure mattress with foot board. *Decreasing pressure on bony prominences and preventing shearing forces serve to prevent skin breakdown.*
- Pad side rails and headrests of special chairs; have the patient wear a football-type helmet. *The patient's violent movements can cause trauma to the head and extremities.*

Impaired Verbal Communication

The inability to control muscles related to speech, swallowing, and facial movement contributes to problems of verbal communication. Because Huntington's disease affects fine motor movement, especially the distal portion of the extremities, the hands are not effective in communication. As the disease progresses, mental abilities are also compromised, making both receptive and expressive communication impossible.

- Choose alternative methods of communication while the patient is able to participate. *Anticipatory planning may facilitate communication and decrease anxiety.*
- Continue to incorporate therapeutic communication techniques, even though patient is not responsive: Maintain eye contact, use touch, and talk directly to the patient rather than to others in the room. *These techniques enhance the individual's dignity and worth.*

Moving Knowledge into Action

1. What actions can the nurse take to avoid decline in the quality of life of a patient with HD?
2. What teaching is most crucial to deliver to families of patients with Huntington's disease?

- Seek input from family about patient's usual preferences and how they are communicated; be alert for subtle cues. *Nonverbal communication techniques may be individualized and more readily recognized by the family member or caregiver who usually provides care.*
- Continue talking to the patient, even though there is no apparent response. *Hearing may not be impaired, even though the patient cannot speak.*

Continuity of Care

Patients with Huntington's disease and their families may know how devastating the illness is because they may have cared for a parent or other close family member who had the illness. Many families are overwhelmed with just the thought of the physical and psychosocial debilitation that the disease brings. Fear, anxiety, and hopelessness leading to depression are common reactions. Teaching ways to cope effectively with the psychosocial and physical changes is an integral part of the nurse's responsibilities. Referrals to appropriate agencies, such as adult day care centers, the Huntington's Disease Foundation, and local support groups or a psychologist should be part of the nursing plan.

Another aspect of patient teaching concerns the genetic transmission of Huntington's disease; referral to a geneticist is appropriate. Nurses may clarify information, especially concerning the transmission, course of illness, and prognosis. However, careful evaluation of HIPAA regulations regarding privacy of information is necessary before further information is provided. A caring, sensitive approach is crucial. Information about transmission of an autosomal-dominant trait is discussed in Chapter 8.

Evidence-based practice guidelines dictate that the decision to start pharmacologic treatment occurs between each patient and his or her healthcare provider so that functional decline and quality of life are considered. This is primarily related to the risk for worsening depression and the high cost of neuroleptic drugs (Rukovets, 2012).

THE PATIENT WITH AMYOTROPHIC LATERAL SCLEROSIS

Amyotrophic lateral sclerosis (ALS), or Lou Gehrig's disease (named for a famous baseball player who died of the disease), is a rapidly progressive and fatal degenerative neurologic disease characterized by weakness and wasting of muscles under voluntary control, without any accompanying sensory changes. There is growing evidence that dementia may accompany the disease in some patients (NINDS, 2013a).

ALS is diagnosed in 1 to 2 people per 100,000 population each year. In up to 90% to 95% of cases, the disease occurs at random without clearly associated risk factors. About 5% to 10% of all cases are inherited in what is termed familial ALS. Most people are middle to late adult age at diagnosis; the incidence is two times higher in men than in women. Most of the health problems a patient with

ALS encounters are related to swallowing and managing secretions, communication, and dysfunction of the muscles used in respiration. The average survival after onset of ALS manifestations is 2 to 5 years, with death from respiratory failure (NINDS, 2013a; Olsson Ozanne et al., 2011; Wagner et al., 2013).

Pathophysiology

ALS affects motor neurons in three locations: the anterior horn cells (lower motor neurons [LMNs]) of the spinal cord, the motor nuclei of the brainstem, and the upper motor neurons (UMNs) of the cerebral cortex. Death of the motor neurons results in axonal degeneration, demyelination, glial proliferation, and scarring along the corticospinal tract. In the early stages of the disease, surviving motor neurons sprout new branches to reinnervate affected muscle fibers, preserving muscle strength. However, when more than half of the lower motor neurons are affected, reinnervation fails and weakness is evidenced.

Although the pathogenesis of ALS is not clear, damage from free radicals, higher than normal glutamate levels, and autoimmune responses are being studied. Echovirus RNA has also been isolated in spinal cord tissue in some patients with nonfamilial ALS. Environmental factors, excess intracellular calcium, and antibodies to calcium channels are also being researched. Other risk factors may include age, dietary factors, and military service.

Manifestations

The initial manifestations relate to dysfunction of upper motor neurons, lower motor neurons, or both. Dysfunction of UMNs results in spastic, weak muscles with increased deep tendon reflexes. Dysfunction of LMNs results in muscle flaccidity, paresis (weakness), paralysis, and atrophy. See the accompanying Manifestations box.

Muscle twitches or weakness in an extremity and slurred speech are common early manifestations. The weakness may initially affect only one muscle group. Manifestations vary according to the particular muscle group involved; fasciculations (twitching) of involved muscles are common in the early stage of the disorder. With the loss of muscle innervation, the muscles atrophy, and paralysis results. Muscle mass decreases, and patients complain of progressive fatigue. Typically, the disease first affects the hands, then the shoulders, upper arms, and finally the legs.

Increasing brainstem involvement causes progressive atrophy of the tongue and facial muscles with eventual dysphagia and dysarthria. Emotional lability and loss of control occur. Muscle weakness and atrophy eventually mean that as the disease progresses the patient is unable to stand, walk, or use the hands or arms, and requires ventilatory support to breathe.

MANIFESTATIONS OF AMYOTROPHIC LATERAL SCLEROSIS

MUSCULOSKELETAL SYSTEM
- Weakness and fatigue
- "Heaviness" of legs
- Fasciculations
- Uncoordinated movements, loss of fine motor control in hands
- Spasticity
- Paresis
- Hyperreflexia
- Atrophy
- Problems with articulation
- Complications: paralysis, loss of ability to perform ADLs, total immobility, aspiration, loss of verbal communication

RESPIRATORY SYSTEM
- Dyspnea
- Difficulty clearing airway
- Complications: pneumonia, eventual respiratory failure

NUTRITIONAL EFFECTS
- Difficulty chewing
- Dysphagia
- Complication: malnutrition

EMOTIONAL EFFECTS
- Loss of control, lability
- Complication: depression

●○● INTERPROFESSIONAL CARE

Because many treatable disorders may cause manifestations similar to those that appear in the initial stage of ALS, a thorough evaluation is required. Once ALS is diagnosed, the primary goal is to support the patient and family in meeting physical and psychosocial needs, particularly as the disease progresses. There is no cure for ALS.

Medical and nursing care for patients with ALS is primarily supportive. Referral for home health management is indicated. Occupational, physical, speech, and respiratory therapy are major supportive and rehabilitative treatments. As the disorder progresses and swallowing becomes ineffective, a gastrostomy tube may be necessary to provide adequate nutritional intake. Ventilatory assistance should be discussed with patients before the need occurs.

DIAGNOSIS

There is no specific test to diagnose ALS. Rather, diagnosis is made based on manifestations and tests to rule out other diseases. A number of disorders may mimic early ALS, including hyperthyroidism, hypoglycemia, compression of the spinal cord, toxic agents, infections, and neoplasms.

MEDICATIONS

Riluzole (Rilutek), an antiglutamate, is the first medication developed to treat ALS. It inhibits the presynaptic release of glutamic acid in the CNS and protects neurons against the excitotoxicity of glutamic acid. This oral medication is administered without food at the same time each day. Patients are regularly monitored for liver function, blood count, blood chemistries, and alkaline phosphatase. They should be warned to report any febrile illness to their healthcare provider and to avoid alcohol.

●○● NURSING CARE

Nursing care focuses on current health problems and on anticipating future difficulties. As with other disorders causing incapacitation and dependence, individualized nursing goals and interventions relate to decreasing complications, especially those associated with loss of muscular function and immobility; promoting independence to the extent possible; initiating referrals, particularly to a support group for both patient and family; and providing physical and psychosocial support as indicated.

Of special consideration is planning for the patient's eventual inability to communicate. Because the patient's eye muscles and movements remain intact, signals can be prearranged before the loss of speech.

Diagnoses, Outcomes, and Interventions

Two nursing diagnoses that frequently apply to patients with ALS are *Risk for Disuse Syndrome* and *Ineffective Breathing Pattern*.

Risk for Disuse Syndrome

Patients with ALS are at risk for developing problems associated with bed rest, not only because they cannot move and reposition themselves, but also because they frequently have altered nutritional and hydration status. Nursing interventions focus on preventing skin breakdown and infections, such as urinary tract infections.

Expected Outcome: In patients with ALS, the risk for disuse syndrome will be eliminated or minimized by demonstration of physical movement, exercise, and performance of daily activities that are consistent with patient's abilities.

- Assess current condition for baseline parameters, particularly skin over bony prominences, lung sounds, and vital signs. *Understanding patient's current condition allows accurate future assessment and realistic planning.*
- Assess skin, provide skin care, and obtain an alternating-pressure mattress. *Pressure points are at risk for breakdown; early detection is crucial to instituting appropriate care.*
- Institute active ROM exercises, as the patient is able. Perform passive ROM exercises every 2 hours, when the patient is turned. *Contractures can develop within a week because extensor muscles are weaker than flexor muscles.*
- Maintain positive nitrogen balance and hydration status: Monitor prealbumin levels, hemoglobin and hematocrit levels, and urine specific gravity. *Adequate protein is required to maintain osmotic pressure and prevent edema; positive nitrogen balance promotes optimal body functioning.*
- Monitor for manifestations of infection; for example, assess urine, especially if a urinary catheter is present. *Urinary catheters place patients at high risk for sepsis; bed rest places the patient at greater risk for urinary stasis.*

SAFETY ALERT

Urinary tract infection (UTI) is indicated by cloudy, foul-smelling urine, pain on urination, fever, and general malaise. Nursing priorities are early detection of such symptoms in order to prevent urosepsis.

Ineffective Breathing Pattern

As the muscle weakness of ALS continues, patients become less able to breathe. The respiratory muscles are affected, and patients eventually may require ventilatory assistance. The nurse initiates measures to support the existing respiratory effort.

Expected Outcome: Patient's ineffective breathing patterns will be eliminated by demonstration of coughing, deep breathing, and expectoration of any secretions, as well as evidence of normal respiratory rate, lungs that are clear to auscultation, well-perfused skin and mucous membranes (pink), and normal range of pulse oximetry.

- Obtain a baseline assessment of breathing pattern, air movement, and oxygen saturation. *Assessments indicating the patient's current condition provide data to plan individualized interventions.*
- Turn at least every 2 hours. *Movement enhances the ability to move pulmonary secretions and prevents stasis.*
- Elevate the head of the bed at least 30 degrees, suction as indicated, and provide oxygen. *This supports ventilation and enhances lung expansion as the patient's condition changes.*
- Monitor temperature and lung sounds routinely; obtain sputum culture as indicated. *Early detection of a possible infectious process leads to prompt treatment.*

Delegation of Nursing Care Activities

As appropriate and allowed by the designated duties and responsibilities of unlicensed assistive personnel, the nurse may delegate nursing care activities such as turning and positioning of the patient at regular intervals, obtaining and reporting of pulse oximetry levels, and obtaining of vital signs to monitor temperature.

Continuity of Care

Initial teaching centers on explaining the disease process, expected course, and prognosis. Referral to a social worker to determine home care needs and financial assistance is helpful. Counseling and referrals to a home health agency, dietitian, and physical, speech, and occupational therapists can help the family meet the patient's changing needs and abilities. The realistic anticipation of needs cannot be overemphasized.

As the patient becomes more debilitated, family members or other care providers focus on preventing complications. For example, family members need to know how to suction the patient and perform the Heimlich maneuver to prevent aspiration. Teaching the family how to prevent problems related to immobility is a primary consideration for the nurse. Another focus of teaching is basic care needs, such as care required to meet elimination needs. Teach families methods to establish a bowel routine, considerations related to a urinary catheter, and the need to promptly report manifestations of an infection.

Throughout the early stage and continued care of the patient and family with ALS, much consideration is given to psychosocial concerns. Depression, anger, and denial may be initial reactions; refer the patient and family to an ALS support group, social worker, psychologist, or psychiatrist as indicated.

Moving Knowledge into Action

A study in 2010 examined quality of life, anxiety, and depression in patients with ALS and their families, and compared those findings with the general population. There was a correlation between patient anxiety and family anxiety, regardless of the level of physical debilitation. Implications for future practice include the need for medical and nursing support for the patient and family immediately after diagnosis and throughout the illness (Olsson Ozanne et al., 2011).

1. What are the priorities of care for a patient with ALS?
2. What risks would the nurse anticipate and monitor for in a patient with ALS?

Peripheral Nervous System Disorders

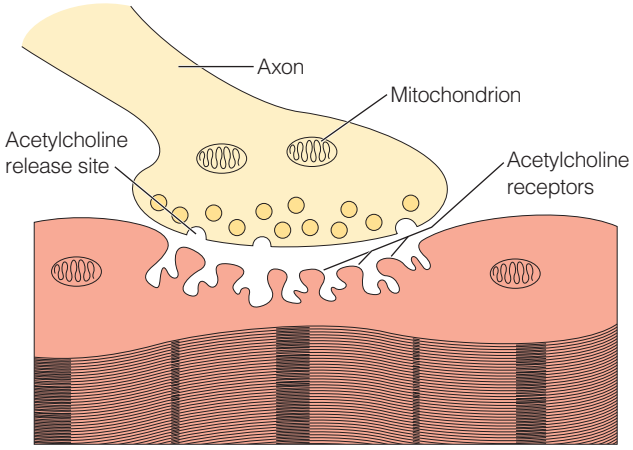
Many etiologic agents are responsible for PNS disorders. Autoimmune disorders, viruses, environmental toxins such as heavy metals, and nutritional deficiencies can affect the PNS.

THE PATIENT WITH MYASTHENIA GRAVIS

Myasthenia gravis (MG) is a chronic autoimmune neuromuscular disorder characterized by fatigue and severe weakness of skeletal muscles. Patients experience periods of remission and exacerbation, and mild forms of the disorder exist. Weakness may remain limited to a few muscle groups, especially the ocular muscles, or may become generalized with all muscles eventually becoming weakened.

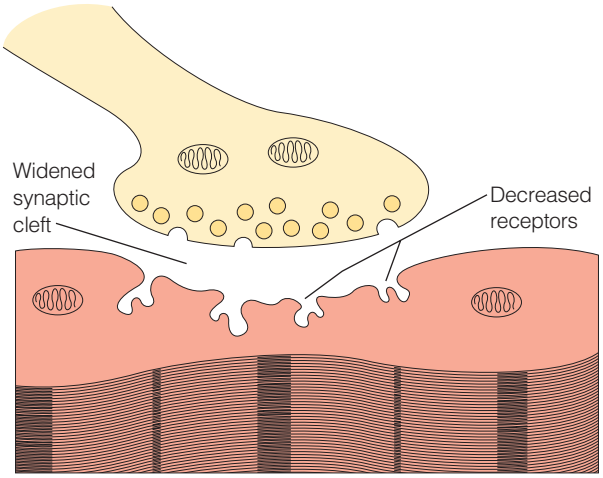
In the United States, an estimated 36,000 to 60,000 people are living with MG. The average age of onset and incidence for both men and women has changed as the population ages, with men affected more than women and the onset of manifestations usually beginning after age 50 (Myasthenia Gravis Foundation, 2013). Treatment with anticholinesterase medications has greatly improved the prognosis and management of manifestations.

Pathophysiology



The axons of motor neurons divide as they enter skeletal muscles, and each axonal ending forms a neuromuscular junction. Although the axonal ending and the muscle fiber are extremely close, they are separated by the synaptic cleft. The transmission of nerve impulses from the nerve to the muscles occurs at the neuromuscular junctions. The neurotransmitter acetylcholine is released from the axonal ending, crosses the synaptic cleft, attaches to acetylcholine receptors on the muscle fiber, and stimulates the muscle.

In MG, antibodies destroy or block neuromuscular junction receptor sites, resulting in a decreased number of acetylcholine receptors. Structural changes also result in diminished acetylcholine uptake. The net result is a decrease in the muscle's ability to contract despite a sufficient amount of acetylcholine. A comparison of a normal neuromuscular junction and one affected by MG is shown in Figure 44–4 ■.



In most patients with MG, the thymus gland, which is usually inactive after puberty, continues to produce antibodies because of hyperplasia of the gland or because of tumors. It is believed that the thymus is a source of an autoantigen that triggers an autoimmune response in MG. The exact mechanism and reason for the thymus gland's antibody production are unknown. MG is sometimes associated with thyrotoxicosis (hyperthyroidism), rheumatoid arthritis, and lupus erythematosus. The disorder is often diagnosed when a patient seeks treatment for a coincidental infection that exacerbates manifestations. Exacerbations may also occur before the menstrual period and during or soon after pregnancy.

Manifestations

The manifestations of MG correspond to the muscles involved. Initially, the eye muscles are affected and the patient experiences either diplopia (unilateral or bilateral double vision) or ptosis (drooping of the eyelid) (Figure 44–5 ■). Next, the facial, speech, and

MANIFESTATIONS OF MYASTHENIA GRAVIS

OCULAR AND FACIAL
- Ptosis
- Diplopia
- Facial weakness
- Dysphagia
- Dysarthria
- Complications: difficulty closing eyes, aspiration, impaired communication and nutrition

MUSCULOSKELETAL
- Weakness and fatigue
- Decreased function of hands, arms, legs, and neck muscles
- Complications: inability to perform ADLs and self-care activities, complications related to immobility, and myasthenic and cholinergic crises

RESPIRATORY
- Weakening of intercostal muscles
- Decrease in diaphragm movement
- Breathlessness and dyspnea
- Poor gas exchange
- Complications: decreasing ability to walk, eat, and perform other ADLs, pneumonia

NUTRITIONAL
- Inability to chew and swallow
- Decreasing ability to move tongue
- Impairment of fine motor movements: inability to feed self
- Complications: weight loss, dehydration, malnutrition, aspiration

mastication muscles become weak, and patients may have periods of dysarthria (speech disorder) and dysphagia (difficulty swallowing). Fatigue is evident even when the patient tries to eat a meal; the chewing muscles tire, and the patient is forced to stop eating momentarily. A smile becomes a snarl or grimace, and the voice is weak with a muffled nasal quality. Problems performing fine motor movements of the hands, such as writing, appear early in the disease.

As the disease progresses, the muscles of the neck and extremities are affected. When the muscles of the neck become affected, the head juts forward. Deep tendon reflexes are usually normal, however, even in weak muscles. Fatigue and weakness are exacerbated with stress, fever, overexertion, and exposure to heat and are relieved by rest. Manifestations vary on a daily basis. Manifestations of MG are listed in the accompanying Manifestations box.

Complications

Complications are directly related to the degree of muscle weakness and the specific muscles involved. For example, when the pharyngeal and palatal muscles are affected, the patient cannot manage swallowing and may aspirate food or fluids. The patient is at increased risk for pneumonia because weakness of the diaphragm and muscles of respiration compromises gas exchange. Patients with MG can develop life-threatening emergencies, including myasthenic crisis and cholinergic crisis. Airway maintenance and ventilatory support are cornerstones of treatment (Kutzin, 2011).

MYASTHENIC CRISIS

Myasthenic crisis is a sudden exacerbation of motor weakness putting the patient at risk of respiratory failure and aspiration. Myasthenic crisis most often is due to undermedication, missed doses of medication, or a developing infection. Manifestations of myasthenic crisis include tachycardia, tachypnea, severe respiratory distress, dysphagia, restlessness, impaired speech, and anxiety.

CHOLINERGIC CRISIS

Cholinergic crisis is the result of overdosage with the anticholinesterase (cholinergic) medications used to treat MG. Gastrointestinal manifestations, severe muscle weakness, vertigo, and respiratory distress are signs of cholinergic crisis. Both types of crises are emergency, life-threatening situations; patients frequently require ventilatory assistance. Differentiation is based on the patient's response to edrophonium chloride (Tensilon). In myasthenic crisis the test is positive, and in cholinergic crisis the test is negative. Treatments for cholinergic crisis include plasmapheresis and intravenous immune globulin therapy (Kutzin, 2011).

●○● INTERPROFESSIONAL CARE

Care of the patient with MG focuses on providing appropriate treatment, preventing complications, and supporting the patient and family in meeting physical and psychosocial needs, especially as the disease progresses.

DIAGNOSIS

Diagnostic tests are conducted following a thorough history and physical examination, with special attention to the facial, oculomotor, laryngeal, and respiratory muscles. Diagnostic tests include the anticholinesterase (Tensilon) test, nerve stimulation studies, and an analysis of antiacetylcholine receptor antibodies.

In the Tensilon test, the patient is injected with edrophonium chloride (Tensilon), a short-acting anticholinesterase. Patients with MG show a significant improvement in muscle strength that lasts approximately 5 minutes. This test is also used to differentiate myasthenic crisis (caused by insufficient medication, so the patient shows improvement with the drug) from cholinergic crisis (caused by overmedication, so the patient does not show improvement).

Single-fiber electromyography can detect delayed or failed neuromuscular transmission in muscle fibers supplied by a single nerve fiber. Serum assay of circulating acetylcholine receptor antibodies, if increased, is strongly diagnostic of MG.

MEDICATIONS

The primary medications used to treat MG are the anticholinesterases. These drugs act at the neuromuscular junction and allow acetylcholine to concentrate at the receptor sites, thus promoting muscle contraction. Pyridostigmine (Mestinon) and neostigmine (Prostigmin) are the most commonly used acetylcholinesterase inhibitors for MG. The patient's decrease in manifestations guides dosage.

Immunosuppression with glucocorticoids, typically prednisone, is another pharmacologic therapy aimed at improving muscle strength. Patients must be aware of the need to stay on the drug at the prescribed dose to determine the least amount required for efficacy. If patients do not respond to prednisone alone, it may be combined with other immunosuppressive agents, such as cyclosporine or azathioprine (Imuran). Medications used to treat MG are discussed in the accompanying Medication Administration box.

MEDICATION ADMINISTRATION

The Patient with Myasthenia Gravis

ANTICHOLINESTERASES/CHOLINESTERASE INHIBITORS

neostigmine (Prostigmin)

ambenonium (Mytelase Caplets)

pyridostigmine (Mestinon, Regonol)

For diagnosis: edrophonium chloride (Tensilon)

Cholinesterase inhibitors are used in MG to enhance the effects of acetylcholine at the remaining skeletal muscle receptors. Cholinesterase inhibitors do not cure or change the underlying pathophysiologic processes, but they can provide effective, lifelong improvement of symptoms. Because the cholinesterase inhibitors are nonselective, the neuromuscular, muscarinic, and ganglionic junctions are each affected.

Adjusting the dose to obtain maximum benefit with minimal side effects is a major consideration when administering cholinesterase inhibitors. Initially, small doses are given followed by incremental increases until optimal muscle strength is obtained. The dose may need to be adjusted when activities result in symptoms of undermedication, such as increased ptosis. Severe undermedication results in myasthenic crisis. Although a sustained-release form of pyridostigmine is available for bedtime use, it should not be used during the day because of its inconsistent absorption.

Cholinesterase inhibitors should not be administered to patients experiencing obstruction of the intestinal or urinary tract. Caution is advised when administering these drugs to patients with asthma, hyperthyroidism, bradycardia, or peptic ulcer disease. Cholinesterase inhibitors can cross the placenta; reproductive counseling is indicated.

Nursing Responsibilities

- Obtain a baseline assessment of muscle strength and abilities, concentrating on swallowing and ptosis.
- Administer the medication parenterally if the patient has dysphagia. Check the dose of the medication carefully when changing from oral to parenteral routes.
- Evaluate the effectiveness of the medication and document the response, for example, time when fatigue occurs in relation to activities.
- Promptly recognize and respond to manifestations of excessive stimulation of muscarinic receptors: excess salivation, urinary urgency, bradycardia, gastrointestinal hypermotility, diaphoresis. Atropine can be administered to combat these manifestations. Respiratory depression and failure can occur and require mechanical ventilation.
- Have a muscarinic antagonist (e.g., physostigmine) readily available to treat poisoning.

Health Education for the Patient and Family

- Balancing symptom control with dosage is crucial; record time of dose and response in a journal. Note the time of day when fatigued and any adverse effects, such as excess salivation, sweating, slow heartbeat, and diarrhea.
- Take the medication about 30 minutes prior to meals to enhance swallowing and chewing.
- Report manifestations of myasthenic crisis immediately: severe muscle weakness, fast heartbeat, restlessness, difficulty breathing, increasing difficulty swallowing or speaking.
- Report slow heartbeat, increased salivation or sweating, and/or decreased blood pressure immediately.
- Review possible causes of myasthenic crisis: physical or emotional stress, infection, or reduction in the medication dosage.
- Wear or carry medical alert identification.

SURGERY

Thymectomy is often recommended for patients younger than 60. The two surgical approaches used are the transcervical approach, which is considered less invasive, and the transsternal approach. The latter approach allows a more extensive removal of the gland; however, it also poses more potential complications because it involves splitting the sternum.

Preoperatively, patients may be tapered from steroid therapy. Usually, pyridostigmine is administered to prevent muscular manifestations during the perioperative period. Postoperative nursing care focuses on preventing complications and controlling pain. Nursing implications for the patient undergoing thymectomy are presented in the accompanying Nursing Care box. Remission may take several years to achieve. Refer to Chapter 36 for care of the patient having a thoracotomy and chest tubes. A tracheostomy may be required when the diaphragm or intercostal muscles are involved.

PLASMAPHERESIS

Plasma exchange in MG may be used in conjunction with other therapies; for example, it may be performed prior to surgical intervention or following administration of high-dose intravenous immune globulin (NINDS, 2012c). The goal of therapy is to remove the antiacetylcholine receptor antibodies, thus improving severe muscle

NURSING CARE OF THE PATIENT

Having a Thymectomy

PREOPERATIVE

- Reinforce the physician's explanation of the procedure, and prepare the patient for chest tubes and tracheostomy. *Realistic preparation of what to expect postoperatively encourages compliance and allays anxiety.*
- Anticipate the need for alternative communication. *The patient may have a tracheostomy; preoperative planning facilitates communication after surgery.*
- Allow sufficient time for questions. *Thymectomy is a major surgery requiring either a thoracotomy and sternal split or transcervical approach. The patient is usually anxious, and adequate time must be allocated to preoperative instruction.*

POSTOPERATIVE

- Provide meticulous pulmonary hygiene: turning, deep breathing, and coughing at least every 2 hours; use an incentive spirometer. *Regardless of surgical approach, measures are aimed at preventing pulmonary complications of atelectasis and pneumonia.*
- Patients with a thoracotomy and sternal split procedure will require care of the anterior chest tube. Observe for complications, such as pneumothorax. *Air may enter the thoracic cavity—be alert for sudden chest pain and dyspnea, decreased breath sounds, and early signs of shock, such as restlessness.*
- Manage pain with scheduled analgesic therapy. *Maintaining a therapeutic blood level of analgesic provides better pain control than waiting until the patient requests medication, as on a prn basis.*

NURSING CARE OF THE PATIENT

Treated with Plasmapheresis

PREPROCEDURE

- Teach about the procedure and what to expect, including what the machine looks like, the need for arterial and venous insertion sites, and the length of time of the procedure (2 to 5 hours). *Giving information, answering questions, and addressing concerns decrease anxiety*.
- Check with physician about holding medications until after the procedure. *Medications may be removed from the body as an incidental part of the plasmapheresis process.*
- Assess vital signs and weight. *Baseline parameters are necessary to evaluate for fluid imbalances and response to therapy.*
- Assess CBC, platelet count, and clotting studies. *Patients undergoing plasmapheresis are at high risk for anemia and coagulation problems secondary to hemolysis of cells*.
- Check blood type and crossmatch for replacement blood products. *Hypersensitivity reactions can occur, and close monitoring is important.*

CARE DURING AND AFTER THE PROCEDURE

- Observe for dizziness or hypotension. *Hypovolemia is a complication of plasma exchange, especially during the procedure when up to 15% of the patient's blood volume is in the cell separator*.
- Apply pressure dressing to access site(s). *Direct pressure helps decrease or prevent bleeding*.
- Monitor for infection and bruises at the intravenous port site. *The site of vascular access is at risk for complications and must be routinely and carefully assessed for signs of infection and for bleeding or hematoma formation.*
- Monitor electrolytes and signs of electrolyte loss. Report imbalances, and replace electrolytes as ordered. Observe for circumoral tingling, Chvostek's and Trousseau's signs if calcium levels are low, and cardiac dysrhythmias and leg cramps if potassium levels are low. *Hypocalcemia and hypokalemia may occur. Hypocalcemia occurs because the anticoagulant citrate dextrose binds with calcium.*
- Reevaluate preprocedure laboratory data, especially CBC, platelet count, and clotting times. *The cell-separating process can damage cells; anticoagulation is part of the procedure.*

weakness, fatigue, and other manifestations. The procedure is frequently performed when respiratory muscle involvement is evident. See Figure 44–6 ■ and the accompanying box for nursing care of the patient undergoing plasmapheresis.

●○● NURSING CARE

Because avoiding fatigue is a major part of teaching, it is important to incorporate interventions to enhance rest and conserve energy (Box 44–2). For example, suggest sitting while preparing meals and while performing hygiene and grooming. Anticipating problems, such as impaired communication, and developing alternative solutions can be helpful in promoting independence.

Figure 44–6 ■ Plasmapheresis is a procedure used to separate the blood's cellular components from plasma. About 50 mL/min is withdrawn to the centrifuge in the plasmapheresis machine. The plasma is replaced with donor plasma or colloids and returned to the patient.
Source: Courtesy of Baxter Healthcare Corporation.

BOX 44–2 Patient and Family Teaching: Myasthenia Gravis

- Schedule periods of rest and avoid stress; conserve energy when possible.
- Avoid cigarette smoke, alcohol, and beverages with quinine (e.g., tonic water).
- Take medications as prescribed. If manifestations change, consult the physician; the dose may need to be adjusted.
- Avoid extremes of temperature; an environment that is too hot or too cold may cause an exacerbation of MG.
- Avoid people with upper respiratory infections; infections can result in an exacerbation and extreme weakness.

Diagnoses, Outcomes, and Interventions

Nursing care of patients with MG focuses not only on present problems but also on anticipated needs. Preventing myasthenic and cholinergic crises and providing psychologic support to patients and families are two important aspects of care. Individualized care depends on the specific therapy instituted.

Ineffective Airway Clearance

The underlying causes of ineffective airway clearance for the person with MG include poor cough mechanism, decreased rib cage expansion, diminished diaphragm movement, and decreased expiratory effort. The following interventions require particular attention if the patient undergoes a thymectomy.

Expected Outcome: Ineffective airway clearance will be minimized as evidenced by patient's ability to expectorate secretions, maintain clear lungs, and demonstrate normal pulse oximetry and oxygenation patterns on assessment.

- Assist with turning, deep breathing, and coughing at least every 2 hours. Teach proper coughing techniques; use an incentive spirometer every 2 hours while the patient is awake. *Position changes promote lung expansion; coughing helps clear secretions from the tracheobronchial tree.*

- Place in a semi-Fowler's position. *This position expands the lungs and alleviates pressure from the diaphragm, especially important if the patient is obese.*
- Maintain hydration status and monitor for dehydration; use a humidifier as needed. If needed, teach family how to perform percussion, postural drainage, and suction. *Interventions to liquefy secretions, such as ensuring a daily fluid intake of up to 2500 mL (perhaps via feeding tube or parenteral route), help the patient mobilize and expectorate sputum.*

Impaired Swallowing

Patients with MG have weakness of the laryngeal and pharyngeal muscles involved with swallowing. Alterations in swallowing place the patient at risk for poor nutrition as well as for possible aspiration. Family members need to be included in teaching, particularly the person who prepares and assists with meals.

Expected Outcome: Risk for aspiration related to impaired swallowing will be prevented by sitting the patient in high-Fowler's position if able to maintain oral intake, and by avoiding thin liquids that increase that risk.

- Assess the ability to safely manage various consistencies of foods; consult with a speech therapist for evaluation. *Dysphagic patients are at risk for aspiration; matching food consistency to the patient's ability to swallow enhances safety.*
- Plan meals to promote medication effectiveness. *Pyridostigmine should be given 30 minutes before the meal to provide optimal muscle strength for swallowing and chewing.*
- Have the patient eat slowly, using small bites of food. Schedule meals during periods when the patient is adequately rested; develop a daily schedule incorporating rest periods. *Fatigue may add to dysphagia, putting the patient at greater risk for aspiration.*
- If necessary, give cues while eating, such as "Chew your food thoroughly; swallow." *Keeping patient focused may enhance swallowing.*
- Teach caregivers the Heimlich maneuver and how to suction. *Knowing specific measures to take in case of aspiration decreases both the patient's and family's anxiety and promotes confidence in managing potential problems.*

Delegating Nursing Care Activities

As appropriate and allowed by the designated duties and responsibilities of unlicensed assistive personnel, the nurse may delegate nursing care activities such as mobilizing, positioning, and turning the patient as well as encouraging coughing and deep breathing. Delegation can include encouraging fluids and monitoring intake and output, as well as feeding patient and monitoring consistency of liquids if taking orally (e.g., thickening of liquids).

- Monitor lung sounds, the rate and character of respirations, and pulse oximetry readings at least every 4 hours or as indicated by patient's condition. *Frequent assessments are critical to early identification of ineffective respirations and oxygenation of tissues.*

Continuity of Care

Teaching the patient and family with MG focuses on prevention and recognition of crisis situations, understanding the disorder, and methods for coping with both physical and psychosocial problems. Setting realistic goals with the patient and family provides opportunities for self-assessment and promotes active participation in rehabilitation. Address the following topics:

- The importance of maintaining consistency in medication dosage and management
- Realistic expectations
- Methods to avoid fatigue and undue stress; specific measures for avoiding upper respiratory infections and exposure to extreme heat or cold
- Birth control measures or referral for counseling (Pregnancy can exacerbate manifestations; also, medications used to control MG, such as neostigmine bromide [Prostigmin], cross the placenta.)
- Referral to support groups
- Helpful resources such as the Myasthenia Gravis Foundation of America, Inc.

THE PATIENT WITH GUILLAIN-BARRÉ SYNDROME

Guillain-Barré syndrome (GBS) is an acute inflammatory demyelinating disorder of the PNS characterized by an acute onset of motor paralysis (usually ascending). Guillain-Barré syndrome is one of the most common PNS disorders, affecting about 3500 people in the United States and Canada each year (Lugg, 2010). The cause is unknown, but precipitating events include a respiratory or gastrointestinal viral or bacterial infection 1 to 3 weeks prior to the onset of manifestations, surgery, viral immunizations, and other viral illnesses. In 60% of cases, *Campylobacter jejuni* is identified as the cause of the preceding infection. Approximately 80% to 90% of patients with GBS have a spontaneous recovery with little or no residual disabilities.

The disease is characterized by progressive ascending flaccid paralysis, accompanied by paresthesias and numbness. About 20% of patients have respiratory involvement to the point that ventilatory assistance is required. GBS is often a medical emergency.

FAST FACTS

GBS is a rare and acute autoimmune disease, affecting men and women in equal numbers. It has a similar morbidity across all age ranges, affecting 2 people per 100,000 every year. In as many as 40% of patients, there is no specific precipitating event (Lugg, 2010).

Pathophysiology

The primary pathophysiologic process in GBS is the destruction of myelin sheaths covering the axons of peripheral nerves. The demyelination is thought to be the result of both a humoral- and cell-mediated immunologic response. Myelin insulates the neuron and facilitates conduction of impulses. The loss of myelin results in poor conduction of nerve impulses, causing sudden muscle weakness and loss of reflex response. In the worst cases, complete paralysis occurs. Up to 30% require mechanical ventilation due to respiratory dysfunction (Lugg, 2010). Other manifestations occur when nerve conduction to various muscles is interrupted. The stages of Guillain-Barré syndrome and their usual manifestations are presented in Box 44–3.

Manifestations

Muscles, sensory nerves, and cranial nerves are commonly affected in patients with GBS. Most people experience symmetric muscle weakness, initially in the lower extremities. The weakness and sensory

BOX 44–3 Stages of Guillain-Barré Syndrome

I. ACUTE STAGE
- Characterized by severe and rapid weakness, especially in the lower extremities; loss of muscle strength progressing to quadriplegia and respiratory failure; decreasing deep tendon reflexes; decreasing vital capacity; paresthesias, numbness; pain, especially nocturnal; facial muscle involvement (inability to wrinkle forehead or change expressions)
- Involvement of the autonomic nervous system manifested by bradycardia, sweating, fluctuating blood pressure (notably hypotension), which may last for 2 weeks

II. STABILIZING/PLATEAU STAGE
- Occurs 2 to 3 weeks after initial onset
- Marks the end of changes in condition; characterized by a "leveling off" of symptoms
- Generally, the labile autonomic functions stabilize

III. RECOVERY STAGE
- May take from several months to 2 years
- Marked by improvement in symptoms
- Generally, muscle strength and function return in descending order

loss then ascends to the upper extremities, torso, and cranial nerves. Sensory involvement includes severe pain, paresthesia, and numbness. Cognition and level of consciousness are not affected. Facial nerve involvement results in the inability to change facial expressions and close the eyes. Muscles involved with chewing, swallowing, and speaking may be affected.

Paralysis of intercostal and diaphragmatic muscles may alter respiratory function. These patients require ventilatory assistance and supportive care. Involvement of the autonomic nervous system is characterized by fluctuating blood pressure, cardiac dysrhythmias and tachycardia, paralytic ileus, syndrome of inappropriate antidiuretic hormone secretion, and urinary retention.

The weakness usually plateaus or improves by the fourth week. Strength then improves slowly over weeks or months. Women who have had GBS are at increased risk for relapse in the first trimester of pregnancy.

●○● INTERPROFESSIONAL CARE

Interventions during the acute phase (1 to 3 weeks) focus primarily on ensuring oxygenation via ventilatory assistance and preventing complications from immobility. Rehabilitation time to regain muscle strength and function varies; most people return to full presyndrome muscle function within 6 months to 2 years.

Care of the patient with GBS requires an interprofessional approach. From the initial acute phase through rehabilitation, many members of the healthcare team are involved. An accurate and rapid diagnosis is needed to ensure prompt supportive treatment, particularly if there is respiratory involvement combined with widespread paralysis.

DIAGNOSIS

GBS is diagnosed after a thorough history and clinical examination, differentiating from several disorders, among them influenza, heavy metal poisoning, Lyme disease, and cranial hemorrhage. Diagnosis is made based on manifestations, history of a recent viral infection, elevated CSF protein levels, and EMG studies reflecting decreased nerve conduction. Although there is no specific test to diagnose this syndrome, several findings support and confirm the diagnosis. If GBS is suspected, then diagnostic procedures to confirm the diagnosis may include computed tomography (CT) scan of the head or body, a lumbar puncture, and/or a nerve conduction study (Lugg, 2010).

MEDICATIONS

No medications are available for the specific treatment of Guillain-Barré syndrome. Other medications may be prescribed to provide support or prophylaxis, or to combat concurrent problems; for example, antibiotics may be prescribed for urinary tract or respiratory infections. The most common organism linked to the onset of GBS is *Campylobacter* (Lugg, 2010). Morphine is commonly administered to control muscle pain. Anticoagulation therapy is usually instituted to prevent thromboembolic complications, such as deep venous thrombosis and pulmonary embolism, which are associated with prolonged bed rest. If hypotension is a problem, vasopressors are prescribed.

SURGERY

Tracheostomy is performed if respiratory failure occurs. An inability to clear secretions or an ineffective gag or swallow reflex may also require an artificial airway, and is usually the result of demyelinated cranial nerves IX, X, and XII (Lugg, 2010). Patients who need ventilatory support are usually able to be weaned after 2 to 3 weeks, but the time frame varies greatly. When the patient's vital capacity reaches 8 to 10 mL/kg, he or she may be weaned from the ventilator (Hickey, 2013). Insertion of a temporary pacemaker may be indicated for bradycardia.

PLASMAPHERESIS

Plasma exchange has been beneficial, particularly when performed within the first 2 weeks of the syndrome's development. Antibodies are removed, and immunosuppressive agents are administered concurrently. Patients typically have five exchanges during an 8- to 10-day period.

NUTRITION AND FLUIDS

Nutritional support for the patient who is immobilized for prolonged periods of time is crucial. Maintaining positive nitrogen balance, ensuring sufficient fluid intake and electrolyte balance, and ensuring recommended caloric intake are goals of therapy. When swallowing problems occur, total parenteral nutrition may be indicated if feeding via a nasogastric or gastrostomy tube is ineffective.

PHYSICAL AND OCCUPATIONAL THERAPY

Long-term physical and occupational therapy are crucial to recovery. Patients with Guillain-Barré syndrome usually require prolonged rehabilitation care, which begins during the acute phase and focuses on preventing complications and limiting the effects of immobility. The severe muscle atrophy and loss of muscle tone require that patients relearn many functions and skills, such as walking. Compromise in respiratory function may delay physical rehabilitation; patients need positive reinforcement when they make even small gains in their progress. Continued attention to

pain control is essential because paresthesia and pain can interfere with physical therapy.

●○● NURSING CARE

Many of the nursing interventions for patients with this syndrome involve monitoring neurologic function, preventing problems of immobility, ensuring adequate hydration and nutrition, and promoting respiratory function. Anticipating needs of both the patient and family is an important aspect of care. For example, developing an alternative method of communication before it is necessary may decrease anxiety.

Priorities of Care

Nursing care focuses on preventing complications that may be fatal by following a rigorous predetermined schedule for turning and respiratory care (e.g., coughing, deep breathing, suctioning), by using strict aseptic technique, and by providing continuous psychosocial support.

Diagnoses, Outcomes, and Interventions

Anxiety and powerlessness are major nursing considerations. The patient is almost always admitted to the ICU for care, and is mentally alert but suddenly mute, ventilator dependent, and immobile. Refer to previous nursing care sections in this chapter for interventions related to anxiety, imbalanced nutrition, impaired swallowing, impaired verbal communication, and ineffective airway clearance. This section focuses on the nursing diagnoses of *Pain* and *Risk for Impaired Skin Integrity*.

Acute Pain Related to Muscle Atrophy

Pain experienced with Guillain-Barré syndrome varies. Frequently, there is a "stocking–glove" pattern, with pain in the hands, feet, and legs. Pain and tenderness in muscles can be severe; interventions are individualized to meet patient needs. The intense pain combined with altered sensations leads to anxiety; nursing interventions can make a difference in breaking the cycle of increasing pain that leads to increased anxiety and in turn causes more pain.

Expected Outcome: Patient's acute pain related to muscle atrophy will be controlled as evidenced by assessments of pain of 1 to 3 on a 0-to-10 pain scale, minimal grimacing, and optimal movement and comfort expressed by patient.

- Listen to the description of pain; determine presence of triggers or a pattern. *Acknowledging the patient's perception of pain is a basis for treatment; listening establishes trust.*
- Use a pain scale for determining extent of pain. *Consistent measurement is essential to evaluate degree of pain and effectiveness of intervention.*
- Use complementary therapies to help manage pain:
  - Application of heat/cold
  - Guided imagery
  - Relaxation techniques
  - Massage.

  Presenting options for managing pain gives the patient control over the situation and helps reduce anxiety. Noninvasive interventions may augment the therapeutic benefit of medications.
- Provide analgesics as indicated; administer on a regular schedule rather than waiting until pain becomes severe. *Anticipating and managing pain before it becomes severe decreases anxiety and averts the cycle of increased anxiety, leading to increased pain.*
- Monitor for side effects of analgesics, particularly respiratory depression; assess respirations and lung sounds. Perform routine pulmonary care measures and monitor for aspiration. *Patients with Guillain-Barré syndrome have weakened thoracic muscles; frequent respiratory monitoring is indicated.*

Risk for Impaired Skin Integrity

During the acute and plateau stages of Guillain-Barré syndrome, patients are at risk for problems related to immobility and malnutrition. Impaired skin integrity is one such problem. Preventing areas of skin breakdown is important. Prophylactic interventions will help ensure that ingested protein and calories are used to maintain ideal body weight and other body functions rather than to heal an avoidable problem. Implicit in interventions is maintenance of adequate nutrition.

Expected Outcome: Patient's risk for impaired skin integrity will be eliminated or minimized as evidenced by absence of skin breakdown.

- Inspect bony prominences and provide skin care at least every 2 hours. Reposition the patient and clean, dry, and lubricate the skin as needed. *These activities stimulate circulation and ensure an even distribution of body weight; baseline observations allow discovery of early signs of altered integrity.*
- Pad bony prominences, such as sacral area, heels, and elbows. *This decreases shearing tears on these pressure points.*
- Use an alternating-pressure mattress or water bed. *Relieving pressure stimulates circulation and promotes oxygenation of tissues.*
- Monitor for incontinence and provide thorough skin care following each episode of incontinence. *Urine is caustic to the skin, and the moisture promotes skin breakdown.*

Continuity of Care

Patients and family members are frequently stunned by the rapid deterioration of function and fear that the paralysis will be permanent. Regularly reinforce teaching because the patient's high anxiety level may interfere with listening and understanding. When possible, include the patient and family in decision making; seek their input when planning a daily schedule of care that incorporates various therapies.

Teaching the rationales for preventive measures reinforces the patient's and family's understanding and may promote compliance during the lengthy rehabilitation. For example, because of autonomic nerve involvement, patients need to be monitored for cardiac dysrhythmias and taught to avoid changing position suddenly to prevent orthostatic hypotension.

Referrals to appropriate therapists are a component of anticipating needs; speech, nutritional, occupational, and physical therapists are an integral part of rehabilitation. Another focus of care is teaching both the patient and family; incorporate explanations for interventions aimed at promoting self-care. For further information, refer the patient and family to the Guillain-Barré Syndrome Foundation, International.

Cranial Nerve Disorders

Disorders of the cranial nerves may be caused by intracranial trauma or by pathologic processes. The pairs of cranial nerves, described in Chapter 41, are numbered in the order in which they arise in the brain and are named according to their anatomic characteristic or primary function. The most common cranial nerve disorders are those affecting the trigeminal (cranial nerve V) and the facial (cranial nerve VII) nerves. These disorders, discussed in the following sections, result primarily in pain or loss of sensory or motor function.

THE PATIENT WITH TRIGEMINAL NEURALGIA

Neuralgia is characterized by severe, brief, repetitive attacks of lightning-like or throbbing pain, occurring along the distribution of a spinal or cranial nerve. The pain usually follows stimulation of the cutaneous region supplied by that nerve. **Trigeminal neuralgia (TN)**, also called *tic douloureux*, is a chronic disease of the trigeminal cranial nerve (V) that causes unilateral excruciating facial pain. The trigeminal nerve has three divisions: ophthalmic, maxillary, and mandibular (Figure 44–7 ■). The maxillary and mandibular divisions are affected in almost all cases of this disorder.

TN is more common in women than in men, occurring most often in middle or late adult life.

Pathophysiology

The actual cause of TN is unclear, but it is generally accepted that TN follows vascular compression and demyelination of the trigeminal nerve (Hickey, 2013). Contributing factors include trauma, dental or jaw infections, flu-like illnesses, aneurysm, tumor, and MS.

Stimulating specific areas of the face, called trigger zones, may initiate the onset of pain. These trigger zones are small areas on the cheek, lip, gum, or forehead that are sensitive to even minimal stimuli. The pain episodes are initiated by many factors, including light touch, eating, swallowing, talking, sneezing, shaving, chewing gum, brushing the teeth, or washing the face. Other factors that may trigger a pain episode include changes in temperature and exposure to wind. In an attempt to control the pain, patients may refuse to wash, shave, eat, or talk.

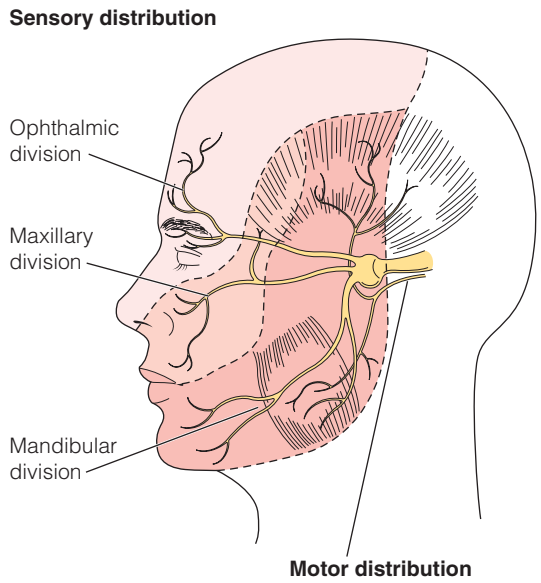

Figure 44–7 ■ Sensory and motor distribution of the trigeminal nerve. The three sensory divisions are ophthalmic, maxillary, and mandibular.

Manifestations

Trigeminal neuralgia is characterized by brief (lasting a few seconds to a few minutes), repetitive episodes of sudden severe facial pain. The pain may occur as often as hundreds of times a day to as infrequently as a few times a year. The pain is experienced over the surface of the skin. It most often begins near one side of the mouth and rises toward the ear, eye, or nostril on the same side of the face.

The episodes of pain may recur for several weeks or months. The disease then spontaneously goes into remission, and the patient is free of pain for periods lasting from days to years. As the patient grows older, the remissions tend to become shorter, and a dull ache may be present between episodes of acute pain.

●○● INTERPROFESSIONAL CARE

There are no specific diagnostic tests for TN. The disorder is diagnosed by the characteristic location and type of pain. The disorder is treated by pharmacologic or surgical interventions.

MEDICATIONS

The drug most useful in controlling the pain is the tricyclic anticonvulsant carbamazepine (Tegretol). If carbamazepine is ineffective, other medications such as the anticonvulsants phenytoin (Dilantin) or gabapentin (Neurontin) or the skeletal muscle relaxant baclofen (Lioresal) may be used. These drugs are administered to decrease paroxysmal afferent impulses and stop the pain. Drugs in this category may cause side effects of dizziness, nausea, and drowsiness. Liver function, bone marrow function, and blood levels of the medications should be monitored on a regular basis.

SURGERY

If medications do not control the pain, surgical procedures may be performed, including various types of rhizotomy, the surgical severing of a nerve root. Closed surgical interventions by percutaneous rhizotomy involve inserting a needle through the cheek into the foramen ovale at the base of the brain and partially destroying the trigeminal nerve with glycerol (an alcohol), by radiofrequency-induced heat, or by balloon compression of the trigeminal ganglion. These procedures carry less risk and result in shorter hospital stays than do open procedures, but there is a possibility of recurrence of pain. Following surgery, the patient may have some facial numbness, but there usually is no residual paralysis. The patient will have some loss of facial sensation (e.g., to temperature, pain, and/or touch) and is at risk for loss of the corneal reflex. Closed procedures provide long-term pain relief and are well tolerated by the older adult. Nursing care of the patient undergoing a percutaneous rhizotomy is presented in the accompanying box.

NURSING CARE OF THE PATIENT

Having a Percutaneous Rhizotomy

POSTOPERATIVE

- Follow routine postoperative interventions for patients having surgery (refer to Chapter 4).
- Monitor cranial nerve function every 2 to 4 hours:
  a. Assess the corneal reflex by lightly touching the cornea with a wisp of cotton. If the reflex is intact, the patient will blink. *Severing the ophthalmic division of the trigeminal nerve destroys the corneal reflex and leaves the cornea at risk for dryness and injury.*
  b. Assess the facial nerve by asking the patient to blow out the cheeks, wrinkle the forehead, frown, wink, and close both eyes tightly. Test taste by placing bitter, salty, and sweet substances on the anterior portion of the tongue. *Facial weakness is evidenced by changes in movement in the involved side of the face. The facial nerve also innervates the anterior two-thirds of the tongue.*
  c. Assess the function of the oculomotor muscles by asking the patient to follow your finger through the cardinal positions of vision (see Chapter 45). *The eyes should move together; alterations in movement indicate an abnormal response*.
  d. Assess the motor portion of the trigeminal nerve by asking the patient to clench the teeth while you palpate the tightness of the contracted masseter and temporal muscles. *Loss of motor function is indicated by loss of bulk and tightness of these muscles.*
  e. Apply, as prescribed, an ice pack to the jaw on the operative site. *Cold decreases bleeding and swelling.*
  f. Teach the patient to avoid rubbing the eye on the involved side. *Loss of the corneal reflex removes protection because the patient no longer has the sensation of pain in the involved eye. Rubbing the eye could cause corneal abrasions.*

●○● NURSING CARE

Priorities of Care

Nursing care for the patient with TN involves teaching self-management at home after medical or surgical intervention. Primary patient concerns are managing pain, maintaining nutrition, and preventing injury.

Diagnoses, Outcomes, and Interventions

Interventions for managing pain and improving nutritional intake are addressed here; teaching to prevent injury following surgery is discussed under patient and family teaching.

Acute Pain

The patient with TN has excruciating pain and often avoids ADLs and socializing with others in an attempt to prevent the onset of pain. Pain management is fully discussed in Chapter 9. Nursing interventions for pain in patients with this disorder focus on strategies for self-management.

Expected Outcome: Patient's acute pain will be controlled at a tolerable level as evidenced by objective and subjective pain assessment (use of pain scale, lack of grimacing, verbal assessment of pain, interaction with others, and vital signs).

- Identify factors that trigger an attack, and discuss strategies to avoid these precipitating factors. *Most patients can clearly identify trigger zones and triggering factors. Identification is the first step in pain control.*
- Determine usual response to pain. *Sensitivity and reaction to pain are influenced by previous experiences with pain and by age, gender, emotional factors, and cultural background.*
- Assess factors that affect the ability to influence pain tolerance, including the knowledge and cause of the pain, the meaning of the pain, the ability to control the pain, cultural background, and support systems. *Pain tolerance, which is the duration and intensity of pain an individual is willing to endure, differs greatly among individuals and may also vary within particular patients in different situations.*
- Monitor the effects of the medication prescribed for the neuralgia. *If the prescribed medication does not provide relief, other medications or methods of treatment may be used to control the pain.*

Delegating Nursing Care Activities

As appropriate and allowed by the designated duties and responsibilities of unlicensed assistive personnel, the nurse may delegate nursing care activities such as prompt reporting of any change in patient's behavior (e.g., complaints of pain to assistive personnel, restlessness, changes in vital signs) and maintenance of a quiet, dark, relaxed environment.

Risk for Altered Nutrition: Less Than Body Requirements

Patients often refuse to eat during periods of pain attacks, fearing that the movements of chewing may precipitate the pain. In addition, the chronic nature of the illness often causes depression, which may depress the appetite.

Expected Outcome: Patient's risk for altered nutrition will be eliminated/minimized by patient's consumption of a healthy and well-balanced diet and weight stability.

- Monitor dietary intake and weight at each visit, and ask the patient to keep a weekly weight record. *Ongoing assessments are necessary for early detection of nutritional deficiencies.*
- Discuss the temperature and consistency of foods eaten, and suggest referral to a dietitian if necessary. *Hot or cold foods may trigger an attack; soft, warm, or cool foods are less likely to act as triggers.*
- Suggest chewing on the unaffected side of the mouth. *Chewing on the unaffected side is less likely to trigger an attack of pain and so facilitates food intake.*
- If unable to tolerate oral food, tube feedings may be necessary. *Adequate kilocalories and nutrients for metabolic processes are essential.*

Delegating Nursing Care Activities

As appropriate and allowed by the designated duties and responsibilities of unlicensed assistive personnel, the nurse may delegate nursing care activities such as monitoring intake and daily weights, and reporting a reduced intake and/or anorexia.

Continuity of Care

The patient with TN who is receiving medical treatment and providing self-care at home requires teaching about the disease process, the medication(s) being taken, and ways to reduce the incidence of attacks of pain. For example, if the home setting is drafty and attacks of pain are triggered by cold air blowing across the face, it may be necessary to encourage the patient to put weather stripping around windows and doors. To prevent injury to affected areas, the topics in the accompanying Meeting Individualized Needs box should be addressed.

THE PATIENT WITH BELL'S PALSY

Bell's palsy, also called *facial paralysis*, is a disorder of the seventh cranial (facial) nerve, characterized by unilateral weakness of the facial muscles. This disorder can occur at any age but is seen most often in adults between the ages of 20 and 60. The incidence is equal in men and women. Eighty percent of patients recover completely within a few weeks to a few months (Hickey, 2013). It may occur as a distinct classic disease, or may accompany other diseases such as Guillain-Barré syndrome, tumor, Lyme disease, or stroke.

Pathophysiology

The cause of the classic disorder is believed to be the herpes simplex virus type 1 and herpes zoster virus.

Manifestations

The onset of Bell's palsy is usually sudden and almost always involves one side of the face. Pain behind the ear or along the jaw may precede the paralysis. The patient initially notices numbness or stiffness of one side of the face that distorts the appearance. As the disease progresses, the distortion becomes more obvious, and the face appears asymmetric. The facial paralysis causes the entire side of the face to droop, and the patient cannot wrinkle the forehead, close the eye, or pucker the lips on the affected side. When the patient attempts to smile, the lower facial muscles are pulled to the opposite side of the face. Some patients have only mild manifestations, whereas others have complete facial paralysis (Figure 44–8 ■). Patients often believe they have had a stroke. Manifestations of Bell's palsy are listed in an accompanying box.

Figure 44–8 ■ The patient with Bell's palsy shows the typical drooping of one side of the face.
Source: Dr. P. Marazzi/Science.

●○● INTERPROFESSIONAL CARE

There are no definitive laboratory or diagnostic tests for Bell's palsy, nor are there any specific treatments. Treatment includes medications and physical therapy. Recent studies have shown that antiviral drugs such as acyclovir combined with an anti-inflammatory drug such as prednisone may be effective by limiting damage to the nerve. Physical therapy to stimulate the facial nerve and help maintain muscle tone may help prevent permanent contractures before recovery takes place. Moist heat applied to the affected side of the face may decrease pain.

●○● NURSING CARE

Health Promotion

Although patients provide self-care at home, the nurse plays a key role in teaching the patient and family about the disease and how to

Meeting Individualized Needs

Teaching for Home Care of Trigeminal Neuralgia

EYE CARE

- Do not rub the eyes; use artificial tears four times a day if the eyes are dry or irritated.
- Wear an eye patch at night.
- Wear protective sunglasses or goggles when outside, when working in dusty areas, when mowing the lawn, and when using any type of spray material (e.g., hair spray, cleaning materials, paint, insecticides).
- Remember to blink frequently.
- Check your eyes for redness or swelling each day.
- Schedule regular eye examinations.

FACE AND MOUTH CARE

- Chew on the unaffected side of the mouth.
- Avoid eating hot foods or drinking hot liquids.
- After every meal, brush your teeth and inspect the inside of your mouth for food that may collect between the gums and cheek.
- Have regular dental examinations; you will not be able to feel pain associated with gum infection or tooth decay.
- Use an electric razor to shave the face.
- Protect your face from very cold or windy conditions.

prevent injury and maintain nutrition. The patient is often anxious about his or her appearance and may require counseling if any deficits in facial expression become permanent.

Priorities of Care

- Use artificial tears four times a day to lubricate the eye; wear an eye patch or tape the eye shut at night. Wear sunglasses or goggles when outside, when working in dusty conditions, and when using any type of spray.
- Massage combined with warm, moist heat often is effective in relieving the pain.
- A soft diet that does not require chewing and six small meals a day are helpful. Chew slowly on the unaffected side and avoid hot foods. Clean the mouth and carefully inspect the area between the gums and cheek for food after each meal.
- As function returns, practice wrinkling the forehead, closing the eyes, blowing air out of the puckered mouth, and whistling for 5 minutes three or four times a day.

CHAPTER HIGHLIGHTS

- **Dementia involves impairment in short- and long-term memory; impairment in language, motor activity, recognition, and/or abstract thinking; and a clinical course characterized by gradual onset and continuing cognitive decline.**
- **Alzheimer's disease (AD) is progressive and relentless, and is characterized by cognitive and functional decline. The disease is characterized by atrophy of brain tissue, loss of neurons, neurofibrillary tangles, and amyloid plaques. There are no effective treatments for preventing AD, although pharmacologic and nonpharmacologic therapies may slow its course. Education of caregivers addresses burdens and expectations, and provides instruction regarding community resources. The goal is to maximize the environment to the patient's functional abilities and safety needs.**
- **Multiple sclerosis (MS) is an autoimmune, demyelinating disease of the central nervous system. MS is multifactorial, with genetic and environmental factors linked to its incidence. Exposure to UVB light and exposure to the Epstein-Barr virus have both been implicated as environmental factors that interact with genes to lead to the onset of MS. The loss of myelin leads to axon dysfunction, which slows and distorts nerve impulses. Medications are used to slow the progression of the disease, decrease the number of exacerbations, and treat manifestations.**
- **Parkinson's disease (PD) is a progressive degenerative neurologic disease characterized by tremor, muscle rigidity, and bradykinesia. The loss of voluntary motor control is the result of pathologic processes resulting in a decrease of dopamine (an inhibitory neurotransmitter) so that it can no longer inhibit acetylcholine (an excitatory neurotransmitter). Medications to treat manifestations include MAO inhibitors, dopaminergics, dopamine agonists, and anticholinergics.**
- **Huntington's disease (chorea) is a progressive, degenerative inherited neurologic disease characterized by increasing dementia and chorea. There is an excess of dopamine, causing excessive, uncontrolled movement.**
- **Amyotrophic lateral sclerosis (ALS) is a rapidly progressive and fatal degenerative motor neuron disease characterized by weakness and wasting of voluntary control muscles, but without sensory or cognitive changes. The patient eventually loses the ability to communicate and breathe.**
- **Myasthenia gravis (MG) is a chronic autoimmune PNS disorder characterized by fatigue and severe skeletal muscle weakness. It results from a decreased number of acetylcholine receptors at the neuromuscular junction, so muscles are unable to contract. Life-threatening emergencies include myasthenic crisis (sudden increase in motor weakness) and cholinergic crisis (from an overdose of the anticholinesterase medications used to treat MG).**
- **Guillain-Barré syndrome (GBS) is an acute inflammatory demyelinating disease of the PNS characterized by an acute onset of flaccid motor paralysis that begins in the lower extremities and ascends to involve the upper extremities, torso, and cranial nerves. Paralysis of intercostal and diaphragmatic muscles often necessitates ventilatory assistance. The acute phase lasts from 1 to 3 weeks, followed by recovery, which takes from 6 months to 2 years.**
- **Cranial nerve disorders include trigeminal neuralgia (TN) and Bell's palsy. TN is a chronic disorder of cranial nerve V and causes severe facial pain. Bell's palsy is an acute disorder of cranial nerve VII, characterized by unilateral paralysis of the facial muscles.**

TEST YOURSELF NCLEX-RN® REVIEW

1. The nurse is reviewing a patient's manifestations to determine if dementia is present. What information will help the nurse with this determination? (Select all that apply.)
   1. Dementia causes impaired short- and long-term memory.
   2. Dementia is an acute disorder, resulting from an injury to the brain.
   3. Dementia is the primary manifestation of Guillain-Barré syndrome.
   4. Dementia describes the cognitive and behavioral manifestations of Alzheimer's disease.
   5. Dementia is a general term used to describe manifestations of damage or death of neurons.
2. A patient is concerned about developing Alzheimer's disease with aging. What manifestation should the nurse instruct as usually being the first indication of the disease?
   1. inability to perform basic ADLs
   2. mild and subtle memory deficits
   3. inability to communicate verbally
   4. wandering and changes in sleep patterns at night
3. The nurse is identifying nursing diagnoses appropriate for a patient with multiple sclerosis. Which diagnosis is appropriate for all patients with MS, regardless of type or severity?
   1. *Fatigue*
   2. *Acute Pain*
   3. *Risk for Aspiration*
   4. *Impaired Gas Exchange*
4. The nurse is preparing medication teaching for a patient with multiple sclerosis. Which medications should be included in this teaching? (Select all that apply.)
   1. antibiotics
   2. antihistamines
   3. immunomodulators
   4. dopamine precursors
   5. adrenocorticosteroids
5. The nurse is teaching a young adult patient with multiple sclerosis about the disease process. What information should the nurse include during this teaching?
   1. onset is before age 20
   2. steps to cure the disease
   3. importance of avoiding extremes of heat and cold
   4. limit in the number of drugs available for the treatment of MS
6. The nurse is preparing to talk with the family of a patient newly diagnosed with Parkinson's disease. How should the nurse explain the cause of this disorder?
   1. genetic defect
   2. effects of a neurotoxin
   3. autoimmune responses to a viral infection
   4. failure of dopamine to inhibit acetylcholine
7. The nurse is preparing instructions for the caregiver of a patient with Parkinson's disease regarding care that will be needed at home. What information should the nurse provide to the caregiver?
   1. ways to prevent falls
   2. interventions to increase appetite
   3. the need to avoid daily baths and showers
   4. ways to prevent an overdose of medications
8. The nurse is preparing medication teaching for a patient with amyotrophic lateral sclerosis. On which drug classification should the nurse focus when providing these instructions?
   1. antiglutamate
   2. anticholinergic
   3. dopamine agonist
   4. anti-inflammatory
9. The nurse is preparing a teaching plan for a patient with Bell's palsy. What information should the nurse include?
   1. "One side of your face will not move normally."
   2. "The disease affects your muscles so you can't walk."
   3. "You will experience severe facial pain during attacks."
   4. "Be sure to boil all home-canned foods before eating them."
10. A patient with Huntington disease is prescribed riluzole (Rilutek). On which body system should the nurse focus additional interventions because of this medication?
    1. liver
    2. heart
    3. lungs
    4. kidneys

UNIT

11 Building Clinical Competencies

Responses to Altered Neurologic Function

CLINICAL SCENARIO

Directions: *Read the following clinical scenarios and answer the questions that follow. To complete this exercise successfully, you will not only use knowledge of the content in this unit, but also principles related to priority setting and maintaining patient safety.*

You have been assigned to care for the following patients on a neurologic hospital unit. Significant data obtained during report are as follows:

- Louie Hemandez is a 74-year-old male who was admitted from the emergency department to the neurologic unit last night. Mr. Hernandez was found by family in his home. He was unable to speak or move the right side of his body and continues to experience paralysis on the right side in both his arm and leg. He is aphasic with facial drooping but is able to nod his head to communicate. Mr. Hemandez has a known history of hypertension, CHF, and type 2 diabetes controlled by oral hypoglycemic medications. He has smoked a package of cigarettes a day for 40 years. BP is now 140/105 mmHg, P 98 bpm, R 24/min. Lungs reported to have crackles. A swallowing evaluation has been ordered to be done today.
- Jane Thomas is a 56-year-old female. She was admitted 4 days ago and underwent a lumbar laminectomy. She was able to ambulate with assistance on day 2 after surgery and now reports no dizziness on ambulation. Her leg strength has progressively increased since surgery. She has equal sensation and is able to wriggle her toes on both feet. Pain is controlled at the patient's desired level of 2 to 3 on a scale of 1 to 10 with oral medications.
- Cesar Phillips is a 39-year-old male, admitted 4 days ago after experiencing paralysis and severe headache at work. He has been diagnosed with stroke following MRI. He has a history of smoking one package of cigarettes per day and hypertension. His wife reported that he had stopped taking his blood pressure medication due to the side effects of impotence. Mr. Phillips is awake and alert, but has exhibited impulsive behavior and dysphagia. He has difficulty remembering words and neglects the left side of his body in ADLs. BP had been 130/85 mmHg at the beginning of last shift, but has increased to 170/119 mmHg. He received an additional blood pressure medication 1.5 hours ago.
- Tonya Walton is a 29-year-old female. She was involved in a car crash 12 hours before her admission 5 days earlier. She developed a headache, drowsiness, confusion, and pupil enlargement several hours after the crash. Following an MRI, Ms. Walton underwent intracranial surgery to evacuate a subdural hematoma. She has been complaining of a headache that has increased in intensity from 2 to 6 on a scale of 1 to 10 on the previous shift. She received two Tylenol ES tabs 1 hour ago. BP was 140–150 mmHg systolic and 90–100 mmHg diastolic for most of the shift. Her BP at the time the Tylenol was administered was 175/115 mmHg. She has not experienced any changes in her neuro assessment except for the increasing headache and blood pressure elevation.

CLINICAL REASONING

1. If you reevaluated Ms. Walton and her headache pain had not decreased, what should be your next priority?
   A. Reposition Ms. Walton on her left side with the head of the bed flat.
   B. Call the physician about patient report of increasing headache.
   C. Decrease stimuli in the room by darkening the room and limiting noise.
   D. Check the prn orders to evaluate if a stronger pain medication has been ordered.

Priority Setting

2. In what order would you visit these patients after report?
   A. _____
   B. _____
   C. _____
   D. _____

Health Promotion

3. Before she is discharged, what instruction should be given to Ms. Thomas regarding lifting and moving objects?
4. What instruction should be given to Mr. Hernandez and Mr. Phillips about smoking cessation programs?

Nursing Process

5. You are completing the beginning-of-shift assessment for Ms. Walton. What changes best indicate that the plan initiated by the previous shift was effective?
   A. Ms. Walton has no neurologic changes or deterioration.
   B. Ms. Walton's BP is 142/94 mmHg.
   C. Ms. Walton's pain level is now 1–2.
   D. Ms. Walton's dressing is dry and intact.

6. You are completing the beginning-of-shift assessment for Mr. Phillips. What changes indicate that the plan initiated by the previous shift was effective?
   A. Mr. Phillips no longer has a craving for cigarettes.
   B. Mr. Phillips' respiratory rate is 18–20.
   C. Mr. Phillips' pain level is now 1–2.
   D. Mr. Phillips' blood pressure has decreased to 145/90 mmHg.

Communication

7. Mr. Phillips' wife says her husband seems too young to have had a stroke. She asks what caused his symptoms. How will you answer her?

8. Mr. Hernandez's daughter asks if he will have to go to a nursing home. How will you answer her?

Delegation

9. For each patient, which interventions can be delegated to the unlicensed assistive personnel (UAP)?
   A. _____
   B. _____
   C. _____
   D. _____

Interprofessional Care

10. If you were planning an effective team meeting with all disciplines that should be collaborating to provide care and a discharge plan for Mr. Phillips who had a stroke, which six disciplines should be represented and why?

Continuity of Care

11. Beyond the acute care setting, patients who have suffered a stroke resulting in physical, emotional, interpersonal, and family issues may require continuity of care in which type of settings?
   A. _____
   B. _____
   C. _____

Safety

12. When a patient is admitted to the emergency department with a diagnosis of stroke, which of the following in a computerized order set is most focused at patient safety?
   A. Perform a dysphagia screening.
   B. Place a tab alarm on the patient.
   C. Insert a Foley catheter to avoid incontinence.
   D. Obtain a physical therapy consult.

Quality Improvement

13. The nurse manager has noted an increase in the number of patients admitted to the medical unit with a diagnosis of ischemic stroke. Describe a community-based project that the nursing staff can implement aimed at earlier identification and treatment of ischemic stroke.

Informatics

14. As a nurse caring for patients in today's environment, it is imperative that beginning nurses express the following competencies:
   A. fundamental computer skills and an understanding of information (i.e., nursing process, evidence-based practice, etc.) to deliver safe and effective care
   B. ability to identify relationships among disparate sources of information
   C. ability to integrate and apply computer science to nursing
   D. ability to conduct informatics research

Responses to Altered Sensory Function

45 Assessing the Eye and Ear 1473

46 Nursing Care of Patients with Eye and Ear Disorders 1491

Cognitive–Perceptual Pattern

The eyes and ears provide pathways for visual and auditory stimuli to reach the brain, allowing interpretation of and interaction with the environment.

45 Assessing the Eye and Ear

LEARNING OUTCOMES

1. Describe the anatomy, physiology, and functions of the eye and the ear.
2. Identify specific topics for consideration during a health history interview of the patient with health problems involving the eye or ear.
3. Give examples of genetic disorders in vision and hearing.
4. Describe normal variations in assessment findings for the older adult.
5. Identify abnormal findings that may indicate impairment in the function of the eye and the ear.

CLINICAL COMPETENCIES

1. Conduct and document a health history for patients having or at risk for alterations in the structure or functions of the eye and ear, eliciting patient preferences, values, and expressed needs.
2. Safely and effectively assess the structure and functions of the eye and ear, documenting and reporting, as appropriate, unexpected findings.
3. Provide appropriate teaching for patients undergoing diagnostic tests of the eyes, ears, vision, or hearing.
4. Monitor the results of diagnostic tests and report abnormal findings.

MAJOR CHAPTER CONCEPTS

- Abnormalities in the structure or function of the eyes and their accessory structures can threaten or impair vision and the patient's safety, independence, and social interactions.
- For hearing to occur, sound waves must travel from the external auditory meatus, through the ear canal, to vibrate the tympanic membrane and bony structures of the middle ear, which in turn activate the receptors of the cochlea.
- Assessment of the eyes, ears, and their sensory functions involves specialized techniques that require practice to develop skill and competence.

refraction, *1477*

EQUIPMENT NEEDED

- Visual acuity charts
- Opaque eye cover
- Pen
- Penlight
- Cotton-tipped applicator
- Ophthalmoscope
- Otoscope
- Tuning fork

The eyes and ears provide pathways for visual and auditory stimuli to reach the brain. In addition, specialized structures within the ear help maintain position sense and equilibrium. Deficits in vision and hearing may limit self-care, mobility, safety, independence, communication, and relationships with others.

Anatomy, Physiology, and Functions of the Eyes

The eyes are complex structures containing 70% of the sensory receptors of the body. Each eye is a sphere measuring about 2.5 cm (1 in.) in diameter, surrounded and protected by a bony orbit and cushions of fat. The primary functions of the eyes are to encode the patterns of light from the environment through photoreceptors and to carry the coded information from the eyes to the brain. The brain gives meaning to the coded information, allowing us to make sense of what we see.

Accessory Structures of the Eye

Although the accessory structures of the eye are outside the eyeball, they are vital to its protection. These include the eyebrows, eyelids, eyelashes, conjunctiva, lacrimal apparatus, and extrinsic eye muscles (Figure 45–1 ■).

The eyebrows shade the eyes. The eyelashes, short hairs that project from the top and bottom borders of the eyelids, protect the eye from foreign bodies, regulate the entry of light into the eye, and distribute tears by blinking. An unexpected touch to the eyelashes initiates the blinking reflex, which protects the eyes from foreign objects. The conjunctiva is a thin, transparent mucous membrane that lines the inner surfaces of the eyelids and also folds over the anterior surface of the eyeball, lubricating the eyes. The palpebral conjunctiva lines the upper and lower eyelids, whereas the bulbar conjunctiva loosely covers the anterior sclera (the white part of the eye). The lacrimal apparatus is composed of the lacrimal gland, the puncta, the lacrimal sac, and the nasolacrimal duct. Together, these structures secrete, distribute, and drain tears to cleanse and moisten the eye's surface.

The six extrinsic eye muscles control movement of the eye, allowing it to follow a moving object and move precisely. The muscles also help maintain the shape of the eyeball. The cranial nerves control the extrinsic muscles (Figure 45–2 ■).

The Eye

The eye receives and transmits visual stimuli to the brain for interpretation. The wall of the eyeball is composed of three layers: the fibrous, vascular, and inner layers. The inner layer of the eye contains photoreceptors (visual receptors). The cavity of the eye is filled with fluids called humors. This cavity is divided into anterior and posterior cavities by the lens, the focusing apparatus of the eye (Figure 45–3 ■).

SCLERA AND CORNEA

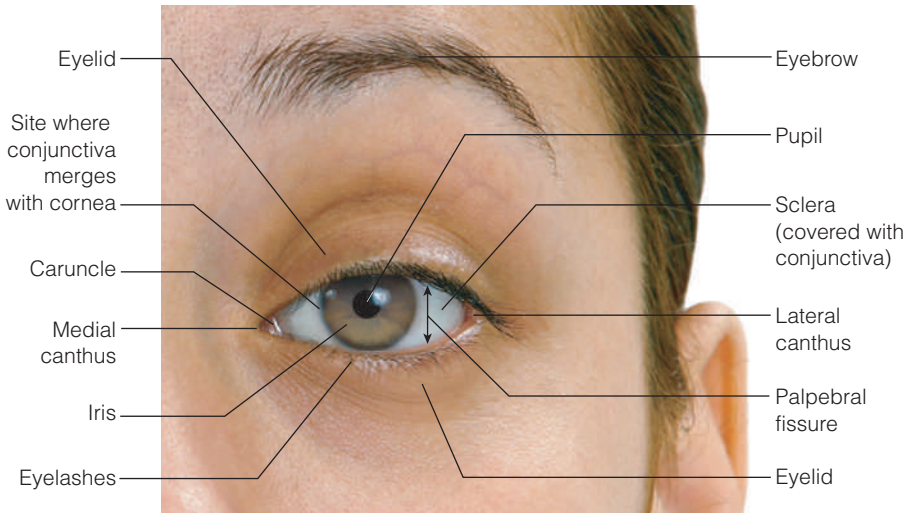
The white sclera, the outer fibrous layer of the eyeball, protects and gives shape to the eyeball. The sclera gives way to the cornea over the iris and pupil. The cornea is transparent, avascular, and sensitive to touch. It forms a window that allows light to enter the eye and is a part of its focusing apparatus. When the cornea is touched, the eyelids blink (the **corneal reflex**) and tears are secreted.

IRIS

The iris, part of the vascular layer of the eye, is a disc of muscle surrounding the pupil and lying between the cornea and the lens. The iris gives the eye its color and regulates light entry by controlling the size of the pupil. The pupil is the dark center of the eye through which light enters. The pupil constricts when bright light enters the eye and when it is used for near vision; it dilates when light conditions are dim and when the eye is used for far vision. In response to intense light, the pupil constricts rapidly in the **pupillary light reflex**.

AQUEOUS FLUID

The anterior cavity is filled with aqueous humor, a clear fluid that circulates through the anterior chamber (the space between the cornea and the iris) and the posterior chamber (the space between the iris and the lens). Aqueous humor is constantly formed by the ciliary body (refer to Figure 45–3) and drained to maintain a relatively constant intraocular pressure. The fluid drains into venous blood via the scleral venous sinus (canal of Schlemm), a network of channels that circles the eye in the angle at the junction of the sclera and the cornea. Aqueous humor provides nutrients and oxygen to the cornea and the lens.



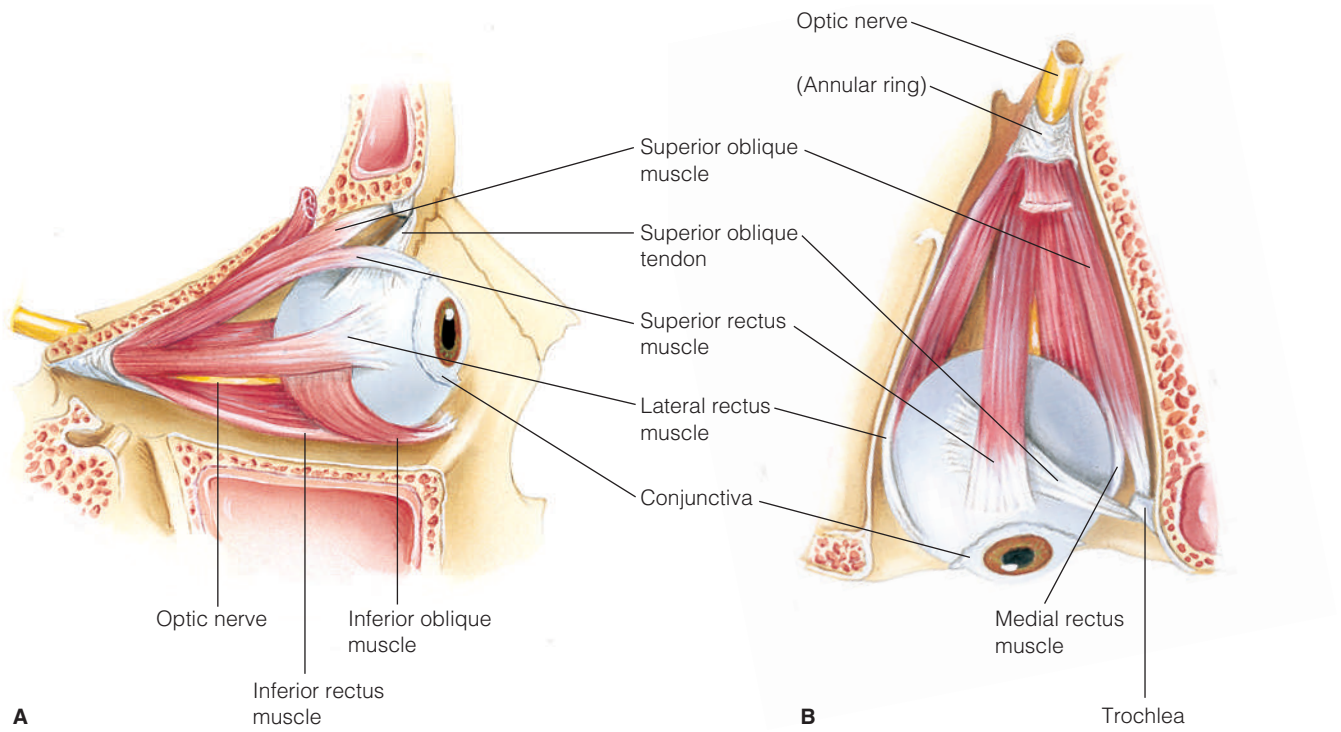


Figure 45–1 ■ Accessory and external structures of the eye.

C

Name	Controlling cranial nerve	Action
Lateral rectus	VI (abducens)	Moves eye laterally
Medial rectus	III (oculomotor)	Moves eye medially
Superior rectus	III (oculomotor)	Elevates eye or rolls it superiorly
Inferior rectus	III (oculomotor)	Depresses eye or rolls it inferiorly
Inferior oblique	III (oculomotor)	Elevates eye and turns it laterally
Superior oblique	IV (trochlear)	Depresses eye and turns it laterally

Figure 45–2 ■ Extraocular muscles. A, Lateral view of the right eye. B, Superior view of the right eye. C, Innervation of the extraocular muscles by the cranial nerves.

INTERNAL CHAMBER

The internal chamber of the eye contains the lens, the posterior cavity and vitreous humor, the ciliary body, the uvea, and the retina.

The lens is a biconvex, avascular, transparent structure located directly behind the pupil. It can change shape to focus and refract light onto the retina. The posterior cavity lies behind the lens. It is filled with a clear gelatinous substance, the vitreous humor, which supports the posterior surface of the lens, maintains the position of the retina, and transmits light.

The vascular layer, also called the uvea, is the middle layer of the eyeball. This pigmented layer has three components: the iris, ciliary body, and choroid. The ciliary body encircles the lens, and along with the iris, regulates the amount of light reaching the retina by controlling the shape of the lens. Most of the uvea is made up of the choroid, which includes an extensive capillary network that delivers oxygen and nutrients to the retina.

The retina is the innermost layer of the eye. The pigmented outer layer of the retina, next to the choroid, absorbs light and serves biochemical functions such as removing wastes and storing vitamin A. The transparent inner neural layer is made up of millions of light receptors in structures called rods and cones. Rods enable vision in dim light as well as peripheral vision. Cones enable vision in bright light and the perception of color. The optic disc, a cream-colored round or oval area within the retina, is the point at which the optic nerve enters the eye. The slight depression in the center of the optic disc is called the physiologic cup. The macula, located laterally to the optic disc, primarily contains cones. The fovea centralis, a slight depression in the center of the macula that contains only cones, is the area of sharpest and most detailed color vision.

The Visual Pathway

Signals produced when photoreceptors are stimulated by light are transmitted to bipolar cells and then to ganglion cells. The optic nerves are cranial nerves formed of the axons of ganglion cells. The two optic nerves meet at the optic chiasma, just anterior to the pituitary gland in the brain. At the optic chiasma, axons from the medial

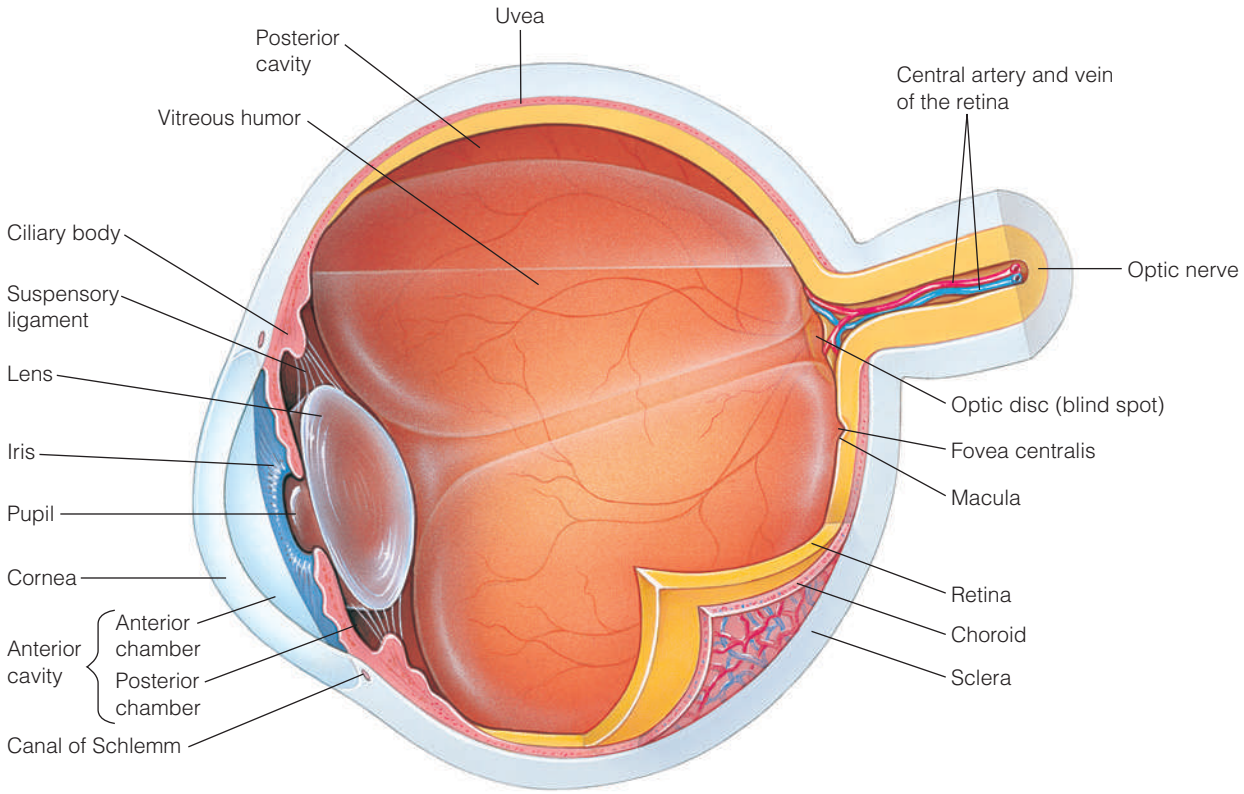

Figure 45–3 ■ Internal structures of the eye.

half of each retina cross to the opposite side to form pairs of axons from each eye. These pairs continue as the left and right optic tracts (Figure 45–4 ■). The crossing of the axons results in each optic tract carrying information from both eyes. The left optic tract carries visual information from the lateral half of the retina of the left eye and the medial half of the retina of the right eye, whereas the right optic tract carries visual information from the lateral half of the retina of the right eye and the medial half of the retina of the left eye.

The axons in the optic tracts travel to the thalamus and synapse with neurons, forming pathways called optic radiations. The optic radiations terminate in the visual cortex of the occipital lobe, where the nerve impulses that originated in the retina are interpreted. Some neurons from the optic tracts send signals to subconscious processing centers of the midbrain, which control pupillary reflexes and eye movement.

The visual fields of each eye overlap considerably and each eye sees a slightly different view. Because of this overlap and the crossing of the axons, information from both eyes reaches each side of the visual cortex, which then fuses the information into one image. This fusion of images accounts for the ability to perceive depth; however, depth perception depends on visual input from two eyes that both focus well.

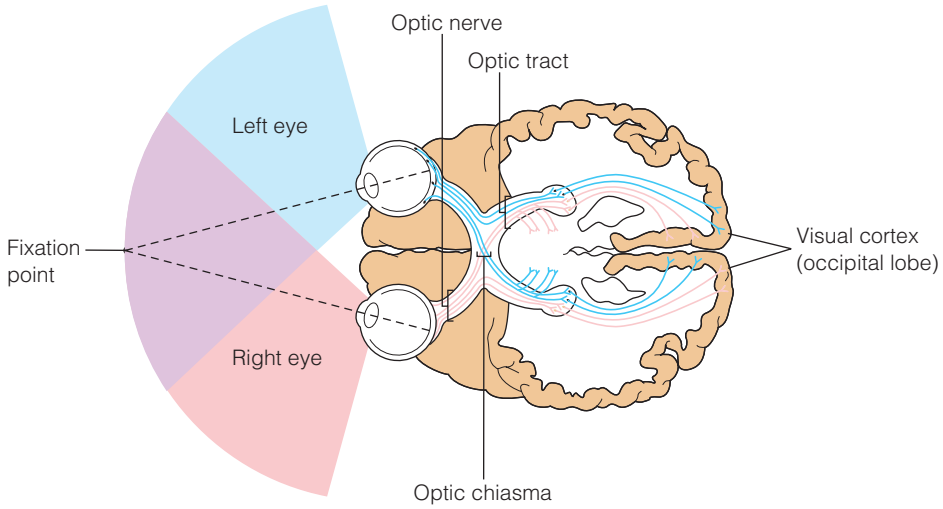

Figure 45–4 ■ The visual fields of the eye and the visual pathways to the brain.

Refraction

Refraction is the bending of light rays as they pass from one medium to another medium of different density. As light rays pass through the eye, they are refracted at several points: as they enter the cornea, as they leave the cornea and enter the aqueous humor, as they enter the lens, and as they leave the lens and enter the vitreous humor. At the lens, the light is bent so that it converges at a single point on the retina. This focusing of the image is called **accommodation**. Because the lens is convex, the image projected onto the retina (the real image) is upside down and reversed from left to right. This real image is coded as electric signals that are sent to the brain. The brain decodes the image so that the person perceives it as it occurs in space.

The eyes are best adapted to see distant objects. When both eyes fix on the same distant image, the ciliary muscle is relaxed and the lens flattened. For people with emmetropic (normal) vision, the distance from the viewed object at which the eyes require no accommodation is 20 ft (6 m). This point is called the far point of vision. To focus for near vision, the ciliary muscles contract, the pupils constrict, and the eyeballs converge. Ciliary muscle contraction reduces the tension on the lens capsule so that it bulges outward (becomes rounder). This change in shape achieves a shorter focal length, focusing close images on the retina. The closest point at which an individual can focus is called the near point of vision; in young adults with normal vision this is usually 20 to 25 cm (8 to 10 in.). Pupillary constriction helps eliminate most of the divergent light rays and sharpens focus. **Convergence** (the medial rotation of the eyeballs so that each is directed toward the viewed object) allows the focusing of the image on the retinal fovea of each eye.

ASSESSING THE EYES

Structures and functions of the eyes are assessed by findings from diagnostic tests, the health assessment interview, and physical assessment of the eyes and vision.

Diagnostic Tests

Diagnostic tests to assess the structure and functions of the eyes are used to support the diagnosis of a specific injury, disease, or vision problem; to provide information to guide treatment; and to monitor the patient's responses to treatment and interventions. These tests are most often conducted in a healthcare provider's office. Diagnostic tests of the eyes are described in the accompanying Diagnostic Tests table.

Regardless of the type of diagnostic test, the nurse is responsible for explaining the procedure and any special preparation, for assessing any medication use that might affect the test outcome, for supporting the patient during the examination as necessary, for ensuring the consent form is signed (if required), and for monitoring the results of the tests. The nurse is also responsible for postprocedure care and patient teaching for self-care at home.

Genetic Considerations

When conducting a health assessment interview and a physical assessment, it is important for the nurse to consider genetic influences on the health of an adult. Several diseases of the eyes have a genetic component. During the health assessment interview, ask about a family history of glaucoma or blindness.

DIAGNOSTIC TESTS of the Eye

Name of Test	Purpose and Description	Related Nursing Interventions
Computed tomography (CT) scan and magnetic resonance imaging (MRI) of the eye	Imaging techniques used to identify foreign objects or tumors within the eye, orbit, or optic nerve. The head is positioned in a cradle and a wide strap is applied around the head to keep it immobilized during the test. MRI is contraindicated if a metallic foreign body is suspected.	Tell the patient to remove all hairpins, clips, and earrings before the test. If a contrast dye is used, dentures must also be removed. Assess for allergies to iodine (for example, to shellfish or previous procedures) and if present, notify the physician. Inform the patient that the test takes 5–10 min. Instruct the patient to increase oral fluid intake after the examination if contrast dye has been used.
Fluorescein angiography	Fluorescein solution is injected IV to evaluate blood vessels in the eye in conditions such as diabetes, macular degeneration, or retinal vessel occlusion.	Informed consent is required for this test. Note current medications and notify the physician if the patient is pregnant. Inform the patient that a hot flush and transient nausea may be experienced when the dye is injected. Monitor for anaphylactic hypersensitivity responses that may occur. Fluorescent yellow-colored urine and a yellow skin color may be noted for 1–2 days after the procedure; these are not harmful.
Refraction, retinoscopy, refractometry	These tests are used to measure refractive error. Either a handheld retinoscope or an instrument with multiple lenses is used; with the latter method the patient chooses lenses that provide best vision.	No special preparation is needed; tell the patient that pupils will be dilated with medication and may be enlarged for several hours.
Tonometry	This test is used to diagnose increased intraocular pressure in glaucoma. A handheld tonometer or computerized device may be used. The cornea is anesthetized prior to being touched with the device. Normal value: 10–22 mmHg.	No special preparation is needed. Instruct the patient not to rub the eyes.
Ultrasonography	Ultrasonography may be used to assess retinal tumors or detachments, vitreous hemorrhage, or to locate foreign bodies.	This noninvasive test is painless and requires no special patient preparation.

GENETIC CONSIDERATIONS

Examples of Eye Disorders

- Glaucoma is a term used for a group of diseases that damage the optic nerve and cause blindness. Increased intraocular pressure (IOP) is commonly associated with glaucoma. Glaucoma is the leading cause of blindness in African Americans (Horton, 2012).
- Leber's hereditary optic neuropathy, which causes gradual painless loss of central vision, usually affects young men.
- Retinitis pigmentosa may be transmitted in an autosomal recessive, dominant, or X-linked pattern, resulting in progressive night blindness, with loss of visual acuity and peripheral vision.

During the physical assessment, assess for any manifestations that might indicate a genetic disorder (see the accompanying Genetic Considerations box). If data are found to indicate genetic risk factors or alterations, refer to an ophthalmologist for a complete examination.

Health Assessment Interview

A health assessment interview to determine problems with the eyes may be conducted during a health screening, may focus on a chief complaint (such as blurred vision or an eye infection), or may be part of a total health assessment. If the patient has a health problem involving one or both eyes, analyze its onset, characteristics and course, severity, precipitating and relieving factors, and any associated symptoms, noting the timing and circumstances. For example, you may ask the patient the following:

- Describe the type of eye pain you experience. Does it affect one or both eyes? When did it begin? How long does it last?
- Have you noticed rings around streetlights at night?
- When did you first notice having difficulty reading the paper?

Throughout the interview, be alert to nonverbal behaviors (such as squinting or abnormal eye movements) that suggest problems with eye function. Explore problems such as watery, dry, or irritated eyes or changes in vision. Assess the patient's use of corrective eyewear and care of eyeglasses or contact lenses. If the patient uses eye medications, ask about the type and purpose as well as the frequency and duration of use. When taking the history, inquire about eye trauma, surgery, or infections, as well as the date and results of the last eye examination. In addition, ask about a history of diabetes, hypertension, thyroid disorders, glaucoma, cataracts, and eye infections. Include questions about a family history of nearsightedness or farsightedness, cancer of the retina, color blindness, and any other eye or vision disorders.

Collect information about environmental or work exposure to irritating chemicals, participation in sports or hobbies that pose the risk of eye injury, and the use of protective eyewear during dangerous activities, such as sawing wood or using a grass trimmer.

Physical Assessment of the Eyes

Physical assessment of the eyes and of visual acuity may be performed as part of a total assessment or separately for patients with known or suspected problems of the eyes. The eyes and vision are primarily assessed through inspection of external structures and assessment of visual fields and visual acuity, extraocular muscle function, and internal structures. Palpation (e.g., of a blocked lacrimal duct) may be used if a problem is identified. Prior to the examination, explain the techniques to the patient to decrease anxiety. The patient may sit or stand during the assessment. Normal age-related findings for the older adult are summarized in the Nursing Care of the Older Adult box.

Figure 45–5 ■ Testing distant vision using the Snellen eye chart.

VISION ASSESSMENT

Visual acuity is assessed with an eye chart such as the Snellen chart or the E chart for distance vision and the Rosenbaum chart for near vision. The Snellen chart contains rows of letters in various sizes, with numbers at the end of each row to indicate the visual acuity of a patient who can read the row at a distance of 20 ft (6 m). (The E chart is used for the patient who is unable to read or does not read English.) The top number at the end of the row is always 20, representing the distance between the patient and the chart. The bottom number is the distance (in feet) at which an individual with normal vision can read the line. An individual with normal vision can read the row marked 20/20. To conduct the assessment, position the person 20 ft from the chart in a well-lit area. Ask the patient to cover one eye with an opaque cover (Figure 45–5 ■). Then ask the patient to read the smallest row discernible. Measure visual acuity in the other eye in the same way, and then assess visual acuity with the patient using both eyes. The patient who wears corrective lenses may be tested with and without the lenses.

The Rosenbaum chart is held at a distance of 30 to 36 cm (12 to 14 in.) from the eyes, with visual acuity measured in the same manner as with the Snellen chart (Figure 45–6 ■). A gross estimate of near vision may also be assessed by asking the person to read from a magazine or newspaper.

Figure 45–6 ■ Testing near vision using the Rosenbaum eye chart.

NURSING CARE OF THE OLDER ADULT

Age-Related Changes in the Eye

Age-Related Change	Significance
ACCESSORY STRUCTURES	
• Decreased musculature of eyelids • Atrophy of lacrimal glands • Loss of orbital fat • Raised, soft yellow plaques called xanthelasma on lids	Eyes appear sunken; upper and lower lids may droop. Decreased tear production leads to dry eyes, with itching and burning. Xanthelasma have cosmetic significance only.
THE CORNEA	
• Lipid deposits around the periphery of the cornea • ↓ corneal sensitivity	A partial or complete white circle may form around the cornea (arcus senilis). Decreased sensitivity increases the risk of eye injury.
THE PUPIL	
• ↓ pupil size and responsiveness to light	Increased light is needed to see clearly and for depth perception. Slowed pupillary reaction causes difficulty adapting to light changes (e.g., moving from a light environment into a dark one or from dark to light).
THE LENS	
• Lens loses elasticity, with reduced ability to change shape and focus light.	Presbyopia, difficulty accommodating for near vision, develops.
• Lens becomes thicker and loses clarity, increasingly opaque.	Light rays scatter, causing glare; color discrimination decreases. Ability to adapt to the dark declines.
THE POSTERIOR CAVITY	
• Vitreous humor shrinks and pulls away from the retina.	Vision is less acute and contains vitreous floaters; risk of retinal detachment increases.
THE RETINA AND VISUAL PATHWAYS	
• Visual fields narrow. • Photoreceptor cells atrophy and are lost. • Light scatter in the retina increases. • Retinal blood vessels thin and sclerose. • Transmission and interpretation of stimuli slow.	Peripheral vision is decreased and color perception is impaired, particularly of blue-green tones. Increased risk of falls as a result of changes in depth perception and adaptation to changes in light. Vision progressively declines with age.

Eye and Vision Assessments

Technique/Normal Findings	Abnormal Findings
Vision Assessment	
Assess distant vision, using the Snellen or E chart. *When standing 20 ft from the chart, the patient can read the smallest line of letters with or without corrective lenses (recorded as 20/20).*	• Changes in distant vision are often the result of **myopia** (nearsightedness). For example, a reading of 20/100 indicates impaired distance vision. An individual has to stand 20 ft from the chart to read a line that an individual with normal vision could read 100 ft from the chart.
Assess near vision, using a Rosenbaum chart or a card with newsprint held 12–14 in. from the patient's eyes. *Normal near visual acuity is 14/14 with or without corrective lenses.*	• Changes in near vision, especially in patients over age 45, can indicate **presbyopia**, impaired near vision resulting from a loss of elasticity of the lens related to aging. In younger patients, this condition is referred to as **hyperopia** (farsightedness).
Visual Fields Assessment	
Assess visual fields using the confrontation test to evaluate peripheral vision (Figure 45–7 ■). The visual fields of the examiner (which must be normal for this assessment) are used as the standard. Sit directly opposite the patient at a distance of 18–24 in. and instruct the patient to look directly at you. Ask the patient to cover one eye while you cover your own eye opposite to the patient (for example, the patient's right eye and examiner's left eye). Move the penlight from the periphery toward the center from right to left, above and below, and from the middle of each of these directions. *Both you and the patient should see the penlight enter the field of vision at the same time if the examiner has normal peripheral vision.*	• Narrowing of visual fields may occur with aging or may indicate an eye disorder such as glaucoma or retinal detachment, or a neurologic disorder.

Figure 45–7 ■ Visual field testing.

(*continued*)

Eye and Vision Assessments (*continued*)

Technique/Normal Findings	Abnormal Findings
Eye Movement Assessment	
Assess the cardinal fields of gaze to evaluate extraocular eye movements. Ask the patient to follow a pen while keeping the head stationary. Move the pen through the six fields one at a time, returning to the central starting point before proceeding to the next field (Figure 45–8 ■). *The eyes should move through each field without involuntary movements.*	• Failure of one or both eyes to follow the object in any given direction may indicate extra-ocular muscle weakness or cranial nerve dysfunction. • An involuntary rhythmic movement of the eyes, **nystagmus**, is associated with neurologic disorders and the use of some medications. • Movement of an eye with the cover test indicates weakness of eye muscles.
The cover test is used to evaluate alignment of the eyes. To conduct the test, hold a pen or your finger about 1 ft from the eyes and ask the person to focus on that object. Cover one of the patient's eyes and note any movement in the uncovered eye; as you remove the cover, assess for movement in the eye that was just uncovered. Repeat the procedure with the other eye. *The gaze should remain steady and fixed with covering and uncovering of the eye.*	
Assess the corneal light reflex. Direct a light source onto the bridge of the nose from 12 to 15 in. away. *Observe for symmetric reflection of the light from each eye.*	• Reflections of the light from different sites on the eyes reveal extraocular muscle weakness.
Assess convergence. Ask the patient to follow an object as you move it toward the patient's eyes. *Normally both eyes converge toward the center.*	• Failure of the eyes to converge equally on an approaching object may indicate a neuromuscular disorder or extraocular muscle weakness.
Pupillary Assessment	
Observe pupil size, shape, and equality. *Pupils should be round and of equal size, 3–5 mm.*	• Pupils that are unequal in size may indicate previous eye surgery or a serious neurologic problem, such as increased intracranial pressure.
Assess direct and consensual pupil response. Ask the patient to look straight ahead. Shine a light obliquely into one eye at a time. Observe for constriction of the pupil in the illuminated eye. Test both eyes. To test consensual pupil response, again shine a light obliquely into one eye at a time as the patient looks straight ahead. Observe constriction of the pupil in the opposite eye. *The normal direct and consensual pupillary response is prompt constriction.*	• Failure of the pupils to respond to light may indicate degeneration of the retina or destruction of the optic nerve. • A patient who has one dilated and unresponsive pupil may have paralysis of the oculomotor nerve. • Some eye medications may cause unequal dilation, constriction, or inequality of pupil size. Morphine and narcotic drugs may cause small pupils with poor responses to light, and anticholinergic drugs such as atropine may cause dilated, poorly responsive pupils.
Test for accommodation. Hold an object at a distance of a few feet from the patient. The pupils should dilate. Ask the patient to follow the object as you bring it to within a few inches of his or her nose. *The pupils should constrict and converge as they change focus to follow the object.*	• Failure of accommodation along with lack of pupil response to light may signal a neurologic problem. • Lack of response to light with appropriate response to accommodation is often seen in patients with diabetes.
External Eye Assessment	
Inspect the eyelids. *Eyelids should be the color of the patient's facial skin, without redness, discharge, or drooping. The lids should just cover the upper and lower borders of the iris.*	• Unusual redness or discharge may indicate inflammation due to trauma, allergies, or infection. • Drooping of one eyelid, called **ptosis**, may be the result of a stroke, indicate a neuromuscular disorder, or be congenital (Figure 45–9 ■). • Unusual widening of the lids may be due to exophthalmos (protrusion of the eyeball). Exophthalmos is often associated with hyperthyroid conditions.

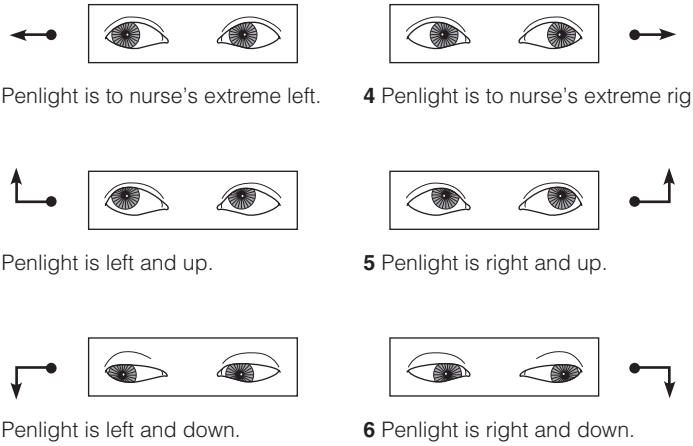

Figure 45–8 ■ The six cardinal fields of gaze.

Figure 45–9 ■ Ptosis.
Source: Medical-on-Line/Alamy.

Eye and Vision Assessments (*continued*)

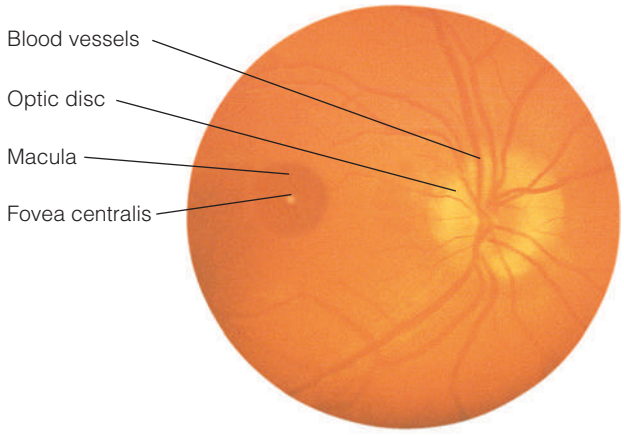
Technique/Normal Findings	Abnormal Findings
	• An acute localized inflammation of a hair follicle is known as a hordeolum (sty) and is generally caused by staphylococcal organisms. • A chalazion is an infection or retention cyst of the meibomian glands.
Inspect the puncta. *The puncta should be free of redness or discharge.*	• Unusual redness or discharge from the puncta may indicate an inflammation due to trauma, infection, or allergies.
Inspect the bulbar and palpebral conjunctiva. *The conjunctiva should be clear, moist, and smooth. The upper and lower palpebral conjunctiva should be clear, without redness or swelling.*	• Increased erythema or the presence of exudate may indicate acute conjunctivitis. • Conjunctival pallor may indicate anemia. • A fold in the conjunctiva, called a pterygium, may be seen as a clouded area that extends over the cornea. This is an abnormal growth of the bulbar conjunctiva, usually seen on the nasal side of the cornea. It may interfere with vision if it covers the pupil.
Inspect the sclera. *The sclera is white in people of European descent; people with darker skin normally have yellow sclera.*	• Unusual redness may indicate an inflammatory state as a result of trauma, allergies, or infection. • Yellow discoloration of the sclera in patients with fair skin may be seen in conditions involving the liver, such as hepatitis. • Bright red areas in the sclera are often subconjunctival hemorrhages and may indicate trauma or bleeding disorders. They may also occur spontaneously.
Inspect the cornea. *The cornea is normally transparent.*	• Dullness, opacities, or irregularities of the cornea may be abnormal. • Corneal arcus is a thin, grayish-white arc seen toward the edge of the cornea. It is normal in older adults.
Assess corneal sensitivity. Lightly touch a wisp of cotton to the patient's cornea. *This action should cause a corneal reflex (blinking of the eye).*	• Failure of the corneal reflex may indicate a neurologic disorder.
Inspect the iris. *The iris is normally round, flat, and evenly colored.*	• Lack of clarity of the iris may indicate a cloudiness of the cornea. • Constriction of the pupil accompanied by pain and circumcorneal redness indicates acute iritis.
Palpate over the lacrimal glands, puncta, and nasolacrimal duct. (Wear gloves if you see any drainage.) *There should be no tenderness, drainage, or excessive tearing.*	• Tenderness over any of these areas or drainage from the puncta may indicate an infectious process. • Excessive tearing may indicate a blockage of the nasolacrimal duct.
Internal Eye Assessment	
Assess internal structures of the eye using the ophthalmoscope, an instrument that allows visualization of the lens, the vitreous humor, and the retina. Box 45–1 provides guidelines for using an ophthalmoscope.	
Inspect for the red reflex. *The red reflex should be clearly visible.*	• Absence of a red reflex often indicates improper position of the ophthalmoscope, but also may indicate total opacity of the pupil by a cataract or a hemorrhage into the vitreous humor.
Inspect the lens and vitreous body. *The lens should be clear.*	• A cataract is an opacity of the lens, often seen as a dark shadow on ophthalmoscopic examination. It may be a result of aging, trauma, diabetes, or a congenital defect.
Inspect the retina. *There should be no visible hemorrhages, exudate, or white patches.*	• Areas of hemorrhage, exudate, and white patches may be a result of diabetes or long-standing hypertension.
Inspect the optic disc. *The optic disc should be round to oval in shape with clear, well-defined borders.*	• Loss of definition of the optic disc, as well as an increase in the size of the physiologic cup, is seen in papilledema from increased intracranial pressure.
Inspect the blood vessels of the retina. *The retinal blood vessels should be distinct.*	• Glaucoma may cause displacement of blood vessels from the center of the optic disc due to increased intraocular pressure. • Hypertension may cause a narrowing of the vein where an arteriole crosses over. • Engorged veins may occur with diabetes, atherosclerosis, and blood disorders.
Inspect the retinal background. *The retina should be a consistent red-orange color, becoming lighter around the optic disc.*	• Variations in color or a pale color overall may indicate disease.
Inspect the macula. *The macula should be visible on the temporal side of the optic disc.*	• Absence of the fovea centralis is common in older patients. It may indicate macular degeneration, a cause of loss of central vision.

BOX 45–1 Guidelines for Using the Ophthalmoscope

The ophthalmoscope has a head and a handle (see figure below). The head contains a focus wheel (also called a lens selector dial) located on the side, lenses of varying magnification, and an opening through which the eye structures are visualized. The focus wheel adjusts the lens refraction, which is measured in diopters. The diopter measurements range from 0 to +40 when the lens is rotated clockwise, and from 0 to –25 when the lens is rotated counterclockwise. By moving the focus wheel, the examiner can focus light rays to visualize the retina. The handle usually contains batteries that can be recharged. *Note:* Assessing the internal eye with the ophthalmoscope is a skill that takes practice.

Before the examination, explain the procedure to the patient. Assemble the ophthalmoscope. Wash your hands and wear disposable gloves if the patient has any drainage from the eyes. Darken the room (to allow the pupils of the patient to dilate) and ask the patient to look straight ahead, focusing on a fixed point such as an object on the wall. Hold the ophthalmoscope in one hand, resting the index finger on the focus wheel (see accompanying figure).

1. Turn on the ophthalmoscope light, and set the focus wheel to 0 diopters. Hold the ophthalmoscope in your right hand with your index finger on the focus wheel. Standing in front of the patient, position yourself at a 15-degree angle to the patient's line of vision.
2. Hold the opening of the ophthalmoscope up to your right eye and direct the light toward the patient's right eye from a distance of about 12 inches.



An ophthalmoscope.

Technique for holding an ophthalmoscope.

3. As the beam of light falls on the patient's pupil, observe for the red reflex, which appears as a sharply outlined orange glow from within the pupil. This glow is the reflection of the light from the retina.
4. Move closer to the patient, turning the focus wheel clockwise toward the positive numbers as needed to maintain clear focus.
5. Examine the lens and the vitreous body, both of which should be clear.
6. Gradually rotate the focus wheel counterclockwise toward the negative numbers as needed, focusing on a structure of the retina (such as the disc or a blood vessel). Turn the focus wheel until the image is clear. Examine the structures of the retina as follows:
   a. *Optic disc* (see accompanying figure). Assess for size, shape, color, distinct margins, and the physiologic cup. The disc is round to slightly oval and about 1.5–2 mm in diameter. It has a yellow to pink color that is lighter than the retina itself. The margins should be sharp and clear. The physiologic cup is a small depression that occupies about one-third of the optic disc, lying temporal to the center of the disc.
   b. *Vessels of the retina.* Assess for color, arteriolar light reflex, ratio of arterioles to veins, and arteriovenous crossings. The arterioles are red, brighter than the veins, and about one-fourth smaller. The arterioles normally have a narrow light reflex from the center of each vessel; veins do not have this light reflex. The ratio of arterioles to veins is usually 2:3 or 4:5. The vessels normally cross and become smaller toward the periphery.
   c. *Retinal background.* Assess color and changes in color. The retina is normally reddish orange and regular in color.
   d. *Macula.* Assess size and color. To assess the macula, ask the patient to look directly into the ophthalmoscope light. The macula is temporal to the optic disc, appears slightly darker than the retina, and has no visible vessels. The fovea centralis may be seen as a bright spot of light. Because looking directly into the light causes some discomfort, conduct this portion of the examination last. The macula is often difficult to visualize.
7. Using the same technique, examine the left eye.

The optic disc as seen through an ophthalmoscope.

Anatomy, Physiology, and Functions of the Ears

As a sensory organ, the ears have two primary functions: hearing and maintaining equilibrium. Anatomically, each ear is divided into three areas: the external ear, the middle ear, and the inner ear (Figure 45–10 ■). All three are involved in hearing, but only the inner ear is involved in equilibrium.

The External Ear

The external ear consists of the auricle (or pinna), the external auditory canal, and the tympanic membrane. The auricles contain sebaceous and sweat glands and sometimes hair. Each auricle has a rim (the helix) and a lobe. The auricle serves to direct sound waves into the ear. The external auditory canal, which is about 2.5 cm (1 in.) long, extends from the auricle to the tympanic membrane. The canal is lined with skin that contains hair, sebaceous glands, and ceruminous glands. The external auditory canal serves as a resonator for the range of sound waves typical of human speech and increases the pressure that sound waves in this frequency range place on the tympanic membrane. The canal's ceruminous glands secrete a yellow to brown waxy substance called **cerumen**. Cerumen traps foreign bodies; it also has bacteriostatic properties, protecting the tympanic membrane and the middle ear from infections.

The tympanic membrane lies between the external ear and the middle ear. It is a thin, semitransparent, fibrous structure covered with skin on the external side and mucosa on the inner side. The membrane vibrates as sound waves strike it; these vibrations are transferred as sound waves to the middle ear.

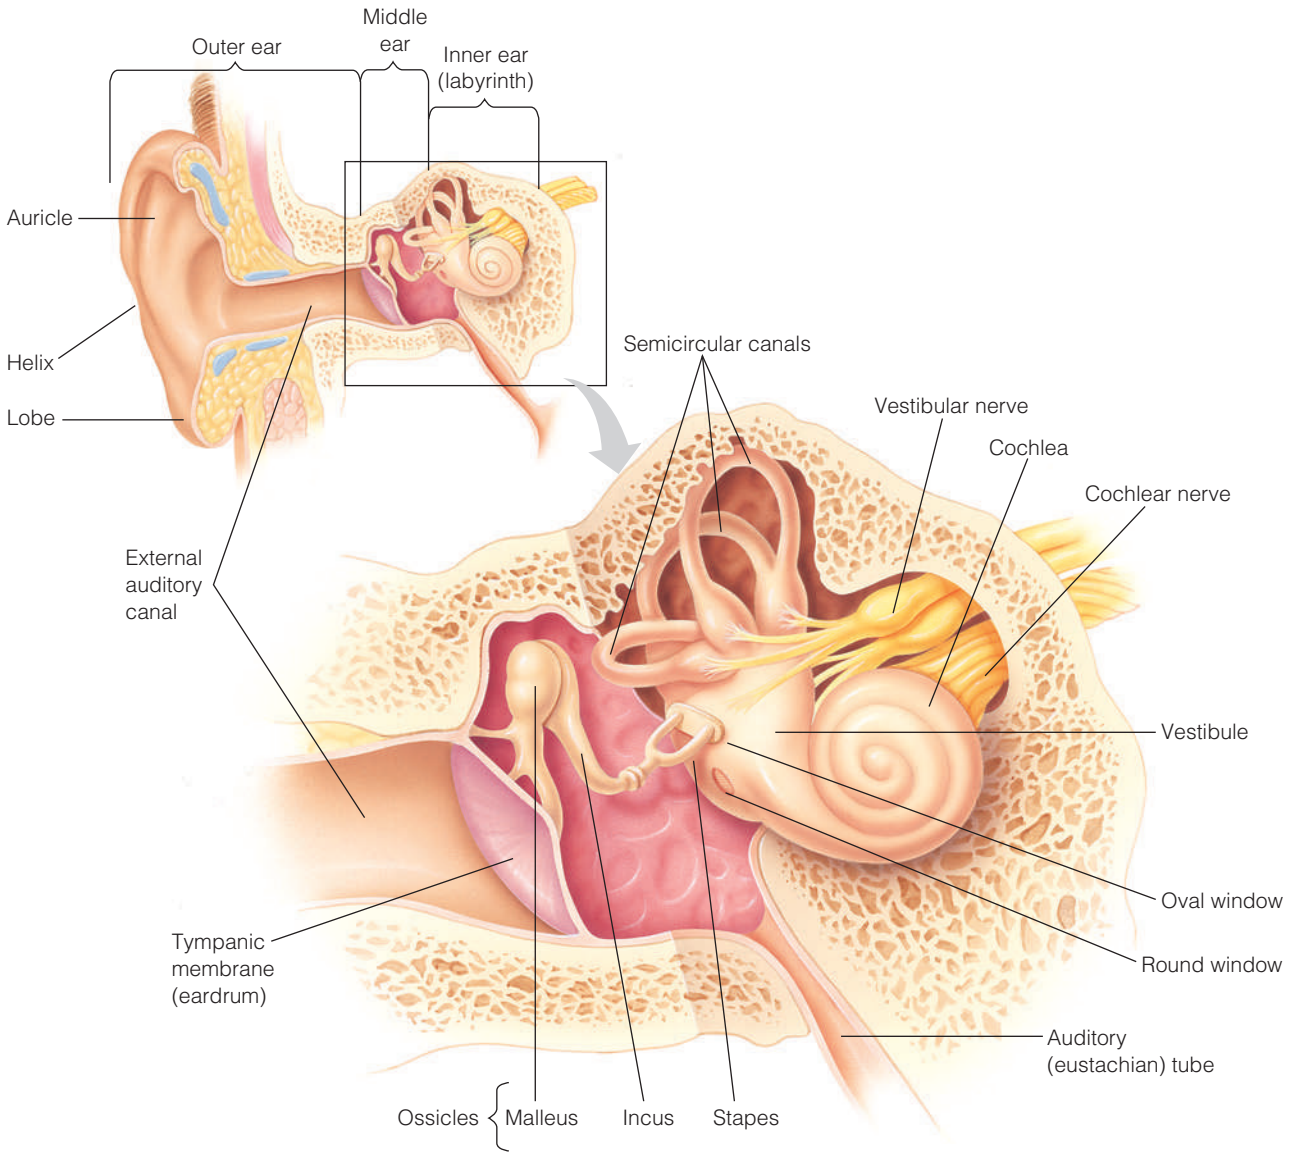

Figure 45–10 ■ Structures of the external ear, middle ear, and inner ear.
Source: Todd Buck.

The Middle Ear

The middle ear is an air-filled cavity in the temporal bone. The middle ear contains the three auditory ossicles: the malleus, the incus, and the stapes. These bones extend across the middle ear to the tympanic membrane. The medial side of the middle ear is a bony wall containing two membrane-covered openings: the oval window and the round window. The posterior wall of the middle ear contains the mastoid antrum, which communicates with the mastoid sinuses. The mastoid sinuses help the middle ear adjust to changes in pressure. The middle ear also opens into the auditory tube (also called the *pharyngotympanic* or *Eustachian tube*), which connects with the nasopharynx. The auditory tube helps to equalize the air pressure in the middle ear by opening briefly in response to differences between middle ear pressure and atmospheric pressure. The mucous membrane lining the middle ear is continuous with the mucous membranes lining the pharynx.

The malleus attaches to the tympanic membrane and articulates with the incus, which in turn articulates with the stapes. The stapes fits into the oval window. When the tympanic membrane vibrates, the vibrations are conducted across the middle ear to the oval window by the ossicles. The vibrations set in motion the fluids of the inner ear, which in turn stimulate the hearing receptors. Two small muscles attached to the ossicles contract reflexively in response to sudden loud noises, decreasing the vibrations and protecting the inner ear.

The Inner Ear

The inner ear, also called the labyrinth, is a maze of bony chambers (the bony labyrinth) located deep within the temporal bone, just behind the eye socket. The membranous labyrinth, a delicate network of interconnected fluid-filled tubes, lies within this maze. Perilymph, a fluid similar to cerebrospinal fluid, flows between the bony and the membranous labyrinth. Within the chambers of the membranous labyrinth is a fluid called endolymph. These fluids conduct sound vibrations and respond to changes in body position and movement.

The bony labyrinth has three regions: the vestibule, the semicircular canals, and the cochlea. The vestibule is the central portion of the inner ear, one side of which is a bony wall containing the oval window. Two sacs within the vestibule (the saccule and the utricle) join the vestibule with the cochlea and the semicircular canals. The saccule and the utricle contain receptors for equilibrium that respond to changes in gravity and changes in position of the head. The three semicircular canals each project into a different plane (anterior, posterior, and lateral). Each canal contains a semicircular duct that communicates with the utricle of the vestibule. Each duct has an enlarged area at one end containing an equilibrium receptor that responds to angular movements of the head.

The cochlea is a tiny bony chamber that houses the organ of Corti, the receptor organ for hearing. The organ of Corti is a series of sensory hair cells, arranged in a single row of inner hair cells and three rows of outer hair cells. The hair cells are innervated by sensory fibers from cranial nerve VIII. The organ of Corti is supported in the cochlea by the flexible basilar membrane, which has fibers of varying lengths that respond to different sound wave frequencies.

Sound Conduction

Hearing is the perception and interpretation of sound. Sound is produced when the molecules of a medium are compressed, resulting in a pressure disturbance evidenced as a sound wave. The intensity or loudness of sound is determined by the amplitude (height) of the sound wave, with greater amplitudes causing louder sounds. The frequency of the sound wave in vibrations per second determines the pitch or tone of the sound, with higher frequencies resulting in higher sounds. The human ear is most sensitive to sound waves with frequencies between 1000 and 4000 cycles per second, but can detect sound waves with frequencies between 20 and 20,000 cycles per second.

Sound waves enter the external auditory canal and cause the tympanic membrane to vibrate at the same frequency. The ossicles not only transmit the motion of the tympanic membrane to the oval window but also amplify the energy of the sound wave. As the stapes moves against the oval window, the perilymph in the vestibule is set in motion. The increased pressure of the perilymph is transmitted to fibers of the basilar membrane and then to the organ of Corti. The up-and-down movements of the fibers of the basilar membrane pull the hair cells in the organ of Corti, which in turn generates action potentials that are transmitted to cranial nerve VIII and then to the brain for interpretation.

Several brainstem auditory nuclei transmit impulses to the cerebral cortex. Fibers from each ear cross, with each auditory cortex receiving impulses from both ears. Auditory processing is so finely tuned that a wide variety of sounds of different pitch and loudness can be heard at any one time. In addition, the source of the sound can be localized.

Equilibrium

The inner ear also provides information about the position of the head. This information is used to coordinate body movements so that equilibrium and balance are maintained. The types of equilibrium are static balance (affected by changes in the position of the head) and dynamic balance (affected by the movement of the head).

Receptors called maculae in the vestibule detect changes in the position of the head. Maculae are groups of hair cells that have protrusions covered with a gelatinous substance. Embedded in this gelatinous substance are tiny particles of calcium carbonate called otoliths (ear stones), which make the gelatin heavier than the endolymph that fills the membranous labyrinth. As a result, when the head is in the upright position, gravity causes the gelatinous substance to bear down on the hair cells. When the position of the head changes, the force on the hair cells also changes, bending them and altering the pattern of stimulation of the neurons. Thus, a different pattern of nerve impulses is transmitted to the brain, where stimulation of the motor centers initiates actions that coordinate various body movements according to the position of the head.

The receptor for dynamic equilibrium is in the crista, a crest in the membrane lining the ampulla of each semicircular canal. The cristae are stimulated by rotatory head movement (acceleration and deceleration) as a result of changes in the flow of endolymph and of movement of hair cells in the maculae. The direction of endolymph and hair cell movement is always opposite to the motion of the body.

ASSESSING THE EARS

The structure and functions of the ears are assessed by findings from diagnostic tests, a health assessment interview, and a physical assessment.

Diagnostic Tests

The results of diagnostic tests are used to support the diagnosis of a specific injury, disease, or hearing problem; to provide information to identify or modify appropriate medications or assistive devices used to treat the disease or problem; and to help monitor the patient's responses to treatment and nursing care interventions. Diagnostic tests of the ear, especially for hearing, are most often conducted in a healthcare provider's office. Diagnostic tests to assess the structure and functions of the ears are described in the Diagnostic Tests table.

Regardless of the type of diagnostic test, the nurse is responsible for explaining the procedure and any special preparation needed, for assessing for any medication use that might affect the outcome of the tests, for supporting the patient during the examination as necessary, for ensuring the consent form is signed (if necessary), for documenting the procedures as appropriate, and for monitoring the results of the tests.

Genetic Considerations

When conducting a health assessment interview and a physical assessment, it is important for the nurse to consider genetic influences on the health of an adult. Several diseases of the ears and types of hearing impairment have a genetic component. During the health assessment interview, ask about a family history of presbycusis, congenital hearing impairment, hearing impairment associated with another disorder such as vision loss or a kidney or thyroid disorder, or tumors of the auditory nerve.

During the physical assessment, assess for any manifestations that might indicate a genetic syndrome such as symptoms of thyroid, kidney, or vision disorders (see the accompanying Genetic Considerations box). If data are found to indicate genetic risk factors or alterations, ask about genetic testing and refer for appropriate genetic counseling and evaluation.

GENETIC CONSIDERATIONS

Examples of Ear Disorders

- Hereditary hearing impairment (HHI) is believed to account for more than 50% of childhood hearing loss, and also can manifest later in life. Most HHI follows an autosomal recessive inheritance pattern (Lalwani, 2012).
- Heredity is increasingly recognized as a contributor to presbycusis (hearing loss associated with aging).
- Pendred syndrome is an inherited disorder that accounts for as much as 10% of hereditary deafness. The deafness is usually accompanied by a thyroid goiter.
- Neurofibromatosis, a rare inherited disorder, is characterized by the development of acoustic neuromas (benign tumors of the auditory nerve) and malignant central nervous system tumors.

Health Assessment Interview

The health history to collect subjective data about the ears and hearing may be part of a health screening, may focus on a chief complaint (such as hearing problems or pain in the ear), or may be part of a total health assessment. If the patient has a problem involving one or both ears, analyze its onset, characteristics and course, severity, precipitating and relieving factors, and any associated symptoms, noting the timing and circumstances. For example, you may ask the following questions:

- Have you noticed any difficulty hearing high-pitched sounds, low-pitched sounds, or both?
- When did you first notice the ringing in your ears? Is it constant or intermittent?
- Is your workplace very noisy? If so, do you wear protective ear equipment at work?

Throughout the examination, be alert to nonverbal behaviors (such as inappropriate answers, requests to repeat statements, or tilting the head toward you) that suggest problems with ear function. Explore changes in hearing, ringing in the ears (tinnitus), ear pain, drainage from the ears, or the use of hearing aids. When taking the history, ask about trauma, surgery, or infections of the ear as well as

DIAGNOSTIC TESTS for Ear Disorders

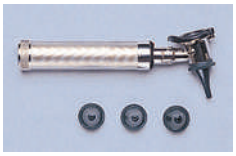
Name of Test	Purpose and Description	Related Nursing Interventions
Audiometry	Audiometry is used to evaluate and diagnose conductive and sensorineural hearing loss. Patient sits in soundproof room and responds when sounds are heard. Speech audiometry tests word recognition and word discrimination.	No special preparation is needed.
Auditory brainstem response (ABR) and auditory evoked potential (AEP)	The ABR and AEP tests measure the electrical activity of the auditory pathway from inner ear to brain to identify the site of sensorineural hearing loss or to diagnose brainstem pathology, stroke, and acoustic neuroma.	No special preparation is needed.
Electronystagmography (ENG) or videonystagmography (VNG)	This test is used to detect eye movements (nystagmus) in response to changes in head position or stimulation of balance sensors in the inner ear using warm and cool water or air. It may be used to evaluate vertigo or help diagnose Ménière's disease.	Instruct the patient to avoid consuming caffeine or alcohol for 24 h prior to the test. Food intake may be restricted for 6 h prior to testing to prevent vomiting.
Vestibular evoked myogenic potentials (VEMP)	This test is used to diagnose inner ear disorders such as Ménière's disease or vertigo by detecting neck and eye muscle contractions in response to the stimulus of sound.	No special preparation is needed.

NURSING CARE OF THE OLDER ADULT

Age-Related Changes in the Ear

Age-Related Change	Significance
THE INNER EAR	
• Loss of hair cells, ↓ blood supply, less flexible basilar membrane, degeneration of spiral ganglion cells, and ↓ production of endolymph result in progressive hearing loss with age (**presbycusis**). • High-frequency sounds are lost; middle- and low-frequency sounds may also be lost or decreased. • Vestibular structures degenerate, organ of Corti and cochlea atrophy.	Older adults may require hearing aids to hear well. With loss of high-frequency sounds, speech may be distorted, contributing to a risk for communication problems. Degeneration and atrophy of inner ear structures concerned with balance and equilibrium increase the risk for falls.
THE MIDDLE EAR	
• Muscles and ligaments weaken and stiffen, decreasing the acoustic reflex.	Sounds made from one's own body and speech are louder and may further interfere with hearing, speech, and communications.
THE EXTERNAL EAR	
• Cerumen is dryer and harder, and tends to accumulate in the ear canal. • Decreased apocrine gland activity in ear canal contributes to cerumen accumulation, as well as dryness and itching.	Accumulated cerumen may impair hearing. The lining of the ear canal is more easily irritated or damaged, increasing the risk of external ear infection.

the date of the last ear examination. In addition, ask the patient about a medical history of infectious diseases, such as meningitis or mumps, as well as the use of medications that may affect hearing. Because ear problems tend to run in families, ask about a family history of hearing loss, ear problems, or diseases that could result in such problems. If the patient has a hearing aid, ascertain the type and assess measures for its care.

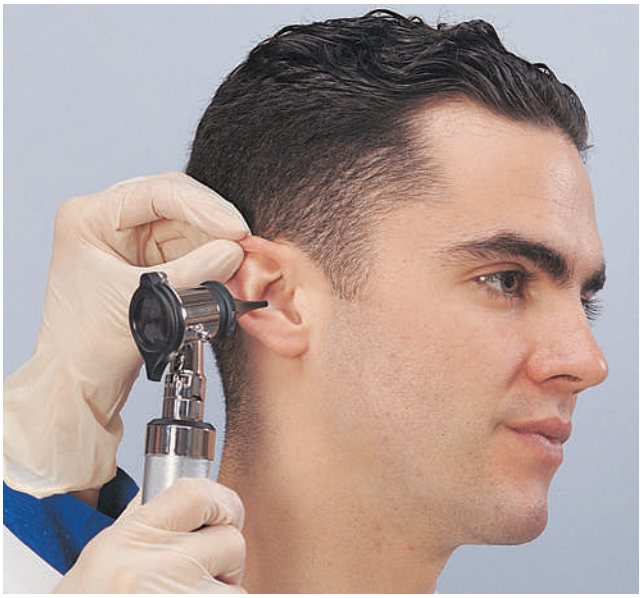


Physical Assessment of the Ears and Hearing

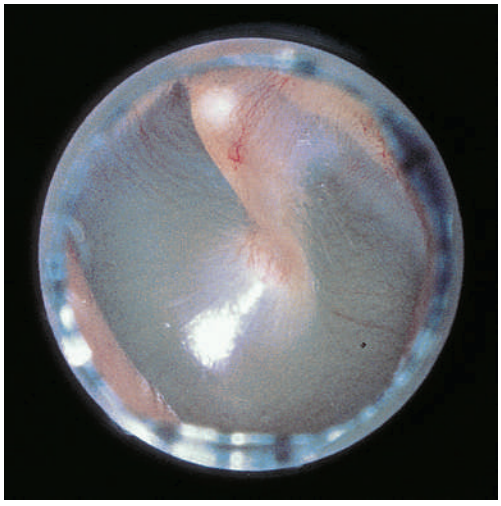
Physical assessment of the ears and hearing may be performed as part of a total health assessment or separately for patients with known or suspected problems with the ears. The ears and hearing are assessed primarily through inspection of external structures, the auditory canal, and the tympanic membrane. Hearing acuity is assessed by the whisper test and using a tuning fork. Normal age-related findings for the older adult are summarized in the Nursing Care of the Older Adult box.

The patient should be sitting, and the examiner's head should be level with the head of the patient. Prior to the assessment, collect all necessary equipment and explain the techniques to the patient to decrease anxiety. The auditory canal and tympanic membrane are inspected with the otoscope. Guidelines for use of the otoscope are listed in Box 45–2.

BOX 45–2 Guidelines for Using the Otoscope



The otoscope is used to inspect the auditory canal and the tympanic membrane. The handle contains batteries for the light; specula of varied sizes are used to direct the light (see accompanying figure).



An otoscope.

Before the examination, explain the procedure to the patient. Assemble the otoscope, using the largest speculum that will fit into the patient's auditory canal without discomfort. Wash your hands; wear disposable gloves if the patient has any drainage from the ears. Turn on the otoscope light. Ask the patient to tip the head slightly toward the shoulder opposite the ear being examined. When the patient is in this position, the auditory canal is aligned with the speculum.

1. Hold the handle of the otoscope in your dominant hand. If the patient is restless, hold the otoscope handle upward, resting the hand against the patient's head.
2. For adult patients, grasp the superior portion of the auricle and pull up, out, and back to straighten the auditory canal (see accompanying figure).
3. Insert the speculum into the ear. While gently advancing the speculum, inspect the walls of the auditory canal for color, obstructions, hair growth, and cerumen. Old cerumen is very dark and may obstruct visualization of part or all of the tympanic membrane.
4. Adjusting auditory canal alignment and otoscope position as needed, inspect the tympanic membrane. A normal membrane is translucent, allowing a portion of the malleus to be seen as a shadow behind the membrane. A cone-shaped light reflection should be visible.
5. Note the color and surface of the membrane. The normal tympanic membrane is pearly gray, shiny, and semitransparent. The surface should be continuous, intact, and either flat or concave.
6. Identify the landmarks on the tympanic membrane (see accompanying figure):
   a. The cone of light, located in the anteroinferior quadrant (5 o'clock position on the right side; 7 o'clock on the left)
   b. The malleus, pars tensa, annulus, pars flaccida, and malleolar folds.
7. Assess movement of the tympanic membrane. If the auditory tube is patent, the membrane moves in and out when air is injected or when the patient performs the Valsalva maneuver.
8. Gently withdraw the speculum. If the speculum is soiled with drainage or cerumen, use a clean speculum for the other ear.
9. Using the same technique, examine the other ear.

Technique for using an otoscope.

The tympanic membrane as it appears through the otoscope.

Ear and Hearing Assessments

Technique/Normal Findings	Abnormal Findings
Hearing Assessment	
Perform the whisper test. Ask the patient to occlude one ear with a finger. Standing behind and 1–2 ft away from the patient, whisper numbers and ask the patient to repeat them. Repeat the procedure, having the patient occlude the other ear. Note whether you need to raise your voice or to stand closer to make the patient hear you. *The patient with no hearing loss will accurately repeat whispered numbers or a phrase.*	• Inability to repeat what is said may indicate a hearing loss.
Assess auditory acuity using a tuning fork. A tuning fork with a frequency of 512 Hz is preferred for auditory evaluation. Hold the tuning fork at the base and make it vibrate by stroking, squeezing, or lightly tapping the prongs on the heel of the opposite hand. The following tests are performed to evaluate conductive versus perceptive hearing loss	
Perform the Weber test. Place the base of a vibrating tuning fork on the midline vertex of the patient's head (Figure 45–11 ■). Ask whether the patient hears the sound equally in both ears or better in one than the other. *Sound is normally heard equally in both ears.*	• Sound heard in, or lateralized to, one ear indicates either a conductive loss in that ear or a sensorineural loss in the other ear. The sound will be louder on the impaired side with a conductive hearing loss. The sound will be softer on the impaired side with a sensorineural hearing loss. Conductive losses may be due to a buildup of cerumen, an infection such as otitis media, or perforation of the eardrum.
Perform the Rinne test. Place the base of a vibrating tuning fork on the patient's mastoid bone. Ask the patient to indicate when the sound is no longer heard. When the patient does so, quickly reposition the tuning fork in front of the patient's ear close to the ear canal. Ask whether the patient can hear the sound. If the patient says yes, ask the patient to indicate when the sound is no longer heard. Repeat over the opposite mastoid bone (Figure 45–12 ■). *The patient will normally hear the sound twice as long by air conduction (AC) as by bone conduction (BC), recorded as AC > BC (air conduction greater than bone conduction).*	• With conductive hearing loss, bone conduction is equal to or greater than air conduction in the affected ear.

Figure 45–11 ■ Performing the Weber test.

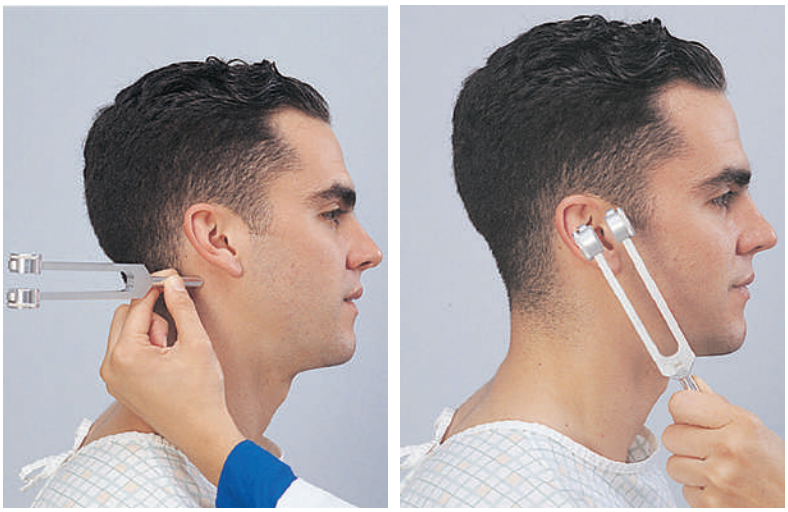


Figure 45–12 ■ Performing the Rinne test for conductive hearing loss.

Ear and Hearing Assessments (*continued*)

Technique/Normal Findings	Abnormal Findings
Ear Assessment	
Inspect the external ears for symmetry, proportion, color, and integrity. *External ears are normally equal in size, of a color that matches the patient's face, and without redness or lesions.*	• Unusual redness or drainage may indicate an inflammatory response to infection or trauma. • Scales or skin lesions around the rim of the auricle may indicate skin cancer. • Small, raised lesions on the rim of the ear are known as tophi and may indicate gout.
Palpate the auricles and over each mastoid process. *There should be no pain or swelling on palpation.*	• Tenderness, swelling, or nodules may indicate inflammation of the external auditory canal or mastoiditis.
Inspect the external auditory canal with the otoscope. *Canal walls should be pink and smooth without lesions. Cerumen is normally present in small, odorless amounts. People with darker skin tend to have darker cerumen.*	• Unusual redness, lesions, or purulent drainage may indicate an infection. • Cerumen varies in color and texture, but hardened, dry, or foul-smelling cerumen may indicate an infection or impacted cerumen.
Inspect the tympanic membrane. *The tympanic membrane should be pearly gray, shiny, and translucent without bulging or retraction.*	• White, opaque areas on the tympanic membrane are often scars from previous perforations (Figure 45–13 ■). • Inconsistent texture and color may be due to scarring from previous perforations caused by infection, allergies, or trauma. • Bulging membranes are indicated by a loss of bony landmarks and a distorted light reflex. Such bulges may be the result of otitis media or auditory tube dysfunction. • Retracted tympanic membranes are indicated by accentuated bony landmarks and a distorted light reflex. Such retraction is often due to an obstructed auditory tube.
Tympanometry may be performed to evaluate the response of the tympanic membrane to changes in air pressure and middle ear function. The results are plotted on a tympanogram. Insert the device into the ear canal. Tell the patient he or she will hear a loud tone as the measurements are taken, and instruct not to speak, move, swallow, or jump when the sound is heard. Repeat for the other ear. *The graphic results indicate normal tympanic membrane movement.*	• Abnormal findings may include little or no tympanic membrane movement, indicative of fluid in the middle ear, or negative pressure in the middle ear, indicative of auditory tube dysfunction.

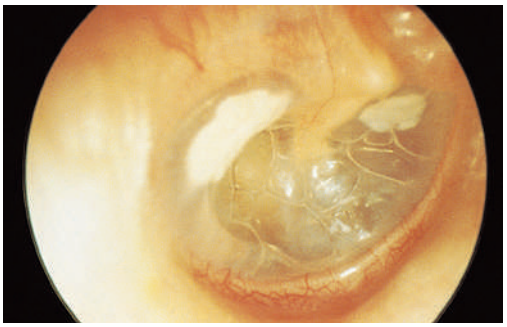

Figure 45–13 ■ Scarring of the tympanic membrane.

SAMPLE DOCUMENTATION

Assessment of the Ear

22-year-old male with complaints of "having some problems hearing these days." States he often listens to music in his car "as loud as it will go" and uses earphones at home so he does not bother other family members. Ears are normally placed bilaterally; skin smooth without lesions. Small amount of dark brown cerumen present in ear canals. Tympanic membranes gray and shiny. No bulging or retraction noted. Whisper test: Unable to repeat back words spoken by examiner. Weber test: Sound lateralized to left ear. Rinne test: BC ≥ AC. No tenderness noted when mastoids palpated. Referred to ear clinic for further evaluation.

CHAPTER HIGHLIGHTS

- **Abnormalities in the structure or function of the eyes and their accessory structures can threaten or impair vision and the patient's safety, independence, and social interactions.**
- **For hearing to occur, sound waves must travel from the external auditory meatus, through the ear canal, to vibrate the tympanic membrane and bony structures of the middle ear, which in turn activate the receptors of the cochlea.**
- **Assessment of the eyes, ears, and their sensory functions involves specialized techniques that require practice to develop skill and competence.**

TEST YOURSELF NCLEX-RN® REVIEW

1. During an eye assessment, a nurse touches the part of the eye covering the iris and pupil. Which patient response should the nurse expect?
   1. dilated pupil
   2. excess tearing
   3. blinking of eyelids
   4. bilateral nystagmus
2. The nurse is conducting a health history with an older patient. Which statement would indicate that the patient is experiencing presbyopia?
   1. "I think I have a lot of earwax in my ears."
   2. "My arms just don't seem long enough to read."
   3. "I can't seem to remember anything these days."
   4. "I just am having so much trouble hearing music."
3. The nurse is planning to assess a patient's sound conduction. What equipment should the nurse use to make this assessment?
   1. penlight
   2. otoscope
   3. tuning fork
   4. ophthalmoscope
4. The nurse is preparing to assess a patient's eyes for accommodation. Which findings should the nurse expect when conducting this assessment? (Select all that apply.)
   1. Rhythmical blinking occurs.
   2. Eyes move in six different directions.
   3. Pupils dilate when focused on a distant object.
   4. Pupils constrict when focused on a near object.
   5. Eyes move in the direction that the head is turned.
5. A patient is scheduled to have eye refraction completed. What should the nurse say to the patient before this test is done?
   1. "Are you allergic to seafood?"
   2. "You will be blindfolded during the test."
   3. "Your pupils will be dilated for several hours."
   4. "This test is uncomfortable, but it doesn't take long."
6. The nurse is concerned that an older patient is experiencing age-related changes in the inner ear. What did the nurse most likely assess in this patient? (Select all that apply.)
   1. loss of balance when walking
   2. loss of ability to hear high-frequency sounds
   3. self-speech sounds louder to the patient
   4. decreased middle- and low-frequency sounds
   5. impacted cerumen and itchy external ear canal
7. The nurse is preparing to assess a patient using the Snellen chart. What is the nurse planning to assess in this patient?
   1. near vision
   2. visual fields
   3. convergence
   4. distant vision
8. The nurse wants to make a rough estimate of a patient's ability to hear. Which assessment should the nurse use to make this estimation?
   1. Rinne test
   2. Weber test
   3. audiometry
   4. whisper test
9. After an assessment the nurse determines that an older patient is experiencing an age-related change to the lens of the eyes. What did the nurse assess in this patient?
   1. complaints of glare
   2. slow reaction to light
   3. dry itchy and burning eyes
   4. unable to discriminate blue and green tones
10. The nurse is preparing to assess a patient's visual fields. Which criterion should be present to accurately assess the patient's visual fields?
    1. Examiner must not wear glasses.
    2. Patient must wear corrective lenses.
    3. Examiner must have normal visual fields.
    4. Patient must have no less than 20/30 vision.

46 Nursing Care of Patients with Eye and Ear Disorders

LEARNING OUTCOMES

1. Describe the pathophysiology of commonly occurring disorders of the eyes and ears, relating their manifestations and effects on vision and hearing to the pathophysiologic process.
2. Explain the risk factors for selected disorders of the eyes and ears, identifying the nursing implications for these risk factors.
3. Describe interprofessional care for specific eye and ear disorders, identifying the nurse's role and responsibilities related to this care.
4. Discuss the effects of and nursing implications for medications prescribed to treat eye and ear disorders.
5. Discuss the nurse's role in caring for patients with impaired vision or hearing loss.

CLINICAL COMPETENCIES

1. Assess vision, hearing, functional health, and safety of patients with eye and ear disorders.
2. Using assessed data and current evidence-based practice guidelines, determine priority nursing diagnoses and interventions for patients with eye and ear disorders.
3. Communicate, collaborate, and coordinate with the interprofessional team to provide safe, effective care for patients with eye and ear disorders.
4. Considering patient preferences, values, and expressed needs, plan and implement appropriate and individualized evidence-based nursing interventions and teaching for the patient with an eye or ear disorder.
5. Safely and effectively administer eye and ear medications and prescribed treatments.
6. Critically evaluate the healthcare environment for threats to the safety of patients with eye and ear disorders.
7. Evaluate the effectiveness of care provided for patients with eye and ear disorders, sharing data and revising practices and individual plans of care as indicated.

MAJOR CHAPTER CONCEPTS

- Structures of the external eye are vulnerable to trauma and infection. Although usually minor, these problems can cause significant pain, scarring and clouding of the cornea, and loss or impairment of vision.
- Cataracts, glaucoma, age-related macular degeneration, and diabetic retinopathy are leading causes of visual impairment in the United States. Although these conditions cannot, in most cases, be prevented, they often can be treated or their progress slowed, preserving vision. Nurses play a vital role in educating patients about these conditions, their risk factors, and the importance of regular exams by an eye professional.
- Disruption of the integrity of any portion of the auditory pathway from the external ear through neural transmission to auditory centers of the brain can impact an individual's ability to hear and interpret sounds. Health promotion activities and prompt treatment of disorders are important measures to preserve hearing.
- Inner ear disorders can affect the perception of sound as well as equilibrium. When balance is affected, the patient is at significant risk for injury, making safety a nursing care priority.
- Hearing loss affects people of all ages, although older adults are disproportionately affected. Impaired hearing significantly affects the ability to communicate, making it a major public health problem. Despite its prevalence, impaired hearing often is undiagnosed and untreated.

Vision and hearing provide the primary means of input for much of what we know about the world. The ability to receive and organize information orients us to our surroundings. These senses allow us to communicate easily, gain access to information, and derive pleasure from the sights and sounds of the world around us.

This chapter discusses conditions affecting vision and hearing as the result of eye and ear disorders. Nursing care focuses on patients with vision and hearing deficits that can result from the disorders presented.

Eye Disorders

Any portion of the eye and its protective structures may be affected by an acute or chronic condition. While many eye disorders are minor and have little or no effect on vision, others can and often do result in vision impairment. Disorders and diseases of the outer, visible portion of the eye often cause discomfort and may have cosmetic effects. With appropriate treatment, vision impairment often can be prevented or reversed. Disorders of the cornea present the greatest risk to vision in this group. The patient who has had eye surgery or minor trauma may have either temporary or permanent visual impairment. Disorders affecting the internal structures or the function of the eye are more likely to have adverse effects on vision. These disorders are more likely to affect adults over the age of 40, and older adults in particular. Nearly 4.2 million adults in the United States have some degree of visual impairment (Prevent Blindness America, 2012).

FAST FACTS

Among adults ages 40 and older in the United States:

- Nearly 4.2 million, or 2.9% of the population, are classified as blind or having low vision.
- The prevalence of impaired vision and blindness increases significantly after age 75.
- Refractory errors, including myopia (nearsightedness) and hyperopia (farsightedness), are the most common causes of impaired vision.
- Other common conditions affecting the vision of middle and older adults, in order of prevalence, are as follows:
  1. Cataracts—17.1%
  2. Macular degeneration—1.4%
  3. Diabetic retinopathy—5.4%
  4. Glaucoma—1.9%.

Source: All data from Prevent Blindness America. (2012). *Vision problems in the U.S.* Retrieved from http://www.preventblindness.org.

Although disorders that commonly affect vision often cannot be prevented or cured, some can be controlled and vision corrected to normal or near normal. Regardless of the real threat a disorder poses to vision, the patient may experience anxiety related to a perceived threat. The box on page 1493 discusses major causes of significantly impaired vision and nursing care for the patient who is blind. These principles of nursing care may apply to patients with many of the disorders discussed in this chapter.

THE PATIENT WITH CONJUNCTIVITIS

The conjunctiva—the thin, transparent membrane that covers the anterior surface of the eye and lines the inner surfaces of the eyelids—is vulnerable to inflammation and infection because of its constant exposure to the environment. **Conjunctivitis**, inflammation of the conjunctiva, is the most common eye disease. Its usual cause is a bacterial or viral infection. These infections can be transmitted to the eye by direct contact (e.g., hands, tissues, towels). Allergens, chemical irritants, and exposure to radiant energy such as ultraviolet light from the sun or tanning devices can also lead to this common condition. Its severity can range from mild irritation with redness and tearing to conjunctival edema, hemorrhage, or a severe necrotizing process with tissue destruction.

Pathophysiology and Manifestations

ACUTE CONJUNCTIVITIS

Infectious conjunctivitis may be bacterial, viral, or fungal in origin. Bacterial conjunctivitis, also known as *pink eye*, is highly contagious, and often is caused by *Staphylococcus* or *Haemophilus.* Adenovirus infection is the leading cause of conjunctivitis in adults. Systemic infections that may affect the eyes include herpes simplex and other viral infections. Contact with genital secretions infected with *Gonococcus* can cause gonococcal conjunctivitis, a medical emergency that can lead to corneal perforation.

Redness and itching of the affected eye are common manifestations of acute conjunctivitis (Figure 46–1 ■). The patient may also complain of a scratchy, burning, or gritty sensation. Pain is not common; however, photophobia (sensitivity to light) may occur. Tearing and discharge accompany the inflammatory process. The discharge may be watery, purulent, or mucoid, depending on the cause of conjunctivitis. The patient may have associated manifestations such as pharyngitis, fever, malaise, and swollen preauricular lymph nodes.

TRACHOMA

Trachoma, a chronic conjunctivitis caused by *Chlamydia trachomatis*, is a significant preventable cause of blindness worldwide. Trachoma is endemic in northern and sub-Saharan Africa, the Middle East, and parts of Asia. Although the prevalence is lower than in endemic

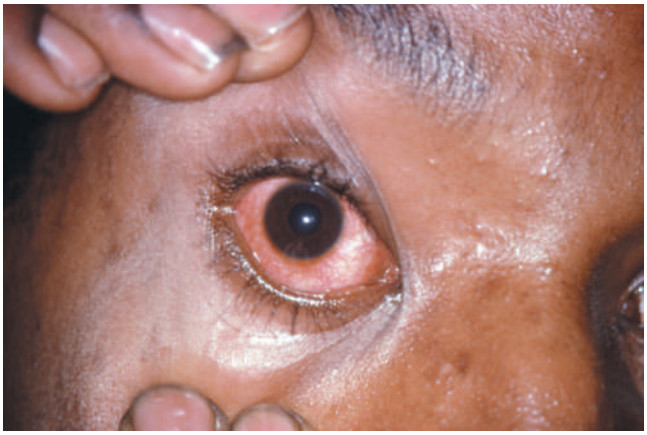

Figure 46–1 ■ The appearance of an eye with conjunctivitis.
Source: Centers for Disease Control and Prevention.

NURSING CARE OF THE PATIENT

Who Is Blind

Visual impairment exists on a continuum from blindness to decreased visual acuity that can be corrected with refractive lenses to normal or near normal. *Visual impairment* is defined as 20/40 vision in the better eye, even with corrective lenses. The legal definition of *blindness* is visual acuity no better than 20/200 in the better eye with optimal correction, or a visual field of less than 20 degrees in diameter (compared to the normal of 180 degrees) (Prevent Blindness America, 2012). Total blindness usually indicates that the patient has no light perception at all. In practical terms, an individual with a visual deficit sufficient to need assistive devices or aid from other people for normal activities of daily living is considered blind.

Ten to twelve million people in the United States have a visual impairment that cannot be corrected. More than 1.2 million Americans are legally blind and an additional 2.9 million are visually impaired. In the United States, blindness is more prevalent among Whites than it is in Blacks and Hispanics (National Eye Institute [NEI], 2012d). Worldwide, between 30 and 40 million people have visual impairment significant enough to be considered blind.

Although blindness often can be prevented or cured, it remains a significant problem worldwide because of lack of access to care, fear of surgery or treatment, poor sanitation and nutrition, and ignorance of need. In the United States, cataracts, age-related macular degeneration, glaucoma, and diabetic retinopathy remain significant causes of blindness in adults.

NURSING CARE

People who are blind need to cope not only with the loss of a major sense but often also with societal attitudes that make them feel inferior, helpless, and inadequate. The idea of losing the ability to see is uniformly feared, leaving sighted people often unable to understand the magnitude and impact of the loss in those who have experienced it. Because of this fear and confusion, sighted people are unsure of what people who are blind expect from them.

The adjustment of the individual who is born blind and raised to become an independent member of society differs from that of the individual who has been sighted and becomes blind. The individual who has been blind from birth has developed numerous adaptive strategies that the newly blind individual has yet to learn.

Although adaptation may be easier for the patient who experiences a gradual loss of vision than for someone with an abrupt loss, both must grieve the lost sense. The patient who becomes blind needs to grieve the lost body function as well as the loss of mobility, self-sufficiency, perhaps economic security, and, to a certain extent, contact with reality as it has been perceived. The patient's self-concept and self-esteem are threatened. Anger, denial, remorse, and self-pity are not uncommon in the initial period following loss of sight. Interpersonal relationships and roles are affected. Communication patterns change with the loss of the ability to perceive many nonverbal cues. Expressions of sexuality may be impaired.

Acceptance of the change from sighted to blind is characterized by releasing the hope that vision will be regained. Self-esteem increases as the patient attempts and masters activities of self-sufficiency such as completing activities of daily living (ADLs), cooking, and becoming mobile outside the known home environment.

Health professionals often confuse the role of someone who is blind with the role of a patient, seeing the individual as helpless, dependent, and lacking in personal identity and control. Although nurses need to take blindness into account in planning care and maintaining patient safety, it is vital to give the patient who is blind the same respect and decision-making power that all patients deserve. Nurses who have dealt with their own emotions and responses to vision loss are better prepared to help the patient adapt.

Nurses can foster independence in the hospitalized patient with a significant vision deficit by doing the following:

- Orient to the environment verbally and physically. Describe the room using a central point such as the bed. Lead the patient around the room, identifying chairs, sink, bathroom, and other landmarks. Be sure that objects such as chairs, personal items, and clothing remain in the same place unless moved by the patient. Leave doors either fully open or closed as the patient wishes, but, to preserve safety, do not leave doors partially open. Keep the room and hallways free of clutter.
- Use verbal communication freely. Describe activities going on around the patient. Introduce yourself as you enter the room and let the patient know when you are leaving.
- Provide other sensory stimuli such as radio and television as desired by the patient.
- Orient to food trays by using the face of a clock to describe the position of food items on the plate and tray (unless the patient has always been blind and cannot visualize a clock face).
- When assisting with ambulation, allow the patient to hold your arm as you walk slightly ahead. Do not hold the patient's arm. Verbally describe the environment, such as "There will be two steps up five feet ahead."
- Do not hesitate to ask what assistance the patient desires.

For the patient with a new loss of sight, refer to available services. Counseling can help the patient cope with and eventually adapt to the loss of sight. People who are blind can receive mobility training, assistance with relearning self-care activities, education in the use of Braille to communicate, and vocational and other forms of rehabilitation. Local, state, and national agencies such as the American Foundation for the Blind, National Braille Association, and National Federation for the Blind coordinate services for the blind. Many assistive devices are available, including guide or pilot dogs, computer services, talking books and tape players, and low-vision aids.

regions, trachoma also is found in parts of Australia, the South Pacific, and in South America. Trachoma is contagious, transmitted primarily by close personal contact (eye-to-eye, hand-to-eye) or by fomites such as towels, handkerchiefs, and flies (Gaydos & Quinn, 2012).

Early manifestations of trachoma include redness, eyelid edema, tearing, and photophobia. Small conjunctival follicles develop on the upper lids. The inflammation also causes superficial corneal vascularization and infiltration with granulation tissue. Scarring of the conjunctival lining of the lid causes entropion (inversion of the lid margin) (Figure 46–2 ■). The lashes then abrade the cornea, eventually causing ulceration and scarring. The scarred cornea is opaque, resulting in loss of vision.

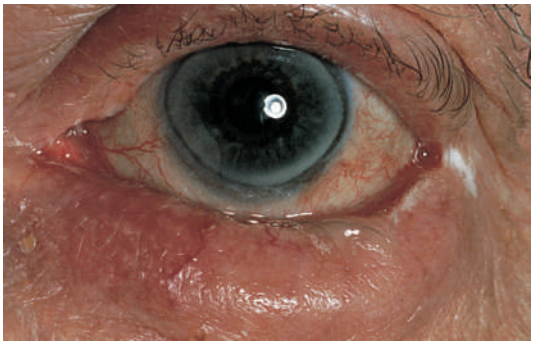

Figure 46–2 ■ Entropion.

●○● INTERPROFESSIONAL CARE

Management of the patient with conjunctivitis focuses on establishing an accurate diagnosis and prompt treatment.

DIAGNOSIS

Accurate diagnosis of conjunctivitis is especially important because other potentially vision-threatening conditions, such as acute uveitis or acute angle-closure glaucoma, can also cause a red eye (Table 46–1). Diagnostic procedures may include the following:

- *Culture and sensitivity* of exudates to determine presence of an infection and identify the infecting organism
- *Fluorescein stain* with slit-lamp examination to identify possible corneal ulcerations or abrasions, which appear green with staining
- *Conjunctival scrapings* are examined microscopically or cultured to identify the organisms.

Additional laboratory testing such as blood counts or antibody titers may be used to identify underlying infectious or autoimmune processes.

MEDICATIONS

Conjunctivitis is treated with antibiotic, antiviral, or anti-inflammatory drugs as appropriate. Topical anti-infectives applied as either eyedrops or ointment may include erythromycin, gentamicin, penicillin, bacitracin, sulfacetamide sodium, amphotericin B, or idoxuridine. For severe infections or cellulitis, anti-infectives may be administered by subconjunctival injection or systemic intravenous infusion. Antihistamines are used to minimize symptoms of conjunctivitis when an allergic response underlies the inflammatory process.

COMPLEMENTARY THERAPIES

Frequent eye irrigations may be ordered to remove the copious purulent discharge associated with conjunctivitis. Soaking the lids with warm saline compresses prior to cleansing promotes comfort and facilitates the removal of crusts and exudate in conjunctivitis.

●○● NURSING CARE

The nursing role in treating conjunctivitis is primarily one of education to prevent the disorder and to prevent its spread when it does occur.

Health Promotion

Education is a vital strategy for preventing conjunctivitis. Teach all patients about proper eye care, including the importance of not sharing towels, makeup, or contact lenses, and avoiding rubbing or scratching the eyes. Instruct to avoid using old eye makeup, which can cause eye infections. Teach contact lens users appropriate care (Box 46–1). Emphasize the need to follow cleaning instructions precisely to avoid bacterial contamination of lenses. If the eyes become red, irritated, or develop discharge, instruct the patient to avoid wearing contact lenses until the inflammatory process has cleared.

Assessment

- *Health history:* presence of redness, discomfort, tearing, photophobia, and drainage; symptom onset; care measures; use of contact lenses; exposure to "pink eye" or recent travel; allergies; previous history of conjunctivitis; presence of any chronic diseases.
- *Physical assessment:* visual acuity; inspection of eyelids, conjunctiva, sclera, and cornea; vital signs including temperature.

Priorities of Care

Nursing care priorities for the patient with conjunctivitis focus on preventing the infection from spreading to others and preventing complications.

Diagnoses, Outcomes, and Interventions

Risk for Infection

Acute conjunctivitis is highly contagious. Although most patients experience no more than discomfort from the disease, the infection carries a risk for scarring and damage to the delicate cornea of the eye. Preventing the spread of this infection is a vital nursing role.

BOX 46–1 Contact Lens Care

- Wash hands thoroughly before handling contact lenses.
- Keep storage case clean.
- Remove lenses before sleep, cleaning and storing as recommended by manufacturer.
- Use cleaning and wetting solutions recommended by an eye care professional or lens manufacturer. Do not use water or homemade solutions for wetting or cleaning lenses.
- If eye redness, tearing, vision loss, or pain occurs, remove lenses and contact an eye care professional as soon as possible.
- Do not share contact lenses or allow another person to "try on" lenses.

TABLE 46–1 Possible Causes of Acute Red Eye

	Acute Conjunctivitis	Corneal Trauma or Infection	Acute Uveitis	Acute Angle-Closure Glaucoma
Incidence	Very common	Common	Common	Rare
Pain	Mild	Moderate to severe	Moderate	Severe
Vision	Normal	Blurred	Blurred	Markedly blurred
Discharge	May be copious	Watery, may be purulent	None	None
Conjunctival erythema	Diffuse	Primarily around cornea	Primarily around cornea	Primarily around cornea
Cornea	Clear	Depends on cause	Usually clear	Cloudy
Pupils	Normal size, response to light	Normal size, response to light	Small, minimal response to light	Moderately dilated, fixed

Expected Outcome: Patient will verbalize an understanding of and willingness to follow measures to prevent infection spread to others.

- Teach to wash hands thoroughly before instilling eye medications. Instruct to avoid touching or rubbing the eyes. Advise to use a new, clean cotton-tipped swab or cotton ball for cleaning each eye. *Hand hygiene is the single most important measure to prevent transmission of infection to the eye. Touching or rubbing the eyes increases the risk of infection and corneal trauma. Using a new swab or cotton ball prevents cross-contamination between eyes.*
- Teach to instill prescribed eyedrops or ointment as ordered. *Prescribed medications reduce inflammation and eliminate infection.*
- Discuss the importance of avoiding contact lens use until the infectious process has cleared and of completing the prescribed treatment. *Use of contact lenses in the inflamed eyes can lead to further damage and impair healing.*

Risk for Impaired Vision

Conjunctivitis can potentially disrupt the integrity or clarity of the cornea. Because of its vital role in focusing light on the retina, corneal damage can impair visual acuity.

Expected Outcome: Patient's infectious process will resolve without adverse effects such as scarring or injury related to impaired vision.

- Assess vision with and without corrective lenses. *Assessment provides a baseline to evaluate possible changes in vision resulting from the infection.*
- Instruct to avoid activities requiring high visual acuity until the infection has cleared. *The inflammatory process, edema of the conjunctiva, and local antibiotic applications can decrease visual acuity and cloud vision.*
- Instruct to use dark sunglasses with appropriate UV protection when out of doors, even on cloudy days. *Photophobia, a common manifestation of conjunctivitis, causes eye pain with increased light intensity.*

Delegating Nursing Care Activities

Because of the importance of maintaining asepsis when caring for the eyes of a patient with conjunctivitis, it is appropriate for the nurse to retain direct responsibility for care activities such as cleansing the lids and instilling eye medications.

Continuity of Care

Patients with conjunctivitis typically are managed in the community, reinforcing the need for effective teaching for home care. Emphasize to the family ways to prevent transmission of infection. If the patient is unable to administer eye medications, involve the family in teaching. Include the following topics:

- Safety and medical asepsis when cleansing the eye
- Instillation of prescribed eyedrops and ointments
- Comfort measures such as reducing lighting intensity and wearing sunglasses
- Avoidance of activities such as excessive reading while eye is inflamed.

Evidence for Nursing Care

The Patient with Conjunctivitis

A resource that nurses may find helpful when planning evidence-based nursing care follows.

- American Academy of Ophthalmology Cornea/External Disease Panel. (2011). *Conjunctivitis*. San Francisco, CA: American Academy of Ophthalmology.

THE PATIENT WITH A CORNEAL DISORDER

The clear cornea allows light rays to enter the eye and transmits images onto the retina. It helps to focus light on the retina and protects the internal eye structures. The cornea can be affected by a variety of disorders, including infection and trauma. Although the cornea heals quickly after minor injuries or abrasions, injury to its deeper layers can delay healing or result in scarring.

Physiology Review

The cornea has three major layers: the outermost epithelium, which consists of five or six layers of cells that are constantly being renewed; the stroma, which makes up 90% of corneal tissue; and the single-cell thickness endothelium adjacent to the aqueous humor of the anterior chamber. The cornea is avascular tissue; the central cornea is dependent on atmospheric oxygen to meet its metabolic needs. Because there is no blood supply, immune defenses have difficulty fending off infections of the cornea.

Pathophysiology and Manifestations

Light enters the eye through the normally clear cornea. As light passes through the curved cornea, it is bent or *refracted* onto the lens, which then focuses the light on sensory cells of the retina. A change in the curvature of the cornea or in its clarity affects the ability of the eye to clearly focus; as a result, vision is distorted or blurred. Refractive errors such as **myopia** (nearsightedness), **hyperopia** (farsightedness), and **astigmatism** (an irregularly shaped cornea or lens that prevents light from focusing properly on the retina) are common. Corneal scarring and ulceration are two major causes of blindness worldwide. Table 46–2 summarizes major disorders of the cornea.

FAST FACTS

- The prevalence of myopia decreases with aging, from an estimated 34.5% of Americans ages 40 to 49 affected (15.1 million) to 17.6% of people ages 80 and older (2 million).
- In contrast, the prevalence of hyperopia increases with aging, affecting an estimated 3.7% of Americans ages 40 to 49 (1.6 million) and 23.3% of people ages 80 and older (2.6 million) (NEI, 2012d).
- Keratitis is the most serious potential complication of contact lens use. Scarring that occurs as a result of keratitis is a leading cause of blindness worldwide

●○● INTERPROFESSIONAL CARE

Management of the patient with a corneal disorder focuses on establishing an accurate diagnosis and prompt treatment to reduce the risk of permanent vision deficit. The history and physical assessment are key in diagnosing these disorders.

Although many eye disorders can be treated in the community, the patient with a severe corneal infection or ulcer may require

TABLE 46–2 Major Disorders of the Cornea

Disorder	Pathophysiology	Manifestations
REFRACTIVE ERRORS		
Myopia	Excessive curvature of the cornea or elongation of the eyeball causes the image to focus in front of the retina instead of on it.	Objects in close range are seen clearly and those at a distance are blurred
Hyperopia	Flattening of the cornea or an eyeball that is too short causes the image to focus behind the retina.	Objects at a distance are seen more clearly than those which are close.
Astigmatism	Irregular or abnormal curvature of the cornea causes light rays to focus on more than one area of the retina.	Both near and distance vision are distorted.
KERATITIS	Inflammation of the cornea. In *nonulcerative keratitis*, all layers of corneal epithelium are affected, but remain intact. *Ulcerative keratitis*, a possible consequence of bacterial conjunctivitis, affects the epithelium and stroma of the cornea, leading to tissue destruction and ulceration.	• Tearing, decreased visual acuity • Discomfort ranging from a gritty sensation in the eye to severe pain • *Blepharospasm* (spasm of the eyelid and inability to open the eye). • Presence of discharge, especially if the conjunctiva is also inflamed • Corneal ulceration may be visible on direct examination.
CORNEAL ULCER	Local necrosis of the cornea, with destruction of epithelium and/or stroma. Scarring and opacity of the cornea may result. Ulcers may be superficial or deep, penetrating underlying layers, and leading to infection of deeper eye structures or extrusion of eye contents. Causes include infection (bacterial conjunctivitis, trachoma, gonorrhea, herpes simplex, or herpes zoster), exposure trauma, or the misuse of contact lenses. Immunosuppression is a risk factor for infection-related corneal ulcer.	• Decreased visual acuity • Conjunctival redness • Eye pain, foreign body sensation • Photophobia, tearing • Partial or total vision loss • Ulceration visible on fluorescein staining and direct examination
CORNEAL DYSTROPHIES	Accumulation of cloudy material in part or parts of the cornea. Usually inherited disorders that progress gradually and affect both eyes. *Keratoconus*, the most common corneal dystrophy, involves progressive thinning and outward bulging of the center of the cornea, affecting its shape and ability to focus light on the lens of the eye.	• Decreased visual acuity • Corneal swelling and possible scarring

hospitalization. Corneal ulcers are medical emergencies, requiring prompt referral to an ophthalmologist for treatment. Pressure dressings may be applied to both eyes for comfort and to reduce the risk of perforation and loss of eye contents.

DIAGNOSIS

Visual acuity is tested on all patients presenting with refractory or corneal disorders. The following tests may be ordered to identify the cause and extent of eye infections or inflammations:

- *Fluorescein stain* with slit-lamp examination allows visualization of any corneal ulcerations or abrasions, which appear green with staining.
- *Conjunctival* or *ulcer scrapings* are examined microscopically or cultured to identify the organisms.

Additional laboratory testing such as blood counts or antibody titers may be used to identify any underlying infectious or autoimmune processes.

MEDICATION

Infectious processes are treated with antibiotic or antiviral therapy as appropriate. Topical anti-infectives applied as eyedrops or ointment may include erythromycin, gentamicin, penicillin, bacitracin, sulfacetamide sodium, amphotericin B, or idoxuridine. For severe infections, central ulcers, or cellulitis, anti-infectives may be administered by subconjunctival injection and/or systemic intravenous infusion. Corticosteroids may be prescribed for keratitis related to systemic inflammatory disorders or trauma; however, it is important to avoid their use with local infections to avoid suppressing the immune and inflammatory responses.

CORRECTIVE LENSES

Corrective lenses, either in the form of eyeglasses or contact lenses, generally are prescribed to restore visual acuity for patients with refractive errors such as myopia, hyperopia, and astigmatism. Specially fitted contact lenses to reduce vision distortion are ordered for patients with keratoconus. Because contact lenses are a risk factor for corneal infection and ulcers, teaching appropriate care is vital (refer to Box 46–1).

SURGERY

LASER EYE SURGERY Laser eye surgery is commonly performed to correct refractive errors such as myopia, hyperopia, and astigmatism. In these surgeries, a laser is used to permanently change the shape of the cornea. In most cases, the need to use corrective lenses is reduced or eliminated. Several surgical procedures are available:

- Laser *in situ* keratomileusis (LASIK)
- Photorefractive keratectomy (PRK)

- Laser epithelial keratomileusis (LASEK)
- Laser thermokeratoplasty (LTK).

These procedures reshape the cornea using laser technology to remove a thin layer of epithelial cells or to shrink and reshape the cornea. Candidates for laser vision-correction surgery should be in good health and must have adequate corneal thickness such that perforation is not a risk.

Following surgery, patients may experience a temporary loss of contrast sharpness (images do not appear as crisp as with corrective lenses), over- or undercorrection of visual acuity, dry eyes, or temporarily decreased night vision with halos, glare, and starbursts. Diffuse lamellar keratitis (DLK) is a rare complication of surgery that, while treatable, can lead to vision impairment if not identified and treated early.

Phototherapeutic keratectomy (PTK) provides an alternative to corneal transplant in treating corneal dystrophies, scars, and some infections. In this procedure, diseased corneal tissue is vaporized and surface irregularities are corrected with little trauma to surrounding tissue. Healing occurs rapidly.

CORNEAL TRANSPLANT Once the cornea has become scarred and opaque, no treatment can restore its clarity. The first successful corneal transplant (or *keratoplasty*), replacement of diseased cornea by healthy corneal tissue from a donor, was performed in 1906. Current corneal transplant procedures have a success rate of approximately 90% (Dana, 2011).

Corneas are harvested from the cadavers of uninfected adults who were under the age of 65 and who died as a result of acute trauma or illness. After harvesting, the cornea can be stored in a tissue-culture medium for up to 4 weeks before being used as a graft. Corneal transplantation is usually an elective surgery, although emergency transplantation may be required for perforation of the cornea.

Corneal transplant may be either lamellar or penetrating. In a lamellar keratoplasty, the superficial layer of cornea is removed and replaced with a graft. The anterior chamber remains intact. In a penetrating keratoplasty, a button or full thickness of cornea is removed and replaced by donor tissue (Figure 46–3 ■). The graft is then sutured in place using suture finer than human hair and a continuous or interrupted stitch. Because the cornea is avascular, these sutures remain in place for up to a year to ensure healing.

Most corneal transplants do not require hospitalization. The eye is patched for 24 hours following surgery. Narcotic analgesia may be required initially because the cornea is extremely sensitive. Corticosteroid eyedrops are ordered to reduce the inflammatory response and prevent edema of the graft. Antibiotic drops may be prescribed to prevent infection.

The risk of transplant rejection is low. Because the cornea is avascular, there is little exposure of the transplanted corneal tissue to the host's immune defenses (Grossman & Porth, 2014). Research suggests that matching of blood type (not tissue type, as is required for major organ transplants) between the donor and the transplant recipient may reduce the risk of transplant rejection (Dana, 2011). When rejection does occur, it occurs within 3 weeks of the transplant, beginning with inflammation at the edge of the grafted tissue and spreading to involve the entire graft. In many cases, rejection can be successfully treated using corticosteroid therapy, preserving the graft.

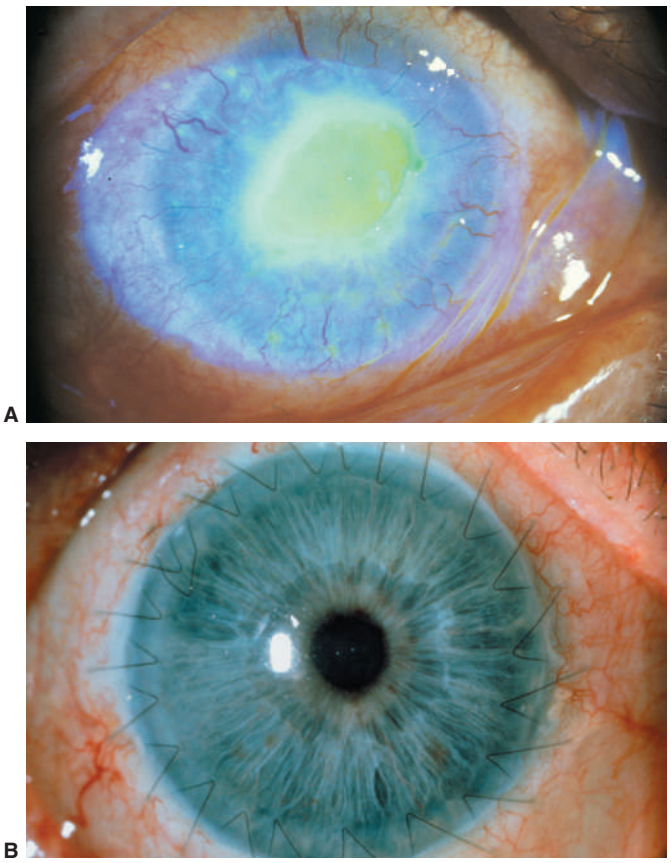

Figure 46–3 ■ Corneal transplant. A, The diseased, opaque cornea. B, The diseased cornea is removed and a corneal graft is sutured in place using material finer than a human hair.
Source: Custom Medical Stock Photo, Inc.

See the box on page 1498 for nursing care of the patient having eye surgery.

●○● NURSING CARE

The nursing role in caring for patients with corneal disorders may involve direct care, but more often focuses on prevention and education. Nurses working in clinics and outpatient surgical settings care for patients undergoing corneal transplant and surgeries to correct refractive errors.

Health Promotion

Education is a vital strategy for preventing many corneal disorders. Teach all patients about proper eye care, including the importance of not sharing towels and makeup, avoiding rubbing or scratching the eyes, and preventing trauma and infection. Teach contact lens users appropriate care and cleaning techniques. Stress the importance of periodic removal of lenses, even extended-wear lenses. In general, lenses should be removed at night, even though manufacturers may claim it is safe to wear them while sleeping. Emphasize the need to follow cleaning instructions precisely to avoid bacterial contamination of lenses and possible corneal infection. If the patient experiences a corneal abrasion or keratitis, instruct to avoid wearing contact lenses until the cornea has healed completely.

NURSING CARE OF THE PATIENT

Having Eye Surgery

PREOPERATIVE CARE

- Provide routine preoperative care as ordered.
- Assess visual acuity of the nonoperative eye prior to surgery. *The patient with limited vision in the nonoperative eye may need additional attention and ADL assistance postoperatively to ensure safety.*
- Assess the patient's support systems and the possible effect of impaired vision on lifestyle and ability to perform ADLs in the postoperative period. *Safety measures such as installing handrails and removing throw rugs from the home can help promote mobility and safety, especially if the patient has limited vision in the unaffected eye.*
- Teach measures to prevent eye injury postoperatively: avoid vomiting, straining at stool, coughing, sneezing, lifting more than 5 lb, and bending over at the waist. *These activities temporarily increase intraocular pressure and may lead to postoperative complications.*
- Remove all eye makeup and contact lenses or glasses prior to surgery. Store corrective lenses in a safe place, and make them readily available to the patient on return from surgery. *Maintaining visual acuity in the unaffected eye helps reduce fear and maintain safety.*
- Administer preoperative medications and eyedrops or ointments as prescribed. *Mydriatic (pupil-dilating) or cycloplegic (ciliary-paralytic) drops and drops to lower intraocular pressure may be prescribed preoperatively.*

POSTOPERATIVE CARE

- Provide routine postoperative care as ordered.
- Assess eye dressing for bleeding or drainage following surgery. *Bleeding or drainage may indicate a surgical complication.*
- Maintain the eye patch or shield in place. *The eye patch or shield helps prevent inadvertent injury to the operative site.*
- Place in semi-Fowler's or Fowler's position on the unaffected side. *Elevating the head of the bed and lying on the unaffected side reduce intraocular pressure in the affected eye.*
- Remind the patient to avoid coughing, sneezing, or straining as needed. *These activities increase intraocular pressure.*
- Assess and medicate as necessary for complaints of pain, aching, or a scratchy sensation in the affected eye. Immediately report complaints of sudden, sharp eye pain to the physician. *An abrupt increase in or onset of eye pain may indicate hemorrhage or other ocular emergency requiring immediate intervention to preserve sight.*
- Assess for potential complications:
  a. Pain in or drainage from the affected eye
  b. Hemorrhage with blood in the anterior chamber of the eye
  c. Flashes of light, floaters, or the sensation of a curtain being drawn over the eye (indicators of retinal detachment)
  d. Cloudy appearance to the cornea (corneal edema).
  Evidence of complications or unusual complaints should be reported to the physician at once. Early intervention is often necessary to preserve sight.
- Approach the patient on the unaffected side. *This approach facilitates eye contact and communication.*
- Place personal articles and the call light within easy reach. *These measures prevent stretching and straining by the patient.*
- Administer antibiotic, anti-inflammatory, and other systemic and topical eye medications as prescribed. *Medications are prescribed to prevent infection or inflammation of the operative site, maintain pupil constriction, and control intraocular pressure.*
- Administer antiemetic medication as needed. *It is important to prevent vomiting to maintain normal intraocular pressures.*

Health Education for the Patient and Family

- Teach the patient and family about home care:
  a. How to instill eyedrops
  b. The name, dosage, schedule, duration, purpose, and side effects of medications
  c. How and when to use the eye patch and eye shield
  d. The importance of avoiding scratching, rubbing, touching, or squeezing the affected eye
  e. Measures to avoid constipation and straining
  f. Activity limitations, if ordered
  g. Symptoms to report, including eye pain or pressure, redness or cloudiness, drainage, decreased vision, floaters or flashes of light, or halos around bright objects
  h. The need to wear sunglasses with side shields when outdoors to reduce photophobia.
- Remind the patient that vision may not stabilize for several weeks following eye surgery. New corrective lenses, if necessary, are not prescribed until vision has stabilized. *Patients may be alarmed that vision seems worse after surgery than before and need reassurance that visual acuity usually improves with time and healing of the affected eye.*
- Emphasize the importance of keeping recommended follow-up appointments. Provide referral to a community home health agency for assistance with home care after discharge as needed.

Assessment

Collect the following data through the health history and physical examination. Additional focused assessments are described in Chapter 45 and with the interventions that follow.

- *Health history:* risk factors; presence of redness, discomfort, tearing, photophobia, edema, and drainage; symptom onset; presence of pain, effect on vision
- *Physical assessment:* visual acuity; inspection of external eye, including conjunctiva, sclera, and cornea; extraocular movements.

Priorities of Care

Corneal disorders often affect visual acuity and can cause acute pain. The priority nursing focus is on preventing complications and promoting healing, promoting comfort, and preventing injury.

Diagnoses, Outcomes, and Interventions

Risk for Impaired Vision

Disorders affecting the cornea may disrupt its integrity or clarity. Because the cornea plays a vital role in focusing light on the retina, corneal damage can affect vision, impairing visual acuity and even causing legal blindness.

Expected Outcome: Patient's visual acuity will be preserved or restored to previous level.

- Assess vision with and without corrective lenses. *Assessment provides a baseline to evaluate possible vision changes resulting from the disorder or treatment.*
- Instruct about thorough hand hygiene before inserting or removing contact lenses or instilling any eye medications. Teach to avoid touching or rubbing the eyes. Instruct to use a new, clean

cotton-tipped swab or cotton ball for cleaning each eye. *Hand hygiene is the single most important measure to prevent transmission of infection to the eye. Touching or rubbing the eyes increases the risk of infection and corneal trauma. Using a new swab or cotton ball prevents cross-contamination between eyes.*
- Emphasize the importance of proper care of contact lenses specific to the type of lens used. *Patients who wear hard contact lenses must remove them daily because the central cornea needs exposure to atmospheric oxygen. Although soft and extended-wear lenses allow the cornea to "breathe," improper cleaning carries a major risk for infection.*
- Teach the importance of using eye protection when engaging in potentially dangerous activities. *Trauma increases the risk of infection and scarring of the cornea.*
- If corneal perforation is suspected, place the patient in the supine position, close the eye, and cover it with a dry, sterile dressing. Notify the physician immediately. *Corneal perforation may occur without warning in patients with corneal ulcers. It places the patient at risk for loss of eye contents. Emergency measures are taken to reduce intraocular pressure and maintain eye integrity to preserve vision.*

PRACTICE ALERT!

Suspect corneal perforation with complaints of sudden, severe eye pain and photophobia.

Acute Pain

The cornea of the eye is extremely sensitive; therefore, corneal disorders frequently cause significant pain. Pain, in turn, increases the stress response and interferes with rest, potentially impairing healing.

Expected Outcome: Patient will demonstrate pain relief through verbal expressions of comfort and nonverbal expressions such as relaxed body posture and ability to rest and focus.

- Assess pain, using verbal and nonverbal cues. *Pain is a subjective experience and can be evaluated only by the patient's response and in terms of its effect on the patient.*
- Administer prescribed analgesia routinely in the first 12 to 24 hours after corneal surgery. *Routine administration of analgesics prevents pain from reaching a level of severity at which it becomes difficult to relieve.*
- Patch both eyes if necessary. *Patching both eyes reduces eye movement and irritation of the affected eye.*
- Teach to apply warm compresses to reduce inflammation and pain. *The use of warm compresses for 15 minutes, three to four times a day, promotes comfort for patients with keratitis or corneal injury.*
- Instruct to use dark sunglasses with appropriate UV protection when out of doors, even on cloudy days. *True photophobia, often associated with corneal disorders, causes eye pain with increased light intensity.*
- Teach to instill prescribed eyedrops as ordered. *Prescribed medications may reduce inflammation and eliminate infection, reducing discomfort.*

Risk for Injury

The patient who has undergone corneal transplantation has an increased risk for injury for several reasons. The eye on which surgery was performed is patched for 24 hours after surgery, changing depth perception and increasing the risk for falls. Increased intraocular pressure or trauma to the eye may damage the graft, resulting in graft rejection.

- Instruct to call for help before getting up or ambulating after surgery. Ensure access to the call light. *It may take time for the patient to adjust to changes in depth perception caused by the eye patch. Assistance helps prevent falls that may not only injure the patient but also traumatize the operative site.*
- Administer prescribed antiemetics and stool softeners postoperatively. *Vomiting and straining at stool increase intraocular pressure, potentially damaging suture lines.*
- Teach how to apply an eye shield at night after the eye patch is removed. *An eye shield may be recommended at night to prevent inadvertent rubbing or trauma to the eye during sleep.*
- Instruct not to rub or scratch the eye. *Rubbing or scratching may disrupt suture lines or damage the grafted tissue.*
- Reinforce the importance of using eye protection during hazardous activities. *Following a corneal transplant, the patient has the same risk of eye injury as other people who perform hazardous activities.*

Continuity of Care

Following treatment, teach patients to manage their condition at home. Emphasize to the family ways to prevent transmission of infection. If the patient is unable to administer eye medications or to perform other eye care techniques, involve the family in the teaching session. The following topics should be included:

- Safety and medical asepsis when cleansing the eye
- Instillation of prescribed eyedrops and ointments
- Application of an eye patch and where to obtain supplies
- Avoidance of activities such as excessive reading while eye is inflamed
- Follow-up appointments after corneal transplant surgery
- Signs of graft rejection
- Avoidance of activities that increase intraocular pressure such as straining, coughing, sneezing, bending over, lifting heavy objects
- Helpful resources: National Eye Institute and the Lighthouse National Center for Vision and Aging.

THE PATIENT WITH A DISORDER AFFECTING THE EYELIDS

The eyelids and eyelashes are constantly exposed to the environment as they protect the eye from damage. When these structures are inflamed, deformed, or their function is impaired, it affects both appearance and their protective functions.

Pathophysiology and Manifestations

The most common disorder affecting the eyelids is *marginal blepharitis*, an inflammation of the glands and lash follicles on the margins of the eyelids. This inflammatory disorder can be caused by a staphylococcal infection or it may be seborrheic in origin; commonly, both types are present. Seborrheic blepharitis is usually associated with seborrhea (dandruff) of the scalp or eyebrows. Irritation, burning, and itching of eyelid margins are common manifestations of blepharitis. The eye appears red rimmed with mucous discharge, and there is crusting or scaling of lid margins. Lid margins may ulcerate, resulting in a loss of eyelashes.

Figure 46–4 ■ Hordeolum.
Source: Science Photo Library/Photo Researchers, Inc.

Infection of one or more of the sebaceous glands of the eyelid may cause a hordeolum (sty). Hordeolum is a staphylococcal abscess that may occur on either the external or internal margin of the lid (Figure 46–4 ■). An external hordeolum is characterized initially by acute pain at the lid margin and redness. A small tender raised area is visible. The patient may also experience photophobia, tearing, and the sensation of a foreign body in the affected eye. Internal hordeola are seen on the conjunctival side of the lid and may have more severe manifestations.

Chronic inflammation of a meibomian gland may lead to formation of a chalazion, a granulomatous cyst or nodule of the lid (Figure 46–5 ■). It presents as a hard swelling on the lid, and surrounding conjunctival tissue is reddened. Chalazion may also follow a hordeolum that was inadequately treated. Unlike a hordeolum, a chalazion is painless. It may slowly increase in size and eventually require removal, but most resolve within several months. A lid lesion that ulcerates or does not heal may indicate basal or squamous cell carcinoma and should be further investigated.

Entropion, inversion of the lid margin (refer to Figure 46–2), may be associated with the normal aging process (senile entropion) or result from an infectious process such as trachoma. Entropion can lead to corneal irritation and, potentially, scarring as the lashes rub on the conjunctiva and cornea during blinking and sleep. *Ectropion*, or eversion of the lid margin, occurs primarily as an effect of aging (Figure 46–6 ■). Other conditions may also lead to ectropion,

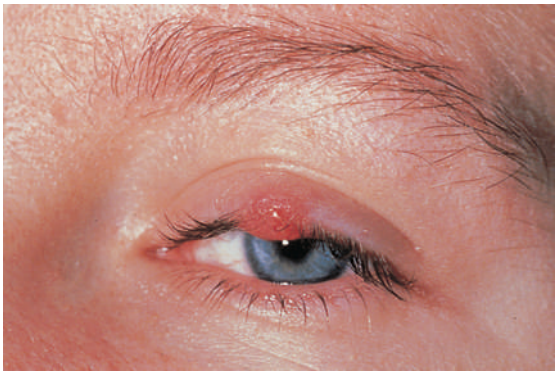

Figure 46–5 ■ Chalazion.
Source: Science Photo Library/Photo Researchers, Inc.

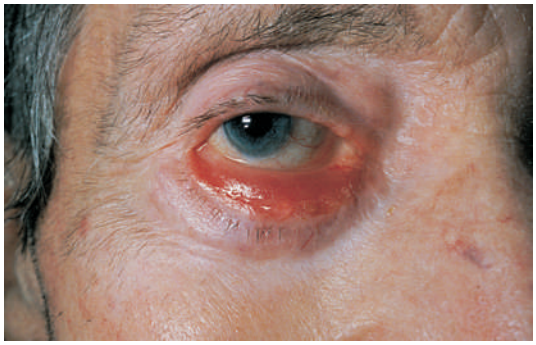

Figure 46–6 ■ Ectropion.
Source: Science Photo Library/Photo Researchers, Inc.

including facial nerve paralysis or palsy (Bell's palsy), scarring, or infection. With ectropion, the eye does not close effectively, increasing the risk for drying and damage to conjunctival membrane and the cornea. Both entropion and ectropion have cosmetic effects as well, altering the appearance of the eye and face.

●○● INTERPROFESSIONAL CARE

Disorders affecting the eyelids typically are managed in the community. Diagnosis is typically made through the history and physical examination. Diagnostic tests are rarely required except to identify corneal or conjunctival damage resulting from the condition.

Topical antibiotics (eyedrops or ointments) may be prescribed for the patient with hordeolum and to treat infection resulting from irritation of the eye by a deformed lid. Careful cleansing of the lid margins using a "no-tears" baby shampoo is often recommended for marginal blepharitis. Soaking the lids with warm saline compresses prior to cleansing facilitates the removal of the crusts and exudate that result from blepharitis. Local heat applications may be used to treat hordeolum or chalazion; excision and drainage may be required if this is not effective. In entropion or ectropion, surgery may be performed to correct the defect, reduce the risk of damage to the eye, and improve cosmetic appearance.

●○● NURSING CARE

The nursing role focuses on education and comfort measures. Teach patients about appropriate eye care, including avoiding rubbing or scratching the eyes. Discuss the importance of not using old eye makeup, which can cause lid infections. Instruct to wash hands well before cleansing the eyelids or instilling any eye medications. Instruct to use a new, clean cotton-tipped swab or cotton ball for cleaning each eye. Teach to instill prescribed eyedrops and apply ointments as ordered. If the patient is unable to administer eye medications, involve the family in teaching. Teach to apply warm compresses to reduce inflammation and discomfort.

THE PATIENT WITH EYE TRAUMA

More than 2 million eye injuries occur each year. Many eye injuries are minor, but without timely and appropriate intervention, even a minor injury can threaten vision. For this reason, all eye injuries should be considered medical emergencies requiring immediate evaluation and intervention.

Pathophysiology and Manifestations

Any part of the eye, especially the exposed parts, may be affected by trauma. Foreign bodies, abrasions, and lacerations are the most common types of eye injury. Traumatic injury may also be due to a burn, penetrating object, or blunt force.

CORNEAL ABRASION

Corneal abrasion is disruption of the superficial epithelium of the cornea. Objects commonly causing corneal abrasion include contact lenses, eyelashes, small foreign bodies such as dust and dirt, and fingernails. Drying of the eye surface and chemical irritants may also result in a corneal abrasion.

Superficial abrasions of the cornea are extremely painful but generally heal rapidly without complication or scarring. Photophobia and tearing are commonly present. When the stroma is damaged by a deep abrasion or laceration, there is an increased risk of infection, slowed healing, and scar formation.

BURNS

The outer surface of the eye may be subjected to burns caused by heat, radiation, or explosion, but chemical burns are the most common. Either acid or alkaline substances may burn the eye. Ammonia, products that contain lye (such as oven and drain cleaners), and acids from car batteries or other sources are often implicated in eye injuries. Burns caused by alkaline substances are particularly serious because tiny particles of the chemical may remain in the conjunctival sac, causing progressive damage. Acid causes rapid damage to the eye, but generally causes less serious burns than alkaline substances.

Explosions and flash burn injuries pose the greatest risk for thermal burns of the eye. Ultraviolet rays can also cause corneal damage ranging in severity from mild to extensive. Depending on the source of the ultraviolet light, these burns may be known by various names such as snowblindness, arc welder's burn, or flash burn.

In addition to giving a history of face and eye contact with a caustic substance or other burning agent, the patient complains of eye pain and decreased vision. Eyelids are often swollen. Burns may also affect the face or lids. The appearance of the eye may vary, depending on the type of burn. The conjunctiva is reddened and edematous; sloughing may be seen, particularly with chemical burns. The cornea often appears cloudy or hazy, and ulcerations may be evident.

PENETRATING TRAUMA

Perforation of the eye occurs from a variety of causes. Metal flakes or other particles produced by high-speed drilling or grinding, glass shards, or other substances may penetrate the eye. Gunshots (including BBs), arrows, and knives can penetrate the eye. In a penetrating injury, the layers of the eye spontaneously reapproximate after entry of a sharp-pointed object or small missile into the globe. These injuries may not be readily apparent with inspection of the eye. In a perforating injury, the layers of the eye do not spontaneously reapproximate, resulting in rupture of the globe and potential loss of ocular contents.

Penetrating injuries may be hidden because of tissue swelling or missed when the patient has other significant injuries that command attention. When the eyelid is lacerated or has a puncture wound, inspection of the underlying eye tissue for possible damage is vital. Eye perforations cause pain, partial or complete loss of vision, and possibly bleeding or extrusion of eye contents.

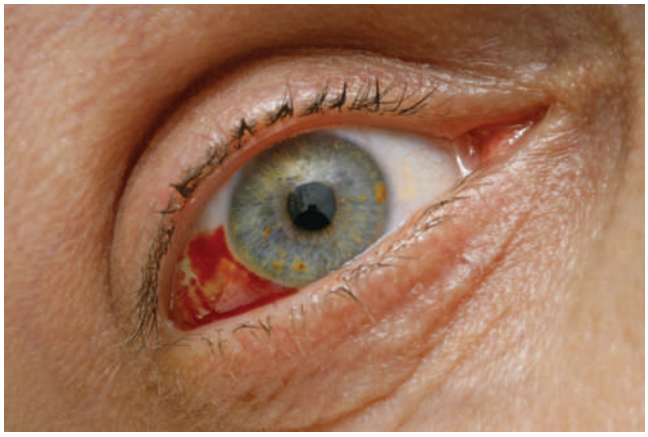

Figure 46–7 ■ Subconjunctival hemorrhage.

BLUNT TRAUMA

Sports injuries are a common cause of blunt trauma to the eye: It may be struck with a ball (baseball, tennis, racquetball, and handball are frequently implicated) or injured in contact sports such as basketball, football, boxing, or wrestling. Motor vehicle crashes, falls, and physical assault are examples of other causes of blunt eye trauma.

Blunt trauma may lead to a minor eye injury such as lid ecchymosis (black eye) or subconjunctival hemorrhage, caused by rupture of a blood vessel in the conjunctiva (Figure 46–7 ■). A well-defined bright area of erythema appears under the conjunctiva. No pain or discomfort is associated with the hemorrhage and no treatment is necessary. The blood typically reabsorbs within 2 to 3 weeks.

Hyphema, bleeding into the anterior chamber of the eye, is a potential result of blunt eye trauma. When the highly vascular uveal tract of the eye is disrupted by blunt force, hemorrhage may result, filling the anterior chamber. The patient complains of eye pain, decreased visual acuity, and seeing a reddish tint. Blood is visible in the anterior chamber.

An orbital blowout fracture is another potential result of blunt eye trauma. Although any part of the eye orbit may be fractured, the ethmoid bone on the orbital floor is the most likely site. Orbital contents, including fat, muscles, and the eye itself, may herniate through the fracture into the underlying maxillary sinus. The patient complains of diplopia (double vision), pain with upward movement of the affected eye, and decreased sensation on the affected cheek. The eye appears sunken (enophthalmos) and has limited movement on examination.

●○● INTERPROFESSIONAL CARE

When trauma to the eye is known or suspected, a thorough examination is conducted to determine the type and extent of the injury. Unless immediate treatment is indicated, as with a chemical burn, vision is evaluated initially. If the patient normally wears corrective lenses, vision assessment is performed while glasses are worn. Eye movement is evaluated unless a penetrating object is present, and the lid and eye are inspected for lacerations. Inspection is performed using strong light and magnification with a headband loupe or slit lamp. Topical anesthesia may be used prior to inspection if eye pain and photophobia make eye opening difficult. Fluorescein staining can help identify foreign bodies and abrasions. Any conjunctival or

anterior chamber hemorrhage is noted, as is the presence or absence of the red reflex. Ophthalmoscopic examination is used to detect hemorrhage or trauma to the interior chamber.

Facial x-rays and CT scans are used to identify orbital fractures or foreign bodies within the globe. Ultrasonography may be employed to detect a detached retina or vitreous hemorrhage.

Foreign bodies are removed using irrigation, a sterile cotton-tipped applicator, or a sterile needle or other instrument. Antibiotic ointment—erythromycin or sulfacetamide sodium—is applied after their removal. In patients with corneal abrasions and large foreign bodies in the eye, an eye patch is applied firmly after the antibiotic application to keep the eye closed for approximately 24 hours.

The immediate priority of care for patients with chemical burns is flushing the affected eye with copious amounts of fluid (Figure 46–8 ■). Physiologic (normal) saline is preferred; however, water may be used if saline is not available. A special contact lens irrigating unit (Morgan lens) or a bottle of irrigant with intravenous tubing held to flush all eye surfaces may be useful. The eyelid is everted to identify and remove material from the conjunctival sac. A topical anesthetic, such as tetracaine drops, helps relieve pain, making inspection and irrigation easier. During irrigation, fluid is directed from the inner canthus of the eye to the outer or lateral canthus. Tipping the patient's head slightly to the affected side prevents contamination of the unaffected eye. Irrigation is continued until the pH of the eye is normal (in the range of 7.2 to 7.4). Following irrigation, a topical antibiotic ointment such as gentamicin ophthalmic is applied.

Penetrating wounds of the eye generally require surgical intervention by an ophthalmic surgeon. Immediate care focuses on relieving pain and protecting the eye from further injury. To prevent loss of intraocular contents, do not place pressure on the eye itself, but gently cover with sterile gauze or an eye pad. If a foreign body is embedded in or sticking out of the eye, no attempt is made to remove it. The object should be immobilized and the eye protected with a metal eye shield until an ophthalmologist can see the patient. A paper cup or other protective device may be used if the object is too large to use an eye shield. Patching the unaffected eye as well decreases ocular movement. Pain is managed using narcotic analgesics such as morphine. The patient may also require sedation (e.g., diazepam) and antiemetic medications to prevent vomiting. Antibiotics such as intravenous cefazolin (Ancef) or gentamicin (Garamycin) are prescribed to prevent infection.

Figure 46–8 ■ A nurse uses sterile normal saline to flush the eye of a patient with a suspected chemical burn.

Interventions for the patient with blunt trauma to the eye include placing the patient on bed rest in semi-Fowler's position and protecting the eye from further injury with an eye shield. The unaffected eye is also patched to minimize eye movement. A carbonic anhydrase inhibitor such as acetazolamide (Diamox) or dichlorphenamide (Daranide) may be prescribed to reduce intraocular pressure.

●○● NURSING CARE

The nursing role involves educating people about the prevention of eye injuries and providing direct care to patients with eye injuries.

Health Promotion

Teaching related to eye injuries focuses on prevention and first-aid measures. Teaching individuals and groups how to prevent eye injuries is an important nursing role, especially for people involved in hazardous occupations and activities. Teach employees and participants in high-risk sports or activities how and when to use eye protection devices. Stress the importance of using seat belts and air bags to prevent eye injury in automobile crashes. Instruct patients to immediately flush the eye with copious amounts of water if a chemical splash occurs. Loose, visible foreign bodies can be removed using a clean, moistened cotton-tipped swab. If an abrasion, penetrating, or blunt injury is suspected, the eye should be covered loosely with sterile gauze and medical attention sought immediately. Instruct patients not to remove objects that penetrate the eye.

Priorities of Care

Ocular injuries require immediate interventions simultaneously with assessment and accurate history collection. The time, type, and extent of injury and the circumstances under which it occurred are determined. In addition, ask about preexisting vision problems.

Diagnoses, Outcomes, and Interventions

Impaired Tissue Integrity: Ocular

All types of eye trauma pose the risk of violating the integrity of the eye and, hence, threatening vision. The goals of nursing care, therefore, are preserving vision and the integrity of the eye and preventing further damage.

Expected Outcome: Patient's injured ocular tissue will heal without complications and previous visual acuity will be restored.

- Assess vision in each eye and both eyes, with and without corrective lenses, on entry into the emergency department or primary care setting. *An initial assessment provides valuable information about the effect of the injury on the patient's vision and a baseline for future comparisons.*
- Inspect eye(s) carefully for evidence of foreign bodies, burns, penetrating injury, or blunt trauma. Note if lacerations, burns, or other trauma are evident in tissues surrounding the eye. *Eye trauma may be hidden by other injuries and, as a result, remain untreated.*
- If a burn or foreign body is present, anesthetic drops may be instilled and the eye irrigated either before or after the physician evaluates the patient. *Blepharism and eye pain may impair assessment of the injured eye. Irrigation to remove the chemical is of higher priority than assessment of the eye.*

- Loose foreign bodies may be removed using a moist, sterile, cotton-tipped applicator. *Prompt removal of foreign bodies may prevent corneal abrasion.*
- For a severe or penetrating injury, promote rest and stabilize the injured eye by applying an eye pad or gauze dressing loosely over both the affected and unaffected eye. Stabilize any penetrating object if possible. *These measures reduce eye movement and can help preserve the patient's vision.*
- Following treatment, apply eyedrops or ointment as prescribed and apply an eye pad or shield if ordered. *An eye pad is applied to the affected eye to reduce pain and photophobia and to promote healing.*

Continuity of Care

Following an injury, discuss the following topics with the patient and family:

- Prescribed medications and possible adverse effects
- Strategies to prevent further trauma
- Application of an eye pad or shield
- Avoidance of activities that increase intraocular pressure
- Importance of activity restrictions.

THE PATIENT WITH UVEITIS

The middle vascular layer of the eye, including the choroid, the ciliary body, and the iris, is known as the uvea and uveal tract. *Uveitis* is inflammation of all or part of this vascular layer. *Iritis*, inflammation of the iris only, occurs more commonly than uveitis.

Uveitis is usually a disease limited to the eye; it may be idiopathic or caused by an autoimmune process, infection, parasitic disease, or trauma. Many cases can be linked to a systemic disease, often an arthritic or autoimmune disorder such as ankylosing spondylitis, Reiter's syndrome, rheumatoid arthritis, or sarcoidosis (see Chapter 40). Uveitis has also been linked with tuberculosis and syphilis. Manifestations of uveitis include pupillary constriction and erythema around the limbus. The patient may complain of severe eye pain and photophobia, as well as blurred vision.

Immunosuppressive therapy may be used to suppress the inflammatory response in patients with severe uveitis. Atropine may also be prescribed for associated inflammation of the iris. The patient may require analgesics such as acetaminophen and/or codeine for pain management. Nursing care is supportive, focusing on promotion of comfort and teaching about the disorder and its management.

THE PATIENT WITH CATARACTS

A **cataract** is an opacification (clouding) of the lens of the eye. This opacification can significantly interfere with light transmission to the retina and the ability to perceive images clearly.

Incidence and Risk Factors

Cataracts are a common and significant cause of visual deficits, affecting more than 22 million people over age 40 in the United States. By age 80, over half of the population is affected. In many cases, however, cataracts do not significantly impair vision. Cataracts affect slightly more women than men, and more Whites than people of other ethnicities. More than a million cataract removal surgeries are performed annually in the United States, costing an estimated 3.4 billion Medicare dollars (Prevent Blindness America, 2012).

FAST FACTS

The prevalence of cataracts in the United States increases rapidly with aging:

- 2.5% (just over 1 million) of adults ages 40 to 49 are affected.
- This increases to more than 2 million (or 6.8%) of those ages 50 to 59, and nearly doubles to over 4 million or 20% of adults ages 60 to 69.
- 68.3% of adults ages 80 and older (over 6 million) are affected by cataracts (NEI, 2012d).

Age is the greatest single risk factor for cataracts. Genetics may contribute to the risk, although the link is unclear. Environmental and lifestyle factors play a role: Long-term exposure to sunlight (UV-B rays) contributes; cigarette smoking and heavy alcohol consumption are associated with earlier cataract development. Although senile cataracts are by far the most common, cataracts also may be congenital or acquired in origin. Eye trauma, including injury to the lens capsule by a foreign body, blunt trauma, or exposure to heat or radiation, can precipitate cataract formation. Diabetes mellitus is associated with earlier development of cataracts, especially when the blood glucose level is not carefully controlled at or near normal levels. Certain drugs such as systemic or inhaled corticosteroids, chlorpromazine (Thorazine), and busulfan (Myleran) also prompt the formation of cataracts.

MEMORY CUE

To remember risk factors for cataracts, use the following mnemonic: CATARACt:

Congenital
Aging
Toxicity (steroids, etc.)
Accidents
Radiation (sunlight)
Altered metabolism (diabetes mellitus)
Cigarette smoking

Pathophysiology

The majority of cataracts are senile cataracts, formed as a result of the aging process. As the lens ages, its fibers and proteins change and degenerate. The proteins clump, clouding the lens and reducing light transmission to the retina. This process generally begins at the periphery of the lens, gradually spreading to involve the central portion. As the cataract continues to develop, the entire lens may become opaque. When only a portion of the lens is affected, the cataract is called immature. A mature cataract is opacity of the entire lens. In addition to clouding, the lens may discolor over time, affecting the ability to accurately discriminate colors.

Manifestations

Cataracts tend to occur bilaterally unless related to eye trauma. Fortunately, they tend to develop at different rates, and one cataract generally matures more rapidly than the other. Because a cataract interferes with light transmission through the lens, visual acuity decreases, affecting both close and distance vision (Figure 46–9 ■). Light rays are scattered as they pass through the lens, causing complaints of glare.

Figure 46–9 ■ A scene as viewed by a patient with cataracts.
Source: Courtesy of National Eye Institute, National Institutes of Health.

Glare affects the ability to adjust between light and dark environments. Color discrimination is impaired, particularly in the blue to purple range. When the cataract is mature, the pupil may appear cloudy gray or white rather than black.

●○● INTERPROFESSIONAL CARE

The diagnosis of a cataract is made based on the history and eye examination. Ophthalmoscopic examination confirms the diagnosis by identifying the location and extent of a cataract. As the cataract matures, ophthalmoscopy reveals a dark area instead of the red reflex.

SURGERY

Surgical removal is the only treatment used at this time for cataracts; no medical treatment is available to prevent or treat them. If the patient presents with bilateral cataracts, surgery generally is performed on one eye at a time. If an intraocular lens (an artificial lens to replace the diseased lens of the eye) is to be implanted during surgery, the corneal curvature and anteroposterior diameter of the eye are measured prior to surgery to determine the lens power needed for the intraocular lens implant.

Surgical removal of the cataract and lens is indicated when the cataract has developed to the point that vision and performance of ADLs are affected. A mature cataract may also be removed when it causes a secondary condition such as glaucoma or uveitis.

Cataract surgery is usually done on an outpatient basis, using local anesthesia. If general anesthesia is required, the patient may be hospitalized overnight. Extracapsular extraction, in which the anterior capsule, nucleus, and cortex of the lens are removed, leaving the posterior capsule intact, is the procedure of choice (Figure 46–10 ■). Using an operating microscope, the surgeon makes a small incision at the edge of the clear cornea and extracts the lens via emulsification and aspiration. In this technique, ultrasound vibrations are used to break the lens material into fragments (phacoemulsification), which are then suctioned out of the eye. The remaining posterior capsule supports the lens implant and protects the retina.

After removal of the lens, a silicone or acrylic resin intraocular lens is implanted to replace the light-focusing functions of the diseased lens. This implant rapidly restores binocular vision and depth perception. Following extracapsular lens removal, the intraocular lens (IOL) is positioned in the posterior capsule behind the iris (refer to Figure 46–10). Currently available intraocular lenses allow for correction of refractive disorders of distance vision or astigmatism, often allowing the patient to no longer rely on corrective lenses for visual acuity. Bifocal and multifocal IOLs also are available (Rothrock, 2011). These specialized lenses are not always appropriate, however. The patient with a preexisting refractive error may continue to require corrective lenses and often needs a prescriptive change after surgery.

Complications of cataract surgery are unusual and occur in less than 1% of the surgeries. Loss of vitreous humor, corneal edema, increased intraocular pressure, hemorrhage, inflammation or infection,

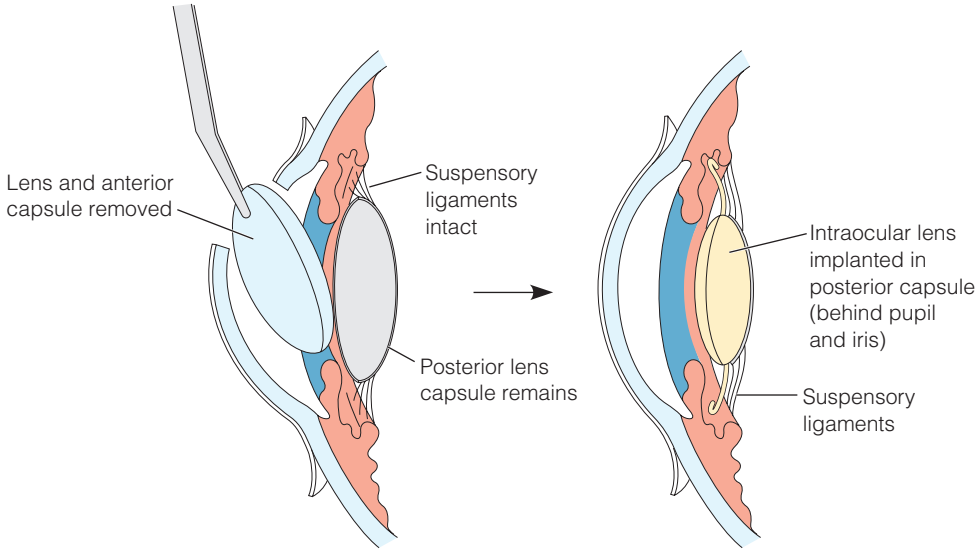

Figure 46–10 ■ Extracapsular cataract extraction with removal of the lens and anterior capsule, leaving the posterior capsule intact. The intraocular lens is implanted within the posterior capsule.

retinal detachment, and displacement of the implanted lens are potential complications. Months or years after cataract removal, opacification of the remaining posterior capsule may develop. Vision can be restored using laser capsulotomy (creating an opening for light to pass through the opacified capsule) or surgical incision into the posterior capsule to allow light to reach the retina (Rothrock, 2011).

●○● NURSING CARE

Health Promotion

Advise all patients about the importance of protecting the eyes from UVB rays by wearing eye protection during activities such as welding and sunglasses with UVB protection when out of doors. Discuss the link between heavy smoking and cataract development. Provide anti–tobacco use education for young people and resources to stop smoking for people who do smoke.

Assessment

- *Health history:* effect of vision changes on lifestyle and activities (e.g., ability to read, watch television, participate in work and recreational activities); history of smoking, diabetes, use of prescription drugs associated with increased risk of cataract or cataract surgery
- *Physical assessment:* general health; visual acuity (using corrective lenses and Snellen chart) in each eye; presence of red reflex.

Priorities of Care

The patient with cataracts often has few physical care nursing needs. Patient advocacy, psychologic and emotional support, and teaching/learning needs are typically of higher priority for these patients. Review nursing care of the patient having eye surgery as outlined in the box on page 1498.

Diagnoses, Outcomes, and Interventions

Decisional Conflict: Cataract Removal

With the initial diagnosis of cataract, the nurse often becomes an important information resource for the patient.

Expected Outcome: Patient will be able to relate the risks and potential benefits of cataract surgery to current lifestyle and roles.

- Explain the nonemergent nature of the condition and help the patient determine the extent to which the cataract is affecting daily life. *This helps the patient decide when to proceed with surgery. Providing information about cataracts and their surgical removal also assists with decision making.*
- Attend to verbalized concerns about surgery and its outcome. Address questions factually and completely. *Fear of blindness is second only to fear of cancer for many patients. Careful listening, teaching, and a caring, understanding attitude can help the patient deal with this fear prior to surgery.*

Readiness for Enhanced Self-Health Management

Expected Outcome: Patient will achieve effective self-care postoperatively.

- Assess for factors that may interfere with the patient's ability to provide self-care postoperatively. *A chronic condition such as arthritis that may affect the ability to administer eyedrops may indicate the need to include a family member in teaching.*
- Assess for other care needs that may be impacted by vision changes in the early postoperative period. *Other care needs, such as insulin injections, may suggest the need for home health or nursing care postoperatively.*

Continuity of Care

With the initial diagnosis, teaching focuses on the disorder, indications for surgery, and vision restoration following cataract removal. Teaching adaptive strategies to deal with effects of the cataract on vision and depth perception are also useful. When surgery is scheduled, provide pre- and postoperative teaching, including a significant other in teaching sessions. Reinforce the following information with written instructions:

- Initial limitations such as avoiding lifting, strenuous activity, sleeping on operative side, or getting water in the eye
- Importance of not rubbing or scratching the eye
- Prescribed medications and side effects
- Importance of follow-up appointments
- Manifestations of postoperative complications such as eye pain, decreased visual acuity or other change in vision, headache, nausea, or itching and redness of the affected eye
- Instillation of eyedrops, and application of eye shield (for nighttime use)
- Anticipated vision changes as appropriate.

THE PATIENT WITH GLAUCOMA

Glaucoma is a condition characterized by optic neuropathy with gradual loss of peripheral vision and, usually, increased intraocular pressure of the eye. Glaucoma is a silent thief of vision. The patient typically experiences no manifestations other than narrowing of the visual field, which occurs so gradually that it often goes unnoticed until late in the disease process.

Incidence and Risk Factors

Glaucoma affects about 2.7 million people over the age of 40 in the United States; it remains undetected in approximately 25% of these cases. Glaucoma is a leading cause of blindness worldwide and the leading cause of blindness among African Americans. Age and race are the primary identified risk factors; it is more common in Blacks and Hispanics than in Whites (Prevent Blindness America, 2012).

Glaucoma is usually a primary condition without an identified cause. Primary glaucoma is most common in adults over the age of 60, but may be a congenital condition in infants and children. Secondary glaucoma can develop as a result of infection or inflammation of the eye, cataract, tumor, hemorrhage, or eye trauma.

Pathophysiology

Aqueous humor, a thick fluid, occupies both the anterior and posterior chambers of the eye. The normal intraocular pressure of approximately 10 to 20 mmHg is maintained by a balance between the production of aqueous humor in the ciliary body, its flow through the pupil from the posterior to the anterior chamber of the eye, and its outflow or absorption through the trabecular meshwork and scleral

Figure 46–11 ■ Narrowing of visual fields typical of untreated glaucoma.
Source: Courtesy of National Eye Institute, National Institutes of Health.

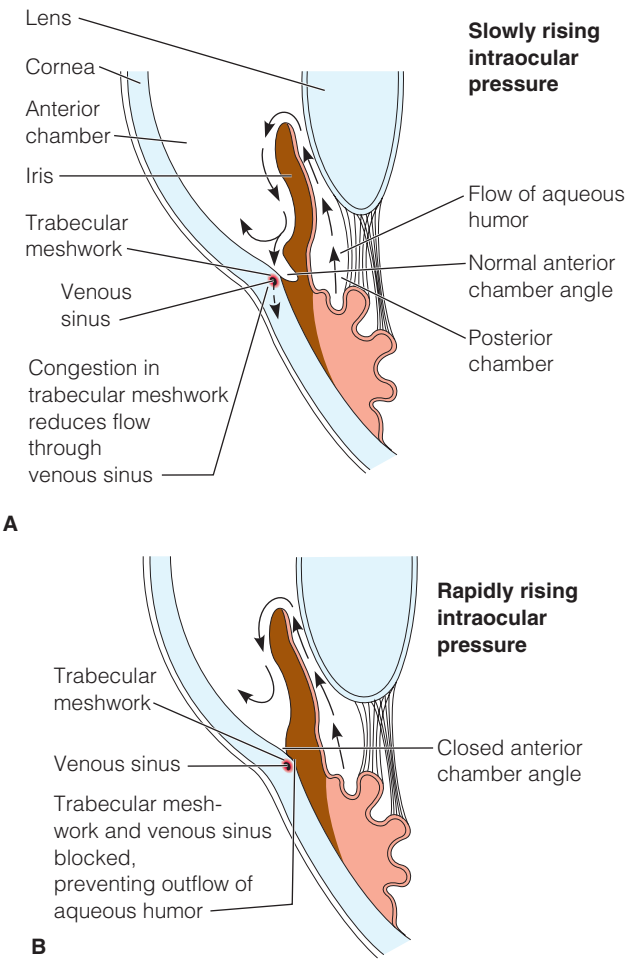

Figure 46–12 ■ Forms of primary adult glaucoma. A, In chronic open-angle glaucoma, the anterior chamber angle remains open, but drainage of aqueous humor through the scleral venous sinus is impaired. B, In acute angle-closure glaucoma, the angle of the iris and anterior chamber narrows, obstructing the outflow of aqueous humor.

venous sinus (canal of Schlemm) (refer to Figure 45–3 in the previous chapter). When this balance is disrupted, usually because of a decrease in the outflow or absorption of aqueous humor, the intraocular pressure increases. Although the exact relationship is unclear, it appears that increased intraocular pressure injures the optic nerve, either by compressing it or by impairing blood flow to the nerve. Axons in the periphery of the optic disc are damaged first. As optic fibers are destroyed, the rim of the optic disc shrinks, and the normal depression in its center (the *optic cup*) becomes larger and deeper (called optic "cupping"). These changes to the optic disc are visible before visual field changes can be detected. As the disease progresses, there is a painless, progressive narrowing of the visual field (Figure 46–11 ■) and eventual blindness. Vision loss is often significant before the patient seeks treatment and glaucoma is diagnosed.

Primary glaucoma in adults has two major forms: open-angle glaucoma and angle-closure glaucoma. Both terms refer to the angle formed at the point where the iris meets the cornea in the eye's anterior chamber (Figure 46–12 ■). Forms of primary glaucoma are compared in Table 46–3.

OPEN-ANGLE GLAUCOMA

Open-angle glaucoma, often called chronic simple glaucoma, is the most common form in adults, accounting for approximately 90% of all glaucoma. Its cause is unknown; it is thought to have a hereditary component, but no clear inheritance pattern can be identified. Open-angle glaucoma occurs more frequently and at an earlier age in African Americans than in Caucasians.

In open-angle glaucoma, the anterior chamber angle between the iris and cornea is normal (Figure 46–12A), hence the term *open angle.* However, the flow of aqueous humor through the trabecular meshwork and into the scleral venous sinus is relatively obstructed; the cause of this obstruction is unknown. Restricted outflow leads to an increased amount of fluid in the eye and increased intraocular pressure. Open-angle glaucoma tends to be a chronic, gradually progressive disease. The trabecular meshwork increasingly inhibits the outflow of aqueous humor, and the intraocular pressure gradually increases. The result is neuronal ischemia and optic nerve degeneration, leading to gradual loss of vision.

Open-angle glaucoma typically affects both eyes, although the pressures and progression may not be symmetric.

MANIFESTATIONS Open-angle glaucoma is painless, with gradual loss of visual fields. This loss of peripheral vision generally occurs so gradually that the patient is often unaware of it and only when it is detected through a comprehensive vision examination is it found. Intraocular pressure usually, but not always, is elevated (Horton, 2012).

ANGLE-CLOSURE GLAUCOMA

Acute angle-closure (also called narrow-angle or closed-angle) glaucoma is the other, less common form of primary glaucoma in adults. It usually affects people with a shallow anterior chamber caused by an inherited defect (Grossman & Porth, 2014). Approximately 1% of people over the age of 35 have narrowed anterior chamber angles; the incidence is higher in older adults and in people of Asian or Inuit (Alaska native) ancestry (Riordan-Eva, 2012).

Narrowing of the anterior chamber angle (refer to Figure 46–12A for an illustration of the normal anterior chamber angle) occurs because of corneal flattening or bulging of the iris into the anterior chamber. When the lens thickens during accommodation or the iris thickens during pupil dilation, this angle can close completely. Closure of the angle blocks the outflow of aqueous humor through the

TABLE 46–3 A Comparison of Open-Angle and Angle-Closure Glaucoma

	Open-Angle Glaucoma	Angle-Closure Glaucoma
Incidence	• Common • Accounts for 90% of all cases of glaucoma	• Uncommon
Risk factors	• Over age 40 • Genetic link • African American ancestry	• Narrow anterior chamber angle • Aging • Asian or Inuit ancestry
Pathophysiology	• Impaired aqueous outflow through the scleral venous sinus • Damage to axons of retinal ganglion cells with optic nerve atrophy • Gradual, consistent increase in intraocular pressure • Usually bilateral	• Pupil dilation or lens accommodation causes already narrowed angle to close, blocking aqueous outflow • Rapid rise in intraocular pressure • Usually unilateral
Manifestations	• No initial manifestations • Frequent lens changes in glasses • Impaired dark adaptation • Halos around lights • Gradual reduction of visual fields with preservation of central vision until late in the disease • Mild to severe increased intraocular pressure	• Abrupt onset of eye pain, headache • Decreased visual acuity • Nausea and vomiting • Reddened conjunctiva • Cloudy cornea • Fixed pupil • Rapid, significant increase in intraocular pressure
Management	• Topical medications such as beta-blockers, adrenergics, prostaglandin analogs • Carbonic anhydrase inhibitors • Laser trabeculoplasty, trabeculectomy	• Topical miotics or beta-blockers • Systemic osmotic agents, carbonic anhydrase inhibitors • Laser iridotomy or peripheral iridectomy

trabecular meshwork and scleral venous sinus, and the intraocular pressure rises abruptly (Figure 46–12B). This abrupt increase in intraocular pressure damages the neurons of the retina and the optic nerve, leading to a rapid and permanent loss of vision if not treated promptly.

Episodes of angle-closure glaucoma are typically unilateral. However, a history of angle-closure glaucoma of one eye increases the risk that it will occur in the other eye.

Because of the effect of pupil dilation on aqueous outflow in angle-closure glaucoma, episodes often occur in association with darkness, emotional upset, or other factors that cause the pupil to dilate. Patients may have intermittent episodes lasting several hours before having a more typical prolonged attack of angle-closure glaucoma. For patients with a history of the condition, it is vital to avoid medications such as atropine and other anticholinergics, which have a mydriatic or pupil-dilating effect.

MANIFESTATIONS Symptoms such as severe eye and face pain, general malaise, nausea and vomiting, seeing colored halos around lights, and an abrupt decrease in visual acuity are associated with acute episodes of angle-closure glaucoma. The conjunctiva of the affected eye may be reddened and the cornea clouded with corneal edema. The pupil may be fixed (nonreactive to light) at midpoint. Some patients may experience periodic mild attacks, usually in the evening, with eye discomfort, impaired vision, and colored rings around lights.

●○● INTERPROFESSIONAL CARE

Although glaucoma cannot be predicted, prevented, or cured, in most cases it can be controlled and vision preserved if diagnosed early. Because the most prevalent type of glaucoma, open-angle glaucoma, has few symptoms, routine eye examinations are recommended for early detection. Optic disc examination, measurement of intraocular pressure, and visual field testing are used for diagnosis and monitoring of treatment effectiveness.

DIAGNOSIS

The following diagnostic studies are used to detect and evaluate for the presence, severity, type, and effects of glaucoma:

- *Tonometry* indirectly measures intraocular pressure (Figure 46–13 ■). Contact or noncontact tonometry may be used. Routine tonometry screening is recommended for all people over the age of 60. A single elevated pressure reading does not warrant a diagnosis of glaucoma; variations in intraocular pressure occur throughout the day.
- *Fundoscopy* (visual inspection of the optic fundus using an ophthalmoscope) identifies pallor and an increase in the size and

Figure 46–13 ■ An eye professional uses a tonometer to indirectly measure the intraocular pressure of a patient's eye.
Source: Courtesy of National Eye Institute, National Institutes of Health.

depth of the optic cup on the optic disc. These changes are significant for diagnosing glaucoma.

- *Gonioscopy* uses a gonioscope to measure the depth of the anterior chamber. This test differentiates open-angle from angle-closure glaucoma.
- *Visual field testing* identifies the degree of central visual field narrowing and peripheral vision loss. The patient with glaucoma may retain 20/20 central vision even though there is severe peripheral vision loss.

MEDICATIONS

Although medications cannot cure glaucoma, many patients with open-angle glaucoma can control intraocular pressure and preserve vision indefinitely with medications. Medications are used alone or in combination with the timing and dosage individually determined by pressure measurements. The primary drugs used to treat glaucoma are topical beta-adrenergic blocking agents, adrenergics (mydriatics), prostaglandin analogs, or carbonic anhydrase inhibitors. An oral carbonic anhydrase inhibitor also may be used.

Prostaglandin analogs such as latanoprost (Xalatan) are generally the drugs of choice for treating chronic glaucoma because they can be administered daily and have a low adverse effect rate. These drugs increase aqueous outflow. Although they have fewer systemic effects, these drugs may cause conjunctival hyperemia and permanent changes in the color of the iris and eyebrows.

Topical beta-adrenergic blocking agents decrease the production of aqueous humor in the ciliary body. Beta-adrenergic blockers can be used once or twice a day, depending on the drug and dosage form. When administering beta-blockers or teaching about their use, it is important to remember that ophthalmic preparations can produce systemic effects, including bronchospasm, bradycardia, and heart failure.

The adrenergic agonist brimonidine may be prescribed along with a beta-blocker or if beta-blockers are contraindicated (e.g., in a patient with heart failure, asthma, or chronic obstructive pulmonary disease [COPD]). Another adrenergic agonist, apraclonidine, may be prescribed when other drugs do not sufficiently reduce intraocular pressure, but adverse effects make it inappropriate for long-term use (Riordan-Eva, 2012).

Dorzolamide (Trusopt), a carbonic anhydrase inhibitor, decreases the production of aqueous humor and reduces intraocular pressure. It is used with other drugs to control pressures and in patients for whom beta-blockers are contraindicated because of heart failure or reactive airway disease (asthma). Acetazolamide (Diamox), a systemic carbonic anhydrase inhibitor, also may be used for some patients.

Nursing implications for the medications used to control chronic glaucoma are outlined in the Medication Administration box on page 1509.

In acute angle-closure glaucoma, diuretics may be administered intravenously to achieve a rapid decrease in intraocular pressure prior to surgical intervention. Both the carbonic anhydrase inhibitor acetazolamide and osmotic diuretics, such as mannitol, are used. Fast-acting miotic drops, such as pilocarpine, are also administered to constrict the pupil and draw the iris away from the angle and from the scleral venous sinus. Prostaglandin analogs, beta-blockers, and adrenergic agents also may be given by topical application.

SURGERY

Surgical intervention is indicated for patients with acute angle-closure glaucoma and for patients with chronic open-angle glaucoma that is not effectively controlled by medication.

Surgical management of chronic open-angle glaucoma involves improving the drainage of aqueous humor from the anterior chamber of the eye. Trabeculoplasty and trabeculectomy filtration surgery are the most commonly used procedures.

In a *laser trabeculoplasty,* an argon laser is aimed through a gonioscope to create multiple laser burns spaced evenly around the trabecular meshwork. As the burns heal, the scars they create cause tension, stretching and opening the meshwork. This noninvasive technique is the treatment of choice because it requires no incision and can be performed as an outpatient procedure.

Trabeculectomy is a type of filtration surgery in which a permanent fistula is created to drain aqueous humor from the anterior chamber of the eye. A portion of trabecular meshwork is removed, and a flap of sclera is left unsutured to create a channel or fistula between the anterior chamber and the subconjunctival space. Aqueous humor is able to drain into the space under the conjunctiva, where it can be absorbed into the systemic circulation. A trabeculectomy is usually performed under general anesthesia and requires hospitalization.

If these procedures are not fully effective, either photocoagulation using an argon laser (heat) or cyclocryotherapy using a probe to freeze tissue may be employed to destroy portions of the ciliary body. This tissue destruction reduces the production of aqueous humor, subsequently reducing intraocular pressure. Another surgical procedure involves insertion of a glaucoma drainage device that regulates the outflow of aqueous humor.

Surgical procedures used in the treatment of acute angle-closure glaucoma include gonioplasty, laser iridotomy, and peripheral iridectomy. Because of the high risk for a future attack of angle-closure glaucoma in the unaffected eye, these procedures are often performed prophylactically.

In *gonioplasty*, the healing and scarring of microscopic lesions created at the periphery of the iris draw the iris away from the cornea, widening the anterior chamber. This widening of the chamber increases the angle and opens drainage channels for aqueous humor.

Laser iridotomy is a noninvasive procedure using a laser to create multiple small perforations in the iris of the eye. These perforations allow aqueous humor to drain from the posterior chamber to the anterior chamber and out through the trabecular meshwork and the scleral venous sinus. During an *iridectomy*, a small segment of the iris is removed to facilitate the flow of aqueous humor between the posterior and anterior chambers and to open the anterior chamber angle.

●○● NURSING CARE

When planning and providing nursing care for the patient with glaucoma, both the specific form of the disease and its actual or potential effects on the patient's vision, lifestyle, safety, and psychosocial well-being must be considered. In the hospitalized patient, glaucoma is typically a concurrent diagnosis rather than the primary reason for seeking care, unless the diagnosis is acute angle-closure glaucoma. For additional nursing activities for the patient with glaucoma, see the accompanying Case Study & Nursing Care Plan.

MEDICATION ADMINISTRATION

The Patient with Glaucoma

ADRENERGIC AGONISTS (MYDRIATICS)

brimonidine (Alphagan)

apraclonidine

Adrenergic agonists dilate the pupil, reduce the production of aqueous humor, and increase its absorption, effectively reducing intraocular pressure in open-angle glaucoma.

Nursing Responsibilities

- Assess for contraindications and adverse reactions to adrenergic agonists, including acute angle-closure glaucoma, hypertension, cardiac dysrhythmias, and coronary heart disease.
- Assess for central nervous system side effects of anxiety, nervousness, and muscle tremors. If these side effects are severe, notify the physician.
- Assess for a hypersensitivity reaction, including itching, lid edema, and discharge from the eyes. Notify the physician if you notice these signs.

Health Education for the Patient and Family

- Report any change in visual acuity or eye pain. (Eye pain may indicate an attack of angle-closure glaucoma and must be reported to the physician immediately.)
- Avoid over-the-counter (OTC) sinus and cold medications containing pseudoephedrine and phenylephrine. They may accentuate the side effects of this drug.

BETA-ADRENERGIC BLOCKERS

betaxolol (Betoptic)

carteolol (Cartrol, Ocupress)

levobunolol (Betagan)

metipranolol (OptiPranolol)

timolol (Timoptic)

Selected beta-adrenergic blockers reduce intraocular pressure by decreasing the production of aqueous humor. Because beta-blockers do not affect pupil size and lens accommodation, they do not have the adverse effects on visual acuity that adrenergic agonists do. Their systemic effects, however, may limit their usefulness for certain patients.

Nursing Responsibilities

- Assess for allergies or contraindications to beta-blocker therapy, including asthma, COPD, heart block, and heart failure.
- Maintain pressure over the lacrimal sac after administration to prevent systemic absorption.
- Assess for side effects such as bradycardia, hypotension, and depression.

Health Education for the Patient and Family

- After instilling the eyedrops, put pressure on the lacrimal sac, at the corner of the eye near the bridge of the nose, to keep the drug from entering your system.
- Your vision may be blurred during the initial period of therapy, but it will improve as you continue to use the drug.
- Report adverse effects, including worsening vision, difficulty breathing, reduced exercise tolerance, and sweating or flushing, to the physician.

CARBONIC ANHYDRASE INHIBITORS

dorzolamide (Trusopt)

brinzolamide (Azopt)

acetazolamide (Diamox)

The carbonic anhydrase inhibitors lower intraocular pressure and are used primarily as adjunctive therapy. Dorzolamide and brinzolamide are administered as eyedrops, whereas acetazolamide may be given PO, IM, or IV.

Nursing Responsibilities

- Assess for allergies or other contraindications to the use of carbonic anhydrase inhibitors, including known allergy to sulfa, or severe renal or hepatic disease.
- Monitor for increased drug interactions of amphetamines, procainamide, quinidine, tricyclic antidepressants, and ephedrine and pseudoephedrine.
- Assess daily weight, intake and output, serum electrolytes, and vital signs in patients taking oral or parenteral carbonic anhydrase inhibitors.
- Administer PO in the morning to prevent sleep disruption because of the diuretic effect.
- If used with another topical ophthalmic, administer 10 minutes apart.

Health Education for the Patient and Family

- For oral medications, maintain a fluid intake of 2 to 3 L/day and rise slowly from lying or sitting positions because you may feel dizzy when you first stand (orthostatic hypotension).
- For topical medications, notify the physician if you have prolonged eye irritation.

PROSTAGLANDIN ANALOGS

bimatoprost (Lumigan)

latanoprost (Xalatan)

travoprost (Travatan)

The prostaglandin analog drugs relax the ciliary muscle, improving the outflow of aqueous humor and reducing intraocular pressure. These drugs have the advantage of requiring only a single daily dose. They do, however, have some adverse effects such as blurred vision and stinging, and, when used long term, cause permanent darkening of the iris of the eye and eyebrows, increased growth of eyelashes, and conjunctival hyperemia (redness).

Nursing Responsibilities

- Assess and note eye color and presence of inflammation, exudates, or pain.
- Note vital signs and most recent liver function test results because these may be altered by the drug.

Health Education for the Patient and Family

- Use once daily at bedtime as directed. This drug may blur vision; use at bedtime minimizes associated safety risks.
- Remove contact lenses before administering this drug.
- Minor eye discomfort, including burning and tearing, may occur with this drug. Notify your doctor if adverse effects are severe or intolerable.
- This drug may cause darkening of your iris, the skin around the eyes, and the eyebrows, as well as increased growth of the eyelashes. These color changes are permanent but will not progress if the drug is discontinued by your doctor.

Note: Drugs identified in *italics* are among the 200 most commonly prescribed medications in the U.S.

Health Promotion

Although glaucoma cannot be prevented, its severity and potentially deleterious permanent effects can be limited with early visual screening. The nurse assumes an important role in educating the public about risk factors for glaucoma such as increased age, and the higher incidence in African Americans and Asians. All people over the age of 40 are encouraged to receive an eye examination every 2 to 4 years, including tonometry screening. Those with a predominant family history should be evaluated more frequently, every 1 to 2 years. After the age of 65, yearly ophthalmologic examinations are recommended.

Assessment

Collect the following data through a health history and physical examination.

- *Health history:* family history; presence of altered vision, halos, and excessive tearing; sudden, severe eye pain; use of corrective lenses; most recent eye examination
- *Physical assessment:* distant and near vision, peripheral fields, retina for optic nerve cupping.

Priorities of Nursing Care

Teaching for effective management of this chronic disease and preventing vision loss is the nursing care priority for the patient newly diagnosed with glaucoma (see the Continuity of Care section that follows). When vision loss has occurred, the visual deficit and reducing the risk for injury are priority nursing care focuses.

Diagnoses, Outcomes, and Interventions

Nursing care planning focuses on problems associated with the temporary or permanent visual impairment, the resultant increased risk for injury, and the psychosocial problems of anxiety and coping.

Impaired Vision

Whether glaucoma, and its resulting impaired vision, is the patient's primary problem or a preexisting condition in a patient with another disorder, it must be a primary consideration in nursing care planning. For additional interventions, see the box on page 1512.

Expected Outcome: Patient will adapt to functioning in healthcare environment without experiencing injury or adverse effects related to impaired vision.

- Address by name and identify yourself with each interaction. Orient to time, place, person, and situation as indicated. State the purpose of your visit. *The patient with impaired vision must rely on input from the other senses. A lack of visual cues increases the importance of verbal ones. For example, the patient with impaired vision cannot see the nurse checking an intravenous infusion and needs a verbal explanation of who is in the room and why. When the patient's normal daily routine is disrupted by illness or hospitalization, additional sensory input such as a radio, television, and explanations of the routine and activities are useful to maintain the patient's orientation.*
- Provide any visual aids that are routinely used. Keep them close, making sure that the patient knows where they are and can reach them easily. *Easy access encourages the patient to use these items and enhances the ability to provide self-care.*
- Orient to the environment. Explain the location of the call bell, personal items, and the furniture in the room. *Patients with visual impairments are usually very capable of providing self-care in a known environment.*
- Provide other tools or items that can help compensate for diminished vision:
  - Bright, nonglare lighting
  - Books, magazines, and instructions in large print
  - Books on tape
  - Telephones with oversize pushbuttons
  - A clock with numbers and hands that can be felt.
- Assist with meals by doing the following:
  - Reading menu selections and marking choices.
  - Describing the position of foods on a meal tray according to the clock system.
  - Placing the utensils in a readily accessible position.
  - Removing lids from containers, buttering the bread, and cutting meat, as needed.
  - If the visual impairment is new or temporary, the patient may need continued assistance during the meal.
    Providing assistance during eating is important to maintain the patient's nutritional status. The patient may be ashamed of needing help or embarrassed to request it and may respond by not eating or by claiming not to be hungry.
- Assist with mobility and ambulation as needed:
  - Have the patient hold your arm or elbow, and walk slightly ahead as a guide. Do not hold the patient's arm or elbow.
  - Describe the surroundings and progress as you proceed. Warn in advance of potential hazards, turns, and steps.
  - Teach to feel the chair, bed, or commode with the hands and the back of the legs before sitting.
    These measures help ensure the patient's safety while providing for mobility and helping prevent complications associated with immobility.
- If the vision loss is unilateral and recent, provide instructions related to unilateral vision loss and change in depth perception:
  - Caution about the loss of depth perception and teach safety precautions, such as reaching slowly for objects and using visual cues as to distance, especially when driving.
  - Teach to scan, turning the head fully toward the affected side to identify potential hazards and looking up and down to compensate for the loss of depth perception.
    The patient with a unilateral vision loss is often unaware of its effect on peripheral vision and depth perception.

Evidence for Nursing Care

The Patient with Glaucoma

Selected resources that nurses may find helpful when planning evidence-based nursing care follow.

- U.S. Preventive Services Task Force. (2009). Clinical guidelines. Screening for impaired visual acuity in older adults: U.S. Preventive Services Task Force recommendation statement. *Annals of Internal Medicine*,*151*, 37–43.
- University of Michigan Health System. (2011). *Adult clinical preventive care*. Ann Arbor, MI: Author.
- Watkinson, S. (2010). Improving care of chronic open angle glaucoma. *Nursing Older People*, *22*(8), 18–23.

Risk for Injury

Whether the patient is experiencing a sudden loss of vision due to acute angle-closure glaucoma or significant visual impairment due to inadequately managed chronic glaucoma, both are at an increased risk for injury. Patients who have had surgical interventions for glaucoma are at even greater risk.

Expected Outcome: Patient will remain free of injury while in healthcare environment.

- Assess ability to perform ADLs. *Patients may be reluctant to request assistance, believing that they should be able to perform these familiar tasks. Careful assessment and provision of needed assistance help prevent injury and maintain the patient's self-esteem.*
- Notify all personnel to avoid changing the arrangement of the patient's room. *The patient with impaired vision is at high risk for falling when in an unfamiliar environment. It is important to maintain a safe, familiar room when the patient is hospitalized.*
- Discuss possible adaptations in the home to help the patient remain as independent as possible and prevent falls or other injuries. *Often minor changes in the home environment, such as removing scatter rugs and small items of furniture, allow the patient to navigate safely in this already familiar environment.*

SAFETY ALERT

Keep traffic areas free of clutter to reduce the risk for injury in patients with impaired vision.

Anxiety

The actual or potential loss of sight threatens the patient's self-concept, role functioning, patterns of interaction, and, potentially, environment. The patient with impaired vision who functions well in a familiar environment will feel anxious in the unfamiliar setting of a hospital or care facility.

Expected Outcome: Patient will report and demonstrate reduced levels of anxiety.

- Assess for verbal and nonverbal indications of level of anxiety and for normal coping mechanisms. Repeated expressions of concern or denial that the vision change will affect the patient's life indicate anxiety. Nonverbal indicators include tension, difficulty concentrating or thinking, restlessness, poor eye contact, and changes in vocalization (rapid speech, voice quivering). Physical indicators include tachycardia, dilated pupils, cool and clammy skin, and tremors. *The patient may not recognize this feeling as anxiety. Identifying and acknowledging the anxiety state can help the patient recognize and deal with it.*
- Encourage to verbalize fears, anger, and feelings of anxiety. *Verbalizing helps externalize the anxiety and allows fears to be addressed.*
- Discuss perception of the eye condition and its effects on lifestyle and roles. *Discussion provides an opportunity to correct misperceptions and introduce alternative activities and assistive devices for patients with visual impairments.*
- Introduce yourself when entering the room, explain all procedures fully before and as they are being performed, and use touch to convey proximity and caring. *The patient with impaired vision must rely on the other senses to make up for the loss of sight. Because the patient cannot see what you are doing, complete explanations of even simple tasks such as refilling a water glass help to relieve anxiety.*
- Identify coping strategies that have been useful in the past and adapt these strategies to the present situation. *Previously successful coping strategies may be employed to increase the patient's sense of control.*

Continuity of Care

Patients with glaucoma require teaching about lifetime strategies for managing the disease at home. Poor adherence to prescribed therapy is a significant problem in many patients with chronic glaucoma (Watkinson, 2010). They need to understand the importance of lifelong therapy to control the disease and prevent blindness. If a permanent visual impairment has resulted, the patient needs information on achieving the maximum possible independence while maintaining safety. The following topics should be discussed with the patient and family:

- Prescribed medications, including proper storage and how to instill eyedrops
- Importance of not taking certain prescription and OTC medications without consulting a physician
- The need for periodic eye examinations with intraocular pressure measurement
- Risks, warning signs, and management of acute angle-closure glaucoma
- Possible surgical options
- Community resources, such as Visually Impaired Society, local library, and transportation services.
- Helpful resources: National Glaucoma Foundation, Young and Under Pressure Glaucoma Foundation, Glaucoma Research Foundation, and Prevention of Blindness Society.

THE PATIENT WITH AGE-RELATED MACULAR DEGENERATION

Age-related macular degeneration (AMD) is a leading cause of legal blindness and impaired vision in older adults (NEI, 2012d).

FAST FACTS

- Age-related macular degeneration rarely affects people under the age of 50 years.
- The incidence and prevalence of AMD increases rapidly with aging, affecting over 0.7% of Americans ages 60 to 69, more than 2% of people ages 70 to 79, and nearly 12% of those ages 80 and older (Prevent Blindness America, 2012).

Although the exact cause of AMD is unknown, factors associated with it include aging, smoking, race, and genetic factors. Whites and Hispanics have a significantly higher risk of developing AMD than Blacks or people of Asian ancestry. Recent evidence suggests that inflammation plays a role in the development of AMD (Horton, 2012), as does the interaction of certain genes with the immune system (NEI, 2012c). Evidence suggests that the risk for developing AMD may be reduced by consumption of omega-3 fatty acids in fish and vegetables high in lutein and zeaxanthin (carotenoids found in vegetables such as spinach, kale, and broccoli).

Pathophysiology

The macula is the area of the retina that provides sharp central vision, receiving light from the center of the visual field. Two forms

CASE STUDY & NURSING CARE PLAN A Patient with Glaucoma and Cataracts

Lila Rainey is an 80-year-old widow who lives alone. She has worn glasses for nearsightedness since she was a young girl, and now wears bifocals to correct her near vision as well. She was diagnosed 4 years ago with chronic open-angle glaucoma, for which she uses timolol (Timoptic) 0.5%. Recently she has noticed difficulty reading and watching television despite a new lens prescription. She has stopped driving at night because the glare of oncoming headlights makes it difficult for her to see. Mrs. Rainey's ophthalmologist has told her that she has cataracts but that they do not need to come out until they bother her. Although her glaucoma is still controlled with timolol maleate 0.5%, one drop in each eye twice a day, her intraocular pressure measurements have been gradually increasing. Mrs. Rainey has taken 325 mg of aspirin daily since a transient ischemic attack 8 years ago. She is being admitted to the outpatient surgery unit for a cataract removal and intraocular lens implant in her right eye.

ASSESSMENT

Mrs. Rainey is admitted to the eye surgery unit by Susan Schafer, RN. In her assessment, Ms. Schafer finds Mrs. Rainey to be alert and oriented, though apprehensive about her upcoming surgery. Assessment findings include BP 134/72 mmHg, P 86 bpm, R 18/min. Mrs. Rainey's physical assessment is essentially normal. Her pupils are round and equal, and react briskly to light and accommodation. Her conjunctivae are pink; sclera and corneas are clear. Using the ophthalmoscope, Ms. Schafer notes that the red reflex in Mrs. Rainey's right eye is diminished. Ophthalmic examination shows visual acuity of 20/150 OD (right eye) and 20/50 OS (left eye) with corrective lenses. Ms. Schafer reviews the operative procedure with Mrs. Rainey, answering her questions and telling her what to expect after surgery. Following preoperative protocols, Mrs. Rainey is prepared and transported to surgery.

MOVING KNOWLEDGE INTO ACTION

1. Do Mrs. Rainey's current medications (timolol eyedrops and daily aspirin) increase her surgical or anesthetic risks? If so, explain what action the nurse, Ms. Schafer, should take.
2. What risks are associated with cataract extraction and intraocular lens implant surgery? Identify important teaching points related to these risks.

DIAGNOSES

- *Impaired Vision* related to myopia and lens extraction
- *Anxiety* related to anticipated surgery
- *Readiness for Enhanced Knowledge* related to postoperative care

EXPECTED OUTCOMES

- Patient will regain sufficient visual acuity to maintain ADLs, including reading and watching television for enjoyment.
- Patient will demonstrate a reduced level of anxiety.
- Patient will demonstrate the procedure for instilling eyedrops postoperatively.
- Patient will demonstrate knowledge of the home care she will require after surgery, signs of complications, and actions to take if complications occur.

PLANNING AND IMPLEMENTATION

- Provide a safe environment, placing the call light and personal care items within easy reach.
- Encourage Mrs. Rainey to express her fears about surgery and its potential effect on vision.
- Explain all procedures related to surgery and recovery.
- Instruct her to avoid rubbing the eye, shutting the eyelids tightly, lifting, or straining to have a bowel movement. Teach her to wear glasses during the day and an eye shield at night to prevent injury to the surgical site.
- Provide verbal and written instructions about postoperative care, including a schedule of follow-up examinations, potential complications, and actions to take in response.

EVALUATION

Mrs. Rainey is discharged the morning after her surgery. She is visibly relieved when the eye patch is removed because her vision in the operated eye is better than before surgery, even without her glasses. She is able to relate the recommended activity restrictions. Mrs. Rainey administers her own eyedrops before discharge and relates an understanding of the prescribed postoperative care and safety precautions. Mrs. Rainey's daughter plans to visit her mother two to three times a week until Mrs. Rainey is able to resume all her previous activities. Mrs. Rainey says that she won't "be so scared when I need my other eye done." She understands the chronic nature of her glaucoma and says that her vision is too important for her to neglect her timolol drops and routine eye exams.

Clinical Reasoning in Patient Care

3. Why did it become more difficult to control Mrs. Rainey's intraocular pressure as her cataract matured?
4. Identify medications that are commonly prescribed following cataract surgery. What are the risks of interactions between these medications and Mrs. Rainey's timolol drops?
5. Develop a care plan for the nursing diagnosis *Bathing Self-Care Deficit*, related to visual impairment and instructions to avoid getting water in the eye.

See Evaluating Your Response in Appendix B.

of age-related macular degeneration are identified, a nonexudative (dry) form and an exudative (wet) form. Although both are progressive disorders, their manifestations and management differ.

Nonexudative, or dry, *macular degeneration* is the more common form of AMD. It is a gradual process that begins with accumulation of deposits called *drusen* beneath the pigment epithelium of the retina. Over time, these deposits enlarge and become more numerous. The pigment epithelium detaches in small areas and becomes atrophic, interfering with sensory function of the macula. Vision loss typically is not significant, and the disorder progresses slowly. There is, however, a risk that the disorder will progress to an exudative stage of the disease.

Exudative macular degeneration is characterized by the formation of new, weak blood vessels in the potential space between the choroid (vascular layer of the eye) and the retina (neurosensory layer). These new vessels are prone to leak, elevating the retina from the choroid and distorting vision. Although exudative macular degeneration typically is a gradual process, bleeding can lead to acute vision loss in some cases. With significant or repeated bleeding episodes, scar tissue forms, and central vision is permanently lost (Horton, 2012).

Manifestations

When the macula is damaged, central vision becomes blurred and distorted, but peripheral vision remains intact. Distortion of vision in one eye is a common initial manifestation; straight lines appear wavy or distorted. With the loss of central vision, activities that require

Figure 46–14 ■ Loss of central vision with advanced age-related macular degeneration.
Source: Courtesy of National Eye Institute, National Institutes of Health.

close central vision, such as reading and sewing, are particularly affected (Figure 46–14 ■).

●○● INTERPROFESSIONAL CARE

AMD is diagnosed through vision and retinal examination. The Amsler grid (Figure 46–15 ■) can be used to identify distortion of central vision caused by AMD. If treatment for wet AMD is planned, a *fluorescein angiogram* may be done. Pictures are taken as the dye passes through the blood vessels of the retina, allowing detection of leaks.

In its early or intermediate stages, the progress of dry AMD can be slowed through the use of vitamins C and E, beta-carotene (vitamin A), and zinc (Horton, 2012).

Two drugs that inhibit the growth of new blood vessels, bevacizumab (Avastin) and ranibizumab (Lucentis), have been shown to improve vision and prevent vision loss in patients with advanced AMD. The drug may be administered monthly or on an as-needed basis (NEI, 2012a).

Wet AMD also may be treated with laser surgery or photodynamic therapy. Although these treatments do not cure the disease, they may slow the rate of vision loss. In laser surgery, fragile blood vessels are destroyed, preventing bleeding. There is a risk, however, of damage to surrounding healthy tissue, some vision loss, and continued growth of new vessels. In photodynamic therapy, verteporfin, a drug that tends to adhere to the surface of new blood vessels, is injected systemically. Light is then shined into the affected eye, activating the drug and destroying new blood vessels. This treatment is relatively fast and painless, but does require avoidance of exposure to direct sunlight or bright indoor light for 5 days following treatment (NEI, 2013).

●○● NURSING CARE

Nurses should be alert for patients demonstrating new and rapid-onset manifestations of macular degeneration and promptly refer these patients for ophthalmologic evaluation. Early intervention may preserve a greater degree of vision and slow the progress of the disease. For patients with slowly progressive manifestations, the nursing focus is on helping the patient and family members adapt to the gradual decline in vision by recommending visual aids and other coping strategies. Large-print books and magazines, the use of a magnifying glass, and high-intensity lighting can help the patient to cope with the reduced vision of macular degeneration. Patient education materials should be in a large-print format.

THE PATIENT WITH DIABETIC RETINOPATHY

Diabetic retinopathy is a vascular disorder affecting the capillaries of the retina. The capillaries become sclerotic and lose their ability to transport sufficient oxygen and nutrients to the retina.

FAST FACTS

- In the United States, more than 7.6 million people have diabetic retinopathy.
- Diabetic retinopathy is the leading cause of new blindness in people ages 20 to 74.
- People with diabetes are 25 times more likely to become legally blind than people unaffected by the disease (Powers, 2012).
- Hispanics are disproportionately affected by diabetic retinopathy; whereas approximately 5% of White adults and 5.4% of Black adults in the United States have diabetic retinopathy, more than 8% of Hispanic adults are affected (Prevent Blindness America, 2012).

The risk of developing diabetic retinopathy is related to the duration of the diabetes and the degree of glycemic control. Hypertension also is a risk factor (Powers, 2012). Retinopathy is seen in both type 1 and type 2 diabetes. Nursing care of the patient with diabetes is discussed in Chapter 20.

Pathophysiology and Manifestations

Diabetic retinopathy has two stages: *nonproliferative* or background retinopathy, and *proliferative* retinopathy. Nonproliferative retinopathy is typically the initial form seen, usually about 10 years after diabetes is diagnosed. The venous capillaries of the eye dilate and develop microaneurysms that may then leak, causing retinal edema, or they may rupture, causing small hemorrhages into the retina. On ophthalmoscopic examination, yellow exudates, cotton-wool patches indicative of retinal ischemia, and red-dot hemorrhages are observed (Figure 46–16 ■). When the peripheral retina is involved, the patient may experience few symptoms other than light glare. Edema of the macula or a large hemorrhage may cause vision loss.

Diabetic retinopathy may progress to the proliferative form. This disease is marked by large areas of retinal ischemia and the formation of new blood vessels (neovascularization) spreading over the inner surface of the retina and into the vitreous body. These vessels are fine and fragile, making them permeable and easily ruptured. Blood and blood protein leakage contribute to retinal edema, and hemorrhage into the vitreous body may occur. The vessels gradually become fibrous and firmly attached to the vitreous body, increasing the risk of retinal detachment.

●○● INTERPROFESSIONAL CARE

Patients with diabetes should be examined yearly by an ophthalmologist. The development of any new visual manifestations is an additional indication for prompt ophthalmologic examination and possibly retinal angiography. Strict control of blood glucose levels and blood pressure are important preventive measures, and may slow the progression of retinopathy as well (Powers, 2012).

Laser photocoagulation is used to treat both the nonproliferative and proliferative forms of diabetic retinopathy. Leaking microaneurysms are sealed and proliferating vessels destroyed, reducing the risk of hemorrhage, retinal edema, and retinal detachment. This treatment also slows the progress of aneurysms and new vessel formation; however, it does not cure the disorder. Injections of the drug ranibizumab (Lucentis) into the eye in combination with laser treatment improve outcomes for patients with diabetic macular edema (fluid accumulation on the retina) (Sieving, 2012). Although conclusive research is lacking, patients with advanced diabetic retinopathy may be advised to avoid physical activity associated with the Valsalva maneuver (e.g., weight training) (Powers, 2012).

●○● NURSING CARE

As with many other eye disorders, the nursing care focus for diabetic retinopathy is primarily educational. The patient who is newly diagnosed with diabetes needs to understand the importance of regular eye examinations beginning approximately 5 years after the onset of type 1 diabetes and at the time of diagnosis of type 2 diabetes. Changes of diabetic retinopathy may already be present when type 2 diabetes is diagnosed.

Teach the patient to report promptly any new visual manifestation, including blurred vision; black spots (floaters), cobwebs, or flashing lights in the visual field; or a sudden loss of vision in one or both eyes. Emphasize to the patient that careful blood glucose control may help prevent diabetic retinopathy from developing; it may also slow its progress. The patient's blood pressure should also be maintained within normal limits to prevent further damage to retinal vessels. Although diabetic retinopathy cannot be halted or cured, its progress can be slowed with aggressive management. Much of the burden for this management falls on the patient, increasing the importance of good teaching.

THE PATIENT WITH A RETINAL DETACHMENT

The retina contains the photoreceptors of the eye, which allow the perception of light and initial processing of images and stimuli for transmission to the optic center of the brain. Disruption of this neural layer of the eye by trauma or disease interferes with light perception and image transmission, potentially resulting in blindness.

Both primary eye conditions and systemic diseases can affect the retina and interfere with vision. Retinal tears or detachments can occur either spontaneously or as a result of trauma.

Pathophysiology and Manifestations

Separation of the retina or sensory portion of the eye from the choroid, the pigmented vascular layer, is known as a *retinal detachment*. Although retinal detachment may be precipitated by trauma, it

usually occurs spontaneously. The vitreous humor normally adheres to the retina at the optic disc, the macula, and the periphery of the eye. With aging, the vitreous humor shrinks and may pull the retina away from the choroid. Aging therefore is a common risk factor, as are myopia and aphakia, absence of the lens (e.g., following lens removal for cataracts).

The retina may actually tear and fold back on itself, or it may remain intact but no longer adhere to the choroid. A break or tear in the retina allows fluid from the vitreous cavity to enter the defect. This, along with fluid that escapes from choroid vessels, the pull of gravity, and traction exerted by the vitreous humor, separates the retina from the choroid. The detached area may rapidly increase in size, increasing loss of vision. Unless contact between the retina and choroid is reestablished, the neurons of the retina become ischemic and die, causing permanent vision loss. For this reason, retinal detachment is a true medical emergency, requiring prompt ophthalmologic referral and treatment.

When the retina detaches, the patient experiences floaters, or "spots," and lines or flashes of light in the visual field. Often the patient describes the sensation of having a curtain drawn across the vision, much like a curtain being drawn over a window. The area of the visual field affected is directly related to the area of detachment. For example, because light rays cross as they pass through the lens, a retinal tear in the superior portion of the eye results in a deficit in the lower part of the visual field. The patient feels no pain, and the eye appears normal to visual inspection. Common manifestations of retinal detachment are listed in the accompanying box.

●○● INTERPROFESSIONAL CARE

Retinal detachment is a medical emergency; prompt treatment is necessary to preserve vision. The manifestations and examination of the ocular fundus by ophthalmoscopy establish the diagnosis of retinal detachment. Early diagnosis and intervention are vital. If the condition is left untreated, the detached portion will become necrotic because of lost contact with the vascular supply of the choroid. The result is permanent blindness in that portion of the eye. If an ophthalmologist is not readily available, the patient's head is positioned so that gravity pulls the detached portion of the retina into closer contact with the choroid.

Interventions are directed toward bringing the retina and choroid back into contact and reestablishing the blood and nutrient supply to the retina. Either cryotherapy, using a supercooled probe, or laser photocoagulation may be used to seal retinal holes, and to create an area of inflammation and adhesion to "weld" the layers together.

A surgical procedure called scleral buckling also may be used. In this procedure, an indentation or fold is created in the sclera, bringing the choroid into contact with the retina. Contact is maintained with a local implant on the sclera or an encircling strap or "buckle." An inert gas may also be injected into the vitreous cavity, a procedure called pneumatic retinopexy. The patient is positioned so that the bubble pushes the detached portion of the retina into contact with the choroid. Silicone oil also may be injected into the eye to reestablish contact between the retina and choroid.

With a retinal tear, it may be necessary to use surgical instruments to manipulate the detached section of retina into place. Air or a liquid is then injected into the vitreous to maintain retinal contact with the choroid, or laser therapy is used to create a bond.

MANIFESTATIONS OF RETINAL DETACHMENT

- Floaters: irregular, dark lines or spots in the field of vision
- Flashes of light
- Blurred vision
- Progressive deterioration of vision
- Sensation of a curtain or veil being drawn across the visual field from the top, side, or bottom
- If the macula is involved, loss of central vision

●○● NURSING CARE

The nursing focus for the patient with a detached retina is on early identification and treatment. Retinal detachment can be successfully treated on an outpatient basis, often in an ophthalmologist's office. For these patients, the nursing focus is on education.

Priorities of Care

Because early intervention is vital to preserve the patient's sight, nurses must recognize early manifestations of retinal detachment and intervene appropriately to obtain definitive treatment for the patient.

Diagnoses, Outcomes, and Interventions

Ineffective Tissue Perfusion: Retinal

Restoring contact between the retina and choroid is a priority of nursing and medical care for the patient with retinal detachment. Vitreous humor may leak through a retinal tear, and fluid exudate may collect behind the tear, causing further detachment. If the macula is detached, central vision is lost, and the prognosis for full vision restoration is poorer.

Expected Outcome: Patient's visual acuity and field will be restored to previous level.

PRACTICE ALERT!

Carefully assess anyone who complains of a sudden rapid loss of vision because this often signals a medical emergency.

- Assess for other manifestations of eye disease. *Retinal detachment is painless and has no outward manifestations. The patient with a red eye or cloudy cornea may be experiencing acute angle-closure glaucoma rather than retinal detachment.*
- Notify physician and the ophthalmologist immediately. *Immediate medical intervention is required in patients with retinal detachment to preserve vision.*
- Position so the area of detachment is inferior. For instance, for a superior temporal retinal detachment of the right eye (with corresponding vision loss in the inferior medial visual field of that eye), place supine with the head turned to the right. *Correct positioning allows the contents of the posterior portion of the eye to place pressure on the detached area, bringing the retina in closer contact with the choroid.*

Anxiety

Retinal detachment causes a rapid decline in vision in the affected eye, often occurring spontaneously and without pain. Unless

previous episodes have occurred, the patient usually does not know what is causing the problem. Anxiety and fear of complete vision loss are common, expected reactions.

Expected Outcome: Patient will report and demonstrate reduced levels of anxiety.

- Maintain a calm, confident attitude while carrying out priority interventions. *Administering care in a calm although urgent manner helps reassure the patient that the problem is treatable and that appropriate measures are being taken.*
- Reassure that most retinal detachments are successfully treated, usually on an outpatient basis. *Reassurance can help allay the patient's fear of permanent vision loss.*
- For spontaneous detachments, assure the patient that he or she did not cause the detachment to occur. *The patient may believe that the detachment is related to a specific activity and feel guilty for somehow causing this loss of vision.*
- Explain all procedures fully, including the reason for positioning. *Explanations facilitate understanding and help relieve anxiety in unfamiliar settings.*
- Allow supportive family members or friends to remain with the patient as much as possible. *Additional support helps lower the patient's anxiety level.*

Continuity of Care

Teaching for the patient undergoing treatment for retinal detachment is similar to that for patients experiencing other types of eye surgery (see page 1500). If the retina remains detached, provide instructions about the change in peripheral vision or other visual fields and changes in depth perception.

Discuss the following topics with the patient and family to prepare for home care:

- Limitations on positioning the head before or following repair
- Activity restrictions such as no bending or straining at stool
- Use of eye shield
- Early manifestations and the importance of seeking immediate treatment
- Follow-up treatment with the ophthalmologist.

THE PATIENT WITH RETINITIS PIGMENTOSA

Retinitis pigmentosa is a hereditary degenerative disease characterized by retinal atrophy and loss of retinal function progressing from the periphery to the central region of the retina. It is inherited as an autosomal dominant, autosomal recessive, or X-linked trait and may be associated with other genetic defects.

In retinitis pigmentosa, the genetic defect appears to cause production of an unstable form of rhodopsin, the receptor protein of rod cells in the retina. Rod cells degenerate, initially at the periphery of the retina. The areas of degeneration and cell death slowly expand, causing vision to narrow. Central vision is finally lost as well.

The initial manifestation of retinitis pigmentosa, difficulty with night vision, is often noted during childhood. As the disease progresses, there is slow loss of visual fields, photophobia, and disrupted color vision. The progression to tunnel vision and blindness is gradual; the patient may be totally blind by age 40.

Currently, there is no effective treatment for retinitis pigmentosa. Research into the role that defective rhodopsin plays in the disease holds future promise for the development of therapy that may at least slow its progress.

Patients with retinitis pigmentosa may benefit from low-vision aids, much like those for the patient with macular degeneration. Additionally, information about the disease and its progress is vital so the patient can plan for the eventual total loss of sight. Patients with retinitis pigmentosa should be referred for genetic counseling prior to starting a family to determine the risk of transmitting the disease to their children.

THE PATIENT WITH AN ENUCLEATION

Occasionally surgical removal of an eye is necessary because of trauma, infection, glaucoma, intractable pain, or malignancy. This procedure is known as **enucleation**.

Enucleation is performed under local or general anesthesia. After the globe is removed, the conjunctiva and eye muscles are sutured to a round implant inserted into the orbit to maintain its shape. A pressure dressing is left in place for 24 to 46 hours. The patient is permitted out of bed on the day of surgery. Hemorrhage and infection are the most commonly seen complications.

Postoperative nursing care includes teaching, psychologic support, and observation for potential complications. The patient may be instructed to apply warm compresses and instill antibiotic ointment or drops postoperatively. If irrigation of the eye socket is ordered, have the patient lean over a sink or basin if possible, or position on the affected side with a clean emesis basin to hold the irrigant as it flows out of the socket. Gently hold the lids open and irrigate the socket using a bulb syringe and clean warm water.

Within 1 week, a temporary prosthesis called a conformer is fitted into the empty socket. The permanent prosthesis is individually designed to closely resemble the patient's other eye. The prosthesis can be fitted 1 to 2 months after surgery. Often it is difficult to discern which eye is functional and which is the prosthesis.

Ear Disorders

For an individual to hear, sound waves must enter the external auditory meatus and travel through the ear canal to vibrate the tympanic membrane and bony structures of the middle ear, which in turn activate the receptors of the cochlea. Trauma or disease involving any portion of this pathway can affect hearing or cause symptoms such as tinnitus, the perception of sound such as ringing, buzzing, or roaring in the ears.

Disorders of the external ear, including the auricle, auditory meatus, and ear canal, can affect the conduction of sound waves and hearing. Obstruction of the external auditory canal or damage to the tympanic membrane, which separates the outer from the middle ear, may lead to conductive hearing loss. Infection or inflammation, trauma, and obstruction of the ear canal with cerumen (wax) or a foreign body are the most common conditions affecting the external ear.

Disorders of the middle ear may be either acute or chronic. Unless these disorders are treated promptly and effectively, damage and scarring of middle ear structures can result in a permanent conductive hearing loss. Infectious or inflammatory disorders such as otitis media and mastoiditis are the most common conditions affecting the middle ear. Otosclerosis, a genetic condition, may also affect the structures of the middle ear.

THE PATIENT WITH OTITIS EXTERNA

Otitis externa, inflammation of the ear canal, accounted for an estimated 2.4 million healthcare visits and nearly $500 million in treatment costs in 2007 (Centers for Disease Control and Prevention, 2011a). Commonly known as *swimmer's ear*, it is most prevalent in people who spend significant time in the water and those who live in warm, humid climates. Competitive athletes, including swimmers, divers, and surfers, are particularly prone to otitis externa. Wearing a hearing aid or ear plugs, which hold moisture in the ear canal, is an additional risk factor. Although *Pseudomonas aeruginosa* or other bacterial infection is the most common cause, external otitis may also be due to fungal infection, mechanical trauma (such as cleaning the ear with a toothpick), or a local hypersensitivity reaction.

Pathophysiology and Manifestations

Disruption of the normal environment within the external auditory canal typically precedes the inflammatory process. Retained moisture, cleaning, or drying of the ear canal removes the protective layer of cerumen, an acidic, water-repellent substance with antimicrobial properties. Its removal leaves the skin of the ear canal vulnerable to invasion and infection. For surfers, the presence of *exostoses*, bony growths in the ear canals resulting from prolonged exposure to cold, predisposes to impaction and retained moisture within the canal.

The patient with otitis externa often complains of a feeling of fullness in the ear. Ear pain typically is present and may be severe. The pain of otitis externa can be differentiated from that associated with otitis media by manipulation of the auricle. In external otitis, this maneuver increases the pain, whereas the patient with otitis media experiences no change in pain perception. Odorless watery or purulent drainage may be present. The ear canal appears inflamed and edematous on examination.

●○● INTERPROFESSIONAL CARE

Management of the patient with an external ear disorder focuses on restoring the normal balance of the external ear canal and teaching the patient how to prevent future problems.

For otitis externa, the following steps are recommended in treatment:

- Thorough cleansing of the ear canal, particularly if drainage or debris is present
- Treatment of the infection with local antibiotics; if cellulitis is present, systemic antibiotics may be necessary
- Medication to relieve the pain and itching
- Teaching to prevent future episodes of swimmer's ear.

A topical antibiotic is often prescribed for the treatment of otitis externa. A topical corticosteroid may be ordered in combination with the antibiotic to provide immediate relief of the pain, swelling, and itching. Polymyxin B-neomycin-hydrocortisone (Cortisporin Otic) is a typical combination preparation used to treat external otitis; these antibiotics are effective against *Pseudomonas*. It is important to identify known sensitivity to any of the drugs in this preparation prior to initiating therapy. Patients who are sensitive to neomycin may develop dermatitis, in which case the drug must be stopped. Other preparations such as 1% tolnaftate solution (Tinactin) may be prescribed for a fungal infection of the ear canal.

●○● NURSING CARE

External otitis can cause severe pain and discomfort. Although the disorder is rarely serious enough to require hospitalization, the nurse teaches the patient about the disorder, comfort measures, and prevention of future episodes.

Diagnoses, Outcomes, and Interventions

Impaired Tissue Integrity

External otitis may result from attempts to clean the ear canal with a toothpick, cotton-tipped applicator, or other implement that damages the skin, allowing an infectious organism to invade the tissue. Even if the canal is not damaged by attempts to clean it, the cleaning process often interrupts normal mechanisms, causing cerumen and debris to collect in the canal. This collected debris, in turn, tends to trap water within the canal, causing maceration of the skin.

Expected Outcome: Integrity of tissues in the patient's external ear canal will be restored.

- Inform that ear canals rarely need cleansing beyond washing of the external meatus with soap and water. Teach patients of all ages not to clean ear canals with any implement. *"Cleaning" increases the risk of tissue damage and impairs the normal mechanism that clears the canal of accumulated cerumen and debris.*
- Teach patient (and, if necessary, a family member) how to instill prescribed eardrops:
  - Wash the hands.
  - Warm the medication briefly by holding the container in the hand or placing it in a pocket for approximately 5 minutes before instilling the drops. *Warming the medication promotes comfort.*
  - Lie on the unaffected side; if sitting, tilt the head toward the unaffected side. *This position allows gravity to assist in moving the medication to the inner portion of the ear canal.*
  - Partially fill the ear dropper with medication.
  - Using the nondominant hand, straighten the ear canal by pulling the pinna of the ear up and back. *Straightening helps the medication travel along the length of the canal.*
  - Administer the prescribed number of drops into the ear canal. *It is important that the full amount of prescribed medication be administered to penetrate the length of the canal and achieve full effectiveness.*
  - Remain in the side-lying position for approximately 5 minutes after the instillation of drops. *This position allows the medication to penetrate into deeper portions of the canal and prevents it from running out when the head is moved upright.*
  - Loosely place a small piece of cotton in the auditory meatus for 15 to 20 minutes. *The cotton helps keep the medication in the canal.*

BOX 46–2 Teaching to Prevent Otitis Externa

- Keep the ear canal as dry as possible while in the water:
  a. Use silicone earplugs, which can keep water out of the ear without reducing hearing significantly.
  b. Wear a tight-fitting swim cap or wet suit hood, especially in cold ocean water. These protect the ear from the cold and from sand and other water debris.
- Dry the ear canal immediately after swimming or showering. Allow water to drain by tilting the head and pulling the earlobe in various directions to straighten the ear canal. Dry the outer ear with a towel, then use a hair dryer on the lowest setting several inches from the ear to dry the canal.
- Do not insert cotton swabs or other objects into the ear canal. This removes the protective layer of cerumen and may damage the canal, increasing the risk of infection. In addition, if debris such as sand is present, the swab may actually push debris further into the canal, forming an impacted mass.
- Consult your primary care provider about using a drying agent in the ear canal after swimming. Commercial alcohol-based eardrops or a 1:1 mixture of white vinegar and rubbing alcohol is effective in drying the canal and restoring its normal acidic environment.
- If it is necessary to remove impacted debris from the ear canal, irrigate the ear with warm tap water. A bulb syringe available over the counter or a 20-mL syringe attached to a short Teflon intravenous catheter (with the needle removed) is effective. With the head tilted toward the affected side, direct a stream of warm water toward the upper wall of the ear canal, allowing the water to run out into a bowl or sink. Repeated instillations may be necessary to break up and flush out impacted wax and debris.
- Follow manufacturer's directions for cleaning and disinfecting pools and hot tubs. Use pool test strips to check pools and hot tubs for adequate disinfectant and pH levels before entering.

- Teach to avoid getting water in the affected ear until it is fully healed. Cotton balls may be used while showering to prevent water from entering the ear canal. The patient should refrain from water sports and activities for 7 to 10 days or until approved by the primary care provider. *Retained moisture in the ear canal can further impair skin integrity, increasing inflammation.*

Continuity of Care

The patient is ultimately responsible for carrying out the prescribed treatment regimen in external otitis and for implementing measures to prevent future episodes. Teaching is vital. Provide verbal and written instructions on use of the prescribed medications. Teach the patient care measures to prevent recurrent episodes especially important in swimmers, divers, and surfers (see Box 46–2).

Cellulitis of the surrounding tissue is a possible complication of external otitis. Instruct the patient to report to the primary care provider any increase in pain, swelling, or redness of surrounding tissues; fever; or other manifestations of infection such as malaise or increased fatigue.

THE PATIENT WITH IMPACTED CERUMEN OR A FOREIGN BODY

The external auditory canal can be obstructed by cerumen or foreign bodies. The curved shape and narrow lumen of the canal make it particularly vulnerable to obstruction.

Pathophysiology and Manifestations

As cerumen dries, it moves down and out of the ear canal. In some individuals it tends to accumulate, narrowing the canal. Aging is a risk factor for impaction because less cerumen is produced and it is harder and drier. The accumulation of cerumen is often aggravated by attempting to remove it using cotton-tipped swabs or hairpins, which pack it more deeply into the ear canal.

A variety of objects become foreign bodies in the ear canal. In adults, implements used to clean the ear canal may break and become lodged. Insects also may enter the ear canal and be unable to exit.

When the ear canal becomes occluded with either cerumen or a foreign body, the patient experiences a conductive hearing loss in the affected ear. Manifestations include a sensation of fullness, along with tinnitus and coughing due to stimulation of the vagal nerve. The foreign body or impacted cerumen may be visualized on otoscopy. Impacted cerumen appears as a yellow, brown, or black mass in the canal.

●○● INTERPROFESSIONAL CARE

Treatment focuses on clearing the canal. If there is no evidence of tympanic membrane perforation, irrigation of the canal is often the initial therapy.

Impacted wax, objects, or insects may require physical removal using an ear curet, forceps, or right-angle hook inserted via an otoscope and ear speculum. Mineral oil or topical lidocaine drops are used to immobilize or kill insects prior to their removal from the ear. When an organic foreign body such as a bean or an insect is suspected, water should not be instilled into the ear canal, because it may cause the object to swell, making its removal more difficult. Smooth, round objects present the biggest challenge to remove from the ear canal. Suction applied using a piece of soft intravenous tubing may be effective.

●○● NURSING CARE

Nurses are often involved in identifying and relieving obstructions of the ear canal, especially in outpatient and community settings. Any patient with evidence of a new conductive hearing loss or complaints of discomfort and fullness in one ear should be evaluated for possible obstruction. Inability to visualize the tympanic membrane or observation of a dark, shiny mass obstructing the canal may indicate a need for an irrigation or other procedure to clear the canal. It is important to determine that the tympanic membrane is intact before irrigating; assessment by a physician or advanced practitioner may be necessary if a ruptured membrane is suspected.

Because obstruction of the ear canal with cerumen or a foreign body is generally preventable, teaching is a key component of nursing care. Patients need to know appropriate care measures for the external ear. Although the ear canal rarely needs cleaning, the patient prone to cerumen impaction needs teaching about the use of mineral oil or commercial products to soften wax and of irrigation to remove it. All patients should understand the importance of not inserting anything smaller than a finger wrapped with a washcloth into the ear canal to avoid trauma to the canal or eardrum. Stress the risk of impacting cerumen against the tympanic membrane when using cotton-tipped swabs to clean the ear canal. Additionally, the swab may break and lodge in the canal. If eardrops have been prescribed, teach the patient and a family member how to instill them.

THE PATIENT WITH OTITIS MEDIA

Otitis media, inflammation or infection of the middle ear, primarily affects infants and young children but may also occur in adults. The tympanic membrane, which separates the middle ear from the external auditory canal, protects the middle ear from the external environment. The auditory (eustachian) tube connects the middle ear with the nasopharynx to help equalize the pressure in the middle ear with the atmospheric pressure. Unfortunately, this connecting tube also provides a route by which infectious organisms enter the middle ear from the nose and throat, causing otitis media, the most common disease of the middle ear.

Pathophysiology

There are two primary forms of otitis media: (1) serous and (2) acute. Both forms are associated with upper respiratory infection and auditory tube dysfunction. The auditory tube is narrow and flat, normally opening only during yawning and swallowing. Allergies or upper respiratory tract infections can cause edema of the tube lining, impairing its function. Air within the middle ear is trapped and gradually absorbed, creating negative pressure in this space.

SEROUS OTITIS MEDIA

Serous otitis media (also called *otitis media with effusion*) occurs when the auditory tube is obstructed for a prolonged time, impairing air pressure equalization in the middle ear. Air within the middle ear space is gradually absorbed; the tube obstruction prevents more air from entering the middle ear. The resulting negative pressure in the middle ear causes sterile serous fluid to move from the capillaries into the space, forming a sterile effusion of the middle ear.

Upper respiratory infection or allergies such as hay fever predispose the patient to serous otitis media. In addition, patients with narrowed or edematous auditory tubes may also be subject to barotrauma. In these patients, the middle ear cannot adapt to rapid changes in barometric pressure such as those that occur during air travel or underwater diving. Barotrauma tends to occur during descent in an airplane because negative pressure within the middle ear causes the auditory tube to collapse and lock. Underwater diving places even greater stress on the auditory tube and middle ear.

MANIFESTATIONS Typical manifestations of serous otitis media include decreased hearing in the affected ear and complaints of "snapping" or "popping" in the ear. On examination, the tympanic membrane demonstrates decreased mobility and may appear retracted or bulging. Fluid or air bubbles are often visible behind the drum (Figure 46–17 ■). Pressure differences such as those occurring with flying or underwater diving may cause acute pain, hemorrhage into the middle ear, rupture of the tympanic membrane, or even rupture of the round window with sensory hearing loss and severe **vertigo** (a sensation of whirling or rotation). *Hemotympanum*, bleeding into or behind the tympanic membrane, may be observed on otoscopic examination.

ACUTE OTITIS MEDIA

The auditory tube also provides a route for the entry of pathogens into the normally sterile middle ear, resulting in acute otitis media. Acute otitis media typically follows an upper respiratory infection. Edema of the auditory tube impairs drainage of the middle ear, causing mucus and serous fluid to accumulate. This fluid is an excellent

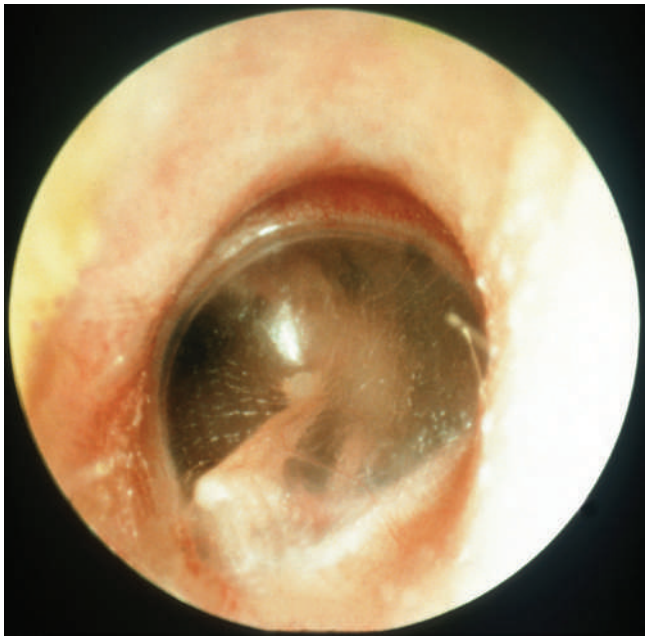

Figure 46–17 ■ The appearance of the tympanic membrane in serous otitis media.
Source: Kevin Kavanagh, MD.

environment for the growth of bacteria, which may enter from the oronasopharynx via the auditory tube. Although a viral upper respiratory infection may predispose the patient to a middle ear infection, the bacteria *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Streptococcus pyogenes* account for most cases of otitis media in adults. Invasion and colonization of the middle ear by bacteria and the resultant migration of white blood cells cause pus formation. Accumulated pus can increase middle ear pressure sufficiently to rupture the tympanic membrane. The bacterial infection may also migrate internally, causing mastoiditis, brain abscess, or bacterial meningitis. A more common complication of otitis media is a persistent conductive hearing loss, which typically resolves when the middle ear effusion clears.

MANIFESTATIONS The patient with acute otitis media experiences mild to severe pain in the affected ear. The patient's temperature is often elevated. Diminished hearing, dizziness, vertigo, and tinnitus are common associated complaints. Pus within the mastoid air cells often causes mastoid tenderness in acute otitis media. On otoscopic examination, the tympanic membrane appears red and inflamed or dull and bulging (Figure 46–18 ■). Decreased movement of the membrane is demonstrated by tympanometry or air insufflation. Spontaneous rupture of the tympanic membrane releases a purulent discharge.

Manifestations such as persistent fever, nausea and vomiting, irritability, lethargy, or persistent headache may indicate a complication such as meningitis, and should be reported immediately to the care provider (Erasmus, 2012).

●○● INTERPROFESSIONAL CARE

The diagnosis of otitis media is usually based on the history and physical examination. The tympanic membrane can be visualized and its mobility evaluated using a pneumatic otoscope that allows a

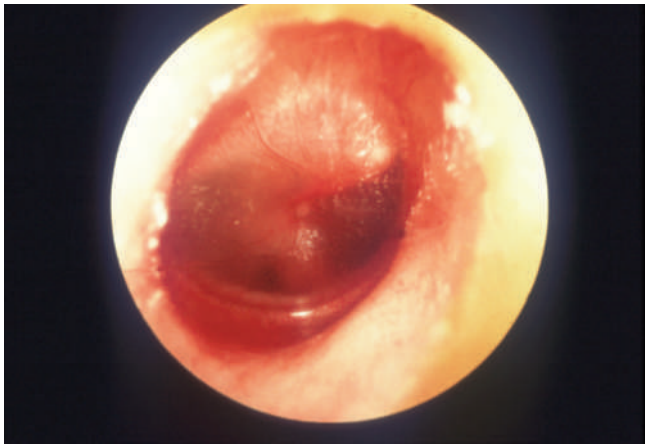

Figure 46–18 ■ A red, bulging tympanic membrane indicative of acute otitis media.
Source: Janet Hayes/Medical Images, Inc.

puff of air to be instilled into the ear canal. Generally, the tympanic membrane moves slightly when air is instilled or the patient performs the Valsalva maneuver. Less movement is seen in patients with auditory tube dysfunction and acute otitis media with effusion.

DIAGNOSIS

- *Impedance audiometry*, also known as tympanometry, is an accurate diagnostic test for otitis media with effusion. A continuous tone is delivered to the tympanic membrane by an audiometer with a sealed probe tip. Compliance of the tympanic membrane and middle ear is measured by recording energy reflected from the membrane surface. With middle ear effusion, compliance is reduced.
- A *complete blood count (CBC)* may be done to assess for an elevated WBC count and increased numbers of immature cells indicative of acute bacterial infection.
- If the tympanic membrane has ruptured or a tympanocentesis or myringotomy is performed, drainage is cultured to determine the infecting organism.

MEDICATIONS

When auditory tube dysfunction and serous otitis media do not spontaneously resolve within 2 to 4 weeks or if they lead to hearing loss, a short course of an anti-inflammatory drug (e.g., oral prednisone for 7 days) may be prescribed to reduce mucosal edema of the tube and improve its patency. Although a decongestant or antihistamine may be used, there is little evidence of their effectiveness in treating serous otitis media.

The patient with auditory tube dysfunction may be taught to autoinflate the middle ear by performing the Valsalva maneuver or by forcefully exhaling against closed nostrils. Additionally, the patient is advised to avoid air travel and underwater diving.

Acute otitis media is usually treated with antibiotic therapy, especially amoxicillin, cefdinir (Omnicef), cefuroxime, or azithromycin for 5 to 10 days. This course of treatment is long enough to ensure eradication of the infective organism, yet short enough to reduce the incidence of bacterial resistance. Analgesics, antipyretics, antihistamines, and local application of heat may provide symptomatic relief.

SURGERY

Myringotomy (an incision of the tympanic membrane) or tympanocentesis may be performed to relieve excess pressure in the middle ear and prevent spontaneous rupture of the eardrum. To perform a tympanocentesis, the physician inserts a 20-gauge spinal needle through the inferior portion of the tympanic membrane, allowing aspiration of fluid and pus from the middle ear to relieve pressure and, if necessary, obtain a specimen for culture. Myringotomy may be performed to relieve severe pain or when complications of acute otitis media, such as mastoiditis, are present. As soon as the pressure is released, pain subsides and hearing improves.

Patients who do not respond to antibiotic therapy may require myringotomy with insertion of ventilation (tympanostomy) tubes. Small tubes are inserted into the inferior portion of the tympanic membrane, providing for ventilation and drainage of the middle ear during healing. The tube is eventually extruded from the ear, and the tympanic membrane heals. While the tube is in place, it is important to avoid getting any water in the ear canal because it may then enter the middle ear space.

●○● NURSING CARE

Patients with otitis media are commonly treated in outpatient and community settings. The nursing role is primarily one of support and education.

Health Promotion

Health promotion for otitis media focuses on educating patients about the importance of seeking medical care for prolonged, severe ear pain with or without drainage combined with an upper respiratory tract infection. Untreated or repeated attacks of otitis media can progress to a chronic form of otitis media, acute mastoiditis, or eardrum perforation.

Assessment

Collect assessment data through a health history and physical examination:

- *Health history:* recent upper respiratory infection; presence, intensity, and nature of pain in affected ear; sense of fullness or pressure in the ear; change in hearing; snapping or popping sensation in the affected ear; presence of vertigo
- *Physical assessment:* temperature; hearing test; inspect tympanic membrane.

Priorities of Care

Patient teaching is a nursing care priority for the patient with otitis media. Just as it is important for the patient to understand the importance of seeking care for acute symptoms, it also is important to understand that antibiotic therapy is not always indicated and the risks of inappropriate antibiotic use.

Diagnosis, Outcomes, and Interventions

Pain can be a significant problem for patients with otitis media, as can the risk of damage to delicate tissues of the middle ear by the infectious and inflammatory processes.

Acute Pain

Tissue edema, effusion of the middle ear, and the inflammatory response can affect the pain-sensitive tissues of the middle ear in otitis

media, causing acute discomfort. This discomfort is increased by pressure changes, such as those that occur during air travel or underwater diving.

Expected Outcome: Patient will report an understanding of measures to relieve pain and promote comfort.

- Assess pain for severity, quality, and location. *A thorough assessment is important to determine the source of the pain. The pain of otitis media, unlike that of external otitis, is not aggravated by movement of the external ear.*
- Encourage the use of mild analgesics such as aspirin or acetaminophen every 4 hours as needed to relieve pain and fever. *These nonprescription medications are effective in reducing the perception of pain. Aspirin also has anti-inflammatory properties that may help relieve the inflammation of the ear.*
- Advise to apply heat to the affected side unless contraindicated. *Heat dilates blood vessels, promoting the reabsorption of fluid and reducing swelling.*
- Instruct to avoid air travel, rapid changes in elevation, or diving. *A rapid change in barometric pressure can increase the patient's pain significantly.*
- Instruct to report promptly an abrupt relief of pain to the primary care provider. *Pain that subsides abruptly may indicate spontaneous perforation of the tympanic membrane with relief of pressure within the middle ear.*

Continuity of Care

The patient who has otitis media needs teaching about the disorder, its causes and prevention, and any specific treatment recommended or prescribed. Discuss the following topics with the patient and family:

- Antibiotic therapy, its indications, use, and potential side effects
- Importance of completing all ordered doses
- Follow-up examinations in 2 to 4 weeks
- Avoidance of swimming, diving, or submerging the head while bathing if ventilation tubes are in place.

If surgical intervention is necessary, teach the patient and family members about the surgery and postoperative care. Provide instruction about any special postoperative precautions, such as avoiding water in the ear canals or avoiding sudden changes in air pressure.

THE PATIENT WITH ACUTE MASTOIDITIS

The mastoid process is a portion of the temporal bone of the skull lying adjacent to the middle ear. It is full of air cavities called mastoid air cells or mastoid sinuses. The infection of acute otitis media generally extends into the mastoid air cells; effective treatment of acute otitis media eliminates the infection from the mastoid cells as well. When treatment is ineffective, pus remains in the mastoid air cells, and acute *mastoiditis*, bacterial infection of the mastoid process, may develop.

The incidence of acute mastoiditis is low in the United States and in other countries in which the use of antibiotics to treat acute otitis media is similar to that of the United States. Its incidence is higher in countries where antibiotics are less likely to be prescribed for acute otitis media (Rubin et al., 2012).

Pathophysiology and Complications

In acute mastoiditis, pressure created by pus in mastoid air cells destroys the bony septa between the cells, forming large spaces. Portions of the mastoid process are eroded. With chronic infection, an abscess may form, or bony sclerosis of the mastoid may result. Acute mastoiditis increases the risk of meningitis because only a very thin bony plate separates mastoid air cells from the brain. Fortunately, this complication is rare since the advent of effective antibiotic therapy for treating otitis media.

Manifestations

Manifestations of acute mastoiditis usually develop approximately 2 to 3 weeks after an episode of acute otitis media and include recurrent earache and hearing loss on the affected side. The pain is persistent and throbbing; tenderness is present over the mastoid process (behind the ear). It may also be red and inflamed. Swelling of the process can cause the auricle of the ear to protrude more than normal. Fever may be accompanied by tinnitus and headache. Profuse drainage from the affected ear may be noted.

●○● INTERPROFESSIONAL CARE

In addition to the manifestations of acute mastoiditis, loss of septa between mastoid air cells may be noted on radiologic examination. Acute mastoiditis is treated aggressively with intravenous antibiotic therapy tailored to the infecting organism. Antibiotics are continued for at least 14 days. Infections that do not respond to medical therapy or that pose a high risk of spreading to the brain may necessitate *mastoidectomy*, surgical removal of the infected mastoid air cells, bone, and pus, and inspection of the underlying dura for possible abscess. The extent of tissue destruction determines the extent of surgery required. In a modified mastoidectomy, as much tissue is preserved as possible to avoid disruption of hearing. A radical mastoidectomy involves removal of middle ear structures including the incus and malleus as well as the diseased portions of the mastoid process. Unless reconstruction is performed at the time of surgery, this surgery results in conductive hearing loss. **Tympanoplasty**, surgical reconstruction of the middle ear, can restore or preserve hearing.

●○● NURSING CARE

Prevention is the primary focus of interprofessional care related to mastoiditis. Adequate, effective antibiotic treatment of acute otitis media prevents mastoiditis in nearly all instances.

Following surgical intervention, carefully assess the wound and drainage for evidence of infection or other complications. The patient's hearing may be temporarily or permanently affected, depending on the extent of the surgery. If the patient has impaired hearing in the unaffected ear as well, develop a means of communication with the patient prior to surgery. If the hearing is preserved in the unaffected ear, position the patient with that ear toward the door. Speak slowly and clearly; do not shout or speak unusually loudly. Be sure that family and staff know about the patient's hearing loss and use appropriate communication techniques. Assist the patient with ambulation initially, because dizziness and vertigo are not unusual following surgery. Nursing care of the patient having ear surgery is discussed in the accompanying box.

Continuity of Care

When teaching about acute mastoiditis, stress the importance of complying with the prescribed antibiotic therapy and recommendations for follow-up. Instruct the patient and family to report any adverse reactions to the primary care provider so that therapy can be adjusted. Teach the patient and family how to change the surgical dressing using aseptic technique. Provide referrals to appropriate community agencies for the patient with a new hearing loss resulting from mastoiditis or its treatment.

THE PATIENT WITH CHRONIC OTITIS MEDIA

Chronic otitis media involves permanent perforation of the tympanic membrane, with or without recurrent pus formation. Changes in the mucosa and bony structures (ossicles) of the middle ear often accompany chronic otitis media. It usually is the result of recurrent acute otitis media and auditory tube dysfunction, but may also result from trauma or other diseases.

Marginal perforations, which usually occur in the posterior-superior portion of the tympanic membrane, are associated with more complications than central perforations. With marginal perforations, squamous epithelium may migrate from the ear canal into the middle ear, where it begins to desquamate and accumulate, forming a *cholesteatoma* (a cyst or mass filled with epithelial cell debris). Its incidence is highest in children and young adults. The desquamating epithelium continues to accumulate and remains infected, producing collagenases (enzymes) that destroy adjacent bone. The inflammatory process impairs the blood supply to the stapes, causing its destruction and conductive hearing loss. Cholesteatomas are benign and slow-growing tumors, which can enlarge to fill the entire middle ear. Untreated, the cholesteatoma can progressively destroy the ossicles and erode into the inner ear, causing profound hearing loss.

Systemic antibiotics are prescribed for exacerbations of purulent otitis media. Tympanic membrane perforation is repaired with a tympanoplasty to restore sound conduction and the integrity of the middle ear. A cholesteatoma may require delicate surgery for its removal. If at all possible, radical mastoidectomy with removal of the tympanic membrane, ossicles, and tumor is avoided.

As with other complications of acute otitis media, a priority of nursing care is prevention of chronic otitis media and cholesteatoma. Patients with chronic otitis media need to understand various treatment options and their risks and benefits, as well as the long-term risk of not treating a perforated tympanic membrane. They are also taught how to instill eardrops, to clean the external auditory meatus, and to not irrigate the ear when the tympanic membrane is perforated or if they think it might be.

If surgical treatment of chronic otitis media will affect the patient's hearing, include this information in preoperative teaching. Teach the patient and family how to use alternative means of communication if this will be necessary postoperatively. When an assistive device is ordered, teach the patient and a family member about its use.

NURSING CARE OF THE PATIENT

Having Ear Surgery

PREOPERATIVE CARE

- Provide preoperative care as ordered or per standard protocol.
- Assess hearing or verify documentation of preoperative hearing assessment. *These data are important in evaluating the results of the surgical procedure.*
- Establish a means of communication to be used after surgery. *Hearing may be impaired after surgery.*
- Explain that blowing of the nose, coughing, and sneezing are restricted postoperatively to prevent pressure changes in the middle ear and potential disruption of the surgical site. Keeping the mouth open during a cough or sneeze minimizes pressure changes in the middle ear. *Providing teaching and the opportunity to practice before surgery promotes cooperation in the postoperative period.*

POSTOPERATIVE CARE
