Brief Contents

UNIT 1 Dimensions of Medical-Surgical Nursing 1

Chapter 1 Medical-Surgical Nursing in the 21st Century 2
Chapter 2 Informatics and Evidence-Based Practice in Medical-Surgical Nursing 17
Chapter 3 Health and Illness Care of Adults 27

UNIT 2 Alterations in Patterns of Health 48

Chapter 4 Nursing Care of Patients Having Surgery 49
Chapter 5 Nursing Care of Patients Experiencing Loss, Grief, and Death 79
Chapter 6 Nursing Care of Patients with Problems of Substance Abuse 96
Chapter 7 Nursing Care of Patients Experiencing Disasters 117

UNIT 3 Pathophysiology and Patterns of Health 135

Chapter 8 Genetic Implications of Adult Health Nursing 136
Chapter 9 Nursing Care of Patients in Pain 151
Chapter 10 Nursing Care of Patients with Altered Fluid, Electrolyte, and Acid–Base Balance 177
Chapter 11 Nursing Care of Patients Experiencing Trauma and Shock 229
Chapter 12 Nursing Care of Patients with Infections 260
Chapter 13 Nursing Care of Patients with Altered Immunity 297
Chapter 14 Nursing Care of Patients with Cancer 333

UNIT 4 Responses to Altered Integumentary Structure and Function 376

Chapter 15 Assessing the Integumentary System 377
Chapter 16 Nursing Care of Patients with Integumentary Disorders 390
Chapter 17 Nursing Care of Patients with Burns 432

UNIT 5 Responses to Altered Endocrine Function 460

Chapter 18 Assessing the Endocrine System 461
Chapter 19 Nursing Care of Patients with Endocrine Disorders 475
Chapter 20 Nursing Care of Patients with Diabetes Mellitus 501

UNIT 6 Responses to Altered Gastrointestinal Function 537

Chapter 21 Assessing the Gastrointestinal System 538
Chapter 22 Nursing Care of Patients with Nutritional Disorders 563
Chapter 23 Nursing Care of Patients with Upper Gastrointestinal Disorders 588
Chapter 24 Nursing Care of Patients with Bowel Disorders 625
Chapter 25 Nursing Care of Patients with Gallbladder, Liver, and Pancreatic Disorders 692

UNIT 7 Responses to Altered Urinary Elimination 731

Chapter 26 Assessing the Renal System 732
Chapter 27 Nursing Care of Patients with Urinary Tract Disorders 746
Chapter 28 Nursing Care of Patients with Kidney Disorders 779

UNIT 8 Responses to Altered Cardiovascular Function 824

Chapter 29 Assessing the Cardiovascular and Lymphatic Systems 825
Chapter 30 Nursing Care of Patients with Coronary Heart Disease 861
Chapter 31 Nursing Care of Patients with Cardiac Disorders 919
Chapter 32 Nursing Care of Patients with Vascular and Lymphatic Disorders 966
Chapter 33 Nursing Care of Patients with Hematologic Disorders 1014

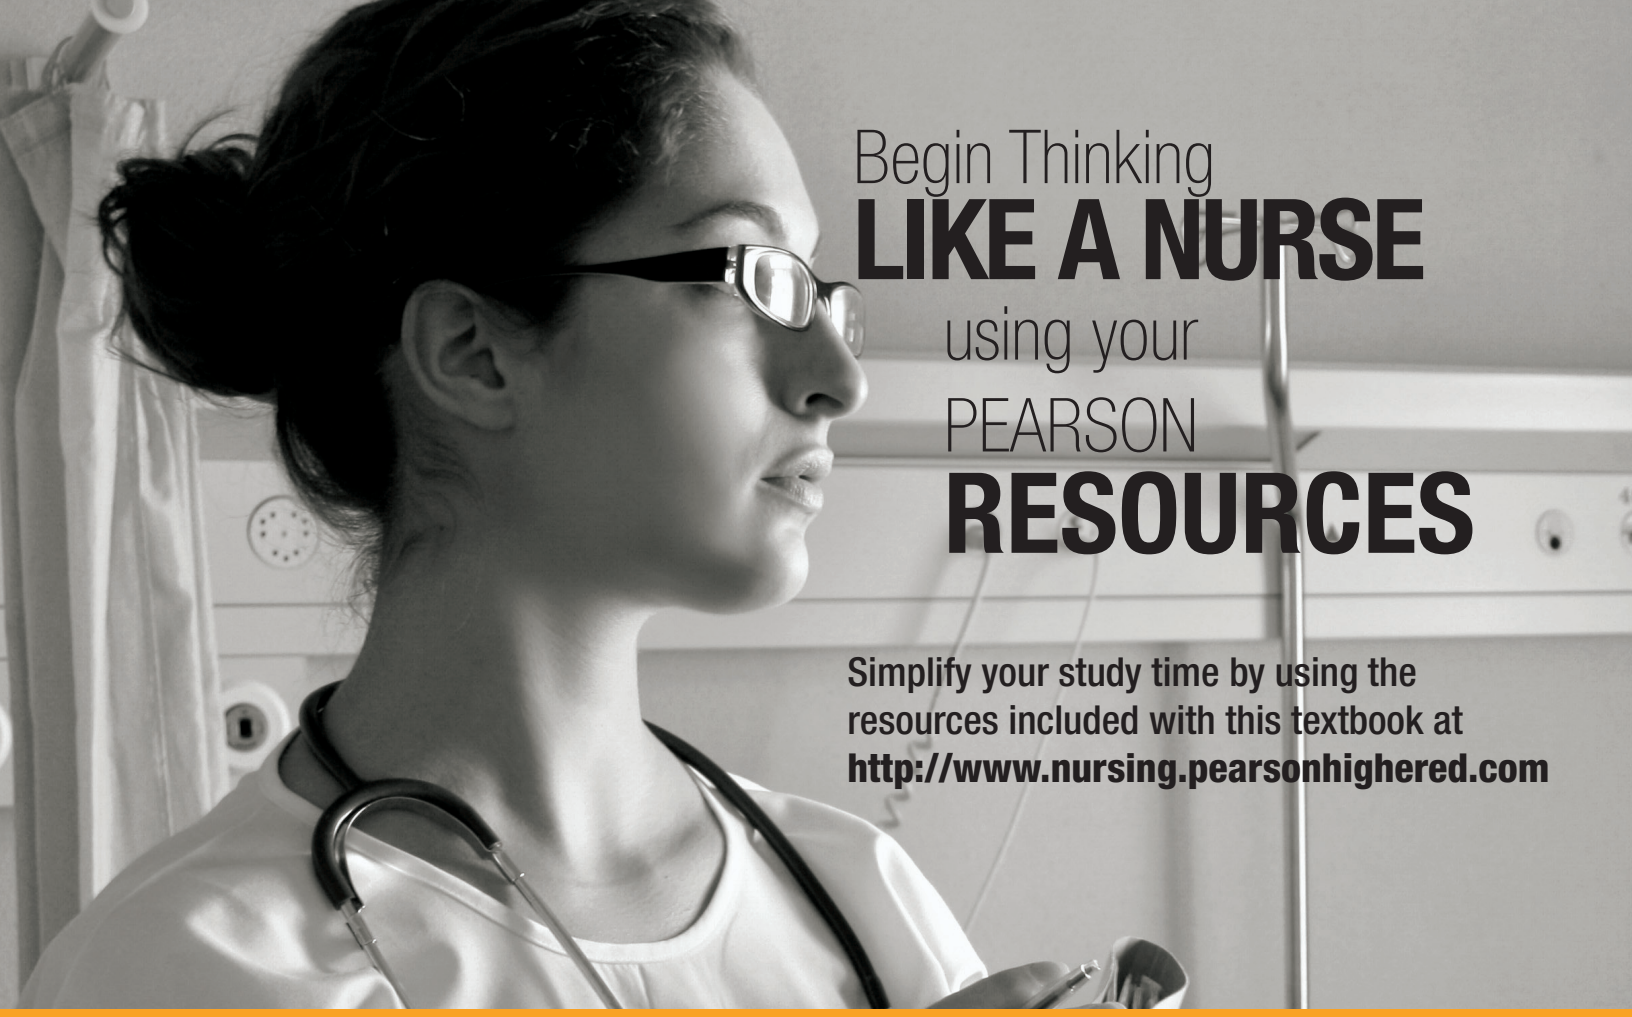
UNIT 9 Responses to Altered Respiratory Function 1064

Chapter 34 Assessing the Respiratory System 1065
Chapter 35 Nursing Care of Patients with Upper Respiratory Disorders 1080
Chapter 36 Nursing Care of Patients with Ventilation Disorders 1114
Chapter 37 Nursing Care of Patients with Gas Exchange Disorders 1165

UNIT 10 Responses to Altered Musculoskeletal Function 1218

Chapter 38 Assessing the Musculoskeletal System 1219
Chapter 39 Nursing Care of Patients with Musculoskeletal Trauma 1234
Chapter 40 Nursing Care of Patients with Musculoskeletal Disorders 1266

UNIT 11 Responses to Altered Neurologic Function 1330



Chapter 41 Assessing the Nervous System 1331
Chapter 42 Nursing Care of Patients with Intracranial Disorders 1352
Chapter 43 Nursing Care of Patients with Spinal Cord Disorders and CNS Infections 1399
Chapter 44 Nursing Care of Patients with Neurologic Disorders 1428

UNIT 12 Responses to Altered Sensory Function 1472

Chapter 45 Assessing the Eye and Ear 1473
Chapter 46 Nursing Care of Patients with Eye and Ear Disorders 1491

UNIT 13 Responses to Altered Reproductive Function 1536

Chapter 47 Assessing the Male and Female Reproductive Systems 1537
Chapter 48 Nursing Care of Men with Reproductive System and Breast Disorders 1555
Chapter 49 Nursing Care of Women with Reproductive System and Breast Disorders 1581
Chapter 50 Nursing Care of Patients with Sexually Transmitted Infections 1621

About the Authors

Priscilla LeMone Koeplin, RN, DSN, FAAN

Associate Professor Emeritus, Sinclair School of Nursing, University of Missouri. Priscilla LeMone-Koeplin spent most of her career as a nurse educator, teaching medical-surgical nursing and pathophysiology at all levels from diploma to doctoral students. She has a diploma in nursing from Deaconess College of Nursing (St. Louis, Missouri), baccalaureate and master's degrees from Southeast Missouri State University, and a doctorate in nursing from the University of Alabama–Birmingham. Dr. LeMone-Koeplin has received numerous awards for scholarship and teaching, including the Kemper Fellowship for Teaching Excellence from the University of Missouri, the Unique Contribution Award from the North American Nursing Diagnosis Association, and being selected as a Fellow in the American Academy of Nursing. Dr. LeMone-Koeplin currently lives in Ohio. She enjoys traveling, gardening, knitting, and reading fiction.

I dedicate this book to all the students who will become the caregivers.

How far you go in life depends on your being tender with the young, compassionate with the aged, sympathetic with the striving and tolerant of the weak and the strong, because someday in your life you will have been all of these. (George Washington Carver)

Priscilla LeMone-Koeplin

Karen M. Burke, RN, MS

Karen Burke began her nursing career working in cardiac and intensive care, moving from there into nursing education, and then nursing education program management with the Board of Nursing. She currently serves as a consultant for nursing education programs.

Ms. Burke earned her diploma in nursing from Emanuel Hospital School of Nursing in Portland, Oregon, later completing baccalaureate studies at Oregon Health & Science University, and a master's degree in nursing at the University of Portland. She has been actively involved in nursing education and clinical nursing education reform. Ms. Burke is coauthor of another text, *Medical-Surgical Nursing Care* (4th edition) with Elaine Mohn-Brown and Linda Eby. Ms. Burke strongly values the nursing profession and the importance of providing a strong education in the art and science of nursing for students preparing to enter the profession, no matter which educational path is being pursued.

Reflecting her passion for nursing and education, Ms. Burke currently serves on boards of directors for Supporters of Oregon Consortium for Nursing Education (OCNE), Clatsop Community College, and Clatsop Care Center Health District. She enjoys gardening and is a member of the Clatsop County Master Gardener Association. Her other interests include family, quilting, and fishing.

I dedicate this book to the leaders and visionaries who provide direction for the future of nursing—and to all the nursing students who will carry our profession into that future and beyond.

Karen Burke

Gerene Bauldoff, RN, PhD, FAAN

Gerene Bauldoff is a Professor of Clinical Nursing at The Ohio State University College of Nursing in Columbus, Ohio. She has been a nurse educator for 14 years, teaching medical-surgical nursing, translational science, and evidence-based practice courses at the baccalaureate, master's, and doctoral levels. Prior to her nursing educator role, her clinical background included home health nurse, lung transplant coordinator, and pulmonary rehabilitation coordinator. Dr. Bauldoff has a diploma from the Western Pennsylvania Hospital School of Nursing, Pittsburgh, Pennsylvania, and a BSN from LaRoche College in Pittsburgh. Her graduate education is from the University of Pittsburgh, with a MSN in medical-surgical nursing (cardiopulmonary clinical nurse specialist) and PhD in nursing in 2001, training under Leslie Hoffman, PhD, RN, FAAN.

Dr. Bauldoff is an active member of multiple professional organizations including the American Academy of Nursing (AAN), Sigma Theta Tau International Honor Society of Nursing, the American Association of Cardiovascular and Pulmonary Rehabilitation (AACVPR), the American Thoracic Society Nursing Assembly, and the American College of Chest Physicians (ACCP). She is a recognized expert in medical-surgical nursing, focusing on the care of the patient with chronic pulmonary disease, serving on committees focusing on patient-centered outcomes in pulmonary rehabilitation. She has been honored with fellowships in AAN, AACVPR, and ACCP. In 2013, Dr. Bauldoff was the keynote speaker at the Nanning Nursing Education Conference in Nanning, China, attended by representatives from more than 100 nursing schools in China.

Dr. Bauldoff views nursing as the greatest profession, using scientific evidence to provide the highest quality of care while maintaining the personal relationship with patients and their families. Her

experiences provide her with insights and lessons learned that she shares with her students.

Dr. Bauldoff resides in central Ohio. She enjoys travelling, walking, bicycling, golf, and spending time with her family and friends.

I dedicate this book to the memory of my parents and to my sisters, Corita Bauldoff, Jilana Alfonso, and Michelle Ciliberto—you are my touchstones to the real world and are my greatest cheerleaders. You help me keep my feet on the ground and my face turned toward new opportunities. I love you and thank you!

Gerene Bauldoff

Paula Gubrud-Howe, RN, MS, EdD., FAAN

Paula Gubrud-Howe is Senior Associate Dean for Academic Affairs and an Associate Professor at Oregon Health and Science University (OHSU) School of Nursing. She has more than 25 years of experience as a nurse educator involving multiple levels of programs from LPN to doctoral education. Dr. Gubrud-Howe is a founding leader and co-director of the Oregon Consortium for Nursing Education, an award winning consortium that includes the five campuses of OHSU and nine community colleges. She also has more than 20 years of experience in medical-surgical nursing, critical care, home health, and hospice. Dr. Gubrud-Howe earned a baccalaureate degree in nursing from Walla Walla University (1980), a MS in community-based nursing from OHSU (1993), and an EdD in postsecondary education from Portland State University (2008). She is a frequent invited speaker at national and international nursing education conferences and consults with other states and countries on the development of competency-based curriculum and nursing education consortiums designed to promote academic progression in nursing education. Her research activity is focused on clinical education redesign and the integration of simulation into nursing curriculum.

Dr. Gubrud-Howe is passionate about nursing and the opportunities it provides members of the profession. She values the sacred relationship nurses experience with patients as they promote health, treat illness, and provide comfort and palliative care. She believes the nation's health depends on highly qualified nurses who are dedicated to lifelong learning in pursuit of evidence-based, patient-centered care.

I dedicate this book to my husband Leland Howe and my children Elizabeth Gubrud-Howe, Gabriel Howe, and Caleb Howe for encouraging me to pursue my professional passions and goals. I also dedicate this book to my father, Allan Gubrud, who instilled insatiable curiosity, a love of learning, and a passion to teach.

Paula Gubrud Howe

Thank You

Contributors

We extend a heartfelt thanks to our contributors, who gave their time, effort, and expertise so tirelessly to the development and writing of chapters and resources that helped foster our goal of preparing student nurses for evidence-based practice.

Reviewers

Our heartfelt thanks go to our colleagues from schools of nursing across the country who have given generously of their time to help create this exciting new edition of our medical-surgical nursing textbook. These individuals helped us plan and shape our book and resources by reviewing chapters, art, design, and more. *Medical-Surgical Nursing: Clinical Reasoning in Patient Care* has reaped the benefit of your collective knowledge and experience as nurses and teachers, and we have improved the materials due to your efforts, suggestions, objections, endorsements, and inspiration. Among those who gave their time to help us are the following:

Wanda G. Barlow, MSN, RN, FNP-BC
Nursing Instructor
Winston Salem University
Winston Salem, North Carolina

Angie Brindowski, MSN, BSN, RN
Department Chair
Clinical Assistant Professor
Carroll University
Waukesha, Wisconsin

Deborah Ellis, RN, MSN, FNP
Associate Professor of Nursing

Associate Professor
Pasco Hernando Community College
New Port Richey, Florida

Preface

WHY WE WROTE THIS BOOK

Dr. LeMone-Koeplin developed the original vision for *Medical-Surgical Nursing: Clinical Reasoning in Patient Care* based on the belief that nursing is a holistic, evidence-based, person-centered profession. Nursing care, therefore, is provided for the whole person, not just for a malfunction of one or more body systems.

The revisions and updates reflected in the sixth edition of *Medical-Surgical Nursing: Clinical Reasoning in Patient Care* further reflect our belief that nurses should possess the necessary knowledge, skills, and attitudes to continuously improve the quality and safety of care in healthcare systems. We believe that nurses need to be able to use evidence-based practice, apply clinical reasoning skills, and understand nursing care standards to safely perform complex skills and tasks. Unit I, *Dimensions of Medical-Surgical Nursing*, has been extensively revised to reflect this belief, with expanded discussions of clinical reasoning, essential nursing competencies for practice (including QSEN competencies), and a new chapter focused on evidence-based practice and informatics in nursing.

In this textbook, discussions of the human responses to illness and disease are structured within the framework of clinical reasoning and the nursing process. Nursing care is presented within the context of nursing problems or diagnoses, emphasizing the importance of developing individualized evidence-based plans of care. The quality and safety implications for nursing care are addressed. Throughout the text, nursing care planning is based on a philosophy that individuals, their families, and communities are active participants in health and illness as well as consumers of healthcare services.

Regardless of the type of healthcare service or setting, medical-surgical nurses must use knowledge and skills to provide competent and safe patient care. The ability to effectively prioritize activities and patient care needs is critical. Nursing care is structured by the activities planned and carried out through clinical reasoning and uses multiple thinking strategies when applying the nursing process. Care of the medical-surgical patient is based on established professional ethics and standards, and is focused on promoting or returning the patient to a state of functional health or providing palliative care at the end of life.

Throughout the text, we make every effort to communicate that both nurses and patients may be male or female; and that patients require holistic, individualized care regardless of their age, gender, or racial, cultural, or socioeconomic background. Our goal is to help students acquire the knowledge, resources, and competencies that ensure a solid base for clinical reasoning and that can be applied to provide safe, individualized, and competent nursing care. We use understandable language and a consistent format, focusing on the most commonly encountered conditions. We have developed multiple learning strategies to facilitate success—audio, illustrations, teaching tips, and video and animation media.

Starting with the first edition, we have held fast to our vision that this textbook:

- Maintains a strong focus on nursing care as the essential element in learning and doing nursing, regardless of the gender, age, race, culture, or socioeconomic background of the patient or the setting for care.
- Provides a balance of pathophysiology, pharmacology, and interprofessional care to support interdependent and independent nursing interventions.
- Emphasizes the nurse's role as a caregiver, educator, advocate, leader and manager, and as an essential member of the interprofessional healthcare team.
- Uses functional health patterns and the nursing process as the structure for providing nursing care in today's world by prioritizing nursing diagnoses and interventions specific to altered responses to illness.
- Fosters clinical reasoning and decision making as the basis for safe, knowledgeable, individualized clinical practice.

Pearson is pleased to offer a complete suite of resources to support teaching and learning, including:

- TestGen Test Bank
- Lecture Note PowerPoints
- Classroom Response System PowerPoints
- New! Annotated Instructor's eText—This version of the eText is designed to help instructors maximize their time and resources in preparing for class. The AIE contains suggestions for classroom and clinical activities and key concepts to integrate into the classroom in any way imaginable. Additionally, each chapter has recommendations for integrating other digital Pearson Nursing resources, including The Neighborhood 2.0, skills videos, and MyNursingLab.

ORGANIZATION

The 50 chapters in this text are organized into units based on alterations in human structure and function. To increase student learning, each chapter in the book includes key terms, learning outcomes and clinical competencies, major concepts, chapter highlights, test yourself NCLEX-type questions, and a bibliography that provides additional reading.

Each unit with a focus on altered health opens with an assessment chapter. This chapter draws on the student's prerequisite knowledge, and serves to reinforce basic principles of anatomy and physiology as applied to assessment in both health and illness.

Following the assessment chapter, nursing care chapters provide information about major illnesses and traumatic injuries. Each nursing care chapter follows a consistent format, including three key components:

PATHOPHYSIOLOGY The discussion of each *major* illness or injury begins with incidence and prevalence, risk factors, and an overview of pathophysiology, followed by manifestations (signs and symptoms) and complications. Selected *Focus on Cultural Diversity* boxes demonstrate how race, age, and gender affect differences in incidence, prevalence, and mortality.

INTERPROFESSIONAL CARE Interprofessional care considers diagnosis and treatment by the healthcare team. The section includes information, as appropriate, about specific tests necessary for diagnosis, medications, surgery and other treatments, fluid management, dietary management, and complementary and alternative therapies. Specific information with related nursing care is highlighted in *Medication Administration* boxes and *Nursing Care of Patients* (such as those having a specific treatment or surgery) boxes.

NURSING CARE Because illness prevention is critical in healthcare today, health promotion information introduces the nursing care discussion of major illnesses or injuries. Discussions of selected major illnesses also include *Evidence for Nursing Care* boxes with resources for additional review in applying evidence to practice.

We discuss nursing assessment and care within a context of priorities of care, diagnoses, outcomes, and interventions, with rationales provided for each intervention. Boxes throughout each illness discussion section present information essential to patient care. These features include *Nursing Care*, *Nursing Care of the Older Adult*, *Meeting Individualized Needs*, *Practice Alerts*, *Safety Alerts,* and *Moving Evidence into Action* (a summary of a nursing study with clinical reasoning questions).

Last, for 80 major disorders or types of trauma, we provide a narrative *Case Study & Nursing Care Plan*. Clinical reasoning questions specific to the care plan are provided in a section called *Clinical Reasoning in Patient Care* (with suggestions for decision-making provided under *Evaluating Your Response* in Appendix B). The nursing care section ends with information about continuity of care with essential patient and caregiver education, and suggestions for referrals and additional patient resources.

CHAPTER REVIEW This end-of-chapter section concludes with 10 or more NCLEX-RN®-style review questions to reinforce comprehension of the chapter content. (The correct answers with rationales are found in Appendix B.)

What's New in the Sixth Edition

- We are delighted to welcome Paula Gubrud-Howe as a coauthor of this book. Information about Dr. Gubrud-Howe is included in About the Authors on page iv.

All the chapters of the sixth edition of this book were extensively reviewed, and reviewer comments were used to make this revision. New features of the sixth edition include the following:

- Chapter 1, *Medical-Surgical Nursing in the 21st Century*, includes a significantly expanded discussion of clinical reasoning and Quality and Safety Education for Nurses (QSEN) competencies.
- Chapter 2, *Informatics and Evidence-Based Practice in Medical-Surgical Nursing,* is totally new, reflecting our belief that students need a strong foundation in nursing research, evidence-based practice, and use of informatics and technology in health care.
- Clinical Competencies at the beginning of each chapter have been revised to clearly reflect QSEN competencies.
- Three to five Major Chapter Concepts are identified at the beginning of each chapter to assist students in focusing their reading and study of the chapter by helping pull out key themes or unifying concepts.
- Additional clinical reasoning questions identified as *Moving Knowledge into Action* appear throughout the book to provide students with opportunities to reflect on and apply their learning to patient care situations.
- Recognizing the overwhelming number and variety of medications nurses must safely administer, the most commonly prescribed drugs are italicized throughout this book.
- Within nursing care sections for major disorders, three new features have been added:
  - *Priorities of Care* help the student prioritize care, particularly in acute situations.
  - *Expected Outcomes* appear after every nursing diagnosis to help the student identify the goal of planned nursing interventions.
  - A *Delegating Nursing Care Activities* feature has been added to assist the student in identifying those nursing care activities that may appropriately be assigned or delegated to assistive personnel.
- *Continuity of Care* replaces the section previously titled Community-Based Care. This section focuses on the nurse's responsibility for preparing the patient and caregivers for transitions of care from one healthcare setting to another or to the home.

Features

Meeting Individualized Needs

Assessing Intimate Partner Violence (IPV)

Most IPV incidents are not reported, thus it is believed that the available data greatly underestimate the true magnitude of the problem. In 2005, it was reported that 329 males and 1181 females were murdered by an intimate partner. It is estimated that between 1 to 33 million women (many millions go unreported) are beaten by their intimate partner every year, resulting in 2 million injuries. Women make up about 84% of domestic violence victims. One out of every 6 American women has been a victim of an attempted or completed rape in her lifetime. Among men, 2.78 million have been victims of sexual assault or rape. IPV is the single largest cause of injury to women in the United States. This is a widespread problem that occurs regardless of age, sex, race, socioeconomic status, or education. IPV is also referred to as partner abuse or spousal abuse (CDC, 2012). In 2009, intimate partner violence made up 20% of violent crime against women. The same year, intimate partners committed 3% of all violent crimes against men.

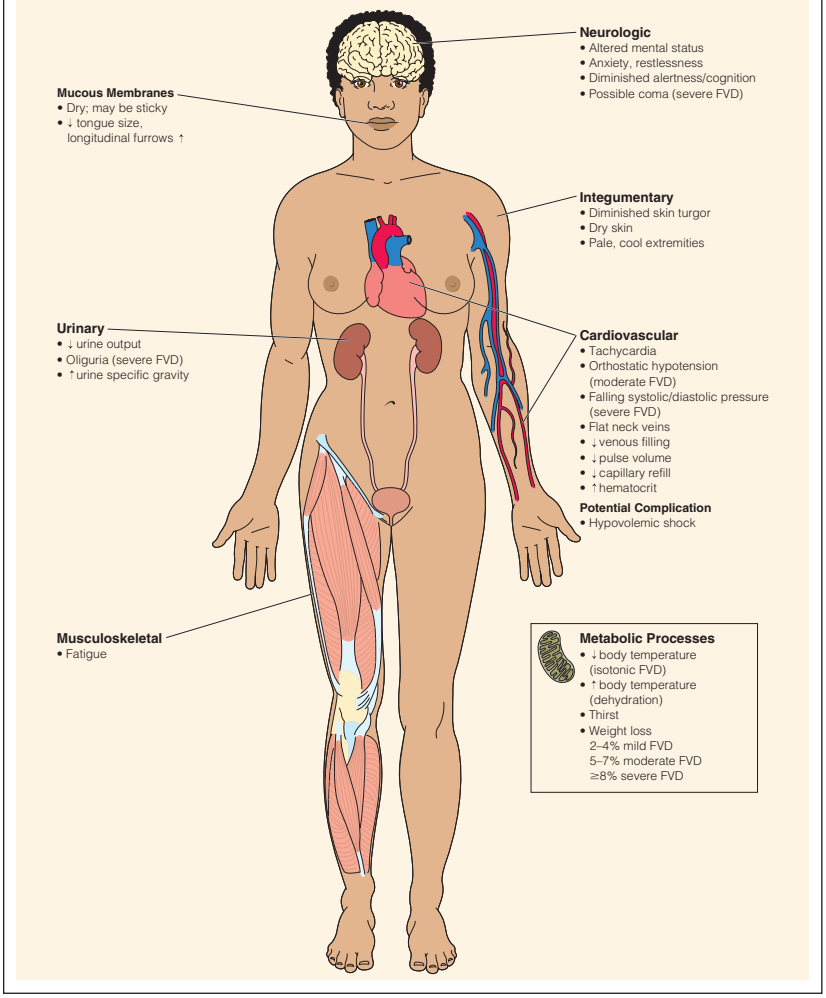
The United Nations Development Fund for Women estimates that at least one of every three women globally will be beaten, raped, or otherwise abused during her lifetime. In most cases, the abuser is a member of her own family (Futures without Violence, 2011).

VIOLENCE IN OLDER ADULTS

Elder abuse is defined as anything that endangers the life of an older adult. This can range from physical or emotional assault to intimidation, neglect, or financial exploitation. In addition, willful deprivation of food or medical care is included. Persons 80 years of age and older experienced abuse and neglect at a rate of two to three times their proportion of the older population. The perpetrator is a family member in 90% of the cases (National Center on Elder Abuse, 2013).

The general approach to diagnosis in abuse situations is challenging and many times hidden. As with spousal, older adult, or child abuse, the task of identification is complex. The following are clues to identify violence-related injuries:

- Injuries that do not correlate with the history
- Injuries that suggest a defensive posture
- Injuries during pregnancy
- Pattern injuries
- Pattern burns
- Sexual abuse/rape
- Unusual or unexplained fractures
- Signs of confinement
- Unusual interaction between patient and caregiver
- Lack of medical attention; immunizations not up to date, poor dental health
- Unexplained dehydration or malnutrition.

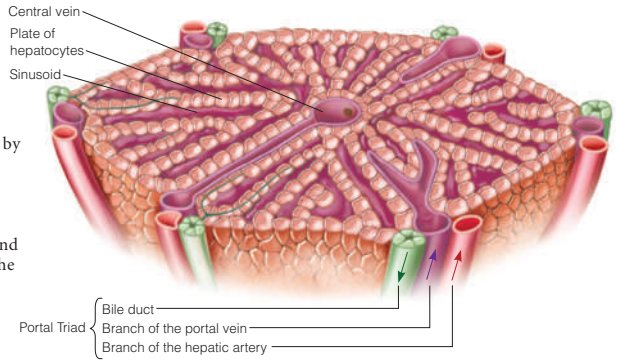


MEETING INDIVIDUALIZED NEEDS

This feature provides essential guidelines for providing nursing care to special populations.

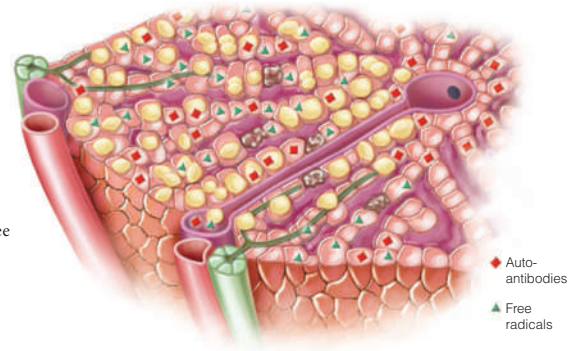
MULTISYSTEM EFFECTS

An illustrated feature that focuses on the specific disorder, with manifestations and effects on body systems.



MULTISYSTEM EFFECTS OF
Fluid Volume Deficit

PATHOPHYSIOLOGY ILLUSTRATED
Cirrhosis and Portal Hypertension



Normal liver

The liver contains multiple lobules made up of plates of hepatocytes, the functional cells of the liver, surrounded by small capillaries called sinusoids. These sinusoids receive a mixture of venous and arterial blood from branches of the portal vein and hepatic artery. Blood from the sinusoids drains into the central vein of the lobule. Hepatocytes produce bile, which drains outward to bile ducts.

Fatty liver

Ingested alcohol is primarily metabolized in the liver. Acetaldehyde, formed when alcohol is metabolized, damages hepatocytes and impairs the oxidation of fatty acids. As a result, fat accumulates within hepatocytes and liver lobules. Other alcohol metabolism by-products, including oxygen free radicals, promote inflammation and may stimulate autoantibody production.

PATHOPHYSIOLOGY ILLUSTRATED

Throughout, Pathophysiology Illustrated and Multisystem Effects of Illness art brings changes in physiologic processes to life, helping the student develop a visual memory of the disorder and its effects.

FOCUS ON CULTURAL DIVERSITY

This feature provides essential guidelines for culturally competent care.

FOCUS ON CULTURAL DIVERSITY

Biologic Variations among Cultures

As genetic science and our understanding of disease and pathology have advanced, there is increasing recognition that differences between peoples of the world are more than skin deep. Certain diseases and conditions are much more likely to develop in some groups than in others; for example, sickle cell disease occurs more frequently in people whose ancestors are from central Africa, the Near East, the Mediterranean region, and parts of India; Caucasian women of small stature and of Scandinavian heritage have a higher risk of developing osteoporosis. Biologic variations also may affect the way the body metabolizes drugs, leading to an effect that is either less than or greater than anticipated. In other cases, selected drugs may be found to be more effective for people of one race than another.

PATHOPHYSIOLOGY LINKAGE

Acute Pain and Associated Manifestations

Manifestation	Related Pathophysiology
Localized, sharp, burning pain	Nociceptors transmit pain stimulus along myelinated Aδ fibers to spinal cord, where it travels via the neospinothalamic tract to the thalamus. From the thalamus, the stimulus is distributed to the somatosensory cortex (perception and interpretation), the limbic system (emotional responses to pain), and brainstem centers (autonomic nervous system responses).
Diffuse, dull, aching pain	Transmission of nociceptive stimuli along unmyelinated C fibers to the spinal cord, and from there to the thalamus via the paleospinothalamic tract. Stimuli are distributed from the thalamus to the somatosensory cortex, limbic system, and brainstem centers.
Increased heart rate, stroke volume, and blood pressure; pupil dilation	Activation of the sympathetic nervous system (SNS) with release of catecholamines, which stimulate receptors in the heart and blood vessels.
Nausea, vomiting	SNS activation causes decreased blood flow to the gut, with decreased gastric acid secretion and intestinal motility; pain, anxiety cause stimulation of the vomiting center in the medulla.
Muscle tension	Protective responses initiated by higher brain centers to reduce nociceptive stimuli.
Anxiety, fear	Emotional responses to pain stimuli generated by limbic system.

PATHOPHYSIOLOGY LINKAGE

Pathophysiology Linkage tables provide the pathophysiologic basis for major manifestations of the disorder to help the student develop a deeper understanding of the disorder's effects on the patient.

MANIFESTATIONS OF DISORDERS

Manifestation boxes summarize specific subjective and objective manifestations of disorders.

MANIFESTATIONS OF IMPENDING DEATH

- Difficulty talking or swallowing
- Nausea, flatus, abdominal distention
- Urinary and/or bowel incontinence, constipation
- Decreased sensation, taste, and smell
- Weak, slow, and/or irregular pulse
- Decreasing blood pressure
- Decreased, irregular, or Cheyne-Stokes respirations
- Changes in level of consciousness
- Restlessness, agitation
- Coolness, mottling, and cyanosis of the extremities

NURSING CARE OF THE PATIENT

Essential information needed for nursing care of various disorders is described—detailed illustrations help students understand the steps of the nursing process.

NURSING CARE OF THE PATIENT

Halo Fixation

- Maintain integrity of the halo external fixation device:
  a. Inspect pins and traction bars for tightness; report loosened pins to physician.
  b. Tape the appropriate wrench to the head of the bed for emergency intervention.
  c. Never use the halo ring to lift or reposition the patient. *Loosening of the apparatus poses the risk of further damage to the cord. It is the responsibility of the nurse to maintain the integrity of the apparatus and the safety of the patient.*
- Assess muscle function and skin sensation every 1 hour in the acute phase and every 4 hours thereafter:
  a. Assess motor function on a scale of 0 to 5, with 0 being no evidence of muscle contraction and 5 being normal muscle strength with full range of motion (ROM).
  b. Assess sensation by comparing touch and pain, moving from impaired to normal areas, and testing both the right and left sides of the body.
  Monitoring muscle function and skin sensation allows early identification of potential neurologic deficits.

MEDICATION ADMINISTRATION

Drugs appropriate for the chapter disorders are featured, as well as the related nursing responsibilities and patient/family teaching.

MEDICATION ADMINISTRATION

Increased Intracranial Pressure

OSMOTIC DIURETICS

mannitol (Osmitrol)

urea

glucose

Osmotic diuretics (hyperosmotic agents) draw fluid out of brain cells by increasing the osmolality of the blood. The effects of these drugs vary with the type of injury. Mannitol therapy is often initiated if the patient's ICP has exceeded 15 to 20 mmHg for at least 10 minutes. Both IV bolus and continuous infusion techniques are used. Repeated use of mannitol can lead to continual elevations in serum osmolality, with attendant risk of seizures and a serious fluid and electrolyte imbalance. Urea is seldom administered IV because a severe local reaction may result if leakage occurs at the injection site. Mannitol and urea are used cautiously if renal disease is present.

Nursing Responsibilities

- Monitor vital signs, urinary output, central venous pressure (CVP), and pulmonary artery pressures (PAP) before and every hour throughout administration.
- Assess for manifestations of dehydration.
- Assess for muscle weakness, numbness, tingling, paresthesia, confusion, and excessive thirst.
- Assess for pulmonary edema while administering the medication.
- Monitor neurologic status and intracranial pressure readings.
- Monitor renal function and serum electrolytes throughout therapy.
- Do not administer the medication if crystals are present in solution. Administer with an inline filter. Observe infusion site frequently for infiltration.
- Do not administer mannitol solution with blood.

LOOP DIURETICS

furosemide (Lasix)

ethacrynic acid (Edecrin)

Loop diuretics such as furosemide and ethacrynic acid inhibit sodium and chloride reabsorption at the ascending loop of Henle. They cause a reduction in the rate of CSF production, thus reducing the ICP.

Nursing Responsibilities

- Monitor vital signs and electrolyte values closely.
- Assess fluid status throughout therapy.
- Monitor blood pressure and pulse before and during administration.
- Monitor renal laboratory studies closely.
- Use infusion pump to ensure accurate dosage.

INTRAVENOUS FLUIDS

Keeping the patient moderately dehydrated to maintain serum osmolality can be effective in reducing cerebral edema. When giving IV fluids, closely monitor the osmolality of the solutions; if patients with IICP are given hypo-osmolar solutions, increased cerebral edema can occur. Preferred solutions include 0.45% to 0.9% sodium chloride solutions.

Nursing Responsibilities

- Monitor fluid status closely.
- Monitor neurologic status closely.
- Avoid administering solutions that become hypo-osmolar, such as 5% dextrose in water.

OTHER PHARMACOLOGIC INTERVENTIONS FOR ICP

- Antipyretics, such as acetaminophen, are used in conjunction with a hypothermia blanket to reduce hyperthermia, thereby decreasing the high cerebral metabolism that contributes to IICP.
- Antiulcer drugs, such as histamine H_2 antagonists (for example, ranitidine [Zantac]) or sucralfate (Carafate), are used in patients with ICP to decrease the development of stress ulcers.
- Antihypertensive agents, such as beta-adrenergic blocking agents, may be used if the mean arterial pressure is high.
- Vasopressors may be used if the mean arterial pressure is low.
- Anticonvulsants may be given to prevent or treat seizures.

Note: Because the patient with IICP often has an altered level of consciousness, patient and family teaching are not discussed in this box.

EVIDENCE FOR NURSING CARE

Evidence for Nursing Care boxes provide resources for additional review in applying evidence to practice.

Evidence for Nursing Care

The Patient with a Stroke

Selected resources that nurses may find helpful when planning evidence-based nursing care follow.

- Miller, E. L., Murray, L., Richards, L., Zorowitz, R. D., Bakas, T., Clark, P., & Billinger, S. A. (2010). Comprehensive overview of nursing and interprofessional rehabilitation care of the stroke patient: A scientific statement from the American Heart Association. *Stroke, 41*(10), 2401–2448.
- Mink, J., & Miller, J. (2011). Stroke, part I: Opening the window of opportunity for treating acute ischemic stroke. *Nursing 2011, 41*(1), 25–33.
- Mink, J., & Miller, J. (2011). Stroke, part 2: Respond aggressively to hemorrhagic stroke. *Nursing 2011, 41*(3), 36–43.

PRACTICE ALERT!

Warning Signs of a Flare

- Increased fatigue
- Pain, abdominal discomfort
- Rash
- Headache
- Fever
- Dizziness

ALERTS

Alerts bring forward critical information for safe and effective nursing practice.

SAFETY ALERT

Gastrointestinal bleeding is a risk for patients taking NSAIDs. Teach patients to watch for bright red bleeding from the stomach (in vomitus) or dark black bowel movements.

MOVING EVIDENCE INTO ACTION

These boxes focus on research into specific topics and how the research relates to current nursing care. Critical-thinking questions help students understand the material.

Moving Evidence into Action

Patients Undergoing an Awake Craniotomy

Brain mapping is a procedure conducted to identify the functional areas of the brain that control language and motor abilities. The patient is awake during the surgery, and a handheld probe is used to stimulate areas of the brain. The areas stimulated become temporarily inactivated (as evidenced by asking the patient to speak or move), so that the surgeon knows which areas to avoid when removing a brain tumor. This study (Manchella et al., 2011) examined the experiences of patients in term of their feelings, what they think about, and how they approach this type of surgery without an anesthetic.

Findings from the study illustrated the complexity of the experience and the effect on the patient. Preoperatively, the patients felt a part of the decision making about being awake during the surgery, needed strong emotional support, kept busy to remain distracted, and avoided thinking about how they would handle the surgery itself. During the surgery, patients concentrated on doing what they were asked to do and having their senses (especially hearing) play the strongest role. After the surgery, the patients tested their ability to speak and move to ensure they had returned to normal, felt tired, and were surprised that no typical postoperative complications (e.g., nausea, pain) occurred.

Implications for Nursing

There is very little in the literature about nursing care of patients who are awake during surgery. This study identified information about the experience, updating the base for guidelines for preoperative, intraoperative, and postoperative nursing interventions. Certainly, having surgery for a brain tumor, having a malignancy, and knowing one will be awake during the procedure are each traumatic, but when combined they can easily be overwhelming. Nursing care before the surgery must focus on meeting the emotional needs of the patient as well as providing interventions (such as active listening and focused discussions) to relieve anxiety and fear. Because hearing the surgeon explain what was being done was very important to the patients, it is important that the nurse discuss this aspect with the physician.

Moving Knowledge into Action

1. Provide examples of leading statements you might use to discuss awake surgery with a patient.
2. In this study, patients wanted to see their family members immediately after surgery to reassure themselves that they were back to normal. Very few hospitals allow visitors in the recovery area. What process would you use to change this general rule? How would you handle the same request from other patients if the rule were changed for this population?
3. Considering the surgery, describe the immediate postoperative care necessary. What would be the priority assessments?

CASE STUDY & NURSING CARE PLAN

The two-column Case Study & Nursing Care Plan includes Assessment, Diagnoses, Expected Outcomes, Planning and Implementation, Evaluation, and Clinical Reasoning in Patient Care.

CASE STUDY & NURSING CARE PLAN A Patient with Gonorrhea

Janet Cirit, a 33-year-old legal secretary, lives in a suburban Midwestern community. She is unmarried but dating a man named Jim Adkins, who lives in an adjacent suburb. Ms. Cirit visits her gynecologist because her periods have become irregular and she is experiencing pelvic pain and an abnormal amount of vaginal discharge. Recently she has developed a sore throat. The pelvic pain has begun to disrupt her sleeping pattern, and she is concerned that she might have cancer because her mother recently died of ovarian cancer.

ASSESSMENT

When Ms. Cirit arrives for her appointment at the gynecologist's office, Marsha Davidson, the nurse practitioner, interviews her. Ms. Davidson completes a thorough medical and sexual history, including questions about her menstrual periods, pain associated with urination or sexual intercourse, urinary frequency, most recent Pap smear, birth control method, history of STI and drug use, and types of sexual activity. Ms. Cirit reports her symptoms and her concern about ovarian cancer. She also indicates that she is taking oral contraceptives and therefore sees no need for her boyfriend to use a condom because she believes their relationship is monogamous.

Physical examination reveals both pharyngeal and cervical inflammation, and lower abdominal tenderness. Her temperature is 37.0°C (98.5°F). There are no signs or symptoms of pregnancy.

The gynecologist orders a Pap smear and cultures of the cervix, urethra, and pharynx to evaluate for gonorrhea and chlamydial infection. Blood is drawn for WBC. Test results are positive for gonorrhea and negative for chlamydia. The WBC is slightly elevated, indicating possible salpingitis. Because Mr. Adkins has been Ms. Cirit's only sexual partner, it is clear that he is the source of infection and needs to be treated as well.

DIAGNOSES

- *Acute Pain* related to the infectious process
- *Anxiety* related to fear about possible cancer
- *Situational Low Self-Esteem* related to shame and guilt because of having an STI
- *Sexual Dysfunction* related to the impaired relationship and fear of reinfection

EXPECTED OUTCOMES

- Patient will experience relief of pain, indicating that the infection has been eradicated.
- Patient will verbalize that she has nothing to be ashamed of and that she has been wise to seek treatment as soon as symptoms occurred.
- Patient will verbalize that she will insist her partner use condoms during future sexual activity.

PLANNING AND IMPLEMENTATION

- Administer ceftriaxone IM and azithromycin PO as ordered.
- Emphasize the need for regular Pap smears and pelvic examinations because of the family history of ovarian cancer.
- Discuss feelings and concerns about the diagnosis of gonorrhea. Stress that such a diagnosis does not reflect on one's self-worth as a person.
- Teach how to talk with a future sexual partner about condom use.

EVALUATION

A week later during her follow-up visit, Ms. Cirit states that she is feeling much better and sleeping well at night since the pain has ended. She has terminated her relationship with Mr. Adkins and is considering joining a health club in the hope of increasing her level of fitness and perhaps meeting someone new.

Clinical Reasoning in Patient Care

1. How are Ms. Cirit's manifestations related to the infectious process of gonorrhea?
2. Should the nurse have suggested that Ms. Cirit also be tested for HIV? Why or why not?
3. Develop a care plan for Ms. Cirit for the nursing diagnosis *Impaired Social Interaction.*

See Evaluating Your Response in Appendix B.

END OF UNIT CLINICAL SCENARIO

This activity presents the student an opportunity to focus on setting priorities while managing a group of patients. Included are NCLEX® questions that evaluate prioritization, delegation and safe nursing care.

CLINICAL SCENARIO

Directions: *Read the following clinical scenarios and answer the questions that follow. To complete this exercise successfully, you will utilize not only knowledge of the content in this unit, but also principles related to priority setting and maintaining patient safety.*

You have been assigned to work with the following four patients for the 0700 shift on a medical-surgical unit. Significant data obtained during report is as follows:

- Mr. Blew is a 54-year-old who is admitted with complaints of polydipsia, polyuria, and polyphagia. There is a fruity odor to his breath and he seems confused at times. Vital signs on admission are temperature 37.2°C (99°F), pulse 90 bpm, respirations 30/min and deep, and blood pressure 110/68 mmHg. His blood glucose is 650 mg/dL on admission at 0630.
- Mrs. Rant is a 65-year-old who is admitted with severe back pain in the flank area on the right side, nausea, and vomiting. She is being evaluated for treatment due to renal calculi. She has a history of hyperparathyroidism. Vital signs are temperature 36.4°C (97.6°F) with clammy skin, pulse 100 bpm, respirations 24/min, and blood pressure of 168/94 mmHg. She is requesting pain medication for the back pain.
- Mrs. Fox is an 86-year-old who was transferred from the medical ICU yesterday. She was admitted after being found in a comatose state by her daughter. On admission her blood sugar was 45 mg/dL, serum sodium was 128 mEq/L, temperature was 35.9°C (96.6°F), and she had a heart rate of 50 bpm. Vital signs this a.m. are temperature 36.9°C (98.4°F), pulse 78 bpm, respirations 18/min, and blood pressure 140/86 mmHg. She is due for electrolytes to be drawn at 0730.
- Mr. Rite is a 56-year-old who was admitted 4 days ago after falling from a ladder and hitting his head. He is complaining of a headache and thirst even after drinking 2000 mL of fluids during the night. Vital signs are temperature 37.8°C (100°F), pulse 98 bmp, respirations 14/min, and blood pressure 114/84 mmHg.

Nursing Care 439
The Patient with a Major Burn 439
Pathophysiology **439**
Interprofessional Care 442
Nursing Care 450

UNIT 5 Responses to Altered Endocrine Function 460

Chapter 18 Assessing the Endocrine System 461

Anatomy, Physiology, and Functions of the Endocrine System 462
Pituitary Gland **462**, Thyroid Gland **463**, Parathyroid Glands **463**, Adrenal Glands **464**, Pancreas **464**, Gonads **464**

An Overview of Hormones 465

Assessing Endocrine Function 466
Diagnostic Tests **466**, Genetic Influences **466**, Health Assessment Interview **470**, Physical Assessment **471**

Chapter 19 Nursing Care of Patients with Endocrine Disorders 475

Disorders of the Thyroid Gland 476

The Patient with Hyperthyroidism 476
Pathophysiology and Manifestations **476**

Interprofessional Care 477

Nursing Care 480

The Patient with Hypothyroidism 482
Pathophysiology and Manifestations **483**

Interprofessional Care 483

Nursing Care 483

The Patient with Cancer of the Thyroid 487

Disorders of the Parathyroid Glands 487

The Patient with Hyperparathyroidism 488
Pathophysiology and Manifestations **488**

Interprofessional Care 488

Nursing Care 488

The Patient with Hypoparathyroidism 488
Pathophysiology and Manifestations **488**

Interprofessional Care 489

Nursing Care 489

Disorders of the Adrenal Glands 489

The Patient with Cushing's Syndrome 489
Pathophysiology **489**, Manifestations **489**

Interprofessional Care 489

Nursing Care 491

The Patient with Chronic Adrenal Insufficiency 493
Pathophysiology **493**, Manifestations **493**

Interprofessional Care 494

Nursing Care 494

The Patient with Pheochromocytoma 496

Disorders of the Pituitary Gland 497

The Patient with Disorders of the Anterior Pituitary Gland 497
Pathophysiology and Manifestations **497**

Interprofessional Care 497

Nursing Care 497

The Patient with Disorders of the Posterior Pituitary Gland 497
Pathophysiology and Manifestations **498**

Interprofessional Care 498

Nursing Care 499

Chapter 20 Nursing Care of Patients with Diabetes Mellitus 501

Diabetes Mellitus 502
Incidence and Prevalence **502**, Overview of Endocrine Pancreatic Hormones and Glucose Homeostasis **502**, Pathophysiology of DM **504**, DM in the Older Adult **506**

Interprofessional Care 506
Complications of Diabetes Mellitus **520**
Chronic Complications **523**

Nursing Care 527

UNIT 6 Responses to Altered Gastrointestinal Function 537

Chapter 21 Assessing the Gastrointestinal System 538

Nutrients 538
Carbohydrates **539**, Proteins **539**, Fats (Lipids) **540**

Vitamins 540
Minerals **540**

Anatomy, Physiology, and Functions of the GI System 542
The Mouth **542**, The Pharynx **543**, The Esophagus **543**, The Stomach **543**, The Small Intestine **543**, The Large Intestine **544**, The Accessory Digestive Organs **544**

Metabolism 545

Assessing Gastrointestinal Function 545
Diagnostic Tests **545**, Genetic Considerations **545**, Nutrition Screening and Assessment **545**

Chapter 22 Nursing Care of Patients with Nutritional Disorders 563

The Patient with Obesity 564
Incidence and Prevalence **564**, Risk Factors **564**, Overview of Normal Physiology **565**, Pathophysiology **565**, Complications of Obesity **565**

Interprofessional Care 566

Nursing Care 570

The Patient with Malnutrition 575
Incidence and Prevalence **575**, Risk Factors **575**, Pathophysiology **575**, Manifestations **576**

Interprofessional Care 576

Nursing Care 580

The Patient with an Eating Disorder 582
Anorexia Nervosa **582**, Bulimia Nervosa **582**, Binge-Eating Disorder **583**

Interprofessional Care 583

Nursing Care 584

Chapter 23 **Nursing Care of Patients with Upper Gastrointestinal Disorders 588**

The Patient with Nausea and Vomiting 589
Pathophysiology **589**
Interprofessional Care 589
Nursing Care 590
Disorders of the Mouth 591
The Patient with Stomatitis 591
Pathophysiology and Manifestations **593**
Interprofessional Care 593
Nursing Care 594
The Patient with Oral Cancer 596
Pathophysiology and Manifestations **596**
Interprofessional Care 596
Nursing Care 597
Disorders of the Esophagus 599
The Patient with Gastroesophageal Reflux Disease 599
Pathophysiology **599**, Manifestations **600**
Interprofessional Care 600
Nursing Care 601
The Patient with Hiatal Hernia 603
The Patient with Impaired Esophageal Motility 604
The Patient with Esophageal Cancer 604
Pathophysiology **604**, Manifestations **605**
Interprofessional Care 605
Nursing Care 605
Disorders of the Stomach and Duodenum 606
Overview of Normal Physiology 606
The Patient with Gastrointestinal Bleeding 607
Pathophysiology **607**
Interprofessional Care 607
Nursing Care 608
The Patient with Peptic Ulcer Disease 609
Risk Factors **609**, Pathophysiology **609**, Manifestations **612**, Complications **612**, Zollinger-Ellison Syndrome **612**
Interprofessional Care 613
Nursing Care 614
The Patient with Gastritis 616
Pathophysiology **617**
Interprofessional Care 617
Nursing Care 618
The Patient with Cancer of the Stomach 619
Risk Factors **619**, Pathophysiology **619**, Manifestations **619**
Interprofessional Care 620
Nursing Care 621

Chapter 24 **Nursing Care of Patients with Bowel Disorders 625**

Disorders of Intestinal Motility 625
The Patient with Diarrhea 626
Pathophysiology **626**, Manifestations **626**, Complications **626**
Interprofessional Care 626
Nursing Care 628
The Patient with Constipation 629
Pathophysiology **629**, Manifestations and Complications **630**
Interprofessional Care 630
Nursing Care 632
The Patient with Irritable Bowel Syndrome 633
Pathophysiology **633**, Manifestations **633**
Interprofessional Care 633
Nursing Care 634
The Patient with Fecal Incontinence 635
Pathophysiology **635**
Interprofessional Care 636
Nursing Care 636
Acute Inflammatory and Infectious Bowel Disorders 637
The Patient with Appendicitis 637
Pathophysiology **637**, Manifestations **637**, Complications **638**
Interprofessional Care 638
Nursing Care 639
The Patient with Peritonitis 640
Pathophysiology **640**, Manifestations **640**, Complications **641**
Interprofessional Care 641
Nursing Care 642
The Patient with Gastroenteritis 643
Pathophysiology **643**, Manifestations **644**, Complications **644**
Interprofessional Care 647
Nursing Care 648
The Patient with a Protozoal Bowel Infection 648
Pathophysiology and Manifestations **649**
Interprofessional Care 650
Nursing Care 650
The Patient with a Helminthic Disorder 651
Pathophysiology **651**
Interprofessional Care 651
Nursing Care 652
Chronic Inflammatory Bowel Disorders 652
The Patient with Inflammatory Bowel Disease 652
Ulcerative Colitis **653**, Crohn's Disease **654**
Interprofessional Care 655

Nursing Care 659
The Patient with Diverticular Disease 663
Pathophysiology **663**
Interprofessional Care 664
Nursing Care 665
Malabsorption Syndromes 666
The Patient with Celiac Disease 666
Pathophysiology **667**, Manifestations **667**
Interprofessional Care 668
Nursing Care 668
The Patient with Lactase Deficiency 669
Manifestations **669**
Interprofessional Care 670
Nursing Care 670
The Patient with Short Bowel Syndrome 670
Interprofessional Care 670
Nursing Care 670
Neoplastic Disorders 671
The Patient with Polyps 671
Pathophysiology **671**, Manifestations **672**
Interprofessional Care 672
Nursing Care 672
The Patient with Colorectal Cancer 672
Pathophysiology **673**, Manifestations **673**, Complications **673**
Interprofessional Care 673
Nursing Care 676
Structural and Obstructive Bowel Disorders 679
The Patient with a Hernia 680
Pathophysiology **680**, Manifestations **680**, Complications **681**
Interprofessional Care 681
Nursing Care 681
The Patient with Intestinal Obstruction 681
Pathophysiology **681**
Interprofessional Care 683
Nursing Care 684
Anorectal Disorders 685
The Patient with Hemorrhoids 685
Pathophysiology and Manifestations **685**
Interprofessional Care 686
Nursing Care 687
The Patient with an Anorectal Lesion 687
Anal Fissure **687**, Anorectal Abscess **687**, Anorectal Fistula **688**, Pilonidal Disease **688**
Nursing Care 688

Chapter 25 **Nursing Care of Patients with Gallbladder, Liver, and Pancreatic Disorders 692**

Gallbladder Disorders 692
The Patient with Gallstones 693
Physiology Review **693**, Pathophysiology and Manifestations **693**
Interprofessional Care 694
Nursing Care 695
The Patient with Cancer of the Gallbladder 697
Liver Disorders 698
Physiology Review **698**, Common Manifestations of Liver Disorders **698**
The Patient with Hepatitis 699
Pathophysiology and Manifestations **699**
Interprofessional Care 701
Nursing Care 704
The Patient with Cirrhosis 706
Pathophysiology **706**, Manifestations and Complications **706**
Interprofessional Care 711
Nursing Care 714
The Patient with Cancer of the Liver 718
Pathophysiology **718**, Manifestations **718**
Interprofessional Care 718
Nursing Care 719
The Patient with Liver Trauma 719
Pathophysiology and Manifestations **719**
Interprofessional Care 719
Nursing Care 719
The Patient with Liver Abscess 719
Pathophysiology and Manifestations **719**
Interprofessional Care 719
Nursing Care 720
Exocrine Pancreas Disorders 720
The Patient with Pancreatitis 720
Physiology Review **720**, Pathophysiology **720**
Interprofessional Care 722
Nursing Care 723
The Patient with Pancreatic Cancer 725
Pathophysiology and Manifestations **725**
Interprofessional Care 726

UNIT 7 Responses to Altered Urinary Elimination 731

Chapter 26 Assessing the Renal System 732

Anatomy, Physiology, and Functions of the Renal System 732
The Kidneys **732**, The Ureters, Urinary Bladder, and Urethra **737**

Assessing Renal System Function 738
Diagnostic Tests **738**, Genetic Considerations **738**, Health Assessment Interview **738**, Physical Assessment **741**

Chapter 27 Nursing Care of Patients with Urinary Tract Disorders 746

The Patient with a Urinary Tract Infection 747
Risk Factors for UTI **747**, Physiology Review **747**, Pathophysiology and Manifestations **748**

Interprofessional Care 749

Nursing Care 751

The Patient with Urinary Calculi 754
Incidence and Risk Factors **755**, Physiology Review **755**, Pathophysiology **756**, Manifestations **756**, Complications **756**

Interprofessional Care 757

Nursing Care 759

The Patient with a Urinary Tract Tumor 761
Incidence and Risk Factors **761**, Pathophysiology **761**, Manifestations **762**

Interprofessional Care 762

Nursing Care 763

The Patient with Urinary Retention 767
Physiology Review **767**, Pathophysiology **768**, Manifestations **768**

Interprofessional Care 768

Nursing Care 768

The Patient with Neurogenic Bladder 769
Pathophysiology **769**

Interprofessional Care 769

Nursing Care 770

The Patient with Urinary Incontinence 771
Incidence and Prevalence **771**, Pathophysiology **771**

Interprofessional Care 772

Nursing Care 775

Chapter 28 Nursing Care of Patients with Kidney Disorders 779

Age-Related Changes in Kidney Function 780

Kidney Disorders 780

The Patient with Polycystic Kidney Disease 780
Pathophysiology **780**, Manifestations **781**

Interprofessional Care 781

Nursing Care 781

The Patient with a Glomerular Disorder 782
Physiology Review **782**, Pathophysiology **782**

Interprofessional Care 785

Nursing Care 787

The Patient with a Vascular Kidney Disorder 790
Hypertension **790**, Renal Artery Stenosis **790**, Renal Artery Occlusion **791**, Renal Vein Occlusion **791**

The Patient with Kidney Trauma 791
Pathophysiology and Manifestations **791**

Interprofessional Care 791

Nursing Care 791

The Patient with a Renal Tumor 791
Pathophysiology and Manifestations **792**

Interprofessional Care 792

Nursing Care 792

Kidney Failure 795

The Patient with Acute Kidney Injury 795
Incidence and Risk Factors **795**, Physiology Review **796**, Pathophysiology **796**, Course and Manifestations **798**, Complications **798**

Interprofessional Care 798

Nursing Care 803

The Patient with Chronic Kidney Disease 807
Incidence and Risk Factors **807**, Pathophysiology **808**, Manifestations and Complications **808**

Interprofessional Care 811

Nursing Care 816

UNIT 8 Responses to Altered Cardiovascular Function 824

Chapter 29 Assessing the Cardiovascular and Lymphatic Systems 825

Anatomy, Physiology, and Functions of the Heart 826

The Heart 826
Chambers and Valves of the Heart **826**, Systemic, Pulmonary, and Coronary Circulation **827**, The Cardiac Cycle and Cardiac Output **829**, The Conduction System of the Heart **830**

The Peripheral Vascular System 830
Structure of Blood Vessels **831**, Arterial Circulation **831** Factors Influencing Arterial Blood Pressure **834**

The Lymphatic System 834

The Hematologic System 835
Red Blood Cells **835**, White Blood Cells **838** Platelets **838**, Hemostasis **838**

Assessing Cardiovascular and Lymphatic Function 839
Diagnostic Tests **839**, Genetic Considerations **839**, The Health Assessment Interview **839**, Physical Assessment **849**

Chapter 30 **Nursing Care of Patients with Coronary Heart Disease 861**

Disorders of Myocardial Perfusion 862
The Patient with Coronary Heart Disease 862
Physiology Review **862**, Pathophysiology **862**, Incidence and Prevalence **863**, Risk Factors **866**
Interprofessional Care 868
Nursing Care 870
The Patient with Angina Pectoris 873
Pathophysiology **873**, Course and Manifestations **873**
Interprofessional Care 874
Nursing Care 875
The Patient with Acute Coronary Syndrome 878
Pathophysiology **878**, Manifestations **878**
Interprofessional Care 878
Nursing Care 882
The Patient with Acute Myocardial Infarction 882
Pathophysiology **883**, Manifestations **887**, Complications **887**
Interprofessional Care 889
Nursing Care 893
Cardiac Rhythm Disorders 895
The Patient with a Cardiac Dysrhythmia 895
Physiology Review **895**, Pathophysiology **897**
Interprofessional Care 904
Nursing Care 909
The Patient with Sudden Cardiac Death 913
Pathophysiology **914**, Manifestations **914**
Interprofessional Care 914
Nursing Care 915

Chapter 31 **Nursing Care of Patients with Cardiac Disorders 919**

Heart Failure 920
The Patient with Heart Failure 920
Incidence, Prevalence, and Risk Factors **920**, Physiology Review **920**, Pathophysiology **922**, Classifications and Manifestations of Heart Failure **923**, Complications **924**
Interprofessional Care 924
Nursing Care 933
The Patient with Pulmonary Edema 935
Pathophysiology **936**, Manifestations **936**
Interprofessional Care 937
Nursing Care 937
Inflammatory Heart Disorders 938
The Patient with Rheumatic Fever and Rheumatic Heart Disease 939
Incidence, Prevalence, and Risk Factors **939**, Pathophysiology **939**, Manifestations **939**
Interprofessional Care 939
Nursing Care 940
The Patient with Infective Endocarditis 941
Incidence and Risk Factors **941**, Pathophysiology **941**, Manifestations **942**, Complications **942**
Interprofessional Care 943
Nursing Care 944
The Patient with Myocarditis 945
Incidence and Risk Factors **945**, Pathophysiology **945**, Manifestations **945**
Interprofessional Care 945
Nursing Care 946
The Patient with Pericarditis 946
Pathophysiology **946**, Manifestations **946**, Complications **947**
Interprofessional Care 948
Nursing Care 948
Disorders of Cardiac Structure 950
The Patient with Valvular Heart Disease 950
Physiology Review **950**, Pathophysiology **950**
Interprofessional Care 956
Nursing Care 957
The Patient with Cardiomyopathy 959
Pathophysiology **959**
Interprofessional Care 962
Nursing Care 963

Chapter 32 **Nursing Care of Patients with Vascular and Lymphatic Disorders 966**

Disorders of Blood Pressure Regulation 967
Physiology Review **967**
The Patient with Primary Hypertension 968
Pathophysiology **969**, Manifestations **969**, Complications **969**, Incidence and Risk Factors **969**
Interprofessional Care 971
Nursing Care 976
The Patient with Secondary Hypertension 979
The Patient with Hypertensive Crisis 980
Disorders of the Aorta and Its Branches 980
The Patient with an Aneurysm 980
Pathophysiology and Manifestations **981**
Interprofessional Care 984
Nursing Care 985

Disorders of the Peripheral Arteries 987
Physiology Review **987**
The Patient with Peripheral Vascular Disease 987
Pathophysiology **987**, Manifestations and Complications **988**, Incidence and Risk Factors **988**
Interprofessional Care 988
Nursing Care 989
The Patient with Thromboangiitis Obliterans 992
Pathophysiology and Course **992**, Manifestations and Complications **992**, Incidence and Risk Factors **992**
Interprofessional Care 992
Nursing Care 993
The Patient with Raynaud's Disease 993
Pathophysiology and Manifestations **993**
Interprofessional Care 994
Nursing Care 994
The Patient with Acute Arterial Occlusion 994
Pathophysiology **994**, Manifestations **995**
Interprofessional Care 995
Nursing Care 995
Disorders of Venous Circulation 996
Physiology Review **996**
The Patient with Venous Thrombosis 997
Pathophysiology **997**
Interprofessional Care 998
Nursing Care 999
The Patient with Chronic Venous Insufficiency 1004
Pathophysiology **1004**, Manifestations **1004**
Interprofessional Care 1004
Nursing Care 1005
The Patient with Varicose Veins 1005
Pathophysiology **1006**, Manifestations **1006**, Complications **1006**, Incidence and Risk Factors **1006**
Interprofessional Care 1006
Nursing Care 1007
Disorders of the Lymphatic System 1008
The Patient with Lymphadenopathy 1009
The Patient with Lymphedema 1009
Pathophysiology and Manifestations **1009**
Interprofessional Care 1009
Nursing Care 1010

Chapter 33 **Nursing Care of Patients with Hematologic Disorders 1014**

Red Blood Cell Disorders 1015
The Patient with Anemia 1015
Physiology Review **1015**, Physiology and Manifestations **1015**
Interprofessional Care 1022
Nursing Care 1024
The Patient with Myelodysplastic Syndrome 1026
Pathophysiology **1026**, Manifestations **1026**
Interprofessional Care 1027
Nursing Care 1028
The Patient with Polycythemia 1028
Pathophysiology **1029**
Interprofessional Care 1029
Nursing Care 1029
White Blood Cell and Lymphoid Tissue Disorders 1030
The Patient with Leukemia 1030
Physiology Review **1030**, Pathophysiology **1030**, Manifestations **1030**, Incidence and Risk Factors **1030**, Classifications **1032**
Interprofessional Care 1034
Nursing Care 1036
The Patient with Malignant Lymphoma 1039
Pathophysiology **1040**, Course **1042**, Incidence and Risk Factors **1042**
Interprofessional Care 1042
Nursing Care 1044
The Patient with Multiple Myeloma 1047
Pathophysiology **1047**, Manifestations **1047**, Incidence and Risk Factors **1047**
Interprofessional Care 1047
Nursing Care 1048
The Patient with Neutropenia 1049
Pathophysiology and Manifestations **1049**
Interprofessional Care 1049
Nursing Care 1049
The Patient with Infectious Mononucleosis 1049
Pathophysiology and Manifestations **1049**
Interprofessional Care 1050
Platelet and Coagulation Disorders 1050
The Patient with Thrombocytopenia 1050
Physiology Review **1050**, Pathophysiology **1050**
Interprofessional Care 1051
Nursing Care 1052
The Patient with Hemophilia 1053
Physiology Review **1053**, Pathophysiology **1053**, Manifestations **1053**
Interprofessional Care 1054
Nursing Care 1054
The Patient with Disseminated Intravascular Coagulation 1056
Pathophysiology **1056**, Manifestations **1057**
Interprofessional Care 1057
Nursing Care 1058

UNIT 9 Responses to Altered Respiratory Function 1064

Chapter 34 Assessing the Respiratory System 1065

Anatomy, Physiology, and Functions of the Respiratory System 1066
The Upper Respiratory System **1066**, The Lower Respiratory System **1067**

Factors Affecting Respiration 1068
Respiratory Volume and Capacity **1068**, Air Pressures **1068**, Oxygen, Carbon Dioxide, and Hydrogen Ion Concentrations **1070**, Airway Resistance, Lung Compliance, and Elasticity **1070**, Alveolar Surface Tension **1071**

Oxygen and Carbon Dioxide Transport 1071
Oxygen Transport and Unloading **1071**, Carbon Dioxide Transport **1072**

Assessing Respiratory Function 1072
Diagnostic Tests **1072**, Genetic Considerations **1072**, Health Assessment Interview **1072**, Physical Assessment **1075**

Chapter 35 Nursing Care of Patients with Upper Respiratory Disorders 1080

Infectious or Inflammatory Disorders 1081

The Patient with Viral Upper Respiratory Infection 1081
Pathophysiology **1081**, Manifestations and Complications **1081**

Interprofessional Care 1081

Nursing Care 1082

The Patient with Respiratory Syncytial Virus (RSV) 1083

The Patient with Influenza 1083
Pathophysiology **1083**, Manifestations **1084**, Complications **1084**

Interprofessional Care 1085

Nursing Care 1085

The Patient with Sinusitis 1087
Physiology Review **1087**, Pathophysiology **1087**, Manifestations and Complications **1087**

Interprofessional Care 1088

Nursing Care 1089

The Patient with Pharyngitis or Tonsillitis 1090
Pathophysiology and Manifestations **1090**, Complications **1090**

Interprofessional Care 1091

Medications 1091

Nursing Care 1091

The Patient with a Laryngeal Infection 1092
Epiglottitis **1092**, Laryngitis **1092**

The Patient with Diphtheria 1092
Pathophysiology and Manifestations **1093**

Interprofessional Care 1093

Nursing Care 1093

The Patient with Pertussis 1093
Pathophysiology **1093**, Manifestations **1093**

Interprofessional Care 1094

Nursing Care 1094

Upper Respiratory Trauma or Obstruction 1094

The Patient with Epistaxis 1094
Pathophysiology and Manifestations **1095**

Interprofessional Care 1095

Nursing Care 1096

The Patient with Nasal Trauma or Surgery 1097
Pathophysiology and Manifestations **1097**

Interprofessional Care 1097

Nursing Care 1098

The Patient with Laryngeal Obstruction or Trauma 1100
Pathophysiology and Manifestations **1100**

Interprofessional Care 1100

Nursing Care 1101

The Patient with Obstructive Sleep Apnea 1101
Pathophysiology **1101**, Manifestations **1101**, Complications **1101**, Risk Factors **1102**

Interprofessional Care 1102

Nursing Care 1102

Upper Respiratory Tumors 1103

The Patient with Nasal Polyps 1103
Pathophysiology and Manifestations **1103**

Interprofessional Care 1103

Nursing Care 1103

The Patient with a Laryngeal Tumor 1103
Pathophysiology and Manifestations **1103**, Risk Factors **1104**

Interprofessional Care 1104

Nursing Care 1106

Chapter 36 Nursing Care of Patients with Ventilation Disorders 1114

Infections and Inflammatory Disorders 1115

The Patient with Acute Bronchitis 1115
Pathophysiology and Manifestations **1115**

Interprofessional Care 1115

Nursing Care 1115

The Patient with Pneumonia 1115
Physiology Review **1116**, Pathophysiology **1116**

Interprofessional Care 1118

Nursing Care 1121

The Patient with Severe Acute Respiratory Syndrome 1124
Pathophysiology **1124**, Manifestations and Complications **1124**

Interprofessional Care 1124

Nursing Care 1126

The Patient with a Lung Abscess 1127
Pathophysiology and Manifestations **1127**

Interprofessional Care 1128

Nursing Care 1128

The Patient with Tuberculosis 1128
Pathophysiology **1128**

Interprofessional Care 1132

Nursing Care 1135

The Patient with Inhalation Anthrax 1140

The Patient with a Fungal Infection 1140
Pathophysiology **1140**

Interprofessional Care 1141

Nursing Care 1141

Disorders of the Pleura 1141

The Patient with Pleuritis 1141

The Patient with a Pleural Effusion 1142
Pathophysiology and Manifestations **1142**

Interprofessional Care 1142

Nursing Care 1143

The Patient with Pneumothorax 1143
Pathophysiology **1144**, Spontaneous Pneumothorax **1144**

Interprofessional Care 1144

Nursing Care 1147

The Patient with Hemothorax 1148

Trauma of the Chest or Lung 1148

The Patient with a Thoracic Injury 1148
Pathophysiology and Manifestations **1149**

Interprofessional Care 1150

Nursing Care 1150

The Patient with Inhalation Injury 1151
Pathophysiology and Manifestations **1151**

Interprofessional Care 1152

Nursing Care 1153

Lung Cancer 1154

The Patient with Lung Cancer 1154
Pathophysiology **1154**, Manifestations **1154**, Complications and Course **1155**, Incidence and Risk Factors **1157**

Interprofessional Care 1157

Nursing Care 1159

Chapter 37 **Nursing Care of Patients with Gas Exchange Disorders 1165**

Reactive Airway Disorders 1166

The Patient with Asthma 1166
Physiology Review **1166**, Pathophysiology **1166**, Manifestations and Complications **1167**, Incidence and Risk Factors **1168**

Interprofessional Care 1168

Nursing Care 1172

The Patient with Chronic Obstructive Pulmonary Disease 1175
Pathophysiology **1175**, Manifestations **1176**, Incidence and Risk Factors **1176**

Interprofessional Care 1177

Nursing Care 1180

The Patient with Cystic Fibrosis 1185
Pathophysiology **1185**, Manifestations **1185**, Incidence and Prevalence **1186**

Interprofessional Care 1186

Nursing Care 1186

The Patient with Atelectasis 1187

The Patient with Bronchiectasis 1187

Interstitial Lung Disease 1188

The Patient with an Occupational Lung Disease 1188
Physiology Review **1188**, Pathophysiology and Manifestations **1188**

Interprofessional Care 1189

Nursing Care 1189

UNIT

1

Dimensions of Medical-Surgical Nursing

1 Medical-Surgical Nursing in the 21st Century 2

2 Informatics and Evidence-Based Practice in Medical-Surgical Nursing 17

3 Health and Illness Care of Adults 27

1 Medical-Surgical Nursing in the 21st Century

LEARNING OUTCOMES

1. Describe the core competencies for healthcare professionals: patient-centered care, interprofessional teams, evidence-based practice, quality improvement, safety, and health information technology.
2. Describe emerging new roles and responsibilities for nurses in an era of healthcare reform.
3. Apply the attitudes, mental habits, and skills necessary for clinical reasoning when using the nursing process in patient care.
4. Explain the importance of nursing and interprofessional codes of ethics and standards of practice as guidelines for clinical nursing practice.
5. Explain the activities and characteristics of the nurse as caregiver, educator, advocate, leader and manager, and researcher.

CLINICAL COMPETENCIES

1. Demonstrate clinical reasoning and apply critical thinking skills when using the nursing process to provide knowledgeable, safe, and patient-centered care.
2. Use health systems technology to provide evidence-based, patient-centered care in all healthcare delivery settings.
3. Provide clinical care that integrates the medical-surgical nursing roles of caregiver, educator, advocate, leader/manager, and researcher.
4. Contribute nursing knowledge and expertise as a member of the interprofessional team to provide safe, quality, and affordable patient-centered care.

MAJOR CHAPTER CONCEPTS

- The changes in healthcare delivery will influence the role of medical-surgical nursing in acute care and new delivery settings.
- Medical-surgical nurses are a crucial member of the healthcare team.
- Developing nursing competency influences the quality of care and the achievement of optimum patient care outcomes.

transitional care, *13*
Triple Aim, *3*

As a new era of healthcare emerges in the 21st century, nursing must embrace the knowledge, skills, and values that define the profession while simultaneously developing roles and ideals based on emerging science, changes in the health concerns of populations, and emerging healthcare delivery models. The **Patient Protection and Affordable Care Act (ACA)** enacted in 2010 is creating new expectations and responsibilities for nurses in all healthcare settings. The ACA will provide access to healthcare services for more Americans and create new models of care. The profession is well positioned to respond to new demands that emphasize health promotion/disease prevention, management of chronic disease, complex acute care, and care coordination during transitions between care settings. As the acuity of hospitalized patients and the prevalence of chronic illness continue to increase, nurses must possess a vast array of knowledge; cognitive, communicative, and technical skills; and well-developed ethical comportment (Benner et al., 2010).

Nursing, as defined by the American Nurses Association (ANA) (2013), "is the protection, promotion, and optimization of health and abilities, prevention of illness and injury, alleviation of suffering through the diagnosis and treatment of human response, and advocacy in the care of individuals, families, communities, and populations." **Medical-surgical nursing** is the health promotion, healthcare, and

illness care of adults based on knowledge derived from the arts and sciences and shaped by knowledge (the science) of nursing. The adult **patient**—the person with whom and for whom nursing care is designed and implemented—ranges in age from the late teens to the early 100s. Medical-surgical nursing focuses on the adult patient's response to actual or potential alterations in health. Medical-surgical nurses must be knowledgeable about all body systems, the disorders that affect them, and the interrelatedness of body systems and health problems. Medical-surgical nurses need to be strong communicators who are able to effectively interact with other members of the healthcare team, patients, and their families. Medical-surgical nurses coordinate patient care during transitions between care settings and provide health education and coaching to promote healing and optimal function. Delegation to and management and supervision of nursing assistive personnel is an ever-increasing component of effective medical-surgical nursing care. Medical-surgical nurses need to be able to apply evidence-based practice, clinical reasoning skills, and nursing care standards to safely perform complex nursing care skills and tasks. Medical-surgical nurses provide individualized quality care while using resources responsibly with an eye toward achieving optimal patient outcomes.

The wide range of ages and the variety of healthcare needs specific to individual patients make medical-surgical nursing an ever-changing and challenging area of nursing practice. It is important to remember that individual patients are part of families and live in communities. In some instances, nursing care is directed toward the family (for example, supporting the family of a dying individual) or even the community (for example, immunizing people to prevent an outbreak of hepatitis A).

In this textbook discussions of the human responses are structured within the framework of clinical reasoning and the nursing process. Nursing care is presented within the context of nursing problems or diagnoses, emphasizing the importance of developing individualized, evidence-based plans of care. The quality and safety implications for nursing care are addressed. Throughout the text, nursing care planning is based on a philosophy that individuals, their families, and communities are active participants in health and illness as well as consumers of healthcare services.

No matter the type of healthcare service or setting, medical-surgical nurses must use their knowledge and skills to provide competent and safe patient care. The ability to effectively prioritize activities and patient care needs is critical. Nursing care is structured by the activities planned and carried out through clinical reasoning. Nurses use multiple thinking strategies when applying clinical reasoning to the nursing process. Care of the medical-surgical patient is based on ethics and standards established by nursing organizations, and is focused on promoting or returning the patient to a state of functional health or providing palliative care at the end of life. This chapter provides a broad overview of the clinical practice of medical-surgical nursing, including core competencies, a framework and guidelines for care delivery, and the roles of the nurse in medical-surgical care.

CORE COMPETENCIES FOR SAFE AND EFFECTIVE HEALTHCARE

The healthcare system in North America faces numerous challenges, including an increasingly older patient population, an increase in the prevalence of chronic illness, changing consumer desires and expectations, rapidly expanding information and technologies, and a focus on improving quality and safety of care. After examining a number of studies about these challenges, the Institute of Medicine (IOM) (2001) found that although misuse of services and injuries resulting from errors are becoming more common, the safety and quality problems exist largely because of problems within the system and not through the fault of highly dedicated healthcare professionals. The Institute of Health Improvement (IHI) launched the **Triple Aim** initiative in 2007 (Berwick et al., 2008). The IHI posits that focusing on three critical objectives simultaneously will result in better models for providing healthcare. The three objectives are:

- Improve the patient care experience (including quality and satisfaction).
- Improve the health of populations.
- Reduce the per capita costs of healthcare.

In 2003 the National Academy of Sciences (2003) proposed a set of five **core competencies** that all healthcare professionals should possess, regardless of their discipline, to meet the needs of the 21st-century health system. In 2011 major health professions organizations united to form the Interprofessional Education Collaborative (IPEC). IPEC further refined the IOM core competencies and developed strategies for achieving them (Interprofessional Education Collaborative Expert Panel, 2011). The competencies are based on using communication, knowledge, technical skills, clinical reasoning, critical thinking, and values in clinical practice. The Quality and Safety Education for Nurses (QSEN) initiative (Cronenwett et al., 2007) focused on developing specific IOM competencies for nursing, with a major goal of providing nurses with the necessary knowledge, skills, and attitudes to continuously improve the quality and safety of care in healthcare systems (Sullivan, 2010, p. 37). The definitions for each QSEN competency are provided in Table 1–1.

CLINICAL REASONING/JUDGMENT IN THE NURSING PROCESS

As nurses care for patients, they use clinical reasoning/judgment, and multiple ways of thinking that includes critical thinking, analytical reasoning, creative thinking, and the nursing process (Benner et al., 2010). These mental activities and their application differentiate nursing from other helping professions.

Clinical Reasoning/Judgment

Clinical reasoning is a "complex process that uses cognition, metacognition, and discipline-specific knowledge to gather and analyze patient information, evaluate its significance, and weigh alternative actions" (Simmons, 2010, p. 1151). Well-developed clinical reasoning abilities are particularly important to promote quality and safe care in the face of ill-defined and ambiguous situations. As a clinical situation changes, nurses use clinical reasoning to respond to the immediate problem at hand. Clinical reasoning involves complex and multiple cognitive processes, which integrates the unique context of a clinical situation and addressing individual concerns of the patient and family (Benner et al., 2010). Clinical judgment is the outcome of the clinical reasoning process and is defined as ". . . an interpretation or conclusion about a patient's needs, concerns or health problems and/or the decision to take action (or not), and to use or modify

TABLE 1–1 Definition of QSEN Competencies

Competency	Definition
Patient-centered care	• Recognize the patient or designee as the source of control and full partner in providing compassionate and coordinated care based on respect for patient's preferences, values, and needs.
Teamwork and collaboration	• Function effectively within nursing and interprofessional teams, fostering open communication, mutual respect, and shared decision making to achieve quality patient care.
Evidence-based practice (EBP)	• Integrate best current evidence with clinical expertise and patient/family preferences and values for delivery of optimal healthcare.
Quality improvement (QI)	• Use data to monitor the outcomes of care processes and use improvement methods to design and test changes to continuously improve the quality and safety of healthcare systems.
Safety	• Minimize risk of harm to patients and providers through both system effectiveness and individual performance.
Use informatics	• Use information and technology to communicate, manage knowledge, mitigate errors, and support decision making.

standard approaches, or to improvise new ones as deemed appropriate by the patients response" (Tanner, 2006, p. 204). Information and knowledge used in clinical reasoning and judgments are derived from knowing the patient as an individual; grasping baseline data; understanding the case; knowing one's self by assessing one's own assumptions, preconceptions, and biases (e.g., critical thinking skills); and knowing the professional standards of practices (Gillespie & Patterson, 2009). Table 1–2 defines these foundational sources of knowledge that nurses use in the clinical reasoning process.

Nurses use a variety of thinking strategies when engaged in clinical reasoning. Thinking strategies include, but are not limited to, critical, deductive, inductive, dialectic, divergent, reflective, systematic, and creative thinking (Banning, 2008; Benner et al., 2010; Gillespie, 2010; Wilkinson, 2012b). A description of each of these kinds of thinking strategies follows.

Critical thinking is used extensively in clinical reasoning and when applying the nursing process. Critical thinking is evident when the nurse challenges assumptions, overtly identifies and acknowledges the values and beliefs he brings to the situation, considers the influence of context, generates possible explanations, and deliberately maintains healthy skepticism (Sullivan, 2012).

Deductive reasoning is the process of starting out with one or more general statements and examining the possibilities to reach a logically certain conclusion (Banning, 2008). For example, a nurse may use what she knows about the time frame during which the effects of insulin peak to determine the best time to assess the patient for signs and symptoms of hypoglycemia.

Inductive reasoning is described as reasoning that moves from the specific to the general (Banning, 2008). For example, a nurse takes care of several patients who are recovering from surgery. Through the experiences of caring for individual patients, the nurse discovers the expected patterns of recovery and uses the specific cases to generalize predictions about normal postoperative healing.

Dialectic reasoning involves thinking about situations in a holistic way. A "… dialectic thinker believes the whole is greater than the sum of the parts and that the whole organizes the parts" (Burns & Grove, 2005, p. 7). Dialectic reasoning involves assessing the strengths and challenges related to a patient's problem rather than focusing solely on the pathophysiologic aspect of the illness (Banning, 2008).

Divergent thinking is the ability to weigh the importance of information. This means that when you collect data from a patient, you can sort out the data that are relevant for care from the data that are not relevant, and explore alternatives to draw a conclusion. Abnormal data are usually considered relevant; normal data are helpful but may not change the care you provide.

Reflective thinking involves two kinds of thinking. Reflecting-in-action occurs while a situation is being addressed. Nurses engage in reflecting-in-action when they purposefully monitor and analyze a situation as it unfolds. Reflecting-on-action is deliberate and occurs after an event and creates embodied knowledge and skillfulness that

TABLE 1–2 Foundational Knowledge Used in Clinical Reasoning

Knowing the profession	Knowledge of standards of practice, scope of practice, competencies, skills and roles of nurses Application of the professions' values and ethics
Knowing self	Knowledge of one's own strengths, limitations, skills, experience, assumptions, preconceptions, learning, and other needs
Knowing the case	Knowledge of pathophysiology, patterns that exist in typical cases, evidence-based practices relevant to appropriate patient population, predicted trajectory, and predictable patient responses
Knowing the patient	Knowledge of a patients' baseline data, patterns that exist in laboratory or other data, and patterns in physiologic responses to pathology and treatment
Knowing the person	Knowledge of a patient's past experience in relation to health and illness, supports and resources, treatment preferences, and knowledge of the patient in the context of family and community

will influence what the nurse perceives as salient when confronted with similar patient situations in the future (Tanner, 2006).

Systematic thinking involves collecting, analyzing, and organizing information in a methodical manner that supports development of pattern recognition (Gillespie, 2010).

Creative thinking involves clinical imagination that integrates science, skilled know-how and practical knowledge to develop unique solutions to individual patient needs (Benner et al., 2010).

The experienced nurse uses numerous sources of knowledge and multiple reasoning strategies simultaneously when addressing a clinical or patient care problem. Student and novice nurses typically rely on fewer patient cues, limited sources of knowledge, and one or two reasoning processes to understand a particular patient problem and to decipher potential solutions (Simmons, 2010). As the nurse gains experience, research indicates nurses use heuristics (informal thinking strategies or cognitive shortcuts) to interpret complex clinical situations. Additionally, expert nurses rely heavily on reflecting-on-action as an aspect of clinical judgment as they create a repertoire of skillful judgment developed through the process of reflecting on paradigm cases. Clinical reasoning is an iterative process using various sources of knowledge, multiple reasoning processes, and metacognition.

As you practice clinical reasoning, you will use the following:

- Knowledge gained through classroom studies, textbooks, and current resources and by interacting with experienced nurses.
- Experience gained by working with patients experiencing similar problems or disorders. Taking time to reflect on each patient encounter will help you develop clinical reasoning and judgment skills.
- An understanding of the patient as an individual, who presents with both current and previous illness experiences. Knowing your patient will help you notice what is salient to each individual patient and understand the situation holistically.
- Personal values and beliefs, including recognition of prejudices that may influence thinking (e.g., believing that all homeless people are dirty, or that older adults cannot learn to care for themselves). Your personal values influence what you notice as salient issues for individual patients. Being aware of your biases will help you analyze situations objectively.
- An ability to identify other possible options, evaluate the alternatives, and reach a conclusion.

It takes practice to make clinical reasoning an integral component of a nurse's ability to address complex and ill-defined situations. The beginning nurse uses a deliberate process of assessing, considering possible alternative causes and action options, and choosing the most appropriate of the alternatives considered. With knowledge and experience, the nurse recognizes expected patterns of response, deviations from the expected, and the probable meaning of the deviation. Clinical reasoning gradually becomes more internalized; the nurse begins thinking like a nurse. Thinking critically and creatively involves more than just cognitive (knowledge) skills. It is strongly influenced by one's attitudes and mental habits. To engage in sound clinical reasoning, you must be aware of your attitudes and how they affect your thinking (refer to Table 1–2). Case studies and questions designed to prompt critical reflection are included throughout this book to provide practice in clinical reasoning.

The Nursing Process

The **nursing process** is the series of critical thinking and clinical reasoning activities nurses use as they provide care to patients. As nurses gain increasing autonomy in their practice, the nursing process helps them identify their independent practice domain. The nursing process provides a common reference system and a common terminology to serve as a base for improving clinical practice through research. In addition, the nursing process can serve as a framework for the evaluation of quality care.

The nursing process can be used in any setting. The purpose of care may be to promote wellness, maintain health, restore health, or provide comfort and facilitate coping with disability or death. Regardless of the purpose of care, the planned process of nursing allows for the inclusion of specific, individualized, and holistic activities.

The nursing process also benefits the patient receiving care and the agency or institution providing that care. The patient receives planned, individualized interventions; participates in all steps of the process; and is assured continuity of care through the written care plan. The nursing process benefits the healthcare institution through better resource utilization, increased patient satisfaction, and improved documentation of care.

The five phases of the nursing process are assessment, diagnosis, planning, implementation, and evaluation. These phases are interrelated and interdependent. They are often used cyclically, with the patient central to all phases, as illustrated in Figure 1–1 ■. The steps have been legitimized by the American Nurses Association (ANA) standards of practice (ANA, 2010), state nursing practice acts, and licensing examinations that are structured on a nursing model of care based on the nursing process.

This textbook assumes that the student already has a basic understanding of the nursing process and is now ready to expand and

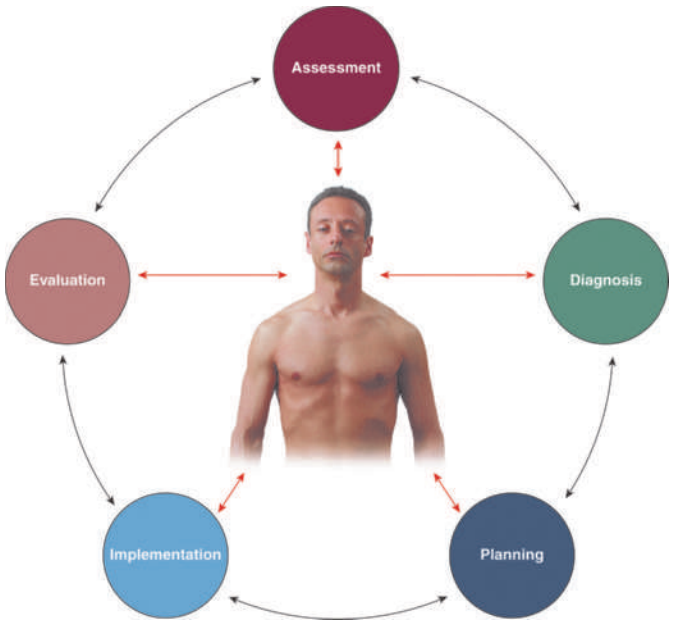

Figure 1–1 ■ Steps of the nursing process. Notice that the steps are interrelated and interdependent. For example, evaluation of the patient might reveal the need for further assessment, additional nursing diagnoses, and/or a revision of the plan of care.

apply that knowledge to adult patients with medical-surgical health problems. The following discussion is intended to serve only as a review; for more information, consult books specifically focused on the use of the nursing process, and read the case studies in the nursing care chapters throughout this textbook.

ASSESSMENT

Assessment is a critical element in each phase of the nursing process. It begins with the patient's first encounter with the healthcare system and continues as long as the patient requires care. During assessment, data (pieces of information) about the patient's health status are collected, validated, organized, clustered into patterns, and communicated either verbally or in written form. Assessment serves as the basis for identifying nursing problems and/or deriving accurate nursing diagnoses, for planning and implementing both initial and ongoing individualized care, and for evaluating care.

The nurse collects holistic assessment data, considering all dimensions of the patient. The data collected are both objective and subjective. Information that the nurse perceives by the senses is *objective data*; it is seen, heard, touched, or smelled, and can be verified by another person (e.g., blood pressure, temperature, pulse, or the presence of infected drainage). Information that is perceived only by the person experiencing it (e.g., pain, dizziness, anxiety) is *subjective data*.

Nurses conduct both initial and ongoing assessments. The initial assessment, conducted through a nursing history and physical assessment, is obtained to provide a comprehensive picture of the patient's health status. The initial assessment is sometimes referred to as the baseline assessment and is necessary to provide comprehensive data about the individual's health responses, identify specific factors that contribute to these responses, and facilitate mutually established goals and outcomes of care.

Focused assessments are ongoing and continuous, occurring whenever the nurse interacts with the patient. In a focused assessment, data are gathered about an identified or potential problem and then used to evaluate nursing actions and make decisions about whether to continue or change interventions to meet outcomes. Assessments provide structure for documenting nursing care. Focused assessments enable the nurse to identify responses to a disease process or treatment modality not present during the initial assessment, and to identify new problems and concerns (Alfaro-LeFevre, 2014; Wilkinson, 2012b). Focused assessments are linked to clinical reasoning as the nurse attends to collecting and analyzing data related to the patient's immediate and salient health concerns.

To make accurate and holistic assessments, nurses must have and use a wide variety of knowledge and skills. The ability to assess the physical status of the patient is essential, as is the ability to communicate effectively. Nurses must know and understand pathophysiology and pharmacology and be able to identify abnormal laboratory and diagnostic test data. Finally, nurses need a solid foundation of nursing knowledge and skill to interpret assessment data and to use that interpretation as the basis for individualized care.

Nurses use a number of clinical reasoning skills when assessing. An attitude of inquiry is used during data gathering. The nurse must distinguish relevant data from those that are irrelevant, as well as important data from unimportant data. In addition, the nurse identifies missing data and seeks additional information to fill in gaps (Wilkinson, 2012b).

MEMORY CUE

Remember that assessment is collecting and interpreting the meaning of data; it is not forming judgments about a particular patient. "Patient is angry and out of control" is a judgment; "patient is pacing, talking loudly and with a rapid cadence" is an assessment.

DIAGNOSIS

The ANA (2013) defines *nursing* as "the protection, promotion, and optimization of health and abilities, prevention of illness and injury alleviation of suffering through the diagnosis and treatment of human response." Many agencies use the term *nursing problem* instead of *nursing diagnosis*. Additionally, with the increasing emphasis on interprofessional and patient-centered care, the practice of identifying health concerns by using brief problem statements is increasing because this approach provides a unified language that is recognized by multiple health disciplines and more understandable to patients than nursing diagnosis nomenclature. We use both problem statements and nursing diagnoses in this text.

In the problem identification/diagnosis phase of the nursing process, the nurse uses assessed data, knowledge of expected responses, intuition, and prior experience to analyze data and draw conclusions about its meaning. The nurse then designates each nursing problem by using a brief statement to define the problem or labels each identified health concern with a nursing diagnosis, a statement that describes the patient's current health status. Nursing diagnoses describe actual or potential health problems that can legally be diagnosed by the nurse, for which the nurse can prescribe the primary interventions, and for which the nurse is accountable (Wilkinson, 2012a).

The nurse analyzes assessment data to support appropriate nursing problem statements and diagnoses. During analysis, the nurse organizes or categorizes data so that it can be used to identify actual or potential health problems. Data can be organized within a variety of frameworks. Methods commonly used are basic human needs (Maslow, 1970), body systems, human response patterns, and functional health patterns (Gordon, 1994). Gordon's functional health patterns are used in many healthcare systems to help nurses organize data and care. Identifying health concerns or needs and delineating a problem statement or making a diagnosis is a complex process that always involves uncertainty. Therefore, the nurse uses diagnostic reasoning to choose a problem statement or nursing diagnosis that best defines the individual patient's health problems. Diagnostic reasoning is used to make decisions about which label (or diagnosis) best describes the patterns of data. Box 1–1 outlines the steps and processes the nurse uses in diagnostic reasoning.

Diagnoses made by nurses generally fall within three categories:

1. Nursing problem/actual nursing diagnoses: a health problem identified during assessment that can be relieved or resolved through nursing interventions
2. Potential (or risk) nursing problem/diagnoses: a health problem that is likely to develop unless the nurse intervenes
3. Collaborative problems: a health problem that requires both medical and nursing interventions; nurses monitor for and intervene to reduce complications (Wilkinson, 2012b).

BOX 1–1 Overview of Diagnostic Reasoning

Interpret the Data

LEVEL I—IDENTIFY SIGNIFICANT CUES

1. *Organize data* in a concise format, using nursing framework.
2. *Compare individual data to standards and norms* to identify significant cues.

LEVEL II—CLUSTER CUES AND IDENTIFY DATA GAPS

3. *Cluster significant cues*; look for patterns and relationships.
4. *Categorize clusters* according to your framework.
5. *Identify data gaps and inconsistencies.*

LEVEL III—DRAW CONCLUSIONS ABOUT THE PRESENT HEALTH STATUS

6. *Think of as many explanations as possible for each cue cluster. Then decide which hypothesis best explains it.* (*Note:* You can sometimes identify both the problem and etiology in this step.)
7. *Identify problem* (wellness diagnoses; actual, potential, and possible nursing problem/diagnoses; collaborative problems; and medical problems).
8. *Identify patient and family strengths.*

LEVEL IV—DETERMINE ETIOLOGIES AND CATEGORIZE PROBLEMS

9. *Determine the etiologies of the problems.*
10. *Categorize problems according to your framework.*

Verify the Problem/Diagnoses

11. *Verify the diagnoses and strengths* with the patient, family, other professionals, and references.

Label the Problem/Diagnoses

12. *Choose standardized problem label.* The appropriate label will be contextual according to the setting and norms of the practice setting. Some settings use NANDA diagnoses, many use standard problem statements specific to the agency. Write formal health status statements: nursing and wellness problem/diagnoses, collaborative problems, and strengths.
13. *Prioritize the problems.*

Record the Data

14. *Record the problem statements* on the appropriate documents: patient care plan, chart, etc.

Source: From Wilkinson, Judith M., *Nursing Process and Critical Thinking*, 5th ed., © 2012b. Reproduced by permission of Pearson Education, Inc., Upper Saddle River, New Jersey.

NANDA Although there is no universal list of diagnoses used in nursing, the ongoing work of NANDA is widely accepted. The diagnoses are classified by a taxonomy; that is, they are grouped into classes and subclasses based on patterns and relationships. The NANDA system was accepted in 1988 by the ANA as the official system of nursing diagnosis for the United States. Nursing problem statements and nursing diagnoses within the NANDA taxonomy are used in this book. Where appropriate, collaborative problems also are identified.

WRITING DIAGNOSES A diagnosis is written in two parts joined by the phrase *related to*. The first part of the statement describes the patient's health status. It identifies what needs to change in a specific patient as a result of nursing interventions, and suggests the patient outcomes that measure the change. The part of the statement that follows the *related to* phrase identifies the physical, psychosocial, cultural, spiritual, and/or environmental factors (etiologies) that cause or contribute to the occurrence of the response.

Many nurses write nursing diagnoses using a method known as PES (Gordon, 1994). Diagnoses written with this method have three components:

1. The problem (P), which is the NANDA label
2. The etiology (E) of the problem, which names the related factors and is indicated by the phrase *related to*
3. The signs and symptoms (S), which are the defining characteristics and are indicated by the phrase *as manifested by.*

Examples of nursing diagnoses written with the PES method are as follows:

- *Anxiety* related to hospitalization as manifested by statements of nervousness and by crying
- *Bowel Incontinence* related to loss of sphincter control as manifested by involuntary passage of stool
- *Fatigue* related to the side effects of chemotherapy as manifested by the inability to carry out normal daily routines and statements of overwhelming exhaustion.

PLANNING

During the planning step, the nurse identifies the desired patient outcomes of care and nursing interventions to achieve those outcomes. Outcomes, which are mutually established by the patient and nurse may include other disciplines involved in the healthcare team and describe the expected patient responses that will occur as a result of the nursing interventions. Nursing interventions (actions) are specifically planned to achieve the desired outcomes. Both outcomes and nursing interventions are documented in a written plan of care that directs nursing activities and documentation and provides a tool for evaluation (Alfaro-LeFevre, 2014).

Nurses plan interventions for problems that require nursing management (stated as nursing diagnoses) and for collaborative or clinical problems. Nursing diagnoses provide the basis for selecting nurse-initiated interventions to achieve outcomes for which the nurse is accountable. Collaborative problems are often based on medical diagnoses (such as hemorrhage) that nurses monitor to detect onset or changes in status.

Outcome criteria for nursing problems/diagnoses are patient centered, time specific, and measurable. They are classified into three domains: cognitive (knowing), affective (feeling), and psychomotor (doing). The nurse considers all three domains to ensure holistic care.

Outcome criteria for collaborative problems follow the same pattern. For example, "Respiratory complications will not occur as evidenced by clear lung sounds, pulse, respiratory rate, and temperature in normal range for patient throughout recovery period."

Planned nursing interventions must be specific and individualized. If, for example, the nurse identifies that a patient is at risk for a fluid volume deficit, it is not enough that the nurse simply encourage the patient to drink increased amounts of fluid. The nurse and the patient together must identify those liquids the patient prefers, the times that will be best for drinking them, and the amount of fluid (in ounces or milliliters); this information is documented as a nursing order on the written care plan. Only then does care truly become a part of the plan of care.

EVIDENCE-BASED PRACTICE GUIDELINES Whenever possible, planned nursing interventions are based on evidence, that is, nursing

Moving Evidence into Action

Quality Improvement

Recognition of the need to pursue quality nursing care based on the best available evidence has significantly increased in recent years (Scott, 2012). The ANA and other healthcare organizations are promoting the identification and measurement of **nursing-sensitive quality indicators (NSQIs)** to promote achievement of better patient outcomes. Healthcare payers such as the Centers for Medicare and Medicaid Services (CMS) recently instituted an incentive program called Pay for Performance that compensates hospitals and health systems based on quality measures. Outcomes that are nursing sensitive are those affected by the quality and quantity of nursing care. Hospital-acquired pressure ulcers, patient falls, IV infiltrations, restraint use, and healthcare-associated infections are examples of NSQIs. Outcomes that are designated as nursing sensitive are identified through rigorous scientific and evidence-based review, input from patients and their families, and input from nurses and other healthcare providers. The ANA has developed the National Database of Nursing Quality Indicators (NDNQI) to provide the mechanism for collecting, evaluating, and reporting NSQIs. The NDNQI currently has 21 measures; 11 are endorsed by the National Quality Forum. Data related to quality measures are presented to frontline nursing staff through easy-to-read dashboard reports, allowing nurses to gain evidence-based understanding of how their practice affects patient care and financial revenue at the point of care. The NDNQI provides comparison data at the unit and hospital levels that can be used to compare performance with similar facilities nationwide.

Implications for Nursing

With increasing emphasis on and recognition of the importance of **quality improvement**, it is clear that practicing nurses need to be knowledgeable about nursing quality indicators. Many nurses in the current workforce were educated at a time when evidence-based quality measures were not taught or emphasized. In addition to administrative leadership and support for implementing evidence-based nursing-sensitive quality indicators, nurses need support for developing the knowledge and skills required to use data that measures NSQIs at the point of care.

Moving Knowledge into Action

1. What implications do you think the ANA's National Database of Nursing Quality Indicators has for influencing nursing practice at the point of patient care?
2. Nurses are responsible for using evidence to promote quality improvement in their nursing practice. What steps might you take to identify a nursing-sensitive quality indicator that needs improvement in your facility?
3. What do you think nurse managers and administrators could do to encourage more nurses to effectively use the NDNQI to improve the quality of nursing care?

research and nursing practice guidelines. Currently, significant work is being done to develop evidence-based nursing practice guidelines. Guidelines are collections of practical information used to help guide decisions related to specific circumstances (Melnyk et al., 2010). Nurses use guidelines to help identify appropriate interventions for a given nursing care problem or diagnosis. Evidence-based nursing care guidelines also show the strength of the evidence (research) used, allowing nurses to evaluate the appropriateness of a given guideline for the individual circumstance. Evidence-based nursing guidelines are available through specialty nursing organizations, healthcare systems, on the web, and in published resources. See Chapter 2 for more information about nurses' use of evidence in nursing practice.

CARE BUNDLES A **care bundle** is defined by the IHI (2012) as a "small set of evidence-based interventions for a defined patient segment/population and care setting that, when implemented together, will result in significantly better outcomes than when implemented individually" (p. 2). Care bundles are **interprofessional care** standards that pull together a short list of interventions and treatments that are already recommended and are generally accepted in national guidelines. Examples of care bundles include the IHI Ventilator Bundle and the IHI Central Line Bundle (Reser et al., 2012). The IHI developed guidelines the intraprofessional team can use when designing care bundles. Box 1–2 outlines the IHI guidelines.

IMPLEMENTATION

The implementation step is the action or doing phase of the nursing process, during which the nurse carries out planned interventions. In some instances, the nurse assigns and supervises nursing assistive personnel in carrying out planned interventions. Ongoing assessment of the patient before, during, and after the intervention is an essential component of implementation in either case. Although the plan may be appropriate, many variables can modify or negate any planned intervention, making a change in the plan necessary. For example, the nurse would not be able to force fluids if the patient were nauseated or vomiting.

When implementing the planned interventions, the nurse follows several important principles:

- Set daily priorities, based on initial assessments and on the patient's condition as reported during the change of shift report and/or documented in the patient's chart. Ensure that critical assessments (such as status of invasive lines, fluids infusing, or changes in health status during the preceding shift) take first priority.
- Be aware of the interrelated nature of nursing interventions. For example, while giving a bath the nurse can also assess physical and psychologic status, use therapeutic communication, teach the patient, do range-of-motion exercises, and provide skin care.

Evidence for Nursing Care

Planning Nursing Care

Selected resources that nurses may find helpful when planning evidence-based nursing care follow.

- Dickson, G. L., & Flynn, L. (2012). Nurses' clinical reasoning: Processes and practices of medication safety. *Qualitative Health Research, 22*(1), 3–16.
- Harder, R. (2013, February). How connected are you? *Nursing Management,* pp. 19–23.
- King, B. J., Mills, P., Fore, A., & Mitchel, C. (2012). The daily plan: Including patients for safety's sake. *Nursing Management,43*(3), 15–18.
- Pavlish, C., Brown-Saltzman, K., Hersh, M., Shirk, M., & Rounkle, A. (2011). Nursing priorities, regrets for ethical situations in clinical practice. *Journal of Nursing Scholarship, 43*(4), 385–395.

- Determine the most appropriate interventions for each patient, based on health status and illness treatment. Examples of appropriate interventions include the following:
  - Directly perform the activity for the patient.
  - Assist the patient to perform the activity.
  - Supervise the patient/family while they are performing the activity.
  - Assign and supervise nursing assistive personnel to perform the activity.
  - Teach the patient/family about healthcare.
  - Monitor the patient at risk for potential complications or problems.
- Use available resources to provide interventions that are realistic for the situation and practical in terms of equipment available, financial status of the patient, and resources available (including staff, agency, family, and community resources).

Documenting interventions is the final component of implementation, and it is a legal requirement. Care can be documented in many different ways. Narrative source-oriented and problem-oriented charting methods are used, as are focused charting, charting by exception, and computer-assisted documentation.

EVALUATION

The evaluation step allows the nurse to determine whether the plan was effective, as well as determine whether to continue the plan, revise the plan, or terminate the plan. The outcome criteria that were established during the planning step provide the basis for evaluation. Evaluation takes place continuously throughout patient care, as illustrated earlier in Figure 1–1.

To evaluate a plan, the nurse collects data from the patient and the patient's chart. The nurse then compares the status of the patient with the written outcomes. If the outcomes have been accomplished, the nurse may either continue or terminate the plan. If the outcomes have not been accomplished, the nurse must modify the nursing problem/diagnoses, outcomes, or plan.

BOX 1–2 IHI Bundle Design Guidelines

The bundle has three to five interventions (elements), with strong clinician agreements. The bundles integrate a short list of already recommended guidelines that are accepted nationally or through consensus by local clinicians.

Each bundle is relatively independent. The bundle is developed so that if one of the interventions of care is not implemented it will not affect whether other bundle elements are implemented.

The bundle is used with a defined patient population in one location. Evidence indicates a bundle is most successful if applied to a particular patient population in a defined location. For example, there are two bundles for patients experiencing sepsis. One bundle applies to managing patients in the emergency department and another for managing patients with sepsis in the critical care environment.

The interprofessional team develops the bundle. Communication and teamwork are essential to successful implementation of a bundle.

Bundle elements should be descriptive rather than prescriptive, to allow for local customization and appropriate clinical judgment. For instance, the interventions that address prophylactic treatment for deep venous thrombosis in the Ventilator Bundle do not specify the type of prophylaxis.

Compliance with bundles is measured using all-or-nothing measurement, with a goal of 95% or greater. If any of the interventions are not documented, implementation of the bundle is considered incomplete and no partial credit is given.

THE NURSING PROCESS IN CLINICAL PRACTICE

With experience, the nurse does not consciously stop and consider each step of the nursing process. Rather, using the process as a framework, care is based on the patient's specific, individualized needs. For example, when caring for a patient who is hemorrhaging, the nurse uses all five steps simultaneously to meet critical, life-threatening needs. In contrast, when considering long-term needs for a patient with a chronic illness or disability, the nurse makes in-depth assessments, mutually determines goals with the patient, and documents a written plan of care that is developed and revised as necessary by all nurses providing care. As a nurse becomes an expert practitioner, the nursing process becomes so much a part of the nurse that he or she may not even consciously consider it while providing care; the practice is the process (Benner, 1984).

GUIDELINES FOR NURSING PRACTICE

Nursing practice is structured by codes of ethics and standards that guide nursing practice and protect the public. Individual nursing practice is held to these standards in a court of law. The guidelines are especially important because nurses encounter legal and ethical problems almost daily.

Codes for Nurses

An established **code of ethics** is one criterion that defines a profession. **Ethics** are principles of conduct. Ethical behavior is concerned with moral duty, values, obligations, and the distinction between right and wrong. Codes of ethics for nurses provide a frame of reference for "professionally valued and ideal nursing behaviors that are congruent with the principles expressed in the Code for Nurses" (Ketefian, 1987, p. 13).

The large number of ethical issues facing nurses in clinical practice makes the established codes for nurses critical to moral and ethical decision making. The codes also help to define the roles of nurses. The codes of ethics presented here were developed by and for members of the International Council of Nurses (ICN) and the ANA.

THE ICN CODE

The *ICN Code of Ethics for Nurses* (2012) helps guide nurses in setting priorities, making judgments, and taking action when they face ethical dilemmas in clinical practice. The ICN code specifies what nurses are accountable for in terms of people, practice, society, coworkers, and the profession. The philosophical basis for the ICN code is that nurses are responsible for promoting health, preventing illness, and alleviating suffering.

THE ANA CODE

The ANA *Code of Ethics for Nurses* (2001) states principles of ethical concern, guiding the behavior of nurses and also defining nursing for the general public (Box 1–3). The ANA *Code of Ethics for Nurses* is a dynamic document and undergoes periodic update. At the time of this publication, the ANA code was undergoing revision using a consensus process. Ensuring awareness of and application in practice of

BOX 1–3 The American Nurses Association Code of Ethics for Nurses

- The nurse, in all professional relationships, practices with compassion and respect for the inherent dignity, worth, and uniqueness of every individual, unrestricted by considerations of social or economic status, personal attributes, or the nature of health problems.
- The nurse's primary commitment is to the patient, whether an individual, family, group, or community.
- The nurse promotes, advocates for, and strives to protect the health, safety, and rights of the patient.
- The nurse is responsible and accountable for individual nursing practice and determines the appropriate delegation of tasks consistent with the nurse's obligation to provide optimum patient care.
- The nurse owes the same duties to self as to others, including the responsibility to preserve integrity and safety, to maintain competence, and to continue personal and professional growth.
- The nurse participates in establishing, maintaining, and improving healthcare environments and conditions of employment conducive to the provision of quality healthcare and consistent with the values of the profession through individual and collective action.
- The nurse participates in the advancement of the profession through contributions in practice, education, administration, and knowledge development.
- The nurse collaborates with other health professionals and the public in promoting community, national, and international efforts to meet health needs.
- The profession of nursing, as represented by associations and their members, is responsible for articulating nursing values, for maintaining the integrity of the profession and its practice, and for shaping social policy.

the most current and approved document is the responsibility of the professional registered nurse.

Standards of Nursing Practice

A **standard** is a statement or criterion that can be used by a profession and by the general public to measure the quality of practice. Established standards of nursing practice make each individual nurse accountable for practice. This means that each nurse providing care has the responsibility or obligation to account for his or her own behaviors within that role. Professional nursing organizations develop and implement standards of practice to identify clearly the nurse's responsibilities to society.

The ANA Standards of Practice (2010) are outlined in Table 1–3. These standards allow objective evaluation of nursing licensure and certification, institutional accreditation, quality assurance, and public policy.

HEALTH INFORMATION PRIVACY RULES

Although the right to privacy of health and other personal information is an accepted ethical principle of nurses and other healthcare providers, federal rules also govern what can be shared and with whom. The Health Insurance Portability and Accountability Act and the Standards for Privacy of Individually Identifiable Health Information, commonly referred to together as HIPAA, are designed to protect individuals' health information while allowing such information to be shared as needed for effective care. The rules apply to those who transmit health information electronically—including nurses and others employed in hospitals, clinics, and other settings.

While often misinterpreted, HIPAA rules allow disclosure of health information for treatment purposes, even without the patient's explicit consent. Although the patient's privacy is to be protected,

TABLE 1–3 ANA Standards of Practice

Standards of Practice	Standards of Professional Performance
• Assessment: The registered nurse collects comprehensive data pertinent to the patient's health or the situation. • Diagnosis: The registered nurse analyzes the assessment data to determine the diagnoses or issues. • Outcomes Identification: The registered nurse identifies expected outcomes for a plan individualized to the healthcare consumer or the situation. • Planning: The registered nurse develops a plan that prescribes strategies and alternatives to attain expected outcomes. • Implementation: The registered nurse implements the identified plan, coordinates care delivery, and employs strategies to promote health and a safe environment. The advanced practice registered nurse also provides consultation and uses prescriptive authority, procedures, referrals, treatments, and therapies.	• Ethics: The registered nurse practices ethically. • Education: The registered nurse attains knowledge and competency that reflects current nursing practice. • Evidence-Based Practice and Research: The registered nurse integrates evidence and research findings into practice. • Quality Nursing Practice: The registered nurse contributes to quality nursing practice. • Communication: The registered nurse communicates in a variety of formats in all areas of practice. • Leadership: The registered nurse demonstrates leadership in the professional practice setting and the profession. • Collaboration: The registered nurse collaborates with patient, family, and others in the conduct of nursing practice. • Professional Practice Evaluation: The registered nurse evaluates her or his own nursing practice in relation to professional practice standards and guidelines, relevant statues, rules, and regulations. • Resource Utilization: The registered nurse utilizes appropriate resources to plan and provide nursing services that are safe, effective, and financially responsible. • Environmental Health: The registered nurse practices in an environmentally safe and healthy manner.

safety protections such as posting the patient's name outside his or her room are allowed to help ensure that care is provided to the correct patient. Unless the patient specifically objects, health information also can be shared with family members who are involved in the patient's care. Other state or federal laws may override the patient's right to privacy of health information, for example, laws that require nurses and other healthcare providers to report evidence of child, older adult, or spousal abuse.

PROFESSIONAL BOUNDARIES

Nurses are expected to act in the best interests of the patient. They must avoid use of their position for personal gain and not become involved in the patient's personal relationships. **Professional boundaries** are the borders between the vulnerability of the patient and the power of the nurse. The nurse's position as care provider and knowledge of private information about the patient places the nurse in a position of power. It is vital that nurses recognize this relationship, and establish boundaries to safely and effectively meet the patient's needs. Confusion between the needs of the nurse and those of the patient can result in boundary violations (National Council of State Boards of Nursing, 2009). It is the nurse's responsibility to establish and maintain professional boundaries, providing an appropriate level of involvement for effective care.

LEGAL AND ETHICAL DILEMMAS IN NURSING

A **dilemma** is a choice between two unpleasant, ethically troubling alternatives. Nurses who provide medical-surgical nursing care face dilemmas almost daily. Many commonly experienced dilemmas involve confidentiality, patient rights, and issues of dying and death. The nurse must use ethical and legal guidelines to make decisions about moral actions when providing care in these and in many other situations.

Nurses respect the right to confidentiality of patient information found in the patient's record or secured during interviews. However, an individual's right to privacy and confidentiality creates a dilemma when it conflicts with the nurse's right to information that may affect personal safety. The law in most states mandates that HIV test results can be given to another person only with the patient's written consent. Many healthcare providers believe that this law violates their own right to personal safety.

The right to refuse treatment (including surgery, medication, medical therapy, and nourishment) also raises nursing dilemmas. The situation, the alternatives, and the potential harm from refusal must be carefully explained. The nurse is faced with the dilemma of respecting the patient's autonomy or following the ethical principle of beneficence, doing what is best for the patient.

Issues surrounding dying and death have become increasingly pressing as advances in technology extend the lives of people with chronic, debilitating illness and major trauma. These changes have altered concepts of living and dying, resulting in ethical conflicts regarding quality of life and death with dignity versus technologic methods of preserving life in any form.

Even if the patient is competent and requests that no heroic measures be used to maintain life, many questions arise in nursing care. What constitutes a heroic measure? Should nursing interventions to provide comfort include administering narcotics at a level known to depress respirations? These and other questions are being debated not only within the healthcare system but also in the courts.

ROLES OF THE NURSE IN MEDICAL-SURGICAL NURSING PRACTICE

Healthcare today is embedded in a vast and complex system. It reflects changes in society, changes in the populations requiring nursing care, changes in reimbursement, and an emphasis on quality and safety and a philosophical shift toward health promotion rather than illness care. The roles of the medical-surgical nurse have broadened and expanded in response to these changes. Medical-surgical nurses are increasingly expected to be caregivers, educators, advocates, leaders and managers, and researchers. The nurse assumes these various roles to promote and maintain health, to prevent illness, and to facilitate coping with disability or death for the adult patient (an individual requiring healthcare services) in any setting.

The Nurse as Caregiver

Nurses have always been caregivers. However, the activities carried out within the caregiver role have changed tremendously in the 21st century. From 1900 to the 1960s, the nurse was regarded primarily as the person who gave personal care and carried out physicians' orders. This dependent role has changed as a result of the increased education of nurses, research in and the development of nursing knowledge, and the recognition that nurses are autonomous and informed professionals.

The caregiver role for the nurse today is both independent and collaborative. Nurses independently make assessments and plan and implement patient care based on nursing knowledge and skills. Nurses also collaborate with other members of the healthcare team to implement and evaluate care (Figure 1–2 ■).

Figure 1–2 ■ The healthcare team discusses the individualized plan of care and outcomes.
Source: Arno Massee/Science Photo Library/Alamy.

As a caregiver, the nurse practices both the science and the art of nursing. In medical-surgical nursing, the science requires a deep understanding of normal physiology and the pathophysiology underlying disease processes commonly affecting adults. Just as the pediatric nurse must understand the physical and psychosocial development of children, the medical-surgical nurse must understand the physical, psychosocial, economic, and developmental differences among adults spanning from the late teens to older adults who are living into their 80s, 90s, and even 100. Using clinical reasoning in the nursing process as the framework for care, the nurse provides interventions to meet not only the physical needs but also the psychosocial, cultural, spiritual, and environmental needs of patients and families. See Box 1–4 for a discussion of culturally competent nursing care. Considering all aspects of the patient ensures a holistic approach to nursing. Holistic nursing care is based on a philosophical view that interacting wholes are greater than the sum of their parts. A holistic approach also emphasizes the uniqueness of the individual.

In providing comprehensive, individualized care, the nurse uses a variety of reasoning skills to analyze and synthesize knowledge from the arts, the sciences, and nursing research and theory. The science (knowledge base) of nursing is translated into the art of nursing through caring. Caring is the means by which the nurse is connected with and concerned for the patient (Benner & Wrubel, 1989). Thus, the nurse as caregiver is knowledgeable, skilled, empathic, and caring.

The Nurse as Educator

The nurse's role as educator is increasingly important for several reasons. Healthcare providers and consumers as well as local, state, and federal governments are placing greater emphasis on health promotion and illness prevention, hospital stays are shorter, and the number of individuals who are chronically ill in our society is increasing. Early discharge of patients from the hospital setting or rehabilitation facility to home care means that family caregivers must learn how to perform complex skills. All of these factors make the educator role essential to maintaining the health and well-being of patients.

Health literacy has become an increasing concern as patients take a more active role in their healthcare. Health literacy is the degree to which individuals have the capacity to obtain, process, and understand basic health information and services needed to make appropriate health decisions (U.S. Department of Health and Human Services, 2010). Medical-surgical nurses are instrumental in assessing the health literacy of patients and fulfilling the role of educator to ensure that patients have and can apply the health information required for achieving optimum health and healing. The framework for the role of educator is the teaching–learning process. Within this framework, the nurse assesses learning needs, plans and implements teaching methods to meet those needs, and evaluates the effectiveness of the teaching. To be an effective educator, the nurse must have

BOX 1–4 Culturally Competent Nursing

The primary focus of nursing care is the patient, as the patient relates to the environment and experiences events or situations related to health or illness. These experiences are given shape and personal meaning by culture—the socially inherited characteristics of a human group. These characteristics include the beliefs, practices, habits, likes, dislikes, customs, and rituals people learn from their families and pass on to their children. Cultural background is an essential component of an individual's ethnic identity. An individual's ethnic identity includes belonging to a social group within a culture and a social system and sharing a common religion, language, ancestry, and physical characteristics.

The healthcare system encompasses patients who are culturally diverse. This diversity includes differences in country of origin, health beliefs, sexual orientation, race, socioeconomic level, and age. Despite increasing diversity, nursing has been slow to address the need for culturally competent care. Many different factors account for this inattention, including ethnocentrism (people's belief that their own cultural group's beliefs and values are the only acceptable ones) and prejudice. The healthcare system is itself a culture, composed primarily of White middle-class people, and it often serves as a barrier to culturally competent care.

The 1992 American Academy of Nursing Expert Panel on Culturally Competent Nursing Care identified several reasons why it has become increasingly important for nurses to plan for and provide culturally competent care:

- The demographic and ethnic composition of the population of the world in general, and the United States in particular, has changed markedly, and there is a lack of ethnic representation in healthcare professionals in the healthcare system. Information on and knowledge about values, beliefs, experiences, and healthcare needs of various populations is limited.
- There is a growing awareness and acceptance of diversity and an increased willingness to maintain and support ethnic and cultural heritage.
- People of color and immigrants are facing increasing unemployment, decreasing opportunity, and limited access to healthcare. These conditions may contribute to the establishment of new minorities, such as the homeless.
- The international focus on providing healthcare for all people (within the context of inequity, barriers, and lack of access) may have raised the consciousness of healthcare professionals to some of the inequities inherent in healthcare systems in both developing countries and developed countries.
- Nurses comprise the largest force in the delivery of healthcare and therefore have the potential to contribute to the changing inequities in and inaccessibility to healthcare.
- Consumers are becoming increasingly aware of what is competent and sensitive healthcare.

This same panel of experts proposed general principles for nurses for becoming sensitive to cultural diversity and providing culturally competent care. For example,

- Nurses must learn to appreciate intergroup and intragroup cultural diversity and commonalties in racial/ethnic minority populations.
- Nurses must understand how social structure factors shape health behaviors and practices among members of racial/ethnic minorities.
- Nurses must confront their own ethnocentrism and racism.
- Nurses must begin rehearsing, practicing, and evaluating services provided to cross-cultural populations.

People of every culture have the right to have their cultural values known, respected, and addressed appropriately in nursing and other healthcare services (Leininger, 1991). To provide nursing care that is culturally competent, nurses must develop sensitivity to personal fundamental values about health and illness; must accept the existence of differing values; and must be respectful of, interested in, and understanding of other cultures without being judgmental.

Figure 1–3 ■ The nurse's role as educator is an essential component of care. As part of the discharge planning process, the nurse is responsible for teaching for self-care at home.
Source: Barros & Barros/Getty Images, Inc.

effective interpersonal skills and be familiar with adult learning principles (Figure 1–3 ■).

A major component of the educator role today is discharge planning. Discharge planning, which begins on admission to a healthcare setting, is a systematic method of preparing the patient and family for exit from the healthcare agency and for maintaining continuity of care after the patient leaves the setting. Discharge planning also involves making referrals, identifying community and personal resources, and arranging for necessary equipment and supplies for home care. Changes in payment systems suggest that hospitals may not be reimbursed for readmission within 30 days of discharge. All of these changes in healthcare delivery are increasing the importance of providing comprehensive discharge planning and teaching.

The Nurse as Advocate

The patient entering the healthcare system may be unprepared to make independent decisions. However, today's healthcare consumer is better educated about options for care, and may have very definite opinions. The nurse as patient advocate actively promotes the patient's rights to autonomy and free choice. The goals of the nurse as advocate are to do the following:

- Assess the need for advocacy.
- Communicate with other healthcare team members.
- Provide patient and family teaching.
- Assist and support patient decision making.
- Serve as a change agent in the healthcare system.
- Participate in health policy formulation.

The nurse must practice advocacy by believing that patients have the right to choose treatment options based on information about the results of accepting or rejecting the treatment, without coercion. The nurse must also accept and respect the decision of the patient, even though it may differ from the decision the nurse would make.

The Nurse as Leader and Manager

All nurses are leaders and managers. They practice leadership and they manage time, people, resources, and the environment in which they provide care. Nurses carry out these roles by directing, delegating, supervising, and coordinating nursing activities. Nurses must be knowledgeable of how and when to delegate, as well as the legal requirements of delegation. Nurses also evaluate the quality of care provided.

MODELS OF CARE DELIVERY

Nurses are leaders and managers of patient care within a variety of models of care delivery. Examples are primary nursing, team nursing, and transitional care coordination. The nursing shortage made the combination of primary and team nursing more economically feasible.

PRIMARY NURSING Primary nursing allows the nurse to provide individualized direct care to a small number of patients during their entire inpatient stay. This model was developed to reduce the fragmentation of care experienced by patients and to facilitate family-centered continuity of care. In primary nursing, the nurse provides and coordinates care; communicates with patients, families, and other healthcare providers; and carries out discharge planning.

TEAM NURSING Team nursing is practiced by teams of variously educated healthcare providers. For example, a team may consist of a registered nurse, a licensed practical nurse, and two unlicensed assistive personnel (UAPs). The registered nurse is the team leader. The team leader is responsible for making assignments and has overall responsibility for patient care by team members. All team members work together, each performing the activities for which he or she is best prepared.

TRANSITIONAL CARE COORDINATION This type of coordination focuses on management of a caseload (group) or panel of patients and the members of the healthcare team caring for those patients. The purpose of care coordination is to achieve the IHI's Triple Aim: to improve the patient care experience, to maximize positive outcomes, and to contain costs. The role of case manager is a similar position and is usually a clinical specialist. The emerging role of care coordination also involves managing a caseload or panel of patients that consists of patients with similar healthcare needs. As case manager or care coordinator, the nurse emphasizes continuity of care during transitions between healthcare settings. Managing **transitional care** involves ensuring that critical information and care planning is continuous between settings with an eye toward ensuring that the healthcare team works together to promote optimum outcomes (Henderson et al., 2012). Patients are at risk for experiencing complications and adverse events during transitions between settings, or when care is transferred from one provider to another. Medications are sometimes administered or taken incorrectly when the patient is discharged to home. Critical signs and symptoms are overlooked and not reported. These disruptions in treatment plans lead to patient suffering, adverse effects on health, and increased healthcare costs (Henderson et al., 2012). The care coordinator may be part of the healthcare team within a **patient-centered medical home (PCMH)** or **accountable care organization (ACA)**. The PCMH/ACA healthcare team is led by the patient's primary care provider and includes a care coordinator who is often an RN. The primary care provider is responsible for leading the development of the plan of care with the patient and the family. The care coordinator collaborates with the patient and the rest of the healthcare team to implement and monitor the plan. The care coordinator makes appropriate referrals to other healthcare providers and manages the quality of care provided, including accuracy, timeliness, and cost.

The case manager/care coordinator also is in contact with patients after discharge, ensuring continuity of care and health maintenance. The expansion of the Affordable Care Act is expanding the role of care coordination, especially in the management of patients with chronic disease and during transitions of care.

DELEGATION

Delegation is carried out when the nurse assigns appropriate and effective work activities to other members of the healthcare team. When the nurse delegates nursing care activities to another person, that person is authorized to act in the place of the nurse, while the nurse retains the accountability for the activities performed. Delegation skills are becoming increasingly important in healthcare as agencies restructure and implement cost containment measures. More categories of healthcare workers with minimal nursing education and experience are being hired to assist the registered nurse as *nurse extenders*, or *UAPs*. The Affordable Care Act includes provisions for an increase in the use of UAPs. Guidelines for delegation include the following:

- Consider the training, experience, and competence of each member of the healthcare team, the complexity of the task to be assigned, and the amount of time available to supervise the tasks.
- Determine the level of nursing judgment and evaluation required for the task.
- Consider the patient's condition and the potential harm and difficulty of performing the task.
- Know the state's nurse practice act and any practice limitations that may exist.
- Delegate only tasks that are within the scope of practice or authorized duties for each category of worker.
- Assign the right job to the right person. Tasks that are routine and standard are the best to assign to others.
- Know when it is appropriate to retain direct responsibility for care activities. The nurse should perform tasks that are complex or require a high level of nursing judgment.
- Give clear and complete directions for assignments. Ask questions to be sure directions have been understood.
- Give the team member the authority to complete the task while remaining accountable for the outcomes of care.
- Monitor the care provided and give constructive evaluation if necessary.

QUALITY AND SAFETY

As a major sector within the healthcare workforce, nurses have a significant responsibility for ensuring the quality and safety of care patients receive. This responsibility goes beyond ensuring that individual patients receive safe and effective patient-centered nursing care to recognizing healthcare system issues that impact quality of care. The current focus of safety initiatives is on minimizing the risk of harm to patients and providers by improving the performance and effectiveness of both individuals and healthcare systems (Cronenwett et al., 2007). All nurses must be prepared to understand, take seriously, and participate in quality and safety improvement strategies.

As a leader and manager, the nurse encourages the use of strategies such as standardized practices, checklists, and technology to improve safety and quality. When an error or near miss occurs, the nurse's focus is on reporting the incident to promote analysis of the factors and systems leading up to it, not on blaming the individuals involved.

In the role of leader and manager, the nurse is responsible for the quality of patient care through a process of quality improvement. Quality improvement uses data to monitor the outcomes of care and the processes used to deliver that care. Changes to improve the quality and safety of healthcare systems are continuously designed and tested through quality improvement strategies and initiatives (Cronenwett et al., 2007). **Health information technology (HIT)** is critical for accessing evidence-based practice standards and guidelines that are used to promote quality improvement strategies. Health information systems are used to collect data, share information, and provide analytic tools that inform approaches to care that lead to better patient outcomes (Cipriano, 2012). The integration of HIT is central to improving care and reducing costs because it reduces duplication of tests, improves access to information about the cost effectiveness of interventions, and provides the ability to compile a comprehensive health history (McBride et al., 2012).

Quality improvement methods are used to evaluate patient care. Nurses commonly evaluate actual care against an established set of standards of care. Nurses and other healthcare providers make this evaluation by reviewing documentation, by conducting patient surveys and nurse interviews, and/or by direct observation of a nurse while patient care is being provided. The data are then used to identify differences between actual practice and established standards and to develop a plan of action to resolve the differences. The actions are then assessed through internal peer review or by an external medical review organization, called a utilization and quality control peer review organization (PRO), to determine whether they were effective in improving practice. HIT is facilitating this process as systems include the patient electronic medical records and access to databases that provide standards of care and evidence-based practice guidelines.

The Nurse as Researcher

Nurses have always identified problems in patient care. Early nurse researchers showed the link between effective preoperative patient education and shorter postoperative hospital stays with fewer complications. Today, nurse researchers are studying a broad variety of questions and issues. To develop the science of nursing, nursing knowledge must be established through clinical research and then published so that the findings can be used by all nurses to provide evidence-based patient care.

To be relevant, nursing research must have a goal to improve the care that nurses provide patients. This means that all nurses must consider the researcher role to be integral to nursing practice. Summaries of relevant nursing research are included in almost all the nursing care chapters of this textbook. After the summary and discussion of each study, a clinical reasoning section specifically related to the findings of the study encourages the student to apply the findings to the clinical setting.

CHAPTER HIGHLIGHTS

- **The Patient Protection and Affordable Care Act will create new models of care and new roles for nurses that emphasize clinical reasoning, interprofessional teams, and knowledge-based technology.**
- **Recommended core competencies for all healthcare professionals include providing patient-centered care, working in interprofessional teams, using evidence-based practice, applying quality improvement, promoting safe healthcare systems, and using informatics.**
- The nursing process is the cyclical series of activities grounded in clinical reasoning and is used by nurses to provide patient care to promote wellness, maintain health, restore health, or facilitate coping with disability or death. The five interrelated phases of the nursing process are assessment, diagnosis, planning, implementation, and evaluation.
- The clinical practice of nursing is guided by codes for nurses and standards of practice.
- The human responses that nurses must consider when planning and implementing care result from changes in the structure and/or function of all body systems, as well as the effects of those changes on the psychosocial, cultural, spiritual, economic, and personal life of the patient.
- **Nurses function as caregivers, educators, advocates, leaders and managers, and researchers to promote and maintain health, prevent illness, improve healthcare delivery and systems, and facilitate coping with disability or death for the adult patient.**

TEST YOURSELF NCLEX-RN® REVIEW

1. The nurse is reviewing the National Academy of Sciences core competencies for healthcare professionals. Which competency fosters open communication, mutual respect, and shared decision making to achieve quality patient care?
   1. patient-centered care
   2. quality improvement
   3. evidence-based practice
   4. teamwork and collaboration

2. When planning care for a patient, the nurse challenges assumptions and generates possible explanations. Which clinical reasoning thinking strategy is the nurse using?
   1. critical thinking
   2. divergent thinking
   3. inductive reasoning
   4. deductive reasoning

3. The nurse is identifying outcomes while planning a patient's care. What will the nurse do when selecting appropriate outcomes?
   1. Emphasize outcomes identified by the physician.
   2. Focus on outcomes requested by family members.
   3. Determine outcomes that are mutually agreeable with the patient.
   4. Select outcomes based on organizational policies and standards.

4. The nurse is using the nursing process when providing care to assigned patients. Place in order the steps in which the nurse will use this process.
   1. planning
   2. outcomes
   3. evaluation
   4. assessment
   5. implementation

5. The nurse focuses on the science of nursing before providing care to a newly admitted patient. On what is the nurse focusing?
   1. holistic care
   2. knowledge base
   3. practice component
   4. clinical competency

6. The nurse is determining appropriate information to include in a patient's discharge instructions. In what role is the nurse functioning at this time?
   1. educator
   2. advocate
   3. caregiver
   4. researcher

7. The nurse is advocating for a patient. What is the nurse doing?
   1. performing range-of-motion exercises
   2. analyzing the effectiveness of exercise
   3. assisting and supporting patient decision making
   4. delegating responsibilities for patient care to others

8. The nurse assigns patient care activities to other members of the team. In which role is the nurse functioning?
   1. caregiver
   2. advocate
   3. researcher
   4. leader/manager

9. The nurse is using the interprofessional healthcare plan that identifies outcomes and timelines for patient goal achievement. Which tool is the nurse using to guide patient care?
   1. policy
   2. regulation
   3. care bundles
   4. quality indicator

10. The nurse delegates vital sign assessment to unlicensed assistive personnel (UAP). Who is accountable for the assessment findings?
   1. UAP
   2. nurse
   3. patient
   4. physician

2 Informatics and Evidence-Based Practice in Medical-Surgical Nursing

LEARNING OUTCOMES

1. Identify the role of nursing informatics in nursing care.
2. Describe the role of information technology such as computers and related software in nursing care.
3. Define evidence-based practice (EBP).
4. Identify the components of EBP.
5. Describe internal evidence and patient preferences in relationship to EBP.
6. List important citation sources used to locate appropriate external evidence.
7. Compare and contrast the steps of the nursing and evidence-based practice processes.
8. Discuss the role of information technology in the evidence-based practice process.
9. Describe the essential steps of the research process and common statistical methods used in nursing evidence.
10. Describe common steps to implementing EBP in medical-surgical nursing.
11. Discuss ethical considerations in EBP.

CLINICAL COMPETENCIES

1. Demonstrate correct use of computers in the planning and documentation of nursing care.
2. Assess nursing care for evidence basis.
3. Demonstrate correct steps in identifying and locating literature that provides practice evidence.
4. Use common EBP steps used to implement evidence-based practice.
5. Apply ethical behaviors when implementing evidence-based practice interventions

MAJOR CHAPTER CONCEPTS

- Nursing informatics encompasses nursing and computer and information sciences to manage information needed for nursing practice.
- Electronic medical records provide an accessible repository of patient information for all members of the healthcare team.
- Evidence-based practice is defined as the practice of nursing in which the nurse makes clinical decisions on the basis of the best available current research evidence, his or her own clinical expertise including internal evidence of patient findings, and the needs and preferences of the patient.

NURSING INFORMATICS

Nursing informatics describes the science of using information systems in nursing practice. The impetus to incorporate nursing informatics into nursing education was the Institute of Medicine's 2003 *Health Professions Education: A Bridge to Quality* report (Greiner & Knebel, 2003). That report identifies the use of informatics as one of the five core competencies for healthcare education. Informatics support effective use of information technology in patient care.

Nursing informatics as a professional focus has been described since the 1970s (Thede, 2012), with nurses playing important roles in its conceptualization, design, and implementation across nursing environments. In 1994, the American Nurses Association (ANA) began development of scope and standards for nursing informatics. The 2008 edition is the current standard. The ANA (2008) defines *nursing informatics* as "a specialty that integrates nursing science, computer science, and information science to manage and communicate data, information, knowledge, and wisdom in nursing practice" (p. 65).

Moving Evidence into Action

Defining Informatics Competencies

Informatics competencies have been described in many different ways. A study by Staggers, Gassert, and Curran (2002) described a Delphi Study design to define nursing competencies. The Delphi Study used three rounds to reach consensus about the competencies by level. The results revealed 281 distinct competencies that reached 80% consensus with 13 competencies not reaching consensus after three rounds.

The authors defined four levels of nurse informatics expertise. Level 1 is the beginning nurse who has fundamental information and technology skills to manage her or his practice. Level 2 builds on the level 1 competency. The experienced nurse who is highly skilled in information and management technology skills while being able to see relationships among data embodies level 2. The informatics specialist is at level 3 and has additional knowledge, beyond that of level 2, that integrates and applies information/computer science to nursing. Level 4 nurses are defined as informatics innovators. At this level, informatics research is conducted and informatics theory is generated. These nurses approach informatics with a sophisticated level of knowledge and skills to develop new processes to maximize outcomes.

Implications for Nursing

As nursing informatics continues to mature, the need and demand for nurse informatics experts will grow. Identifying specific skill sets for different levels of expertise will clarify the roles.

Source: From Staggers, N., Gassert, C. A., & Curran, C. (2002). A Delphi study to determine informatics competencies for nurses at four levels of practice. *Nursing Research, 51*(6), 383–390.

To support the full integration of **electronic medical records (EMRs)** by 2014, the Technology Initiative Guiding Education Reform (TIGER) program was established to "enable practicing nurses and nursing students to fully engage in the unfolding digital era of health care" (TIGER, 2007, p. 3). The TIGER initiative provides case studies that exemplify the incorporation of data-driven decisions in day-to-day nursing practice. Recommendations were provided for professional organizations, academic institutions, government and policy makers, vendors, healthcare delivery organizations, health information management professionals, and librarians to promote a multi-prong approach to the integration of informatics into nursing practice.

Nursing Informatics Competencies

The National League of Nursing described the initial categories for informatics competencies in 1988 that were developed from the International Medical Informatics Association (Peterson & Gerdin-Jelger, 1988). By 1998, the American Association of Colleges of Nursing (AACN) had provided general guidelines about nurse education in healthcare and information technologies.

As part of the TIGER initiative, informatics competencies have been described (Hebda & Calderone, 2010). The building blocks of informatics competencies include **computer literacy** (personal computer familiarity) and **information literacy** (ability to locate, evaluate, and use appropriate information effectively). Competencies have been stratified by basic competencies (all nurses), beginning nurses, and experienced nurses (Table 2–1).

TABLE 2–1 Informatics Competencies for Noninformatics Nurses

All nurses	• Retrieve and enter electronically data that relate to patient care. • Analyze and interpret information as part of planning care. • Use informatics applications designed for nursing practice. • Implement policies relevant to best practice.
Beginning nurses	• Demonstrate basic computer literacy and the ability to use desktop applications and electronic communication. • Access data and perform documentation using computerized patient records. • Recognize the role of informatics in nursing. • Acquire knowledge to support clinical and administrative processes to support evidence-based practice. • Support patient safety initiatives using information technology.
Experienced nurses	• Able to build on the competencies required for entry-level and beginning nurses. • Demonstrate expertise as a content expert in system design. • See relationships among data elements. • Execute clinical judgment based on observed data patterns. • Safeguard access to quality information. • Participate in efforts to improve information management and communication.

INFORMATION TECHNOLOGY IN HEALTHCARE

The advent and development of healthcare **information technology (IT)** has been dependent on the development of computers and applications specific to the needs of healthcare delivery, management, and reimbursement processes. From the limited use of mainframe computers in the 1960s for administrative and financial processes, through the introduction and maturation of the personal computer in the 1970s and 1980s, to the revolution of the Internet in the recent past, IT has become an integral component in quality care. Accelerating the integration of IT has been healthcare reimbursement reform. With the focus on quality and the central role of the patient, healthcare IT reached its current role and includes the use of EMRs, bar coding for identification verification, and personal digital devices. In 2004, a U.S. healthcare IT agenda was proposed that called for an electronic health record for every American by 2014. In 2009, the agenda was updated to include an all-electronic record within 5 years. Embracing IT in healthcare is not limited to developed countries; the World Health Organization's World Alliance for Patient Safety also recommends the use of technology to improve patient safety and outcomes.

Information Technology in Nursing Practice

Integral to the nursing process is the collection, recording, and utilization of patient information. Nurses use IT to document care provided, including medication and therapeutic treatment administration; to access patient results from other departments; and to manage patient scheduling. The interface between biomedical monitoring and healthcare IT systems continues to improve, allowing for real-time documentation of minute-by-minute changes in patient status.

NURSING CARE DOCUMENTATION

Nurses use computers every day in delivery of direct patient care. The EMR provides the repository for all patient-related information. The computerization of the EMR allows for data entry and retrieval by all members of a healthcare team. EMRs have been shown to reduce errors. For example, an EMR can be programmed to alert clinicians when incompatible medications have been ordered. Such warnings have been shown to reduce medication errors. The use of standardized forms and language reduces time spent searching for information and misinterpretation of recorded information. Incorporation into IT systems of NANDA nursing diagnoses, NIC nursing interventions, and NOC nursing outcomes can streamline the nursing process when developing the nursing care plan (Figure 2–1 ■).

Various types of computerized systems are used to handle patient information. Desktop systems placed in unit stations are common, as are bedside data entry systems. Systems range from traditional desktop computers to wireless handheld pads (Figure 2–2 ■). The use of such systems is not limited to inpatient settings. Laptops and other portable devices are used in outpatient and home-based care environments. While such systems provide convenience for the clinician, caution must be taken to protect confidential patient health information (PHI).

As the nurse integrates these systems into practice, the ability to navigate and troubleshoot problems becomes essential to reduce care delays and frustrations if technical problems arise. Be sure to always address the patient before using the computer. It is the nurse's role to explain the computer, why and how it is used, and how the patient's confidential information is protected.

OTHER USES OF INFORMATION TECHNOLOGY IN NURSING

Although patient care is the most common use for IT, other applications are useful in nursing practice. Accrediting agencies such as the Joint Commission mandate compiling of quality assurance and improvement documentation. Searchable databases can be used to store, manage, and organize policies and procedures, standards of care, and employee information such as annual clinical competency documentation. Resource management systems are commonly used for medical supply inventory, pharmacy, and security. Human resources and financial departments maintain databases and information for managing employees and making cost and reimbursement projections.

Because nursing is based in science, the ability to locate, appraise, and use evidence to provide the highest quality of care results in optimal outcomes. Skills related to evidence searching and evaluation are required to conduct evidence-based practice.

EVIDENCE-BASED PRACTICE

Evidence-based practice (EBP) is defined as the practice of nursing in which the nurse makes clinical decisions on the basis of the best available current research evidence; his or her own clinical expertise, including internal evidence of patient findings; and the needs and preferences of the patient (Melnyk & Fineout-Overholt, 2011). EBP uses careful and diligent decision making, taking into consideration each individual clinical situation.

History and Factors That Promote EBP in Nursing

Nursing practice based on evidence extends back to Florence Nightingale, whose systematic assessment and evaluation of the environment and the impact on outcomes (mortality, etc.) are widely

described. EBP is a problem-solving approach to clinical practice questions.

Evidence-based medicine (EBM) has been around for more than a century, but came into the modern medical lexicon in the early 1990s, arising out of Great Britain. Dr. Sackett and colleagues defined the attributes and exceptions to EBM in 1996, cautioning that EBM is not "cookbook medicine," where clinical care is based on general evidence without consideration of the practitioner's expertise or the patient's specific situation and values. Another important early innovator in EBP was Dr. Archie Cochrane, a British medical researcher who promoted the systematic evaluation of evidence to support the highest quality clinical decisions. Dr. Cochrane noted that with the limited resources available to the practitioner, an efficient and effective method was needed to evaluate evidence. The Cochrane Collaboration, named for Dr. Cochrane, is a worldwide network of clinical experts (more than 28,000 persons) who develop, publish, and update reviews of research literature related to specified topics. The Cochrane Collaboration databases are recognized for their high quality related to healthcare effectiveness.

EBP implementation has increased with a stronger focus on quality of care by policy makers and healthcare reimbursement organizations like the Centers for Medicare and Medicaid Services (2013). The Institute of Medicine (IOM), a part of the National Academy of Science, focuses on developing and recommending policies related to the health of the U.S. population. In 2007, the IOM set the goal that by 2020, 90% of all healthcare decisions will be based on evidence (IOM, 2007; Melnyk et al., 2009). As described by Rycroft-Malone and colleagues (2004), "Rising health costs, the management principle of doing things right and the desire for quality improvement have created a climate for the evolution of evidence-based health care" (p. 1). Supporting the movement toward EBP, the ANA has included evidence-based practice and research as the ninth standard in the ANA's *Nursing Scope and Standards of Practice* (2010).

WHY USE EBP IN NURSING?

The use of EBP in nursing is imperative because it can help to (1) promote the best patient outcomes, (2) reduce costs, (3) reduce care variations due to geographic location, and (4) encourage healthcare worker retention.

EBP Overview

COMPONENTS OF EBP

EBP has been described as a problem-solving approach for clinical practice that includes three foundational legs:

1. **External evidence**—where nurses search, appraise, and synthesize the relevant research findings related to their clinical question. External evidence comes from well-designed research studies.
2. Clinical expertise and **internal evidence**—which includes nurses' own clinical expertise incorporating their patient assessments and evaluations as well as internal evidence, which is derived from quality improvement and outcomes evaluations.
3. **Patient preferences** and values—where nurses incorporate the individualization to their specific patient that is a benchmark for quality nursing care. It is the patient experience and circumstances that influence a nurse's choice of nursing intervention (Melnyk & Fineout-Overholt, 2011).

Starting with the Clinical Question

As with any process, it has to have a beginning. One approach is to develop the clinical question in a format that will support searching for answers in the literature. The PICOT question format, first described by McKibbon and Marks (2001), has been well-described by Melnyk and colleagues in multiple publications (2009, 2011). **PICOT** is an acronym for terms to be included in the clinical question. These include:

- **P**atient population
- **I**ntervention or issue of interest
- **C**omparison intervention or group
- **O**utcome
- **T**ime frame.

PICOT questions can be framed to ask different types of questions about intervention, diagnosis, prognosis, etiology, or meaning (Stillwell et al., 2010a).

Nursing Research as External Evidence

Well-conducted research studies make up the basis of external evidence. Many different approaches, designs, and methodologies are available that provide differing levels of reliable information. With generation of the PICOT question, the next step is to determine the level of evidence that best answers the question. Evidence is ranked hierarchically, with the strongest evidence at the peak of the pyramid with lower levels for study designs with more risk for bias. The hierarchy includes seven levels:

Level I: Systematic reviews or meta-analyses of randomized controlled trials
Level II: Randomized controlled trials
Level III: Controlled trials without randomization
Level IV: Case control and cohort studies
Level V: Systematic reviews of descriptive and qualitative studies
Level VI: Single descriptive or qualitative studies
Level VII: Opinion of authorities and/or reports of expert committees.

Levels I and V are considered preappraised literature because these contain review and analysis of multiple studies. Levels II, III, IV, and VI are individual studies. Level VII is not actually data-based research, but evidence that is based on expert opinion. See Figure 2–3 ■ for the evidence hierarchy pyramid.

APPRAISAL OF EXTERNAL EVIDENCE

Appraisal of the external evidence requires a discerning review of the strengths and weaknesses of the literature of interest. According to Melnyk and Fineout-Overholt (2011), appraisal is based on three questions: (1) Are the study results valid? (validity of the study); (2) What are the results? (reliability of the study); and (3) Will the results help me care for my patient(s)? (applicability of the study) (p. 83).

Validity is determined by evaluating the soundness of the scientific methods and the internal and external validity. External validity refers to how the results can be applied to others beyond the sample studies (generalization). External validity can be controlled by replication of the study. This is the underlying concept to the strength of meta-analyses and systematic reviews. Use of a control group also supports external validity.

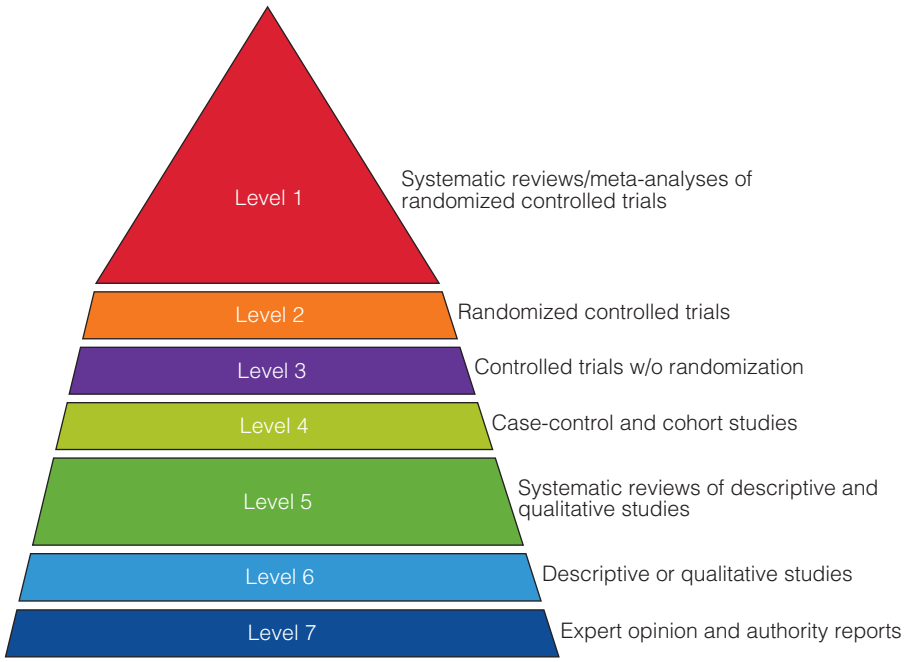

Figure 2–3 ■ Hierarchy of evidence.

Internal validity refers to the extent that you can be assured that the independent variable (intervention) actually influenced the dependent variable (outcome). To evaluate for internal validity, one must focus on how the study was conducted (Did it follow rigorous procedures?) and sampling. Problems with study procedures are called *bias*. Bias can be controlled through activities like blinding that prevent the investigator and/or the participants from knowing whether the experimental intervention or the nonintervention is assigned to a specific participant. A single-blind study is one in which the researchers collecting the data do not know group assignment; a double-blind study is one in which neither the researchers nor participants know group assignment.

Reliability deals with the quantitative results. How large of an effect did the intervention have on the outcomes? How precise was the effect estimate? The type of data and the selected statistical tests are evaluated to determine reliability.

Reliability and validity can also refer to the quality of the instruments used in the research. Instrument validity is defined as the degree to which an instrument measures what it is supposed to measure. Instrument reliability refers to the consistency with which an instrument measures the topic of interest.

Applicability focuses on the extrapolation of research findings to your specific patient situation. Although the statistical analysis information may not be used to answer applicability, this is extremely important because it provides the support for using the evidence to individualize your patient care.

Relationship between Research Process and Nursing Process

The nursing process and the research process have many similarities. Both use a systematic approach, set goals, collect data used as evidence, analyze the data, and then evaluate the results of the process. See Table 2–2 for a comparison of the nursing process and research process.

TABLE 2–2 Comparison of the Nursing and Research Processes

Nursing Process	Research Process
Assessment • Data collection • Data interpretation	Problem/purpose identification • Identify research question • Knowledge of nursing • Clinical experiences
Nursing diagnosis	• Conduct literature review • Choose a theory (if appropriate)
Planning • Setting goals • Planned interventions	Choose appropriate methods
Implementation	Collect information (data)
Evaluation	Conduct analysis (analyze results) Report findings

Use of Technology in EBP: Locating the Evidence

Effective literature searching is a necessary foundation to locating appropriate external evidence. With computerization of databases, searching no longer requires hours in the library culling through stacks of journals. Selection of an appropriate database is central to efficient literature searching. The terms from the PICOT question may be used as keywords. Additionally, databases often have the ability to use controlled vocabulary terms (medical subject heading [MeSH] terms). These terms are structured to retrieve the more specific terms

that fall under a general term. MeSH terms are common in the large databases.

Examples of large databases include PubMed from the National Library of Medicine; Cumulative Index of Nursing and Allied Health Literature (CINAHL), and the Cochrane Collaboration. Subscriptions may be needed to access some benefits of the databases. Academic libraries as well as many medical and hospital libraries maintain such subscriptions. Additionally, public libraries may have access. Working with the librarian is the best source of specific information about available databases and other evidence resources. Some databases are specific to medical specialties. Additionally, the National Guideline Clearinghouse provides an open access database of clinical guidelines.

Research Approaches, Designs, and Methods

RESEARCH APPROACHES

Quantitative research is the use of numerical computations and statistical analysis to answer empirical questions. Research questions and hypotheses attempt to identify associations, determine causation, or predict outcomes. Quantitative designs and methods are described later in the chapter.

Qualitative research focuses on the participant's experience and his or her perceived meaning of the situation of interest. Context, or application of prior experiences, is an important consideration in qualitative research. Qualitative research is a completely separate approach to answering a research question that focuses on the meaning of the experience. Three major methodologies are used in qualitative research: ethnography, phenomenology, and grounded theory. See Table 2–3 for descriptions of these approaches and their common products.

Although quantitative and qualitative approaches are very different, some similarities exist. See Table 2–4 for a comparison of quantitative and qualitative approaches.

PURPOSES OF RESEARCH

Research focuses on five levels of questions. The first is identification: What is the phenomenon of interest? The second level is description. Descriptive research is conducted at this level to define the characteristics of the phenomenon. The third level is exploration. At this level factors that are related to the phenomenon are examined. The fourth level is explanation. Questions at this level ask "What caused the phenomenon?" "How does the phenomenon work?" The fifth and final level is prediction and control. At this level questions focus on the conditions under which the phenomenon occurs. How can the phenomenon be altered to see a change in an outcome of interest?

VARIABLES

Variables are any occurrence of a phenomenon or outcome that acts differently, or varies. Two classifications of variables are important in quantitative research. The **independent variable** is the presumed cause of a change in an outcome. In a study where a variable is manipulated, this is the independent variable. The **dependent variable** is the presumed effect from the manipulation of the independent variable. In other words, the dependent variable is often the outcome of interest. The change in the dependent variable is due to the manipulation or application of a specific intervention: thereby, the dependent variable result is dependent on the manipulation of the independent variable.

Variables are defined in two different ways: the conceptual definition and the operational definition. The **conceptual variable** defines the qualities of the variable of interest. For example, the

TABLE 2–4 Similarities/Differences between Quantitative and Qualitative Research Steps

Quantitative Research	Qualitative Research
Develop research problem.	Identify problem of interest.
Review related literature.	Review related literature. (*Note:* Not done by all qualitative researchers.)
Formulate hypotheses.	Develop overall approach.
Design the study/ experiment.	Develop emergent research design.
Collect the data.	Conduct the study.
Analyze the data.	Confirm and close the study (verify trustworthiness of the data).
Interpret the results.	Interpret data in an ongoing manner throughout the study.
Disseminate the findings.	Disseminate the findings.

TABLE 2–3 Qualitative Research Approaches

	Definition	Product
Ethnography	Study of the meanings, patterns, and experiences of a defined cultural group in their natural setting	Rich, contextual descriptions of a culture; descriptions of behavioral and social patterns
Phenomenology	Concerned with the lived experience	Rich, descriptive detail about meanings of phenomena: • Lived space or spatiality • Lived body or corporeality • Lived time or temporality • Lived human relation or relationality
Grounded theory	Focus on the development and evolution of a social experience	Rich contextual description of relevant recurring themes

conceptual definition of pain can be "an unpleasant sensory sensation." In contrast, the **operational variable** is a description of how a variable is measured. For example, the operational variable definition of pain could describe the use of a pain scale from 0, meaning no pain, to 10, meaning the worst pain imaginable.

RELATIONSHIPS AMONG VARIABLES

Variable relationships can be described in a couple of different ways. **Association** is a relationship that describes only association, but it does not indicate cause and effect. **Causation** is a relationship in which cause and effect are determined. Causation is commonly where descriptions of independent (cause) and dependent (effect) variables are used. Ultimately, research strives to explain and predict phenomena and the component variables.

RESEARCH DESIGN

The **research design** serves as a blueprint or recipe for conducting a study. The design goal is maximum control of factors that could interfere with the validity of the findings (confounding variables). Good study design minimizes the potential for the results to be due to variables that were not part of the study. Research design is very important—if it is determined to be flawed, then the study findings will be suspect and, therefore, not useful. In quantitative research, research design is based on the research question and the answers being sought. Often these studies are described in time or temporal-related terms such as retrospective (backward) or prospective (forward). A cross-sectional design indicated that data is collected at a single time point (think of a snapshot). In contrast, a longitudinal design collects data at more than one time point (think of a movie). See Table 2–5 for common quantitative research design terms.

TABLE 2–5 Quantitative Research Design Terms

Time Dimensions	
Retrospective	Collecting data about variables that have already occurred
Prospective	Collecting data about variables that are occurring at the time of data collection
Cross-sectional	Data collection at one point in time
Longitudinal	Data collection at two or more points in time

QUANTITATIVE DESIGNS

In quantitative research the design is commonly designated as belonging to one of three areas: nonexperimental, quasi-experimental, and experimental (Table 2–6). In a *nonexperimental design*, variables are not manipulated. The purpose of nonexperimental designs is to describe or explore relationships among variables. There are no independent variables in nonexperimental designs. In a *quasi-experimental design*, variables are manipulated, but there may or may not be random group assignment or a control group. In an *experimental design*, all three components must be present: variable manipulation (an independent variable), a control group (a group not receiving the manipulated variable), and random group assignment (control vs. manipulated variable or experimental group). The experimental design is the most powerful to evaluate for cause-and-effect relationships. Within each designation are additional descriptions related to conduct of the study.

METHODS: DESCRIPTION VERSUS INFERENCE

When defining the level of the research question, the goal drives the question. A *research question* asks about the variables of interest. Research questions are used with descriptive or exploratory studies as there is no prediction of outcome. In contrast, a *hypothesis* (plural: *hypotheses*) is an educated guess about the relationships among variables and the expected outcomes. Hypotheses can be simple (one independent variable and one dependent variable) or complex (two or more independent variables and two or more dependent variables). Hypotheses can be either directional, where there is a specified direction to the variable relationship, or nondirectional, where no direction is described between the variables. The null hypothesis indicates that there is no relationship between the variables. The research or alternative hypothesis is the prediction by the researcher of a relationship between the variables.

Descriptive statistics only describe the findings. **Inferential statistics** are based on the laws of probability. Inferential statistics help the researcher draw conclusions about whether the results observed in the sample are likely to also occur in the population. This is termed *generalizability*.

THE PARTICIPANTS: SAMPLE VERSUS POPULATION

In research literature, it is important to understand the difference between a *population* and a *sample*. The population is composed of all possible individuals, while the sample is a subset of the population. Often, the sample is the most accessible group of the population.

TABLE 2–6 Quantitative Research Design Examples

Nonexperimental	Descriptive: Describes phenomena. Correlational: Looks for associations among two or more variables.
Quasi-experimental	Time series: Used to collect data over several periods both prior to and after application of the independent variable. Nonequivalent control group: No random assignment to group, but uses experimental and control groups.
Experimental All assume random group assignment, control group, manipulated variable	Post-test only: Testing is done only after an experimental group has been exposed to independent variable. Pretest post-test: The pretest verifies the equivalence of groups. Solomon's Four: Four groups; this controls for the effect of the pretest and the experimental condition. Factorial: Used with more than one independent variable; looks not only at impact of independent variable on dependent variable, but also at the interaction between the two independent variables. Repeated measures: Uses two or more groups with more than two data collection points.

TABLE 2–7 Levels of Data

Level	Definition	Statistical Summary
CATEGORICAL		
Binary	Choice between only two options	Proportions or odds
Nominal	Mutually exclusive categories that only name No hierarchy	Mode
Ordinal	Clear order or hierarchy Not on a calibrated scale	Median
CONTINUOUS		
Interval	Data achieved from a calibrated scale Does not have an absolute zero (but can have an arbitrary zero) *Example:* temperature, IQ scores	Mean or median
Ratio	Data achieved from a calibrated scale Has an absolute zero Has a constant scale that includes zero Highest level of data possible *Examples:* height, weight, age, length	Mean or median

The goal of a research study is to enroll participants who are alike (homogeneous). This goal of homogeneity can be addressed using eligibility or inclusion criteria that describe the characteristics of people.

STATISTICAL ANALYSIS

Statistical analysis is the manipulation and testing of data in quantitative studies to determine if changes seen are due to the experiment or if the differences are due to chance. The research question/hypothesis and level of data influence which statistical test is used. To begin to understand the rules for statistical analysis, first you must understand the different levels of data. Five levels of data influence how they should be described and analyzed. The five levels are divided across two major categories: categorical data, which includes binary, nominal, and ordinal data, and continuous data, which includes interval and ratio data. A general rule of thumb is that categorical data commonly use descriptive statistical procedures, whereas continuous data use both descriptive and inferential statistical procedures. See Table 2–7 for a list of the levels of data, their definitions, and commonly used statistical summaries for each.

Concepts of central tendency are important concepts used to describe quantitative data. The common central tendency terms used are *mean*, *median*, and *mode*. The data set is referred to as a *frequency distribution*. The mean is defined as the sum of all scores divided by the number of participants. The median is the exact middle score in a frequency distribution (where you write all scores out from lowest to highest). The mode is the score or value that occurs most often in a frequency distribution. The median and mode are important values because these descriptors allow for correction of outliers that can pull the mean to one end or the other. An outlier is a score that is far away from the center (median) of the data, leading to a spurious mean or average score.

The term *data distribution* refers to how the data are spread out. A normal distribution is not a value judgment—it only means that the data meets a distribution pattern that allows application of a specific type of statistical procedure called parametric statistics. Nonparametric statistics are the alternative procedures for nonnormally distributed data. The reason nonparametric procedures are indicated is because data that are not normally distributed do not meet the underlying assumptions that make parametric procedures appropriate.

The standard deviation measures the degree of variability in a set of scores, allowing the researcher to describe the variance of the sample in the same units used to measure the variable. For example, using a set of temperature scores, one could identify the mean temperature in Fahrenheit degrees and then also list the standard deviation in Fahrenheit degrees.

Statistical test selection is based on the research question or hypothesis. The number of groups in the study also influences the selection of the statistical test. See Table 2–8 for suggested statistical tests for specific research designs.

Implementing EBP in Medical-Surgical Nursing

Evidence-based practice in nursing can be broken down into a five-step process:

1. Formulate a searchable question.
2. Search the literature efficiently.
3. Appraise the literature critically.
4. Apply the result to clinical practice or patient.
5. Evaluate the outcomes of the applied evidence in the practice or patient.

It is important to measure outcomes to determine the impact of EBP change. The goal is positive changes in patient outcomes that impact healthcare quality.

TABLE 2–8 Statistical Tests for Specific Research Designs

Assumed Distribution	Parametric	Nonparametric
Benefits	Can draw more conclusions	Less affected by outliers
Correlation to look for association	Pearson	Spearman
Independent measures, two groups	Independent *t*-test	Mann-Whitney test
Independent measures, more than two groups	Analysis of variance (ANOVA)	Kruskal-Wallis test
Repeated measures on two conditions or groups	Matched pair *t*-test	Wilcoxon test
Repeated measures on more than two conditions or groups	Repeated measures ANOVA	Friedman's test

Ethical Considerations of EBP

As with all nursing care, EBP has a basis in ethical principles. However, not all approaches used to improve quality are evidence-based or ethical. The Institute of Medicine has described a framework for healthcare that can lead to practical improvements. It emphasizes safety, effectiveness, patient centeredness, timeliness, equity, and efficiency. Other ethical concepts related to EBP include the following:

- *Social/scientific value*—activities must be worth doing to be ethical.
- *Scientific validity*—EBP is meant to be applied at the local level; it is not to be generalizable like research is. Remember, individual clinical expertise and each specific patient situation are components of EBP.

In conclusion, EBP is a central concept in the delivery of quality nursing care. As a registered nurse, there is a professional expectation that you will be able to identify appropriate clinical questions and effectively appraise the literature as the external evidence component of EBP, while also applying clinical expertise and the individual patient situation and preferences to provide the highest quality care.

CHAPTER HIGHLIGHTS

- **Nursing Informatics combines nursing science, information management science, and computer science to manage and process nursing data, information, and knowledge in delivering quality care to the public. The goal of nursing informatics is the use of information structures, processes, and technologies through the integration of data, information, and knowledge to support decision-making for the health of populations, communities, families, and individuals.**
- Nursing informatics competencies have been identified to describe the skills and knowledge expected of nurses at specified levels of experience.
- **Electronic medical records allow for access to patient information by all members of the healthcare team while reducing errors.**
- **Evidence-based practice (EBP) is defined as the practice of nursing in which the nurse makes clinical decisions on the basis of the best available current research evidence; his or her own clinical expertise, including internal evidence of patient findings; and the needs and preferences of the patient.**
- The use of EBP in nursing is imperative because it can help to (1) promote the best patient outcomes, (2) reduce costs, (3) reduce care variations due to geographic location, and (4) encourage healthcare worker retention.
- EBP has been described as a problem-solving approach for clinical practice that includes three foundational legs: external evidence, clinical expertise and internal evidence, and patient preferences and values.
- Appraisal of the external evidence requires a discerning review of the strengths and weaknesses of the literature of interest. It also requires a working knowledge of research design and methods to be an educated consumer.
- There is a professional expectation that registered nurses will be able to identify appropriate clinical questions and effectively appraise the literature as the external evidence component of EBP, while also applying clinical expertise and the individual patient situation and preferences to provide the highest quality care.

TEST YOURSELF NCLEX-RN® REVIEW

1. The nurse has a personal goal of becoming competent in nursing informatics. Which action will help the nurse achieve this goal?
   1. Return to school and earn a nursing informatics degree.
   2. Continue to function in the role of a nurse within the healthcare team.
   3. Obtain experience working within the different levels of informatics competencies.
   4. Inform nursing administration of the goal so that work assignments can be adjusted accordingly.

2. Before conducting an assessment, a patient refuses to allow any personal health information to be input into the computer because of the threat of information being breached. What should the nurse include in the response to this patient's concerns?
   1. Explain password protection and access levels to the information.
   2. Describe the extreme amount of training that was provided to learn the system.
   3. Summarize how the use of computers has streamlined patient care and reduced errors.
   4. Discuss the amount of money invested by the organization to provide computers for all workers.

3. The staff development trainer is conducting a presentation on evidence-based practice for a group of nurses. What should the trainer explain as the foundation of evidence-based practice during this learning session?
   1. external evidence and hospital policy
   2. research evidence and hospital policy
   3. external evidence, internal evidence, and patient preferences and values
   4. external evidence, internal evidence, and quality improvement outcomes
4. The nurse manager is participating on a committee to implement evidence-based practice within the nursing department. What should the committee emphasize when explaining the benefits of using this problem-solving approach?
   1. EBP shifts the focus to quality and cost-effective care.
   2. EBP engages staff nurse participation in research projects.
   3. EBP increases nursing staff exposure to research findings.
   4. EBP supports the IOM recommendation for using evidence-based practice by 2030.
5. The nurse researcher is identifying the methods that will be used when conducting a research study. In which phase of the nursing process is the nurse researcher functioning?
   1. planning
   2. assessment
   3. implementation
   4. nursing diagnosis
6. The nurse is reviewing a research study for applicability to evidence-based practice. On which characteristics will the nurse focus when conducting this review?
   1. validity, quality, and consistency
   2. validity, reliability, and applicability
   3. reliability, quantity, and applicability
   4. quality, quantity, and cost effectiveness
7. A patient agrees to participate in a study where an intervention is going to be manipulated and the patient can select to be in either the study or control group. Which type of design is this research study?
   1. descriptive
   2. experimental
   3. nonexperimental
   4. quasi-experimental
8. The nurse researcher is designing a study in which patients will be asked to discuss something based on a lived experience. Which qualitative approach is the nurse researcher using for this study?
   1. ethnography
   2. phenomenology
   3. grounded theory
   4. existential theory
9. When analyzing the results of a study, the nurse researcher uses inferential statistics. What is the purpose of using this approach when analyzing the data?
   1. Uses the laws of probability.
   2. Describes sample characteristics.
   3. Accounts for confounding variables.
   4. Draws conclusions from the population to the sample.
10. When collecting data for a study, the nurse researcher measures patients' body temperatures. Which level of data is the nurse collecting?
    1. ratio
    2. ordinal
    3. interval
    4. nominal

3 Health and Illness Care of Adults

LEARNING OUTCOMES

1. Define health and discuss factors affecting the health of individuals, families, and communities.
2. Compare and contrast health risks, assessment, and health promotion for the young adult, middle adult, and older adult.
3. Discuss the nurse's role in health promotion.
4. Differentiate between disease and illness.
5. Describe illness behaviors and needs of the patient with acute illness and chronic illness.
6. Describe essential elements and goals of coordinated primary care models such as the Transitional Care Model and the Patient-Centered Medical Home.
7. Describe services, settings, and essential components of community-based care and home healthcare.
8. Discuss nursing interventions to deliver safe, effective, and competent care to patients in their homes.

CLINICAL COMPETENCIES

1. Use knowledge of individual and family variables to promote, restore, and maintain health when planning and implementing patient-centered care for adults.
2. Engage patients, family members, and other health team members in active partnerships to promote and maintain health and safety of the adult.
3. Use high-quality electronic sources to plan and promote health for the adult.
4. Base individualized plans to promote and maintain health status on patient values, current evidence, and standards of practice.
5. Provide safe and effective individualized patient care in community-based settings and the home.
6. Use quality measures to evaluate and improve community-based and home care for adults.

MAJOR CHAPTER CONCEPTS

- Health is a dynamic state influenced by multiple internal, external, physical, and psychosocial factors.
- Nurses play a major role in promoting the health of individuals, families, and communities. Health promotion focuses on increasing the well-being and maximizing the potential of the individual, family, or community.
- The primary health risks for the individual and family vary, depending on age and developmental stage, among other factors. Behaviors to promote individual health, however, remain very consistent throughout the life span.
- Diseases are characterized by identifiable signs and symptoms, and usually a recognized pathophysiology and etiology. Illness is the response to a disease, affected not only by the disease itself but also by the individual's perception of the disease and that of others.
- Nurses play an instrumental role in interprofessional care teams to improve the health and effective management of patients with chronic disease.
- Most health and illness care occurs outside the acute hospital environment, in community-based and primary care settings. Home healthcare is increasingly important as hospital stays become shorter or are avoided altogether.
- Ensuring safety and patient and family education are major responsibilities of the home healthcare nurse. In this setting, the patient and family are primary members of the team and are instrumental in establishing priorities of care.

transitional care, *39*
wellness, *28*

Nurses promote and protect health as well as treat patient responses to disease and illness. The ever-increasing cost of illness care has resulted in initiatives to promote and maintain health in which nurses can and do play integral roles.

In the healthcare system of the 21st century, hospitals are primarily acute care providers with services focused on high-technology care for severely ill or injured people or for people having major surgery. Even those patients rarely remain in the hospital for long. They are transitioned as rapidly as possible to less acute care settings within the hospital and then to community-based and home care. Healthcare has become a managed care, community-based system.

HEALTH AND WELLNESS

In 1948, the World Health Organization (WHO) defined **health** as "a state of complete physical, mental, and social well-being, and not merely the absence of disease or infirmity." This definition, which WHO (1974) maintains to date, is multidimensional, addressing the importance of the physical, mental, emotional, and social components of health. Health is not just a state of being, but the resources (e.g., physical, personal, social) used by each person in dealing with the challenges of living.

The **health–illness continuum**, a conceptual model developed by Dunn (1959), represents health as a dynamic process, with high-level **wellness** at one extreme of the continuum and death at the opposite extreme. Individuals place themselves at different locations on the continuum at specific points in time. As commonly illustrated, the health–illness continuum fails to account for the complexity and interrelatedness of health and illness. Health does exist in individuals affected by disease, and people with no evidence of disease can have poor health. Pender, Murdaugh, and Parsons (2011) present a model with multiple parallel lines representing levels of health throughout the life span. Illnesses (acute or chronic) are shown as events occurring along the lines. An individual who has achieved optimum health may develop an acute or chronic illness (Figure 3–1 ■). Illness, in turn, can either inhibit or promote the individual's desire and actions to achieve high-level wellness.

Factors Affecting Health

A variety of factors influence wellness, including self-concept, environment, culture, and spiritual values. These factors often interact to promote health or to become risk factors for alterations in health. **Holistic healthcare** considers all aspects of an individual (physical, psychosocial, cultural, spiritual, and intellectual) as essential components of individualized care.

GENETIC MAKEUP

Each person's genetic makeup influences health status throughout life. Genetic makeup affects personality, temperament, body structure, intellectual potential, and susceptibility to alterations in health. Examples of chronic illnesses that are known to be associated with genetic makeup include sickle cell disease, hemophilia, diabetes mellitus, and cancer.

COGNITIVE ABILITIES AND EDUCATION

Although cognitive abilities are determined prior to adulthood, cognitive development affects whether people view themselves as healthy or ill; cognitive levels also may affect health practices. Injuries to and illnesses affecting the brain may alter cognitive abilities. Educational level affects the ability to understand and follow guidelines for health. For example, within all age groups, women who have some college education are more likely to be screened on a regular basis for breast and cervical cancer than women without a college education (National Center for Health Statistics [NCHS], 2012).

ETHNICITY AND CULTURE

Certain diseases have a higher rate of incidence in some cultural and ethnic groups than in others. For example, in the United States hypertension is more common in African Americans, diabetes mellitus and chronic liver disease are among the leading causes of illness in Native Americans, and eye disorders are more prevalent in Chinese Americans. (See the accompanying Focus on Cultural Diversity feature.) The ethnic and cultural background of an individual also influences health values and behaviors, lifestyle, and illness behaviors. Every culture defines health and illness in a way that is unique; in addition, each culture has its own health beliefs and illness treatment practices.

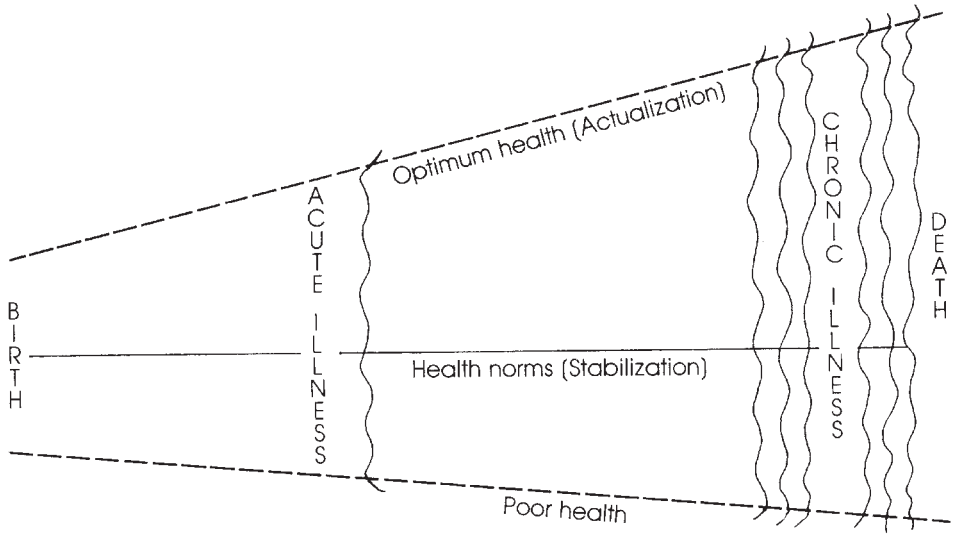

Figure 3–1 ■ The health continuum throughout the life span.

FOCUS ON CULTURAL DIVERSITY

Biologic Variations among Cultures

As genetic science and our understanding of disease and pathology have advanced, there is increasing recognition that differences between peoples of the world are more than skin deep. Certain diseases and conditions are much more likely to develop in some groups than in others; for example, sickle cell disease occurs more frequently in people whose ancestors are from central Africa, the Near East, the Mediterranean region, and parts of India; Caucasian women of small stature and of Scandinavian heritage have a higher risk of developing osteoporosis. Biologic variations also may affect the way the body metabolizes drugs, leading to an effect that is either less than or greater than anticipated. In other cases, selected drugs may be found to be more effective for people of one race than another.

Biologic differences among people of various cultural groups also affect both food preferences and food tolerance. Up to 90% of Mexican Americans, African Americans, Native Americans, and Asians are lactose intolerant; that is, they do not produce enough lactase to tolerate large amounts of dairy products. If too much milk (or yogurt or milk chocolate) is eaten, undigested lactose in the intestine causes manifestations such as cramping, flatulence, abdominal bloating, and diarrhea (Giger, 2013).

Although known biologic variables among people of different races and cultures can be helpful in providing individualized health education, it is important to avoid stereotyping based on racial and cultural differences. For example, an individual who appears to be African American may actually identify with Native American culture as a result of having a Native American parent; a recent emigrant from Ethiopia has a significantly different cultural background than a Black person who is a descendent of U.S. slaves. Making assumptions about health risk factors and preferences could lead to inappropriate care planning for these individuals.

LIFESTYLE AND ENVIRONMENT

The components of an individual's lifestyle that affect health status include patterns of eating, use of chemical substances (alcohol, nicotine, caffeine, legal and illegal drugs), exercise and rest patterns, and coping methods. Examples include the relationship of obesity to hypertension, cigarette smoking to chronic obstructive pulmonary disease, and a sedentary lifestyle to heart disease and certain cancers. The environment has a major influence on health. Occupational exposure to toxic substances (such as asbestos and coal dust) increases the risk of pulmonary disorders. Air, water, and food pollution increase the risk of respiratory disorders, infectious diseases, and cancer. Environmental temperature variations can result in hypothermia or hyperthermia, especially in the older adult.

SOCIOECONOMIC BACKGROUND

Both lifestyle and environmental influences are affected by income level. The culture of poverty, which crosses all racial and ethnic boundaries, negatively influences health status. Needed medical care often is delayed or lacking, particularly among uninsured adults. As a result, illness may be more severe, the risk for complications greater, and hospital stays longer (NCHS, 2012). Living at or below the poverty level may result in crowded living conditions, increasing the risk of contracting communicable diseases. Other problems include lack of infant and child care, inadequate nutrition, use of addictive substances, and violence.

GEOGRAPHIC AREA

The geographic area in which one lives influences health status, health risks, and access to healthcare. Vector-borne diseases such as Rocky Mountain spotted fever (RMSF) and Lyme disease are more prevalent in certain regions of the United States (RMSF in south-central and southern states, Lyme disease in the eastern states). More healthcare providers, including specialists, are available in urban settings than in rural areas.

FAMILY

Family structure and function affect the health status of individuals within the family unit. Although some people have no family ties, most have one or more significant individuals in their lives. A **family** is a social unit of two or more people who are emotionally involved with each other and who depend on one another for emotional, physical, and psychosocial support.

Although every family is unique and influenced by cultural values and beliefs, all families have certain structural and functional features in common. Healthy families are characterized by the following (Murray et al., 2009):

- ***Interdependence***. A sense of relationship, and positive and supportive interactions among members.
- ***Maintaining boundaries***. Clear boundaries guide family members, provide a distinct and unique family culture, and allow interactions with those outside the family.
- ***Adapting to change***. The healthy family is able to adapt to change and loss.
- ***Performing family tasks***. Clear social roles and a hierarchy of power in which the parents have more power than children help to maintain the stability and continuity of the family.

While the influence of family on health generally is positive, patterns of family coping and lifestyle factors such as family violence and use of alcohol, tobacco, or other substances of abuse can have a negative impact on health.

AGE, GENDER, AND DEVELOPMENT

Age and gender are factors in health and illness. Cardiovascular disorders are uncommon in young adults, but the incidence increases after the age of 40. Myocardial infarctions are more common in men than women until women are postmenopausal. Some diseases occur only in one gender or the other (e.g., prostate cancer in men and cervical cancer in women). The older adult often has increased incidence of chronic illness and increased potential for serious illness or death from infectious illnesses such as influenza and pneumonia.

The adult years commonly are divided into three stages: the young adult (ages 18 to 40), the middle adult (ages 40 to 65), and the older adult (over age 65). Although developmental markers are not as clearly delineated in the adult as in the infant or child, changes in physical status, psychosocial development, and major health risks do occur with aging. (See Table 3–5 later in this chapter for health screening recommendations for adults.)

THE YOUNG ADULT From ages 18 to 25, the healthy young adult is at the peak of physical development (Figure 3–2 ■). All body systems are functioning at maximum efficiency. Then, during the 30s, some normal physiologic changes begin to occur. Table 3–1 summarizes physical characteristics typical of the young adult. Major health risks

Figure 3–2 ■ Regular exercise is a key healthy behavior for the young adult.
Source: Stockbyte/Getty Images, Inc.

TABLE 3–1 Physical Characteristics of the Young Adult Years

Assessment	Status
Skin	Smooth, even temperature; some wrinkles may appear
Hair	Slightly oily, shiny; graying may begin
	Balding may begin
Vision	Snellen 20/20
Musculoskeletal	Strong, coordinated
Cardiovascular	Maximum cardiac output
	60–90 bpm
	Mean BP: 120/80 mmHg
Respiratory	Rate: 12–20/min
	Full vital capacity

for the young adult include accidents, sexually transmitted infections, substance abuse, and physical or psychosocial stressors. These risk factors may be interrelated (see the Moving Evidence into Action feature).

INJURIES Unintentional injuries are the leading cause of injury and death in people between ages 15 and 44 (NCHS, 2013). Most injuries and fatalities occur as the result of motor vehicle crashes, but injuries and death also result from assaults (homicide), drowning, fire, guns, occupational accidents, and exposure to environmental hazards. Accidental injury or death is often associated with the use of alcohol or other chemical substances, or with psychologic stress. Suicide is the third leading cause of death in those 15 to 24 years old, but drops to the fourth leading cause in ages 25 to 44. In both groups, the suicide rate in significantly higher in males than in females (NCHS, 2013).

SEXUALLY TRANSMITTED INFECTIONS Sexually transmitted infections include genital herpes, chlamydia, gonorrhea, syphilis, and HIV/AIDS. The young adult who is sexually active with a variety of partners and who does not use barrier protection is at greatest risk for development of these diseases.

SUBSTANCE ABUSE Substance abuse is a major cause for concern in the young adult population. Although alcohol abuse occurs at all ages, binge drinking (consuming four or more drinks in about 2 hours, leading to a blood alcohol concentration of 0.08%) is more common among young adults (Centers for Disease Control and Prevention [CDC], 2012c). Alcohol contributes to motor vehicle crashes and physical violence, and it is damaging to the developing fetus in pregnant women. It can also cause liver disease, contributing to chronic liver disease and cirrhosis, the sixth leading cause of death among young adults ages 25 to 44 years (NCHS, 2013).

Other commonly abused substances include nicotine; marijuana; stimulants such as amphetamine, methamphetamine, and cocaine; and opioid pain relievers (National Institute on Drug Abuse, 2011). Smoking increases the risk of respiratory and cardiovascular diseases. Marijuana can affect memory and learning for days to weeks after its use. Methamphetamine, a highly addictive substance, can lead to structural and functional changes in the areas of the brain associated with emotion and memory. Cocaine can cause death from cardiovascular effects (increased heart rate and ventricular dysrhythmias), and can lead to addiction and health problems in the baby born to an addicted mother. Opioid pain relievers cause drowsiness and impair coordination, and can cause fatal overdose.

PHYSICAL AND PSYCHOSOCIAL STRESSORS Malignancies are among the top five leading causes of death in the young adult. For this reason, emphasizing the importance of attending to changes in their bodies is critical. Behavioral patterns established in young adulthood also impact the risk for many chronic diseases more commonly diagnosed in middle or late adulthood, including obesity, coronary heart disease, diabetes, chronic lung disease, and chronic liver disease. Health promotion for young adults must include teaching about healthy behaviors and eating habits associated with reduced risk for developing cancers and chronic diseases (see page 33).

The young adult is subject to physical stressors such as work-related risks (e.g., electrical hazards, mechanical injuries, exposure to hazardous materials), exposure to the sun, participation in high-risk activities (e.g., contact sports, driving too fast), ingestion of chemical substances (e.g., caffeine, alcohol, nicotine), and pregnancy.

Many different and individualized psychosocial stressors may affect the young adult. Choices about education, occupation, relationships, independence, and lifestyle affect both current and future health. The young adult without adequate education or job skills may face unemployment, poverty, homelessness, and limited access to healthcare. Young adults are more likely to be uninsured than are people in other age groups; as a result, they are more likely to delay or avoid needed medical care due to cost (NCHS, 2012).

THE MIDDLE ADULT The physical status and function of the middle adult, ages 40 to 65, is similar to that of the young adult. However, many changes take place between ages 40 and 65. Table 3–2 lists the physical changes that normally occur in the middle years.

Moving Evidence into Action

Health Promotion for Young Adults

Traditional college students who fall into the young adult age group (ages 18 to 24) often engage in risky behaviors that increase their health risks. Students responding to a 2011 survey by the American College Health Association reported the following:

- Stress that interfered with academic performance (28%)
- Sleep difficulties (19%)
- Consuming one to four drinks while partying (48%)
- Engaging in behaviors they regretted after drinking (35%)
- Feeling depressed (31%).

On a positive note, approximately 50% of college students report engaging in moderate to vigorous cardio or aerobic exercise five or more days per week.

Implications for Nursing

Nurses in college-based health centers and primary care settings are in a position to provide resources and education for college-age students. Interventions that focus on wellness, health promotion, and coping strategies can have a positive impact on student outcomes (Ahern, 2009). Nurses should reach out to young, college-age adults to provide support and education to promote healthy behaviors.

Moving Knowledge into Action

1. Considering the current preferred methods of communicating among adolescents and young adults, develop potential strategies for outreach to and health and wellness education for students on a traditional, residential college campus.
2. How might you modify these planned strategies to reach students enrolled in a college where the primary student population is made up of commuters?
3. Would your strategies and focus change if your goal was health promotion for nontraditional college students (ages 25 and older)?

TABLE 3–2 Physical Changes in the Middle Adult Years

Assessment	Changes
Skin	• Decreased turgor, moisture, and subcutaneous fat result in wrinkles. • Fat is deposited in the abdominal and hip areas.
Hair	• Loss of melanin in hair shaft causes graying. • Hairline recedes in males.
Sensory	• Visual acuity for near vision decreases (presbyopia) during the 40s. • Auditory acuity for high-frequency sounds decreases (presbycusis); more common in men. • Sense of taste diminishes.
Musculoskeletal	• Skeletal muscle mass decreases by about age 60. • Thinning of intervertebral disks results in loss of height (about 2.5 cm [1 in.]). • Postmenopausal women may develop low bone density or osteoporosis.
Cardiovascular	• Blood vessels lose elasticity. • Systolic blood pressure may increase.
Respiratory	• Loss of vital capacity (about 1 L from age 20 to 60) occurs.
Gastrointestinal	• Large intestine gradually loses muscle tone; constipation may result. • Gastric secretions are decreased.
Genitourinary	• Hormonal changes occur: menopause, women (↓ estrogen); andropause, men (↓ testosterone).
Endocrine	• Gradual decrease in glucose tolerance occurs.

The middle adult is at risk for alterations in health from obesity, cardiovascular disease, cancer, substance abuse, and physical and psychosocial stressors. These factors often are interrelated.

OBESITY Weight gain is common in middle adulthood, usually the result of continuing to consume the same number of calories while decreasing physical activity. Obesity affects all of the major organ systems of the body, increasing the risk of atherosclerosis, hypertension, elevated cholesterol and triglyceride levels, and diabetes. Obesity is also associated with cancer, osteoarthritis, and gallbladder disease.

CARDIOVASCULAR DISEASE Cardiovascular disease (CVD) ranks second only to cancer as the leading cause of death for middle-age adults (NCHS, 2013). Diabetes, hypertension, and obesity, prevalent chronic diseases among this age group, are major risk factors for CVD, as are male gender, family history, physical inactivity, cigarette smoking, and elevated blood cholesterol levels. Stroke, kidney disease, and peripheral vascular disease are other potential consequences of CVD.

CANCER Cancer is the leading cause of death in adults between ages 45 and 64 in the United States (American Cancer Society [ACS], 2011). Cancers of the breast, colon, lung, and reproductive system are common in the middle years. Prolonged exposure to environmental carcinogens and use of alcohol and nicotine are significant cancer risk factors for the middle adult.

SUBSTANCE ABUSE Although the middle adult may abuse a variety of substances, the most commonly abused are alcohol, nicotine, and prescription drugs. Excess alcohol use in the middle adult contributes to an increased risk of liver cancer, cirrhosis, pancreatitis, hyperlipidemia, and anemia. Alcohol abuse also increases the risk of accidental injury or death and disrupts careers and relationships. Cigarette smoking increases the risk of cancers of the upper respiratory tract and lung, upper gastrointestinal tract, pancreas, bladder, and kidney. It is a major risk factor for chronic obstructive pulmonary disease and cardiovascular disease.

PHYSICAL AND PSYCHOSOCIAL STRESSORS The middle adult years are ones of change and transition, frequently resulting in stress. Both men and women must adapt to changes in physical appearance and function. Children may leave home or choose to remain at home longer than they are welcome. Parents are aging, with illness probable and death inevitable. The middle adult thus becomes part of what has been called the "sandwich generation," caught between the need to care for both children and aging parents. Career changes may occur by choice or due to unforeseen factors such as health, and approaching retirement becomes a reality. Divorce in the middle years is a major emotional, social, and financial stressor.

THE OLDER ADULT The older adult period begins at age 65, but it can be further divided into three periods: the young-old

(ages 65 to 74), the middle-old (ages 75 to 84), and the old-old (age 85 and over). With increasing age, a number of normal physiologic changes occur, as listed in Table 3–3.

The older adult population is increasing more rapidly than any other age group. In the last century, the number of adults in the United States living to age 65 or older increased from 4% in 1900 to 13.3% in 2012. There will be 79.7 million older adults by the year 2040, more than twice the number in 2000. In 2010, the average life expectancy in the United States was 78.7 years, with an average of 76.2 years for men and 81.1 years for women (Administration on Aging [AOA], 2012; Murphy et al., 2012).

FAST FACTS

Diversity in Older Adults

- Currently, older adults of a racial or ethnic minority comprise 21% of all older Americans.
- By 2030, the minority older adult population is projected to increase by 125%, compared with 54% for the older adult White population.
- Minority older adults will increase as follows: Hispanics = 155%; Asians and Pacific Islanders = 119%; American Indians, Eskimos, and Aleuts = 116%; and African Americans = 104%.

Source: Administration on Aging. (2012). *A profile of older Americans: 2012.* Retrieved from http://www.aoa.gov/AoARoot/Aging_Statistics/Profile/2012/4.aspx.

TABLE 3–3 Physical Changes in the Older Adult Years

Assessment	Changes
Skin	• Decreased turgor and sebaceous gland activity result in dry, wrinkled skin. Melanocytes cluster, causing "age spots" or "liver spots."
Hair and nails	• Scalp, axillary, and pubic hair thins; nose and ear hair thickens. Women may develop facial hair. • Nails grow more slowly; may become thick and brittle.
Sensory	• Visual field narrows, and depth perception is distorted. • Pupils are smaller, reducing night vision. • Lenses yellow and become opaque, resulting in distortion of green, blue, and violet tones and increased sensitivity to glare. • Production of tears decreases. • Sense of smell decreases. • Age-related hearing loss progresses, involving middle- and low-frequency sounds. • Threshold for pain and touch increases. • Proprioception (sense of physical position) may be altered, increasing risk for falls.
Musculoskeletal	• Loss of overall mass, strength, and movement of muscles occurs; tremors may occur. • Loss of bone structure and deterioration of joint cartilage results in kyphosis, increased risk of fractures, and restricted range of motion.
Cardiovascular	• Systolic blood pressure rises. • Cardiac output decreases. • Peripheral resistance increases, and capillary walls thicken.
Respiratory	• Continued loss of vital capacity occurs as the lungs become less elastic and more rigid. • Anteroposterior chest diameter and residual volume increase. • Although blood carbon dioxide levels remain relatively constant, blood oxygen levels decrease by 10% to 15%.
Gastrointestinal	• Decreased saliva production and loss of taste buds decrease ability to taste salt and sweet. • Gag reflex is decreased, stomach motility reduced, and gastric emptying is delayed. • Both large and small intestines have some atrophy, with decreased peristalsis. • The liver decreases in weight and storage capacity; gallstones increase; pancreatic enzymes decrease.
Genitourinary	• Kidneys lose mass, and the glomerular filtration rate is reduced (by nearly 50% from young adulthood to old age). • Bladder capacity decreases, and the micturition reflex is delayed. Urinary retention is more common. • Women may have stress incontinence; men may have an enlarged prostate gland. • Reproductive changes in men occur: • Testosterone decreases. • Sperm count decreases. • Testes become smaller. • Length of time to achieve an erection increases; erection is less full. • Reproductive changes in women occur: • Estrogen levels decrease. • Breast tissue decreases. • Vagina, uterus, ovaries, and urethra atrophy. • Vaginal lubrication decreases. • Vaginal secretions become alkaline.
Endocrine	• Pituitary gland loses weight and vascularity. • Thyroid gland becomes more fibrous, and plasma T_3 levels decrease. • Pancreas releases insulin more slowly; increased blood glucose levels are common. • Adrenal glands produce less cortisol.

Figure 3–3 ■ The older adult population is increasing more rapidly than any other age group, making gerontologic nursing an integral component of medical-surgical nursing practice.
Source: Miriam Doerr/Shutterstock.

The increasing numbers of older adults have important implications for nursing. Patients in all healthcare settings will be older, with nursing care and teaching needs that differ from those of young and middle adults. Although gerontologic nursing (care of the older adult) is a nursing specialty area, it is also an integral component of medical-surgical nursing (Figure 3–3 ■).

The older adult is at risk for alterations in health from a variety of causes. Most older adults have one or more chronic health problems; many have multiple illnesses. The most frequently occurring conditions in the older adult are arthritis, heart disease, cancer, diabetes, and hypertension (AOA, 2012). The leading causes of death are heart disease, cancer, and chronic lower respiratory diseases. Like the middle adult, the older adult is at risk for alterations in health from obesity and a sedentary lifestyle. Other risk factors specific to this age group include accidental injuries, pharmacologic effects, and physical and psychosocial stress.

INJURIES Injuries in the older adult can lead to hospitalization, self-care deficits, loss of independence, and even death. The risk of injury is increased by normal physiologic changes that accompany aging, pathophysiologic alterations in health (e.g., cardiac irregularities, decreased sensation related to diabetes mellitus), environmental hazards, and lack of support systems. The three major causes of injury in the older adult are falls, fires, and motor vehicle crashes. Of these, falls with resultant hip fractures are the most significant in terms of long-term disability and death.

PHARMACOLOGIC EFFECTS A number of risk factors predispose the older adult to toxic drug effects. Age-related changes in tissue and organ structure and function alter the absorption of both oral and parenteral medications. Poor nutrition and decreased liver function may alter drug metabolism. The aging kidney may not excrete drugs at the normal rate. Self-administration of both prescribed and over-the-counter (OTC) medications presents risks for error resulting from confusion, forgetfulness, or misreading the directions. The older adult may require drugs for several chronic diseases, increasing the risk for adverse drug interactions. In addition, the older adult living on a fixed income may have to make a choice between buying medications or food, resulting in undermedication and ineffective treatment of an illness.

PHYSICAL AND PSYCHOSOCIAL STRESSORS The older adult is exposed to the same environmental hazards as the young and middle adult, but the effects of an accumulation of years of exposure may now appear. For example, exposure to the sun in earlier years may be manifested by skin cancer, and the long-term effects of exposure to noise pollution can result in impaired hearing. The older adult is at increased risk for respiratory disorders as a result of years of smoking, occupational toxins, or environmental pollutants. Living conditions and economic constraints may prevent the older adult from having necessary heating and cooling, contributing to thermal-related illnesses and even death. Elder abuse and neglect further increase the risk of injury or illness.

Psychosocial stressors for the older adult include the illness or death of a spouse, decreased or limited income, retirement, isolation from friends and family because of lack of transportation or distance, return to the home of a child, or relocation to a long-term healthcare facility. A further stressor may be role loss or reversal—for example, when the wife becomes the caretaker of her chronically ill husband. Depression is a common problem among older adults. The prevalence of depressive symptoms increases with age, affecting 18% of people ages 85 and older (Federal Interagency Forum on Aging-Related Statistics, 2012).

HEALTH PROMOTION AND MAINTENANCE

The U.S. Department of Health and Human Services (HHS) has published national public health objectives each decade since 1980. *Healthy People 2020* (HHS, 2010) provides a foundation for disease prevention and wellness activities across public and private sectors, as well as a model for measuring achievement of identified goals and objectives. Broad goals for the current decade are described in Box 3–1.

Health promotion for individuals is directed at increasing well-being and maximizing potential (Pender et al., 2011). Health promotion goes beyond disease prevention (e.g., maintaining immunization status), to include health screening and managing chronic illness. Teaching health-promoting behaviors is an essential component of medical-surgical nursing.

Healthy behaviors that are known to promote health and wellness include the following:

- Eat a balanced diet, following two overarching concepts: (1) Maintain calorie balance over time to achieve and sustain a healthy weight; and (2) focus on consuming nutrient-dense foods and beverages (Box 3–2). The U.S. Department of Agriculture provides a general guideline of what to eat each day, illustrated as MyPlate (Figure 3–4 ■). A website is available to individualize the plan by helping consumers choose foods and amounts. After entering their age, gender, activity level, and goals, consumers get their own plan at an appropriate calorie level, and can print out a miniposter and worksheet to track progress.
- Exercise moderately and regularly, engaging in at least 30 minutes of continuous activity (such as walking) five or more days per week.
- Sleep 7 to 8 hours each day.
- Eliminate smoking and use of other tobacco products such as smokeless tobacco.
- Keep sun exposure to a minimum; use sunscreen liberally when out of doors.

BOX 3–1 *Healthy People 2020*: Overarching Goals

With a vision of "a society in which all people live long, healthy lives," and the overall mission of improving the nation's health, *Healthy People 2020* has four major goals. These goals address factors that contribute to the health status of individuals or populations, and include social and physical determinants of health.

OVERARCHING GOALS

- Attain high-quality, longer lives free of preventable disease, disability, injury, and premature death.
- Achieve health equity, eliminate disparities, and improve the health of all groups.
- Create social and physical environments that promote good health for all.
- Promote quality of life, healthy development, and healthy behaviors across all life stages.

HEALTH INDICATORS

Health indicators address determinants of health and provide a means of assessing the nation's health. These are organized under 12 areas:

- Access to health services (people with health insurance, people with a usual primary care provider)
- Clinical preventive services (e.g., cancer screening, hypertension management)
- Environmental quality (air quality, exposure to secondhand smoke)
- Injury and violence
- Maternal, infant, and child health (infant deaths, preterm deaths)
- Mental health (suicides, major depressive episodes in adolescents)
- Nutrition, physical activity, and obesity (e.g., obesity in adults and children, vegetable intake)
- Oral health
- Reproductive and sexual health
- Social determinants (high school graduation rates)
- Substance abuse (e.g., binge drinking, alcohol or illicit drug use in adolescents)
- Tobacco use.

Source: U.S. Department of Health and Human Services. (2010, November). *Healthy People 2020*. Washington, DC: Author.

BOX 3–2 Dietary Guidelines for Health

- Balance food intake with physical activity to manage body weight throughout the life span. Increase physical activity and reduce time spent in sedentary behaviors.
- Increase fruit and vegetable intake, including dark-green, red, and orange vegetables as well as beans and peas.
- Increase intake of whole grains, replacing refined grains with whole grains.
- Increase intake of fat-free or low-fat dairy products such as milk, yogurt, cheese, or fortified soy beverages.
- Choose a variety of protein foods, including seafood, lean meat and poultry, eggs, beans and peas, soy products, and unsalted nuts and seeds.
- Use oils to replace solid fats where possible, reducing intake of saturated fats, *trans* fats, and cholesterol.
- Reduce intake of calories from added sugars.
- Limit sodium intake to less than 2,300 mg/day. People who are age 51 or older, African American (of any age), or who have hypertension, diabetes, or chronic kidney disease should limit sodium intake to 1,500 mg/day.
- Limit intake of alcoholic beverages to no more than one drink per day for women and two drinks for men.

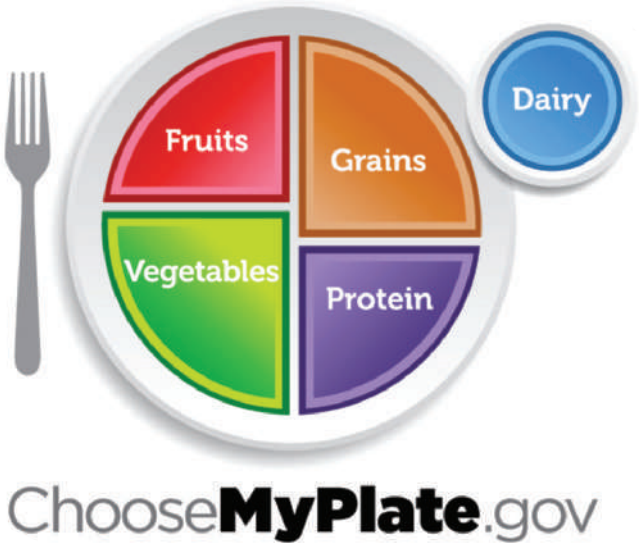

Figure 3–4 ■ MyPlate is designed to be used as a method of helping Americans make healthy food choices and be active every day.

Evidence for Nursing Care

Health Promotion for Adults

Selected resources that nurses may find helpful when planning evidence-based nursing care follow.

- Appel, L., Frohlich, E., Hall, J., Pearson, T., Sacco, R., Seals, D. R., . . . Van Horn, L. V. (2011). The importance of population-wide sodium reduction as a means to prevent cardiovascular disease and stroke. A call to action from the American Heart Association. *Circulation 2011, 123*, 1138–1143. Retrieved from http://circ.ahajournals.org
- Conn, V., Hafdahl, A., & Mehr, D. (2011). Interventions to increase physical activity among healthy adults: Meta-analysis of outcomes. *American Journal of Public Health, 101*(4), 751–758.
- Institute for Clinical Systems Improvement. (2011). *Healthy lifestyles*. Bloomington, MN: Author.

- Practice safer sex (monogamy, use of barrier protection).
- Have regular dental examinations and cleanings.
- Maintain recommended immunizations (Table 3–4).
- Follow guidelines for recommended health screening (Table 3–5).

The nurse promotes health by teaching the activities that maintain wellness, by providing information about the characteristics and consequences of diseases when risk factors have been identified, and by supplying specific information about decreasing risk factors (Pender et al., 2011).

The nurse also promotes health by following healthy practices and serving as a role model. In an analysis of interventions to increase physical activity among healthy adults, Conn, Hafdahl, and Mehr (2011) found that behavioral interventions and modeling of physical activity behavior presented directly to individuals were more effective than both interventions targeting knowledge, attitudes, or beliefs, and those using mass media or community-wide strategies.

TABLE 3–4 Recommended Immunizations for Adults

Vaccine	Indications	Do Not Give to
Measles-mumps-rubella	Anyone born after 1956 and never infected, or those likely to be exposed, such as those entering college or the military and healthcare personnel.	Pregnant women, immunocompromised people, or anyone with a history of anaphylactic reaction to egg protein or neomycin.
Tetanus, diphtheria, pertussis (Td, Tdap)	All adults should receive one dose of Tdap followed by a Td booster every 10 years.	People with a history of anaphylactic reaction to the vaccine. People with a history of encephalopathy following pertussis vaccine should not receive Tdap.
Hepatitis A	Anyone who wishes protection and those traveling to countries in which hepatitis A infection is endemic.	People with a history of hypersensitivity to aluminum hydroxide or phenoxyethanol.
Hepatitis B	Adults under age 60 who have diabetes. Anyone likely to have repeated exposure (such as healthcare providers or sexually active individuals not in a mutually monogamous relationship) or who have had exposure (such as a needlestick injury to a healthcare worker).	People with a history of anaphylactic reaction to common baker's yeast.
Human papillomavirus (HPV)	All previously unvaccinated women and men through age 26 years.	People with a history of anaphylactic reaction to the vaccine or its components.
Influenza	All adults should receive annual immunization against seasonal influenza.	Those with a high fever, or a history of anaphylactic reaction to egg protein.
Meningococcal disease	Those at high risk for exposure, including military recruits.	People with a severe allergic reaction to vaccine component or following a prior dose of vaccine; those currently experiencing moderate or severe acute illness.
Pneumococcal pneumonia	Anyone at high risk for pneumococcal disease, those over 65 years of age.	Pregnant women.
Varicella	Anyone never infected, especially healthcare providers and child care workers.	Pregnant women, immunocompromised people, those who have received an immune globulin or a blood transfusion within 5 months, or those with a history of anaphylactic reactions to neomycin or gelatin.
Zoster (shingles)	People ages 60 years and older.	Pregnant women, immunocompromised people, and those with a history of anaphylactic reactions to neomycin or gelatin.

Setting activity goals, self-monitoring, and an exercise prescription are examples of behavioral strategies.

DISEASE AND ILLNESS

Disease and *illness* are terms that are often used interchangeably, but in fact they have different meanings.

Disease

Disease (literally meaning *without ease*) is defined as any alteration in a body system or organ structure or function. Diseases are characterized by identifiable signs and symptoms, and usually a recognized pathophysiologic process and etiology, although the cause of many diseases is still unknown. Diseases are generally categorized as either congenital (present at birth) or acquired (caused by events that occur after birth) (Grossman & Porth, 2014). We now recognize that many diseases involve the interaction of a genetic predisposition and environmental factors. Recognized causes of disease include:

- Genetic variations
- Environmental factors such as exposure to viruses, chemicals, or drugs that affect the developing fetus
- Infectious agents
- Tissue injury due to lack of oxygen, temperature extremes, radiation, or toxins (e.g., alcohol, drugs, cigarette smoke)
- Poor nutrition (obesity, malnutrition)
- Inadequate or disordered immune responses
- Neoplasia.

Diseases may be classified as acute or chronic, communicable, congenital, degenerative, functional, malignant, idiopathic, or iatrogenic. These classifications are defined in Table 3–6. In all types of disease, alterations in structure or function cause signs and symptoms (**manifestations**) that prompt an individual to seek treatment from a physician or traditional healer. Both subjective symptoms and objective signs commonly are present. Subjective symptoms may include such manifestations as nausea, general malaise, or fatigue, chest pain, shortness of breath, or abdominal pain. Bleeding, vomiting, diarrhea, limited movement, swelling, and changes in elimination are all examples of objective signs. Pain (a subjective symptom) is often the primary reason that prompts an individual to seek healthcare.

Illness

Illness is the response an individual has to a disease. This response is highly individualized because the individual responds not only to her own perceptions of the disease but also to the perceptions of others.

TABLE 3–5 Recommended Health Screening for Healthy Adults (without specific risk factors)

	Recommended Frequency		
Examination	**Young Adults (Ages 18–40)**	**Middle Adults (Ages 40–65)**	**Older Adults (Ages 65 and Older)**
Health maintenance examination: • Height, weight, body mass index • Risk evaluation and counseling (including alcohol and tobacco use) • Safety • Behavioral assessment (including depression)	Every 1–5 years	Every 1–3 years	Every 1–2 years
Abdominal aortic aneurysm			Men ages 65–75 who have ever smoked
Blood pressure	Every 2 years; annually if 120–139/80–89 mmHg	Every 2 years; annually if 120–139/80–89 mmHg	Every 2 years; annually if 120–139/80–89 mmHg
Breast cancer:			
• Clinical breast exam • Mammography	Every 3 years	Annually Every 1–2 years ages 50 and older	Annually Every 1–2 years to age 75
Cervical cancer (Pap test)	Every 3 years ages 21–29; every 3 years after age 30; every 5 years when combined with an HPV test	Every 3 years; every 5 years when combined with an HPV test	Discontinue if no abnormal results indicating serious cervical precancer in 20 years
Cholesterol and lipid profile	Every 5 years for men over age 34	Every 5 years for men and women over age 44	Every 5 years
Chlamydia	All sexually active women under age 26	Women with new or multiple partners	Women with new or multiple partners
Colorectal cancer:			
• Fecal occult blood test (FOBT) or fecal immunochemical test (FIT)		Annually beginning at age 50	Annually
• Flexible sigmoidoscopy *or* double contrast barium enema *or* CT colonography (virtual colonoscopy)		Every 5 years beginning at age 50	Every 5 years
• Colonoscopy		Every 10 years beginning at age 50	Every 10 years to age 80
Glaucoma			Every 2 years
Osteoporosis		Bone mineral density for postmenopausal women who are at high risk	Bone mineral density; repeat every 2 years for those at risk
Prostate cancer		Consider prostate-specific antigen (PSA) blood test every 1–2 years beginning at age 50 (age 45 for Black males and men with strong family history of prostate cancer)	Consider PSA test every 1–2 years
Vision and hearing		Hearing screening	Objective vision and hearing screening

Sources: American Cancer Society. (2013). *Guidelines for the early detection of cancer*. Retrieved from http://www.cancer.org; American Cancer Society. (2012). *Cancer prevention & early detection: Facts & figures 2012*. Retrieved from http://www.cancer.org; Institute for Clinical Systems Improvement. (2011). *Health care guideline: Preventive services for adults* (17th ed.). Retrieved from http://www.icsi.org/preventive_services_for_adults/preventive_services_for_adults_4.html.

Illness integrates pathophysiologic alterations; the psychologic effects of those alterations; the effects on roles, relationships, and values; and cultural and spiritual beliefs. An individual may have a disease and not categorize himself as ill, or may validate feelings of illness through the comments of others ("You don't look as though you feel well today").

ACUTE ILLNESS

An **acute illness** occurs rapidly, lasts for a relatively short time, and is self-limiting. The condition responds to self-treatment or to medical-surgical intervention. Patients with uncomplicated acute illnesses usually have full recovery and return to normal pre-illness functioning.

TABLE 3–6 Disease Classifications and Definitions

Classification	Definition
Acute	A disease that has a rapid onset, lasts a relatively short time, and is self-limiting
Chronic	A disease that requires continuing management over a long period—years or even decades
Communicable	A disease that can spread from one person to another
Congenital	A disease or disorder that exists at or before birth
Degenerative	A disease that results from deterioration or impairment of organs or tissues
Functional	A disease that affects function or performance but does not have evidence of organic changes
Malignant	A disease that tends to become worse and cause death
Idiopathic	A disease that has an unknown cause
Iatrogenic	A disease that is caused by medical therapy

Illness behaviors are highly individualized and are influenced by age, gender, family values, socioeconomic status, culture, educational level, and mental status. The commonly recognized sequence of illness behaviors follows:

1. ***Experiencing symptoms***. In the first stage of an acute illness, an individual experiences one or more manifestations such as pain, fever, bleeding, or swelling that prompt awareness of a change in normal health. If the manifestations are mild or are familiar (such as symptoms of the common cold or influenza), the individual usually uses a traditional remedy for self-treatment such as rest or OTC medications. If the symptoms are relieved, no further action is taken; however, if the symptoms are severe or become worse, the individual moves to the next stage.
2. ***Assuming the sick role***. In the second stage of illness behavior, the individual assumes the sick role, accepting the symptoms as indicative of an illness. A focus on alterations in function resulting from the illness is characteristic of this stage. If the illness is resolved, the individual resumes normal activities; however, if manifestations remain or increase in severity, the individual moves to the next stage by seeking medical care.
3. ***Seeking medical care***. In our society, a physician or other healthcare provider usually provides validation of illness. People who believe themselves to be ill (and who are encouraged by others to contact a healthcare provider) make the medical contact for diagnosis, prognosis, and treatment of the illness. If the medical diagnosis is of an illness, the individual moves to the next stage.
4. ***Assuming a dependent role***. The stage of assuming a dependent role begins when an individual accepts the diagnosis and planned treatment of the illness. The responses of the individual to care depend on many different variables: the severity of the illness, the degree of anxiety or fear about the outcome, the loss of roles, the support systems available, individualized reactions to stress, and previous experiences with illness care. The cause and severity of the illness and the individual's resources affect whether the individual moves to the next stage, recovery and rehabilitation, or to chronic illness or even death.
5. ***Achieving recovery and rehabilitation***. The final stage of an acute illness is recovery and rehabilitation. The individual gives up the dependent role and resumes normal roles and responsibilities.

CHRONIC ILLNESS

Chronic illness is a term that encompasses many different long-term pathologic and psychologic alterations in health. It is the leading health problem in the world today, accounting for 70% of all deaths in the United States (CDC, 2012a). In the United States, chronic disease management and treatment account for more than 85% of healthcare spending (O'Connor et al., 2013). The incidence and prevalence of chronic illness are increasing, and that trend is predicted to continue. Current trends contributing to an increased incidence of chronic illnesses include an aging population, diseases of lifestyle and behavior (e.g., obesity, smoking), and environmental factors. The staggering physical, psychosocial, and economic costs of chronic illness have made its prevention and effective management a focus of the Affordable Care Act of 2010.

Chronic illness is defined as a condition that requires continuing management over a long period—years or even decades. Chronic diseases include communicable diseases such as tuberculosis and HIV infection and noncommunicable diseases (e.g., cancer, heart disease, diabetes, chronic lung disease); long-term mental health disorders such as schizophrenia; and physical, sensory, or structural impairments (e.g., arthritis, visual impairment). Four common behavioral risk factors account for most chronic disease: lack of physical activity, poor nutrition, tobacco use, and excessive alcohol consumption (CDC, 2012a).

The intensity of a chronic illness and its related manifestations range from mild to severe. More than one body system often is affected. With effective management, many chronic diseases can remain stable for extended periods of time. Often, however, patients experience progressive symptoms and periodic acute crises. Some chronic diseases are characterized by periods of remission and exacerbation. During periods of **remission**, the individual does not experience symptoms, even though the disease is still clinically present. During periods of **exacerbation**, the symptoms reappear.

Each person with a chronic illness has a unique set of responses and needs. The response of the individual to the illness is influenced by factors such as the disease itself; the life state at which it develops; the effect of disease-related limitations on physical, psychologic, and social functioning; and emotional responses to the illness. These factors are highly complex and interrelated, resulting in individualized illness behaviors and needs. Although the experience of each person

FAST FACTS

- Nearly half of all adults in the United States have at least one chronic disease; many of those have multiple chronic diseases.
- Heart disease, cancer, and stroke cause more than 50% of all deaths annually.
- One-third of American adults are obese, as are nearly one-fifth of children between ages 6 and 19.
- Diabetes is the leading cause of kidney failure, nontraumatic lower-extremity amputations, and blindness among adults.
- Arthritis is the most common cause of disability and activity limitations (CDC, 2012a).

Figure 3–5 ■ In chronic illness, the patient must learn how to manage the disorder, including medications.
Source: Bill Aron/PhotoEdit.

with a chronic illness is unique, people with chronic illness face common challenges, including:

- Recognizing and appropriately responding to symptoms
- Using medications effectively (Figure 3–5 ■)
- Learning to manage an ongoing treatment plan
- Modifying lifestyle to adapt to and minimize the impact of the disease
- Developing effective strategies for coping with the psychosocial effects of chronic illness
- Maintaining a feeling of being in control
- Interacting effectively with the healthcare system on an ongoing basis (Schulman-Green et al., 2012).

Many people with chronic illness successfully manage health-related needs, whereas others do not. Research indicates that adaptation is influenced by variables such as anger, depression, denial, self-concept, locus of control, hardiness, and disability. Nurses play an increasingly important role in promoting independent functioning, reducing healthcare costs, and improving well-being and quality of life for patients with chronic illnesses.

ILLNESS PREVENTION

In addition to health promotion goals and activities as outlined in *Healthy People 2020*, actions taken by the individual patient and healthcare provider to prevent illness and limit its progression are important. Three levels of illness prevention have been defined: primary, secondary, and tertiary prevention.

Primary prevention focuses on activities and specific actions to prevent disease by eliminating risk factors for disease to the extent possible. Primary prevention often occurs within communities outside the healthcare system. In some cases, primary prevention measures are legislated, such as clean air and water standards and the use of seatbelts in automobiles. Following are examples of primary prevention activities:

- Eating nutritious foods and balancing calorie intake with energy expenditure
- Reducing exposure to industrial hazards such as noise and dust
- Practicing safer sex
- Obtaining immunizations
- Eliminating the use of alcohol and cigarettes
- Avoiding cell phone use and texting while driving.

Secondary prevention, which usually occurs within the healthcare system, involves activities that emphasize early diagnosis and treatment of disease to effect an early cure or prevent disease progression (Grossman & Porth, 2014). Following are examples of secondary prevention activities:

- Screening for common diseases such as hypertension, diabetes mellitus, malignancies, and glaucoma
- Obtaining regular physical examinations
- Performing self-examination for breast and/or testicular cancer
- Obtaining specific treatment for illness (e.g., treatment of streptococcal infections of the throat helps prevent secondary disorders involving the heart and/or kidneys).

Tertiary prevention focuses on preventing further health decline and reducing complications associated with disease. The goal is to return and maintain the affected individual at his or her highest possible level of function. For acute illness, tertiary prevention activities primarily revolve around rehabilitation, such as the following:

- Specific rehabilitation programs for cardiovascular problems, head injuries, and strokes
- Work training programs following illness or injury
- Educating the public to employ rehabilitated people to the fullest possible extent

Tertiary prevention activities for the individual with chronic illness focus on effective disease management to promote high-level functioning and prevent acute crises. Recognition of spiraling costs has led to an increased focus on and initiatives to promote coordinated interprofessional primary care for patients with multiple chronic conditions and complex care needs. Nurses play a significant role in several evidence-based models for chronic care as outlined in the following section of this chapter.

HEALTH AND ILLNESS CARE

In the healthcare system of the 21st century, hospitals are primarily acute care providers with services focused on high-technology care for severely ill or injured people or for people having major surgery. Healthcare has become a managed care, community-based system, in which most healthcare services are provided outside the hospital. The Affordable Care Act of 2010 places increasing emphasis on effective patient management to prevent hospital admission or readmission following discharge. Discussion of selected current models and alternate settings of care follows. It is important to note that these models and settings are not mutually exclusive; for example,

primary care often is delivered in community-based settings, and disease management often occurs within programs associated with acute medical centers.

Primary Care

Primary care is comprehensive first contact health and illness care across the life span. Preventive care services as well as care for acute and chronic diseases are encompassed within the primary care model (Berryman et al., 2013).

Primary care settings are increasingly diverse. While traditionally delivered by physician-led teams within a physician's office or clinic, primary care increasingly occurs in retail walk-in clinics, hospital-affiliated practices, workplace settings, and in nonphysician provider practices (Hoff, 2013).

The **patient-centered medical home (PCMH)**, also called a *healthcare home*, is a primary care model that focuses on all levels of illness prevention. The PCMH, led by a primary care provider (e.g., physician, nurse practitioner, advanced practice nurse), is designed to provide accessible, comprehensive, and coordinated patient and family care within the community (Berenson et al., 2008; Berryman et al., 2013; Grant & Greene, 2012). For people with chronic illnesses, the goal of the PCMH is to provide comprehensive care with a focus on preventing acute disease crises. In addition to the primary care provider, the PCMH interprofessional team often includes care coordinators or case managers, a role often filled by nurses, as well as social workers and rehabilitation therapists. Basic facets of the PCMH include an ongoing patient–primary care provider relationship, responsibility for total patient care, improving access to care and reducing health disparities, increasing preventive services, and improving chronic disease management (Grant & Greene, 2012).

Care and Disease Management

In the care management model for chronically ill patients and their families, a nurse or social worker helps assess problems, communicate with healthcare providers, and navigate the healthcare system (Boult et al., 2009). Under the care management model, patients report improved satisfaction and quality of care; quality of life and survival also are improved.

Improved patient outcomes also are demonstrated with the disease management model. This model focuses on providing education and instruction about the disease (e.g., heart failure, diabetes mellitus, chronic obstructive pulmonary disease), its management, self-monitoring, and interactions with healthcare providers.

Transitional Care

Transitional care focuses on interventions to facilitate transitions from one healthcare setting to another or to home (Boult et al., 2009). Transitional care interventions to prepare the patient and caregiver for transitions typically are led by a nurse or advanced practice nurse. Interventions include development of an evidence-based plan of care, ongoing support, and an emphasis on early identification of and response to risks and symptoms to avoid adverse events. The goal of transitional care is to improve the care and outcomes of chronically ill patients by streamlining plans of care, improving the ability of patients and caregivers to manage care needs, and interrupting patterns of frequent acute health crises (Naylor et al., 2011).

Community-Based Care

Community-based care is a primary care model that centers on individual and family healthcare needs. In contrast to community health nursing, which focuses on the health of the community, the nurse in community-based care settings provides direct services to individuals to manage acute or chronic health problems and to promote self-care. The care is provided in the local community, is culturally competent, and is family centered. The philosophy of community-based nursing directs nursing care for patients wherever they are, including where they live, work, play, worship, and go to school (Figure 3–6 ■).

Nurses provide community-based care in settings ranging from leading support groups in a hospital (for individuals and family members diagnosed with such illnesses as cancer or diabetes) to managing a freestanding clinic to providing care at the patient's home. Box 3–3 illustrates the varied settings within the community in which a nurse may provide care.

Extended Care

Extended or long-term care facilities often provide multiple levels of care within the community. Many provide an aging-in-place model that allows older adults to remain on the same campus as independence diminishes and increasing levels of care are required.

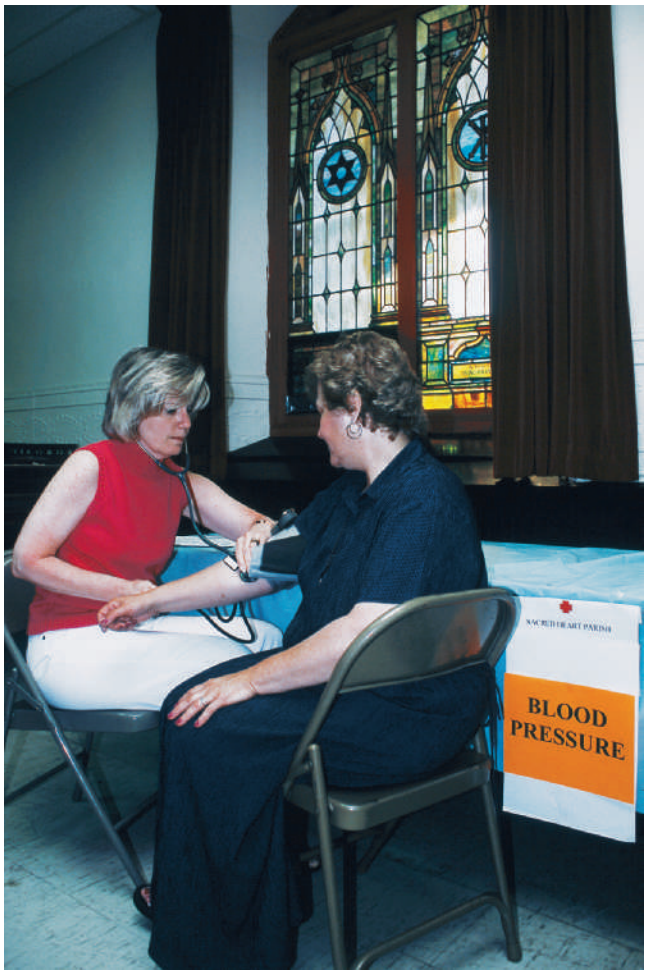

Figure 3–6 ■ Community-based nursing care occurs in settings where people work, worship, or play.
Source: Al Dodge Photography.

BOX 3–3 Selected Community-Based Nursing Care Settings

- Medical centers
  - Outpatient (ambulatory) surgery
  - Cardiac rehabilitation
  - Disease management groups
- County health departments
- Long-term care
- Parish nursing
- Homeless shelters
- Mental health centers
- Ambulatory surgery centers
- Alcohol/drug rehabilitation
- Industry
- Jails and prisons

Increasingly, intermediate or skilled care is provided for patients as an alternative to hospitalization (step-up care) or for rehabilitation as the patient transitions from acute care to home (step-down care) (Figure 3–7 ■).

Patient-centered primary care, often provided by a geriatric advanced practice nurse (nurse practitioner or clinical nurse specialist), within extended care has been shown to improve the quality of care and reduce emergency department visits and hospital admissions of residents. In this model, the nurse regularly assesses residents, trains caregivers to recognize and respond to changes, treats residents within the extended care setting, and communicates with families (Boult et al., 2009).

Figure 3–7 ■ A patient receives physical therapy in an extended care facility.

Rehabilitation

Rehabilitation is the process of learning to live to one's maximum potential with a chronic impairment and its resultant functional disability. Rehabilitation nursing is based on a philosophy that each person has a unique set of strengths and abilities that can enable that person to live with dignity, self-worth, and independence. Nursing care to promote rehabilitation primarily focuses on patients with chronic illnesses or impairments. Rehabilitation most often begins in the acute phase of an illness or injury. Settings in which rehabilitation services are delivered include the patient's home, skilled care facilities, and specialty programs within medical centers or in the community.

Rehabilitation promotes reintegration into the patient's family and community through a team approach. Many different aspects of the patient's life are included in the plan of care: physical function, mental health, interpersonal relationships, social interactions, family support, and vocational status. Assessment includes functional health level and self-care abilities, educational needs, psychosocial needs, and the home environment. It is critical to determine the priorities of needs from the patient and family perspective before establishing any plan of care.

Interventions are planned and implemented to prevent complications, assist in achieving a realistic level of independence, educate the patient and family about home care, and make referrals to community agencies (for nursing care, special equipment or supplies, support groups, counseling, therapy, vocational guidance, and assistance with daily living activities).

Home Healthcare

Home care is not simply illness care at home, nor is it the act of setting up a hospital room in someone's house. **Home healthcare** is the delivery of services to restore or maintain the health of individuals and families in the home (Guido, 2014). Home healthcare includes a variety of services, including skilled nursing, physical and occupational therapy, pharmacy services, and durable medical equipment such as ventilators and enteral feeding pumps. Home nursing care services include acute and chronic illness care and palliative care that reduces hospital admissions or readmissions.

Home healthcare services must be necessary and medically indicated, and ordered by a qualified healthcare provider (e.g., physician, nurse practitioner) in order to qualify for reimbursement by private insurance, Medicare, or Medicaid. A physician, nurse, social worker, discharge planner, or family may make the referral for home care. Home healthcare agencies are public or private organizations that provide skilled nursing and other therapeutic services in the patient's home. These agencies primarily differ in the way their programs are organized and administered (for example, private not-for-profit agencies, proprietary agencies, institution-based agencies). All home care agencies are similar in that they must meet uniform standards for licensing, certification, and accreditation.

Medicare is home healthcare's largest single reimbursement source, although other sources exist (Medicaid, other public funding, private insurance, and public donations). There were more than

12,000 Medicare-certified home health agencies in 2011, serving more than 3.6 million patients (Centers for Medicare and Medicaid Services, 2014). Medicare does not reimburse visits made to support general health maintenance, health promotion, or patients' emotional or socioeconomic needs. Both patient and nurse must meet specific criteria to secure Medicare reimbursement. The patient must meet all of the following criteria:

- The physician must decide that the patient needs care at home and make a plan for home care.
- The patient must need at least one of the following: intermittent (not full-time) skilled nursing care, physical therapy, speech language pathology services, or occupational therapy.
- The patient must be homebound. This means leaving the home is a major effort. When leaving the home, it must be infrequent, for a short time, to get medical care, or to attend religious services.
- The home care agency must be Medicare approved.

Medicare will reimburse only when the skilled provider performs at least one of the following tasks:

- Teaching about a new or acute situation (Figure 3–8 ■)
- Assessing an acute process or a change in the patient's condition
- Performing a skilled procedure or a hands-on service requiring the professional skill, knowledge, ability, and judgment of a licensed nurse

Home care encompasses both healthcare and social services provided in the home. Among patients who benefit from home care services are those who:

- Cannot live independently at home because of age, illness, or disability.
- Have chronic, debilitating illnesses such as congestive heart failure, heart disease, kidney disease, respiratory diseases, diabetes mellitus, or muscle-nerve disorders.
- Are terminally ill and want to die with comfort and dignity at home.
- Do not need in-patient hospital or nursing home care but require additional assistance.
- Need short-term help at home for postoperative care.

Figure 3–8 ■ Skilled professional nursing care provided in the patient's home.
Source: Petert2/Fotolia.

When a referral for home healthcare is made, an initial assessment visit by a registered nurse must occur within 48 hours. A comprehensive assessment, including review of all medications and their effects, must be completed within 5 days after the start of care (Guido, 2014). Licensed nurses provide nursing care based on physician orders. These nurses conduct initial and ongoing assessments, develop and implement plans of care, supervise other care providers, coordinate patient care with the physician, advocate for the patient and family, and teach family members and friends how to care for the patient when professional services are no longer necessary.

SAFETY ALERT

Promoting Safety in Home Care

When preparing patients for discharge to home, the nurse focuses on safety first. Even when home care is planned, a day or two may elapse before services begin and patients must be able to manage until then. Information and supplies to get the patient through the first few days at home must be provided prior to discharge. Additionally, patients should have contact information for the nurse and physician, and complete written information about their medications and manifestations they should report. Finally, all patients should be able to perform necessary procedures safely and obtain necessary supplies in the community.

Nursing practice in the home is a unique experience that differs in many ways from nursing practice in a hospital setting. The individual receiving care and the family are the patients in home care. Nurses are invited into homes, meaning they are guests and cannot assume entry as they do in formal clinical settings. The environment belongs to the patient, who retains control. Every nursing action must communicate respect for these boundaries. To negotiate both repeated entry and a share of power in the patient's domain, the nurse must establish trust and rapport quickly. This is often difficult because most home care nurses are with each patient for only 1 hour a few times a week. See the accompanying Nursing Care of the Older Adult feature.

Caregiver burden is not easily hidden in the home. In the United States, an estimated 52 million people are taking care of relatives and friends who have disabilities (Family Caregiver Alliance, 2012). Many of these caregivers are themselves older adults. Caregiving has only recently been acknowledged as a complex activity, requiring adjustment in family living patterns, relationships, and finances. Early hospital discharge of family members with chronic conditions places enormous emotional, physical, and financial burdens on family caregivers. For some families, the crisis of caregiving is short lived, but for others it lasts for years. As a result, caregivers are at great risk for both physical and emotional illness. Because the success of home care depends heavily on the supports in place, addressing the needs of the support network is imperative.

Hospice and Respite Care

Hospice care is a special component of home care, designed to provide medical, nursing, social, psychologic, and spiritual care for terminally ill patients and their families. Hospice care relies on a philosophy of relieving pain and suffering and allowing the patient to die with dignity in a comfortable environment. Licensed nurses, medical social workers, physicians, occupational and physical therapists, and volunteers provide care. See Chapter 5 for more information about hospice and palliative care.

NURSING CARE OF THE OLDER ADULT

Special Needs of Older Adults Living Alone

Many older adults live alone. Some may have current or potential caregivers nearby, whereas others, for various reasons, have no one. These people often require considerable nursing support to remain strong, independent, and resourceful. Caring for "families of one" can take a toll on even the strongest home care nurse. Some nurses have reported calling between visits, keeping in touch after discharge, and driving by on days off because they have such difficulty "letting go" of their concerns about these patients. Transitioning between healthcare settings is especially problematic for those with chronic illness or long-term health problems. Older adults are at high risk for "falling through the gap" and frequently need assistance to navigate the complex healthcare system. High-quality transitional care can reduce adverse events and rehospitalization rates while improving patient satisfaction with care (Naylor et al., 2011).

Respite care provides short-term or intermittent home care, often using volunteers. These services exist primarily to give the family member or friend who is the primary caregiver some time away from care. Respite care does much to relieve the burden of full-time caregiving.

Home Health Nursing Care

Despite differences in the setting, nursing care for patients in their homes is a highly rewarding clinical practice.

Establishing trust and rapport with the patient and family is essential in home health nursing. To do so, the nurse must communicate an understanding that she is a guest in the patient's home—offering suggestions in a way that acknowledges the patient's right to say no, sensing and honoring "where people are in their situation," maintaining a respectful distance, letting go of ethnocentric views ("my way is the best way"), and noticing and honoring family customs ("I see that no one wears shoes in your house; I'll take mine off, too."). Nurses should negotiate their schedules around the family's needs; nursing should enhance family coping, not complicate it.

Above all, the nurse should validate patients' illness experiences, remembering that everyone needs someone who is willing to listen and say, "I hear what you are saying, and I think I have a sense of how you feel." The nurse speaks slowly and directly to the patient, within the patient's range of vision (the patient may need to lip-read), and refrains from shouting at patients who have a hearing impairment.

On the first nursing visit, the nurse stresses the essential information and repeats it on subsequent visits to avoid overwhelming the patient with too much information. The nurse can suggest that patients have someone else present "to help listen." When making suggestions, the nurse offers patients the pluses and minuses of each alternative. Informed decisions are difficult to make if people are too overwhelmed to think of their options. The nurse must also allow time for families to process new information. See Table 3–7 for additional suggestions when teaching and caring for the patient in the home.

It is important to avoid overwhelming families with numerous healthcare providers in the home. Most people dislike having strangers in their home, no matter how helpful they may seem to be. The nurse can help families manage moments of crisis by staying as close as possible. If abuse is suspected, the nurse must notify authorities and/or remove patients from potentially dangerous situations.

BOX 3–4 Home Safety Assessment Checklist

GENERAL HOUSEHOLD SAFETY

1. Do stairwells and halls have good lighting?
2. Do staircases have handrails on both sides?
3. Are rugs securely tacked down?
4. Is the telephone readily accessible? Are the numbers easy to read?
5. Are electrical cords in good condition and out of the way?
6. Is furniture sturdy?
7. Is the temperature of the home comfortable?
8. Are protective screens in front of fireplaces or heating devices?
9. Are smoke detectors and carbon monoxide detectors present and working?

BATHROOM

1. Are grab bars present in the tub and/or shower? Around the toilet?
2. Are toilet seats high enough?
3. Are nonskid materials (rugs, mats) on the floor, tub/shower?
4. Are medications stored safely? Out of the reach of children?
5. Is the water temperature safe?
6. Are electrical outlets and appliances a safe distance from the tub?

KITCHEN

1. Are floors slippery? Are nonskid rugs used?
2. Is the stove in good working order?
3. Is the refrigerator in good working order? Clean?
4. Are electrical outlets overloaded with appliance cords?
5. Are sharp objects kept in a special container or safe area?
6. Is food storage adequate? Clean?
7. Are cleaning materials stored safely?

SAFETY

Performing a safety assessment in the home is a nursing responsibility and a legal requirement. Nurses cannot close their eyes to an unsafe environment. Upon entering the home and on a continuing basis, the nurse must alert the family to unsafe and hazardous conditions, suggest remedies, and document in the clinical record the family's response to the nurse's suggestions. See Box 3–4 for a sample home safety assessment list. In addition, nurses must remain alert to the following:

- How patients ambulate and handle stairs
- How patients manage care when alone
- A supply of expired medications
- Inappropriate clothing or shoes
- Cooking habits that may precipitate a fire
- An inadequate food supply
- Poorly functioning utilities
- Signs of abusive behavior.

Although nurses cannot change the family's living space and lifestyle, they can register their concern and react appropriately if the risk for injury is significant or if abuse or neglect is suspected. Ignoring an unsafe environment is considered nursing negligence.

The disposal of toxic medications and sharp objects (such as needles used for injections) is a safety issue in the home, especially

TABLE 3–7 Interventions in Home Health Nursing

Set goals and boundaries.	• Explore the patients' and families' expectations of home care. • Explain the primary goal (to achieve self-care). • Define nurse and patient roles within this framework and discuss limitations (e.g., "No, a home care nurse is not the same as a private duty nurse"). • Stress mutual accountability, choice, and negotiation as part of the process.
Assess the home environment.	• Survey the environment and members of the household, noting hygiene and dress; verbal and nonverbal communication; significant relationships and visiting patterns; appearance of the house, yard, sidewalk, and neighborhood. • Assess the effect of illness on the family. • Ask questions and listen carefully to stories and offhand remarks.
Set priorities.	• Develop an initial plan to address issues of safety and those of greatest concern to the patient and family. • Mutually establish short-term and long-term goals, remembering that those priorities that primarily belong to the nurse may not be met. • Be prepared to modify the plan according to conditions within the home and family.
Promote learning.	• Actively promote learning by identifying what is most important to the patient. • Prioritize material on a needs-to-know (e.g., information to ensure safety), wants-to-know, ought-to-know basis, assessing and responding to learner readiness. • Timing is important; people who are not ready to listen cannot learn. • Allow sufficient time, teaching while providing care when possible. • Ask patients how and when they learn best, and use appropriate methods and materials when possible. • Capitalize on patients' frustrations and desires to regain control of self-care. • Empower learners by talking them through tasks, encouraging them to ask questions, and urging them to write thoughts and questions to discuss during the next visit or doctor's appointment.
Limit distractions.	• To the extent possible, limit distractions such as children, animals, noise, clutter, and mannerisms that are controlling, manipulative, or aggressive. • Elicit the patient's help by asking, for example, "May I please turn off your television while we visit?" or "I would like to schedule my next visit for a time when the children are in school. Is that all right with you?" • Do not debate the priority of the visit over the distraction (such as a favorite television show), which may risk losing the patient's trust and rapport. • Attend to environmental and behavioral distractions that can yield useful information; for example, a dirty house could indicate a lack of interest in housekeeping, outright neglect and abuse, depression, or increased disability. • Be truthful about allergies, fear of a patient's pet, or difficulty hearing in a particular room. • If all efforts at limiting distractions fail, leave the home and return on another day: "I can see this is not going to work for us today. I will need to leave." • Seek out a colleague to discuss personal distractions, such as fear of harm, reaction to the patient's lifestyle, preoccupation with role or a feeling of being overwhelmed by the situation in the home.
Make do.	• Be resourceful and cost conscious with equipment, supplies, and services in the home. • When necessary to make do or improvise, do so in a low-key manner to avoid causing the family additional anxiety. • Make every effort to convey the message that the situation is under control; react as necessary after leaving the home.

if young children are present. The nurse must address this with the patient, demonstrate safe disposal, and provide the necessary equipment for safe disposal. Documentation should address what information the nurse has covered, the family's response to the teaching, and assessment of the family's ongoing practice of safety precautions.

Nurses must focus on personal safety and survival as well as their patients' safety and survival. When traveling in the community, the nurse takes such precautions as keeping car doors locked, having a cellular phone, keeping supplies out of sight, and staying inside the car in potentially dangerous situations. Colleagues, families, and community members can offer useful guidelines for maintaining safety and self-protection.

INFECTION CONTROL

Infection control in the home centers on protecting patients, caregivers, and the community from the spread of disease. Within the home, nurses may encounter patients with infectious or communicable diseases, patients who are immunocompromised, and/or patients with multiple access devices, drainage tubes, or draining wounds. The home presents a challenging environment in which to practice infection control for several reasons: Families have habitual patterns of behavior; caregivers often lack any formal education on the subject; the setting itself may not be conducive; and facilities for even the most basic of aseptic practices (hand hygiene) may be lacking.

Health teaching is the single most important nursing intervention in controlling infection. Patients and caregivers need to know the importance of effective hand hygiene, the use of gloves, the disposal of wastes and soiled dressings, the handling of linens, and the practice of standard precautions. Unfortunately, teaching about infection control does not always bring about a change in behavior. Changing a family's values and behavior frequently demands a great deal of ingenuity from the nurse.

CHAPTER HIGHLIGHTS

- **Health is a dynamic state influenced by multiple internal, external, physical, social, and mental factors.**
- These factors include those that cannot be changed (e.g., genetic makeup, gender, age, ethnicity, and culture) as well as modifiable factors (e.g., lifestyle and environment).
- Community factors affecting health include social support systems, access to healthcare services, the environment, and economic resources.
- **Nurses play a major role in promoting the health of individuals, families, and communities. Health promotion focuses on increasing the well-being and maximizing the potential of the individual, family, or community.**
- **The primary health risks for the individual and family vary, depending on age and developmental stage, among other factors. Behaviors to promote individual health, however, remain very consistent throughout the life span.**
- Young adults are at risk for alterations in health from injuries, sexually transmitted infections, substance abuse, and physical and psychologic stressors. Cancers are a leading cause of death, and behaviors established in young adulthood affect risk for developing common chronic diseases in the future.
- Middle adults are at risk for alterations in health from obesity, cardiovascular disease, cancer, substance abuse, and the stresses of change and transition.
- Older adults are at risk for alterations in health from chronic illnesses, injuries, drug toxicities, and changes in income and marital status.
- **Diseases are characterized by identifiable signs and symptoms, and usually a recognized pathophysiology and etiology. Illness is the response to a disease, affected not only by the disease itself but also the individual's perception of the disease and that of others.**
- **Chronic disease is now recognized as the leading worldwide threat to health and a major factor driving increasing healthcare costs. Nurses play an instrumental role in interprofessional care teams to improve the health and effective management of patients with chronic disease.**
- Most health and illness care occurs outside the acute hospital environment, in community-based and primary care settings. Home healthcare is increasingly important as hospital stays become shorter or are avoided altogether.
- In contrast to community health, which focuses on health of a population, community-based care focuses on individual and family healthcare needs.
- **Ensuring safety and patient and family education are major responsibilities of the home healthcare nurse. In this setting, the patient and family are primary members of the team and are instrumental in establishing priorities of care.**

TEST YOURSELF NCLEX-RN® REVIEW

1. During an assessment the nurse asks a patient to rate her current health status on a continuum from being well to being ill. Which health factor is the nurse assessing in this patient?
   1. culture
   2. genetic makeup
   3. cognitive abilities
   4. lifestyle and environment

2. The nurse is concerned that an older patient is at risk for a health problem because of psychosocial stressors. What did the nurse most likely assess in this patient?
   1. caring for ailing spouse
   2. recent fall resulting in a hip fracture
   3. 30-year history of smoking cigarettes
   4. use of over-the-counter pain medication

3. The nurse is preparing an educational session that focuses on health promotion activities for the middle-aged adult. What is the purpose of this teaching?
   1. Diagnose diseases.
   2. Emphasize activities that maintain wellness.
   3. Explain success of medical treatments for illnesses.
   4. Focus on adhering to prescribed medication regimens.

4. The nurse is planning care to prevent the onset of illness for a patient with a chronic disease. Which secondary prevention activities would be appropriate for this patient?
   1. Receiving recommended immunizations
   2. Scheduling regular physical examinations
   3. Eliminating the use of alcohol and cigarettes
   4. Participating in disease rehabilitation programs

5. After seeing a healthcare provider for upper respiratory illness symptoms, a patient is being admitted to the hospital for care. Which illness behavior should the nurse keep in mind when planning care for this patient?
   1. seeking medical care
   2. assuming the sick role
   3. experiencing symptoms
   4. assuming a dependent role

6. The nurse is participating in a conference to identify interventions for an older patient who has started hemodialysis while hospitalized and will be returning home within the week. What is the ultimate goal for this planning session?
   1. Navigate through the healthcare system.
   2. Deliver services to maintain the patient's health in the home.
   3. Improve the patient and family's ability to manage care needs.
   4. Manage acute or chronic health problems and promote self-care.

7. A hospital committee is tasked with designing a patient-centered medical home to be implemented for newly discharged patients with chronic diseases. Which concept should the committee chair emphasize when reviewing the purpose of this primary care approach for these patients?
   1. Reduce health disparities.
   2. Prevent acute disease crises.
   3. Increase preventive services.
   4. Improve the patient–primary care relationship.

8. The nurse is determining if a patient with Medicare coverage is a candidate for home care. On which purpose should the nurse focus to determine if Medicare will cover this patient's home care services?
   1. Patient is recently widowed and is having difficulty spending time alone in the home.
   2. Patient is newly diagnosed with diabetes and is learning how to self-administer insulin.
   3. Patient has difficulty with bathing and needs assistance with clothing and home chores.
   4. Patient requests nursing visits to occur during meals to provide socialization while eating.

9. During a home visit the nurse sees that an older patient has a supply of expired antibiotics. What should the nurse do after making this discovery?
   1. Suggest that the medications be thrown out.
   2. Explain how to safely dispose of these medications.
   3. Remind the patient to take medications that are not expired.
   4. Move the expired medications to the back of the medication area.

10. The nurse is making a home visit to a patient recovering from bacterial pneumonia. Which intervention is the most important to control infection in the home environment?
   1. Teaching the patient to conduct hand hygiene after expectorating into tissues
   2. Isolating the patient from family members while still taking prescribed antibiotics
   3. Separating the patient's bath towels and clothing from the rest of the family's items
   4. Reminding home caregivers to wash the patient's eating utensils in hot soapy water

UNIT

1 Building Clinical Competence

Dimensions of Medical-Surgical Nursing

CLINICAL SCENARIO

Directions: *Read the following clinical scenario and answer the related questions. To complete this exercise successfully you will not only use knowledge of the content in this unit, but also principles related to setting priorities and maintaining patient safety.*

You have been assigned to work with the following home healthcare patients on the day shift. You receive a report at 0800. Significant data obtained during report is as follows:

- Mrs. Cora Swank, a 76-year-old female, had surgery 10 days ago for an obstructed colon that resulted in a permanent transverse colostomy. She was discharged from the acute care hospital yesterday. She lives with her 78-year-old husband. You need to evaluate her care of the colostomy and how well she can care for herself at home.
- Tom Smith is a 24-year-old who is at home due to osteomyelitis in the left leg from a previous leg fracture obtained when the motorcycle he was riding was involved in a crash. You need to change his left leg dressing and administer IV vancomycin (Vancocin) that is to be given every 12 hours. The next dose is due at 0930.
- Marguerite Garcia is an 86-year-old Hispanic who lives alone. She has hypertension, type 2 diabetes mellitus, and congestive heart failure. She is to have her blood pressure taken and a glucometer check for her blood sugar level. You will need to make sure she is taking her prescribed medications and set up her medications for the week.
- Sebastian Huian is a 56-year-old Asian who had a stroke, which left him with left-sided weakness and some speech difficulties in addition to speaking little English. He smokes a half a pack of cigarettes daily. He is being discharged from the rehabilitation unit this morning. You will be doing an intake as the first home health visit to determine what his needs will be and how much assistance he will need from home health.

CLINICAL REASONING

1. Mr. Smith reports new onset of a rash on the trunk of his body. The home care nurse examines the rash and documents its characteristics in the electronic health record. What additional steps does the nurse need to take at this time?

Priority Setting

2. What factors will you consider when deciding in which order you will visit these patients after report?
   A. _____
   B. _____
   C. _____

Health Promotion

3. Which is an example of a tertiary level of prevention for Mr. Huian?
   A. Eating a nutritious diet to promote healing and gain more strength
   B. Having screenings for other disease processes, such as hypertension
   C. Enrolling in a work-training program for individuals with extremity weakness
   D. Eliminating the use of smoking and alcohol

Nursing Process

4. Besides obtaining vital signs, what diagnosis-specific assessment data should be collected for each patient?
   A. _____
   B. _____
   C. _____
   D. _____

5. Nursing interventions to ensure competent home care for Mr. Huian include which of the following? Select all that apply.
   A. Establish trust and rapport.
   B. Have his 14-year-old son translate for him.
   C. Assess the home environment for safety.
   D. Discuss having family members feed him due to his left arm weakness.
   E. Set goals for home healthcare and rehabilitation.

6. The nurse explains a diet of low-sodium foods to Mrs. Garcia. What is the best way to evaluate Mrs. Garcia's understanding of the low-sodium diet?

Communication

7. What information will you report to the next home health nurse who will be caring for Mr. Huian?

Delegation

8. What care or data collection for each patient can be delegated to a home health certified nursing assistant?

Interprofessional Care

9. The home care nurse makes a visit to Mrs. Garcia. Which of the following assessment findings requires collaboration with the healthcare provider?
   A. Patient has gained 1 pound since last visit 2 days ago.
   B. Blood glucose level immediately prior to noon meal is 128.
   C. Bibasilar coarse crackles are auscultated in previously clear lungs.
   D. Blood pressure on right arm = 128/78 mmHg; blood pressure on left arm = 120/70 mmHg.

Continuity of Care

10. Which of the following is an example of electronic documentation that will assist the next home care nurse in evaluating patient progress?

A. Mr. Huian lives in a two-story home.
B. The condition and size of Mr. Smith's wound.
C. Mrs. Swank's stoma is red and moist.
D. Medication container has been set up for Mrs. Garcia for a 1-week time period.

Safety

11. The home care nurse has performed a safety assessment of Mr. Huian's home. Which of the following situations observed in the home raise a safety concern and need to be discussed with the patient/family? Select all that apply.

A. The patient does not own a scale.
B. There are grab bars in the shower stall.
C. There is one smoke detector in the home.
D. The home has a bathroom/bedroom on the first floor.
E. Throw rubs are scattered throughout the living room.

Quality Improvement

12. Identify a home care quality improvement project focused on preventing hospital readmissions for congestive heart failure.

Nursing Ethics

13. During your initial visit to Mr. Smith, he states, "When my leg is better, let's go dancing." How will you respond?

Informatics

14. When documenting the assessment findings in the electronic health record for each of the patients assigned to you, match the type of form you would expect to use for the specific assessment data:

_____ Flow sheet
_____ Progress note
_____ Nursing care plan
_____ Interprofessional communication notes

A. Documentation that details a telephone call to the referring physician to report a new significant finding
B. Documentation of nursing diagnosis, outcomes, and interventions
C. Documentation of vital signs
D. Documentation that provides narrative detail of a patient teaching session

UNIT

2

Alterations in Patterns of Health

4 Nursing Care of Patients Having Surgery 49

5 Nursing Care of Patients Experiencing Loss, Grief, and Death 79

6 Nursing Care of Patients with Problems of Substance Abuse 96

7 Nursing Care of Patients Experiencing Disasters 117

4 Nursing Care of Patients Having Surgery

LEARNING OUTCOMES

1. Compare the differences and similarities between outpatient and inpatient surgery.
2. Identify the three phases of perioperative care.
3. Interpret the significance of data used in the perioperative period to determine the patient's health status and risk profile.
4. Explain nursing implications for medications prescribed for the surgical patient.
5. Identify variations in perioperative care for patients across the life span and with differing needs based on culture.
6. Describe principles of pain management specific to acute postoperative pain control.
7. Differentiate the care needed for patients receiving varying levels of anesthesia care.

CLINICAL COMPETENCIES

1. Assess the physiologic and psychosocial health status of patients scheduled for surgery to determine their ability to tolerate surgery and identify risks for complications.
2. Develop an understanding of patient-centered care based on a respect for patient's preference, values, and needs prior to anesthesia, during postoperative care, and prior to discharge from the facility.
3. Function effectively within an interprofessional team using written and oral techniques to minimize risks associated with handoffs among team members during transitions between phases of the perioperative experience.
4. Observe and participate as appropriate with nursing responsibilities and interventions that integrate best current evidence to promote quality and patient safety in the perioperative environment.
5. Use the nursing process and technology to plan, provide, and document safe and effective nursing care for the patient in the preoperative, intraoperative, and postoperative phases of surgery.

MAJOR CHAPTER CONCEPTS

- Surgery is a major physiologic and psychologic stressor that carries significant risks. Nurses have a critical role in protecting the safety of, maintaining the physiologic and psychologic integrity of, advocating for, and promoting recovery of the patient undergoing surgery.
- Systematic and effective communication among all members of the interprofessional team is essential for safe and effective perioperative care. Care transitions (preoperative to surgery, surgery to postanesthesia recovery, and postanesthesia recovery to postoperative care) present significant opportunities for errors, emphasizing the importance of effective communication.
- Assessing, coordinating, and implementing preoperative preparation, evaluating and ensuring the patient's readiness for surgery, and teaching are key preoperative nursing roles.
- Nurses' focus during the intraoperative phase is on promoting and maintaining patient safety. Patient advocacy is a critical nursing role during this phase, because the patient is unable to speak for or meet his or her own needs.
- During the postoperative phase, nurses are instrumental in promoting the patient's comfort and initial recovery, identifying and preventing potential complications, and teaching the patient and family or caregivers about continuing care needs.

preoperative phase, *50*
regional anesthesia, *59*
scrub person, *62*
surgery, *50*

Perioperative nursing, care provided immediately before, during, and after surgery, is a specialized area of practice that requires knowledge and understanding of the following:

- Surgical anatomy
- Anticipated physiologic disruptions related to the surgery and their potential consequences
- Potential injuries to the patient and their prevention
- Risk factors and potential complications of the surgery
- Evidence-based nursing care to promote optimal recovery
- The emotional and psychosocial effects of the surgery on the patient and family.

Perioperative nursing incorporates the three phases of the surgical experience: preoperative, intraoperative, and postoperative. The **preoperative phase** begins when the decision for surgery is made and ends when the patient is transferred to the operating room. The **intraoperative phase** begins with the patient's entry into the operating room and ends with admittance to the postanesthesia care unit (PACU), or recovery room. The **postoperative phase** begins with the patient's admittance to the PACU and ends with the patient's complete recovery from the surgical intervention.

SURGERY

Surgery is an invasive medical procedure performed to diagnose and treat disease, repair injury, or correct deformity. Although surgery is a medical treatment, the perioperative nurse works in collaboration with the interprofessional team to identify and meet the patient's needs. The nurse has the primary responsibility and accountability for nursing care of the patient undergoing surgery. Multidisciplinary and autonomous nursing care prevent complications and promote the surgical patient's optimal outcomes.

Classification of Surgical Procedures

Surgical procedures can be classified according to purpose, risk, technique, and urgency (see Table 4–1). Many procedures may be performed using either a minimally invasive or an open procedure based on the health status, condition, and purpose of the surgical intervention. Minimally invasive surgery can be done in a variety of cavities in the body using a specialized camera and telescopic lens system. Based on this information, nursing care can be individualized to best meet patient needs and reduce risk for complications.

Settings for Surgery

Surgical patients may be inpatients or outpatients. The complexity of the surgery and recovery and the expected level of care needed on completion of the surgery are the major differences. Inpatient and outpatient (or *ambulatory* or *same-day*) surgeries are performed in the same operating suites in many hospitals. Outpatient surgery is also performed in freestanding surgical facilities and in physician's offices. The number of outpatient surgeries has grown rapidly in the past decade as part of the effort to contain the high costs of surgery. Diagnostic procedures, minimally invasive and laparoscopic procedures, and biopsies are commonly performed as outpatient surgeries. Moreover, increasingly complex surgeries on patients with complicated medical problems are now commonly performed on an outpatient basis. This increase in the number of outpatient procedures and the acuity level of the patients has presented a challenge to the perioperative nurse, the patient, and the family. The role of the nurse to monitor and educate the patient and his or her family both pre- and postoperatively is critical in preventing complications and poor outcomes.

Outpatient surgery potentially offers several advantages:

- Decreased cost to the patient, hospital, and insuring agency
- Reduced risk of healthcare-associated infection
- Less interruption in the patient's and family's routine
- Possible reduction in time lost from work and/or other responsibilities
- Less physiologic stress to the patient and family.

TABLE 4–1 Classification of Surgical Procedures

	Classification	Function	Examples
Purpose	Diagnostic	Determine or confirm a diagnosis	Breast biopsy, bronchoscopy, diagnostic laparoscopic procedure
	Ablative	Remove diseased tissue, organ, or extremity	Appendectomy, amputation, radio-frequency ablation of tumor cells
	Constructive	Build tissue/organs that are absent (congenital anomalies)	Repair of cleft palate
	Reconstructive	Rebuild tissue/organ that has been damaged	Skin graft after a burn, total joint replacement
	Palliative	Alleviate symptoms of a disease (not curative)	Bowel resection in patient with terminal cancer
	Transplant	Replace organs/tissue to restore function	Heart, lung, liver, kidney transplant
Risk	Minor	Minimal physical assault with minimal risk	Removal of skin lesions, dilation and curettage (D&C), cataract extraction
	Major	Extensive physical assault and/or serious risk	Transplant, total joint replacement, thoracotomy, colostomy, nephrectomy
Technique	Minimally invasive surgery (MIS)	Minimize incision and tissue disruption	Laparoscopic cholecystectomy, laparoscopic-assisted vaginal hysterectomy
	Laser surgery	Minimize tissue damage	Laser iridotomy, laser polypectomy
Urgency	Elective	Suggested, though no foreseen ill effects if postponed	Cosmetic surgery, cataract surgery, tubal ligation
	Urgent	Necessary to be performed within 1–2 days	Heart bypass surgery, amputation resulting from gangrene, closed fractures
	Emergency	Performed immediately	Obstetric emergencies, bowel obstruction, ruptured aneurysm, life-threatening trauma

Many similarities exist between nursing care of inpatient and outpatient surgical patients. Physical care is provided in much the same manner in the preoperative, intraoperative, and immediate postoperative phases of surgery. The major differences lie in the degree of teaching and emotional support that are necessary for outpatient surgical patients and their families. In addition to the physiologic insult of surgery, the outpatient surgical patient must cope with the additional stress of needing to learn a great deal of information in a short span of time. The nurse teaches the patient and family in both the preoperative and postoperative periods to enable the patient to perform self-care following discharge. Successful postoperative outcomes rely on the patient and family becoming participants in the maintenance of homeostasis and prevention of complications. The nurse has an extensive role in ensuring that education is provided at all phases of the perioperative process and that learning has occurred. This will help reduce complications as lengths of stay are shorter and as more patients have their surgical procedures performed on an outpatient basis.

Following outpatient surgery, the patient is discharged after meeting the institution's criteria, which are typically as follows:

- Patient is able to tolerate fluids or food without nausea/vomiting.
- Vital signs are stable: within approximately 10% of preoperative status.
- Patient is able to stand and begin to walk without dizziness or nausea.
- Pain is controlled or alleviated with oral medication that will be used after discharge.
- Patient is able to urinate.
- Patient is oriented, or is at preoperative mental status.
- Patient and/or significant other demonstrates understanding of postoperative instructions.

Informed Consent

The surgeon who performs a procedure is responsible for obtaining the patient's consent for care. The surgeon should discuss the procedure with the patient and family in language they can understand. **Informed consent** is disclosure to the patient of risks associated with the intended procedure or operation, and is usually obtained by means of a legal document required for all invasive procedures or therapeutic measures, including surgery. The language of the document varies according to the statutory and common laws of each state. This legal document protects the patient, nurse, physician, and healthcare facility. Informed consent includes the following information:

- Need for the procedure in relation to the diagnoses
- Description, purpose, and intended outcome of the proposed procedure
- Possible benefits and potential risks
- Likelihood of a successful outcome
- Alternative treatments or procedures available
- Anticipated risks should the procedure not be performed
- Physician's advice as to what is needed
- Right to refuse treatment or withdraw consent.

Ideally, the nurse should be present when the preceding information is provided. Later, the nurse can discuss the information with the patient and family, if necessary. If the patient has questions or concerns that were not discussed or made clear, or if the nurse questions the patient's understanding, the surgeon is responsible for supplying further information. If these situations arise, the nurse should contact the surgeon before having the patient sign a consent for the operation or special procedures. Following a thorough discussion of the consent, the nurse witnesses the patient's voluntary signature on the form. The nurse also signs the form, indicating that the correct patient (or legal designee) is signing the form and that the patient was alert and aware of what was being signed.

Surgical Risk and Safety

The Surgical Care Improvement Project (SCIP) is a national quality partnership of organizations that participate in improving the care provided to patients undergoing surgical care by reducing complications and improving overall outcomes in these patients through prescribed evidence-based measures. This project originated through a campaign in 2004 designed to prevent the avoidable deaths in hospitals related to complications and medical errors.

SCIP focuses on evidence-based interventions to reduce surgical complications including surgical site infections, adverse cardiac events, and blood clots. Perioperative nursing should support and follow guidelines that will lead to achievement of these goals (Brendle, 2007). The Joint Commission aligns with the Centers for Medicare and Medicaid Services (CMS) in monitoring the performance of measures to prevent and reduce complications for patients undergoing surgery in both ambulatory care and inpatient settings (see Box 4–1). The interventions specific to the perioperative environment are noted as core measures and are used as quality indicators for both reimbursement and ratings for the organization.

Effective communication with the patient and among all members of the healthcare team is an essential element of perioperative patient safety. Effective communication of information must occur during a **handoff** (or *handover*), when responsibility for care is transferred from one individual or care unit to another. Handoff reports provide essential, up-to-date, and specific patient information. Handoffs also must include an opportunity to ask and respond to questions. Timely, accurate, complete, and clear information that is understood by the recipient is necessary for effective communication. Use effective communication strategies and techniques such as SBAR (situation, background, assessment, and recommendations) to help ensure clarity and reduce the risk for error.

BOX 4–1 Quality Indicators for Surgery

- Prophylactic antibiotic received within 1 hour prior to surgical incision
- Prophylactic antibiotic discontinued within 24 hours after surgery end time
- Cardiac surgery patients with controlled 6 a.m. blood glucose postoperatively
- Surgery patients with appropriate hair removal
- Indwelling urinary catheter removed within 24 hours postoperatively
- Perioperative temperature management
- Surgery patients with recommended venous thromboembolism prophylaxis ordered

Prior to planning and implementing care for the surgical patient, the nurse must first assess the patient's individual needs and the factors that may increase the risks associated with surgery. The type of surgical procedure determines the assessment and interventions planned by the nurse. However, a complete history and assessment are also necessary to identify *risk factors* in order to determine the patient's overall health status. Table 4–2 lists common risk factors for the patient undergoing surgery and the related nursing interventions and implications. For example, when a patient is admitted for a right total knee arthroplasty, it should be of concern to the nurse if this patient has type 2 diabetes that requires insulin, smokes 1.5 packs of cigarettes per day, has numbness in the right foot, and is taking medication for hypertension. This information should be incorporated into a care plan, using appropriate nursing diagnoses and

TABLE 4–2 Nursing Implications for Surgical Risk Factors

Factor	Associated Risk	Nursing Implications
Advanced age	Age-related changes affect physiologic, cognitive, and psychosocial responses to the stress of surgery; decrease tolerance of general anesthesia and postoperative medications; and delay wound healing.	Selected nursing interventions are summarized in Table 4–6 later in this chapter. Need to understand and develop an individualized plan of care addressing multiple comorbidities.
Malnutrition	Reserves may not be sufficient to allow the body to respond satisfactorily to the physical assault of surgery; organ failure and shock may result. Increased metabolic demands may result in poor wound healing and infection.	Promote weight gain by providing a well-balanced diet high in calories, protein, and vitamin C. Administer parenteral nutrition, nutritional supplements, and enteral feedings as prescribed. Daily weights and calorie counts also may be ordered.
Obesity	The patient with obesity is at increased risk for delayed wound healing, wound dehiscence, infection, pneumonia, atelectasis, thrombophlebitis, dysrhythmias, impaired skin integrity, and heart failure.	Promote weight reduction if time permits. Monitor closely for wound, pulmonary, and cardiovascular complications. Encourage coughing, turning, and breathing exercises and early ambulation.
Low socioeconomic status	Because of limited access to healthcare, pathology may be more advanced at diagnosis. Risk is greater for emotional stress, poor nutrition, lack of exercise, and poor social support systems.	Assess for undiagnosed chronic conditions and nutritional status. Involve social services for help with resources. Low educational or reading level may require adaptation of discharge instructions or education.
CHRONIC CONDITIONS		
Alcoholism	The patient may be malnourished and experience delirium tremens (acute withdrawal symptoms). More general anesthesia may be required. Altered coagulation, hemorrhage, and delayed wound healing can result from liver damage and poor nutritional status.	Monitor closely for signs of delirium tremens, responses to anesthesia and analgesia, bleeding, and wound complications. Encourage well-balanced diet. Administer supplemental nutrients as ordered. Administer antagonist medications such as naloxone or flumazenil with caution.
Arthritis	Inflammation or degenerative changes in joints limit mobility and comfort. Ask about timing of last dose of NSAID or ASA.	Position and pad arthritic joints including the spine. Handle joints gently to avoid strain on ligaments and tendons. Monitor for bleeding.
Cardiovascular disorders	Cardiovascular disease increases the risk of heart failure, hemorrhage and shock, hypotension, venous thrombosis, pulmonary embolism, stroke (especially in the older patient), and fluid volume overload.	Diligently monitor vital signs, reporting changes such as tachycardia, dysrhythmias, tachypnea, or dyspnea. Closely monitor fluid intake and output to prevent circulatory overload. Assess skin color, oxygen saturation, and lung sounds. Report hypoxia, chest pain, lung congestion, or peripheral edema. Administer oxygen as ordered. Promote early postoperative ambulation to reduce the risk of venous thrombosis and pulmonary embolism. Determine that prescribed beta-blockers are given preoperatively.
Diabetes mellitus	Diabetes increases the risk for fluctuating blood glucose levels, which can lead to life-threatening hypoglycemia or ketoacidosis. Diabetes also increases the risk for cardiovascular disease, delayed wound healing, and wound infection.	Monitor blood glucose levels every 4 hours or as ordered; report levels of 180 mg/dL or higher or outside prescribed limits. Administer insulin as prescribed. Monitor for manifestations of hypoglycemia and hyperglycemia. Encourage intake of food at the designated meal and snack times.
Immune suppression	Suppressed immunity impairs ability to resist infection and promote tissue repair. Advanced age, immune deficiency diseases, malnutrition, chronic disease, cancer treatment, and alcohol abuse compromise immunity.	Prevent hypothermia, maintain sterile fields, consistently prevent infection. Nourishment and normoglycemia promote wound healing.

TABLE 4–2 Nursing Implications for Surgical Risk Factors (*continued*)

Factor	Associated Risk	Nursing Implications
Nicotine use	Cigarette smokers are at increased risk for respiratory complications such as pneumonia, atelectasis, and bronchitis because of increased mucous secretions and a decreased ability to expel them.	Support efforts to quit smoking. Monitor closely for respiratory difficulties. Encourage breathing, coughing, turning, and early ambulation. Promote fluid intake to 2500–3000 mL (unless contraindicated) to help liquefy respiratory secretions. A nicotine patch may reduce withdrawal symptoms during the postoperative period.
Renal and liver disorders	Renal or liver dysfunction may affect the ability to tolerate general anesthesia, cause fluid/electrolyte and acid–base imbalances, decrease the metabolism and excretion of drugs, increase the risk for hemorrhage, and delay wound healing.	Monitor I&O; fluid, electrolyte, and acid–base balance; and responses to medication. Note that patients may require lower doses of medications due to renal or liver disease.
Respiratory disorders	Patients with pulmonary disease are at higher risk for developing respiratory complications such as atelectasis and pneumonia. Respiratory depression from general anesthesia and acid–base imbalance may also occur.	Closely monitor respirations, pulse, oxygen saturation, and breath sounds. Also assess for hypoxia, dyspnea, lung congestion, and chest pain. Encourage coughing, turning, and breathing exercises and early postoperative ambulation.
MEDICAL THERAPIES		
Medications	Anesthesia interaction with some medications can cause respiratory depression, hypotension, and circulatory collapse. Other medications can produce side effects that increase surgical risk.	Inform the anesthesiologist of all prescribed and over-the-counter medications, as well as any herbal preparations.
Anticoagulants/ platelet inhibitors	May cause intraoperative and postoperative hemorrhage.	Monitor for bleeding. Assess PT/PTT/INR values.
Antidepressants (particularly monoamine oxidase inhibitors)	Increase the hypotensive effects of anesthesia.	Closely monitor blood pressure.
Antihypertensives	Increase the hypotensive effects of anesthesia.	Closely monitor blood pressure.
Antibiotics (particularly the “mycin” group)	May cause apnea and respiratory paralysis.	Monitor respirations.
Diuretics	May lead to fluid and electrolyte imbalances, producing altered cardiovascular response and respiratory depression.	Monitor I&O and electrolytes. Assess cardiovascular and respiratory status.
Herbal supplements	Some may prolong the effects of anesthesia. Others may increase the risks of bleeding or raise blood pressure.	Inquire about the use of herbs or other dietary supplements. These should be discontinued at least 2 weeks before surgery.
Immunosuppressants	Steroids, drugs to treat cancer and autoimmune disorders, and transplant rejection drugs suppress the immune system and increase the risk of infection and hypothermia (Harle et al., 2010).	Monitor CBC with differential for leukopenia. Document current dosage of medications and time of last dose. Administer prescribed steroids in the perioperative period to prevent adrenal crisis. Prevent hypothermia and maintain asepsis. Monitor wound healing.
Treatments	Radiation therapy	Tissue integrity may be compromised in targeted fields.
IN THE OR		
Fluid/electrolyte imbalance	Depending on the type and extent of fluid and electrolyte imbalance, cardiac dysrhythmias or heart failure may occur. Liver and renal failure may also result.	Administer intravenous fluids as ordered. Monitor I&O. Monitor patient for evidence of electrolyte imbalance.
Hypothermia/ hyperthermia	Hypothermia or hyperthermia increase the risk for infection, cardiac morbidity, myocardial ischemia, surgical bleeding, skin damage, and patient discomfort.	Monitor core temperatures and prevent chilling or overheating. Remove wet drapes and test the temperature of fluids used.
Surgical site infections	Sterile field contamination, opening body organs containing pathogens (e.g., the bowel) increases risk for infection.	Administer antibiotics prior to incision as ordered. Carefully maintain sterile fields. Monitor and sustain core body temperature between 36° and 38°C (96.8° and 100.4°F).
Venous stasis	Lower limbs, especially when tourniquets are applied, are susceptible to blood clotting. Patients with cancer have higher risks of blood clots.	Promote venous circulation with intermittent pneumatic compression devices as ordered. Monitor circulation in arms and legs during surgery.

interventions to meet the patient's needs and assist the patient toward full postoperative recovery.

Risks are associated with all phases of surgery. For example, transporting the patient to and from the operating room (OR) requires assessment of the needs of the patient for supplemental oxygen, intravenous therapy, cardiac monitoring, and safety issues pertaining to the means of transport. Many patients enter the operating suite highly anxious and may benefit from medication to help them relax prior to administration of anesthesia. This can be discussed with the **anesthesia care provider (ACP)**. Chemicals, electrical equipment, and environmental hazards in the surgical area have the potential for harm and must be monitored and maintained carefully. Nutritional status, skin integrity, and mobility status may play a role in the positioning of the patient for the surgery and maintenance of skin integrity during the perioperative period. Also read about risks for the older patient in the Nursing Care of the Older Adult box on page 64.

PATIENT AND PROCEDURE IDENTIFICATION

The 2014 National Patient Safety Goals issued by the Joint Commission (Box 4–2) focus on problems in healthcare safety and solutions to improve patient safety. These goals specifically address patient and procedure identification prior to any treatment or procedure. The patient must be actively involved in identification procedures, and if the patient is not able to participate or if his reliability is questioned, the family or designated caregiver is responsible for verifying identification. Hence, the caregiver should accompany any patient whose reliability is questionable into the surgical area for the "time-out" procedure (Association of periOperative Registered Nurses [AORN], 2013a).

In 2004, the Joint Commission issued the Universal Protocol; it was revised in 2010 based on feedback from stakeholders and users in the field. The current Universal Protocol (Box 4–3) mandates three key elements that should be performed preoperatively: (1) Conduct a preprocedure verification process, (2) mark the procedure site, and (3) perform a time-out. A time-out is a method used to verify patient identity and intended-site operations. A time-out should be conducted in the OR/procedure room before the anesthesia or sedation is administered. It should involve all members of the operative team and use active communication. The time-out is documented on the operative/procedure record and includes verification of the correct patient identity, correct site and side, and agreement on the procedure to be done (AORN, 2013a). A Surgical Safety Checklist (Figure 4–1 ■), available online through the World Health Organization (WHO), provides a guideline for documenting safety checks at specific points during the perioperative experience.

BOX 4–2 The Joint Commission 2014 Hospital National Patient Safety Goals

1. Identify patients correctly.
   - Use at least two ways to identify patients (e.g., name and date of birth).
   - Make sure the correct patient gets the correct blood when she receives a transfusion.
2. Improve staff communication.
   - Report test and diagnostic procedure results to the appropriate person in a timely manner.
3. Use medications safely.
   - Label medications and solutions that are not given immediately.
   - Use additional precautions with anticoagulant medicines.
   - Maintain and communicate accurate information about the patient's current medications. Compare current medications with those taken by the patient before admission. Make sure the patient knows which medications to take at home.
4. Prevent infection.
   - Use current CDC or WHO guidelines for hand hygiene. Set and use goals to improve hand hygiene.
   - Use evidence-based practices to prevent healthcare-associated infections (HAIs), including those that are difficult to treat, bloodstream infections, surgical site infections, and catheter-associated urinary tract infections.
5. Prevent mistakes in surgery.
   - Make sure the correct surgery is done on the correct body part of the correct patient.
   - Mark the correct place on the patient's body where the surgery is to be done.
   - Pause before surgery to make sure a mistake is not being made.

SAFETY ALERT

Studies have demonstrated that well-defined surgical safety policies that are maintained at a zero tolerance toward deviation are the best strategy for reducing the incidence of retained surgical items (Stanislaw et al., 2013).

RETAINED FOREIGN OBJECTS

Retained foreign bodies (items left in the surgical cavity) such as instruments, needles, or sponges are a surgical risk. To prevent accidental retention, the AORN recommends the following:

- A consistent multidisciplinary approach to preventing retained objects should be used and enforced during all surgical and invasive procedures.
- Radiopaque surgical soft goods (e.g., sponges, towels, textiles), sharps, and instruments should be counted for all procedures.
- Standardized measures for investigation and reconciliation of count discrepancies should be taken during the closing count and before the end of surgery. When a discrepancy in the count(s) is identified, the surgical team should carry out steps to locate the missing item.
- Perioperative staff members may consider the use of adjunct technologies to supplement manual count procedures and to ensure no unintended item remains.
- Measures taken for the prevention of retained objects should be documented in the patient's medical record.
- Policies and procedures for the prevention of retained objects and unretrieved device fragments should be developed, reviewed periodically, revised as necessary, and readily available in the practice setting.

While not all surgeries have equal risk for retainment of items, those that do must include a careful count procedure with appropriate action if the count is incorrect. Stopping a closing procedure to recount and search for missing items increases anesthesia and wound exposure, but retained items contributes to serious infections and other potential liabilities.

BOX 4–3 The Universal Protocol

The Joint Commission's Universal Protocol to reduce surgical errors calls for three specific actions by the healthcare team:

1. *Conduct a preprocedure verification process.* The preprocedure verification process addresses missing information or discrepancies before the procedure is performed. The patient should be involved in the verification process whenever possible. It is conducted when the procedure is scheduled, on admission to the facility, before entering the procedure room, and whenever the patient is transferred to another caregiver, and includes the following steps:
   - Verify the correct procedure, for the correct patient, at the correct site.
   - Identify the items that must be available for the procedure, at a minimum to include:
     - Relevant data (history and physical, signed consent form, preanesthesia assessment)
     - Labeled diagnostic and radiology test results that are properly displayed (x-rays, CT scans, pathology reports or biopsy reports)
     - Any required blood products, implants, devices, or special equipment.
2. *Mark the procedure site.* At a minimum, mark the site when there is more than one possible location for the procedure and when performing the procedure in a different location could harm the patient.
   - The site is marked and initialed before the procedure and while the patient is awake.
   - Site marking is done and initialed by the licensed independent practitioner who is ultimately accountable for the procedure and will be present when the procedure is performed.
   - The mark is clear and unambiguous, made at or near the procedure site.
3. *Perform a time-out.* Conduct a time-out immediately before starting the invasive procedure or making the incision. The procedure is not started until all questions or concerns have been resolved.
   - A designated member of the team starts the time-out.
   - A time-out is a standardized part of the process.
   - The time-out involves all immediate members of the procedure team.
   - All relevant members of the procedure team actively communicate during the time-out.
   - During the time-out, the team members agree, at a minimum, on the following:
     - Correct patient identity
     - Correct site
     - Procedure to be performed.
   - Document the completion of the time-out.

MEDICATION RECONCILIATION

A complete history of medications the patient has been taking regularly is vital information at every transition point in the care continuum. Over-the-counter medicines and herbal preparations as well as prescription medications may interact with drugs given during surgery, putting a patient at increased risk. This information should be obtained in a matter-of-fact and nonjudgmental manner as part of the preoperative planning and teaching. A judgmental attitude could cause the patient to withhold information. This process needs to be repeated at every transition: admission to the hospital, preoperatively, in postoperative reports, and at discharge.

Medications may interact with anesthesia drugs during surgery, augmenting hemodynamic effects such as hypertension or hypotension. Some categories of medication require special consideration in

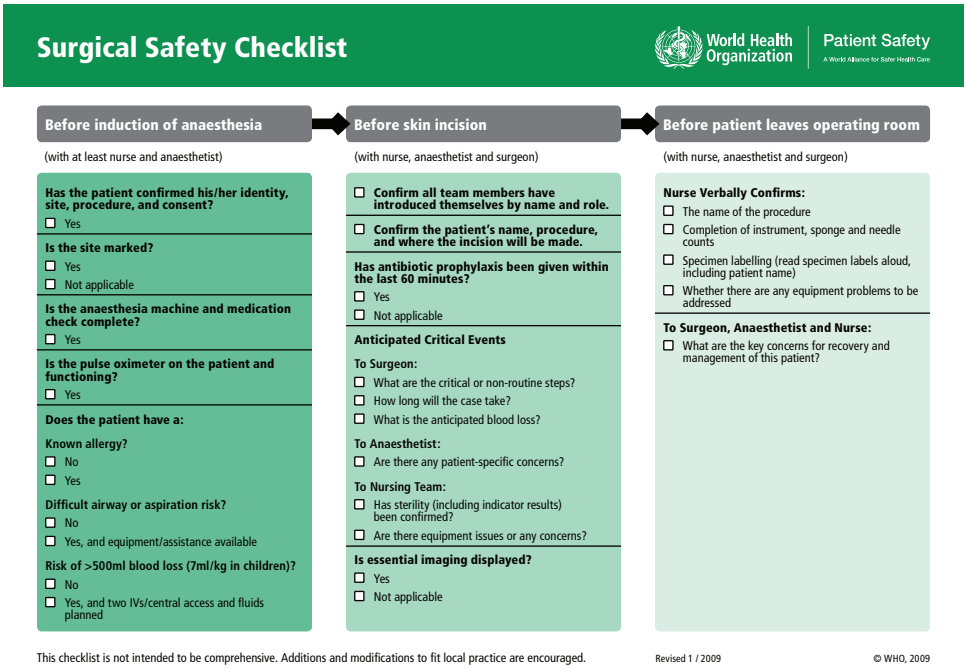

Figure 4–1 ■ The WHO surgical safety checklist.
Source: World Health Organization. (2009). *Surgical safety checklist*. Retrieved from http://www.who.int/patientsafety/safesurgery/en.

regard to surgery, including drugs that alter blood clotting, cardiovascular drugs, bronchodilators, drugs that affect neurologic or endocrine function, glaucoma drugs, and immunosuppressants. Patients with diabetes or HIV infection require expert advice.

Anticoagulant medications should be discontinued prior to surgery to prevent excessive blood loss during surgery. These include aspirin and nonsteroidal anti-inflammatory drugs (NSAIDs). If laboratory tests of bleeding time, prothrombin time (PT), partial thromboplastin time (PTT), and International Normalized Ratio (INR) are elevated, the surgery may be cancelled. Guidelines for discontinuing use vary according to the particular medication; it is generally recommended that aspirin or products containing aspirin, NSAIDs, and medications that alter platelet function and clotting be discontinued 5 days or longer before surgery. Similarly, herbs or nutritional supplements that impair clotting should be discontinued 2 weeks prior to surgery. The most common herb and supplements that may inhibit coagulation are vitamin E, garlic, ginkgo, ginseng, fish oil, and chamomile. Many plants contain coumarins with the potential to interact with warfarin and inhibit coagulation. Others inhibit platelet aggregation or prevent the conversion of fibrinogen to fibrin. Patients taking warfarin for the risk of blood clots due to atrial fibrillation will be counseled about the appropriate time to withdraw warfarin. If surgery is urgent due to trauma or sudden onset of morbidity, the impact of anticoagulants needs to be evaluated with PT, PTT, and INR before the operation and appropriate support for clotting is administered.

Herbal medicines or dietary supplements also may produce levels of chemicals that interact with conventional medications, exacerbating or impairing the intended effect. Anesthesia drugs often decrease hepatic blood flow and interfere with the metabolism and elimination of medications. This increases the risk of adverse drug–herbal supplement interactions during surgery. Cardiovascular instability, impaired glucose control, increased metabolism of perioperative medication, and unpredictable response to anesthesia are categories of adverse reactions of perioperative herbal use.

THROMBOEMBOLISM

The risk of bleeding has to be balanced against the risk of postoperative deep venous thrombosis (DVT) and thromboembolism. Prophylactic anticoagulation with low-dose unfractionated heparin, low-molecular-weight heparin, factor Xa, or warfarin may be used for this purpose. Aspirin-only therapy is not considered adequate protection from DVT formation. In addition, use of intermittent pneumatic compression devices (IPCDs) and graduated compression stockings is recommended. DVT can lead to pulmonary embolism (PE) and to significant patient morbidity, mortality, and increased healthcare costs. Each patient's risk for developing DVT and PE needs to be assessed and appropriate prophylaxis initiated when indicated.

HYPOTHERMIA

Hypothermia is a risk in the perioperative period. The anesthetized patient loses heat intraoperatively and is unable to restore temperature through the normal mechanisms of shivering or muscle contractions. Typically, surgical suites are maintained at a lower room temperature for the comfort of the personnel gowned in several layers of protective clothing and wearing masks. Research shows that normothermia (core body temperature in the range of 36.0° to 37.5°C [96.8° to 99.5°F]) in the patient reduces the risk for infection, cardiac morbidity, myocardial ischemia, surgical bleeding, and patient discomfort. Methods to minimize the risk of hypothermia include applying warm blankets, limiting the amount of skin exposed, warming intravenous fluids, and monitoring the patient's temperature.

Hyperthermia should also be avoided. Heating of fluids or use of heating units necessitates accurate measurement of the temperature and assessment of the patient's skin integrity. Body temperature is best evaluated through core temperature monitoring, which includes esophageal or tympanic assessment (AORN, 2013a).

SURGICAL SITE INFECTIONS

Despite the carefully cleaned surgery environment and use of sterile equipment, gloves, and gowns, a significant percentage of patients develop wound infections. Patients suffer increased morbidity and mortality and healthcare costs increase dramatically as a result of surgical site infections (SSIs). Four strategies are recommended by SCIP guidelines: prophylactic antibiotics in select procedures, appropriate hair removal, glucose control in patients having major cardiac surgery, and normothermia in patients undergoing colon surgery. Prophylactic antibiotic administration immediately before the surgical incision is indicated for hip and knee arthroplasty, cardiac surgery including coronary artery bypass graft, hysterectomy, and some colon and vascular procedures.

ADVERSE CARDIAC EVENTS

Myocardial infarction is a risk following major surgery, especially among older adults. The circulatory system is stressed during surgery, increasing the risk for cardiac ischemia. Beta-blocker medications inhibit sympathetic nervous system stimulation of the myocardium and reduce oxygen demand, thereby reducing the risk for infarction. Any patient who is taking beta-blocker medication regularly needs to take the usual dose prior to any type of surgery.

Interpreting and responding to identified risk factors require nursing judgment. It is important to bring information to the attention of the surgeons and anesthesiologists prior to surgery so necessary modifications can be made for the patient.

●○● INTERPROFESSIONAL CARE

The patient undergoing surgery receives care from a number of healthcare providers. Surgeons, nurses, scrub technicians, anesthetists, phlebotomists, x-ray technicians, registration clerks, and transporters are often involved in securing the safety and health of patients. Case managers, social workers, and spiritual care providers are available based on patient need and desire. This interprofessional approach focuses on placing the patient in the best possible health status before, during, and after surgery.

DIAGNOSTIC TESTS

Diagnostic tests performed prior to surgery provide baseline data and may reveal problems that may place the patient at additional risk during and after surgery. These studies are performed within a week prior to elective surgery and immediately before surgery in emergency situations.

Complete blood counts, electrolyte studies, coagulation studies, and urinalysis are the most commonly performed preoperative laboratory tests. Table 4–3 discusses the significance and nursing implications of abnormal findings for these common tests. Additional diagnostic tests may be performed as the history and physical

TABLE 4–3 Laboratory Tests for Perioperative Assessment

Test	Significance of Increased Values	Significance of Decreased Values	Nursing Implications
Hemoglobin (Hgb) and hematocrit (Hct)	Dehydration, excessive plasma loss, polycythemia	Fluid overload, excessive blood loss, anemia	Monitor oxygenation and vital signs; assess for bleeding.
Glucose and hemoglobin A_1c (Hgb A_1c)	Impaired glucose metabolism, stress, or infection	Inadequate glucose intake in relation to insulin	If decreased, monitor for manifestations of hypoglycemia. Notify surgeon of glucose <70 mg/dL or >180 mg/dL.
White blood cell (WBC) count	Infectious/inflammatory processes, leukemia	Immune deficiencies	Monitor for manifestations of inflammation; monitor drainage, temperature, and pulse. Use strict standard precautions.
Platelet count	Malignancies, polycythemia vera	Clotting deficiency disorders, chemotherapy	If decreased, assess for bleeding at incision sites and drainage tubes, and assess for hematomas.
Carbon dioxide (CO_2)	Emphysema, chronic bronchitis, asthma, pneumonia, respiratory acidosis, vomiting, nasogastric suctioning	Metabolic acidosis, hyperventilation	Monitor respiratory status and arterial blood gases (ABGs).
Electrolytes			
Potassium (K^+)	Kidney dysfunction, dehydration, suctioning	Diuretic therapy, vomiting, NG suctioning	Monitor K^+ level, cardiac and neurologic function, and perioperative diuretic therapy.
Sodium (Na^+)	Kidney dysfunction, dehydration, saline-containing intravenous fluids	Diuretic therapy, vomiting, NG suctioning, fluid volume excess	Monitor Na^+ level and I&O; assess for peripheral edema and effects of perioperative diuretic therapy.
Chloride (Cl^-)	Kidney dysfunction, dehydration, alkalosis	Diuretic therapy, vomiting, NG suctioning	Monitor Cl^- level and I&O; assess for peripheral edema and perioperative diuretic therapy.
Prothrombin time (protime, PT, INR) and partial thromboplastin time (PTT)	Defect in mechanism for blood clotting, anticoagulant therapy (aspirin, heparin, warfarin), potential effect of other drugs affecting clotting time	Hypercoagulability of the blood may lead to thrombus formation in the veins	If clotting time is elevated, monitor PT/PTT values. Assess for bleeding at incision site and drainage tubes and for hematomas. If clotting time is decreased, monitor for thrombus formation (pulmonary emboli, venous thrombosis), and evaluate PT and PTT values.
Urinalysis	Varied	Varied	Used to detect abnormal substances (e.g., protein, glucose, red blood cells, or bacteria) in the urine. Notify surgeon if abnormalities are detected.
Serum creatinine, BUN	Renal dysfunction	Malnutrition, musculoskeletal wasting	Monitor urinary output, wound healing.

findings indicate. For example, if the patient has a low hemoglobin and hematocrit, and significant blood loss during surgery is anticipated, the surgeon may order a type and crossmatch of the patient's blood for a possible transfusion.

In addition to laboratory tests, older patients or those with risk factors related to heart and lung function typically have a chest x-ray. This radiologic procedure provides baseline information about the size, shape, and condition of the heart and lungs. Pulmonary complications such as lung disease or pneumonia may require that surgery be postponed to allow further evaluation or treatment. If findings are abnormal and the surgery cannot be postponed, information from the chest x-ray study can be used to determine the safest form of anesthesia.

An electrocardiogram (ECG) is ordered routinely for patients undergoing general anesthesia when they are over 40 years of age or have cardiovascular disease. The ECG provides data for evaluation of either new or preexisting cardiac conditions. The patient's surgery may be cancelled or postponed if a life-threatening cardiac condition is discovered.

Additional diagnostic tests may be performed preoperatively to gather further assessment data. For example, for patients who have chronic obstructive pulmonary disease, pulmonary function studies often are performed to determine the extent of respiratory dysfunction. This information guides the anesthesiologist before and during surgery in choosing the type of anesthetic to be used, and it guides the surgeon and nursing staff in the recovery phase.

Renal function is evaluated on the basis of glomerular filtration rate (GFR), which is estimated by using serum creatinine (reported as the eGFR) or by measuring urinary creatinine. Creatinine is a stable product of muscle mass; it is filtered by the kidneys or secreted by the kidney tubules. In kidney failure, serum creatinine rises and the GFR is low. The best indicator of GFR is the creatinine clearance, a comparison of both serum and urinary creatinine levels. In older adults with decreased muscle mass and low dietary meat intake, serum creatinine may be falsely low. Older adults are especially susceptible to renal insufficiency, which puts them at risk for fluid volume overload in the perioperative period and for accumulation

of metabolic by-products and medications dependent on renal clearance.

MEDICATIONS

The patient having surgery receives medications before, during, and after surgery to achieve specific therapeutic outcomes. For inpatients, all medication orders typically are cancelled when the patient goes to surgery and must be rewritten by the physician when the patient returns to the postsurgical care unit. Following surgery it is very important that medications are reordered so that chronic as well as acute conditions are treated.

PREOPERATIVE MEDICATIONS A combination of preoperative drugs may be ordered to induce sedation, reduce anxiety, induce amnesia to minimize unpleasant surgical memories, increase comfort during preoperative procedures, reduce gastric acidity and volume, promote gastric emptying, decrease nausea and vomiting, and reduce the risk of aspiration by drying oral and respiratory secretions.

The surgical patient usually is given preoperative medications 45 to 70 minutes before the scheduled surgery. Any delay in administration should be reported promptly to the surgical department and ACP. Preoperative medications are often given in the surgical holding area.

Preoperative antibiotic prophylaxis is effective in the prevention of postoperative complications in many surgeries. The term *prophylaxis* originates from the Greek word *prophulaktikos*, which means "advanced guard." This corresponds with the goal of administering preoperative antibiotics, which is to guard against or prevent the patient from contracting an SSI. Table 4–4 outlines commonly prescribed preoperative medications including antibiotics. See Chapter 12 for the nursing implications for common antibiotics.

An increasingly common strategy to prevent intense or lingering pain is the use of *preemptive analgesia*. The goal of preemptive analgesia is to prevent sensitization of the central and peripheral nervous system from painful stimuli by blocking the pain pathways

TABLE 4–4 Examples of Commonly Used Preoperative Medications

Generic Name	Trade Name	Action by Category	Nursing Implications
ANTIBIOTICS			
Cefazolin	Ancef	Prevents SSIs in orthopedic and general surgeries and is associated with lower risk of mortality in older adult patients.	Patients with beta-lactam allergies receive vancomycin or clindamycin.
BENZODIAZEPINES			
Midazolam	Versed	Decreases anxiety and produces sedation to some extent.	Monitor for respiratory depression, hypotension, drowsiness, and lack of coordination.
Diazepam	Valium	Induces amnesia.	
Lorazepam	Ativan	May induce substantial amnesia.	
OPIOID ANALGESICS			
Morphine Fentanyl *Oxycodone* *Hydrocodone* *Tramadol*	Morphine Sublimaze Roxicodone Vicodin Ultram	Decreases anxiety, provides analgesia. Allows reduced anesthetic dose.	Monitor for respiratory depression and safety if ambulating. See Chapter 9 for nursing implications of specific opioid analgesics.
ANTACIDS			
Sodium citrate	Bicitra	Increases the pH and reduces volume of gastric fluid; used in patients with GERD and/or trauma.	No significant factors in this setting.
H_2 RECEPTOR ANTAGONISTS			
Cimetidine *Famotidine* Nizatidine *Ranitidine*	Tagamet Pepcid Axid Zantac	Reduces gastric acid volume and concentration.	Monitor for confusion and dizziness in older adults.
GASTRIC ACID (PROTON) PUMP INHIBITORS			
Lansoprazole *Omeprazole* *Pantoprazole*	Prevacid Prilosec Protonix	Suppresses gastric acid secretion.	Monitor for dizziness and headache, rash, or thirst.
ANTIEMETICS			
Metoclopramide Ondansetron	Reglan Zofran	Enhances gastric emptying. Affects the vomiting center in the brain.	Monitor for sedation and extrapyramidal symptoms (involuntary movement, muscle tone changes, and abnormal posture).
ANTICHOLINERGICS			
Atropine sulfate Glycopyrrolate Scopolamine	Atropine sulfate Robinul Scopolamine	Reduces oral and respiratory secretions to decrease risk of aspiration; decreases vomiting and laryngospasm.	Monitor for confusion, restlessness, and tachycardia. Prepare patient to expect a dry mouth.

Note: Drugs identified in *italics* are among the 200 most commonly prescribed medications in the U.S.

with local, regional, or epidural analgesia prior to incision. Sensitization to pain is believed to prolong the painful experience; blocking the sensitization throughout the perioperative period should result in decreased pain in the postoperative period, shortened hospital stay, quicker return to self-care, and decreased residual pain. To date, the best combination of methods and medications for the great variety of surgical interventions has not been identified. The best method to improve postoperative pain scores, reduce total analgesic consumption, and extend the time to first rescue dose following anesthesia seems to be a combination of epidural, local wound infiltration, and NSAIDs (Duncan & Haigh, 2012; Hernandez et al., 2011).

Decisions about which of the patient's routine medications to administer prior to surgery when the patient is NPO require careful analysis. The best guideline is to confer with the surgeon and anesthetist about specific medications. The reason for caution has to do with potential interactions between anesthesia and medications and the effect on the patient if drugs such as steroids, antiseizure medications, and tranquilizers are discontinued abruptly. Generally, insulin is withheld when the patient is NPO, but depending on the anticipated length of the surgery, the dosage may be adjusted for the previous evening as well as the morning of surgery. Under anesthesia, the manifestations of hypoglycemia (insulin reaction) are absent, so withholding insulin the morning of surgery when the patient is NPO is advisable. Blood glucose is monitored intermittently during surgery with the goal of maintaining normal blood sugar level (refer to Table 4–3). Patients who ordinarily manage their diabetes mellitus with oral medications often are placed on sliding scale insulin to manage blood glucose during the perioperative experience. Evidence-based practice supports subcutaneous basal insulin administration for patients with hyperglycemia to maintain blood glucose levels below 180 mg/dL throughout the perioperative period. This practice is associated with better healing, fewer infections, and shorter hospital stays (Powers, 2012; Richards et al., 2012).

INTRAOPERATIVE MEDICATIONS **Anesthesia** is used to produce sedation, analgesia (freedom from pain), reflex loss, and muscle relaxation during a surgical procedure. **General anesthesia** produces a state of unconsciousness, muscle relaxation, analgesia, and amnesia, whereas **regional anesthesia** results in analgesia, reflex loss, and muscle relaxation in an area of the body but does not cause the patient to lose consciousness. An anesthesiologist (physician) or certified registered nurse anesthetist (CRNA) administers anesthetics during the intraoperative phase of surgery.

GENERAL ANESTHESIA General anesthesia is most commonly administered by a combination of intravenous drugs and inhalation agents. It produces central nervous system depression. As a result, the patient loses consciousness and does not perceive pain, the skeletal muscles relax, and reflexes diminish.

Advantages to general anesthesia include rapid excretion of the anesthetic agent and prompt reversal of its effects when desired. Additionally, general anesthesia can be used with all age groups and any type of surgical procedure. It produces amnesia.

Disadvantages of general anesthesia include risks associated with circulatory, respiratory, hepatic, and renal side effects. Patients with serious respiratory or circulatory diseases, such as emphysema or congestive heart failure, are at greater risk for complications. Patients with renal or hepatic disease cannot metabolize and eliminate anesthetics safely. Inhalation agents are avoided in patients with a history of malignant hyperthermia (MH) because they can trigger MH (Box 4–4). With the increase in ambulatory and minimally invasive surgeries, anesthetics are used that enable shorter recovery phases. Drugs with a very short half-life have a rapid recovery phase, allowing *fast-tracking*, often bypassing the PACU.

BOX 4–4 Malignant Hyperthermia

Malignant hyperthermia (MH) is a rare multifactorial genetic disorder that can be triggered by inhalational anesthetic gases and succinylcholine, a depolarizing neuromuscular blocker. The initial manifestations are an unexplained rise in end-tidal carbon dioxide that does not respond to ventilation and sustained skeletal muscle contraction (Rothrock, 2011). The temperature rises rapidly to as high as 43°C (109.4°F) as a result of sustained hypermetabolism. Cardiac dysrhythmias develop and oxygen and ATP are rapidly consumed. Lactate and carbon dioxide, by-products of metabolism, are produced in excess (Grossman & Porth, 2014). If unchecked the condition will progress to hyperkalemia, myoglobinuria, disseminated intravascular coagulation, congestive heart failure, bowel ischemia, and compartment syndrome in the limbs.

MH can develop during surgery or when the patient returns to the PACU. If the early symptoms of MH (e.g., increased carbon dioxide levels, tachycardia and tachypnea, muscle stiffness or rigidity, escalating temperature) are identified, suspected triggering agents are immediately discontinued. Oxygen is immediately administered with a nonrebreather mask. The patient should not be unattended, good IV access should be maintained, and the anesthesia provider should be summoned. Dantrolene, a muscle relaxant, is administered and measures to decrease core body temperature should be started at once and continued until core temperature is 36.0°C (96.8°F). A urinary catheter should be placed to monitor urine output and blood drawn for testing. Blood gases should be drawn to measure pH; sodium bicarbonate is given to correct metabolic acidosis. Insulin may be ordered to decrease serum potassium. This patient may be transferred to the ICU for continued monitoring and doses of dantrolene every 4–6 hours.

The phases of general anesthesia are divided into three distinct categories: induction, maintenance, and emergence. During the induction phase, the patient receives the anesthetic agent intravenously or by inhalation. During this phase, airway patency is achieved and maintained with either endotracheal intubation or newer devices including the laryngeal mask airway (LMA), esophageal-tracheal Combitube, or lighted stylet or wand. These newer methods of airway maintenance allow effective ventilation but do not require direct visualization of the vocal cords for placement.

The next phase of general anesthesia is maintenance. During this period, the patient is positioned, the skin is prepared, and surgery is performed. The anesthesiologist maintains the proper depth of anesthesia while constantly monitoring physiologic parameters such as heart rate, blood pressure, respiratory rate, temperature, and oxygen and carbon dioxide levels.

The final phase of anesthesia is the patient's emergence from this altered physiologic state. As the anesthetic agents are withdrawn or the effects reversed pharmacologically, the patient begins to awaken. The endotracheal tube or laryngeal mask is removed (extubated) once the patient is able to reestablish voluntary breathing. It is critical to ensure airway patency during this period, because extubation may cause bronchospasm or laryngospasm.

Common side effects that may occur with general anesthesia include nausea and vomiting, a hangover effect, confusion, and

amnesia. Adjunct medications including corticosteroids, antiemetics, and anxiolytics may be administered preoperatively and interoperatively to reduce or prevent these side effects.

REGIONAL ANESTHESIA Regional anesthesia is a type of anesthesia in which medication instilled around the nerves blocks transmission of nerve impulses in a particular area. Regional anesthesia produces analgesia, relaxation, and reduced reflexes. The patient is awake and conscious during the surgical procedure but does not perceive pain. Regional anesthesia may be classified in several ways:

- Local nerve infiltration is achieved by injecting lidocaine, bupivacaine, or tetracaine around a local nerve to suppress sensation over a limited area of the body. This technique may be used when a skin or muscle biopsy is obtained or when a small wound is sutured.
- Nerve blocks are accomplished by injecting an anesthetic agent at the nerve trunk to produce a lack of sensation over a specific larger area, such as an extremity.
- Epidural blocks are local anesthetic agents injected into the epidural space, outside the dura mater of the spinal cord. This type of intraspinal anesthesia provides safe and effective pain relief for patients of all ages with less risk of adverse effects than general anesthesia. It is indicated for surgeries of the arms and shoulders, thorax, abdomen, pelvis, and lower extremities. The epidural catheter is often left in place for pain relief in the postoperative period; it can also be used for chronic pain management.

Spinal anesthesia is administered similarly to epidural except the anesthetic medication is infused in a single injection. Spinal anesthesia is effective for approximately 90 minutes. Surgeries of the lower abdomen, perineum, and lower extremities are likely to use this type of regional anesthesia. Leakage of cerebrospinal fluid (CSF) into the epidural space can cause reduced CSF pressure and postoperative headaches. Treatment may include hydration, caffeine, analgesics, or administration of an epidural blood patch. Hypotension is common with epidural and spinal anesthesia. Blood pressure should be monitored and, if critical hypotension occurs, the anesthesia provider should be alerted and expected to increase intravenous fluids and administer vasoactive medications.

CONSCIOUS SEDATION An increasing number of surgical and diagnostic procedures are being performed using **conscious sedation**, also called *moderate sedation/analgesia*. This type of anesthesia provides analgesia, amnesia, and moderate sedation. The patient under conscious sedation has an altered level of consciousness but is still able to maintain a patent airway and respond to verbal and environmental stimuli (Rothrock, 2011). The pharmacologic effects are produced by administering a combination of intravenous medications with opioids (such as morphine sulfate or fentanyl [Sublimaze]) or sedatives (such as diazepam [Valium] and midazolam [Versed]). Propofol (Diprivan) is an anesthetic agent commonly used for conscious sedation. Physician supervision is always required and a registered nurse must be prepared to initiate rescue interventions if sedation becomes too deep or loss of protective reflexes occurs. See the accompanying Medication Administration box for the nursing implications for midazolam and propofol. Institutions base their policies defining the qualifications of those who care for patients undergoing conscious sedation on professional organization guidelines, regulatory agency requirements, and state law.

MEDICATION ADMINISTRATION

Safely Administering Midazolam and Propofol

Midazolam hydrochloride (Versed) is most commonly administered intravenously as a preoperative sedative or used in conjunction with opioids for sedative effects during conscious sedation. Preoperative doses range from 0.5 to 2 mg based on age, weight, and any comorbidities of patient. Dosages used during conscious sedation are titrated in 0.5- to 1-mg increments based on the length and depth of sedation needed as well as patient's response to the medication. Patients receiving midazolam should be in a care setting where continuous respiratory and cardiac monitoring are available.

Propofol (Diprivan) has a rapid onset (40 to 60 seconds) and short duration of action, making it one of the most commonly administered anesthetic agents in the United States. It is used for induction and maintenance of anesthesia, for conscious sedation, and may be used to sedate patients undergoing mechanical ventilation or other procedures. Intravenous doses used during conscious sedation range from 5 to 80 mcg/kg/min. Profound respiratory depression and hypotension can occur with propofol; continuous respiratory and cardiac monitoring are essential and respiratory support must be immediately available.

Assessment prior to conscious sedation includes evaluating the appropriateness of this type of sedation for the patient based on physical status. Patients with compromised circulation or airway, a history of sleep apnea or snoring, a history of problems with anesthesia or analgesia, or who use medications that would potentially interact with conscious analgesia medications may require the anesthesiologist to manage conscious sedation procedures. Patients need to be appropriately fasting, and baseline vital signs must be taken prior to giving the sedative. The patient must sign a consent form, and a patent IV line must be in place. Equipment to rescue the patient should be available if sedation becomes too deep. Oxygen saturation, pulse, breathing, and level of consciousness must be monitored throughout the procedure.

Common adverse effects include venous thrombosis, phlebitis, local irritation, confusion, drowsiness, hypotension, and apnea. Reversal agents (naloxone hydrochloride [Narcan] and flumazenil [Romazicon]) are used as needed to enhance the safety of conscious sedation.

POSTOPERATIVE MEDICATIONS Management of acute postoperative pain by medication improves with greater understanding of pain physiology and the development of better methods to deliver adequate pain medication. For more information on the assessment of pain and its management, see the Moving Evidence into Action box on page 62 and Chapter 9, Nursing Care of Patients in Pain.

Established, persistent, severe pain is more difficult to treat than pain that is at its onset. Therefore, postoperative analgesics should be administered at regular intervals around the clock (ATC) to maintain a therapeutic blood level. Administering analgesics as needed (prn) lowers this therapeutic level; delays in medication administration further increase pain intensity. Therefore, prn administration of analgesics is not recommended in the first 36 to 48 hours postoperatively. Patients using patient-controlled analgesia (PCA) or patient-controlled epidural analgesia (PCEA) in the postoperative period need to be taught the importance of using the allowed dosages regularly to prevent increasing pain levels.

PRACTICE ALERT!

Nurses are responsible for assessing patients' pain level and administering pain medication. They must work collaboratively with surgeons to ensure an effective dose and schedule for postoperative analgesics.

NSAIDs treat mild to moderate postoperative pain. This category of drugs should be given soon after surgery (orally, parenterally, or rectally) along with opioids unless contraindicated. Although NSAIDs may not be sufficient to control pain, they allow lower doses of opioid analgesics and therefore fewer side effects. NSAIDs can be given safely to older patients, but they should be observed closely for side effects, particularly gastric and renal toxicity. The accompanying box discusses administration of ketorolac (Toradol), an NSAID commonly used in the initial postoperative period.

Opioid analgesics, such as morphine, are considered the foundation for managing moderate to severe postoperative pain. Opioid dosage requirements vary greatly from one patient to another, so the dosage must be individually tailored. In the immediate postoperative period, older adult patients benefit from the same protocol for morphine titration as do younger patients. Intravenous morphine may be initiated at a slightly reduced dose and then titrated to the same protocol as for younger patients. Morphine-related adverse effects such as nausea, vomiting, respiratory depression, constipation, urinary retention, pruritus, and allergy or sedation are similar among varying age groups. PCEA may be more effective for older adult patients and is associated with earlier improved mental status and bowel activity.

Later in the postoperative recovery period, opioid analgesics (oral or parenteral) may be given prn. In this way, pain relief can be maintained, while the potential for drug side effects is decreased. Older adult patients often require fewer opioids than younger patients in the later postoperative period.

When moving from parenteral analgesia to oral analgesics, it is important to remember that oral and parenteral doses may differ significantly. The oral dose of an opioid such as morphine, codeine, or hydromorphone may be two to five times higher than the parenteral dose to achieve equivalent pain relief.

Contrary to the belief of many healthcare providers (including nurses), physical dependence and tolerance to opioid analgesics rarely develops with short-term postoperative use. Additionally, opioid analgesics, when used to treat acute pain, rarely lead to psychologic dependence and addiction. According to the WHO pain ladder (2009b), acute pain is appropriately treated with opioids, tapering to nonprescription analgesics as healing progresses.

Analgesic options continue to develop, especially methods of delivery. Using combinations of analgesics and methods of delivery, the patient can experience better pain control and fewer analgesic gaps (periods of ineffective pain control) with lower doses. Among the newer methods to achieve control are transdermal fentanyl and extended-release epidural morphine.

MEDICATION ADMINISTRATION

Safely Administering Ketorolac

Ketorolac tromethamine (Toradol) is most commonly administered at the end of a surgical procedure or postoperatively to assist with pain management. It is an NSAID that should be used with caution in patients over 65 years of age, those under 50 kg (110 lb), and those with reduced or potentially reduced renal function. The usual adult dose is 30 mg given intravenously every 6 hours for a period of 24 to 48 hours. This medication is given in conjunction with an opioid analgesic as well. Contraindications include hypersensitivity to ASA or other NSAIDs, active GI bleeding, or peptic ulcer disease and pregnancy.

SAFETY ALERT

Older patients tend to be more sensitive to the analgesic effects of opioids, experiencing a higher peak effect with a longer duration of pain control. Kidney function often declines with aging, slowing drug excretion and increasing the risk for drug toxicity. Carefully monitor older adults for the desired and adverse effects of analgesia, particularly CNS depression.

SURGICAL ENVIRONMENT

MEMBERS OF THE SURGICAL TEAM Because of the complexity of the intraoperative environment, members of the surgical team must function as a coordinated unit. The surgeon, surgical assistant(s), anesthesiologist or CRNA, circulating nurse, and scrub person or operating room technician (Figure 4–2 ■) constitute the surgical team. Each member provides specialized skills and is essential to the successful outcome of the surgery.

The surgeon is the physician performing the procedure. As head of the surgical team, the surgeon is responsible for all medical actions and judgments.

Figure 4–2 ■ A scrub nurse in the operating room.

Moving Evidence into Action

Assessing Postoperative Pain

Pain is a subjective experience. Nurses rely heavily on patients' assessments of the pain they are experiencing (Al-Shaer et al., 2011). Rating of pain intensity by the patient is the gold standard for knowing when to provide an intervention to decrease pain, and it is considered more accurate than nurses' evaluations of behavioral manifestations of pain. However, in a study of nurse's knowledge and attitudes about pain assessment (Al-Shaer et al., 2011), a majority of nurse participants responded that as many as 33% of patients overreport pain. In this study, nurses' experience made a difference; those with more nursing experience demonstrated a higher level of knowledge about pain assessment and management.

Patients who cannot verbally communicate pain (e.g., due to dementia or intubation) present a significant challenge for nurses. A comprehensive search on the reliability and validity of observational pain scales by Stites (2013) indicated that both the Critical-Care Pain Observation Test and the Behavioral Pain Scale reliably demonstrate pain and its intensity. These scales use such factors as facial expression, movement, and muscle tension to evaluate pain.

Implications for Nursing

Findings from these studies highlight the importance of coaching patients to report their pain experience candidly, particularly in the immediate postoperative period. Establishing trust within the nurse–patient relationship is critical to relieving pain. Coaching patients to describe their pain location, intensity, and sensation gives them permission to communicate in a manner with which they may feel uncomfortable at first. Coaching often is necessary to dispel myths about analgesic use and to allow patients control and independence so that they are willing to ask for pain medications. Exploring with older patients their perception of pain, as well as the significance it has for recovery from illness, is a necessary element in providing adequate pain relief and restoring health (Chapman, 2010). Although the challenge of assessing and managing pain in nonverbal patients is greater, it is equally important to the patient's comfort, recovery, and risk for operative complications.

Implications for Future Research

As the population of patients over age 65 requiring surgical interventions grows, nursing must find improved ways to manage postoperative pain. Communication with patients who have different cultural and generational beliefs can be a barrier to assessing the needs of these patients prior to a surgical procedure and postoperatively. Further research is needed, including a tool that addresses these generational and cultural needs in order to more accurately assess and manage perioperative pain in our aging population.

Moving Knowledge into Action

1. Your patient tells you "I deserved this pain, so I don't want to take anything to make it better." How should you respond?
2. A man of Native American descent replies that "something doesn't feel right" when asked to rate his pain on a scale of 0 to 10. His pulse is increased and he is protective of his abdominal incision. What could you ask or do to accurately assess his pain?
3. An independent 85-year-old woman has a PCA pump for analgesia following major surgery. She continuously presses the pump button, but continues to complain of severe pain. What should you do now?

The surgical assistant works closely with the surgeon in performing the operation. The number of assistants varies according to the complexity of the procedure. The assistant may be another physician, a nurse, a physician assistant, or other trained person. RNs may become certified to function as a first assistant (RNFA) through academic preparation and clinical training (AORN, 2013b). The assistant performs such duties as exposing the operative site, retracting nearby tissue, sponging and/or suctioning the wound, ligating bleeding vessels, and suturing or helping suture the surgical wound.

The anesthesiologist or CRNA administers anesthesia and assumes responsibility for the patient's general well-being during surgery. The anesthesiologist or CRNA evaluates the patient preoperatively, administers the anesthesia and other required medications, transfuses blood or other blood products, infuses intravenous fluids, continuously monitors the patient's physiologic status, alerts the surgeon to developing problems and treats them as they arise, and supervises the patient's immediate postoperative recovery.

The **circulating nurse** is a registered nurse who coordinates and manages a wide range of activities before, during, and after the surgical procedure. The circulating nurse oversees the physical aspects of the operating room and required equipment, assists with transferring and positioning the patient, prepares the surgical site, ensures that no break in aseptic technique occurs, and counts all sponges and instruments. The circulating nurse assists all other team members, including the anesthesiologist or CRNA. Thorough documentation of the case in the surgical area is essential, and the circulating nurse is responsible for documenting intraoperative nursing activities, medications, blood administration, placement of drains and catheters, and length of the procedure. The circulating nurse also formulates a care plan based on physiologic and psychosocial assessments of the patient. Finally, the circulating nurse is at all times an advocate for the safety and well-being of the patient.

A scrub nurse or technician handles sutures, instruments, and other equipment immediately adjacent to the sterile field. This role requires technical skills, manual dexterity, and in-depth knowledge of the anatomic and mechanical aspects of a particular surgery. Depending on hospital policy and the complexity of the surgery, the **scrub person** may be a registered nurse or an operating room technician (ORT).

The role of nurses in surgery continues to evolve to improve patient care. Registered nurses are responsible for patient outcomes including the performance of the person functioning in the role of scrub person. The AORN (2013a) believes that registered nurses should maintain an active presence in the role of scrub person to ensure appropriate delegation and supervision of scrub duties and to maintain an integral link between scrub and circulating responsibilities.

In recent years, nurses have begun to specialize within the already specialized field of perioperative nursing. Specialty surgical teams are developing in response to the demands of increasingly complex technical surgeries. For example, a designated cardiac surgical team may be responsible for all open heart surgery cases and

ordinarily not be involved with other procedures. The use of specialty surgical teams allows nurses to become highly skilled in a particular range of procedures.

SAFETY Safety in the surgical environment is the responsibility of all surgical team members. All members of the surgical team are involved in preventing wrong site surgery and retained foreign objects. Following the Universal Protocol and using audible, visual, and concurrent correct count processes are critical in the surgical environment (Rothrock, 2011). Other critical patient safety elements include effective labeling and handling of specimens (for example, tissue specimens); measures to prevent electrical, thermal, or chemical burns; safe blood, fluid, and medication administration; and prevention of positioning injuries.

In addition to patient safety, the safety of surgical personnel is also important. Team members need to be aware of and strictly comply with guidelines to prevent exposure to scatter radiation when fluoroscopy is used in surgical procedures. Fluoroscopy provides a real-time continuous image of the internal structures of a patient. This technique is used in many types of procedures and surgeries including cardiac catheterization, orthopedic procedures, and surgeries involving the urologic, cardiovascular, and digestive systems. Protective equipment such as lead aprons, protective eyeglasses, and thyroid shields are available to all personnel at risk for exposure. Although the amount of radiation exposure involved with each event is small, the cumulative dose may exceed safe limits. Therefore, personnel need to be informed about protection and limit their exposure (AORN, 2013a).

SURGICAL METHODS Open invasive surgical procedures were traditionally the gold standard for successful outcomes. This approach was necessary in order to see and protect vital structures surrounding a target organ. Today, miniaturization and technology allow minimally invasive surgeries carried out through small incisions with the aid of cameras and remotely controlled tools and instruments for incising and suturing. While laparoscopic surgeries have been available since 1985, a newer method of minimally invasive surgery is robot-assisted surgery. Robotic technology offers three-dimensional views, whereas laparoscopic technology offers only two-dimensional views. With the robotic systems, instruments are easier for the surgeon to manipulate. Robotic, computer-aided surgical systems are not independent systems: The primary surgeon operates the robotic controls and another surgeon at the patient's side exchanges sterile instruments, retracts patient tissues, and manipulates nonrobotic sterile instruments used to assist the procedure. Nurses must be familiar with the equipment and the procedures and ready to assist at all times.

Minimally invasive surgery, whether performed robotically or laparoscopically, has advantages for patients. There is less operative trauma, leading to improved postoperative comfort and decreased pain. Although these procedures may take longer than similar open surgeries, they result in shorter hospital stays and fewer complications such as adhesions (bands of scar tissue). General anesthesia is required for most minimally invasive surgeries, and the risk for some complications similar to those for open surgeries remains.

SURGICAL ATTIRE Strict dress codes in the surgical department facilitate infection control, reduce cross-contamination between the surgery department and other patient care areas or departments, and promote the health and safety of patients and personnel. All personnel in the surgical department wear surgical attire to minimize bacterial shedding and reduce wound contamination. The surgical department is divided into three zones: *unrestricted*, *semirestricted*, and *restricted*. Unrestricted zones permit access by individuals in hospital uniforms or street clothes. These areas facilitate communication with operating room personnel.

Semirestricted zones require scrub attire, including a scrub suit, shoe covers, and a cap or hood (Figure 4–3 ■). Hallways, work areas, and storage areas are considered semirestricted. Today, based on data comparing hospital and home-laundered apparel, home-laundered scrubs are accepted by many institutions, although others may require personnel to change from street attire to hospital-laundered scrubs. No fabric other than the approved scrub uniform fabric can be exposed to the environment. Only woven or disposable fabrics that will not harbor bacteria are allowed, and all items of apparel must be covered by appropriate fabric. AORN guidelines (2013a) suggest that home-laundered scrubs be brought to the OR in a clean covering and donned at the facility, not worn into the hospital from home. Artificial nails are discouraged in surgery and anywhere the nurse will have direct contact with high-risk patients. These nails are associated with glove tears, and even after careful hand hygiene can harbor potential pathogens.

Restricted zones are within operating rooms. Personnel wear masks, sterile gowns, and gloves in addition to appropriate scrub

Figure 4–3 ■ Surgical attire. Scrub attire includes scrub suit, shoe covers, and cap or hood to cover hair, as shown on the left. Personnel in restricted zones also wear a mask, and those at the operating table wear sterile gown and gloves over their scrub attire.

NURSING CARE OF THE OLDER ADULT

Surgical Risk with Increased Age

Because of cardiovascular and tissue changes that result from aging, long, complicated surgeries (especially of the thorax and abdomen) place the older adult at increased risk for complications. The older adult is more prone to hypotension, hypothermia, and hypoxemia resulting from anesthesia and the cool temperature in the operating room.

Positioning may cause complications in the older adult. Intraoperative positioning of arthritic joints can cause postoperative joint pain unrelated to the operative site. Also, the longer the surgery is, the greater the chance of decubitus ulcer formation. The older patient is at increased risk for developing decubitus ulcers because of decreased subcutaneous fat tissue and reduced peripheral circulation.

Immune function declines with aging, increasing the risk for surgical infections in the older adult. The classic signs of infection, fever, redness, pain, and swelling may be diminished in the older adult patient; instead, manifestations such as confusion, lethargy, and anorexia may develop. The focus of care needs to be strongly on prevention.

Finally, the older adult often has some degree of hearing and/or visual impairment. These impairments coupled with a strange environment can make the operating room a frightening, disorienting place. By effectively communicating with the patient, the nurse can provide support and reassurance to minimize these factors. To decrease confusion and assist in communication, hearing aids and glasses should be used when appropriate and possible.

Factors that contribute to successful surgical outcomes for older adults include stabilizing nutrition and hydration, controlling concurrent chronic conditions with appropriate medication reconciliation, and providing information for realistic expectations about the surgery and the recovery. Advanced age alone is not a contraindication for surgery.

attire if they are participating at the operating table (Figure 4–3). The outer sterile covering is changed between procedures and when it becomes soiled or wet. These practices are designed to protect the patient and the practitioner, especially from bloodborne pathogens.

SURGICAL SCRUB The surgical scrub is performed to render hands and arms as clean as possible in preparation for a procedure. All personnel who participate directly in the procedure must perform a surgical scrub with a sponge or brush and an antimicrobial agent or FDA-approved alcohol-based antiseptic surgical hand rub. Skin cannot be rendered sterile, but it is considered "surgically clean" following the scrub. The purposes of the surgical scrub are to do the following:

- Remove dirt, skin oils, and transient microorganisms from nails, hands, and forearms.
- Increase patient safety by reducing the number of resident microorganisms on surgical personnel.
- Leave an antimicrobial residue on the skin to inhibit growth of microbes for several hours.

Following the 5- to 10-minute surgical scrub, hands and arms are dried with sterile towels.

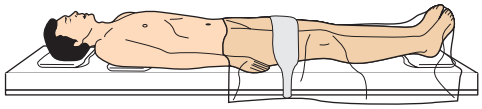
PATIENT PREPARATION

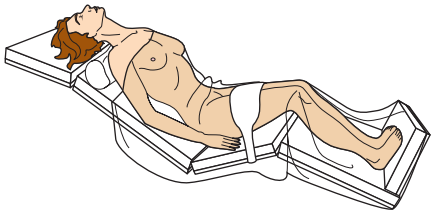
Although much preparation has taken place prior to the patient's transfer to the surgical department, additional activities such as hair removal and positioning may be performed there. The skin preparation, which usually includes cleansing the area with a prescribed antimicrobial agent, may have been performed either by the patient or by nursing personnel before the transfer to the surgical department. Additional skin cleansing is performed in the surgical department to further decrease microorganisms on the skin, thereby reducing the possibility of wound infection.

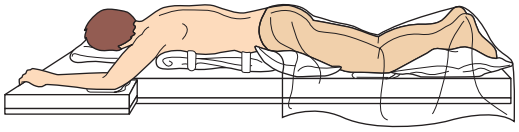
Shaving as part of skin preparation is associated with increased risk for infection secondary to nicks in the skin. When necessary, hair removal by clippers or by depilatory solutions is preferable. The surgeon may order hair removed in and around the proposed incision area. This is more often performed in the holding area of the surgical department. Generally, the prepared area is wider than the planned incision because of the possibility of unexpected extension of the incision. Hospital policy and surgeon preference should be followed.

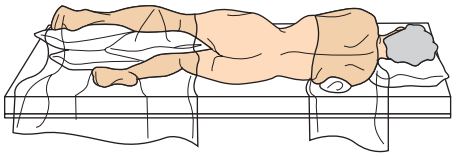
Preparing the patient for surgery also includes positioning the patient on the operating table. Table 4–5 shows frequently used positions and describes corresponding surgical procedures and possible adverse effects. Positioning exposes the operative site and provides access for anesthesia administration.

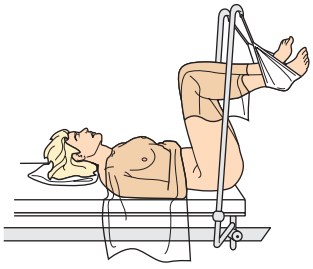
SAFETY ALERT

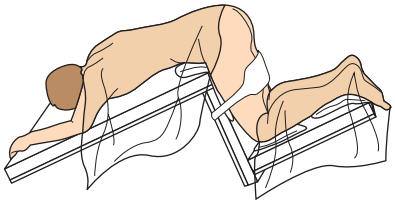












Proper positioning is imperative to prevent injury to the patient. Pressure, rubbing, and/or shearing forces can cause injury to the tissue over bony prominences. Improper positioning can overstretch tendons and ligaments, resulting in muscle or joint injury.

Improper positioning also can lead to sensory and motor dysfunction, resulting in nerve damage. Pressure on peripheral blood vessels can decrease venous return to the heart and negatively affect the patient's blood pressure. Additionally, oxygenation of the blood can be decreased if the patient is not properly positioned to promote lung expansion.

Because the anesthetized patient cannot respond to discomfort, it is the surgical team's responsibility to position the patient not only for the best surgical advantage but also for patient safety and comfort. The circulating nurse refers to hospital policy, the surgeon's preference, and the patient's history to ensure optimal positioning, and continuously assesses the patient.

INTRAOPERATIVE AWARENESS Prior to induction of anesthesia, the circulating nurse establishes rapport with the patient to assess the patient's psychologic status. This assessment is continued throughout the surgical procedure. All members of the surgical team are responsible for managing noise and other distractions during surgery. After anesthetic medications have been given, the patient may appear oblivious to the surroundings; however, patients are particularly vulnerable to noise stress during induction and emergence from anesthesia. *Intraoperative awareness* is the patient's subconscious awareness of what is being said and done during surgery. Although most patients do not consciously remember what happened or what was said, psychologic trauma can result if conversations are unprofessional. Measures to reduce noise during the intraoperative phase include minimizing the number of people present, reducing voice volume, and minimizing conversations among surgical team members or use of the telephone.

TABLE 4–5 Common Surgical Positions

Position and Use	Possible Adverse Effects and Nursing Interventions
(a) The *dorsal recumbent* (or *supine*) *position* is used for many abdominal surgeries (e.g., colostomy and herniorrhaphy) as well as for some thoracic surgeries (e.g., open heart surgery) and some surgeries on the extremities. 	This position may cause excessive pressure on posterior bony prominences, such as the back of the head, scapulae, sacrum, coccyx, and heels. Use a pressure-reducing mattress and additional padding as needed. To avoid compressing blood vessels and nerve damage, ensure that armboards are level with the mattress and the knees are not flexed. Use trochanter rolls or other padding to avoid internal or external rotation of the hips and shoulders.
(b) The *semisitting position* is used for surgeries on the head, face, neck, and shoulder areas. 	In addition to placing pressure on bony prominences of the back and buttocks, this position can lead to postural hypotension and venous pooling in the legs. Sciatic nerve injury is possible. Assess for hypotension. Ensure that knees are not sharply flexed. Use soft padding to prevent nerve compression.
(c) The *prone position* is used for spinal fusions and rectal surgeries. 	This position causes pressure on the face, breasts, genitalia, knees, thighs, and toes. Use a pressure-reducing mattress and additional padding as needed. Support arms in a flexed position and the feet under the ankles. To promote optimum respiratory function, use chest rolls and closely monitor respiratory function. Corneal abrasion could occur if the eyes are not closed or are insufficiently padded.
(d) The *lateral chest position* is used for some thoracic surgeries, kidney surgeries, as well as hip replacements. 	This position may cause excessive pressure on the bony prominences on the dependent side. Ensure adequate padding and support, especially of the downside arm. The weight of the upper leg may cause peroneal nerve injury on the downside leg. Both legs must therefore be padded. Cardiovascular and respiratory compromise is a risk; monitor carefully.
(e) The *lithotomy position* is used for gynecologic, perineal, or rectal surgeries. 	This position causes an 18% decrease (from a standing position) in vital capacity of the lungs. Monitor respirations, and assess for hypoxia and dyspnea. The lithotomy position can lead to hip dislocation or fracture, peroneal nerve damage, and an increased risk for DVT. To avoid injury, ensure adequate padding and support, apply antiembolic stockings or sequential compression devices, manipulate both legs into the stirrups simultaneously, and carefully monitor cardiorespiratory status.
(f) The *jackknife position* is used for rectal surgeries and for some spinal surgeries. 	This position causes a 12% decrease (from a standing position) in vital capacity of the lungs and increases the risk for DVT. Monitor respirations, assess for hypoxia and dyspnea, and apply antiembolic stockings or sequential compression devices. Support the patient with pads at the groin and knees, as well as at the ankles. Padding of the chest and knees helps prevent skin breakdown. Padding and proper positioning help prevent pressure on the ear, the neck, and the nerves of the upper arm.

PRACTICE ALERT!

While the patient is unconscious, do not say anything that would be inappropriate if the patient were awake. Maintain a respectful, professional demeanor throughout the operative period.

NUTRITION AND FLUID MANAGEMENT

Fluids commonly are administered intravenously until the patient is fully awake and bowel sounds are present. Balanced electrolyte solutions are often used to prevent electrolyte imbalance related to fasting. Potassium chloride may be added to the intravenous solution if nasogastric suction is in place or fasting will be prolonged. Although intravenous fluids maintain hydration and electrolyte balance, they do not provide nutrition. See the fluid and electrolyte chapter (Chapter 10) for more information about intravenous fluids and fluid balance.

Wound healing after surgery depends on adequate nutritional intake. Oral fluids and feeding are resumed as soon as possible, based on the type of surgery performed, the patient's mental status, resumption of peristalsis (either audible bowel sounds or passage of flatus), and the patient's ability to tolerate liquids without nausea and vomiting. Surgery is a physiologic insult that results in a hypercatabolic state with accelerated protein loss. Recent studies have shown a significant risk for protein-calorie malnutrition (PCM) in the postoperative patient when fasting is prolonged for 12 or more hours. PCM slows wound healing and impairs immune defenses, increasing the risk for postoperative complications. Reestablishing food intake early in the postoperative period also supports gastrointestinal function. Blood flow is diverted from the GI tract to organs such as the heart and brain during physiologic stress, which can lead to tissue ischemia and atrophy in the gut. Enteral intake supports blood flow and perfusion of the GI mucosa, maintaining its absorptive barrier and immunologic functions. Atrophy of GI mucosa is identified as a major risk factor for sepsis in high-acuity patients (Wagner et al., 2010).

Unless balanced nutrition through gastrointestinal intake can be reestablished within 3 to 4 days, parenteral nutrition is critical for homeostasis and wound healing. Glucose solutions of up to 10% concentration can be administered peripherally (peripheral parenteral nutrition). Peripheral parenteral nutrition is used for short-term nutritional support (less than 7 days). These solutions, which contain glucose, amino acids, and electrolytes, are approximately isotonic to prevent damage to the veins. Despite this, phlebitis is a common complication of peripheral parenteral nutrition. When the need for parenteral nutritional support is prolonged, central vein access must be established. The large diameter and blood flow in central veins allows administration of high-calorie solutions with protein, carbohydrates, lipids, vitamins, and minerals (total parenteral nutrition). This is important for patients who have extended recovery periods without eating after surgery. Risks associated with parenteral nutrition include fluid and electrolyte imbalances, hyperglycemia, infection, and sepsis.

●○● NURSING CARE

The following section discusses nursing care priorities in each of the three phases of surgery. The Case Study & Nursing Care Plan at the end of the section follows one patient through the postoperative experience, bringing this information together.

Preoperative Nursing Care

The patient's response to planned surgery varies greatly. When planning and implementing nursing care, consider individual psychologic and physical differences, the type of surgery, and the circumstances surrounding the need for surgery.

Before planning and implementing care for the surgical patient, gather assessment information by taking a complete nursing history and performing a physical examination. Use this information to establish baseline data, identify physical needs, determine teaching needs and psychologic support for the patient and family, and prioritize nursing care. The type of surgical procedure directs the assessment and intervention planned by the nurse. When obtaining a medication history, be sure to assess information about use of OTC medications including herbal supplements. These drugs can interact with medications administered in the perioperative period.

Surgery is a significant and stressful event. Regardless of the nature of the surgery (whether major or minor), the patient and family will be anxious. The degree of anxiety they will feel is not necessarily proportional to the magnitude of the surgical procedure. For example, a patient scheduled to have a biopsy to rule out cancer, which is considered minor surgery, may be more anxious than a patient undergoing gallbladder removal, which is considered major surgery.

The nurse's ability to listen actively to both verbal and nonverbal messages is imperative to establishing a trusting relationship with the patient and family. Therapeutic communication can help the patient and family identify fears and concerns. The nurse can then plan nursing interventions and supportive care to reduce the patient's anxiety level and assist the patient to cope successfully with the stressors encountered during the perioperative period.

Preoperative Teaching

Patient teaching is an essential nursing responsibility in the preoperative period. Patient education and emotional support have a positive effect on the patient's physical and psychologic well-being, and on family members, both before and after surgery. Although the time available for teaching patients undergoing ambulatory or outpatient surgery is limited, the responsibility of the patient and family for postoperative care and monitoring increases its importance. Because outpatient surgical stays are brief, it is valuable for nurses to be sensitive, perceptive, and able to listen to and identify the patient as an individual within a unique family.

Patient teaching should begin as soon as the patient learns of the upcoming surgery and may be done in the physician's office or at the time of preadmission testing. Although education continues during postoperative care, most teaching is done before surgery because pain and the effects of anesthesia can affect the patient's ability to learn.

The amount of information desired varies from patient to patient. Therefore, assess the patient's need for and readiness to accept information. The teaching will be directed in part by the particular surgical procedure being performed and by the type of anesthesia. The information in Box 4–5 is relevant to most patients undergoing major surgery.

In addition to teaching the patient and family about measures that will decrease the risk of complications, provide other preoperative information to prepare the patient and family for surgery. This information should include the following:

- Diagnostic tests—reasons and preparations
- Arrival time if surgery is scheduled the day of admission

BOX 4–5 Preoperative Patient Teaching

BREATHING AND COUGHING EXERCISES

Diaphragmatic (abdominal) breathing and coughing exercises help prevent pulmonary complications such as atelectasis and pneumonia. Risk factors for pulmonary complications include general anesthesia, abdominal or thoracic surgery, history of smoking, chronic lung disease, obesity, and advanced age. Diaphragmatic breathing promotes lung expansion and ventilation and enhances blood oxygenation, while coughing helps loosen, mobilize, and remove pulmonary secretions. Splinting an abdominal incision decreases the physical and psychologic discomfort associated with coughing.

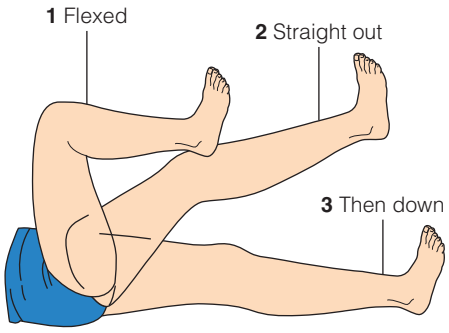
1. Assist the patient, as needed, to a sitting position.
2. Ask the patient to place the hands lightly on the abdomen (see the following figure).

3. Instruct to breathe in deeply through the nose, allowing the chest and abdomen to expand.
4. Have the patient hold the breath for a count of 5.
5. Instruct to exhale completely through pursed (puckered) lips, allowing the chest and abdomen to deflate.
6. After five deep breaths, instruct the patient to inhale deeply, hold breath briefly, then cough once or twice while contracting abdominal muscles.
7. Instruct the patient for whom coughing is painful to splint the incision with interlocked hands or a pillow (see the following figure).

8. Instruct or remind the patient to repeat the exercises every 1 to 2 hours while awake, taking short rest periods between coughs if necessary.

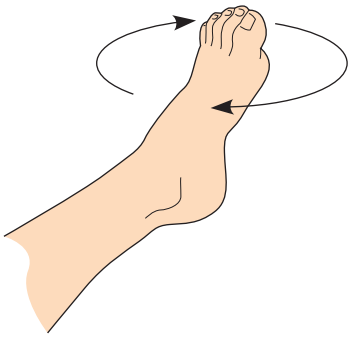
SAFETY ALERT

Coughing may be contraindicated after some surgeries (such as neurosurgery). Pay close attention to orders and protocols for postoperative care as they relate to specific surgeries.



LEG, ANKLE, AND FOOT EXERCISES

Leg exercises are taught to the patient who is at risk for developing deep venous thrombosis (DVT; formation of blood clots in a vein). Risk factors for DVT include decreased mobility; a history of circulatory disorders; and cardiovascular, pelvic, or lower extremity surgeries.



As the leg muscles contract and relax, blood is pumped back to the heart, promoting cardiac output and reducing venous stasis. These exercises also maintain muscle tone and range of motion, which facilitate early ambulation.

Teach the patient to perform the following exercises while lying in bed:

1. *Muscle pumping exercise:* Contract and relax calf and thigh muscles at least 10 times consecutively.
2. *Leg exercises:*
   a. Bend the knee and raise it toward the chest (see the following figure).

   b. Straighten leg and hold for a few seconds before lowering the leg back to the bed.
   c. Repeat exercise five times consecutively prior to alternating to the other foot.
3. *Ankle and foot exercises:*
   a. Rotate both ankles by making complete circles, first to the right and then to the left (see the following figure).

   b. Repeat five times and then relax.
   c. With feet together, point toes toward the head and then to the foot of the bed (see the following figure).

(*continued*)

BOX 4–5 Preoperative Patient Teaching (*continued*)

d. Repeat this pumping action 10 times, and then relax.

Encourage the patient to perform leg, ankle, and foot exercises every 1 to 2 hours while awake, depending on the patient's needs and ambulatory status, the physician's preference, and institutional protocol.

TURNING IN BED

The patient may need to be taught to minimize discomfort when turning in bed. Advise the patient that use of prescribed analgesics and splinting the incision with the hand and a small pillow or blanket can ease discomfort when turning. Encourage the patient to turn at least every 2 hours while awake.

1. Instruct to grasp the side rail toward the direction to be turned, to rest the opposite foot on the mattress, and to bend the knee.
2. Instruct to roll over in one smooth motion by pulling on the side rail while pushing off with the bent knee.
3. Pillows may need to be positioned behind the patient's back to help maintain a side-lying position. The older patient may also need padding over pressure points between the knees and ankles to decrease the chance of decubitus ulcer formation from pressure.

- Preparations for surgery, including fasting prior to surgery, skin preparation, indwelling catheter or bladder elimination, start of intravenous infusion, preoperative medication, handling of valuables (rings, watch, money)
- Instructions regarding current medications and any preoperative medications to be taken before admission
- Informed consent
- Expected timetable for surgery and the recovery room
- Location of the surgical waiting area and method to inform family of progress throughout surgery
- Anticipated postoperative routine and devices or equipment (drains, tubes, equipment for IV infusions, oxygen or humidifying mask, dressings, splints, casts)
- Plans for postoperative pain control
- Appropriate clothing for dressing prior to discharge from outpatient surgery.

The American Society of Anesthesiologists (2011) provides guidelines for preoperative fasting in healthy patients undergoing elective procedures; they are available online. Withdrawal from caffeine in beverages such as coffee or colas may cause headaches and irritability. Dehydration, hypovolemia, and hypoglycemia are other recognized side effects. Thirst, worry, and hunger are reported by patients to be related to fasting. Fasting does not ensure that the stomach will be empty or that the gastric contents will be less acidic.

Preoperative Patient Preparation

A preoperative surgical checklist (Box 4–6) serves as an outline for finalizing preparation of the patient for surgery in most institutions.

Patient handoffs, when responsibility for care of the patient is transferred from one caregiver or unit to another, are identified as opportunities for errors to occur. To provide for continuing care of the patient during the intraoperative and postoperative periods, communicate with the surgical nursing team and, as appropriate, nurses on the unit to which the patient will be returning. Some hospitals allow a family member or significant other to accompany the patient in the holding area while awaiting transfer to the operating room.

Intraoperative Nursing Care

The intraoperative phase of surgery begins when the patient enters the operating room and ends when the patient is transferred to the postanesthesia care unit. Nursing care in this phase focuses on keeping the patient and the environment safe and providing physiologic monitoring and psychologic support. Circulating nurses and scrub nurses, according to specific role definitions, support and care for the patient and assist the surgeons.

On entry into the surgical suite, the nurse verifies the patient's identity, the type and site of surgery, and previously obtained assessment data. The nurse participates in the Universal Protocol, calling for a "time-out" before the procedure to conduct final verification of the correct patient, site, positioning, and procedure, and to ensure that all relevant documents, information, and equipment are available.

The patient is appropriately positioned, using safety belts to secure him while ensuring that distal circulation remains unimpaired. Bone prominences are padded to reduce the risk of tissue breakdown. During surgery, the nurse observes for and informs the team if any breaks or potential breaks in sterile technique are noted.

SAFETY ALERT

Objects on the sterile drape are considered sterile. Remain a minimum of 30 cm (12 in.) away from draped tables and sterile fields to avoid contamination if you are not attired in sterile gown and gloves.

In addition to acting as patient advocate throughout the operative procedure, the nurse documents assessment data, care provided, sponge and instrument counts as appropriate, and any adverse or unexpected events that occur during surgery.

BOX 4–6 Preoperative Nursing Care

DAY OF SURGERY

Verify Medical Record Includes:

- ☑ Completed, signed, and witnessed consent for the procedure
- ☑ Completed history and physical exam
- ☑ Laboratory and diagnostic test results
- ☑ Current vital signs
- ☑ Documentation of preoperative care, all medications administered.

PATIENT PREPARATION

- ☑ Identification, blood, and allergy bands are correct, legible, and secure.
- ☑ The operative site is accurately and appropriately marked.
- ☑ Reinforce, clarify, and supplement teaching. Provide support for patient and family.
- ☑ Remove and secure jewelry, hair pins, glasses, contact lenses, and prostheses. Remove nail polish per policy.
- ☑ Remove and secure dentures unless instructed to do otherwise.
- ☑ Leave a hearing aid in place if the patient cannot hear without it, and notify the surgical team.
- ☑ Assist with bathing, hygiene, and changing into operating room gown as needed.
- ☑ Verify fasting status for the prescribed period. Notify the anesthesiologist if fasting orders have not been followed.
- ☑ Complete skin or bowel preparation as ordered.
- ☑ Instruct to empty the bladder before the preoperative sedation is given.
- ☑ Insert an indwelling catheter, intravenous line, or nasogastric tube as ordered.
- ☑ Administer preoperative medication as scheduled (refer to Table 4–4).
- ☑ Ensure safety after medication administration with side rails up and call light within reach.

Transferring Care to Surgical Team:

- ☑ Verify the patient's identity, the procedure to be performed, and surgical site. Include specific procedural information as appropriate, including which side or organ surgery is to be performed on when there is a risk for error (e.g., the right kidney, the left hip).
- ☑ Report pertinent information including:
  - Current vital signs, pain level, allergies, medications taken or administered before surgery
  - Specific laboratory data or medical history (e.g., chronic diseases, alcohol or tobacco use) as appropriate, and code status
  - The presence or absence of pertinent documents in the record
  - The patient's readiness for, level of understanding about, and psychologic response to the surgery
  - Specific patient needs, requests, or precautions, including special needs related to communication, sensory perception, ambulation, or daily living activities
  - Relevant cultural and spiritual or religious implications
  - Most recent interaction with physician and anesthetist
  - Contact information for the family.
- ☑ Allow time and opportunity to clarify information and address questions or concerns (Amato-Vealey et al., 2008).
- ☑ Assist with patient transfer as needed.

On completion of the procedure, the nurse communicates pertinent information to nursing personnel in the recovery area or postoperative unit, including:

- Patient name and other identifying information and the surgery or procedure done, including any modifiers (e.g., right hip arthroplasty)
- The anesthesiologist or CRNA, type of anesthesia used; all medications, fluids, blood, or blood products administered during surgery; estimated blood loss during surgery; presence of any drains or devices; and any significant events occurring during surgery
- Vital signs, respiratory and circulatory status; temperature; urine output; pain level and management; and any surgical complications
- Immediate postoperative orders and any specific conditions for discharge from the recovery unit (Amato-Vealey et al., 2008).

Provide an opportunity to address any questions or concerns when handing off the patient to PACU or unit staff.

Postoperative Nursing Care

Immediate Postoperative Care

Immediate postoperative care begins when the patient has been transferred from the operating room to the PACU. The PACU nurse immediately assesses the patient's airway and breathing and monitors vital signs and the surgical site to determine the response to the surgical procedure and to detect significant changes. Assessing mental status and level of consciousness is an ongoing nursing responsibility, and the patient may require repeated orientation to time, place, and person. Emotional support also is essential, because the patient is in a vulnerable and dependent position. Assessing and evaluating hydration status by monitoring intake and output is crucial to detecting cardiovascular or renal complications. In addition, the PACU nurse assesses the patient's pain level. Careful administration of analgesics provides comfort without compounding the potential side effects from the anesthesia.

Care When the Patient Is Stable

When awake and after being stabilized, the patient is transferred to her room. The PACU nurse communicates information about the patient's condition and postoperative orders to the floor nurse prior to the patient's arrival. The above format, which includes patient identifiers, the procedure performed, medications, blood and intravenous fluids administered, current vital signs, pain level, and cardiorespiratory and neurologic status, and other pertinent information such as chronic diseases or cultural considerations, provides appropriate and necessary information. This prepares the floor nurse for additional problems or needed equipment.

Immediate and continuing assessment is essential to detect and/or prevent complications. In documenting assessment findings, the nurse completes a flow record of the individual patient's situation. Baseline data are obtained and compared with preoperative data. A postoperative head-to-toe assessment includes but may not be limited to the following:

- General appearance
- Vital signs
- Level of consciousness

- Emotional status
- Quantity of respirations
- Skin color and temperature
- Discomfort/pain
- Nausea/vomiting
- Type of intravenous fluids and flow rate
- Dressing site
- Drainage on the dressing and/or bed linen
- Urinary output (catheter or ability to urinate)
- Ability to move all extremities.

Hospital policy or physician's orders dictate the frequency of follow-up assessments. After major surgery, the nurse generally assesses the patient every 15 minutes during the first hour and, if the patient is stable, every 30 minutes for the next 2 hours, and then every hour during the subsequent 4 hours. Assessments are then carried out every 4 hours, subject to change according to the patient's condition and protocol for the particular surgical procedure. It is critically important to inform the surgeon immediately if the assessment reveals any signs of impending shock or other life-threatening changes.

After carrying out the initial assessment and ensuring the patient's safety by lowering the bed and placing the call light within reach, the nurse notes the physician's postoperative orders. These orders guide the nurse in the care of the postoperative patient. For example, the orders specify activity level, diet, medications for pain and nausea, antibiotics, continuation of preoperative medications, frequency of vital sign assessments, administration of intravenous fluids, and laboratory tests such as hemoglobin and potassium level. In most institutions, orders written prior to surgery must be reordered following surgery because the patient's condition is presumed to have changed.

Managing Acute Postoperative Pain

Pain is expected after surgery. It is neither realistic nor practical to eliminate postoperative pain completely. Nevertheless, the patient should receive substantial relief from and control of this discomfort and experience minimal episodes of ineffective pain relief. Controlling postoperative pain not only promotes comfort but also facilitates coughing, turning, deep-breathing exercises, earlier ambulation, and decreased length of hospitalization, resulting in fewer postoperative complications and therefore reducing healthcare costs. Despite the apparent benefits and methods of effective pain control and improved understanding of pain physiology, pain control remains a challenge for many postoperative patients.

Managing acute postoperative pain is an important nursing role before, during, and after surgery. Successful pain management involves the cooperative efforts of the patient, physician, and nurse. Refer to the previous section of this chapter on postoperative medications and Chapter 9 for more information on managing postoperative pain.

The patient's input and participation in assessing pain and pain relief are essential to a successful pain control regime. For example, the patient can rate the pain using a standard pain scale. Assess and document pain at scheduled intervals to determine the degree of pain control, to observe for drug side effects, and to assess the need for changes in the dosage and/or frequency of medication administration. When a range of dosage is ordered, carefully titrate opioid dosages based on individual assessments of need and response to therapy.

Complementary Therapies

Various nonpharmacologic approaches to pain management may be used alone or in combination to help control acute postoperative pain. Relaxation, music, distraction, and imagery techniques can decrease mild pain and anxiety. Massage and the application of heat or cold can also relieve postoperative pain. Transcutaneous electrical nerve stimulation (TENS) has been used successfully to decrease postoperative incisional pain. Other approaches include acupuncture, acupressure, and therapeutic touch.

Nursing Care of Common Postoperative Complications

Nursing care before, during, and after surgery is aimed at preventing complications and/or minimizing their effects. Wound healing and common postoperative wound, cardiovascular, and respiratory complications, and problems associated with elimination are discussed next.

Wound Healing and Complications

Surgical wounds heal by *primary* or *secondary intention* (Figure 4–4 ■). Tissue healing by cell regeneration or primary intention occurs when the wound is uncomplicated and clean and has sustained little tissue loss. The edges of the incision are well approximated (have come together well) with sutures, staples, or superglue. This type of surgical incision heals quickly, and very little scarring is expected.

Healing by secondary intention occurs when the wound is large, gaping, and irregular. Tissue loss prevents wound edges from approximating; therefore, connective scar tissue (granulation tissue) fills in the wound to restore its structural integrity. This type of wound takes longer to heal, is more prone to infection, and develops more scar tissue.

Wound healing occurs in three phases: the inflammatory phase, the proliferative phase, and the remodeling phase. Healing time varies according to factors such as age, nutritional status, general health, and the type and location of the wound.

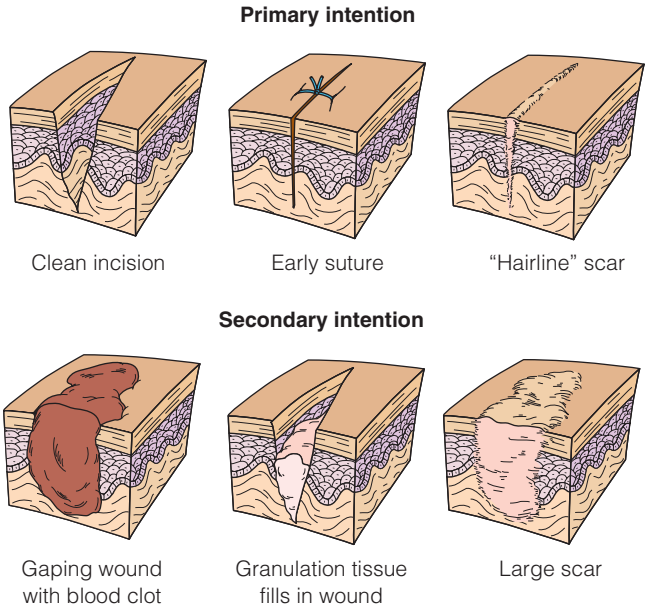


Figure 4–4 ■ Wound healing by primary and secondary intention.

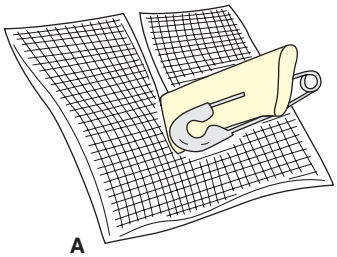
The *inflammatory phase* begins with the surgical incision. Physiologic mechanisms to maintain hemostasis and promote blood clotting are activated. Blood vessels initially constrict, then dilate and become more permeable to bring plasma and blood cells to the site. Phagocytic WBCs remove invading organisms and debris from the area. These cells also release growth factors to stimulate tissue repair.

Wound drainage (exudate) results from the inflammatory process during initial wound healing. The drainage is composed of escaped fluid and cells from the rich blood supply that surrounds the wound tissue. Wound drainage is described as serous, sanguineous, or purulent:

- Serous drainage contains mostly the clear serous portion of the blood. The drainage appears clear or slightly yellow and is thin in consistency.
- Sanguineous drainage contains both serum and red blood cells and has a thick, reddish appearance. This is the most common type of drainage from an uncomplicated surgical wound.
- Purulent drainage is composed of white blood cells, tissue debris, and bacteria. Purulent drainage results from infection. Its consistency is greater than that of serous or sanguineous drainage, and the color and odor vary by infecting organism.

Box 4–7 describes and illustrates various types of wound drainage devices. These devices decrease pressure in the wound area by removing excess fluid, which promotes healing and decreases complications.

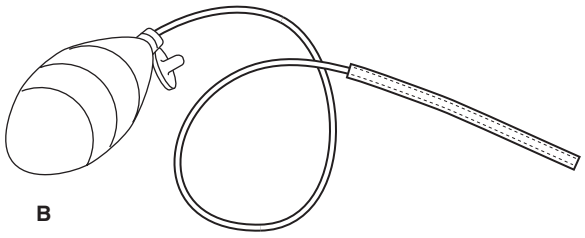
The *proliferative phase* begins within 2 to 3 days after surgery. Fibroblasts (connective tissue cells that synthesize collagen, growth factors, and other wound healing elements) and vascular endothelial cells proliferate to form granulation tissue. This tissue initially is fragile and bleeds easily. Epithelial cells proliferate at the wound edges to form a new surface.



Sutures or staples are removed during this phase of wound healing. Wound strength is only about 10% of normal tissue strength at the time of their removal, but increases significantly during the next 4 weeks (Grossman & Porth, 2014). Sutures or staples may be removed over a period of several days, with initial removal of every third suture/staple, then half of the remaining sutures/staples, and finally all remaining. Wound closure strips (e.g., Steri-Strips) or surgical adhesives may be used to maintain approximation of wound edges that are not fully healed.

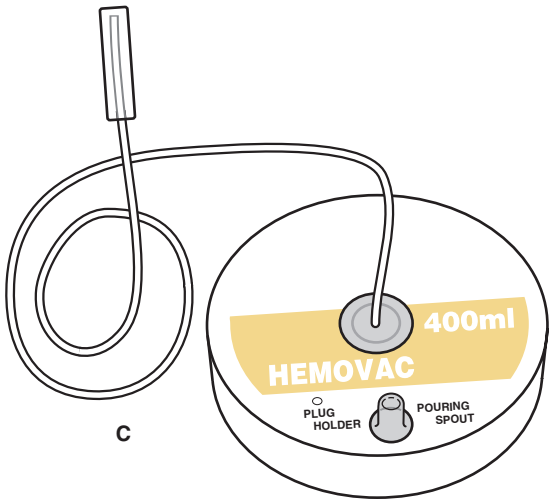
During the *remodeling phase,* scar tissue is remodeled by a process of collagen synthesis and breakdown to increase its strength. This phase begins about 3 weeks after surgery and can continue for 6 or more months.

Nursing care of the postoperative patient with a surgical wound focuses on preventing and monitoring for wound complications. The nurse assumes a leading role in supporting the wound healing process, providing emotional support to the patient, and teaching wound care to the patient.



BOX 4–7 Wound Drainage Devices

A drain promotes drainage of wound debris and healing from the inside to the outside. The use of the drain decreases the chance of abscess formation. The safety pin in the Penrose drain (see figure A) prevents the exposed end from slipping down into the wound. Wound care focuses on cleaning around the drain with a prescribed solution, such as sterile normal saline, and replacing the dressing as necessary to keep the surrounding skin dry and encourage further drainage. An absorbent dressing is placed over the drain and gauze (not shown).



A

Wound suction devices promote drainage of fluid from the incision site, decreasing pressure on healing tissues and reducing abscess formation. Shown are the Jackson-Pratt and Hemovac wound suction devices (see figures B and C).

B

C

The frequency with which the device is emptied depends on the time elapsed since surgery, type of surgery, amount of drainage, and agency policy. For example, immediately after surgery the nurse may empty the device every 15 to 60 minutes. As drainage decreases, the device is emptied every 2 to 4 hours (per policy). Care is taken to maintain asepsis when emptying suction devices, avoiding contamination of the drain or the drain plug. Amount, color, consistency, and odor of drainage are documented. Usually, the drain is removed on the second to fourth day after surgery. Removal causes minor patient discomfort. After removal, the drain site is cleaned and a sterile dressing is applied.

Common assessment findings of an infected wound include pain; purulent, odorous discharge and redness; warmth; tenderness; and edema around the edges of the incision. Additionally, the patient may have a fever, chills, and increased respiratory and pulse rates. Nursing care includes the following measures:

- Maintain medical asepsis (e.g., by using good hand hygiene technique) and standard precautions.
- Observe aseptic technique during dressing changes and handling of tubes and drains.
- Assess vital signs, especially temperature.
- Evaluate the characteristics of wound discharge (color, odor, and amount).
- Assess the condition of the incision (approximation of the edges, sutures, staples, or drains).
- Clean, irrigate, and pack the wound in the prescribed manner.
- Maintain the patient's hydration and nutritional status.
- Culture the wound prior to beginning antibiotic therapy.
- Administer antibiotics and antipyretics as prescribed.
- Provide supportive measures to patient and family.

Dehiscence is a separation in the layers of the incisional wound (Figure 4–5A ■). Treatment depends on the extent of wound disruption. If the dehiscence is extensive, the incision must be resutured in surgery. **Evisceration** is the protrusion of body organs from a wound dehiscence (Figure 4–5B ■). These serious complications may result from delayed wound healing or may occur immediately following surgery. They also may occur after forceful straining (coughing, sneezing, or vomiting). When dehiscence occurs, immediately cover the wound with a sterile dressing moistened with normal saline. Emergency surgery is performed to repair these conditions.

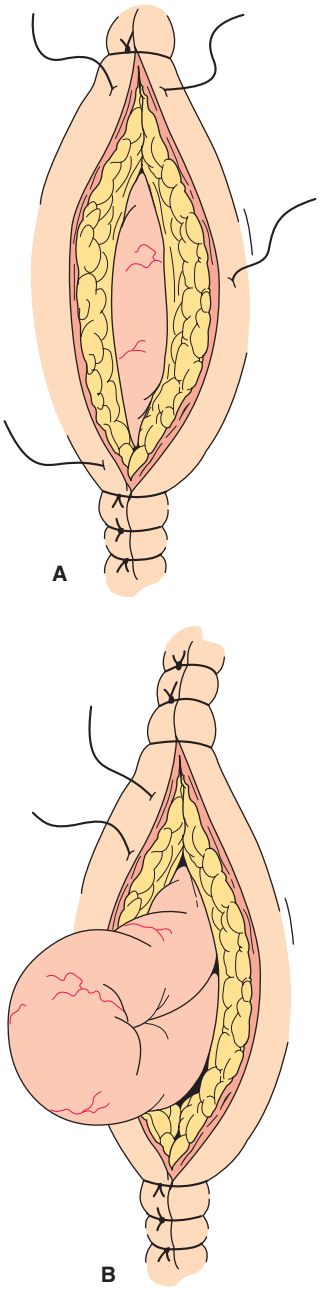


Figure 4–5 ■ Wound complications. A, Dehiscence is a disruption in the incision resulting in a separation of the layers of the wound. B, Evisceration is a protrusion of a body organ through a surgical incision.

Cardiovascular Complications

Common postoperative cardiovascular complications include hemorrhage, shock, deep venous thrombosis, and pulmonary embolism.

Hemorrhage

Hemorrhage is an excessive loss of blood. A concealed hemorrhage occurs internally from a blood vessel that is no longer sutured or cauterized or from a drainage tube that has eroded a blood vessel. An obvious hemorrhage occurs externally from a dislodged or ill-formed clot at the wound. Hemorrhage also may result from clotting abnormalities due to a pathologic condition or adverse medication effects.

Hemorrhage from a venous source oozes out quickly and is dark red, whereas an arterial hemorrhage is characterized by bright red spurts of blood pulsating with each heartbeat. Whether the hemorrhage is from a venous or an arterial source, hypovolemic shock will occur if sufficient blood is lost from the circulation.

Assessment findings with hemorrhage depend on the amount and rate of blood loss. Restlessness and anxiety are observed in the early stage of hemorrhage. The patient may have manifestations such as tachycardia; cool, pale skin; and decreased urine output. The blood pressure may remain normal. Frank bleeding may be obvious or may only be noted when turning or repositioning the patient if blood pools under the back or buttocks.

Care of the patient who is hemorrhaging centers around stopping the bleeding and replenishing the circulating blood volume. The surgeon is immediately notified as emergency surgery may be required. Pressure is applied using a snug pressure dressing or with gloved hands. An intravenous line is established and maintained with isotonic fluids. The patient and family should be supported and prepared for the possibility of emergency surgery.

Shock

Shock is a life-threatening postoperative complication. It results from an insufficient blood flow to vital organs, an inability to use oxygen and nutrients, or the inability to rid tissues of waste material. The most common type of shock in the postoperative patient is hypovolemic shock, which results from a decrease in circulating fluid volume due to blood or plasma loss or, less commonly, severe prolonged vomiting or diarrhea. Manifestations of hypovolemic shock include an altered

level of consciousness, confusion, and restlessness; tachycardia and tachypnea, weak, thready pulses, and possible hypotension; decreased urine output; and cool, clammy, pale, or cyanotic skin.

Chapter 11 provides a detailed discussion of nursing care of the patient with various types of shock.

Deep Venous Thrombosis

DVT is the formation of a thrombus (blood clot) in association with inflammation in deep veins. This complication most often occurs in the lower extremities of the postoperative patient. It may result from the combination of several factors, including vessel trauma during surgery and sluggish blood flow during and after surgery. Risk factors for postoperative DVT include:

- Orthopedic surgery to lower extremities; urologic, gynecologic, or obstetric surgeries; or neurosurgery
- Age over 40 years
- Pregnancy, varicose veins, hormone replacement therapy, or use of birth control pills
- History of previous DVT or pulmonary emboli
- Prolonged immobility
- Cigarette smoking
- Infection or sepsis
- Malignancy.

Prevention of venous stasis is an important nursing responsibility; it reduces adverse patient outcomes and decreases healthcare costs. Early ambulation is the key to preventing venous stasis. Anticoagulant medications such as low-molecular-weight heparin are used in high-risk populations. Use of mechanical prophylactic devices such as IPCDs on the foot, entire leg, or calf only is documented as effective prevention.

Common assessment findings reveal pain or cramping in the involved calf or thigh. Redness and edema of the entire extremity may occur along with a slightly elevated temperature. The patient may have a positive Homans' sign (pain in the calf on dorsiflexion of the affected foot), although this is an unreliable sign of DVT.

Nursing care of the patient with DVT includes assessing the affected extremity, administering and monitoring the effects of prescribed anticoagulants, maintaining activity restrictions as ordered, and teaching and supporting the patient and family. See Chapter 32 for more information about caring for the patient with DVT.

Pulmonary Embolism

A pulmonary embolism is a dislodged blood clot or other substance that lodges in a pulmonary artery. DVT is the major risk factor for pulmonary embolism. Early detection of this potentially life-threatening complication depends on the nurse's astute, continuing assessment of the postoperative patient.

Common assessment findings of the patient experiencing a pulmonary embolism include mild to moderate or severe dyspnea, chest pain, diaphoresis, anxiety, restlessness, rapid respirations and pulse, dysrhythmias, cough, and cyanosis. The severity of the symptoms is determined by the degree of pulmonary vascular blockage. Sudden death can occur if a major pulmonary artery becomes completely blocked.

Stabilizing respiratory and cardiovascular functioning while preventing the formation of additional emboli is of utmost importance in the care of the patient with a pulmonary embolism. Nursing care includes prompt notification of the physician and frequent assessment of cardiac, respiratory, and neurologic status. Oxygen saturation is monitored, and supplemental oxygen may be administered. Intravenous access is maintained; anticoagulants and analgesics may be prescribed. The nurse also focuses on supporting the patient and family during this crisis.

Chapter 37 provides more information about care of the patient experiencing pulmonary embolism.

Respiratory Complications

Common postoperative respiratory complications include pneumonia and atelectasis.

Pneumonia

Pneumonia is inflammation of lung tissue. Inflammation is caused either by a microbial infection or by a foreign substance in the lung, which leads to inflammation. Numerous factors may be involved in the development of pneumonia, including aspiration of gastric contents, retained pulmonary secretions, impaired cough reflex, and decreased mobility.

Common assessment findings of the postoperative patient with pneumonia are as follows:

- Chills and fever
- Tachycardia, tachypnea
- Cough, which may be productive
- Dyspnea
- Chest pain
- Crackles and wheezes.

Treating the pulmonary infection, supporting the patient's respiratory efforts, promoting lung expansion, and preventing the organisms' spread are the goals in the care of the patient with pneumonia. Frequently assess vital signs, oxygen saturation, and the patient's ability to tolerate activity. Elevate the head of the bed and administer oxygen as ordered to support lung ventilation and gas exchange. Encourage mobility as tolerated and use of the incentive spirometer at least every 1 to 2 hours. Promote hydration to help liquefy respiratory secretions, and administer medications as ordered. Teach proper disposal of tissues, to cover the mouth when coughing, and good hand hygiene technique.

Care of the patient with pneumonia is discussed in Chapter 36.

Atelectasis

Atelectasis is an incomplete expansion or collapse of lung tissue resulting in inadequate ventilation and retention of pulmonary secretions. Common assessment findings include dyspnea, diminished breath sounds over the affected area, anxiety, restlessness, crackles, and cyanosis.

Promoting lung expansion and systemic oxygenation of tissues is a goal in the care of the patient with atelectasis. Nursing care is similar to that provided for the patient with pneumonia as outlined above.

Complications Associated with Elimination

Common postoperative complications associated with elimination include urinary retention and altered bowel elimination. Urinary retention may occur postoperatively as a result of the recumbent position, effects of anesthesia and narcotics, inactivity, altered fluid balance, nervous tension, or surgical manipulation in the pelvic area.

Assess for bladder distention if the patient has not voided within 7 to 8 hours after surgery or if the patient is urinating small amounts frequently. Use a portable ultrasound scanner to determine the amount of urine in the bladder. This noninvasive procedure provides information to prevent unnecessary catheterization and decreases the potential for urinary tract infections and urethral trauma from repeated catheterizations. Promote fluid intake as allowed, monitoring intake and output. Use measures to promote normal urinary elimination:

1. Provide privacy.
2. Assist the patient to use the bedside commode or walk to the bathroom.
3. Assist male patients to stand to void.
4. Pour a measured amount of warm water over the perineal area. (If urination occurs, subtract the amount of water from the total amount for an accurate output measurement.)

Bowel elimination frequently is altered after abdominal or pelvic surgery and sometimes after other surgeries. Return to normal gastrointestinal function may be delayed by general anesthesia, narcotic analgesia, decreased mobility, or altered fluid and food intake during the perioperative period.

Nursing care centers on assessing for and promoting the return of normal bowel function. To assess for the return of peristalsis, ask the patient about the passage of flatus, auscultate bowel sounds every 4 hours while awake, assess the abdomen for distention, and monitor for defecation. A distended abdomen with absent bowel sounds may indicate paralytic ileus (impaired propulsion of intestinal contents). Measures to promote bowel function include encouraging ambulation, promoting fluid intake of 2500 to 3000 mL (unless contraindicated), and providing for privacy during elimination. The patient receiving opioid analgesics may require a stool softener or mild laxative to prevent constipation, a side effect of these drugs. If no bowel movement has occurred within 3 to 4 days after surgery, a suppository or an enema may be ordered.

Special Considerations for Older Adults

Physiologic, cognitive, and psychosocial changes associated with the aging process place the older adult at increased risk for postoperative complications. These age-related changes with selected nursing interventions are summarized in Table 4–6. With an ever-increasing population of older adults, particularly the very old, the nurse must be aware of these normal changes and modify nursing care accordingly in an effort to provide safe, supportive care.

Continuity of Care

Because the postoperative phase does not end until recovery is complete, the nurse's role as educator is vital as the patient nears discharge. As the patient prepares to recuperate at home, provide information

TABLE 4–6 Nursing Interventions for Older Adults Undergoing Surgery

System	Age-Related Changes	Nursing Interventions
Body composition	Decreased lean muscle mass and strength, increased body fat; decreased thirst	Assist to change positions frequently. Monitor I&O, assess for dehydration and fluid imbalance.
Nutrition-immune status	Decreased appetite, taste, and saliva production increase risk for malnutrition; immune function declines with aging	Assess for inflammation and wound healing; monitor temperature and laboratory values for evidence of infection, malnutrition; minimize duration of fasting
Integument	Loss of subcutaneous fat, thinning of dermis and epidermis, decreased moisture and elasticity	Position carefully to prevent pressure ulcers. Avoid shearing forces which can tear skin. Examine mucous membranes, laboratory studies, and urine output to evaluate hydration status.
Sensory-perceptual	Age-related vision and hearing impairment	Encourage patient to wear glasses and hearing aids whenever possible; speak clearly, not loud; minimize noise in environment; provide adequate room light; remain within patient's field of vision when speaking.
Respiratory	Decreased vital capacity and increased residual volume; increased ventilation/perfusion mismatch; diminished cough reflex	Assess baseline parameters and monitor respiratory status and lung sounds. Teach and encourage coughing and diaphragmatic breathing exercises. Encourage ambulation.
Cardiovascular	Decreased cardiac reserve; increased risk for postural hypotension	Monitor vital signs, pulse strength, skin color and temperature, and urine output. Assess for cardiac dysrhythmias and edema. Encourage ambulation and leg exercises to prevent DVT.
Gastrointestinal	Gum disease, loss of teeth, and dry mouth affect appetite and food intake; slowed GI motility contributes to early satiety and constipation	Provide mouth care; avoid alcohol-based products that dry mucous membranes. Encourage adequate fluid intake and small, frequent meals, soft diet. Monitor bowel function.
Genitourinary	Decreased kidney function; decreased bladder capacity; potential prostate enlargement in men	Monitor I&O, serum electrolyte, BUN, and creatinine levels. Assess for drug side effects. Assist to normal voiding position as needed.
Musculoskeletal	Decreased bone density; loss of muscle mass; increased joint stiffness	Carefully position on OR table. Move carefully and gently. Prevent pressure sores. Encourage and assist with postoperative ambulation.
Cognitive-psychologic	Cognition remains stable, but information processing slows; more difficulty with word retrieval, naming	Provide ample time for teaching and learning, encourage repetition; provide supplemental written materials and instructions.

CASE STUDY & NURSING CARE PLAN A Patient Having Surgery

Martha Overbeck is a 74-year-old widow who lives alone in a senior citizens' housing complex. She is active there, as well as in the Lutheran Church. She has been in good health but has become progressively less active as a result of arthritic pain and stiffness. Mrs. Overbeck has degenerative joint changes that have particularly affected her right hip. On the recommendation of her physician and following a discussion with her friends, Mrs. Overbeck has been admitted to the hospital for an elective right total hip replacement. Her surgery has been scheduled for 8:00 a.m. the following day.

Mrs. Eva Jackson, a close friend and neighbor, accompanies Mrs. Overbeck to the hospital. Mrs. Overbeck explains that her friend will help in her home and assist her with the wound care and prescribed exercises.

ASSESSMENT

Gloria Nobis, RN, is assigned to Mrs. Overbeck's care on return to her room. Ms. Nobis performs a complete head-to-toe assessment and determines that Mrs. Overbeck is drowsy but oriented. Her skin is pale and slightly cool. Mrs. Overbeck states she is cold and requests additional covers. Ms. Nobis places a warmed cotton blanket next to Mrs. Overbeck's body, adds another blanket to her covers, and adjusts the room's thermostat to increase the room temperature. Mrs. Overbeck states that she is in no pain and would like to sleep. She has even, unlabored respirations and stable vital signs as compared to preoperative readings.

Mrs. Overbeck is NPO. An intravenous solution of dextrose and water is infusing at 100 mL/h per infusion pump. No redness or edema is noted at the infusion site. Ms. Nobis notes that the antibiotic ciprofloxacin hydrochloride (Cipro) is to be administered by mouth when the patient is able to tolerate fluids. Mrs. Overbeck has a large gauze dressing over her right upper lateral thigh and hip with no indications of drainage from the wound. Tubing protrudes from the distal end of the dressing and is attached to a passive suctioning device (Hemovac). Ms. Nobis empties 50 mL of dark red drainage from the suctioning device and records the amount and characteristics on a flow record. Mrs. Overbeck has a Foley catheter in place with 250 mL of clear, light amber urine in the dependent gravity drainage bag.

Mrs. Overbeck's feet are slightly cool and pale with rapid capillary refill time bilaterally. Dorsalis pedis and posterior tibial pulses are strong and equal bilaterally. Ms. Nobis notes slight pitting edema in the right foot and ankle as compared with the left extremity. She also notes sensation and ability to move both feet and toes, without numbness or tingling (paresthesias).

Ms. Nobis records these findings on the electronic medical record (EMR). After ensuring that Mrs. Overbeck is safely positioned and can reach her call light, Ms. Nobis gives Mrs. Overbeck's friend, Mrs. Jackson, a progress report.

DIAGNOSES

Ms. Nobis makes the following postoperative nursing diagnoses for Mrs. Overbeck:

- *Risk for Infection* of right hip wound related to disruption of normal skin integrity by the surgical incision
- *Risk for Injury* related to potential dislocation of right hip prosthesis secondary to total hip replacement
- *Pain* related to right hip incision and positioning of arthritic joints during surgery
- *Risk for Impaired Physical Mobility* related to right hip wound.

EXPECTED OUTCOMES

The expected outcomes established in the plan of care specify that Mrs. Overbeck will:

- Regain skin integrity of the right hip incision without experiencing signs or symptoms of infection.
- Verbalize signs and symptoms of infection to be reported to her physician.
- Describe measures to be taken to prevent dislocation of right hip prosthesis.
- Report control of pain at incision and in arthritic joints.
- Remain afebrile.
- Remain free of complications related to immobility.

PLANNING AND IMPLEMENTATION

Ms. Nobis develops a care plan that includes the following interventions to assist Mrs. Overbeck during her postoperative recovery:

- Use aseptic technique while changing dressing.
- Monitor temperature and pulse every 4 hours to assess for elevation.
- Assist to change positions frequently (q2h) and cough and deep breathe. Assist with early ambulation.
- Assess wound every 8 hours for purulent drainage and odor. Assess edges of wound for approximation, edema, redness, or inflammation in excess of expected inflammatory response.
- Teach Mrs. Overbeck and Mrs. Jackson the signs and symptoms of infection and when to report findings to the physician.
- Review and discuss with Mrs. Overbeck the written materials on total hip replacement.
- Convey empathetic understanding of Mrs. Overbeck's incisional and arthritic joint pain.
- Medicate Mrs. Overbeck every 4 hours (or as ordered) to maintain a therapeutic analgesic blood level.

EVALUATION

Throughout hospitalization, Ms. Nobis works with Mrs. Overbeck and Mrs. Jackson to ensure that Mrs. Overbeck can care for herself after discharge from the hospital. Five days after her surgery, Mrs. Overbeck is discharged with a well-approximated incision with no indications of an infection. Prior to discharge, Ms. Nobis is confident that with Mrs. Jackson's help Mrs. Overbeck can properly assess the incision. She can cite the signs and symptoms of an infection, take her own oral temperature, and describe preventive measures to decrease the chances of dislocating her prosthetic hip. Because of her reduced mobility the past 5 days, Mrs. Overbeck says she can tell the arthritis in her "old bones" is "acting up." She reports less pain in her right hip than before the surgery. Mrs. Overbeck tells Ms. Nobis she will be back the following winter to have her left hip replaced.

Clinical Reasoning in Patient Care

1. Describe risk factors for Mrs. Overbeck's safety. What changes in her home environment would you suggest to promote safety until she recovers more fully?
2. Why is Mrs. Overbeck placed on the antibiotic Cipro although she has no indications of an infection? What teaching would you do?
3. Mrs. Overbeck's clotting time is slightly elevated as a result of an ordered anticoagulant. Why would this medication be ordered? Consider the patient's age and the area of surgery.
4. Mrs. Overbeck is 30 pounds above her ideal weight and has osteoarthritis. Develop a care plan for the nursing diagnosis *Ineffective Health Maintenance* related to intake in excess of metabolic requirements.

See Evaluating Your Response in Appendix B.

and support as needed for self-care. Written guidelines, directions, and information should accompany all aspects of teaching. Opportunities for patient and family teaching often are brief, necessitating an organized, coordinated effort. The most common teaching needs include the following:

- Wound care. Demonstrate and explain the procedure, then encourage the patient and family to participate in the care. As time allows, have the patient or caregiver do a return demonstration of the procedure. Ideally, teaching is carried out over several days, evaluated, and reinforced.
- Signs and symptoms of a wound infection. The patient should be able to determine what is normal and what should be reported to the physician.
- How and when to take one's temperature.
- Limitations or restrictions on such activities as lifting, driving, bathing, sexual activity, and other physical activities.
- Control of pain. If analgesics are prescribed, teach the patient about the dosage, frequency, purpose, common side effects, and other side effects to report to the physician. Reinforce effective analgesic use, and provide information on managing side effects such as gastric upset or constipation.

When the patient is discharged to a transitional, rehabilitation, or skilled care facility for additional recovery before returning home, it is important to convey information both verbally and in writing. Include the following information:

- Patient name and identifying data; the surgery or procedure done, including any modifiers (e.g., right hip arthroplasty)
- Wound management, current medications and their purpose, prescribed activity and any limitations (e.g., limited weight bearing or restricted joint flexion)
- Current status, including vital signs and temperature; respiratory and circulatory status; pain level and management; fluid balance and nutrition; skin status; current activity level and degree of independence; pertinent cultural, emotional, psychosocial, or spiritual care needs; specific patient requests, needs, or values
- Specific rehabilitation orders and conditions for discharge from rehabilitation or skilled care (Amato-Vealey et al., 2008).

Provide an opportunity to address any questions or concerns when handing off the patient to facility staff.

CHAPTER HIGHLIGHTS

- **Surgery is a major physiologic and psychologic stressor that carries significant risks. Nurses have a critical role in protecting the safety of, maintaining the physiologic and psychologic integrity of, advocating for, and promoting recovery of the patient undergoing surgery.**
- Surgeries take place in traditional and nontraditional settings with increasing use of minimally invasive procedures that expedite discharge, facilitate healing, and increase patient satisfaction.
- Surgery is an invasive procedure requiring that legal guidelines be followed to protect the patient and the healthcare providers. The surgical team includes surgeons, anesthetists, nurses, and technicians; all are responsible for the safety of the patient and the progression of the surgery.
- **Systematic and effective communication among all members of the interprofessional team is essential for safe and effective perioperative care. Care transitions (preoperative to surgery, surgery to postanesthesia recovery, and postanesthesia recovery to postoperative care) present significant opportunities for errors, emphasizing the importance of effective communication.**
- The focus on safety during surgery continues to increase with attention directed to preventing wrong site and wrong patient surgeries (using the Universal Protocol), surgical site infections, DVT and PE, and adverse cardiac events. A team approach to safety works best; each member of the team must feel accountable for the results of the surgery and entitled to share observations and concerns as the procedure progresses.
- **Assessing, coordinating, and implementing preoperative preparation, evaluating and ensuring the patient's readiness for surgery, and teaching are key preoperative nursing roles.**
- **Nurses' focus during the intraoperative phase is on promoting and maintaining patient safety. Patient advocacy is a critical nursing role during this phase, because the patient is unable to speak for or meet his or her own needs.**
- **During the postoperative phase, nurses are instrumental in promoting the patient's comfort and initial recovery, identifying and preventing potential complications, and teaching the patient and family or caregivers about continuing care needs.**
- Patient teaching prior to and following surgery empowers patients to achieve successful recovery, discharge, and rehabilitation. Most of the care patients receive during healing is either provided by self or a caregiver outside the healthcare environment. Patients and their families need to know appropriate assessments and interventions to monitor the healing process and contact information for additional help.
- Pain management is offered prior to, during, and after surgery with methods designed to give the best therapeutic response. Although acute pain may be associated with the surgery, many patients also experience chronic pain that affects their response to pain management therapies.
- Behaviors characteristic of older adult patients and ethnically diverse populations increase the need for individualized care. Assessment of physical and emotional status can be more difficult when patients have hearing or visual impairments or when individuals speak

and understand a foreign language. Surgery can be frightening to patients and their families and they need reassurance and interventions to decrease pain, relieve anxiety, and promote healing.

- Operating room and postanesthesia care nursing are professional specialties that require unique orientation and education. These professionals make careful assessments of the risks each patient faces and make plans to ensure safe, successful surgical outcomes. Special attention is focused on early recognition and treatment of postoperative complications associated with cardiopulmonary function, respiratory function, wound healing, elimination, and pain.

TEST YOURSELF NCLEX-RN® REVIEW

1. Which action should the nurse perform when implementing informed consent?
1. Define the risks and benefits of the surgery.
2. Witness the patient's signature on the consent form.
3. Explain the right to refuse treatment or withdraw consent.
4. Advise the patient and family about what is needed for the diagnosis.

2. The nurse is caring for a patient recovering from surgery provided through an outpatient surgical center. On what teaching should the nurse focus to assist this patient with her recovery?
1. nutritional needs
2. pain medication doses
3. identifying complications
4. fluid and hydration status

3. When providing patient-centered care to a patient recovering from surgery, why should the nurse provide nonsteroidal anti-inflammatory drugs?
1. To increase amnesia
2. To stimulate appetite
3. To potentiate analgesia
4. To improve renal function

4. When reviewing the medical record for a patient scheduled for surgery, the nurse notes an abnormal laboratory value. Which value should the nurse report to the healthcare provider?
1. increased chloride
2. decreased glucose
3. increased creatinine
4. decreased hemoglobin

5. The nurse is concerned that a patient who has undergone knee surgery is developing a vascular problem distal from the operative site. What did the nurse most likely assess in this patient?
1. bounding pedal pulse
2. poor muscle tone in the foot
3. skin that is cool to the touch
4. redness or swelling in the calf

6. The nurse notes that a patient did not receive ordered medications prior to having surgery. What should the nurse do about the patient's medications?
1. Resume them now.
2. Decrease doses by half for 36 hours.
3. Check for new orders before providing.
4. Withhold until fully recovered from anesthesia.

7. The nurse is preparing a patient with type 1 diabetes mellitus for surgery and withholds the morning insulin dose. Why was this medication withheld for the patient?
1. There is no risk for hyperglycemia during surgery.
2. The patient will benefit from hypoglycemia during anesthesia.
3. The patient received an extra dose the evening before the surgery.
4. Manifestations of hypoglycemia will not appear under anesthesia.

8. The nurse is reviewing the pain management orders for a patient recovering from surgery. What should the nurse anticipate regarding these medications for the patient?
1. Progress from NSAIDs to opioids
2. Progress from oral to parenteral routes
3. Scheduled rather than prescribed to be given as needed
4. Induce a strong sedative effect to decrease the risk of nausea

9. The nurse is preparing an older patient for a surgical procedure that is planned to take 8 hours. Which postoperative risk is this patient more prone to experiencing?
1. memory loss due to blood loss
2. hearing loss due to extended anesthesia
3. weight loss due to lack of nutritional intake
4. pressure sores and joint pain from operative positioning

10. A patient has just been admitted to the PACU. Why should the nurse provide interventions to reduce hypothermia in this patient?
1. To decrease cardiac ischemia
2. To reduce the risk for wound infection
3. To increase patient comfort and analgesia
4. To reduce the risk for cardiac problems and surgical bleeding

5 Nursing Care of Patients Experiencing Loss, Grief, and Death

LEARNING OUTCOMES

1. Explain how theories of loss and grief influence provision of patient-centered care for individuals experiencing loss, grief, and death.
2. Explain factors affecting patient and family responses to loss.
3. Analyze common legal and ethical issues in end-of-life care.
4. Describe the philosophy and activities of hospice and palliative care.
5. Describe the physiologic responses associated with the end of life.

CLINICAL COMPETENCIES

1. Recognize physiologic changes in the dying patient.
2. Use assessments, patient values, and evidence-based practice guidelines to provide nursing interventions that enhance quality of life and promote a comfortable and dignified death for patients and their families.
3. Use principles of palliative care to manage pain and other symptoms associated with the end of life.
4. Effectively communicate with and function within the interprofessional team to plan and provide individualized care for patients and families experiencing loss, grief, and death.
5. Integrate individual and cultural values and variations, as well as expressed needs and preferences, into the plan of care for patients and families experiencing loss, grief, and death.
6. Identify self-care strategies to use when caring for patients and families experiencing loss, grief, and death.

MAJOR CHAPTER CONCEPTS

- Caring for patients and families experiencing loss, grief, and death emphasizes integration of holistic nursing interventions focused on providing individualized patient-centered care.
- Providing direct patient care, coordinating, leading, and participating as a member of the interprofessional team is an essential role for the registered nurse when caring for this population.

Loss may be defined as an actual or potential situation in which a valued object, person, body part, or emotion that was formerly present is lost or changed and can no longer be seen, felt, heard, known, or experienced. A loss may be temporary or permanent, complete or partial, objectively verifiable or perceived, physical or symbolic. Only the individual who experiences the loss can determine the meaning of the loss. Although the order of importance varies with the individual, people most commonly fear the losses listed in Box 5–1.

Loss always results in change. The stress associated with the loss may be the precipitating factor leading to physiologic or psychologic change in the individual or family. The effective or ineffective resolution of feelings surrounding the loss determines the individual's ability to deal with the resulting changes. There are many different types of loss, with responses to the loss individualized within each person.

BOX 5–1 Types of Losses

- Death
- Health
- Body part
- Social status
- Lifestyle
- Marital relationship (i.e., through divorce)
- Reproductive function
- Sexual function

This chapter considers loss from both a general and from a specific focus. There is, within the chapter, a greater emphasis on loss from death, as this is often a difficult situation because nurses care for the person who is dying and also for the people who are left to experience

the loss. Some of the terms that are used throughout the chapter are introduced in the following paragraphs.

Grief is the emotional response to loss and its accompanying changes. Grief as a response to loss is an inevitable dimension of the human experience. The loss of a job, a role (e.g., the loss of the role of spouse, as occurs in divorce), a goal, body integrity, a loved one, or the impending loss of one's own life or a loved one's life may trigger grief. Although death is the ultimate loss, losses that occur in any phase of the life cycle may produce grief responses as intensely painful as those observed in the death experience.

Grieving may be thought of as the internal process the individual uses to work through the response to loss. **Mourning** describes the actions or expressions of the bereaved, including the symbols, clothing, and ceremonies that make up the outward manifestations of grief. Both grieving and mourning are healthy responses to loss because they ultimately lead the individual to invest energy in new relationships and to develop positive self-regard.

Death is defined in many ways. One commonly used definition of death is an irreversible cessation of circulatory and respiratory functions or irreversible cessation of all functions of the entire brain, including the brainstem. With the current life-support systems available, the most often used criterion for determining death is whole-brain death (permanent irreversible cessation of the functioning of all areas of the brain). The criteria for whole-brain death are listed in Chapter 11, Nursing Care of Patients Experiencing Trauma and Shock.

Although death is an inevitable part of life, it is often an immensely difficult loss for the person who is dying and for his or her loved ones. Death may be accidental (for example, from trauma); purposeful (from suicide); occur suddenly or at the end of a long and painful struggle with a chronic or terminal illness such as congestive heart failure, cancer, or AIDS; or be the natural end of the aging process.

THEORIES OF LOSS, GRIEF, AND DYING

Medical-surgical nurses often care for patients exhibiting responses typical of various stages of the grieving process. Highly individual in quality and duration, the grief process may range from discomforting to debilitating, and it may last a day or a lifetime, depending on what the loss means to the person experiencing it. Although each person experiences loss in a different manner, knowledge of some of the major theories of loss, grief, and dying can give the nurse a framework for holistic care of the patient and family anticipating or experiencing a loss. Table 5–1 summarizes these theories.

Freud: Psychoanalytic Theory

Sigmund Freud (1917/1957) wrote about grief and mourning as reactions to loss. Freud described the process of mourning as one in which the individual gradually withdraws attachment from the lost object or person. He observed that with normal grieving, this withdrawal of attachment is followed by a readiness to make new attachments. In comparing melancholia (prolonged gloominess, depression) with the normal emotions of grief and its expression in mourning, Freud observed that the "work of mourning" is a nonpathologic condition that reaches a state of completion after a period of inner labor.

Bowlby: Attachment Theory

John Bowlby (1973, 1980) believed that the grieving process initiated by a loss or separation from a loved object or person successfully ends when the grieving person experiences feelings of emancipation from the lost object or person. He divided the grieving process into three phases and identified behaviors characteristic of each phase:

- ***Protest.*** The protest phase is marked by a lack of acceptance of the loss. All energy is directed toward protesting the loss. The person experiences feelings of anger toward self and others, and feelings of ambivalence toward the lost object or person. Crying and angry behaviors characterize this phase.
- ***Despair.*** The person's behavior becomes disorganized. Despair mounts as efforts to deny the loss compete with acceptance of permanent loss. Crying and sadness, coupled with a desire for the lost object or person to return, result in disorganized thoughts as the patient recognizes the reality of the loss.
- ***Detachment.*** As the person realizes the permanence of the loss and gradually relinquishes attachment to the lost object, a reinvestment of energy occurs. Both the positive and negative aspects of the relationship are remembered. Expressions of hopefulness and readiness to move forward are characteristic of this phase.

Bowlby's theory was used as a base for a "continuing bonds" theory, developed by Field, Gao, and Paderna (2005). This theory poses the belief that mourners of loved ones lost by death continue to have memories of the deceased, feel their presence, and save meaningful belongings. These actions bring comfort to the bereaved, and allow a new relationship to form with those lost by death. As a result the mourners resolve their grief and accept the loss.

Engel: Acute Grief, Restitution, and Long-Term Grief

George Engel (1964) related the grief process to other methods of coping with stress: After the individual perceives and evaluates the loss (the stressful event), the individual adapts to it. Engel's recognition of

TABLE 5–1 Summary of Selected Theories of Loss

Theorist	Dynamics
Freud	Grief and mourning are reactions to loss. Grieving is the inner labor of mourning a loss. Inability to grieve a loss results in depression.
Bowlby	The successful grieving process initiated by a loss or separation ends with feelings of emancipation from the lost person or object.
Engel	After the individual perceives and evaluates the loss, the individual adapts to it. Shock and disbelief, developing awareness, and restitution occur during the first year following the loss; in the months following, the individual puts the lost relationship into perspective.
Lindemann	A sequence of responses is experienced following a catastrophic event; concepts of anticipatory grieving and morbid grief reactions are defined.
Caplan	Periods of psychologic crisis are precipitated by hazardous circumstances; successful resolution of grief involves feelings of hope and engaging in activities of ordinary living.
Kübler-Ross	Five stages define the response to loss: denial, anger, bargaining, depression, and acceptance. Stages are not necessarily sequential.

the effect of cognitive factors on the grieving process was an important contribution to the understanding of grieving. The acute stage is initiated by shock and disbelief and may be manifested by denial, which in turn may help the individual to cope with the overwhelming pain. As the shock and disbelief begin to fade, the loss becomes a reality, and pain, anguish, anger, guilt, and blame surface. Culturally patterned behaviors, such as maintaining a stoic pose in public or weeping openly, characterize this phase. During restitution friends and family gather to support the grieving person through rituals dictated by their culture. The mourner continues to feel a painful void and is preoccupied with thoughts of the loss. The mourner may join a support group or seek other social support for coping with the loss. This stage lasts about 1 year, after which the mourner begins to come to terms with the loss and interests in people and activities are renewed.

Lindemann: Categories of Symptoms

Erich Lindemann (1944) interviewed people who had lost a loved one during the course of medical treatment, disaster victims, and relatives of members of the armed forces who had died. Lindemann's research led him to describe normal grief, anticipatory grieving, and morbid grief reactions. He placed symptoms characteristic of normal grief into categories of somatic (physical symptoms without an organic cause) distress, preoccupation with the image of the deceased, feelings of guilt, hostile reactions, and loss of patterns of conduct.

Anticipatory grieving was defined as a cluster of predictable responses to an anticipated loss. These responses include the range of feelings experienced by the individual or family preoccupied with an anticipated loss. The term *morbid grief reaction* described delayed and dysfunctional reactions to loss; a variety of debilitating health problems were seen in people who displayed excessive or delayed responses to loss.

Caplan: Stress and Loss

Gerald Caplan's (1990) theory of stress and its relationship to loss is useful in understanding the grief process. He expanded the focus of the grief process to include not only bereavement but also other episodes of stress that people experience, such as may result from surgery or childbirth. Caplan described three factors that influence the person's ability to deal with a loss. He believed these factors might cause distress for a year or more following the loss:

- The psychic pain of the broken bond and the agony of coming to terms with the loss
- Living without the assets and guidance of the lost person or resource
- The reduced cognitive and problem-solving effectiveness associated with the distressing emotional arousal.

Caplan described the process of building new attachments to replace those that have been lost as involving two elements: a feeling of hope and the assumption of regular activity as a form of participating in ordinary living.

Kübler-Ross: Stages of Coping with Loss

Elisabeth Kübler-Ross's (1969, 1978) research on death and dying provided a framework for gaining insight about the stages of coping with an impending or actual loss. According to Kübler-Ross, not all people dealing with a loss go through these stages, and those who do may not experience the stages in the sequence described. In identifying the stages of death and dying, Kübler-Ross stressed the danger of prematurely labeling a stage and emphasized that her goal was to describe her observations of how people come to terms with situations of loss.

Some or all of the following reactions may occur during the grieving process and may reappear as the person experiences the loss:

- ***Denial.*** A person may react with shock and disbelief after receiving word of an actual or potential loss. After receiving a terminal diagnosis, notification of a death, or other serious loss, people may make such statements as "This can't be happening to me" or "This can't be true."
- ***Anger.*** In the anger stage, the person resists the loss. The anger is often directed toward family and healthcare providers.
- ***Bargaining.*** The bargaining stage serves as an attempt to postpone the reality of the loss. The person makes a secret bargain with God, expressing a willingness to do anything to postpone the loss or change the prognosis.
- ***Depression.*** The person enters a stage of depression as the full impact of the actual or perceived loss is realized. The person prepares for the impending loss by working through the struggle of separation. While grieving over "what cannot be," the person may either talk freely about the loss or withdraw from others.
- ***Acceptance.*** The person begins to come to terms with the loss and resumes activities with hopefulness for the future. Some dying people reach a stage of acceptance in which they may appear to be almost devoid of emotion. The struggle is past, and the emotional pain is gone.

FACTORS AFFECTING RESPONSES TO LOSS

A variety of factors affect an individual's responses to loss. These include age, social support, families, culture and spiritual practices, and rituals of mourning.

Age

The understanding of and reaction to loss is influenced by the age of the person experiencing the loss. In general, as people experience life transitions, their ability to understand and accept the losses associated with the transitions increases. From the age of 3 years, the development of the concept of death as a loss proceeds rapidly. Table 5–2 outlines the development of the concept of death throughout the life span.

Social Support

Grieving is painful and lonely. An individual's social support system is significant because of its potentially positive influence on the successful resolution of grief. Some losses may lead to social isolation, placing affected people at high risk for dysfunctional grief reactions. For example, partners of people who die with AIDS often report feeling excluded by the deceased person's family and by healthcare providers. Characteristic factors that can interfere with successful grieving include the following:

- Perceived inability to share the loss
- Lack of social recognition of the loss

TABLE 5–2 Development of the Concept of Death

Age	Beliefs/Attitudes about Death
3	Fears separation; lacks comprehension of permanent separation.
4–5	Believes death is like sleeping and is reversible. Expresses curiosity about what happens to the body.
6–10	Understands finality of death. Views own death as avoidable. Associates death with violence. Believes wishes can be responsible for death.
11–12	Reflects views of death expressed by parents. Expresses interest in afterlife as an understanding of mortality develops. Recognizes death as irreversible and inevitable.
13–21	Usually has a religious and philosophic view of death but seldom thinks about it. Views own death as distant or a challenge, acting out defiance through reckless behavior. Previously held developmental awareness of death may still be present.
22–45	Does not think about death unless confronted with it. Emotionally distances self from death. Attitude toward death influenced by religious and cultural beliefs.
46–65	Experiences the death of parents or friends. Accepts own mortality. Experiences waves of death anxiety. Puts life in order to prepare for death and decrease anxiety.
66 and older	Fears lingering, incapacitating illness. Views death as inevitable but from a philosophical viewpoint, that is, as freedom from pain and illness or as a spiritual reunion with deceased friends and loved ones.

- Ambivalent relationships prior to the loss
- Traumatic circumstances of the loss.

A move, a divorce, or even the death of a pet can cause an individual to feel extremely isolated, yet the person experiencing these types of loss does not ordinarily receive the same social support offered to the person mourning the death of a loved one. A woman having an abortion or giving up a child for adoption seldom receives the same social support as the mother of a child who died at birth. It is therefore especially important for nurses not to place a value on any patient's loss when assessing the need for support.

The painful nature of grief can cause the patient to withdraw from a previously established social support system, thereby increasing the feelings of loneliness caused by the loss. A recently widowed woman, for example, may refuse invitations involving married couples with whom she had socialized while her husband was alive, even though her needs for social interaction remain similar to those established before the loss.

Families

A well-functioning family usually rallies after the initial shock and disbelief and provides support for each other during all phases of the grieving process. After a loss, the functional family is able to shift roles, levels of responsibility, and ways of communicating. See the Moving Evidence into Action box for research about how nurses can support and facilitate family presence during the active dying phase, at the time of death, and immediately following the patient's death.

The patient and family members are considered the unit of care when providing end-of-life care in any setting. Care that addresses the needs of both patient and family is complex. The family may have negative as well as positive effects on the patient. For example, the dying patient may request that someone the family perceives as an outsider be near, and the family may respond with anger to the perceived intrusion. Similarly, certain family members may express hurt feelings or anger if the patient is unresponsive to other family members. Well-meaning family members also may try to shield the patient from the pain of grieving. It is rare for the family and the patient to experience anger, denial, and acceptance in unison. While one member is in denial, another may be angry because "not enough is being done."

Culture and Spiritual Practices

The influence of culture and ethnic identity on communication, family values, and beliefs about and practices related to illness and death are important considerations when providing nursing care. There are countless ethnocultural and religious differences in the way people observe dying, death, and mourning. For example, differences in the way death is expressed in the United States include "passed away," "died peacefully," "departed this life," "went home to be with God," and "passed from this life." Objects such as masks, statues, and candles may be expressions of death and death rituals. Examples of religious traditions in mourning and end-of-life rituals (Spector, 2013) include the following:

- ***Catholicism:*** An obligation to take ordinary, not extraordinary, measures to prolong life. Autopsy and organ donation are acceptable.
- ***Buddhist:*** Euthanasia is seen as unnecessary because medication and spiritual contentment will alleviate suffering. Healthcare providers and family members may be prohibited from touching the deceased's body for 3 to 8 hours after death because Buddhists believe the spirit may linger on for some time after death. Autopsy and organ donation are permitted. Cremation is common.
- ***Hinduism:*** Thread may be tied around the wrist to signify a blessing and should not be removed. Autopsy and organ donation are acceptable. Cremation is common and ashes may be disposed of in holy rivers.
- ***Islam:*** Euthanasia is prohibited. Medical help to prolong life is not sought. The body is washed only by Muslims of the same gender.
- ***Judaism:*** The body is ritually washed and burial is as soon as possible. There is a 7-day mourning period. Neither autopsy nor organ donation is acceptable.
- ***Protestantism:*** Prolonging of life may have restrictions. Organ donation, autopsy, burial, and cremation are individual decisions.

Spiritual Beliefs

Patients who are dying often ask questions of themselves and others as to what their life has meant, why this illness has affected them, and what will happen to them when they die. They may feel abandoned by God, or worry that their behavior caused the illness resulting in death. These questions and concerns lead to spiritual distress, which if

unresolved may lead to hopelessness, anxiety, and depression. When spiritual distress is resolved, the patient can die more peacefully.

The principles, values, personal philosophy, and meaning of life by which the patient has pursued goals and self-actualization may be called into question when the patient responds to an actual or perceived loss. Because of a fear of intruding on the personal spiritual beliefs and practices of the patient, the nurse often feels uncertain about implementing interventions that would be helpful to the patient responding to a loss. The following questions (using the mnemonic device FICA) may be used to assess a patient's spiritual or religious practices (American Association of Colleges of Nursing [AACN], 2013):

- ***Faith:*** What is your faith or belief? Do you consider yourself a spiritual or a religious person? Does religious faith or spirituality play an important part in your life? What do you believe gives your life meaning?
- ***Influence:*** How does your religious faith or spirituality influence your thoughts about health? How does it affect the way that you take care of yourself?
- ***Community:*** Do you consider yourself part of a spiritual or religious community or congregation? How is that community or congregation a source of support for you?
- ***Address:*** Do you have any special religious or spiritual issues or concerns that you would like me to address with you? Is there someone else you would like to speak to about these matters?

It is often difficult for patients with an incurable illness to maintain hope and a sense that their lives have had meaning. To meet spiritual needs, nurses can help patients accept the uncertainty that comes with their illness and future death, and respect the spiritual beliefs and practices of patients and their families. Patients who are religious need opportunities for prayer, devotions, and religious rituals. Other resources for spirituality include meditation, guided imagery, music, and art. Privacy and space for these activities should be provided without question.

Rituals of Mourning

Through participation in religious ceremonies such as baptism, confirmation, and bat or bar mitzvah, people joyously celebrate progression to a new stage of life and loss of a former way of being. The funeral ceremony serves many of the same purposes in meeting the needs of the bereaved as people gather to share loss. Through the ceremony, people symbolically express triumph over death and deny the fear of death. Culture is the primary factor that dictates the rituals of mourning. See the accompanying Focus on

Moving Evidence into Action

End-of-Life Care: Supporting Families

While the number of deaths occurring in non-acute care settings is increasing, sixty percent of all deaths occur in hospitals (Freeman, 2013). Nurses are the healthcare professionals who spend the most time directly caring for patients and working closely with families of dying patients in acute care settings. Palliative care has emerged as the predominant model of end-of-life (EOL) care, and staff nurses are responsible for providing holistic care of dying patients while supporting the family during this difficult time.

Family presence is an essential aspect of facilitating quality EOL care, yet the hospital environment can create barriers to ensuring that dying patients and their families have access to quality time together throughout the dying process. Often, family members are not adequately prepared to effectively manage the multiple stressors associated with being present with a dying loved one. Williams and associates (2012) conducted a study to identify EOL nursing actions identified by next-of-kin who had a veteran family member who died in an acute care setting. Through in-depth interviews, family participants ". . . described how nurses encouraged, supported and guided family members, enabling them to be present and to function adaptively before, during and after the loved one's death" (p. 545). The actions identified as supportive nursing interventions by the dying patients' next-of-kin were (1) keeping the family informed (ensuring family were appraised of changes in patient status), (2) providing reassuring attentiveness (assessing family response to the EOL situation, including the family in care, and advocating for family preferences about care), (3) being a compassionate presence (providing the dying patient's next-of-kin with physical comfort and emotional and spiritual support), (4) facilitating final acts (supporting final presence, last good-byes, and private time after death), and (5) honoring patient dignity (caring for the deceased's body in a thoughtful and dignified way).

Implications for Nursing

Although this study focused on veteran patients who died while hospitalized, the findings are applicable to nurses providing EOL care for patients representing other populations and receiving care in other healthcare settings. The findings from this study affirm the importance of holistic and patient-centered care that incorporates the physical, emotional, and spiritual needs of dying patients and their families. For many families, the study found the nursing staff was the face of the hospital, and the quality of EOL was evaluated by nursing actions. This study supports the importance of family presence throughout the dying process and the impact of nursing actions associated with supporting quality EOL care. Nurses must develop the skilled know-how of providing physical care and demonstrate expertise associated with facilitating patient comfort, while providing emotional and spiritual support. Nurses must also know how to help family members learn how to be present at the patient's side during the dying process. Nurses can provide emotional support by being available to provide information and guidance to families throughout EOL care. Providing postmortem care that honors the patient and is thoughtful is perceived as promoting the patient's dignity. Caring for the family of a dying patient is a crucial nursing role in EOL care.

Moving Knowledge into Action

1. The son of a patient who is dying of advanced lung cancer says, "I am uncomfortable sitting in the room with him. I don't know what to do or say." How would you respond?
2. The daughter of an 83-year-old woman who has had three major strokes and also has Alzheimer's disease wants to help with her mother's bath. How will you instruct the nursing assistant who is assigned to bathe the patient?
3. The wife of a man dying of kidney failure says, "I just can't leave him. I need to go home and take care of the dog and I don't have anyone to call who can do it for me." What possible solutions would you explore with her?

Source: Data from Williams, B. R., Lewis, D. R., Burgio, K. L., & Goode, P. (2012). Wrapped in their arms: Next-of-kin's perceptions of how hospital nursing staff support family presence before, during and after the death of a loved one. *Journal of Hospice and Palliative Nursing, 14*(8), 541–551.

Cultural Diversity feature, which provides examples of values and rituals for death in selected groups of people.

Nurses' Response to Patients' Loss

Nurses care for patients and families at various stages of the grief process and may feel that crisis situations are not the time for self-reflection. However, because the nurse's conscious or unconscious reactions to the patient's responses to the loss will influence the outcome of any intervention, nurses need to take time to analyze their own feelings and values related to loss and the expression of grief. The nurse can promote self-awareness by reflecting on the following questions:

- What are my personal feelings about how grief should be expressed?
- Am I making judgments about the meaning of this loss to the patient?
- Are unresolved losses in my own life preventing me from relating therapeutically to the patient?

The following Internet resources may be useful in helping nurses provide care to dying patients:

- AARP Grief and Loss Program
- City of Hope Pain and Palliative Care Resource Center
- Dying Well
- Hospice Foundation of America
- National Hospice and Palliative Care Organization
- GriefNet
- Physician Orders for Life-Sustaining Treatment

END-OF-LIFE CARE

The term **end of life** refers to the final weeks of life when death is imminent. End-of-life nursing care that ensures a peaceful death was mandated by the International Council of Nurses in 1997 and further supported by the AACN in 1999. Following are selected competencies necessary for nurses to provide high-quality end-of-life care as defined by the AACN (2013):

- Promote the provision of comfort care to the dying as an active, desirable, and important skill, and an integral component of nursing care (Figure 5–1 ■).

Figure 5–1 ■ The patient can visualize the hospital room as a more safe and comfortable place to die when surrounded by familiar pictures and objects.

FOCUS ON CULTURAL DIVERSITY

Cultural Aspects of Terminal Illness Care

Culture/Ethnicity	Nursing Considerations
Native American	Some tribes prefer not to openly discuss terminal prognosis and do-not-resuscitate (DNR) decisions, because negative thoughts may make inevitable loss occur sooner. Suggest a family meeting to discuss care and end-of-life issues. If the family feels comfortable, all members of the family and close friends may remain 24 hours a day (eating, joking, and singing). Mourning is done in private, away from the dying person. After death, the family may hug, touch, sing, and stay close to the deceased.
Black/African American	Suggest that the family have a family meeting or talk with a minister or family elder. Patients may decide to have an older family member disclose a poor prognosis. Care for the dying family member is often done at home until death is imminent.
Chinese American	Ensure the head of the family is present when terminal illness is discussed. The patient may not want to discuss approaching death. Special amulets or cloths may be brought from home. Family members may prefer to bathe the body after death.
Iranian	Information about a terminal illness should be presented by a trusted member of the healthcare team to the family and never to the patient when he or she is alone. Most Iranians believe in *tagdir* (will of God) in life and death as a predestined journey. DNR decisions are often made by the family. When death occurs, notify the head of the family first. The family may want to bathe the body.
Mexican American	Based on the belief that worry may make health worse, the family may want to protect the patient from the seriousness of the illness. The information is often handled by an older daughter or son. Extended family members are obligated to pay respects to the sick and dying, although pregnant women do not care for dying persons or attend funerals. The family may prefer the patient die at home. Prayers, amulets, and rosary beads are used, and the priest should be notified. Death is seen as an important spiritual event. The family may spend time with and bathe the body.
Vietnamese	Consult head of family before telling patient about a terminal illness. The entire family will make DNR decision, often with assistance from a priest or monk. Patients often prefer to die at home. Family should have extra time with the body, and may cry loudly and uncontrollably. Spiritual/religious rites are often conducted in the room.

Source: Spector, R. E. (2013). *Cultural diversity in health & illness* (8th ed.). Upper Saddle River, NJ: Prentice Hall Health.

- Communicate effectively and compassionately with the patient, family, and healthcare team members about end-of-life issues.
- Recognize one's own attitudes, feelings, values, and expectations about death and the individual, cultural, and spiritual diversity existing in those beliefs and customs.
- Demonstrate respect for the patient's views and wishes during end-of-life care.
- Use scientifically based standardized tools to assess manifestations (e.g., pain, dyspnea [breathlessness], constipation, anxiety, fatigue, nausea/vomiting, and altered cognition) experienced by patients at the end of life.
- Use data from assessment to plan and intervene in symptom management using state-of-the-art traditional and complementary approaches.
- Evaluate the impact of traditional, complementary, and technologic therapies on patient-centered outcomes.
- Assess and treat multiple dimensions, including physical, psychologic, social, and spiritual needs, to improve quality at the end of life.
- Assist the patient, family, colleagues, and one's self to cope with suffering, grief, loss, and bereavement in end-of-life care.
- Demonstrate skill at implementing a plan for improved end-of-life care within a dynamic and complex healthcare delivery system.

Nurses care for the dying patient in critical care units, emergency departments, hospital units, long-term care facilities, and the home. Regardless of the setting, the patient's wishes about death should be respected. The Dying Person's Bill of Rights states that each person has "the right to be cared for by caring, sensitive, knowledgeable people who will attempt to understand my needs and will be able to gain some satisfaction in helping me face my death" (Barbus, 1975).

Legal and Ethical Issues

Issues such as those involved in advance directives and living wills, euthanasia, and quality of life are especially important to nurses in upholding the specific care requests of their patients.

ADVANCE DIRECTIVES

Advance directives are legal documents that allow an individual to plan for healthcare and/or financial affairs in the event of incapacity. They include living wills, healthcare surrogates, durable powers of attorney, and physician orders.

FAST FACTS

Types of Advance Directives

- **Living will**: A document that provides written directions about life-prolonging procedures to provide instructions when an individual can no longer communicate in a life-threatening situation.
- **Healthcare surrogate**: An individual selected to make medical decisions when an individual is no longer able to make them for him- or herself.
- **Durable power of attorney**: A document that can delegate the authority to make health, financial, and/or legal decisions on an individual's behalf. It must be in writing and must state that the designated person is authorized to make healthcare decisions.
- **Physician orders for life-sustaining treatment (POLST)**: A form for patients with serious, progressive, chronic illnesses that translates their wishes regarding life-sustaining treatment into actionable medical orders.

A living will is a legal document that formally expresses an individual's wishes regarding life-sustaining treatment in the event of terminal illness or permanent unconsciousness. It is not a type of durable power of attorney and usually does not designate a substitute decision maker. It is the responsibility of the nurse as an advocate to request and record the patient's preference for care and include it in the plan of care. The nurse's documentation helps communicate these preferences to the other members of the healthcare team.

Facilities that receive Medicare and Medicaid funds are required to provide all patients with written information and counseling about advance directives and the institution's policies governing them. The specific terms of this requirement are found in the Patient Self-Determination Act (PSDA). A copy of the signed advance directive must be kept in the patient's medical record, but patients do not have to sign it in order to be treated. Nurses are the healthcare providers in close contact with patients, so they often support patients and families with unresolved feelings about the moral, ethical, and legal aspects of their actions. Although advance directives do not ease the pain of seeing patients die, they do help facilitate patient-centered care by providing guidance so nurses can implement patient preferences for EOL care.

DO-NOT-RESUSCITATE ORDERS

A **do-not-resuscitate order (DNR)**, or no-code, is written by the physician for the patient who has a terminal illness or is near death. This order is based on the wishes of the patient and family that no cardiopulmonary resuscitation be performed for respiratory or cardiac arrest. A "comfort measures only" order indicates that no further life-sustaining interventions are necessary and that the goal of care is a comfortable, dignified death. Agency protocols should be established defining comfort care for consistency in nursing care. Confusing or conflicting DNR orders create dilemmas because nurses are involved in resuscitation and either begin CPR or ensure that unwanted attempts do not occur. The American Nurses Association (ANA) (2012) recommends that the DNR order should be directed by what the informed patient wants or wanted. The ANA further recommends that guidelines and policies be developed to help resolve conflicts between patients and their families, between patients and healthcare professionals, and among healthcare professionals.

EUTHANASIA, ASSISTED SUICIDE, AND AID IN DYING

Euthanasia (from the Greek for "painless," "easy," "gentle," or "good death") is now commonly used to signify ending a life, prompted by some humanitarian motive. Many arguments are made for and against euthanasia, and nurses have often found themselves at the center of the debate. The ANA position statement titled *Euthanasia, Assisted Suicide, and Aid in Dying* (2013) opposes nurse participation in euthanasia and emphasizes the obligation of the nurse to provide compassionate EOL care aimed at promoting comfort, alleviating suffering, providing adequate pain control, and at times forgoing the provision of life-sustaining treatment. Additionally, nurses have pushed for the development of appropriate guidelines and procedures for DNR orders. When no such orders exist, the nurse faces a dilemma. Certainly, there are situations in which the nurse's role is clear. For example, it is considered malpractice to participate in slow codes (in which the nurse does not hurry to alert the emergency team when a terminally ill patient who does not have a DNR order stops breathing).

In **assisted suicide**, the means to end the patient's life is provided to the patient with knowledge of the patient's intention. In assisted suicide someone makes the means of death accessible but does not act as the direct agent of death. **Aid in dying** is an end-of-life care option in which mentally competent, terminally ill adults can ask their physician to provide a prescription for medication that the patient can self-administer to end life peacefully (ANA, 2013). Nurses should be aware of state laws governing this practice and be familiar with the laws and professional position statements regarding this practice in the state in which they are licensed. Because care settings offer many complex and technologic interventions, it is not likely that the ethical aspects of euthanasia, assisted suicide, and aid in dying will soon be resolved. However, advance directives do give patients a much more active role in decisions about their own care.

Settings and Services for End-of-Life Care

Settings and services for end-of-life care range from the critical care unit in a hospital to the patient's own home. Two methods of providing end-of-life care—hospice and palliative care—are described in this section.

HOSPICE

Hospice is a philosophy of care rather than a program of care. It is comprehensive and coordinated care for patients with limited life expectancy that reaffirms the right of every patient and family to fully participate in the final stages of life. Provided by hospice agency nurses and other members of a healthcare team (including social workers, clergy, home health aides, and volunteers), it is based on a philosophy of death with comfort and dignity, encompassing biomedical, psychosocial, and spiritual aspects of the dying experience. Although most hospice care is provided in the home, it may also be provided in hospitals, long-term care facilities, or other community-based settings.

There are more than 5300 hospice agencies in the United States, with services and care reimbursed by private insurance or a Medicare hospice benefit (National Hospice and Palliative Care Organization, 2012). Services are reimbursed by Medicare for an initial 90-day period, followed by a subsequent 90-day period, and an unlimited number of 60-day periods as long as the patient continues to meet eligibility requirements. The average length of service is 83 days (Hospice Association of America, 2010). Hospice services usually begin when the patient has 6 months or less to live and ends with the family 1 year after the death of the patient. This continuation of care for the family is called bereavement care (**bereavement** is the time of mourning experienced after a loss).

To be eligible for hospice benefits from Medicare or Medicaid, the patient must have a serious, progressive illness with a limited life expectancy. In most cases, a family (or other) caregiver must be continuously in the home with the patient. The patient must have Medicare, waive traditional Medicare benefits for the terminal illness, have physician certification of a terminal illness with a life expectancy of 6 months or less, and care must be provided by a Medicare-certified hospice agency or program. Hospice care under Medicare includes home care, inpatient care when needed, and a variety of services not otherwise covered by Medicare (U.S. Department of Health & Human Services, 2013). The focus is on care, not cure.

PALLIATIVE CARE

Palliative care is an area of care that has evolved out of the hospice experience, but exists outside of hospice programs, is not restricted to the end of life, and is used earlier in the disease experience. The World Health Organization defines palliative care as "an approach that improves the quality of life of patients and their families facing the problem associated with life-threatening illness, through the prevention and relief of suffering by means of early identification and impeccable assessment and treatment of pain and other problems, physical, psychosocial and spiritual" (WHO, 2012). Palliative care can be used in all types of healthcare settings and is focused on the relief of physical, mental, and spiritual distress for individuals who have an incurable illness. The goal of palliative care is to prevent and relieve suffering by early assessment and treatment of pain and other physical, psychosocial, and spiritual needs to improve the patient's quality of life.

It has evolved into a specialized medical field and aims to relieve symptoms such as pain, nausea, respiratory distress, anxiety, agitation, delirium, and stress. The palliative care team provides symptom management related to serious chronic illness such as cancer, chronic obstructive pulmonary disease, congestive heart failure, kidney failure, Alzheimer's disease, and dementia.

Although palliative care may be provided by a single person, it usually involves the combined efforts of an interprofessional team, including physicians, nurses, social workers, chaplains, home health aides, and volunteers. Care is provided at any stage of serious illness and the plan of care is continuous, following the patient between settings. Palliative care is the focus of end-of-life care. The expected outcomes of care are directed by interventions to manage current manifestations of the illness and to prevent new manifestations from occurring.

Physiologic Changes in the Dying Patient

Death is a highly individualized process, and may occur rapidly or slowly. Physiologic changes are a part of the dying process. These changes result in any or all of the manifestations listed in the accompanying box as death nears. Although each person responds differently, certain manifestations are common in the dying process, regardless of the trauma or disease process that is causing death. The discussion that follows includes treatments and related nursing care.

MANIFESTATIONS OF IMPENDING DEATH

- Difficulty talking or swallowing
- Nausea, flatus, abdominal distention
- Urinary and/or bowel incontinence, constipation
- Decreased sensation, taste, and smell
- Weak, slow, and/or irregular pulse
- Decreasing blood pressure
- Decreased, irregular, or Cheyne-Stokes respirations
- Changes in level of consciousness
- Restlessness, agitation
- Coolness, mottling, and cyanosis of the extremities

BOX 5–2 Providing Comfort for the Patient Nearing Death

- Maintain clean skin and bed linens.
- Use a draw sheet to turn the patient as often as possible so the patient is comfortable.
- Position the patient to promote comfort and protect bony areas with padding. Reposition the patient and raise the head of the bed if fluids accumulate in the upper airways and back of the throat.
- Use bed pads or insert a Foley catheter (if ordered) for urinary incontinence.
- Use gentle massage to improve circulation and shift edema.
- Provide small, frequent sips of fluids, ice chips, or Popsicles.
- Provide oral care, using a soft moist brush.
- Clean secretions from the eyes and nose.
- Administer ordered pain medications as needed to maintain comfort.
- Administer oxygen as prescribed to relieve dyspnea.

PAIN

Pain is a common problem for patients at the end of life, and what people often say they fear the most. Pain, a subjective experience, is influenced by the patient's emotions, previous experiences with pain, and family and culture. Unfortunately, pain is sometimes undertreated at the end of life because patients, families, physicians, and nurses fear that the high doses of opioids necessary to control pain will cause addiction or other harm. However, nearly all pain at the end of life can be managed without causing addiction or hastening death through respiratory depression. There is no maximum allowable dose for full agonist opioids such as morphine sulfate; the dose should be increased to whatever is necessary to relieve pain. Meperidine (Demerol) is not useful for chronic pain because it has a short half-life and a toxic metabolite that can cause irritability and seizures (Papadakis et al., 2013). It is of utmost importance to keep the patient comfortable by providing general comfort measures (Box 5–2) and by administering ordered medications for pain, neuropathic pain (which is rarely relieved by opioids), seizures, and/or anxiety. The pathophysiology, treatment, and nursing care of patients experiencing pain are fully described in the chapter titled Nursing Care of Patients in Pain.

DYSPNEA

Respiratory changes, including dyspnea, are normal as death nears. Dyspnea is a subjective experience, and the patient often reports having a feeling of suffocation, shortness of breath, or tightness in the chest. Up to 50% of dying patients have severe dyspnea, especially those with lung tumors (primary or metastatic), restrictive lung disease, or pleural effusion (Papadakis et al., 2013). Regardless of the terminal illness or fatal injury, the final cause of death is a lack of oxygen to the brain.

Morphine is the medication of choice for palliative treatment of dyspnea. It may be necessary to gently instruct the family that the patient is dying and will stop breathing as a result of the disease, not the morphine.

As death nears, respirations often become fast or slow, shallow, and labored. The patient may have apnea or Cheyne-Stokes respirations (regular periods of deep, rapid breathing followed by no breaths for 5 to 30 seconds). Fluid may accumulate in the lungs, causing crackles, especially in patients who are well hydrated, and in those who are having difficulty swallowing or coughing. These sounds are not painful for the patient, but they may be treated with oxygen, opioids (to improve respirations and decrease anxiety), and medications to decrease secretions (atropine, scopolamine, hyoscyamine, or glycopyrrolate). Note that oxygen and suctioning are only temporary measures, and (especially with suctioning) may even be traumatic for the patient. Nursing care to improve respirations include keeping the head of the bed elevated. Keeping the room cool and providing a breeze from a fan often makes the patient more comfortable.

ANOREXIA, NAUSEA, AND DEHYDRATION

Although anorexia and a decrease in food and fluid intake are normal in the dying patient, the family often views this as giving up. Anorexia may be a protective mechanism; the breakdown of body fats results in ketosis, which leads to a sense of well-being and helps decrease pain. Parenteral or enteral feedings do not improve manifestations or prolong life and may actually cause discomfort. As weakness and difficulty swallowing progress, the gag reflex is decreased and patients are at increased risk for aspiration if oral foods are given.

Nausea, with or without vomiting, is a common problem in dying patients. Nausea and vomiting may be caused by reduced gastric emptying, constipation (a side effect of morphine), bowel obstruction, uremia, or hypercalcemia. If the patient is conscious and complains of nausea, antiemetics such as prochlorperazine (Compazine) or ondansetron (Zofran) should be administered.

Dehydration is less of a problem than overhydration. Forcing fluids or initiating intravenous fluids for hydration may in turn increase fluid in the lungs, peripheral edema, ascites, and vomiting. Dehydration in the patient nearing death primarily causes discomfort from dry mouth and thirst. The patient should be given small sips of water, or an atomizer can be used to spray the inside of the mouth. Oral care should be given at least every 2 hours, and more often if the patient is breathing through his or her mouth.

ALTERED LEVELS OF CONSCIOUSNESS

Neurologic dysfunction results from any or all of the following: decreased cerebral perfusion, hypoxemia, metabolic acidosis, sepsis, an accumulation of toxins from liver and renal failure, the effects of medications, and disease-related factors. These changes may result in decreased level of consciousness, restlessness, or delirium. Patients with terminal **delirium** may be confused, restless, or agitated. Moaning, groaning, and grimacing often accompany the agitation and may be misinterpreted as pain. Level of consciousness often decreases to the point where the patient cannot be aroused. Terminal or agitated delirium can result from a variety of causes including pain, bladder distention and stool impaction, or unfinished business with family members. Although decreased consciousness and agitation are both normal states at the end of life, they are very distressing to the patient's family.

Several tools can be used to assess the underlying cause of delirium. These include the Mini-Mental State Examination, Delirium Observation Scale, Memorial Delirium Assessment Scale, and the Bedside Confusion Scale. Careful assessment will aid in identifying the underlying cause of terminal delirium, which will help determine patient-centered nursing actions (Close & Long, 2012).

Medications for treating terminal delirium include low doses of neuroleptics, tranquilizers, or antianxiety medications. A patient near death often has altered cerebral function, so the nurse must stand near the bedside and speak clearly. Hearing is thought to be the last sense a dying patient loses; the nurse should never whisper or engage in conversation with the family as if the patient were not there. Nursing care for the comatose patient includes the following:

- Using artificial tears if the patient does not blink
- Keeping lights at a low level
- Keeping skin clean and dry
- Covering the patient only with a light blanket
- Using adult incontinence pads or pants for incontinence
- Turning every 2 hours and maintaining joints in positions of comfort.

HYPOTENSION

As death nears, the cardiac output decreases, as does intravascular blood volume. As a result, blood pressure gradually decreases and the pulse is often rapid and irregular. The extremities are cooler, and cyanosis is present in nail beds, skin, and lips. The skin on the legs and in dependent areas may become mottled in color. Renal perfusion decreases and the kidneys cease to function. Urinary output is scanty. The patient will have tachycardia, hypotension, cool extremities, and cyanosis with skin mottling.

Support for the Patient and Family

As the patient's condition deteriorates, the nurse's knowledge of the patient and family guides the care provided. It may be necessary to provide opportunities for patients to express personal preferences about where they want to die and about funeral and burial arrangements. If the family feels that this is morbid, the nurse explains that it helps patients to keep a sense of control as they approach death.

The patient needs the opportunity to say good-bye to others. The nurse encourages and supports the patient and family as they terminate relationships as a necessary part of the grief process. The nurse acknowledges that termination is painful and, if the patient or family desires, stays with them during this time. Family members are often afraid to be present at the moment of death, yet dying alone is the greatest fear expressed by patients.

Death

The manifestations listed in the accompanying box are seen after death occurs, and are the basis for pronouncing death. They appear gradually and not in any special order. To confirm death, a physician or other healthcare provider is legally required to pronounce death. The time of death, with any related data, is documented in the patient's chart.

The nurse may also fear being present at the moment of the patient's death. In fact, Kübler-Ross (1969) noted that the nurse's fear of death frequently interferes with the ability to provide support for the dying patient and family. Thoughts such as "Please, God, don't let him die on my shift" are common, and they express the nurse's emotional turmoil in dealing with the task. Nurses who have worked through their own feelings about death and dying are more at ease in assisting the dying patient toward a peaceful death.

MANIFESTATIONS OF DEATH

- Absence of respirations, pulse, and heartbeat
- Fixed and dilated pupils; eyes may stay open
- Release of stool and urine
- Waxen color (pallor) as blood settles to dependent areas
- Body temperature drops
- Lack of reflexes
- Flat encephalogram

After the death, the family is encouraged to acknowledge the pain of loss. The nurse's presence and support as the bereaved express their sorrow, anger, or guilt can help them resolve their grief. It is important for the bereaved not to suppress the pain of grieving with drugs. By accepting variations in the expression of grief, the nurse supports the family's grief reactions.

Resolution of grief begins with acceptance of the loss. The nurse can encourage this acceptance by maintaining open, honest dialogue and by providing the family with the opportunity to view, touch, hold, and kiss the person's body. As family members realize the finality of the death, they are often comforted by the presence of the nurse who cared for the patient during the final days.

POSTMORTEM CARE

The nurse documents the time of death (required for the death certificate and all official records), notifies the physician, and assists the family (if needed) in choice of a funeral home. If the patient dies at home, death must be pronounced before the body is removed. In some states and in some situations, nurses can pronounce death; for specifics, consult state practice acts, laws, and agency policy. All jewelry is removed and given to the family unless the request is made that it be left on. The body is kept in place until the family is ready and gives permission for it to be moved. If an autopsy is required or requested, the body must be left undisturbed (e.g., do not remove any tubes) for transportation to the medical examiner.

Documentation of the death is completed by sending a completed death certificate to the funeral home (for a death in the home), or by completing the required paperwork and sending the body to the morgue or funeral home (for a death in the hospital or long-term care setting).

SELF-CARE

Caring for dying patients and their families can be very stressful for the nurse. The nurse who has developed a close relationship with a patient who has died may experience strong feelings of grief. Crying with families, at one time considered unprofessional, is now recognized as an expression of empathy and caring. Sharing grief with the family after the death of a loved one helps both the nurse and family to cope with their feelings about the loss. Taking time to grieve after the death of a patient provides a release that can help prevent "blunting" of feelings, a problem often experienced by nurses who care for patients who are terminally ill. Debriefing with peers, communicating feelings, and identifying strategies that promote personal emotional health should become part of the nurse's self-care practices.

Nurses working with critically or terminally ill patients should be aware that witnessing a patient's death and the family's grief may

reactivate feelings about some unresolved grief in their own lives. In these cases, nurses may need to reflect on their responses to their own losses. Also, nurses who work with dying patients need support from peers and other professionals to work through the often overwhelming feelings that result from dealing with death, grief, and loss.

●○● INTERPROFESSIONAL CARE

Interventions for loss and grief may be planned and implemented by any or all members of the healthcare team. Nurses and social workers provide interventions to help patients or families adapt to a loss. They also make referrals to mental health professionals (grief counselors, social services), support groups, chaplains, and legal or financial assistance agencies.

Grieving patients frequently enter the healthcare system with significant somatic symptoms. In some cases, the symptoms of grief and loss are overlooked until the patient reaches a crisis state requiring psychiatric medical intervention. Collaborative care by the physician and the nurse early in the normal grieving process can help the patient achieve an early and effective resolution of grief and avoid physical or psychiatric health problems.

●○● NURSING CARE

Nurses practicing in all types of settings care for patients who are in various stages of the grieving process. Grief is highly individual. The grief process may range from uncomfortable to debilitating, and it may last for a day or a lifetime, depending on what the loss means to the person experiencing it. A case study and care plan for a patient who is grieving is included at the end of this section.

Health Promotion

In planning and implementing nursing care for the patient experiencing a loss, the nurse considers the individual responses, which may vary greatly. In an era of short acute care stays for patients, nurses may feel that an elaborate grief assessment is impossible or, at the least, impractical. But research and clinical experience suggest that patients who delay the grieving process after a loss are prone to have health problems that may last a lifetime. See the accompanying box for an end-of-life checklist for older adults.

Assessment

Knowledge of the expected physical reactions to loss provides the nurse with a basis for identifying reactions requiring further assessment. To assess the extent of physical distress, the nurse observes for changes in sensory processes and asks questions about the patient's sleeping and eating patterns, activities of daily living, general health status, and pain.

Physical Assessment

People who experience a loss may experience one or more predictable somatic (physical) symptoms. Gastrointestinal manifestations such as indigestion, nausea or vomiting, anorexia, weight gain or loss, constipation, or diarrhea occur frequently. The shock and disbelief that accompany a loss may cause shortness of breath, a choking sensation, hyperventilation, or weakness. Some people also report insomnia, preoccupation with sleep, fatigue, and decreased or increased activity level.

Crying and sadness are observed during normal grief states. Crying may make the individual feel exhausted and interfere with carrying out activities of daily living. However, an individual who is unable to cry may have difficulty completing the mourning process. If the person does not express feelings of grief, somatic symptoms may increase.

Reactions to loss are not always obvious. For example, in patients who experience an illness following a serious loss, assessment may reveal somatic complaints related to the grief state as well as the illness. When an individual who has been healthy begins to develop patterns of increased illness, the nurse should be aware that this may signal dysfunctional grieving. This is especially common in the loss and grieving associated with a change in body image. In addition to making a physical assessment, assess the patient's perception of the alteration in body image. The loss of a body part, weight gain or loss, and scars from surgery or trauma can be difficult for a patient to accept. Some patients may grieve hair loss that accompanies chemotherapy used in cancer treatment.

It is imperative for the dying patient's concerns about pain to be assessed, especially if the patient has cancer or another painful illness. Knowledge of pain theories and pain assessment can help the nurse assess the need for pain medication (see Chapter 9). During the last stages of dying, the patient usually becomes very weak, and sensations and reflexes decrease; these changes call for careful assessment of the patient's physical needs.

Spiritual Assessment

Because spiritual beliefs and practices greatly influence people's reaction to loss, it is important to explore them with the patient when assessing a loss. The spiritually healthy patient has inner resources that help work through the grief process. Faith, prayer, trust in God or a superior being, perception of a purpose in life, or belief in immortality are examples of the inner resources that may sustain the patient during an actual or perceived loss. Patients who had not considered themselves religious before the actual or perceived loss often turn to religion to seek comfort or to cope with feelings of despair, helplessness, hopelessness, or guilt.

Assessing the dying patient's spiritual life and its significance to the patient and family helps identify spiritual support systems. Some nurses are uncomfortable with assessing a patient's spiritual needs; the following questions may be helpful:

- What are the spiritual aspects of the patient's philosophy about life? Death?
- Are the values and beliefs about life and death congruent with those of people who are important to the patient?
- Which spiritual resources and rituals have significance for the patient?

Belief systems that are incompatible with those of family members can be an additional source of stress for patients dealing with a loss. The anger and resentment often observed among families faced with decisions concerning dying members may be avoided if the nurse assesses the potential effect of differing beliefs.

Patients coping with a loss often perceive that it is a punishment from God for their wrongdoing or for their failure to remain faithful to their religious practices. Therefore, it is important to assess the

NURSING CARE OF THE OLDER ADULT

End-of-Life Checklist

- Take time a day or so before appointments with your healthcare provider to think about the questions you need answered and concerns you want to discuss. It is often a good idea to keep a pad of paper and a pen handy so you can write down things as they come to you.
- Do not hesitate to have your doctor explain your diagnosis again if you didn't understand the explanation the first time or if you missed some key points. The same goes for details about using medications and possible side effects.
- You may wish to have a friend or family member go with you to medical appointments.
- When you visit the doctor, take an up-to-date list of all the medications (prescribed and over-the-counter) you are currently taking.
- If you have physical pain, tell your healthcare provider. You will probably be asked to rate your pain on a scale of 1 (no pain) to 10 (severe pain). Your rating helps determine what pain relief measures are appropriate.
- It is a good idea to ask your healthcare provider about hospice services well before you are likely to need them.
- Your family and close friends should be aware of your treatment preferences (such as the existence of a DNR order). You might consider documenting your wishes in a living will.
- Think about asking and appointing someone you trust to make your healthcare decisions in case the moment comes when you can no longer make them yourself.
- If you are feeling depressed or anxious or need emotional support, consider talking to a pastor, chaplain, rabbi, or other trusted person in your faith community. If necessary, ask your healthcare provider to recommend someone to help you sort out your feelings.
- Avoid withdrawing from social activities. Keep communicating with your family, friends, and the people who help care for you. If you are open with them, you are more likely to get the care you need.

level of guilt the patient or family expresses. Assessing the patient's comments regarding feelings of responsibility for the loss helps determine whether these feelings are an expected phase of grieving or indicate dysfunctional grieving.

Psychosocial Assessment

When working through the grief process, patients can be overwhelmed by the fears associated with the loss and the changes it will produce. The patient responding to an actual or perceived loss commonly expresses anxiety (fear of the unknown). An extreme level of anxiety can threaten the patient's well-being. Assessment includes helping patients openly acknowledge their fears. Some patients may fear the feelings they experience while proceeding through the grief process more than the loss itself. The most common fear expressed by patients facing a loss is that of losing self-control.

Talking with dying patients is often difficult. The following suggestions may be helpful:

- When patients initiate conversations about dying, you may feel unprepared for their questions. They can take you by surprise, and may lead you to believe that the patient expects a crystal ball response. Remember that the purpose of all such discussions is to keep the lines of communication open with the patient. The idea is to make the subject of dying discussible, and to communicate to the patient that it does not make you afraid to do so. An open-ended statement such as "Tell me what concerns you the most" provides a means of encouraging communication.
- Some patients may be too fearful to ask physicians such questions. They often approach staff who they perceive as less intimidating or more approachable. The question often comes in the middle of the night, when there are no distractions, when anxiety or pain may keep the patient awake, and when the patient may feel most alone with psycho-spiritual distress. In any case, the nurse may be the person present when questions about dying arise.
- Because of the surprising nature of such questions, you may feel tempted to escape ("I've got to go take that patient's vital signs right now") or pass the buck ("That sounds like a question for your doctor"). Be vigilant about such impulsive behavior and realize that it only serves your own need to reduce your anxiety, but does nothing to assist the patient with his or her anxiety. It is well within the scope of your professional practice as a competent nurse to provide counseling and death education, especially when the patient asks you for it or indicates an unmet need for such information and support. *When in doubt, ask a question in response, such as "Tell me how you feel about that" or "What have you been told already?"* This will accomplish several things. First, it will help you to regain your composure. The second point of asking a question is that it will give you more information about what is on the patient's mind so that your intervention can be as specific and responsive to that patient as possible.
- Do not provide false reassurance. It is important to remember that avoiding discussions about death robs the patient of precious time to accomplish goals that produce hope. Dying people hope for many things even when they cannot hope for a cure, such as hope for freedom from pain, to be surrounded by loved ones, and for the rest of their allotted time to be spent in meaningful pursuits.

Awareness of the altered sensorium observed during the stage of shock and disbelief provides parameters for assessment. The nurse may note in the patient feelings of numbness, unreality, and emotional distance, intense preoccupation with the lost person or object, helplessness, loneliness, and disorganization. As awareness of the loss begins to develop, preoccupation with the lost person or object may increase, and self-accusation and ambivalence toward the lost person or object may follow.

Priorities of Care

- Nursing interventions designed to achieve the optimum level of comfort are the priority in providing quality end-of-life care.
- Managing dyspnea is often a priority of care for terminal patients. A variety of interventions including oxygen, positioning, and administration of opiates and sedatives is common.
- Restlessness and delirium are common for actively dying patients and require aggressive intervention. Determining the cause of terminal delirium so the appropriate intervention can be identified is a nursing care priority.
- Providing time for the patient and family to be together is essential during end-of-life care.
- Providing emotional and spiritual support for patients and families experiencing grief and loss is important. A holistic approach that addresses physical, psychosocial, and spiritual needs of the patient and family is essential.

Diagnoses, Outcomes, and Interventions

A variety of nursing problems and/or diagnoses may be appropriate for the patient experiencing loss and grief, as well as for the patient who is nearing death. Nurses practicing medical-surgical nursing will often provide interventions to alleviate pain and symptoms associated with the end of life and interventions for grieving, chronic sorrow, and death anxiety.

Pain and Symptom Management

The focus of palliative care is to promote comfort by alleviating pain and other symptoms experienced because of terminal illness. Pain is the most common symptom requiring aggressive management and monitoring. In addition to providing adequate pain control, nursing actions involve treating other symptoms such as nausea, dyspnea, and delirium.

Expected Outcome: Pain and other symptoms associated with end of life will be minimized as demonstrated by the patient's verbal description of comfort level or absence of nonverbal expressions and gestures commonly associated with discomfort.

- Systematically assess pain and other symptoms related to serious and terminal illness. *Continuous assessment will facilitate early treatment of pain and other symptoms.*
- Advocate for adequate pain control for the patient including around-the-clock, scheduled, or continuous infusion of opioids. *Around-the-clock dosing provides optimal pain control and does not lead to addiction.*
- Avoid unnecessary procedures, tests, and activities for dying patients. Stop or modify vital signs for dying patients. Stop or reduce tube feedings; turn off monitors and alarms. *Avoiding tests and procedures creates a calm environment and facilitates a peaceful death.*
- Provide time for the patient and family to be together. *Ensuring that the patient and family have the needed time to say good-bye will facilitate effective grieving.*
- Turn and reposition the patient only for comfort. Modify bathing routine or stop per family request. *Limiting interventions that do not promote comfort facilitates a peaceful death.*
- Provide frequent oral care. *Dry oral mucous membranes are a common source of discomfort for dying patients.*
- Explain mottling and cyanosis as part of the dying process to family members. *Family members may think the patient is cold. Explaining what is a normal physiologic response will reassure them that their loved one is being well cared for.*
- Provide temperature comfort measures such as a cool washcloth, warm blanket, or ice packs as appropriate. *Family can provide these simple measures and participating in care may be comforting.*
- Administer supplemental oxygen, provide optimal positioning to promote oxygenation (e.g., semi-Fowler's), and consider use of oral suctioning as appropriate. *Dyspnea is common at end of life and treating these symptoms will promote a peaceful death.*
- Consider obtaining medication orders to treat dyspnea such as morphine, glycopyrrolate, scopolamine patch, Atropine 1% ophthalmic solution, and antianxiety agents. *These medications will reduce secretions.*
- Treat delirium and restlessness aggressively: Maintain a calm environment, minimize bright lights, talk softly to the patient, and use touch and presence. *Creating a calm environment will reduce the patient and family's anxiety.*

Grieving

Grieving is a combination of intellectual and emotional responses and behaviors by which people adjust their self-concept in the face of an actual or potential loss. Grieving may be a response to one's own future death; to loss of body parts or functions; to loss of a significant person, animal, or possession; or to loss of a social role. Nursing interventions are designed to assist with grief resolution.

Expected Outcome: Patient/family will demonstrate successful adaptation to loss using effective and positive coping mechanisms.

- Assess for factors causing or contributing to the grief. Ask about support systems, how many losses have occurred, relationship with the lost person, significance of the body part, and previous experiences with loss and grief. *Grief and mourning occur when an individual experiences any type of loss.*
- Use open-ended questions to encourage the person to share concerns and the possible effect on the family. *Grief resolution cannot occur until the patient acknowledges the loss.*
- Promote a trusting nurse–patient relationship: Allow enough time for communications; speak clearly, simply, and concisely; listen; be honest in responses to questions; do not give unrealistic hope; offer support; and demonstrate respect for the person's age, culture, religion, race, and values. *An effective nurse–patient relationship begins with acceptance of the patient's feelings, attitudes, and values related to the loss. If the patient is ready to talk, listening and being present are the most appropriate interventions.*
- Ask about strengths and weakness in coping with the other losses. *Current responses are influenced by past experiences with loss, illness, and death. Socioeconomic and cultural backgrounds, as well as cultural and spiritual beliefs and values, affect an individual's ability to adapt to loss.*
- Teach the patient and family the stages of grief. *This helps them to be aware of their emotions in each stage and reassures them that their reactions are normal.*
- Provide time for decision making. *In periods of stress, people may need extra time to make informed decisions.*
- Provide information about appropriate resources, including support from family, friends, support groups, community resources, and legal/financial aids. *Support from others decreases feelings of loneliness and isolation and facilitates grief work.*

Chronic Sorrow

Chronic sorrow is a "cyclical, recurring, and potentially progressive pattern of pervasive sadness experienced in response to continual loss, throughout the trajectory of an illness or disability" (NANDA International, 2012, p. 379). It is triggered by situations that bring to mind the person's losses, disappointments, or fears. Chronic sorrow may be experienced by a patient, parent or caregiver, or person with chronic illness or disability.

Expected Outcomes: Patient will identify emotional triggers that lead to intense feelings of grief and loss and describe coping strategies to use that will promote an optimal level of function.

- Explain the difference between chronic sorrow and chronic grieving. *Grieving is time limited and ends in adaptation to the loss. Chronic sorrow may vary in intensity, but it persists as long as the person with the disability or chronic sorrow condition lives.*
- Encourage verbalization of feelings about the loss, and about the personal relevance of the changes and hopes for the future. *Expressing feelings is normal and necessary to decrease the emotional pain.*

- Help identify triggers that intensify the sorrow, such as birthdays, anniversaries, and holidays. *When triggers have been identified, helpful coping strategies and support can be identified.*
- Refer to appropriate community support groups. *Participating in support groups with others experiencing grief is helpful in coping with loss.*
- Encourage use of personal, family, significant other, and spiritual support systems *to facilitate coping with loss.*

Death Anxiety

Death anxiety is worry or fear related to death or dying. It may be present in patients who have an acute life-threatening illness, who have a terminal illness, who have experienced the death of a family member or friend, or who have experienced multiple deaths in the same family.

Expected Outcome: Patient or family will express fears related to death or dying and identify effective coping strategies that will minimize the adverse effects of uncontrolled anxiety.

- Explore the patient's knowledge of the situation. For example, ask, "What has your doctor told you about your condition?" *This provides information about the patient's knowledge base about the condition and about his or her ability to make informed decisions.*
- Ask the patient to identify specific fears about death. *This provides data about any unrealistic expectations or misperceptions.*
- Determine the patient's perceptions of strengths and weakness in coping with death. *Identifying past strengths can help the patient cope with loss, illness, and death.*
- Ask the patient to identify needed help. *This determines whether available resources are adequate.*
- Encourage independence and control in decisions about treatment and care. *This promotes self-esteem, decreases feelings of powerlessness, and allows the patient to retain dignity in dying.*
- Facilitate access to culturally appropriate spiritual rituals and practices. *This provides spiritual comfort.*
- Explain advance directives and assist with them if necessary. *Advance directives help ensure that the patient's wishes for end-of-life care are carried out.*
- Encourage life review and reminiscence. *Life review is self-affirming.*
- Encourage activities such as listening to music, aromatherapy, massage, or relaxation exercises. *These activities decrease anxiety.*
- Suggest keeping a journal or leaving a written legacy. *A written document provides continuing support to others after death.*

Continuity of Care

In addition to teaching patients and families to carry out the physical skills that are necessary to the patient's care, nurses also provide information on identifying signs of deterioration and additional sources of support. General guidelines for teaching patients and families about grief include those suggested in the accompanying Meeting Individualized Needs feature. In addition, suggest the following resources:

- Hospice
- Home healthcare agencies
- Support groups
- Public health departments
- Church, synagogue, or mosque
- Pastoral counseling centers
- Mental health agencies

Meeting Individualized Needs

Teaching for Patients Experiencing a Loss

- Encourage both children and adults to discuss expected or impending loss and to express feelings.
- Teach problem-solving skills: Define what the possible changes and problems are related to the predicted loss, develop potential strategies for dealing with problems, list pros and cons of each strategy, and decide which strategies might be most useful to try first to solve potential problems associated with loss.
- Teach individuals and families how to support a person who is dealing with an impending loss.
- Explain what to expect with a loss: sadness, fear, rejection, anger, guilt, loneliness.
- Teach signs of grief resolution:
  - No longer living in the past, becoming future oriented
  - Breaking ties with the lost object or person (acute stage often shows signs of resolving in 6 to 12 months)
  - The possibility of having painful waves of grief years after the loss, especially on the anniversary of the loss and in response to triggers such as pictures, events, songs, or memories

CASE STUDY & NURSING CARE PLAN Loss and Grief

Pearl Rogers is a 79-year-old woman who is admitted to the Methodist Home Nursing Center. Mrs. Rogers lived with her husband of 58 years until his death 9 months ago. She had one son who died in an auto crash 2 years ago, and she has one daughter who lives nearby. After her husband's death, Mrs. Rogers lived with her daughter until her admission to the nursing center. Mrs. Rogers has become increasingly agitated and helpless, complaining constantly of pain. Her daughter states that Mrs. Rogers is chronically constipated, has difficulty sleeping, and has stopped engaging in all social activities, including weekly church services. She cries frequently. Extensive medical testing prior to her admission to the nursing center revealed Mrs. Rogers has arthritis but no other pathologic disorder.

ASSESSMENT

On admission to the nursing center, Mrs. Rogers says, "I'm a sick woman, and no one will listen to me! I can't walk, I'm so weak. My head hurts, and I'm always sick at my stomach. I haven't had a bowel movement in a week, and I never sleep more than three hours a night." Physical assessment findings include swollen knees and ankles, with limited mobility of the lower extremities.

DIAGNOSES

- *Grieving* related to stress of husband's death
- *Disturbed Sleep Pattern* related to grieving
- *Constipation* related to inactivity

EXPECTED OUTCOMES

- Engage in normal grief work: Work through grief process, discuss reality of losses, use nondestructive coping mechanisms, and discuss positive and negative aspects of the loss.
- Experience adequate and restful sleep: Fall asleep 20 to 30 minutes after retiring and awaken feeling rested after 7 to 8 hours of sleep.
- Have a bowel movement with soft, formed stools at least every other day.

PLANNING AND IMPLEMENTATION

- Promote trust: Show empathy and caring, demonstrate respect for Mrs. Rogers' culture and values, offer support and reassurance, be honest, and engage in active listening.
- Assist in labeling Mrs. Rogers' feelings: anger, fear, loneliness, guilt, isolation.
- Explore previous losses and the ways in which the patient has coped.
- Encourage review of Mrs. Rogers' relationship with her dead husband.
- Reinforce expressions of behaviors associated with normal grieving.
- Encourage participation in usual spiritual practices.
- Encourage participation in a grief group that meets at the facility.
- Consult with the physical and recreational therapist to help the nursing staff provide afternoon activities.
- Provide measures that assist in bowel evacuation: Encourage exercise as tolerated, including walks and rocking in a rocking chair. Offer foods that stimulate bowel movements. Offer privacy: Close the door, ensuring that the emergency call bell is within reach, and do not interrupt.
- Administer a mild laxative and/or stool softener, if necessary, but discontinue as soon as possible.

EVALUATION

After 4 weeks at the nursing center, Mrs. Rogers states, "I don't feel any better, but I know I have to accept my situation." Although Mrs. Rogers states that she doesn't feel better, she is walking the length of the hall, sleeping better, and having regular bowel movements. Mrs. Rogers is also less withdrawn and has openly discussed her feelings related to her husband's death, including her anger at the loss of her son and her husband less than 2 years apart. She has attended the grief group once and has attended chapel services on Sunday for the past 2 weeks. Her daughter visits her each Saturday and takes her in a wheelchair to the shopping mall.

Clinical Reasoning in Patient Care

1. What common physical manifestations of grief did Mrs. Rogers experience?
2. How might Mrs. Rogers' daughter be more involved in developing and implementing her mother's plan of care?
3. Suppose Mrs. Rogers says that she does not want any help, that she just wants to be left alone to die. How would you respond?

See Evaluating Your Response in Appendix B.

CHAPTER HIGHLIGHTS

- **Caring for patients and families experiencing loss, grief, and death emphasizes integration of holistic nursing interventions focused on providing individualized patient-centered care.**
- **Providing direct patient care, coordinating, leading, and participating as a member of the interprofessional team is essential role for the registered nurse when caring for this population.**
- Grief is the emotional response to a loss, experienced by an individual as grieving. Bereavement, a form of depression accompanied by anxiety, is a common response to loss of a loved one by death. Death, although inevitable, is an immensely difficult loss.
- There are many different theories of how people respond to loss, grief, and death. These theories are useful when providing nursing care to patients and families.
- An individual's response to loss is influenced by age, social support, family members, culture and spiritual beliefs, and rituals of mourning. Nurses need to assess the way in which they respond to loss to better care for patients.
- Legal and ethical issues involved in end-of-life care include advance directives (living wills, healthcare surrogates, durable powers of attorney, physician orders for life-sustaining treatment), do-not-resuscitate orders, euthanasia, assisted suicide, and aid in dying.

- Palliative care is focused on the relief of physical, mental, and spiritual distress for people with an incurable illness. Pain control is an essential aspect of palliative care.
- Hospice, a model of care for patients and their families when faced with limited life expectancy, supports a dignified and peaceful death. Palliative care is the focus of hospice care.
- To provide knowledgeable and compassionate care at the end of life, nurses must recognize physiologic changes as the patient nears death, support the patient and family, provide postmortem care, and resolve their own grief.
- Nursing care of patients experiencing an actual or potential loss includes accurate physical, spiritual, and psychosocial assessment. It also includes provision of interventions to alleviate pain and symptoms associated with the end of life and interventions for the human responses of grieving, chronic sorrow, and death anxiety.

TEST YOURSELF NCLEX-RN® REVIEW

1. The nurse is planning care for a patient whose spouse recently passed away. Which statement should the nurse keep in mind when planning care for this patient who has experienced a loss?
1. Loss is the same as grief and mourning.
2. Grief and mourning are determined by one's cultural values.
3. Coping with a death is largely dependent on support of family and friends.
4. The feeling of loss can only be determined by the person who experiences it.

2. A patient newly diagnosed with a terminal illness states, "I hate this cancer." According to Kübler-Ross, what stage of loss is being verbalized?
1. anger
2. denial
3. bargaining
4. depression

3. The nurse is caring for a patient who has experienced a loss. For what should the nurse assess that will help the patient successfully resolve grief?
1. social isolation
2. support systems
3. triggers of grief
4. loss acknowledgment

4. A terminally ill patient has died and the nurse is waiting for the family to arrive before moving the patient. What is the primary factor that dictates this family's ritual of mourning?
1. age
2. culture
3. gender
4. religion

5. A patient says, "I don't want anything heroic done if I die. Just let me go." Which document should the patient complete that expresses wishes for life-sustaining treatment in the event of terminal illness or permanent unconsciousness?
1. living will
2. no-code order
3. healthcare surrogate
4. durable power of attorney

6. A patient has been referred to hospice and asks what it means. What should the nurse respond to the patient about this type of care?
1. It is a special place of care.
2. It is a lifelong type of care.
3. It is a model of care rather than a place of care.
4. It is designed for patients with serious chronic illness.

7. A patient nearing death requests that no medication be given that would cause a loss of consciousness, including pain medication. What should the nurse do to provide the best end-of-life care for this patient?
1. Give the medication; comfort is the highest priority.
2. Give half the ordered dose to provide compassionate care.
3. Discuss this with family members and follow their wishes.
4. Respect the patient's wishes and withhold pain medications.

8. The nurse is caring for a patient who is dying. Which sense is believed to be the last one lost as an individual nears death?
1. smell
2. touch
3. vision
4. hearing

9. A patient with a terminal illness is demonstrating signs of imminent death. What should the nurse keep in mind about the treatment of pain at the end of life?
1. Refrain from administering opioids to the dying patient.
2. There is no maximum allowable dose for opioids during end-of-life care.
3. As a patient nears death, no pain is perceived and no medications are necessary.
4. It is important to withhold pain medications if the patient has respiratory changes.

10. A patient, recently widowed, tells the nurse, "I just can't even get out of bed in the mornings anymore." What response by the nurse would be most helpful in resolving the patient's grief?
1. "I don't know why you feel that way."
2. "This must be a difficult time for you."
3. "Why do you think you feel this way?"
4. "After you get up, you will feel better."

6 Nursing Care of Patients with Problems of Substance Abuse

LEARNING OUTCOMES

1. Recognize the pathophysiology, manifestations, and complications of substance abuse.
2. Discuss risk factors associated with substance abuse.
3. Describe common characteristics of people with substance abuse problems.
4. Explain the effects of addictive substances on physiologic, cognitive, psychologic, and social well-being.
5. Support interprofessional care for the patient with substance abuse problems, including diagnostic tests, emergency care for overdose, and treatment of withdrawal.
6. Recognize the potential for substance abuse in coworkers.

CLINICAL COMPETENCIES

1. Assess and monitor the health status of patients with substance abuse or dependence.
2. Monitor for signs of withdrawal and life-threatening conditions.
3. Provide skilled nursing care during the detoxification period respecting expressed needs, values, and preferences.
4. Collaborate and coordinate with the patient and other members of the interprofessional team when caring for patients with substance abuse problems.
5. Educate patients about stress management, coping skills, nutrition, relapse prevention, and healthy lifestyle choices.
6. Using assessed data and current standards of practice, plan and implement individualized nursing care for patients experiencing problems with substance abuse.
7. Evaluate patient responses to care, revising the plan of care as needed to promote, maintain, or restore functional health status to patients with substance abuse problems.
8. Participate in studies and projects to improve outcomes for patients with substance abuse disorders.
9. Apply technology and information management tools to support safe processes of care for patients with substance abuse disorders.

MAJOR CHAPTER CONCEPTS

- Combinations of genetic, biologic, psychologic, and sociocultural factors contribute to substance abuse or dependence.
- Addictive behavior has been linked to biochemical changes in brain levels of dopamine and serotonin as well as heredity, ethnic differences, and peer pressure.
- People with substance abuse problems share characteristics such as risk-taking behavior, low tolerance for frustration or pain, compulsive preoccupation with the substance, anxiety, anger, and low self-esteem.
- Alcohol is the most commonly used and abused legal substance in America; however, polysubstance abuse is frequent in many individuals. Marijuana is the most commonly used illicit drug.
- Severe alcohol withdrawal or delirium tremens is a medical emergency that usually occurs 2 to 5 days following cessation of alcohol use. A symptom-triggered approach to the administration of benzodiazepines during alcohol withdrawal results in less total medication use and requires a shorter duration of treatment.

THE PATIENT WITH SUBSTANCE ABUSE PROBLEMS

Substance abuse refers to the use of any chemical in a fashion inconsistent with medical or culturally defined social norms despite physical, psychologic, or social adverse effects. Anxiety and depressive disorders frequently occur with substance abuse. More than 90% of people who commit suicide have a depressive or substance abuse disorder (National Institute of Mental Health, 2012). In 2010, more than 22.1 million Americans, or 8.7% of the population, were classified with substance dependence or abuse (Substance Abuse and Mental Health Services Administration [SAMHSA], 2011).

The *Diagnostic and Statistical Manual of Mental Disorders*, fifth edition (*DSM-5*) (American Psychiatric Association, 2013) includes a classification scheme for distinguishing between substance abuse and substance dependence. **Substance dependence** refers to a severe condition occurring when the use of the chemical substance is no longer under an individual's control for at least 3 months. Continued use of the substance usually persists despite adverse effects on the person's physical condition, psychologic health, and interpersonal relationships. The *DSM-5* criteria deal with the behavioral aspects and the maladaptive patterns of substance use, emphasizing the physical symptoms of tolerance and withdrawal. **Tolerance** is a cumulative state in which a particular dose of the chemical elicits a smaller response than before. With increased tolerance, the individual needs higher and higher doses to obtain the desired effect. When an individual is physically addicted to the drug and stops taking it, **withdrawal symptoms** can occur within hours. **Withdrawal** is an uncomfortable state lasting several days, manifested by tremors, diaphoresis, anxiety, high blood pressure, tachycardia, and possibly convulsions.

Pathophysiology, Manifestations, and Complications

The human tendency to seek pleasure and avoid stress and pain is partially responsible for substance abuse. Although far from definite, evidence implicates the endogenous opioid system in the development and maintenance of addictive behaviors. Current data suggest that alcohol increases endogenous opioid neurotransmission and that this activation is partly responsible for its reinforcing effect. Dopamine has been identified as the primary neurotransmitter responsible for sustaining the addictive quality of drugs and for increasing drug-seeking behavior. The reinforcing properties of drugs can create a pleasurable experience and reduce the intensity of unpleasant experiences.

Manifestations of substance abuse include failure to meet major role obligations (e.g., work, education, family), engaging in hazardous activities while impaired, and a pattern of legal or interpersonal relationship problems (APA, 2013). Individuals with substance dependence use the drug in larger dosages and for longer than it is intended to be used, and demonstrate tolerance to the drug and withdrawal symptoms when the drug is withheld or unavailable. These individuals often withdraw from family and friends, focusing instead on obtaining, taking, and recovering from the drug (APA, 2013).

Although there is no greater prevalence of psychiatric illness in people with substance abuse problems than in the general population, co-occurring disorders are often present. **Co-occurring disorders** (previously called dual diagnosis and dual disorders) refer to the coexistence of substance abuse or dependence and a psychiatric disorder in one individual. One disorder can be an indication of another, such as the relationship between alcoholism and depression. Alcohol dependence and major depression commonly occur together, each posing a significant risk for the development of the other disorder. A depressed person may use self-medication in the form of alcohol to treat the depression, or the person with alcoholism may become depressed. The most commonly co-occurring mental disorders in adults are alcohol abuse or alcohol dependence with depression or psychoses. Patients with co-occurring disorders are more likely to be unemployed younger males living in unstable conditions with more than one psychiatric diagnosis and a personality disorder. The combination of these factors results in more crises and a greater risk to the person and others. Table 6–1 lists terminology associated with substance abuse.

Risk Factors

Various risk factors help explain why one person becomes addicted while another does not. Genetic, biologic, psychologic, and sociocultural factors shed light on how an individual may abuse or become dependent on a substance:

- ***Genetic factors*** include an apparent hereditary factor, especially with alcohol use and dependence. Most of the related genetic research has focused on alcoholism. The discovery that the DRD2 A1 allele gene appears to be associated with alcoholism has led to a growing body of genetic research into substance abuse disorders (Stuart, 2012). A meta-analysis of gene and genome-wide association studies identified over 840 combinations of alleles (DNA sequences) linked to addiction susceptibility (Li et al., 2011). Women drink less alcohol and have fewer alcohol-related problems than men. In addition, women are less likely to have the characteristics associated with heavy drinking including aggressiveness, drinking to reduce distress, and antisocial tendencies. See the Genetic Considerations box.
- ***Biologic factors*** were first identified by Jellinek in his disease model of alcoholism. He hypothesized that addiction to alcohol may have a biochemical basis and identified specific phases of the disease (Jellinek, 1946). Expanding on Jellinek's early work, researchers have implicated low levels of dopamine and serotonin in the development of alcohol dependence. Dopamine and dopamine receptor sites are intricately involved in the complex workings between the nervous system and abusive substances. Any drug's ability to have an impact on the biochemical mechanisms

TABLE 6–1 Terminology Associated with Substance Abuse

Term	Definition
Abstinence	Voluntarily going without drugs or alcohol.
Addiction	A disease process characterized by the continued use of a specific chemical substance despite physical, psychologic, or social harm (used interchangeably with substance dependence).
Codependence	A cluster of maladaptive behaviors exhibited by the significant others of an individual who abuses substances that serves to enable and protect the abuse at the expense of living a full and satisfying life.
Co-occurring disorders	Concurrent diagnosis of a substance use disorder and a psychiatric disorder. One disorder can precede and cause the other, such as the relationship between alcoholism and depression.
Cross-tolerance	Tolerance to one drug confers tolerance to another.
Delirium tremens	A medical emergency usually occurring 3 to 5 days following alcohol withdrawal and lasting 2 to 3 days. Characterized by paranoia, disorientation, delusions, visual hallucinations, elevated vital signs, vomiting, diarrhea, and diaphoresis.
Detoxification	The process of helping an addicted individual safely through withdrawal.
Dual diagnosis	The coexistence of substance abuse/dependence and a psychiatric disorder in one individual (used interchangeably with dual disorder and co-occurring disorders).
Kindling	Brain sensitization to events such as stress, trauma, or the effects of substance use.
Korsakoff's psychosis	Secondary dementia caused by thiamine (B_1) deficiency that may be associated with chronic alcoholism; characterized by progressive cognitive deterioration, confabulation, peripheral neuropathy, and myopathy.
Physical dependence	A state in which withdrawal syndrome will occur if drug use is discontinued.
Polysubstance abuse	The simultaneous use of many substances.
Psychologic dependence	An intensive subjective need for a particular psychoactive drug.
Substance abuse	Continued use of a chemical substance in a fashion inconsistent with medical or social norms, for at least 1 month, despite related problems.
Substance dependence	A severe condition occurring when the use of the chemical substance is no longer under control for at least 3 months; continued use persists despite adverse effects (used interchangeably with addiction).
Tolerance	State in which a particular dose elicits a smaller response than it formerly did. With increased tolerance the individual needs higher and higher doses to obtain the desired response.
Wernicke's encephalopathy	Caused by thiamine (B_1) deficiency, characterized by nystagmus, ptosis, ataxia, confusion, coma, and possible death. Thiamine deficiency is common in chronic alcoholism.
Withdrawal syndrome	Constellation of signs and symptoms that occurs in physically dependent individuals when they discontinue drug use.

GENETIC CONSIDERATIONS

Family Risk Factors for Alcoholism

Children of alcoholics (COAs) are about four times more likely to develop alcohol problems than children of nonalcoholics (National Institute on Alcohol Abuse and Alcoholism [NIAAA], 2012). This is primarily true with male relatives. One type of alcoholism seen mostly in the sons of fathers with alcoholism is associated with an early onset, inability to abstain, and an antisocial personality (Stuart, 2012). However, alcoholism is not solely determined by genetics; more than half of all COAs are not alcoholics. Research shows that many factors influence the risk of developing alcoholism (NIAAA, 2012). Some factors lower the risk, while others increase the risk. Researchers think an individual is at increased risk if the following situations are present:

- An alcoholic parent is depressed or has other psychological problems;
- Both parents abuse alcohol and other drugs;
- The parents' alcohol abuse is severe; and
- Conflicts lead to aggression and violence in the family (NIAAA, 2012).

of the brain must be able to do so at a receptor site or at a number of receptor sites (Figure 6–1 ■). Most abused substances either mimic or block the brain's most important neurotransmitters at their respective receptor sites. For example, heroin and other opiates mimic natural opiate-like neurotransmitters such as endorphin, enkephalin, and dynorphin. In contrast, cocaine and other stimulants block the reuptake of dopamine, serotonin, and norepinephrine (Stuart, 2012).

- ***Psychologic factors*** attempt to explain substance abuse through a combination of psychoanalytic, behavioral, and family system theories. Psychoanalytic theorists view substance abuse as a fixation at the oral stage of development, while behavioral theorists see addiction as a learned, maladaptive behavior. Family system theory focuses on the pattern of family relationships throughout several generations. No addictive personality type has been identified; however, several common factors seem to exist among people with alcoholism and substance abuse problems. Many people with substance abuse problems have experienced sexual or physical abuse in their childhood and as a result have low

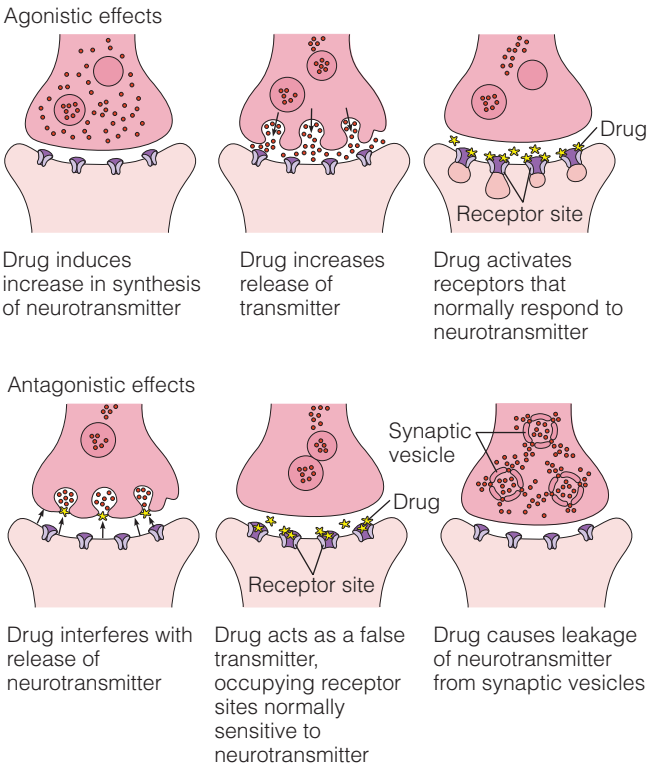

Figure 6–1 ■ Action of abusive substances at brain receptor sites.

self-esteem and difficulty expressing emotions. A link also exists between substance abuse and psychiatric disorders such as depression, anxiety, and antisocial and dependent personalities. The habit of using a substance becomes a form of self-medication to cope with day-to-day problems, and over time develops into an addiction. Another type of alcoholism may be more environmentally influenced and is linked with onset after the age of 25, inability to stop after one drink, and a passive-dependent personality (Stuart, 2012).

- ***Sociocultural factors*** often influence individuals' decisions as to when, what, and how they use substances. Ethnic differences in the way alcohol is metabolized may explain why some individuals choose not to drink. When alcohol is first metabolized, it is converted into a by-product known as acetaldehyde, which in turn is broken down by aldehyde dehydrogenase 2 (ALDH2), an enzyme. Approximately 36% of the Asian population possesses a deficiency of the ALDH2 enzyme that causes toxic symptoms due to the buildup of acetaldehyde in the brain when they drink alcohol (Brooks et al., 2009). These toxic effects, including reddened skin, vomiting, and tachycardia, are a natural deterrent to alcohol consumption for some Asians. Compared to other ethnic groups, Asian Americans report the lowest prevalence of family history of alcoholism. Caucasians, Hispanics, and African Americans, on the other hand, have sufficient ALDH2 for metabolizing alcohol and report higher alcoholism rates (SAMHSA, 2011). Religious background may also correlate with the likelihood that an individual will abuse alcohol. Among major religions, people of Jewish faith have the lowest rate of alcoholism, while Roman Catholics have the highest rate. See the accompanying Focus on Cultural Diversity feature.

FOCUS ON CULTURAL DIVERSITY

Substance Use and Ethnicity

Ethnic identity plays a unique role in drug use behavior. Patterns of substance use are influenced by cultural norms and practices, in addition to other environmental and biologic factors. Adolescents in particular are influenced by ethnic and cultural practices. Factors such as strong ethnic affiliation, attachment, and pride may protect adolescents against drug use and help them form resistant behaviors to substance abuse (Feinstein et al., 2012; Hornberger & Smith, 2011). A higher number of Black and Hispanic children are exposed to alcohol problems in the home than White children (Hornberger & Smith, 2011). Use of tobacco, alcohol, and illicit drugs are reportedly different in racial and ethnic groups. American Indians and Alaska Natives have higher levels of tobacco, alcohol, and illicit drug use when compared to other racial groups. Substance abuse and type 2 diabetes are serious health problems among American Indians. Asian Americans have the lowest rates of tobacco, alcohol, and illicit drug usage (SAMHSA, 2011).

Moving Knowledge Into Action

1. You are a school nurse with a large population of Native Americans, Latin Americans, and African Americans in the community. An increasing problem with alcohol use and binge drinking among the high school students has become evident. The school superintendent has asked you for ideas to address this problem. How would you respond?
2. You are caring for a 23-year-old Asian American female brought to the emergency department by her boyfriend who tells you they were at a college party where she had alcohol for the first time. She is weak, her face is flushed, and she is vomiting violently. What would you do?

Many factors place an individual at risk for substance use, abuse, and dependence. No single cause can explain why one individual develops a pattern of drug use and another person does not. Thorough assessment of these factors is necessary to understand the whole person and plan appropriate interventions.

Characteristics of People Who Abuse Substances

As mentioned, no addictive personality type exists; however, many people with substance abuse problems have several characteristics in common. Addictive behavior associated with alcoholism and other substances is characterized by compulsive preoccupation with obtaining the substance, loss of control over consumption, and development of tolerance and dependence as well as impaired social and occupational functioning. People who abuse substances tend to indulge in impulsive, risk-taking behaviors and often have a low tolerance for frustration and pain. Often, they rebel against social norms and engage in various antisocial and risky behaviors such as stealing, promiscuity, driving while intoxicated, and violence against others. There is also a tendency toward anxiety, anger, and low self-esteem in people with substance abuse problems. Many people have a desire for social acceptance and initiate drug use to fit in with a peer group. Others may suffer from social anxiety and need drugs or alcohol to feel less inhibited while interacting with others.

ADDICTIVE SUBSTANCES AND THEIR EFFECTS

Caffeine

Caffeine is a stimulant that increases the heart rate and acts as a diuretic. Although commonly consumed daily in soft drinks, coffee, tea, chocolate, and some pain relievers, an excessive amount of caffeine can cause negative physiologic effects, especially cardiac-related risks. Approximately 300 mg/day is safe for most people, but over 600 mg is considered excessive and not recommended (Kneisl & Trigoboff, 2013). Individuals with a history of cardiac disease are advised to cut down or eliminate caffeine intake altogether. Caffeine, if consumed in large quantities, can also cause higher total cholesterol levels and insomnia.

A caffeine-addicted person who abruptly withdraws from caffeine often experiences headaches and irritability. A rising number of adolescents are developing caffeine dependence by consuming sizable quantities of soft drinks and coffee.

Nicotine

Nicotine is found in tobacco and enters the system via the lungs (cigarettes and cigars) and oral mucous membranes (chewing tobacco as well as smoking). In low doses, nicotine stimulates nicotinic receptors in the brain to release norepinephrine and epinephrine, causing vasoconstriction. As a result, the heart rate accelerates and the force of ventricular contractions increases. Gastrointestinal (GI) effects include an increase in gastric acid secretion, increased tone and motility of GI smooth muscle, and promotion of vomiting. Nicotine acts on the central nervous system (CNS) as a stimulant, binding to acetylcholine receptors in the brain and causing the release of dopamine and norepinephrine. This dopamine release reinforces the addictive craving for nicotine, increasing the difficulty of quitting smoking. Smoking cessation can pose a problem for hospitalized patients (see the Moving Evidence into Action feature).

Initially, nicotine increases respiration, mental alertness, and cognitive ability, but eventually depresses these responses (Kneisl & Trigoboff, 2013). Moderate doses of nicotine can cause tremors. Tolerance can develop to nausea and dizziness, but not to the cardiovascular effects. High doses of nicotine, found in some insecticides, can cause acute poisoning, resulting in convulsions and death.

Nicotine dependence results from chronic use with withdrawal seen as craving, nervousness, restlessness, irritability, impatience, increased hostility, insomnia, impaired concentration, increased appetite, and weight gain. Gradual reduction in nicotine use seems to prolong suffering.

Chronic health problems from smoking have been well established in the form of cancer, heart disease, emphysema, hypertension, and death (Kneisl & Trigoboff, 2013). Smoking is now the number one cause of preventable death and disease among women. An estimated 21.5% of women (about one in five) in the United States are current smokers (SAMHSA, 2011). Far more women are dying of lung cancer than of breast cancer. Women are also confronted with unique health concerns from smoking during pregnancy. Smoking during pregnancy leads to increased risks for infants such as low birth weight, stillbirth, preterm delivery, perinatal mortality, and sudden infant death syndrome (Centers for Disease Control and Prevention [CDC], 2012). Secondhand effects from smoking have been demonstrated, especially to fetuses during pregnancy. Smoking also increases the risk for infertility. Postmenopausal women who smoke have lower bone density and

Moving Evidence into Action

Smoking Cessation in Hospitalized Patients

Despite the well-publicized deleterious health effects posed by cigarette smoking and the legally restricted access to cigarettes to minors, smoking remains a persistent problem. Smoking has been banned in stores, malls, hospitals, office buildings, college campuses, and restaurants. A systematic review and meta-analysis provided evidence that brief interventions for smoking cessation have potential benefits (Aveyard et al., 2012). Nicotine replacement therapy (NRT) also increases quit rates with or without additional counseling (Beard et al., 2010). NRT aims to reduce withdrawal symptoms from tobacco products by replacing nicotine in the blood. All forms of NRT, available as chewing gum, skin patches, nose spray, inhalers, and tablets, increase the likelihood that an individual will succeed in quitting smoking.

Implications for Nursing

Admission to the hospital provides an excellent opportunity for nurses to assist patients to quit smoking. Patients in hospitals may find it easier to quit in an environment where smoking is restricted or prohibited. In addition, individuals may be more open to cessation efforts when faced with the risks associated with surgery. Healthcare professionals, especially nurses, can be very instrumental in smoking cessation efforts. Advising hospitalized smokers to quit and referring them to online and community resources to aid smoking cessation is an easy, cost-effective method to reduce tobacco dependence (Sarna et al., 2012).

Effective nursing strategies include asking patients about their tobacco use, counseling those who want to quit, reinforcing cessation efforts, and early follow-up with those who quit smoking. This evidence points to the important role nurses possess to encourage their patients to quit smoking and the need for nurses to incorporate smoking cessation interventions as part of their standard practice.

Moving Knowledge into Action

1. You are caring for a 55-year-old man recently hospitalized for acute angina who asks you what is the best way to stop smoking. How would you answer?
2. Why do you think nurses and other healthcare professionals should (or should not) quit smoking?
3. You are caring for a 12-year-old girl who tells you she has smoked cigarettes occasionally and believes it makes her more popular with her older friends. She admits that she knows that smoking is supposed to be bad for you but doesn't see the harm in smoking a few cigarettes every day. How would you respond?

higher risk for hip fracture than women who have never smoked (CDC, 2012).

Cannabis

Cannabis sativa is the source of marijuana. According to 2010 National Survey on Drug Use and Health (NSDUH) data, marijuana is the most commonly used illicit drug (17.4 million users) (SAMHSA, 2011). A majority of illicit drug users (56.2%) reported that their first drug was marijuana, supporting the notion that marijuana is a gateway drug. The greatest psychoactive substances are in the flowering tops of the cannabis plant. Marijuana (also known as *grass*, *weed*, *pot*, *dope*, *joint*, and *reefer*) and hashish are the most common derivatives. The psychoactive component of marijuana is an oily chemical known as delta-9-tetrahydrocannabinol (THC). THC activates specific cannabinoid receptors in the brain. Evidence suggests that marijuana may act like opioids and cocaine in producing a pleasurable sensation, probably by causing release of endogenous opioids and then dopamine (Kneisl & Trigoboff, 2013).

The physiologic effects of cannabis are dose related and can cause an increase in heart rate and bronchodilation in short-term use. Chronic long-term use can lead to airway constriction, bronchitis, sinusitis, asthma, and increased risk for respiratory cancer. The reproductive system is also affected by marijuana; it causes decreased spermatogenesis and testosterone levels in males and suppresses follicle-stimulating, luteinizing, and prolactin hormones in females, impairing breast-feeding for new mothers. Birth defects may also be associated with cannabis use. Marijuana crosses the placental barrier and is spread to fetal tissues. When a pregnant woman smokes marijuana, she increases the risk of abnormalities in the fetus such as CNS disturbances, low birth weight, decreased length, smaller head circumference, and fetal death (Kneisl & Trigoboff, 2013).

Subjective effects of marijuana include euphoria, sedation, and hallucinations. Chronic use of marijuana can result in amotivational behaviors such as apathy, dullness, poor grooming, reduced interest in achievement, and disinterest. At extremely high doses, tolerance and physical dependence result.

Alcohol

Alcohol is the most commonly used and abused legal substance in the United States. Alcohol and other CNS depressants act on neurotransmitters in the brain such as gamma-aminobutyric acid (GABA). GABA is the most prevalent inhibitory neurotransmitter in the brain and has a major role in decreasing neuronal excitability. Alcohol creates an additive effect with GABA, further inhibiting arousal and depressing the autonomic nervous system. This may explain why cross-tolerance effects occur when alcohol and other CNS depressants are used in combination. When taken together, alcohol and other CNS depressants such as benzodiazepines and barbiturates can lead to respiratory depression and death.

Slightly more than half, or an estimated 135.5 million, of the nation's population over age 12 report current alcohol use. Of this number, an estimated 17 million, or one in every seven, report heavy drinking (defined as binge drinking on at least 5 days in the past 30 days) (SAMHSA, 2013b). Although the legal drinking age in all 50 states is 21, many underage people use alcohol. Of the 14 million adults in America who abuse alcohol, 95% report drinking before the age of 21 (SAMHSA, 2011). Alcohol use increases with increasing age among underage persons; unfortunately, this pattern has remained stable since 2002. In 2010, slightly more than half (50.7%) of 18- to 20-year-olds drank alcohol during the month before they were surveyed (SAMHSA, 2011). Alcohol is considered a gateway drug, sometimes leading to the use of highly addictive and injectable substances such as cocaine, heroin, or methamphetamine. Nearly 140,000 alcohol-related emergency department (ED) visits were made during 2010 by patients under the age of 21 (SAMHSA, 2012). Almost one-third (31%) of those alcohol-related ED visits for minors involved other substances as well. Table 6–2 lists the drugs most frequently reported with alcohol in ED visits.

FAST FACTS

Underage Drinking

- The rate of underage drinking remains consistently high. In 2010, approximately 10 million persons ages 12 to 20 reported drinking alcohol in the past month (26.3% of this age group).
- Of these, nearly 17% were binge drinkers, and 5.1% were heavy drinkers.
- Among persons ages 12 to 20 in 2010, past-month alcohol use rates were lowest among Asians (15.4%) and highest among Whites (29.3%).
- College students (ages 18 to 22) enrolled full time were more likely to use alcohol in the past month (63.3%), binge drink (42.2%), and drink heavily (15.6%) than peers not enrolled in college.
- Driving under the influence of alcohol in 2010 steadily increased from ages 16 to 17 (5.8%), peaked at ages 21 to 25 (23.4%), and declined beyond age 25.

Source: SAMHSA (2011).

Alcohol is absorbed in the mouth, stomach, and digestive tract. The liver metabolizes approximately 95% of the ingested alcohol and the rest is excreted via the skin, kidney, and lungs. Generally an individual can break down approximately 1 ounce of whiskey every

TABLE 6–2 Drugs Most Frequently Reported with Alcohol-Related ED Visits

Rank	Drug	Estimated Visits
1	No other drug	126,704
2	Cocaine only	101,588
3	Marijuana only	41,653
4	Cocaine and marijuana	21,241
5	Heroin only	14,958
6	Stimulants only	7,895
7	Alprazolam only	8,007
8	Cocaine and heroin	10,628

90 minutes. Factors such as body mass, food intake, and liver function can affect the rate of alcohol absorption.

When used in moderation, alcohol can have positive physiologic effects by increasing levels of desirable cholesterol (HDL) and lowering levels of bad cholesterol (LDL). Alcohol in moderation also decreases platelet aggregation, thereby decreasing coronary artery disease and protecting against stroke. However, when consumed in excess, alcohol can severely diminish one's ability to function and can ultimately lead to life-threatening conditions. Chronic use of alcohol can cause debilitating neurologic and psychiatric disorders. Damage to the liver occurs with chronic alcohol abuse, and can progress from fatty liver to other liver diseases such as hepatitis or cirrhosis. Chronic alcoholism is the major cause of fatal cirrhosis. Alcohol causes damaging effects to many other systems; its potential effects include myocardial disease, erosive gastritis, acute and chronic pancreatitis, sexual dysfunction, and an increased risk of breast cancer.

Malnutrition is another serious complication of chronic alcoholism, especially thiamine (B_1) deficiency that can result in neurologic impairments. Thiamine depletion is thought to cause the Wernicke-Korsakoff syndrome observed in people with chronic alcoholism (Stuart, 2012). Severe cognitive impairment is a principal feature of **Wernicke's encephalopathy** and **Korsakoff's psychosis**. Although these are sometimes considered to be two distinctive disorders, they are actually different phases of the same disease, commonly called Wernicke-Korsakoff syndrome. Wernicke's encephalopathy indicates the acute stage of the illness, and Korsakoff's psychosis indicates the chronic stage.

Although alcohol is a CNS depressant, it actually disrupts sleep, thus altering the sleep cycle, decreasing the quality of sleep, intensifying obstructive sleep apnea, and reducing total sleeping time. Heavy drinkers have a higher mortality rate and many fatalities occur from alcohol-related accidents. Blood alcohol levels (BALs) are highly predictive of CNS effects. Euphoria, reduced inhibitions, impaired judgment, and increased confidence are seen at 0.05% (Kneisl & Trigoboff, 2013). The legal level of intoxication in many states is 0.08%. Toxic levels in excess of 0.5% can cause coma, respiratory depression, peripheral collapse, and death (Kneisl & Trigoboff, 2013).

Chronic consumption of alcohol produces tolerance and creates cross-tolerance to general anesthetics, barbiturates, benzodiazepines, and other CNS depressants. If alcohol is withdrawn abruptly, the brain becomes overly excited because receptors previously inhibited are no longer inhibited. This hyperexcitability manifests clinically as anxiety, tachycardia, hypertension, diaphoresis, nausea, vomiting, tremors, sleeplessness, and irritability. Severe manifestations of alcohol withdrawal include seizures, convulsions, and **delirium tremens (DT)**. Episodes of delirium tremens have a mortality rate of 1% to 5%.

CNS Depressants

Central nervous system depressants, including barbiturates, benzodiazepines, paraldehyde, meprobamate, and chloral hydrate, are also subject to abuse. Cross-dependence exists among all CNS depressants and cross-tolerance can develop to alcohol and general anesthetics. Chronic users of barbiturates require progressively higher doses to achieve subjective effects as tolerance develops, but they develop little tolerance to respiratory depression. The depressant effects related to barbiturates are dose dependent and range from mild sedation to sleep to coma to death. With larger doses over time and a combination of alcohol and barbiturates, the risk of death increases greatly. The risk of accidental overdose and death resulting from barbiturates has resulted in decreased prescription use, yet barbiturates are still clinically useful for seizure disorders and alcohol withdrawal. Benzodiazepines have replaced barbiturates as the drugs of choice for anxiety-related disorders. Benzodiazepines alone are safer than barbiturates, because an overdose of oral benzodiazepines rarely results in death. However, CNS depressants when taken together (for example, alcohol and benzodiazepines) can result in death.

Psychostimulants

Psychostimulants such as cocaine and amphetamines have a high potential for abuse. Euphoria is the main subjective effect associated with cocaine and amphetamines, leading to addiction. **Cocaine** powder has been snorted (inhaled through the nostrils) for thousands of years, but a more dangerous method now is called freebasing. Cocaine base (freebased cocaine, also called *crack*) is heat stable and is usually cooked in a baking soda solution and smoked. Cocaine hydrochloride (HCl) is diluted or cut before sale and the pure form (*rocks*) is administered intranasally (snorted) or injected intravenously. *Skin popping*, a subcutaneous method used by many people with substance abuse problems to administer drugs, may lead to the formation of abscesses under the skin.

Mild overdose of cocaine produces agitation, dizziness, tremor, and blurred vision. Major overdose produces anxiety, hyperpyrexia, convulsions, ventricular dysrhythmias, severe hypertension, and possible hemorrhagic stroke, angina, or myocardial infarction (MI). The use of cocaine during pregnancy is especially problematic because the drug crosses the placenta and enters the fetal bloodstream. Spontaneous abortion, premature delivery, retardation of intrauterine growth, congenital abnormalities, and fetal addiction can result. Long-term intranasal use of cocaine can cause atrophy of the nasal mucosa, necrosis and perforation of the nasal septum, and lung damage.

With an estimated 1 million injection drug users (IDUs) in the United States, injection drug use requires serious attention, because this new drug use behavior is associated with increased rates of high-risk behaviors (Ropelewski et al., 2011). Recent research indicates that IDUs exhibit significantly higher rates of risky health behaviors. High-risk sexual behaviors were especially prevalent among female crack cocaine injectors. Higher self-reported rates of adverse health outcomes, such as sexually transmitted infections (STIs), hepatitis B and C infections, and other skin and soft-tissue injuries among crack injectors were found, although no differences in rates of HIV infection were self-reported (Ropelewski et al., 2011).

Amphetamine use causes arousal and an elevation of mood with a sense of increased strength, mental capacity, and self-confidence, as well as a decreased need for food and sleep. These stimulant drugs, however, pose a severe health risk to society due to devastating physical and neurologic consequences, including amphetamine-induced mental disorders.

Methamphetamine, which is illegally manufactured, distributed, and abused, is a powerful stimulant drug commonly referred

to as *speed*, *crystal*, *crank*, *go*, and, most recently, *ice*. The manufacture of methamphetamine is a relatively simple process and can be carried out by individuals without special knowledge or expertise in chemistry. In 2007, there were an estimated 529,000 users of methamphetamine ages 12 or older. The number and percentage of nonmedical users of amphetamine and of methamphetamine peaked in 2006 and has remained relatively stable since 2007. In 2012, there were a reported 440,000 methamphetamine users (SAMHSA, 2013b). Methamphetamine is often taken in combination with other drugs such as cocaine and marijuana and, like heroin and cocaine, can be inhaled, injected, ingested, or smoked.

It appears that methamphetamine is an equal-opportunity drug for addiction without regard to gender, age, race, or sexual preferences. The highest percentage rates of methamphetamine use were found among Native Hawaiians or other Pacific Islanders; the lowest rates of methamphetamine use were among Caucasians, Hispanics, Asians, and African Americans (SAMHSA, 2012).

Methamphetamine use has been linked with HIV infection and high rates of STIs in homosexual, heterosexual, and bisexual men and women all over the United States (Carrico et al., 2012; Ropelewski et al., 2011). Heterosexual men and women displayed severe to moderate depressive symptoms due to perceived stigma associated with methamphetamine use, emphasizing the importance of identifying and treating depression in this population (Carrico et al., 2012).

Methamphetamine users experience numerous physical symptoms including weight loss, tachycardia, tachypnea, hyperthermia, insomnia, and muscular tremors. The behavioral and psychiatric symptoms reported most often include violent behavior, repetitive activity, memory loss, paranoia, delusions of reference, auditory hallucinations, and confusion or fright. A psychotic state with hallucinations and paranoia is common with long-term use, requiring treatment similar to other psychotic disorders. The cardiovascular effects of amphetamines are comparable to those of cocaine, including vasoconstriction, tachycardia, hypertension, angina, and dysrhythmias. Tolerance to mood elevation, appetite suppression, and cardiovascular effects develops with amphetamines; however, dependence is more psychologic than physical.

Withdrawal from amphetamines produces dysphoria and craving with fatigue, prolonged sleep, excessive eating, and depression. Although a large number of people cope with amphetamine and polysubstance dependence worldwide, limited evidence exists for effective pharmacologic treatment. In a randomized controlled trial, Tiihonen and colleagues (2012) found that patients treated with naltrexone implants reported decreased heroin and amphetamine use, and improved control of withdrawal symptoms, thus providing promising evidence for an effective treatment for polysubstance dependence.

Opiates

Opiates such as morphine, meperidine, codeine, hydrocodone, and oxycodone are narcotic analgesics. Examples of some common brand names include Vicodin, Percocet, OxyContin, and Darvon. Narcotic analgesics are a type of pain reliever derived from natural or synthetic opiates. A small percentage of individuals are originally exposed to opiates in the context of prescription pain management; however, most people use opiates under social or illicit circumstances. The urban poor constitute the majority of those who abuse opiates, although opiates are used and abused by people of all socioeconomic statuses.

The problem of abuse of and addiction to prescribed narcotics is a major issue for the United States. In 2012, nearly 5 million Americans over the age of 12 reported nonmedical use of prescription pain relievers (SAMHSA, 2013b). According to the 2012 NSDUH, the number of nonmedical users of OxyContin declined from 566,000 in 2010 to 358,000 in 2012. The prevalence of prescription opiate abuse seems to reflect, in part, changes in medication prescribing practices, changes in drug formulations, and fairly easy access via the Internet or from family and friends. Approximately 54% of persons abusing pain relievers reported that the source of the drug was from a friend or relative for free.

Although the use of narcotic analgesics for acute pain management is appropriate and accepted, long-term use has been associated with significant rates of abuse or addiction. OxyContin is a controlled-released form of oxycodone prescribed for the management of moderate to severe pain. OxyContin diversion and abuse has become a major problem in certain areas of the United States, particularly rural areas and Appalachia. Nearly 1.2 million ED visits in 2010 involved illicit use of prescription or over-the-counter (OTC) pharmaceuticals (SAMHSA, 2012). The most frequent opiates included methadone, oxycodone, and combination forms (e.g., hydrocodone with acetaminophen).

Heroin has been abused for many centuries and is usually administered intravenously. It induces a rush or kick that lasts less than a minute, followed by a sense of euphoria lasting several hours. Tolerance develops to the euphoria, respiratory depression, and nausea but not to constipation and miosis.

Physical dependence occurs with long-term use of opiates. Initial withdrawal symptoms such as drug craving, lacrimation, rhinorrhea, yawning, and diaphoresis usually take 10 days to run their course. The second phase of opiate withdrawal lasts for months with insomnia, irritability, fatigue, and potential problems of GI hyperactivity and premature ejaculation. Methadone is a synthetic opiate used to treat chronic pain and addiction to other opiates. Methadone does not hinder one's ability to function productively as other narcotics do and is a viable support for withdrawal (Stuart, 2012).

Hallucinogens

Hallucinogens are also called *psychedelics* and include phencyclidine (PCP), 3,4-methylenedioxymethamphetamine (MDMA), D-lysergic acid diethylamide (LSD), mescaline, dimethyltryptamine (DMT), and psilocin. Psychedelics bring on the same types of thoughts, perceptions, and feelings that occur in dreams. PCP (also called *angel dust* and *peace pill*) was developed in the 1950s as an anesthetic similar to ketamine, but due to severe adverse effects its development for human use was discontinued. PCP is known for inducing violent behavior and negative physical reactions such as seizures, coma, and death. The most common route of administration is smoking tobacco, marijuana, or herbal cigarettes laced with PCP powder or the liquid form of PCP.

MDMA, commonly known as Ecstasy or X, was popular in the 1980s as a recreational drug associated with dance clubs (raves) and has reappeared in recent years as a date rape drug. According to 2010

NSDUH data, the current rate of Ecstasy use among adolescents (ages 12 to 17) reached an all-time low of 0.3% in 2004 but has peaked once again at more than 0.5% (SAMHSA, 2011). Parties where other drugs such as marijuana or alcohol are present may lead to easier access or availability of Ecstasy, thereby increasing the chances for first-time Ecstasy use.

LSD was first used to simulate psychosis. It affects serotonin receptors at multiple sites in the brain and spinal cord. LSD is usually taken orally but can be injected or smoked in tobacco or marijuana cigarettes laced with LSD. An individual's response to a trip (the experience of being high on LSD) cannot be predicted and psychologic effects and flashbacks are common. Serotonin imbalance is thought to affect impulse control and may be responsible for uninhibited sexual responses in women who have been given the drug without their knowledge. Other hallucinogens are similar to LSD but with different potency and course of action. Because physical dependence to hallucinogens does not appear to occur, withdrawal symptoms are not present.

Inhalants

Inhalants are categorized into three types: anesthetics, volatile nitrites, and organic solvents. Nitrous oxide (laughing gas) and ether are the most abused anesthetics. Amyl nitrite, butyl nitrite, and isobutyl nitrite are volatile nitrites used especially by men who have sex with other men to induce venodilation and anal sphincter relaxation. Amyl nitrite is manufactured for medical use, but butyl and isobutyl nitrites are sold for recreational use. Other names for butyl and isobutyl nitrites are *Climax*, *Rush*, and *Locker Room*. Street names for amyl nitrite are *poppers* or *snappers* (Table 6–3). Sudden sniffing death or brain damage can occur whether it is the first, tenth, or hundredth

TABLE 6–3 Common Street Names for Abused Substances

Substance	Street Name
Alcohol	Beer, wine, liquor, cooler, malt liquor, booze, hootch
Amphetamines	Benz, Hearts, biphetamine, Footballs, Dexedrine, Black Beauties, Copilots, Bumble Bees, Bennies, Dominoes, speed, uppers/ups
Barbiturates	Barbs, Beans, Blue Angels, Candy, downers, Goof Balls, Ludes, Nebbies, Reds, Sleepers, Tranks, Yellow Jackets, Yellows
Benzodiazepines	Bennies, Blues, Rainbows, Reds, Sopors, Yellows
Cocaine	Coke, Snow Birds, Nose Candy, Flake, Snow, Blow, White, Big C
Crack	Applejacks, Baseball, Pony, Freebase, Pebbles, Rock, 151, Half Track
Dextromethorphan (DXM)	Dex, Robo, Tussin, Skittles, C-C-C, Triple C, Red Devils
Ecstasy (MDMA)	E, XTC, Adam, Hug Drug, Clarity, Beans, Roll, Molly
Energy drinks	Red Bull, Monster, Cocaine, Rockstar, Blow, Full Throttle, 5 Hour Energy, Crunk (There are more than 500 brands on the market today.)
Foxy/AMT	Foxy Methoxy, fake Ecstasy
GHB	Gamma hydroxybutyrate, Georgia Home Boy, Somatomax, Liquid Ecstasy, Grievous Bodily Harm, Goop, Scoop
Heroin, morphine	Smack, Big H, Mud, Black Tar, Dope, Horse, Junk
Inhalants	Nitrous oxide, Whippets, laughing gas, poppers, huffing, bagging
Ketamine	Cat Valium, Jet, New Ecstasy, Ketaject, Breakfast Cereal, Super K, Special K, Ketalar, Vitamin K
Lysergic acid diethylamide	Acid, Barrels, Microdot, Window Panes, Sugar Cubes, Yellow Sunshine, LSD, tabs, blotter
Marijuana	Weed, pot, reefer, grass, dope, Mary Jane, Aunt Mary, 420, sinsemilla, Chronic, Gangster, ganja, herb, kif
Melatonin and valerian root	Downer Drinks, Drank, Ichill, RelaxZen, Vacation in a Bottle, Blue Cow, Lazy Cakes, Downer Brownies
Methamphetamine	Meth, speed, crank, Crypto, White Cross, tweak, Beanies, Fire, Crystal, glass, ice, Cristy, Quartz, Crink
Methylmethcathinone	4MMC, bath salts, plant food, White Rush, Plantman
Mushrooms	Magic mushrooms, shrooms, caps, psilocin, psilocybin
OxyContin	Oxy, OC/O, Killers, Oxycotton, Oxycodone, Hillbilly Heroin, Poor Man's Heroin, 40, Cotton, 80, Kicker, pills
PCP	Angel dust, peace pill, Ozone, Wack, rocket fuel, embalming fluid, elephant tranquilizers, dust
Ritalin	Methylphenidate, Vitamin R, Smart Drug, West Coast
Rohypnol	Rophies, R2, Rib, Roofies, La Roche, Funitrazepam, date-rape drug, Rope, Roach, Roofenol, Forget Pill
Steroids	Rhoids, Juice, Sauce, Slop
Synthetic cannabinoids	Potpourri, incense, air fresheners, spice, Bocomo dew, K2, K3, etc.
Tobacco	Cigarettes, cigars, pipes, cancer stick, butt, snuff, bone, coffin nail, smoke
Vicodin	Hydrocodone, Vics, hydrocodone bitartrate, Vike, Watson 387, Hydros

The table provides a partial list of common street names for specific drugs but others have been used over the years and there are many new names.

time an individual uses an inhalant. This danger makes the use of inhalants more hazardous than some other substances.

Another danger is the wide assortment of organic solvents that are available to and inhaled by young children. Organic solvents are ingested in three different methods: bagging, huffing, or sniffing. *Bagging* involves pouring the solvent in a plastic bag and inhaling the vapor. *Huffing* refers to pouring the solvent on a rag and inhaling. *Sniffing* refers to inhaling the solvent directly from the container. Common organic solvents are toluene, gasoline, lighter fluid, paint thinner, nail polish remover, benzene, acetone, chloroform, and model airplane glue. The effects from inhaling organic solvents are similar to alcohol, with prolonged use leading to multiple toxicities and an increased risk for abusing other substances. There are no antidotes for these inhalants; therefore, management of overdose is supportive.

●○● INTERPROFESSIONAL CARE

Effective treatment of substance abuse and dependence results from the efforts of an interprofessional team specializing in the treatment of psychiatric and substance abuse disorders. Substance dependency treatment occurs in two major phases: acute and rehabilitation. Therapies may include detoxification, aversion therapy to maintain abstinence, group and/or individual psychotherapy, psychotropic medications, cognitive-behavioral strategies, family counseling, and self-help groups. Patients with substance abuse can be treated in either inpatient or outpatient settings.

Diagnostic Tests

Diagnostic tests can provide valuable information about the patient's physical condition and help determine the course for treatment.

The body fluids most often tested for drug content are blood and urine, although saliva, perspiration, and even hair can be tested. The simplest method of detecting blood alcohol content is to use a Breathalyzer. Urine drug screens (UDSs) and/or blood alcohol levels (BALs) are the main biologic measures for assessment purposes.

Urine drug screening is noninvasive and the preferred method for detecting substances in the body. The length of time that drugs can be found in blood and urine varies according to dosage and metabolic properties of the drug. All traces of the drug may disappear within 24 hours or may still be detectable 30 days later. The psychoactive substance found in marijuana, THC, is stored in fatty tissues (especially the brain and reproductive system) and can be detected in the body for up to 6 weeks (Kneisl & Trigoboff, 2013).

Knowledge of an individual's BAL is helpful in ascertaining level of intoxication, level of tolerance, and whether the person accurately reported recent drinking. At 0.10% (after 5 to 6 drinks in 1 to 2 hours), voluntary motor action becomes clumsy and reaction time is impaired. The degree of impairment varies with gender, weight, and food ingestion. Small women who drink alcohol on an empty stomach will experience intoxication more rapidly than large males who have eaten a full meal. At 0.20% (after 10 to 12 drinks in 2 to 4 hours), function of the motor area in the brain is depressed, causing staggering and ataxia (Kneisl & Trigoboff, 2013). A level above 0.10% without associated behavioral symptoms indicates the presence of tolerance. A BAL greater than 0.08% is considered legal intoxication in most states. High tolerance is a sign of physical dependence. Assessing for withdrawal symptoms is important when the BAL is high.

PRACTICE ALERT!

Medications given for treatment of withdrawal from alcohol are usually not started until the BAL is below a set norm (usually below 0.10%) unless withdrawal symptoms become severe. The BAL may be repeated several times, several hours apart, to determine the body's metabolism of alcohol and when it is safe to give the patient medication to minimize the withdrawal symptoms.

High-Acuity Care

EMERGENCY CARE FOR OVERDOSE

A substance overdose is a life-threatening condition that requires emergency treatment. The care of a patient who has overdosed on any substance is a serious medical emergency. Respiratory depression may require mechanical ventilation. The patient may become severely sedated and difficult to arouse. Every effort must be made to keep the patient awake; however, stupor and coma may often result. A seizure is another serious complication that requires emergency treatment. If the overdose was intentional, the patient must be constantly monitored for further signs of suicidal ideation. Never leave an actively suicidal patient alone. Signs of overdose and withdrawal from major substances are summarized in Table 6–4 along with recommended treatments.

WITHDRAWAL

The patient who is intoxicated on entry into the hospital or treatment center requires **detoxification**, or removal of the substance from the body. The withdrawal syndrome also begins acutely, necessitating support by the interprofessional team.

Withdrawal symptoms from opiates and stimulants can be very unpleasant but are generally not life threatening. The patient experiencing an acute phase of cocaine withdrawal may become suicidal. Common drugs used in the treatment of substance abuse and withdrawal are presented in Table 6–5.

Alcohol and CNS depressants such as benzodiazepines and barbiturates share the same withdrawal syndrome. Manifestations of withdrawal syndrome include tremor, agitation, and anxiety, along with excessive autonomic nervous system activity: tachycardia, a rapid respiratory rate, hyperthermia, and insomnia (Schuckit, 2012). Early signs of withdrawal appear within a few hours following cessation of the drug, peak after 24 to 48 hours, and then rapidly improve. Patients who have used higher quantities of alcohol, those who have abused additional drugs, and those with chronic diseases may experience a withdrawal seizure or *delirium tremens (DTs)* (Schuckit, 2012). Delirium tremens is a medical emergency that usually occurs 2 to 5 days following alcohol withdrawal and persists 2 to 3 days. Patients with DTs experience disorientation, paranoid delusions, visual hallucinations, and marked withdrawal symptoms.

In managing alcohol withdrawal, the goal is to minimize adverse outcomes, such as injury, seizures, delirium, and mortality. The patient is assessed for gastrointestinal bleeding, liver failure, cardiac dysrhythmias, and glucose and fluid and electrolyte imbalances. Nutrition is assessed, and multiple B vitamins are administered

TABLE 6–4 Signs and Treatment of Overdose and Withdrawal

	Overdose		Withdrawal	
Drug	**Manifestations**	**Treatment**	**Manifestations**	**Treatment**
CNS Depressants: Alcohol Barbiturates Benzodiazepines	Cardiovascular or respiratory depression or arrest (mostly with barbiturates) Coma Shock Convulsions Death	Frequent VS and cardiorespiratory assessment *If awake:* Keep awake Induce vomiting Activated charcoal to absorb drug *Coma:* Clear airway, intubate IV fluids Gastric lavage Seizure precautions Possible hemo- or peritoneal dialysis	Nausea and vomiting Tachycardia Diaphoresis Anxiety or agitation Tremors Marked insomnia Grand mal seizures Delirium (after 5–15 years of heavy use)	Carefully titrated detoxification with similar drug
Stimulants: Cocaine-crack Amphetamines	Respiratory distress Ataxia Hyperpyrexia Convulsions Coma Stroke Myocardial infarction (MI) Death	Antipsychotics Management for 1. Hyperpyrexia 2. Convulsions 3. Respiratory distress 4. Hypertension 5. Dysrhythmias	Fatigue Depression Agitation Apathy Anxiety Sleepiness Disorientation Lethargy Craving	Antidepressants (desipramine) Dopamine agonist (bromocriptine)
Opiates: Heroin Meperidine Morphine Methadone	Pupillary constriction Bradycardia Respiratory depression-arrest Coma Shock Convulsions Death	Narcotic antagonist (nalozone [Narcan]) quickly reverses CNS depression	Yawning, insomnia Irritability Rhinorrhea Panic Diaphoresis Cramps Nausea and vomiting Muscle aches Chills and fever Lacrimation Diarrhea	Methadone tapering Clonidine-naltrexone detoxification Buprenorphine substitution
Hallucinogens:		Low stimuli with minimal light, sound, activity	No pattern of withdrawal	
Lysergic acid diethylamide (LSD)	Panic episode Psychosis Brain damage	Have one person "talk down patient," reassure Speak slowly and clearly Diazepam for anxiety		
Phencyclidine piperidine (PCP)	Agitation Possible hypertensive crisis Respiratory arrest Hyperthermia Seizures Encephalopathy and coma	Gastric lavage Acidify urine to help excrete drug Minimal stimulus Do NOT attempt to talk down, speak slowly in low voice Diazepam or haloperidol (Haldol)		
Inhalants: Volatile solvents such as butane, paint thinner, airplane glue, or nail polish remover	*Intoxication:* Excitation Drowsiness Disinhibition Staggering Light-headedness Agitation *Adverse effects:* Damage to nervous system Death	Support affected systems	No pattern of withdrawal	
Nitrates	Enhance sexual pleasure	Neurologic symptoms may respond to vitamin B_{12} and folate		
Anesthetics such as nitrous oxide	Giggling, laughter Euphoria	Chronic users may experience polyneuropathy and myelopathy		

TABLE 6–5 Drugs Used in the Treatment of Substance Withdrawal/Abuse

Drug	Dose	Purpose
Benzodiazepines		
Chlordiazepoxide (Librium) *Diazepam* (Valium) Oxazepam (Serax) *Lorazepam* (Ativan)	15–100 mg 4–40 mg 30–120 mg 2–6 mg	Diminishes anxiety and has anticonvulsant qualities to provide safe withdrawal. May be ordered q4h or prn to manage adverse effects from withdrawal; then dose is tapered to zero.
Vitamins		
Thiamine (Vitamin B_1) Folic acid Multivitamins	100 mg/day 1 mg/day 1 tab/cap daily	Prevents Wernicke's encephalopathy. Corrects vitamin deficiency caused by heavy long-term alcohol abuse.
Anticonvulsants		
Phenobarbital Magnesium sulfate	30–320 mg 1 g q6h	For seizure control and sedation. Reduces postwithdrawal seizures.
Abstinence Medications		
Disulfiram (Antabuse) Naltrexone (ReVia) Acamprosate (Campral) Methadone *Buprenorphine/naloxone (Suboxone)*	250 mg/day 50 mg/day 300 mg/tid 40 mg/day 4/1–24/6 mg/day	Prevents breakdown of alcohol. Diminishes cravings for alcohol and opioids. Diminishes cravings for alcohol. Blocks craving for heroin. Blocks craving for opioids.
Antidepressants		
Fluoxetine (Prozac) *Sertraline* (Zoloft)	20–80 mg/day 50–200 mg/day	Enhances and stabilizes mood and diminishes anxiety.

Note: Medications identified in *italics* are among the 200 most frequently prescribed drugs in the U.S.

orally. Thiamine (vitamin B_1) supplements are continued for a week or longer to prevent Wernicke's encephalopathy.

Close monitoring is essential to ensure protection of the patient. Critical care monitoring may be indicated to manage alcohol withdrawal delirium, particularly when very high doses of benzodiazepines are needed, or when there are significant concurrent medical conditions. Medications such as benzodiazepines are effectively used to manage symptoms associated with alcohol withdrawal and prevent serious adverse effects, such as seizures and aggressive behavior. Antipsychotic medications such as haloperidol (Haldol) or olanzapine (Zyprexa) may be used, although they are less effective in suppressing withdrawal seizure activity (Schuckit, 2012).

Rehabilitation

Rehabilitation from problems of substance abuse begins when detoxification is complete and the patient is abstinent. This phase of treatment continues indefinitely.

Medications used to treat alcoholism are disulfiram (Antabuse), naltrexone (ReVia, Depade), and acamprosate (Campral). Disulfiram is a form of aversion therapy that prevents the breakdown of alcohol, causing physical illness (intense vomiting) if taken while drinking alcohol. All forms of alcohol, including OTC cough and cold preparations, must be avoided.

Naltrexone (Vivitrol) is used along with counseling and social support to help people who have stopped drinking large amounts of alcohol or who have stopped abusing opiate medications or street drugs to avoid abusing these substances again. Naltrexone can help reduce the craving for alcohol by blocking the pathways to the brain that trigger a feeling of pleasure when alcohol and narcotics are used. Patients should discontinue all opiates 7 to 10 days before starting on naltrexone. Because naltrexone blocks opiate receptors, patients should avoid taking any narcotics, such as codeine, morphine, or heroin, while on naltrexone. It is recommended that patients wear a medical alert bracelet stating they are on naltrexone, in case of emergency medical treatment. While on disulfiram or naltrexone, psychosocial treatments such as Alcoholics Anonymous meetings, individual counseling, or group therapy are important, because the desire to take a break from treatment can overcome the patient's motivation to continue taking the medication. Naltrexone also is available by injection, which can improve compliance.

Acamprosate is another medication prescribed for patients who want to abstain from alcohol. The chemical structure of acamprosate is similar to GABA and glutamate neurotransmitters. Acamprosate is thought to block glutamate receptors while simultaneously activating GABA receptors in the brain, thus stabilizing the chemical imbalance that is disrupted by alcoholism. Acamprosate is fairly effective in reducing cravings of alcohol-dependent patients when used in combination with psychosocial and other supportive interventions.

Buprenorphine (Buprenex, Subutex) is used solely for the treatment of opioid dependence. Buprenorphine has been used in detoxification treatment since the early 1980s. Suboxone (buprenorphine/naloxone) binds tightly to mu-opioid receptors and is not easily displaced by opioid antagonists, causing a longer duration of action.

This may explain the lack of significant withdrawal symptoms upon cessation of the drug and may also contribute to its effectiveness in opioid detoxification (Steele & Cunningham, 2012). However, buprenorphine treatment has some limitations. Limited numbers of physicians are certified to treat opioid dependence with Suboxone, which makes this type of treatment difficult to access. It is also more expensive than traditional treatment with older medications such as clonidine (Steele & Cunningham, 2012). In addition, patients complain about the taste of the sublingual (SL) tablet, the time it takes for the tablet to dissolve, and the difficulty of traveling with SL tablets. A new form of delivery (Suboxone Film) is now marketed in individual unit dose packets, and is reported to taste better and dissolve faster than the tablets.

MEMORY CUE

Alcohol abuse is a disease with a genetic propensity, passed from generation to generation through family members' DNA. The three main medications currently available to help alcohol-dependent patients maintain sobriety can be easily remembered by using the acronym DNA: Disulfiram, Naltrexone, and Acamprosate. Disulfiram interacts with alcohol to cause adverse effects, whereas naltrexone and acamprosate help to reduce the craving for alcohol.

●○● NURSING CARE

Nurses may interact with patients experiencing substance abuse or substance dependence in a variety of settings. Patients admitted to acute care settings with an acute illness or exacerbation of a chronic disease may have co-existing substance abuse or dependence. Patients with substance abuse or dependence have impaired senses and risk-taking behaviors that lead to injuries from falls and accidents requiring medical attention. Nurses will frequently encounter these patients in hospital EDs as well as medical and surgical units. Box 6–1 summarizes key safety considerations for hospitalized patients with substance abuse problems. Nurses also may encounter patients in an alcohol and drug abuse (ADA) treatment program where patients are hospitalized for 20 to 30 days for detoxification and in-patient therapy. These patients may be voluntarily admitted but many are court-ordered to undergo treatment after charges of driving under the influence (DUI) or driving while intoxicated (DWI). Occupational nurses and community health nurses will also interact with patients who have substance abuse problems in employee assistance programs and community health departments. Urgent and ambulatory care centers and pain clinics are other settings in which patients with substance abuse disorders will frequently appear for minor health problems associated with chronic disorders related to substance abuse or dependence.

BOX 6–1 Safety Considerations for Hospitalized Patients with Substance Abuse

- Closely monitor patients admitted for a drug overdose for signs of suicidal ideation.
- Never leave an actively suicidal patient alone.
- During acute alcohol withdrawal (first 72 hours), assess for withdrawal symptoms and administer benzodiazepines as ordered.
- Monitor unconscious patients closely for possibility of aspiration. Never place an intoxicated, unconscious patient in a supine position.
- Seizure precautions are indicated for patients experiencing acute withdrawal symptoms.
- Expect signs of delirium tremens to occur after 72 hours of abstinence from alcohol.
- Monitor patients for signs of hallucinations, delusions, or altered sensory perceptions that may lead to injuries.
- Assess for fall and choking risk. Provide one-to-one assistance as needed.
- Maintain fluid and electrolyte balance.

Health Promotion

Nursing care of the patient with substance abuse or dependence is challenging and requires a nonjudgmental atmosphere promoting trust and respect. Health promotion efforts are aimed at preventing drug use among children and adolescents and reducing the risks among adults. Adolescence is the most common phase for the first experience with drugs (Stuart, 2012); therefore, teenagers are a vulnerable population, often succumbing to peer pressure. Healthy lifestyles, parental support, stress management, good nutrition, and information about ways to steer clear of peer pressure are important topics for the nurse to provide in school programs.

Nurses should provide adults with information on healthy coping mechanisms, relaxation, and stress reduction techniques to decrease the risks of substance abuse. Nurses have a responsibility to educate their patients about the physiologic effects of substances on the body as well as ways to manage stress and anxiety. Nurses must encourage and support periods of abstinence while assisting patients to make major changes in lifestyles, habits, relationships, and coping methods. See Nursing Care of the Older Adult for meeting the individualized needs of older patients with substance abuse problems.

Assessment

A comprehensive approach to the assessment of substance use is essential to ensure adequate and appropriate intervention. Use therapeutic communication techniques to establish trust prior to the assessment process. Questions should be asked in a nonthreatening, matter-of-fact manner, phrased so as not to imply wrongdoing. For instance, a nonthreatening question such as "How much alcohol do you drink?" is preferable to the judgmental question "You don't drink too much alcohol, do you?" Open-ended questions that elicit more than a simple yes or no answer help to determine the direction of future counseling. Examples of open-ended questions are provided in Box 6–2. Three important areas to assess are a history of the patient's past substance use, medical and psychiatric history, and the presence of psychosocial concerns.

Substance Use History

A thorough history of the patient's substance use is important to ascertain the possibility of tolerance, physical dependence, or withdrawal syndrome. The following questions are helpful in eliciting a pattern of substance use behavior:

- How many substances has the patient used simultaneously (**polysubstance abuse** or simultaneous use of many substances)?

NURSING CARE OF THE OLDER ADULT

Substance Abuse in the Older Adult

Substance abuse in older adults is likely to increase over subsequent decades as baby boomers reach retirement age. People of any age can have substance abuse problems, but the consequences in older adults can be more critical (Briggs et al., 2011). Falls and accidents can rob older adults of their independence, and substance abuse increases the risk of falls by affecting alertness, judgment, coordination, and reaction time. In addition, older adults (especially older women) are more likely than younger people to use prescription or OTC medicines, which can be harmful when mixed with alcohol and/or illicit drugs (Outlaw et al., 2012). Alcohol and drug abuse can also make certain medical problems hard to diagnose, for example, by dulling a pain sensation that might warn of a heart attack.

Substance abuse and dependence is less likely to be recognized and can be difficult to detect in older adults because many of the symptoms of abuse (e.g., insomnia, depression, loss of memory, anxiety, musculoskeletal pain) may be confused with conditions commonly seen in older patients (Briggs et al., 2011). Healthcare professionals frequently attribute these symptoms to the aging process and fail to address the misuse and abuse of substances. Often, the *symptoms* of substance abuse are treated rather than confronting the abuse itself. Alcohol negatively interacts with the natural aging process to increase risks for injuries, hypertension, cardiac dysrhythmias, cancers, gastrointestinal problems, cognitive deficits, bone loss, and emotional challenges such as depression in older adults (Outlaw et al., 2012). Because depression and alcohol abuse are the most frequently found disorders in completed suicides, nurses should routinely screen older adults for both substance abuse and mental disorders.

- How often, how much, and when did the patient first use the substance(s)?
- Is there a history of blackouts, delirium, or seizures?
- Is there a history of withdrawal syndrome, overdoses, and complications from substance use?
- Has the patient ever been treated in an alcohol or drug abuse clinic?
- Has the patient ever been arrested for DUI or charged with any criminal offense while using drugs or alcohol?
- Is there a family history of drug or alcohol use?

Medical and Psychiatric History

The patient's medical history is an important area for assessment and should include the existence of any concomitant physical or mental condition (e.g., HIV, hepatitis, cirrhosis, esophageal varices, pancreatitis, gastritis, Wernicke-Korsakoff syndrome, depression, schizophrenia, anxiety, or personality disorder). Ask about prescribed and OTC medications as well as any allergies or sensitivity to drugs. A brief overview of the patient's current mental status is also significant.

BOX 6–2 Examples of Open-Ended Questions for Assessment

- On average, how many days per week do you drink alcohol or use drugs?
- On a typical day when you use drugs or alcohol, how many hits or drinks do you have?
- What is the greatest number of drinks you have had at any one time during the past month?
- What drug(s) did you take before coming to the hospital or clinic?
- How long have you been using the substances?
- How often and how much do you usually use?
- What kinds of problems has substance use caused for you, your family, friends, finances, and health?

- Is there a history of abuse (physical or sexual) or family violence?
- Has the patient ever tried to commit suicide?
- Is the patient currently having suicidal or homicidal ideation?

Psychosocial Issues

Information about the patient's level of stress and other psychosocial concerns can help in the assessment of substance use problems.

- Has the patient's substance use affected his or her ability to hold a job?
- Has the patient's substance use affected relationships with spouse, family, friends, or coworkers?
- How does the patient usually cope with stress?
- Does the patient have a support system that helps in times of need?
- How does the patient spend his or her leisure time?

Screening Tools

Several screening tools may help the nurse determine the degree of severity of substance abuse or dependence. These screening tools provide a nonjudgmental, brief, and easy method to ascertain patterns of substance abuse behaviors:

- The *Michigan Alcohol Screening Test (MAST) Brief Version* (Pokorny et al., 1972) is a 10-question, dichotomous, self-administered questionnaire that takes 10 to 15 minutes to complete. An answer of yes to three or more questions indicates a potentially dangerous pattern of alcohol abuse.
- The *CAGE questionnaire* (Ewing, 1984) is more useful than the MAST when the patient may not recognize he or she has an alcohol problem or is uncomfortable acknowledging it. This questionnaire is designed to be a self-report of drinking behavior or may be administered by a professional. One affirmative response indicates the need for further discussion and follow-up. Two or more yes answers signify a problem with alcohol that may require treatment.
  - Have you ever felt you should ***C****ut* down on your drinking?
  - Have people ***A****nnoyed* you by criticizing your drinking?
  - Have you ever felt bad or ***G****uilty* about your drinking?
  - Have you ever had a drink first thing in the morning (an "***Eye-opener***") to steady your nerves or to get rid of a hangover?
- The *Brief Drug Abuse Screening Test (B-DAST)* (Skinner, 1982) is a yes/no self-administered questionnaire that is useful in identifying people who are possibly addicted to drugs other than alcohol. A positive response to one or more questions suggests significant drug abuse problems and warrants further evaluation. Because self-report tools are not always answered truthfully, all patients who screen positive for drug addiction should be evaluated according to other diagnostic criteria.

Physical Assessment

Focused physical assessment of the patient with substance abuse includes level of consciousness, orientation to time, place and person,

and mental status. Observe the patient's apparent general health (height and weight, balance, gait, skin color and condition, hair and nails), nutritional status, and for evidence of recent or past trauma. Obtain vital signs, including orthostatic vital signs, and blood glucose. Assess skin turgor and for presence of edema.

Withdrawal Assessment Tools

Nurses working in medical-surgical units, psychiatric units, and special substance abuse units routinely care for patients experiencing acute alcohol or opiate withdrawal. Several assessment tools are available to determine the severity of withdrawal symptoms and indicate the need for pharmacologic treatment to manage withdrawal symptoms. A symptom-triggered approach to the administration of benzodiazepines during alcohol withdrawal results in less total medication use and requires a shorter duration of treatment (Donnelly et al., 2012). Examples of withdrawal assessment tools include the following:

- The *Clinical Institute Withdrawal Assessment of Alcohol-Revised (CIWA-Ar)* (Sullivan et al., 1989) (Figure 6–2 ■) is used widely in clinical and research settings for initial assessment and ongoing monitoring of alcohol withdrawal signs and symptoms (Keys, 2011). The CIWA-Ar scale is a validated 10-item assessment tool that can be used to monitor and medicate patients going through alcohol withdrawal. The CIWA-Ar assesses for several alcohol withdrawal symptoms (e.g., high blood pressure, rapid pulse and respirations, tremors, insomnia, irritability, sweating, and convulsions) and results in a score that is used to direct the administration of benzodiazepines or other drugs to relieve associated symptoms of withdrawal and prevent seizures. A score of 8 points or fewer corresponds to mild withdrawal symptoms. Scores of 9 to 15 points indicate moderate withdrawal, while a score of 16 or greater denotes severe withdrawal and an increased risk of delirium tremens and seizures.
- The *Clinical Opiate Withdrawal Scale (COWS)* (Wesson & Ling, 2003) rates 11 common signs or symptoms of opiate withdrawal. The summed total score of the 11 items can be used to assess the intensity of opiate withdrawal and determine the extent of a patient's physical dependence on opioids. A score of less than 12 on the COWS indicates mild or no opiate withdrawal symptoms, whereas a score of 13 or more indicates moderate to severe withdrawal symptoms.

Diagnoses, Outcomes, and Interventions

The primary nursing diagnoses, outcomes, and interventions for patients with substance abuse problems are listed in this section. Implications for nursing care in acute and home care settings are combined in this discussion. See the Case Study & Nursing Care Plan on page 112 for the patient experiencing withdrawal from alcohol.

Priorities of Care

Monitoring safety is a key component of care, as is protecting the patient from risk for injury.

Risk for Injury

Expected Outcome: Patient will be free of injury as evidenced by steady gait and absence of subsequent falls.

Evidence for Nursing Care

The Patient with Substance Use Disorders

Selected resources that nurses may find helpful when planning evidence-based nursing care follow.

- Michigan Quality Improvement Consortium. (2011). *Screening, diagnosis and referral for substance use disorders.* Southfield, MI: Michigan Quality Improvement Consortium.
- Naegle, M. (2012). Substance misuse and alcohol use disorders. In: M. Boltz, E. Capezuti, T. Fulmer, and D. Zwicker (Eds.). *Evidence-based geriatric nursing protocols for best practice* (4th ed.). New York, NY: Springer Publishing Company.

- Assess patient's level of consciousness and orientation to determine specific risks to safety. *Knowledge of the patient's level of cognitive functioning is essential to the development of an appropriate plan of care.*
- Obtain a drug history as well as urine and blood samples for laboratory analysis of substance content. *Subjective history is often not accurate and knowledge regarding substance use is important for accurate assessment.*
- Place patient in a quiet, private room to decrease excessive stimuli, but do not leave patient alone if excessive hyperactivity or suicidal ideation is present. *Excessive stimuli increase patient's agitation.*
- Frequently orient patient to reality and the environment, ensuring that potentially harmful objects are stored outside the patient's access. *Patient may harm self or others if disoriented and confused.*
- Monitor vital signs every 15 minutes until stable and assess for signs of intoxication or withdrawal. *The most reliable information about withdrawal symptoms is vital sign measurements; they provide information about the need for medication during detoxification.*

Ineffective Coping

Expected Outcomes: Patient will express true feelings associated with using substances and identify healthy adaptive methods of coping with stressful situations.

- Establish trusting relationship. Be genuine, honest, and respectful of the patient. Keep all promises and convey an attitude of acceptance of the patient. *Trust is essential to the nurse–patient relationship. The development of a nonjudgmental, therapeutic nurse–patient relationship is essential to gain the patient's trust.*
- Encourage patient participation in therapeutic group activities such as co-occurring disorder group or Alcoholics Anonymous meetings with other people who are experiencing or have experienced similar problems. *Peer feedback is often more accepted than feedback from authority figures.*
- Set limits on manipulative behavior and maintain consistency in responses. *Patient is unable to set own limits and must begin to accept responsibility without being manipulative.*
- Encourage patient to verbalize feelings, fears, or anxieties. Use attentive listening and validate patient's feelings with observations or

Clinical Institute Withdrawal Assessment of Alcohol Scale, Revised (CIWA-Ar)

Patient:_____ **Date:** _____ **Time:** _____ (24 hour clock, midnight = 00:00)

Pulse or heart rate, taken for one minute:_____ **Blood pressure:**_____

NAUSEA AND VOMITING -- Ask "Do you feel sick to your stomach? Have you vomited?" Observation.
0 no nausea and no vomiting
1 mild nausea with no vomiting
2
3
4 intermittent nausea with dry heaves
5
6
7 constant nausea, frequent dry heaves and vomiting

TACTILE DISTURBANCES -- Ask "Have you any itching, pins and needles sensations, any burning, any numbness, or do you feel bugs crawling on or under your skin?" Observation.
0 none
1 very mild itching, pins and needles, burning or numbness
2 mild itching, pins and needles, burning or numbness
3 moderate itching, pins and needles, burning or numbness
4 moderately severe hallucinations
5 severe hallucinations
6 extremely severe hallucinations
7 continuous hallucinations

TREMOR -- Arms extended and fingers spread apart. Observation.
0 no tremor
1 not visible, but can be felt fingertip to fingertip
2
3
4 moderate, with patient's arms extended
5
6
7 severe, even with arms not extended

AUDITORY DISTURBANCES -- Ask "Are you more aware of sounds around you? Are they harsh? Do they frighten you? Are you hearing anything that is disturbing to you? Are you hearing things you know are not there?" Observation.
0 not present
1 very mild harshness or ability to frighten
2 mild harshness or ability to frighten
3 moderate harshness or ability to frighten
4 moderately severe hallucinations
5 severe hallucinations
6 extremely severe hallucinations
7 continuous hallucinations

PAROXYSMAL SWEATS -- Observation.
0 no sweat visible
1 barely perceptible sweating, palms moist
2
3
4 beads of sweat obvious on forehead
5
6
7 drenching sweats

VISUAL DISTURBANCES -- Ask "Does the light appear to be too bright? Is its color different? Does it hurt your eyes? Are you seeing anything that is disturbing to you? Are you seeing things you know are not there?" Observation.
0 not present
1 very mild sensitivity
2 mild sensitivity
3 moderate sensitivity
4 moderately severe hallucinations
5 severe hallucinations
6 extremely severe hallucinations
7 continuous hallucinations

ANXIETY -- Ask "Do you feel nervous?" Observation.
0 no anxiety, at ease
1 mild anxious
2
3
4 moderately anxious, or guarded, so anxiety is inferred
5
6
7 equivalent to acute panic states as seen in severe delirium or acute schizophrenic reactions

HEADACHE, FULLNESS IN HEAD -- Ask "Does your head feel different? Does it feel like there is a band around your head?" Do not rate for dizziness or lightheadedness. Otherwise, rate severity.
0 not present
1 very mild
2 mild
3 moderate
4 moderately severe
5 severe
6 very severe
7 extremely severe

AGITATION -- Observation.
0 normal activity
1 somewhat more than normal activity
2
3
4 moderately fidgety and restless
5
6
7 paces back and forth during most of the interview, or constantly thrashes about

ORIENTATION AND CLOUDING OF SENSORIUM -- Ask "What day is this? Where are you? Who am I?"
0 oriented and can do serial additions
1 cannot do serial additions or is uncertain about date
2 disoriented for date by no more than 2 calendar days
3 disoriented for date by more than 2 calendar days
4 disoriented for place/or person

Total **CIWA-Ar** Score _____
Rater's Initials _____
Maximum Possible Score 67

*The **CIWA-Ar** is not* copyrighted and may be reproduced freely. This assessment for monitoring withdrawal symptoms requires approximately 5 minutes to administer. The maximum score is 67 (see instrument). Patients scoring less than 10 do not usually need additional medication for withdrawal.

CASE STUDY & NURSING CARE PLAN A Patient Withdrawing from Alcohol

George Russell, age 58, fell at home and broke his arm. His wife took him to the ED and an open reduction and internal fixation (ORIF) of his right wrist was performed under general anesthesia in the operating room. He was admitted to the postoperative unit for observation following surgery because he required large amounts of anesthesia during the procedure.

Mr. Russell has a ruddy complexion and looks older than his stated age. He discloses that he was laid off from his factory job 2 years ago and has been working odd jobs until last week when he was hired by a local assembly plant. His father was a recovering alcoholic and his 30-year-old son has been treated for alcohol abuse in the past. Mr. Russell states that he knows alcoholism runs in the family, but he feels that he has his drinking under control. However, he cannot remember the events that led up to his fall and how he might have broken his arm.

ASSESSMENT

During the nursing assessment, Mr. Russell is hesitant to provide information and refuses to make eye contact. Prior to surgery, a BAL was drawn because the ED nurse detected alcohol on his breath. His BAL was 0.40%, which is 5 times the legal limit for intoxication in many states. His vital signs are within the upper limits of normal, but he is confused and disoriented with slurred speech and a slight tremor of the hands. He is 6 feet tall and weighs 140 pounds. His total albumin is 2.9 mg and he has elevated liver enzymes. His wife states that he rarely eats the meals she prepares because he is usually drinking and has no appetite for food.

Clinical Reasoning in Patient Care

1. What factors could be contributing to Mr. Russell's unhealthy use of alcohol as a coping mechanism?
2. What safety issues should be addressed with Mr. Russell?
3. What teaching should be done to reduce Mr. Russell's future risk of alcohol-related diseases?

DIAGNOSES

- *Ineffective Coping*
- *Risk for Injury*
- *Imbalanced Nutrition: Less Than Body Requirements*

EXPECTED OUTCOMES

- Patient will express his true feelings associated with using alcohol as a method of coping with stressful situations.
- Patient will identify three adaptive coping mechanisms he can use as alternatives to alcohol in response to stress.
- Patient will verbalize the negative effects of alcohol and agree to seek professional help with his drinking.
- Patient will be free of injury as evidenced by steady gait and absence of subsequent falls.
- Patient will gain 0.45 kg (1 lb) per week without evidence of increased fluid retention. Serum albumin levels will return to normal range.

PLANNING AND IMPLEMENTATION

- Establish trusting relationship with patient and spend time with him discussing his feelings, fears, and anxieties.
- Consult with a physician regarding a schedule for medications during detoxification and observe for signs of withdrawal syndrome.
- Explain the effects of alcohol abuse on the body and emphasize that prognosis is closely associated with abstinence.
- Teach a relaxation technique that the patient feels is useful.
- Provide community resource information about self-help groups and, if patient is receptive, a list of meeting times and phone numbers.
- Consult with a dietitian to determine number of calories needed to provide adequate nutrition and realistic weight gain. Document intake, output, and calorie count.
- Consult with physician to begin vitamin B_1 (thiamine) and dietary supplements.

EVALUATION

Mr. Russell was discharged from the postoperative unit without complications. He successfully underwent detoxification and contacted the employee assistance program (EAP) at his new place of employment. He was on medical leave while his arm completely healed and now attends Alcoholics Anonymous meetings 5 days a week. He reports that he enjoys taking long walks with his wife in the warm weather and that his appetite has returned. He has gained 10 pounds in the past 6 weeks and feels physically better than he has in many years.

Clinical Reasoning in Patient Care

4. Explain why it would be important to include questions about Mr. Russell's medication history and his use of other medications during the initial nursing assessment.
5. Mr. Russell asks you to explain the risks of taking disulfiram (Antabuse). What should you tell him?
6. Develop a care plan for Mr. Russell for the nursing diagnosis of *Imbalanced Nutrition: Less Than Body Requirements.* Why is this necessary?

See Evaluating Your Response in Appendix B.

statements that acknowledge feelings. *Verbalization of feelings helps patient to develop insight into behaviors and long-standing problems.*

- Encourage the patient to focus on strengths and accomplishments rather than weaknesses and failures. *Minimize attention to negative ruminations.*
- Encourage participation in therapeutic group activities. Offer recognition and positive feedback for actual achievements. *Success and recognition increase self-esteem.*

Imbalanced Nutrition: Less Than Body Requirements

Expected Outcomes: Patient will gain 0.45 kg (1 lb) per week without evidence of increased fluid retention. Serum albumin levels will return to normal range.

- Administer vitamins and dietary supplements as ordered by physician. *Vitamin B_1 is necessary to prevent complications from chronic alcoholism such as Wernicke's syndrome.*
- Monitor lab work (e.g., total albumin, complete blood count, urinalysis, electrolytes, and liver enzymes) and report significant changes to physician. *Objective laboratory tests provide necessary information to determine the extent of malnourishment.*
- Collaborate with dietitian to determine number of calories needed to provide adequate nutrition and realistic weight gain. Document intake, output, and calorie count. Weigh daily if condition warrants. *Weight loss or gain is important assessment information so that an appropriate plan of care can be developed.*
- Teach the importance of adequate nutrition by explaining the USDA MyPlate food guide and relating the physical effects of

malnutrition on body systems. *Patient may have inadequate knowledge of proper nutritional habits.*

Readiness for Enhanced Knowledge

Expected Outcome: Patient will verbalize the negative effects of substance abuse and agree to seek professional help to quit abusing substances.

- Assess the patient's level of knowledge and readiness to learn the effects of drugs and alcohol on the body. *Baseline assessment is required to develop appropriate teaching material.*
- Develop a teaching plan that includes measurable objectives. Include significant others, if possible. *Lifestyle changes often affect all family members.*
- Begin with simple concepts and progress to more complex issues. Use interactive teaching strategies and written materials appropriate to the patient's educational level. Include information on physiologic effects of substances, the propensity for physical and psychologic dependence, and the risks to a fetus if the patient is pregnant. *Active participation and handouts enhance retention of important concepts.*
- Teach assertiveness techniques and effective communication techniques such as the use of "I feel" rather than "You make me feel" statements. *Previous patterns of communication may have been aggressive and accusatory, causing barriers to interpersonal relationships.*

Acute Confusion

Expected Outcome: Patient will be alert and oriented to time, place, and person and free of hallucinations or delusions.

- Observe for withdrawal symptoms. Monitor vital signs. Provide adequate nutrition and hydration. Place on seizure precautions. *These actions provide supportive physical care during detoxification.*
- Assess level of orientation frequently. Orient and reassure the patient of safety in presence of hallucinations, delusions, or illusions. *Patient may be frightened.*
- Explain all interventions before approaching the patient. Avoid loud noises and talk softly to the patient. Decrease external stimuli by dimming lights. *Excessive stimuli increase agitation.*
- Administer prn medications according to detoxification schedule. *Benzodiazepines help to minimize the discomfort of withdrawal symptoms.*
- Use simple, step-by-step instructions and face-to-face interaction when communicating with the patient. *Patient may be confused or disoriented.*
- Express reasonable doubt if the patient relays suspicious or paranoid beliefs. Reinforce accurate perception of people or situations. *It is important to communicate that you do not share that false belief as reality.*
- Do not argue with delusions or hallucinations. Convey acceptance that the patient believes a situation to be true, but that the nurse does not see or hear what is not there. *Arguing with the patient or denying the belief serves no useful purpose, because delusions are not eliminated.*
- Talk to the patient about real events and real people. Respond to feelings and reassure the patient that he or she is safe from harm. *Discussions that focus on the delusions may aggravate the condition. Verbalization of feelings in a nonthreatening environment may help the patient develop insight.*

Delegating Nursing Care Activities

As appropriate and allowed by the designated duties and responsibilities of unlicensed assistive personnel, nursing care activities such as monitoring vital signs, assessing for symptoms of withdrawal, obtaining daily weights, assisting with ADLs, and providing for distraction and socialization for the patient with acute withdrawal symptoms may be delegated.

Continuity of Care

The community provides many options for treating substance abuse including a mixture of individual, group, and family therapy. Medical detoxification can occur in hospitals, psychiatric units, special substance abuse units, methadone clinics, or outpatient settings. Less restrictive environments include residential rehabilitation programs, halfway houses, and partial hospitalization programs. These programs provide structured environments for individuals recovering from substance abuse problems while maintaining a viable presence in the community. In addition, patients can obtain vocational counseling, become involved in self-help groups such as Alcoholics Anonymous or Narcotics Anonymous, and receive drug and health education.

Teaching the patient and family includes the following:

- The negative effects of substance abuse, including physical and psychologic complications of substance abuse
- The signs of relapse and the importance of after-care programs and self-help groups to prevent relapse
- Information about specific medications that help to reduce the craving for alcohol (naltrexone [ReVia] and acamprosate [Campral]) and maintain abstinence (disulfiram [Antabuse]), including their potential side effects, possible drug interactions, and any special precautions to be taken (e.g., avoiding OTC medications such as cough syrup that may have alcohol content)
- Ways to manage stress including techniques such as progressive muscle relaxation, abdominal breathing techniques, imagery, meditation, and effective coping skills.

In addition, suggest the following resources:

- Alcoholics Anonymous, Narcotics Anonymous, and other self-help groups
- Employee assistance programs
- Individual, group, and/or family counseling
- Community rehabilitation programs
- National Alliance on Mental Illness.

MEMORY CUE

Patients are at highest risk for relapse within the first few months after stopping the abused substance. An acronym that can assist the patient in recognizing behaviors that lead to relapse is HALT: hungry, angry, lonely, and tired. Nurses should emphasize the importance of a balanced diet, adequate sleep, healthy recreation activities, and a caring support system to prevent relapse.

IMPAIRED NURSES

By the nature of their roles, dentists, pharmacists, physicians, and nurses are in frequent contact with drugs and are at high risk for substance abuse problems. Healthcare professionals have a higher risk for opiate abuse than other professionals due to the accessibility of opiates in their line of work (Horton-Deutsch et al., 2011). Nurses experience many pressures in the workplace and often have easy access to drugs. This may result in greater vulnerability for substance abuse and dependence and can lead to impaired professional practice.

Nurses must act responsibly when coworkers display signs of substance use. If colleagues are showing signs of a substance abuse problem, information about impaired nurse programs is available through most state boards of nursing to help individual nurses. Nurses convicted of working or driving under the influence of alcohol, illegal substances, or nonmedical use of prescription drugs are subject to disciplinary action by their state board of nursing. A disciplinary hearing is held and may result in censure, probation, or suspension of a professional license. The loss of professional licensure is the most severe form of disciplinary action and may prevent an individual from ever practicing nursing again. Warning signs of impaired nurses in the workplace are listed in Table 6–6.

TABLE 6–6 Warning Signs of Impaired Nurses in the Workplace

At-Risk Situations	Observable Warning Signs
Easy access to prescription drugs	Inaccurate narcotic counts or frequent missing drugs Patients complain of ineffective pain control, deny receiving pain meds Excessive "wasting" of drugs Volunteering to give medications to patients Frequent trips to the bathroom
Role strain	Frequent tardiness or absenteeism, especially before and after scheduled days off Haphazard, shoddy charting Patient care judgment errors Unorganized, erratic behavior, unkempt appearance
Depression	Irritability, unable to focus or concentrate Abrupt mood swings Isolating self, taking long breaks Apathetic, depressed, lethargic Unexplained absences from assigned unit
Signs of alcohol or drug use	Smell of alcohol on breath Excessive use of perfumes, mouthwash, or mints Slurred speech, flushed face, reddened eyes, unsteady gait Wearing long sleeves in hot weather to cover up arms
Signs of withdrawal	Tremors, restlessness, sweating, watery eyes, runny nose, stomachaches

CHAPTER HIGHLIGHTS

- Substance abuse is the use of any chemical despite adverse effects on the individual's physical, psychologic, interpersonal, or social health.
- Substance dependence occurs when control over the chemical substance is lost and the individual must use increasing amounts to produce the desired effect (tolerance) and must use the substance to avoid or relieve uncomfortable symptoms (withdrawal).
- **Combinations of genetic, biologic, psychologic, and sociocultural factors contribute to substance abuse or dependence. Addictive behavior has been linked to biochemical changes in dopamine and serotonin brain levels as well as to heredity, ethnicity, and peer pressure. Thorough assessment of individual risk factors is necessary to plan and deliver appropriate nursing interventions.**
- Adolescents are particularly influenced by society and peers to use substances, predominantly tobacco, alcohol, and illicit drugs. A positive cultural identity and family environment act as protective deterrents for substance use.
- **People with substance abuse problems have common characteristics including risk-taking behavior, low tolerance for frustration or pain, compulsive preoccupation with the substance, anxiety, anger, and low self-esteem. Stress management, anger control, social support, and counseling are helpful strategies to avoid substance abuse and dependence.**
- **Alcohol is the most commonly used and abused legal substance in America; however, polysubstance abuse is frequent in many individuals. Marijuana is the most commonly used illicit drug. Both alcohol and marijuana are considered gateway drugs to harder substance abuse. Substances such as cocaine and methamphetamine are often used in conjunction with alcohol. Abuse of prescription antianxiety agents and narcotic analgesics is a significant problem.**

- Nursing care of patients experiencing substance abuse problems includes health promotion efforts to prevent substance abuse; comprehensive physical, spiritual, and psychosocial assessment; and interventions for the human responses of ineffective coping and denial, imbalanced nutrition, readiness for enhanced knowledge, acute confusion, and risk for injury or violence.
- **Severe alcohol withdrawal or delirium tremens is a medical emergency that usually occurs 2 to 5 days following cessation of alcohol consumption. A symptom-triggered approach to the administration of benzodiazepines during alcohol withdrawal results in less total medication use and requires a shorter duration of treatment than other treatments.**
- The community provides many options for treating substance abuse including a mixture of individual, group, and family therapy. A successful after-care program includes resources to help manage stress and prevent relapse.
- Nurses and other healthcare professionals are susceptible to substance abuse due to pressures in the workplace and easy access to drugs. Nurses need to assess their response to stress and seek early treatment for depressive symptoms to avoid practicing while impaired.

TEST YOURSELF NCLEX-RN® REVIEW

1. The nurse is reviewing the laboratory values for a patient who is intoxicated. Which alcohol level is considered the minimum for an individual to be considered intoxicated?
   1. 0.05%
   2. 0.08%
   3. 0.50%
   4. 1.00%
2. Which question is the most appropriate for the nurse to use when interviewing a patient who is suspected of having alcohol abuse problems?
   1. "Have you been drinking lately?"
   2. "You don't drink much alcohol, do you?"
   3. "Typically, how many days per week do you drink alcoholic beverages?"
   4. "Has your drinking caused a lot of problems between you and your spouse?"
3. The nurse is caring for a patient with chronic alcoholism. Why should the nurse prepare to administer thiamine (vitamin B_1) for this patient?
   1. To prevent acute pancreatitis
   2. To prevent cirrhosis of the liver
   3. To prevent hepatic encephalopathy
   4. To prevent Wernicke's encephalopathy
4. The nurse is planning care for a patient who is demonstrating signs of substance withdrawal. Which substances present the highest medical danger during withdrawal?
   1. opiates and marijuana
   2. alcohol and CNS depressants
   3. amphetamines and hallucinogens
   4. CNS stimulants and amphetamines
5. A patient with a history of alcohol abuse has been prescribed disulfiram (Antabuse). What should the nurse teach the patient about the purpose of this medication?
   1. It decreases the discomfort of withdrawal symptoms.
   2. It decreases the pleasant, reinforcing effects of alcohol.
   3. It blocks the signs and symptoms of alcohol withdrawal.
   4. It prevents the breakdown of alcohol to inhibit impulsive drinking.
6. The nurse manager is concerned that a staff nurse has a substance abuse problem. What behavior did the manager most likely observe in the nurse?
   1. Working overtime to complete documentation
   2. Unkempt appearance, disorganized, erratic behavior
   3. Patients consistently reporting effective pain control
   4. Early completion of assignment to attend education programs
7. The nurse is completing an education session on smoking cessation with a group of patients in a prenatal clinic. Which participant statement indicates that additional teaching is required?
   1. The smoking rates for women have steadily declined.
   2. Women who smoke have an increased risk for stroke and heart disease.
   3. Women who smoke during pregnancy have a higher risk for spontaneous abortions.
   4. Smoking is the leading known cause of preventable death and disease among women.
8. The nurse is teaching a patient with a history of substance abuse about the medication naltrexone (ReVia). Which patient statement indicates that teaching has been effective?
   1. "I should stop taking all pain medications before starting on naltrexone."
   2. "I should wear a medical alert bracelet that states I'm taking naltrexone."
   3. "I should read labels of OTC cold medicines to make sure they don't have alcohol."
   4. "I should go to my Narcotics Anonymous meetings for one month, then I can stop going."
9. The nurse and patient are establishing goals of care for a substance abuse problem. Which would be a realistic goal for this patient?
   1. The patient will be able to use alcohol or drugs in moderation.
   2. The patient will focus on negative aspects of past behaviors and interpersonal relationships.
   3. The patient will identify ways to deal with stressful situations instead of resorting to substance use.
   4. The patient will refrain from using substances until craving for the substance has been eliminated.
10. The nurse is reviewing assessed data and determining nursing diagnoses appropriate for a patient with substance abuse. Which diagnosis should the nurse use to guide the care for this patient?
    1. *Acute Confusion* related to infectious process and pain
    2. *Excess Fluid Volume* related to increased intake of vitamins and dietary supplements
    3. *Ineffective Coping* related to inability to recognize maladaptive behaviors related to substance use
    4. *Imbalanced Nutrition: More Than Body Requirements* related to food intake in excess of energy expenditure

7 Nursing Care of Patients Experiencing Disasters

LEARNING OUTCOMES

1. Explain the difference between an emergency and a disaster.
2. Describe the types of injuries and manifestations associated with biologic, chemical, or radiologic terrorism.
3. Describe accepted triage principles used to manage multiple or mass casualty incidents and disasters.
4. Recognize situations requiring the need for patient isolation or patient decontamination.
5. Discuss the role of the nurse in disaster preparedness, mitigation, response, and recovery.
6. Discuss common nursing interventions for the treatment of injuries related to biologic, chemical, or radiologic terrorism.
7. Identify federal, state, local, and voluntary resources that provide and support assistance with disaster preparedness, response, and recovery.

CLINICAL COMPETENCIES

1. Activate a personal and family disaster plan to allow for your participation in disaster response.
2. Apply accepted triage tools and systems adopted by local emergency medical services and hospitals to establish care based on disaster situation and available resources.
3. Adapt evidence-based standards of nursing practice, based on resources available, to implement nursing care for patients with injuries suffered as a result of a disaster.
4. Provide safe and knowledgeable nursing care to treat disaster-related injuries.
5. Evaluate and revise plan of care to restore functional health status to patients who have sustained injuries due to a disaster.
6. Maintain personal safety and the safety of others at the scene of a disaster.
7. Provide education to promote participation in core preparedness activities.

MAJOR CHAPTER CONCEPTS

- As the largest healthcare workforce, every nurse must be competent to participate in all phases of the disaster continuum.
- The disaster continuum is characterized by three major phases: preimpact (before), impact (during), and postimpact. Distinct nursing competencies have been identified related to each phase.
- Nurses perform multiple roles in disaster situations; competent performance requires initial and continued professional development to ensure competency is established and maintained.
- Guidelines for triage in disaster and mass causality incidents differ from those used in daily triage.
- Preparation for disaster involves preparing yourself and your family.
- Identifying and initiating disaster preparedness for high-risk and high-vulnerability populations who are at increased risk of being exposed to disaster are essential nursing priorities.

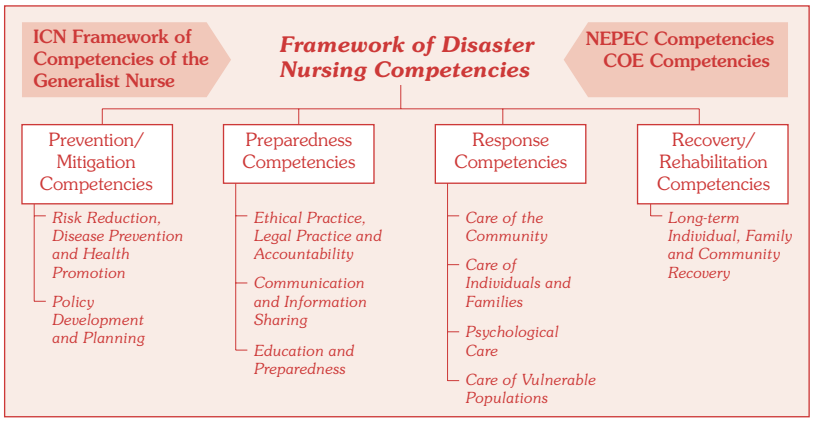
Disasters occur nearly every day somewhere in the world with significant health consequences for individuals, families, healthcare systems, and communities. All nurses are expected to know how to provide care for victims of disasters whether they work in acute care settings, ambulatory sites, long-term care facilities, or at home in their communities. There is no way to know where or when disasters may strike. Because of this, nurses must be prepared to develop a personal plan to protect their own family so they are available to assist patients, families, friends, healthcare workers, first responders, and communities in their recovery from disastrous events. The frequency of disasters is increasing.

There are a number of basic competencies that nurses should be cognizant of related to disaster preparedness. The World Health Organization (WHO) and International Council of Nurses (ICN) published the *ICN Framework of Disaster Nursing Competencies* (2009) (Box 7–1). This framework defines competencies pertinent to all registered nurses and addresses nursing actions required in each phase of disaster management (Figure 7–1 ■). Awareness of critical competencies prepares nurses to participate in disaster prevention/mitigation and preparedness, respond effectively to mass casualty events, and contribute nursing care during the recovery/rehabilitation phase. Nurses are expected to have sufficient knowledge to recognize the potential for a disaster event to occur; when such an event has occurred; and what they can do to protect themselves, family members, and community members from harm or from potential exacerbation of conditions. Nurses need to be aware of their role in disaster planning, response, mitigation, and recovery. Equally important, nurses must be aware of professional limitations and be able to respond to mass casualty incidents appropriately within the scope of nursing practice.

BOX 7–1 Disaster Nursing Competencies



1. Risk reduction, disease prevention, and health promotion
2. Policy development and planning
3. Ethical practice, legal practice, and accountability
4. Communication and information sharing
5. Education and preparedness
6. Care of communities
7. Care of individuals and families
8. Psychologic care
9. Care of vulnerable populations
10. Long-term care needs

DISASTERS AND EMERGENCIES

Veenema and Woolsey (2013) define a disaster as ". . . any destructive event that disrupts the normal functioning of a community" (p. 3). **Disasters** may be natural or human generated. **Natural disasters** are caused by acts of nature or emerging diseases. They may be unexpected or predictable through advanced meteorologic technologies. For example, Hurricane Katrina hit landfall on August 29, 2005, along the Central Gulf Coast. The hurricane caused vast devastation as its storm surge breached the levee system that protected New Orleans from Lake Pontchartrain and the Mississippi River. Most of the New Orleans area was flooded, and heavy damage was also inflicted on the coasts of Mississippi and Alabama. Katrina is considered one of the most destructive and costliest natural disasters in the history of the United States (U.S. Department of Homeland Security, 2011). **Human-generated disasters** are designated into three broad categories: complex emergencies, technologic disasters, and disasters that are not caused by natural hazards but occur in human settlements. Human-generated disasters are either accidental or intentional. Examples of human-generated disasters include mass shootings; war; chemical, biologic, radiologic, and nuclear terrorism; transportation accidents; group violence; food or water contamination; deforestation; and building collapse. Using bacteria or a toxin to contaminate large amounts of vegetable at a grocery store is an example of a deliberate or intentional human-generated disaster. A campfire that has been left unattended such that the embers are carried by high winds to the dry trees and brush nearby, creating a massive forest fire, is an example of a human-generated accidental disaster.

An **emergency** is distinguished from a disaster in that an emergency encompasses an unforeseen combination of circumstances calling for immediate action for a range of victims from one to many. For example, a motor vehicle crash may call for emergency assistance for a small number of individuals whose injuries are minor to very severe or fatal. Emergencies are generally accommodated

within the emergency management system. Complex emergencies such as a multivehicle crash may be labeled as a multiple casualty event that does not exceed the capacity of local resources to provide needed medical care. In contrast, disasters seldom involve a single victim. Instead, disasters are complex emergencies that significantly overwhelm available hospitals, emergency medical services, facilities, and resources. Disasters are typically labeled as **mass casualty incidents (MCIs)** because the event occurs quickly and suddenly and overwhelms local resources with many seriously ill or injured victims needing care. An example of a mass casualty incident is that of an entire community affected by the release of a hazardous material, such as a chemical, as a result of a train derailment. With human fatalities of approximately 222,000 and 1,300 in Haiti and the Gulf Coast, respectively, the 2010 earthquake in Haiti and Hurricane Katrina are prime examples of MCIs (International Federation of Red Cross and Red Crescent Societies, 2012).

In summary, the key difference between an emergency and a disaster is that an emergency can be handled by the usual emergency management systems already in place, whereas a disaster overwhelms general emergency systems and requires additional resources.

THE DISASTER CONTINUUM

The cycle of activity related to disaster is referred to as the *disaster continuum* (Veenema & Woolsey, 2013). This cycle is characterized by three major phases: preimpact (before), impact (during), and postimpact (after). Actions taken during each phase, in combination with the nature and scope of the preparedness, influence the extent of illness, injury, and death that occurs. The five basic phases of disaster management are preparedness, mitigation, response, recovery, and evaluation (Veenema & Woolsey, 2013) (Figure 7–2 ■).

Preparedness refers to proactive planning and preparation while the threat of a disaster is still in the future, and efforts are aimed at developing a disaster response prior to occurrence. Preparedness means having a comprehensive disaster plan in place that coordinates efforts among many people, agencies, and levels of government. The plan is based on familiarity with possible disaster agents based on previous experiences, as well as experiences of others from various regions and countries. It is imperative that all individuals and agencies who may be involved in the disaster response be involved in the planning. In this way, information is shared and representatives from each agency explain and offer their respective resources and expertise and note deficiencies in the plan. Planning committees will exist on all levels—federal, regional, state, local, and individual agencies.

Figure 7–2 ■ Disaster management is a cyclical process that includes preparedness, mitigation, response, recovery, and evaluation.

In the United States, disaster preparedness has been a priority issue for government and military agencies. These efforts have been expanded to public and private healthcare sectors. Healthcare professionals are among the essential personnel in addressing disaster preparations and in dealing with the consequences of a disaster. Nurses comprise the largest group of healthcare professionals, and will play key roles in disaster relief whether they work in hospitals, residential facilities, ambulatory care, schools, or at home in their communities. The general public looks to nurses for information and trusts that what nurses advise is true and accurate. Nurses have a responsibility to be educated and to assimilate the new skills and demands necessary to assist patients, families, and communities in preparing for and responding to disastrous situations effectively. National Incident Management System (NIMS) courses are offered free of charge through the Federal Emergency Management Agency (FEMA) and provide needed education to prepare nurses for providing care in disasters.

Numerous disaster agencies are involved in disaster planning, response, and mitigation depending on the severity of the disaster and the resultant necessary response. The U.S. National Response Framework (NRF) is a national effort designed to integrate resources of the local, state, and federal governments and includes voluntary relief agencies, the private sector, and international resources if needed to provide assistance to communities following natural or human-made disasters (Slepski et al., 2013). The Department of Homeland Security (DHS) and FEMA coordinate the NRF to provide assistance when local and state resources are not sufficient to provide needed disaster response. The NRF and NIMS work together to facilitate the nation's incident management capacity and improve efficiency. NRF and NIMS ensure that jurisdictions and disciplines work together to respond to disasters by following standardized practices (Slepski et al., 2013).

Local disaster response plans include action plans for various types of disaster situations, designation of the overall incident commander, and identification of community resources. The local emergency management agency is also represented in the state management planning efforts.

Hospitals and other healthcare agencies develop their own disaster plans. However, it is very important for each agency to understand its role within the larger community disaster plan. When disasters occur, competing healthcare systems must put the competition aside and work collaboratively in the response effort to ensure favorable outcomes following a disaster.

Nurses participate in disaster planning by having a nurse representative on the planning committee at least at the agency level. Disaster preparedness involves identifying potential vulnerabilities and anticipating the propensity for a disaster to occur. For example, some geographic locations are prone to tornadoes so buildings are equipped with tornado shelters and citizens participate in tornado drills.

Hospital disaster planners must prepare for the possibility that a disaster may involve the hospital. The hospital's response may include the evacuation of patients as well as relocating and operating from an independent facility. **Surge capacity** is the healthcare

system's ability to rapidly expand beyond normal services to meet the increased demand for qualified personnel, medical care, and public health in the event of a large-scale disaster. The Agency for Healthcare Research and Quality (2005) published a report discussing the use of former "shuttered" hospitals to expand surge capacity during mass casualty events. Hospitals must be constantly aware of the number of beds available, which patients may be discharged, staffing, equipment, other resources, and their overall ability to manage casualties quickly.

The **mitigation** phase includes measures to reduce the harmful effects of a disaster and occurs when there is knowledge about an impending disaster that has not yet occurred. Activities during this stage include warning, preimpact mobilization, and evacuation if appropriate.

The **response** phase happens after a disaster has occurred. It involves the immediate response to the effects of the disaster. National agencies have state and local offices that respond to disasters. However, the most immediate response is from the local groups and organizations. The community relies on local assistance or aid because outside sources of aid have not yet arrived. The local disaster response organizations include fire departments, police departments, public health departments, public works, emergency services, and the local branch of the American Red Cross. The community is rapidly assessed for damage, and the types and extent of injuries suffered as well as the immediate needs of the community determined.

Assistance from outside of the affected area arrives later, and search and rescue operations commence as well as first aid, emergency medical assistance, establishment or restoration of communication and transportation, assessment of infectious diseases and mental health problems, and evacuation of residents, if necessary. Individual states may request aid from neighboring states or the federal government if the disaster exceeds local and state resources.

Nurses should follow the disaster plan of their agencies, communities, and the local emergency management agency. This includes having a disaster plan for the nurse's immediate family. In this way, the nurse will feel secure in the fact that the immediate family is situated safely and the nurse can respond to the staging area to await instructions.

Nurses use a multitude of nursing knowledge and skills to assist in a disaster. Nurses use their expertise in infectious disease control and in assessing physical as well as psychosocial needs. In a disaster, mental health issues are extremely significant for victims, families, friends, first responders, and all healthcare workers. Nurses will ensure that patients receive follow-up care for both physical wounds and mental health concerns. Advanced practice nurses may take on significantly greater responsibilities, especially if they are competent and prepared in emergency and trauma care. Protocols and standards of care are in place to guide the practice of all nurses. Nurses need to determine the boundaries of their practice in times of emergencies when mass numbers of victims must be treated without the luxury of an on-site physician.

In the **recovery** and reconstruction phase, restoration and reconstitution take place. This stage involves rebuilding and returning to some semblance of normalcy. During this phase, restoration, reconstitution, and mitigation take place. Restoration includes rebuilding, replacing lost or damaged property, returning to school and work, and continuing life without those who were killed in the disaster. Reconstitution occurs when the life of the community returns to a new normal.

The final stage of recovery is the **evaluation phase** (Veenema & Woolsey, 2013). The evaluation phase involves determining what worked and what did not work, and what anticipated and unanticipated issues and challenges emerged. Evaluation is also an activity in the preparation and planning aspects of the nondisaster stage. This illustrates the cyclical nature of planning and disaster response; the work is never complete. Future-oriented activities take place to prevent subsequent disasters or to minimize their effects. Some of these activities may include increased security and surveillance measures. Nurses may suggest ideas for responding to the victims of disasters more effectively and efficiently. For example, nurses may communicate the need for carts stocked with specific items that will assist them in treating patients faster. They may suggest a more efficient method of tracking patients as they enter the healthcare system and move from area to area based on the patients' acuity and condition.

TERRORISM

Terrorism is defined by the U.S. Department of Defense (2013) as the "unlawful use of violence or the threat of violence to instill fear and coerce governments. Terrorism is often motivated by religious, political or other ideological beliefs and committed in the pursuit of goals that are usually political." One of the goals of terrorism is to cause psychologic effects that reach a much wider audience than the immediate victims or object of an attack. High-profile acts draw attention to the terrorists and their cause. It is thought that terrorists seek to obtain leverage, influence, and power through the publicity generated by their violence (Hoffman, 2006).

The weapons terrorists use are often described as conventional and nonconventional. **Conventional weapons** include bombs and guns. Car/truck and package bombs have become powerful weapons in attacks such as the Boston Marathon bombing on April 15, 2013. Terrorists use explosive devices such as letters, parcels, pipes, pressure cookers, barometric and fertilizer truck bombs, as well as incendiary bombs such as Molotov cocktails. Other types of conventional terrorist weapons include handguns, rifles, semiautomatic weapons, hand grenades, rocket-propelled devices, and even surface-to-air, shoulder-fired missiles that can bring down helicopters, fighter aircraft, and civilian airliners.

Nonconventional terrorist weapons include those in the chemical, biologic, and nuclear categories. Chemical terrorism attacks may manifest as the release of a toxin into highly populated areas, bodies of water, and unventilated areas. Another type of chemical terrorism is a specific attack on a particular product, especially a food product. This is accomplished by introducing a toxic chemical substance directly into the product. The anthrax attacks against U.S. public officials after the September 11, 2001, terrorist attacks illustrate how small amounts of white powder can encourage mass panic and hysteria in the public (Croddy & Ackerman, 2013) (Box 7–2).

BIOTERRORISM

Bioterrorism involves the use of etiologic agents (disease) with deliberate intent to cause illness or death in a population, food, and/or livestock. Bioterrorism includes the use of organisms such as bacteria, viruses, and rickettsia and the use of products of organisms—toxins. The main purpose of biologic weapon use is

BOX 7–2 Biologic Threat Infections

Following the terrorist attacks on September 11, 2001, and the development of anthrax cases in the United States, concern has arisen about the possible use of biologic weapons. The most deadly pathogens to be used for this purpose include anthrax, smallpox, botulism, pneumonic plague, tularemia, and viral hemorrhagic fevers.

Anthrax is an acute bacterial infection caused by *Bacillus anthracis*, a gram-positive, spore-producing organism that occurs in inhaled, cutaneous, and gastrointestinal forms. The spores are impervious to temperature and sunlight, and remain viable for years.

Inhalation anthrax carries the highest mortality rate because spores of 1 to 5 microns are easily inhaled and deposited in the alveoli. The patient initially exhibits influenza-like symptoms such as fever, nonproductive cough, headache, and malaise. These symptoms advance to respiratory distress, mediastinal widening, and hemodynamic collapse in 3 to 5 days. Death may occur shortly thereafter. Untreated patients die in 2 to 3 days. The characteristic lesion of cutaneous anthrax progresses from an itching papule to a painless, serosanguineous-filled vesicle that forms a black necrotic center. Patients who ingest the anthrax bacillus develop nausea, vomiting, severe abdominal pain, and bloody diarrhea. Diagnosis is confirmed by a positive blood culture, polymerase chain reaction, and serology. On confirmation of anthrax exposure, prophylaxis is initiated with oral ciprofloxacin (Cipro) or doxycycline (Doxycin) for 60 to 100 days; people with confirmed systemic anthrax cases must receive anti-infectives intravenously (CDC, 2014).

In 1980, WHO certified that *smallpox* was eradicated. Routine smallpox vaccination was discontinued in 1972, leaving people born after that year at risk for this disease if it reappears or is used as a weapon. Smallpox spreads by direct contact or by inhalation of respiratory droplets. Symptoms include a high fever, headache, and malaise, followed by a vesicular/pustular rash appearing simultaneously on the face and extremities. Once the lesions break open and spread large amounts of the virus into the mouth and throat, people are highly contagious and should be placed in negative-pressure rooms. Anyone exposed to the patient should be vaccinated and monitored closely. Vaccination up to 4 days after exposure and before a rash appears provides almost complete protection and new antiviral drugs may be effective (WHO, 2013).

Healthcare providers should be alert to illness patterns that could indicate an unusual infectious disease outbreak. Indicators of a biologic agent release include increased disease incidence among people in the same geographic area (e.g., people who attended the same event); the disease pattern is inconsistent with patient age, such as chickenpox among adults; and a patient presents with symptoms of a rare disease. The presence of one or more of these indicators should be reported to public health authorities to determine the infectious disease source and to prevent further exposure (WHO, 2013).

mass devastation. Unfortunately, it is not uncommon for the results of a biologic attack not to be known for several hours or days after the attack because aerosolized biologic particles are odorless, colorless, and tasteless. Unless the terrorists announce the biologic attack, its occurrence may remain unknown until patients begin to present at emergency departments or physicians' offices a few days or weeks after the release of the agent. Detection is difficult because of the numerous different healthcare facilities available for patient treatment. Surveillance is essential to detect such an event. The goal of the surveillance system is to determine the status of the public's health and detect any sudden change in that status. Fortunately, biologic weapons are not as common, accessible, or available as chemical weapons.

Healthcare providers must be alert to the recognition, reporting, and treatment of high-priority biologic agents. A disaster preparedness plan should be established in every healthcare facility to outline the protocol and procedures to be taken in response to a suspected bioterrorism attack. Hospital staff will alert the infection control nurse when subtle changes or trends in symptoms among patients are seen. The public health department is also given this data. When an unusual disease pattern presents itself, laboratories perform tests on cultures that would normally be discarded as contaminants. Laboratory personnel report unusual clusters of laboratory results. Special laboratories have been established to perform a battery of tests on suspicious specimens of rarely seen bacteria, toxins, viruses, or increased numbers of a particular strain or specimen. The Centers for Disease Control and Prevention (CDC) has created detailed fact sheets about bioterrorism agents and diseases for healthcare providers.

NUCLEAR/RADIOLOGIC TERRORISM

The nuclear category of nonconventional terrorist weapons encompasses the use of a nuclear device to cause mass murder and devastation. This category of terrorism includes the use, or threat of the use, of fissionable radioactive materials in an attack. A purposeful explosion at a nuclear power plant is an example of this type of terrorism. Using conventional weapons against one of the many nuclear reactors in the world could cause an explosion that would cause extensive and possibly irreversible environmental damage. Damage to the reactors could cause radioactive matter to be released into the atmosphere, potentially endangering large population centers (U.S. Department of State, 2013).

The radiologic dispersion bomb is probably the most accessible nuclear device to be used by terrorists. Another name for this device is *dirty bomb* because it consists of a conventional explosive combined with radioactive waste by-products from nuclear reactors. The dirty bomb discharges deadly radioactive particles into the environment. It is cheaper to make than a nuclear bomb and radioactive waste material is relatively easy to obtain. Radioactive waste is found throughout the world and is typically not as well guarded as nuclear weapons.

TYPES OF DISASTERS WITH COMMON INJURIES

This section describes a variety of disasters and the injuries that are common to each specific disaster. Table 7–1 outlines types of disasters with related injuries and nursing implications.

Hurricanes and Tornadoes

A hurricane is a type of tropical cyclone. It is a low-pressure system that generally forms in the tropics. Hurricanes can wreak havoc on coastlines as well as several hundred miles inland. Hurricanes and tropical storms can also spawn tornadoes, create storm surges along the coast, and cause extensive damage from heavy rainfall. Floods are deadly

TABLE 7–1 Types of Disasters and Common Injuries

Type of Disaster	Common Injuries	Nursing Implications
Hurricane-related injuries	Drowning; cleanup injuries; aggravation of chronic illnesses; stress-related symptoms; upper respiratory infections; gastrointestinal illnesses; animal, snake, and insect bites; obstetric complications; contaminated water supplies and insect-breeding grounds; heat-related illnesses; lack of sanitation and safe housing	Asphyxia; wounds; bone, joint, and muscle injuries; infections; skin irritations; waterborne and insect-borne diseases; dehydration; starvation or malnutrition; diseases. Evaluate for hidden injuries and responses, in addition to those that are apparent.
Tornado-related injuries	Flying debris; injuries similar to hurricane-related injuries	Injuries and fatalities can occur.
Thunderstorm-related injuries	Resistance of body tissues to electrical current *Least resistance:* nerves, blood, mucous membranes, muscle *Intermediate resistance:* dry skin *Most resistance:* tendon, fat, bone	Potential for tissue destruction with longer duration of contact with high-voltage current; if energy current is dissipated at the skin surface, significant surface burns result, especially in calloused areas.
Earthquake-related injuries	High incidence of mortality and morbidity; explosions	May result in stress-related symptoms; wounds; bone, joint, and muscle injuries; cleanup injuries; gastrointestinal and respiratory problems; aggravation of chronic illnesses; obstetric complications; burns.
Tsunami-related injuries	"Tsunami lung," a severe infection caused by aspirating muddy, bacteria-laden water	Requires aggressive respiratory and ventilator management, blood transfusions, antibiotics, and other medical support.
Snowstorm-related injuries	Overexertion and exhaustion	Myocardial infarction can occur.
Disaster-related eye injuries	Specks of dust or debris; cuts, punctures, or stuck objects; blows to the eye	Administer eyewash or flushing versus rubbing; stabilize eye with rigid shield. Apply cold compress, no pressure; patient should visit healthcare professional to rule out serious injury or internal eye damage.
Blast injuries	Auditory	Tympanic membrane rupture, ossicular disruption, and cochlear damage occur; damage from foreign body can occur.
	Eye, orbit, face	Perforated globe, air embolisms, fractures are common; damage from foreign body can occur.
	Respiratory	May result in blast lung, hemothorax, pneumothorax, pulmonary contusion and hemorrhage, atrioventricular fistulas (source of air embolism), airway epithelial damage, aspiration pneumonitis, sepsis.
	Digestive	May result in bowel perforation, hemorrhage, ruptured liver or spleen, sepsis, mesenteric ischemia from air embolism.
	Circulatory	Cardiac contusion, myocardial infarction from air embolism, shock, vasovagal hypotension, peripheral vascular injury, and air embolism–induced injury can occur.
	Central nervous system injury	Concussion, closed and open brain injury, stroke, spinal cord injury, air embolism–induced injury can occur.
	Renal injury	May result in renal contusion, laceration, acute kidney injury due to rhabdomyolysis, hypotension, and hypovolemia.
	Extremity injury	Traumatic amputation, fractures, crush injuries, compartment syndrome, burns, cuts, lacerations, acute arterial occlusion, air embolism–induced injury can occur.
Blunt trauma	Head and torso blunt trauma, penetrating trauma	Fractured limbs, spinal injury, pulmonary and cardiac contusions can occur.
Pressure trauma	Lungs	Tearing of the alveoli causes swelling, fluid accumulation, possible pulmonary emboli, eventual hypoxia.
	Ear injury: ear pain, hearing loss	Keep auditory canal clean.
	Bowel injury	Make the patient comfortable.
Radiologic dispersion bomb (dirty bomb) blast	Radiation sickness	Get rid of contaminated clothes, shower, and evacuate the area within a day of a small or medium blast. Those close to the blast could suffer radiation sickness and require hospital care.

TABLE 7–1 Types of Disasters and Common Injuries (*continued*)

Type of Disaster	Common Injuries	Nursing Implications
Nuclear detonation	Thermal burns	May involve only the epidermis and upper layers of dermis with short duration of heat exposure.
Bright light flash of nuclear detonation	Eye burn injuries	May blind the patient momentarily, effects will disappear with time, can impair a patient's ability to perform self-care and other ADLs.
Radiation exposure injury	Bone marrow and blood cell damage	A reduction in the blood's oxygen-carrying capacity results in nausea, fatigue, and a general feeling of malaise. Reduced platelet production causes clotting disorders and possibly hemorrhage. When the body's white blood cells are destroyed, it is important to reduce the patient's exposure to infection. Infection at the time of reduced WBC production can be severe and even fatal.
	Bowel	Cells that reproduce the bowel lining are damaged, resulting in nausea, loss of appetite, vomiting, diarrhea, fluid loss, and malaise in the acute stage; later, dehydration, malnutrition, bowel hemorrhage, and perforation may occur; if radiation exposure is not exacerbated by other injury or pathology, patients will generally survive.
	Integument	Erythema or generalized reddening of the skin occurs when skin cells are damaged, with the appearance of a sunburn; more serious burns may occur with persistent exposure or extremely high radiation doses.
	Nervous and cardiovascular systems	With acute radiation exposure, blood vessel and nerve cells are damaged and the patient is incapacitated and experiences cardiovascular collapse, confusion, and even an "on fire" sensation throughout the body; symptoms this severe generally do not permit survival.
Chemical burns	Range from minor to life-threatening injuries	Remove clothing from injury site as well as any jewelry; flush chemical from skin with thorough decontamination; cover wounds loosely with a dry, sterile, or clean cloth.

Sources: Adapted from CDC (2013a) and Daley et al. (2008).

and destructive. Excessive rain can trigger landslides or mudslides, especially in mountainous regions. Flooding on rivers and streams may persist for several days or more after the storm (FEMA, 2012).

Common physical effects of hurricanes include asphyxia due to drowning; wounds; bone, joint, and muscle injuries; aggravation of chronic illnesses; stress-related symptoms; upper respiratory infections; gastrointestinal illnesses; cleanup injuries; animal, snake, and insect bites; skin irritations and infections; obstetric complications; and waterborne and insect-borne diseases from contaminated water supplies and insect breeding grounds (Veenema & Landesman, 2013).

As a result of Hurricane Katrina, many people lost their homes, family members, friends, and the environment that supported their daily routines. Many basic physical needs in the aftermath of the hurricane could not be met, which put survivors at risk of dehydration, starvation or malnutrition, heat-related illnesses, and diseases and injuries related to lack of sanitation and safe housing (Veenema & Landesman, 2013). The CDC (2013b) offers a number of specific strategies to promote health and safety after a hurricane.

Flying debris causes most fatalities and injuries in tornadoes. The physical effects include bone, muscle, and joint injuries; fractures; aggravation of chronic illnesses; obstetric complications; stress-related symptoms; upper respiratory infections and those associated with fiberglass; eye injuries; cleanup wounds; and gastrointestinal illnesses (Veenema & Landesman, 2013). Box 7–3 outlines first aid for eye injuries.

BOX 7–3 First Aid for Eye Injuries

SPECKS IN THE EYE
- Do not rub the eye.
- Flush the eye with large amounts of water.
- Seek medical attention if the speck does not wash out.

CUTS, PUNCTURES, AND FOREIGN OBJECTS IN THE EYE
- Do NOT wash out the eye.
- Do NOT try to remove a foreign object stuck in the eye.
- Seek immediate medical attention.

CHEMICAL BURNS
- Immediately flush the eye with water or any drinkable fluid. Open the eye as wide as possible. Continue flushing for at least 15 minutes. For caustic or basic solutions, continue flushing while on the way to medical care.
- If a contact lens is in the eye, begin flushing over the lens immediately. Flushing may dislodge the lens.
- Seek immediate medical attention.

BLOWS TO THE EYE
- Apply a cold compress without pressure, or tape crushed ice in a plastic bag to the forehead and allow it to rest gently on the injured eye.
- Seek immediate medical attention if pain continues, if vision is reduced, or if blood or discoloration appears in the eye.

Source: National Institute for Occupational Safety and Health. (2009). *Eye safety for emergency response and disaster recovery.* Retrieved from http://www.cdc.gov/niosh/topics/eye/eyesafe.html.

Thunderstorms

Risk of a lightning strike is possible during a thunderstorm. The short duration of a lightning strike results in a very short flow of current internally, despite the high voltage of lightning. Additionally, the almost immediate flashover of current around the body usually results in very little, if any, skin breakdown or burning of muscle and tendon

tissues (Veenema & Landesman, 2013). However, the pathway that the current takes will determine the tissues at risk and the type of injury, as well as the duration of contact with the electrical current.

High electrolyte and water content in the body conduct the greatest electrical current. Hence, the greatest conductors of electrical current in the body are the nerves, muscles, and blood vessels. High resistors to electric current are bone, tendon, and fat, due to their tendency to heat up and coagulate instead of transmitting current. Much of the energy current may be dissipated at the skin surface. This may result in surface burns, especially in calloused areas (Veenema & Landesman, 2013).

Earthquakes and Tsunamis

Earthquakes have a high incidence of mortality and morbidity. The most common health effects experienced by victims of earthquakes include stress-related symptoms; wounds; bone, joint, and muscle injuries; burns from explosions; cleanup injuries; gastrointestinal and respiratory problems; aggravation of chronic illnesses; obstetric complications; and death (Veenema & Landesman, 2013).

A tsunami, a seismic sea wave, is a series of ocean waves characterized by having a long period and wavelength and the ability to travel at speeds greater than 500 miles per hour. As a tsunami encounters shallow water, its height increases drastically, resulting in a sudden increase in sea level, thereby flooding low-lying coastal areas. Injuries are similar to those seen with hurricanes.

Snowstorms

Overexertion and exhaustion are major problems resulting from the snow shoveling that is done following a snowstorm. The exertion required to shovel heavy snow in the extreme cold may cause a myocardial infarction.

Hazardous Materials

Hazardous materials pose a potential risk to life, health, or property if they are released because of their chemical, biologic, or physical nature. The hazard exists during any stage of use, from the production and storage of these substances to their transportation, use, or disposal. Hazardous materials accidents range from the unintentional release of household hazardous materials, to chemical spills on highways, to groundwater contamination by naturally occurring methane gas (Veenema & Woolsey, 2013). Symptoms will vary depending on the type of hazardous material patients are exposed to. The nurse works closely with the intraprofessional team to identify the hazardous substance and develop a specific treatment plan.

Explosives

Blast injuries are the result of explosive munitions, often involving car or package bombs. Penetrating and blunt injuries are common following explosions. Care for individuals injured by blast injuries typically focuses on abdominal and lung injuries, penetrating wounds, traumatic amputations, and burns. There is high risk for hemorrhage so patients should be assessed and treated quickly (Sacco, 2013).

RADIOLOGIC DISPERSION BOMB BLAST

A radiologic dispersion bomb blast (dirty bomb) consists of a conventional explosive such as trinitrotoluene (TNT) packed with radioactive waste by-products from nuclear reactors. When the dirty bomb explodes, the radioactive material spreads in the wind like a dust cloud. In this way, it reaches far wider areas than the initial explosion (Karam, 2013). The long-term destructive force of the dirty bomb is caused by ionizing radiation from the radioactive material. In an individual's body, an ion's electrical charge may lead to unnatural chemical reactions inside the cells. The charge can break DNA chains. Cells with broken DNA strands either die or the DNA develops a mutation. Diseases develop as the result of widespread cell death. If the DNA mutates, a cell may become cancerous. The cancer may spread and the cells may malfunction. This series of events may result in a wide variety of symptoms collectively referred to as **radiation sickness**. Although this condition can be deadly, with stem cell transplantation it is survivable.

People are exposed to ionizing radiation frequently, but in small doses, with little if any ill effects. Some of the sources of this everyday exposure are outer space, stars, the sun, natural radioactive isotopes, and x-ray machines. The risk of cancer and radiation sickness is increased by exposure to a dirty bomb and the subsequent rise in radiation levels above normal. The fatal effects of the dirty bomb may not be apparent in the short term after exposure, but could kill people years later.

NUCLEAR DETONATIONS

With a nuclear detonation, a thermal burn is the most common mechanism of injury and death. A tremendous amount of thermal energy is created by a nuclear reaction. This energy travels unimpeded through the air. The energy is absorbed by the contact surface where it may create burns or ignite combustibles. The burns may involve only the epidermis and upper layers of dermis because of the short duration of heat exposure; however, thermal burn injuries can be severe and are treated like any other burn. Radiation exposure results in injury from ionizing radiation altering some cell structures. Cells are damaged from the changes in DNA in bone marrow, blood, bowel, skin, and nervous and cardiovascular systems. Radiation suppresses the immune system, so special care must be taken to reduce the potential infection often associated with full-thickness burns. More information on burn care can be found in Chapter 17.

The major activities performed for patients who have suffered a nuclear casualty are triage, evacuation or sheltering, search and rescue, radioactive monitoring, decontamination, and direct patient care. The patient will be assessed for injuries such as burns or blunt trauma. Pressure injuries such as lung injury, difficult breathing, or minor stroke-like symptoms (air emboli) must be assessed quickly. Early complaints of radiation exposure may include nausea or fatigue. The manifestations of serious radiation exposure may not occur for several hours and do not suggest imminent death. Since radiation has a cumulative danger, shorter exposure times are less damaging. Flash blindness to the eyes caused by a detonation blast lasts only a few minutes during daylight and up to 30 minutes at night. Reassure patients that their eyesight will return, and have someone remain with them until their sight is restored.

The patient, along with the healthcare provider and first responders, should be evacuated from the exposure area. Wind shifts are monitored continuously to minimize exposure. Triage is done to classify the patients into categories of immediate, delayed, and minimal. Comfort measures, such as psychologic support and empathy, are given to patients.

CASUALTY MANAGEMENT

During a disaster, nurses may be expected to perform triage. **Triage** means sorting. Nurses perform triage every day in every emergency department. Upon learning of a disaster, one of the most urgent unit-level priorities is triaging hospitalized patients to expedite the discharge or transfer of the lowest acuity patients to free up resources for disaster victims. At the disaster site, a very basic triage system is to categorize or label victims needing the most support and emergency care as *red* (Table 7–2). Those less critical but still in need of transport to emergency centers for care are classified as *yellow*. Victims who have minor injuries and do not warrant transport to an emergency center are categorized as *green*. Victims who are least likely to survive or are already deceased are color coded as *black*. These are the triage levels given to patients under normal circumstances or when there are only a few victims. However, when there is a mass casualty event with more than 100 patients, **reverse triage** may be instituted. Reverse triage works on the principle of the greatest good for the greatest number. For example, if there were a collision between a train full of railroad cars filled with toxic chemicals and a full tour bus in a highly populated area, this disaster would likely be called a mass casualty event. In this case, those persons who were the most ambulatory and least injured would be transported or instructed to move quickly to the warm zone, away from the immediate accident site to get decontaminated and processed first (Box 7–4). Those with minor injuries would be decontaminated next. Those with more severe to most severe injuries would be treated in that order. In this way, the most victims with the greatest chance of survival could be saved most efficiently with limited resources. Many emergency personnel will share the difficulty of making these decisions at disaster sites when the first inclination might be to rescue the most severely injured.

Triage is a continuous process in which priorities are reassigned as needed treatments, time, and the condition of the victims change. This process must balance human lives with the realities of the situation, such as supplies and personnel (Box 7–5). The triage role requires an individual who is able to rapidly assess patients' conditions under stressful, often adverse conditions and assign a category. Those assigned to triage are expected to function independently, yet as part of a coordinated team effort (Olchin & Krutz, 2012). It has been suggested that emergency personnel should triage/categorize the victims so that physicians and nurses can be best utilized in the treatment area, performing patient care. Advanced practice personnel will continue to triage and perform more complete assessments.

BOX 7–4 Hot, Warm, and Cold Zones

The site of a disaster where a weapon was released or where contamination occurred is called the **hot zone**. It is considered contaminated and only those persons in the appropriate **personal protective equipment (PPE)** may enter it. PPE is equipment used for the protection of personnel and includes gloves, masks, goggles, gowns, and biologic disposal bags. Typically, fire, police, and military personnel will collect evidence and begin their investigation in this zone. The **warm zone** is adjacent to the hot zone. Another name for this area is the *control zone*. This area is where decontamination of victims or triage and emergency treatment take place. The level of PPE required is based on the dynamic risk assessment of the threat and agent involved. The **cold zone** is considered to be the safe zone. It is adjacent to the warm zone and is the area where a more in-depth triage of victims would occur. Survivors may find shelter in this area, and the command and control vehicles would be found here as well as the emergency transport vehicles.

BOX 7–5 Key Triage Points to Remember

1. Use a triage system that is easy to learn, easy to implement in stressful conditions, and does not require advanced diagnostic skills yet allows for basic patient interventions.
2. Use the incident management system (defined by each facility, and based on the area's civilian and military authorities) for every incident and wear personnel identification vests. Incident management systems use logical management structure, defined responsibilities, clear reporting channels, and a common language (Romig, 2013).
3. Get accurate preliminary and final patient counts and relay this information to the incident commander.
4. Use some type of visual color-coded identification system to indicate patient priority.
5. Do not fall into the trap of using your time providing one-to-one patient care.
6. Retriage patients frequently, at the incident, on arrival at the treatment area, and periodically thereafter.
7. Make certain the walking-wounded are gathered and treated.
8. Preplan for potential incidents that may occur.
9. Be aware that emergency responders may be potential targets.
10. Practice, practice, practice.

TABLE 7–2 Simple Triage and Rapid Transport (START) System

Red (emergent)	Critically injured, with problems that will require immediate intervention to correct. Patients with a respiratory rate above 30 are tagged *red*. If their respirations are below 30, assess their circulatory status. If capillary refill takes more than 2 seconds, tag them *red*. If it is below 2 seconds, assess mental status.
Yellow (urgent)	Injured, and will require some medical attention, but will not die if care is delayed while you care for other patients; not ambulatory and will require a stretcher for transportation. Patients who can follow simple commands such as hand grips are tagged as *yellow.* Patients who cannot follow simple commands are tagged *red.*
Green (ambulatory)	Not critically injured, and can walk and care for themselves. Have them walk to a safe place, but do not lose track of them; every patient triaged at an incident is tracked to the best of the responder's ability.
Black (expectant)	Deceased, or have such catastrophic injuries that they are not expected to survive. If the patient is not breathing, open the airway manually. If the patient remains apneic, tag him or her *black*; if the patient begins breathing, he or she is tagged *red*.

Isolation and Personal Protective Equipment

Persons suspected of having a highly contagious disease will need to be isolated from other patients, visitors, or healthcare personnel. For example, persons with pulmonary tuberculosis and a severe illness requiring hospitalization should be placed in a private room with negative-pressure ventilation. Patients are taught to cover their nose and mouth when coughing or sneezing. All persons entering the room should wear personal respiratory protective devices capable of filtering submicron particles. Decontamination of the air may be achieved through ventilation and supplemented by ultraviolet light.

Gas masks are used in a broad range of military, industrial, and emergency situations to protect the user from hazardous dust, gas, or other aerosols. Biologic contaminants that are spread through aerosolized droplets create a threat to those not wearing PPE. A gas mask may be considered a high-performance respirator and is usually equipped with both eye protection and air supply protection or treatment. A hood, helmet, or headgear is generally worn to protect the skin, eyes, airways, and respiratory systems. Protective clothing is made to guard against mild irritants and even serious lethal materials. Some protective suits are disposable, intended for one use only. Others are durable, multilayered fabrics that are completely impermeable and are reusable. The Occupational Safety and Health Administration (OSHA) (2006) has issued guidelines to inform healthcare workers and first responders about the correct level of PPE for various situations. The Chemical, Biological, Radiological, and Nuclear (CBRN) Personal Protection Equipment Selection Matrix for Emergency Responders and other information specific to PPE can be located online at the OSHA website.

In addition to the isolation of patients, special air handling systems are used in isolation rooms to prevent the spread of contaminated droplets into the general hospital air vents. Many hospitals have the ability to shut off airflow in contaminated areas to prevent the spread of contaminants to other clean areas of the hospital. The heating, ventilation, air conditioning, and refrigeration (HVAC) systems are closely monitored and can be shut down in designated areas to avoid air intake from the outside as well, especially in cases of outdoor environmental contamination.

Recording Victim Data

Various types of instruments are used to record triage data. Typically emergency medical systems (EMS) use a common triage tag state- or region-wide. The triage tag includes a sequential number and barcoded stickers for assigned categories. The triage personnel should include whatever information is available, such as patient's name, presenting injury or complaint, any interventions performed in the field, and allergy and medication history if possible.

Crowd Control

When a disaster occurs, many people converge on the site. Those who come include the curious as well as those who truly mean to assist in the rescue and recovery of victims. This crowd of people needs to be controlled by authorities in charge of the site and rescue and recovery. Similarly, crowds may arrive at the hospital or healthcare delivery sites when injured or even when they think they may be injured or contaminated in some way. The job of crowd control is not under the auspices of nurses or other healthcare personnel. The agency's security personnel and/or the local police force must control these crowds. If control is not maintained, chaos ensues and those in greatest need of medical assistance may be unable to reach healthcare providers in order to avoid further declines in their health status. In fact, nurses, physicians, and other healthcare workers should not enter an area that has not been secured. To put one's safety at risk jeopardizes the potential treatment of many. Additionally, social services personnel or psychiatric service providers should be available to assist the worried-well to cope with the trauma they have experienced, witnessed, or heard about through the news media.

Psychosocial Needs

The importance of mental health services for victims, the public, first responders, and healthcare workers cannot be overstated. Both those individuals directly affected by the disaster as well as those indirectly affected will seek medical care and advice. Many who seek medical attention are simply anxious about the threat of injury. At times, reassurance is all that is necessary. However, with large numbers of people seeking healthcare, the system is quickly overwhelmed. Mental health experts may quickly assess individual needs, offer immediate advice, and refer for follow-up care if deemed appropriate.

People react to disasters in a variety of ways, both physically and behaviorally. Their reactions depend on the severity of the threat and their proximity to the area of direct impact. The closer the person is to the area of impact and the longer the exposure, the greater the likelihood of a more severe reaction to the event. Table 7–3 summarizes the normal initial responses aimed at survival (Murray et al., 2009; Plum & Meeker, 2013; Selye, 1965).

Most people exhibit great coping mechanisms and resilience in the aftermath of a disaster. For those who do not, mechanisms should be developed for identifying and referring them to psychologic counseling. After the September 2001 terrorist attacks on the World Trade Center and the Pentagon, it was reported that 71% of people surveyed felt depressed, 49% had difficulty concentrating, and 33% had trouble sleeping at night. Most (92%) felt sad when watching news coverage of the event, yet 63% stated a compulsion to continue to watch the news (Pew Research Center for the People and the Press, 2001). Reactions to terrorist events and disasters in general are influenced by developmental level and maturity, prior experiences with disasters, and cultural background (Plum & Meeker, 2013).

●○● NURSING CARE

The Role of the Nurse in Disaster Relief

Nurses have roles in many facets of disaster management, including identifying the event, functioning as a first responder at the scene, working with a rapid needs assessment team to identify needed resources, and providing direct care to disaster victims in hospitals, federal medical stations, public health departments, or field medical teams (Slepski et al., 2013). Nurses may be involved in managing communications and working with the media, or assuming leadership roles in the coordination of multiple disaster response activities. Because nurses have an obligation to keep current in new and emerging trends in healthcare and threats to society, learning about

TABLE 7–3 Responses to Stress: General Adaptation Syndrome (GAS) and Levels of Anxiety

Gas Stage	Physical Response	Behaviors Related to Anxiety
Alarm stage	Pupils dilate; blurred vision Hearing sharper or diminished	Misinterpretation of stimuli; confusion; poor concentration; selective inattention; need for assistance
Severe anxiety or panic	Stronger, faster heart rate and respirations; palpitations, arrhythmias, elevated blood pressure	Feeling of impending doom; terror; fear; agitation; irritability; increased demands; impulsivity; paresthesias
	Muscle tone increased. Headaches	Muscle tension; excitability, restless movements; tremors; rigidity; weakness
	Basal metabolism rate increased. Body temperature increase; perspiration. Altered glucose, protein, and lipid metabolism	Insomnia; urgency of speech and movement; fatigue; dehydration; weight loss; appetite changes. Smooth muscle of gastrointestinal and urinary tracts less motile, interfering with digestion and elimination of wastes
	Increased startle response	
	Hypoglycemia from glycogenolysis due to high energy demands	Blood glucose increase; appetite changes; dehydration; fatigue; poor concentration
	Increased blood clotting and suppressed immune response if stage persists	Blood stasis; thrombus formation
		Resistance to infection and disease reduced

the prevention and mitigation of disasters is essential. Nurses should remain aware of the roles they play in all aspects of disaster preparedness and response (Box 7–6). Nurses must first know how to take care of themselves in order to assist others. By educating oneself and being proactive in regular drills and practice of skills, nurses take an active role in helping others to save lives and fulfill an important obligation to society.

Applying basic first aid skills can be very helpful in immediate disaster relief efforts until emergency help can be obtained. The American Red Cross invites nurse volunteers and will provide the necessary training. Many nurses have taken advantage of online disaster certificate programs, and efforts are being made to integrate disaster preparedness content into nursing courses.

In many different practice settings, nurses serve on disaster preparedness and response planning committees. Nurses are receiving in-service education on biologic, chemical, and radiologic threats to patient health as well as surveillance and reporting of suspicious activities. Although nursing professionals may not be asked to don decontamination gear to aid victims, nurses should be aware of decontamination procedures so that they will remain safe from exposure and be able to direct others when threatened with contamination. Some nurses choose to be actively involved with disaster medical assistance teams as part of the National Disaster Medical System (NDMS). The NDMS is a multiagency program (Department of Health and Human Services, Department of Defense, Veterans Administration, Department of Homeland Security), coordinated by the NRF that supplements an integrated national medical response to assisting states and local authorities in dealing with the medical aspects of peacetime disasters.

In a true mass casualty event, it is impossible to have physicians present at every station where they are needed. Nurses may have to assume expanded roles in making decisions for the most appropriate treatment of casualties. Discussions should take place among physicians, nurses, and policy makers regarding the necessity of the nurses' expanded roles in crisis situations. As noted earlier in the chapter, these agency policies must be documented in an agency-wide plan. Additionally, all healthcare personnel must receive specialized training required to be safe and competent practitioners of the expanded duties. This training must be practiced and updated, and those participating in the training must be tracked and notified of additional requirements as necessary. Refer to your state's nurse practice act or guidance on scope of practice issues related to disaster response. See the Moving Evidence into Action box on page 128.

BOX 7–6 Roles of Nurses in Disasters

1. Prepare selves, families, friends, and communities for disasters in conjunction with the local disaster preparedness plan.
2. Continue educating self on various types of disasters and appropriate response.
3. Provide emergency services with consideration of victims' abilities, deficits, culture, language, or special needs.
4. Assist in the mobilization of healthcare personnel, food, water, shelter, medication, clothing, and other assistive devices.
5. Collaborate with agencies in authority including local, state, and federal representatives to deploy resources based on the greatest good for the greatest number.
6. Consider needs of victims including shelter both temporary and permanent, as well as psychologic, economic, legal, and spiritual factors.
7. Become involved with local, state, and national disaster planning agencies to schedule regular meetings to continually review and modify disaster plans.

Roles of Nurses Working with Victims of Disasters

The role of the nurse in a disaster depends on a number of variables, including the nature of the disaster, the number of victims and severity of injuries, the location of the disaster as well as the location of the nurse, and the availability of supplies, rescue and command personnel, and other necessary resources. The nurse must be able to perform under stressful conditions but will not be expected to endanger self, other nurses, or other rescuers.

If it is safe to do so, the nurse begins by triaging and assessing the victims for the best care and best use of available resources. Very quick, direct treatment may be given, or the nurse may be involved in extended periods of time with a mobile surgical unit. Local authorities such as the police, fire, and emergency medical services will guide the nurse in securing the area and determining the safe zone for the nurse and others to work. The National Disaster Medical System is the agency responsible for coordinating disaster relief with local fire,

Moving Evidence into Action

Disaster Education

The nursing profession has recognized the need to develop resources to teach practicing and future nurses to improve their response to disaster events. Surge capacity is a critical aspect of the healthcare system's ability to expand quickly beyond normal services to meet the increased demand for medical care in the event of a disaster. The purpose of a quasi-experimental study by Chiu et al. (2012) was to examine the effect of a blended education intervention (in-class and independent learning modules) developed to enhance public health nurses' confidence in 25 disaster surge competencies. The competencies address roles and tasks in disaster preparedness, response, and recovery. Fifty-four nurses participated in the study by completing pre- and post-intervention surveys to evaluate self-perceived confidence and the need for further training in the 25 competencies. Confidence in preparedness, response, and recovery competencies significantly increased and self-perceived need for further competency training decreased. The researchers concluded that a blended learning approach to disaster surge training effectively improved nurses' confidence when responding to disasters.

Implications for Nursing

Surge capacity is a critical aspect of disaster preparedness. Nurses are the single largest professional group in the healthcare workforce and must be able to quickly respond to disasters. The nation's emergency healthcare planners and trauma nurses will have a major challenge preparing more nurses for disasters, especially mass casualty events. The public expects nurses to deliver safe and competent care to the victims of terrorism. Disaster care competency should be a part of the curriculum in all basic nursing education schools and be available to all nurses through continuing education courses that are accessible and convenient. All nurses must develop basic disaster preparedness competencies to ensure the nation is prepared to respond to the increased healthcare demands that arise during disaster situations.

Moving Knowledge into Action

1. Make a list of all the barriers that nurses might express as reasons why they do not need or value disaster education and preparation.
2. Discuss the rationale for including basic disaster preparedness content in all basic nursing education programs and as a required component of continuing education for all nurses.
3. What can be done to support disaster training efforts for all nurses?

Source: Chiu, M., Polivka, B. J., & Stanley, S. A. (2012). Evaluation of a disaster-surge training for public health nurses. *Public Health Nursing, 29*(2), 136–142.

police, and emergency medical services to provide overall disaster assistance. Victim assistance may be offered in the field in mobile shelters, in local clinics, in hospitals, or in makeshift buildings.

Nurses take on a variety of roles based on their expertise and the needs of the victims. Nurses are expected to follow the emergency preparedness plans outlined in their communities and in their agencies of employment. Communication and teamwork are essential when involved in disaster response. Moreover, individual nurses should be the leaders in their communities in discussing emergency preparedness and contingency plans.

Considerations for Patients with Special Needs

Older Adults

It is not appropriate to generalize the needs of all older adults. Many are quite independent and active into their 90s. However, some older persons lack the physical stamina to recover quickly from disastrous events. The nurse must assess the individual's ability to cope with and recover from unexpected events, socioeconomic factors, support systems, potential healthcare needs, and resources. See the accompanying Case Study & Nursing Care Plan.

Teaching about disaster preparedness is important in all communities. Older adults need to determine the appropriateness of sheltering in place should there be an environmental event outside of their homes. Evacuation plans for older adults who cannot care for themselves for prolonged periods of time should be addressed. Consideration should be given to additional factors such as the time of year and need for heating and cooling during an extended power outage. This becomes a very real issue when roads become impassable or usual modes of transportation and communication are disrupted.

Older adults should be encouraged to keep a current list of medications, doses, and times of administration in an easily accessible, secure place. The names and phone numbers of significant individuals, relatives, those with power of attorney, healthcare providers, or any others to be notified in case of emergency should also be kept in an easily accessible place. Additionally, the following materials should be considered essential to keep with the person should evacuation to a shelter be necessary: eyeglasses and eyeglass prescriptions, style and serial numbers of medical devices such as pacemakers, healthcare policies and numbers, identification, list of allergies, blood type, checkbook, credit cards, insurance agent's name and number, driver's license, 72-hour supply of medications, dentures, list of special dietary needs, sturdy shoes, warm clothing, blankets, incontinence briefs, prostheses, hearing aids, hearing aid batteries, extra wheelchair batteries, oxygen, and other assistive devices.

Immunocompromised Patients

Patients who are immunocompromised pose special problems for the healthcare community, especially if access to healthcare is unavailable due to a disaster situation. A compromised immune system may be due to treatments such as chemotherapy or immunosuppressants or from an underlying disease such as HIV. The immunocompromised population would be at greater risk for complications and death than the general population should a bioterrorist attack occur. For example, a potential complication following smallpox vaccination is generalized vaccinia. It is believed to result from a vaccinia viremia with skin manifestations. In noncompromised persons, generalized vaccinia consists of vesicles or pustules appearing on normal skin distant from the vaccination site. The rash is generally self-limited and usually requires only supportive therapy. However, immunocompromised patients may have a toxic course and require vaccinia immune globulin (VIG), available only from the CDC (2009).

An additional issue the nurse should discuss with this population is the patients' preparation for disaster events related to infection control. Patients should carry treatment calendars with them at all times so that any healthcare provider can determine where they

are in their treatment program and disease process. Patients should plan a backup location to visit for chemotherapy if their usual office is inaccessible. Nurses should assess their patients' knowledge level regarding the avoidance of raw seafood or possibly contaminated water. Bottled water should be ready so the patient can avoid drinking water of questionable purity. Bone marrow and stem cell transplant patients are instructed not to eat fresh fruits and vegetables due to the risk of contamination and subsequent infection. It is safest for this population of patients to consume processed or canned foods if they can be heated to the proper temperatures.

Patients with Sensory, Speech, or Literacy Deficits

Persons who have sensory deficits, speech or language impairments, or who are illiterate must be assessed for the most effective means of communicating steps to be taken in the case of a disaster. Emergency personnel or rescue teams may need to learn a few basic phrases in American Sign Language. Something as simple as carrying a notepad and pencil or directions in large print may be what is necessary to share information with people who have hearing impairments or visual impairments, respectively. People with sensory or speech impairments will not all choose one particular means of communication; they will have individual preferences. A multitude of communication means are available through technologic support systems as well as written and visual cue boards. Public service announcements or reverse 911 calls may inform the general public about impending natural disasters and about proper steps to be taken to be safely rescued or sheltered. Nurses are in the position of alerting community leaders about special needs of members of their communities. Public service personnel, including fire, police, and emergency services, should be alerted to extenuating circumstances and needs of specific individuals in the community. The collaborative planning efforts of the individual, family members, caregivers, and emergency service personnel will help alleviate any undue pain and suffering caused by the lack of understanding of emergency messages and directives.

Patients with Mobility Deficits

As the U.S. population ages, many people require the use of assistive technology devices (ATDs) to accommodate mobility and other impairments. Careful planning must be in place in order to provide necessary support during and after a disaster. Arrangements should be made in advance to provide adequate numbers of volunteers or staff to assist when this group must be relocated or regrouped in a safe room or shelter. These individuals or their caregivers must provide input to service personnel to determine what kind of support services would be necessary in an emergency or disaster.

Non–English-Speaking Patients

The literacy of non–English-speaking patients should be assessed in both their own language and in English. One cannot assume that individuals are literate in their own language. It is ideal to obtain the assistance of an interpreter, preferably an interpreter with whom the patient is familiar (a family member or neighbor), to assist in translating information for the patient. Communication aids can be prepared in advance of disasters to be used during emergencies. The communication aids or disaster preparedness and response procedures should be practiced on a regular basis prior to an emergency. The use of visual aids is very helpful. Do not use children as interpreters if adults are available. The stress of interpretation can be overwhelming to the children and place an unnecessary burden on them.

Spiritual Considerations

Religion tends to be a source of comfort for those who are experiencing the threat of loss of life, property, or way of living. Churches, synagogues, mosques, and religious leaders become active in supporting their congregations in times of disaster. Religious leaders should be actively involved in community planning for disaster preparedness, especially if certain religious considerations should be strictly followed. For example, in some religions, the human body and all of its parts are considered sacred. To be sensitive to this religious belief, all tissues and blood would be collected at the site of a disaster by those trained to collect such material, as opposed to washing this matter away from the scene. In general, rescue personnel would need to be informed of specific religious obligations or rights in order to be sensitive to the individual's religious beliefs and practices.

CASE STUDY & NURSING CARE PLAN A Patient with Injuries from a Natural Disaster

Mr. Ed Jones, an 84-year-old widower, is retired from his job as a cabinetmaker. He continues to work with wood as a hobby in the basement of his home located on the banks of the Deep River. He sells small toys at craft fairs and flea markets in nearby communities. His daughter lives approximately 20 minutes away and checks in on him at least every weekend. Mr. Jones is independent and sees his primary care physician occasionally for monitoring of his blood pressure, which is controlled with antihypertensive medications. Following a week of heavy rainstorms, flash flooding occurred in the area and Mr. Jones's basement sustained much water damage and ruined most of his stored wood, wooden toy products, and the woodworking machinery. Mr. Jones waded through the waist-deep water to get to the rescue boat rather than wait for the boat to get to him. He is subsequently admitted to the medical-surgical unit due to concerns from the EMTs who triaged him at the fire station 5 miles inland from Mr. Jones's neighborhood.

ASSESSMENT

Lisa Smith, RN, obtains a nursing assessment. Mr. Jones states that he has been on antihypertensive medications for "a few years" but only takes his medication "once in awhile" since it has been some time since his last office visit and he wants his remaining pills "to last" until he can get back to the doctor. He has had numerous cuts to his hands from his woodworking and has had a big ulcer on his right foot "for a few weeks" caused by a tool that fell on his foot. He did not seek medical care because he believed it would get better on its own. "It looks worse than it is. It really doesn't even hurt."

When asked about his home, he states, "Everything is gone. My wife is gone, my wood, my tools . . . it's all over."

Physical assessment findings include T 39.1°C (100.7°F) PO, P 96 bpm, R 20/min, and BP 178/100 mmHg. Skin cool and dry with multiple lesions on both hands and a stage II ulcer on his

(*continued*)

CASE STUDY & NURSING CARE PLAN A Patient with Injuries from a Natural Disaster (*continued*)

right dorsal foot with yellow-green exudate. Pain rated at a 2 on a 10 scale, with 10 being the worst pain there could be. Lungs are clear, heart rate regular. No edema noted. Abdominal assessment is normal. Neurologically intact. Weight is normal for height and frame. A culture is ordered and taken of the yellow-green exudate of the right foot.

Preliminary blood work results show WBCs at 15,000/mm^3. A peripheral IV is initiated with continuous fluids, and IV antibiotics are ordered every 6 hours. An antihypertensive medication is ordered on a regular schedule plus a prn antihypertensive for systolic >180 and diastolic >90.

NURSING PROBLEMS/DIAGNOSES

- *Impaired Skin Integrity* of the right foot and hands related to lesions (cuts) on the hands and stage II ulcer with exudate on the right foot
- *Powerlessness* related to perceived loss of control over life situation
- *Ineffective Thermoregulation* related to trauma
- *Acute Pain* related to expression of pain secondary to skin lesions

EXPECTED OUTCOMES

- Patient will regain skin integrity—ulcer on right foot and lesions on hands will heal.
- Patient will identify aspects of his life still under his control.
- Patient will maintain body temperature at normothermic levels.
- Patient will express feeling of comfort and relief from pain.

PLANNING AND IMPLEMENTATION

- Assess skin every shift; describe and document skin condition; report changes.
- Clean lesions on hands and right foot every 8 hours and assess healing.
- Administer prescribed antibiotics and assess for effectiveness in treating infection.
- Arrange psychosocial consult(s).
- Guide Mr. Jones through a life review. Encourage reflection on past achievements.
- Help Mr. Jones identify the aspects of his life that are still under his control.
- Monitor temperature every 4 hours, more often if indicated.
- Monitor and record patient's heart rate and rhythm, blood pressure, and respiratory rate every 4 hours.
- Administer analgesics, antipyretics, and medications as indicated.
- Maintain hydration; monitor intake and output.
- Assess level of pain and administer pain medication as prescribed.

EVALUATION

Mr. Jones was hospitalized for 3 days, receiving intravenous antibiotic therapy, analgesics, an antidepressant, monitoring of his cardiac response to a new antihypertensive medication, wound care, and sessions with the social services representative and his daughter. His hand lesions are healed, the foot ulcer has developed new granulation tissue with no signs of infection, he is afebrile, and his blood pressure is maintained within normal limits. He will be discharged to his daughter's home until his home can be assessed for the extent of the water damage and feasibility of repair. He has agreed to visit a therapist to work through his feelings of grief and loss. He has expressed an interest in attending monthly support group meetings with his neighbors who also experienced losses in this disaster.

Clinical Reasoning in Patient Care

1. What action did Mr. Jones take that probably exacerbated his skin lesions?
2. What other testing might you anticipate related to Mr. Jones's delayed healing?
3. What were the contributing factors to Mr. Jones's fever?
4. What life situations contributed to Mr. Jones's attitude about life?

See Evaluating Your Response in Appendix B.

CHAPTER HIGHLIGHTS

- **As the largest healthcare workforce, every nurse must be competent to participate in all phases of the disaster continuum.**
- Nurses play a key role in disaster planning mitigation, response, and recovery efforts and are expected to participate in their communities' and agencies' disaster preparedness systems.
- **The disaster continuum is characterized by three major phases: preimpact (before), impact (during), and postimpact. Distinct nursing competencies have been identified related to each phase.**
- **Nurses perform multiple roles in disaster situations and acquiring and maintaining competency requires continued professional development to ensure competency is established and maintained.**
- Disasters require extraordinary efforts beyond those needed to respond to everyday emergencies, and effective disaster management requires system capacity, competent responders, and a defined, executable, and practiced disaster response plan.
- Nurses have an obligation to keep current in new and emerging trends in healthcare and threats to society.
- **Triage in disaster and mass casualty incidents involves different guidelines than those used in daily triage.**
- Distinct patterns of illness and injury are associated with different types of disasters and early identification of risks can reduce morbidity and mortality.
- The principle in reverse disaster triage is to do the greatest good for the greatest number of people.

- **Preparation for disaster involves preparing yourself and your family.**
- **Identifying and initiating disaster preparedness for high-risk and high-vulnerability populations who are at increased risk of being exposed to disaster are essential nursing priorities.**
- Nurses will be actively engaged in assessing the physical as well as the mental needs of victims, their families, first responders, and other healthcare personnel.

TEST YOURSELF NCLEX-RN® REVIEW

1. The nurse has been asked to participate on the disaster planning committee. What should the nurse realize as being the difference between emergencies and disasters?
1. Emergencies are controlled.
2. Disasters result from human-generated errors.
3. Emergencies can typically be handled by available emergency services.
4. Disasters typically involve the local emergency services and no other agencies.

2. The nurse is reviewing the competencies needed when preparing and caring for victims of a disaster. In which activity is the nurse least likely to participate?
1. Communicate and share findings from disaster situations.
2. Lead the incident command center at the site of a disaster.
3. Participate in developing policies and planning for disasters.
4. Educate the community about reducing human-generated disasters.

3. The nurse is using reverse triage with victims of a human-generated disaster. Which statement best describes the nurse's actions?
1. Saving scarce resources for future use
2. Saving those persons who are in the most critical condition
3. Testing first responders on their triage classification categories
4. Doing the greatest good for the greatest number with limited resources

4. The nurse is assessing a foreign-born patient in both English and the patient's primary language. Why is the nurse doing this?
1. The patient is most comfortable reading in the primary language.
2. The patient is most comfortable speaking in the primary language.
3. The patient may not be able to read and comprehend in the primary language.
4. The patient may be self-conscious about communicating in English if it is not the primary language.

5. Prior to assessing a victim of a human-generated disaster, the nurse applies personal protective equipment. What is the reason for this equipment to be used?
1. It creates a barrier against hazards.
2. Wearing PPE is an expectation for all healthcare personnel.
3. It reduces the likelihood of occupational injury and/or illness.
4. It prevents the need to follow universal precautions.

6. The charge nurse is observing a nurse set up and provide decontamination for victims of a human-generated disaster. For which decontamination practice should the charge nurse counsel the nurse?
1. Decontamination completed before the patient enters the hospital
2. Decontamination started in the hot zone, closest to the site of the disaster
3. Decontamination done by sweeping strokes away from the nurse and the patient
4. Decontamination corridor set up in an area downwind from the hospital entrance

7. The nurse is caring for a victim of a radiologic dispersion bomb. Which intervention would be appropriate when caring for this victim?
1. Apply sterile dressings over burn.
2. Assess for abdominal organ damage.
3. Explain that eye injuries will heal in time.
4. Assess for manifestations of radiation sickness.

8. The nurse is a member of a disaster response task force that is currently reviewing the reconstitution of a community after several tornadoes. What is the committee assessing at this time?
1. How the harmful effects of the disaster were reduced
2. The extent to which the community has achieved a new normal
3. What worked and what did not work when responding to the disaster
4. The local healthcare organizations' abilities to respond beyond normal services

9. Why should the nurse assess the special needs of older adults as part of an emergency preparedness plan?
1. All older adults will need some kind of special support.
2. Some older adults will take the lead in evacuation efforts in nursing homes.
3. Not all older adults need the same level of support in emergencies and disasters.
4. Some older adults will be unable to evacuate even with multiple support systems.

10. After victims of a human-generated disaster are triaged and admitted to the hospital, the emergency department nurses are scheduled for appointments with a mental health professional. Why is this being done?
1. Determine which nurses need time off after the disaster.
2. Problem solve mental health issues of the patients admitted from the disaster.
3. All nurses need the help of a mental health worker at some point in their careers.
4. The nurses may feel overwhelmed and traumatized from the disaster in a manner similar to that of the victims.

UNIT

2 Building Clinical Competence

Alterations in Patterns of Health

CLINICAL SCENARIO

Directions: *Read the following clinical scenario and answer the related questions. To complete this exercise successfully you will not only use knowledge of the content in this unit, but also principles related to setting priorities and maintaining patient safety.*

You have been assigned to work with the following four patients for the 0700 shift on a medical-surgical unit. Significant data obtained during report is as follows:

- Louis Black is a 46-year-old who was admitted from the emergency department 2 hours ago for observation after being thrown 50 yards during a tornado. His vital signs on admission were stable: T 37.7°C (99.8°F), P 86 bpm, R 24/min, and BP 140/86 mmHg. He had multiple abrasions and lacerations that were sutured in the emergency department. He is now complaining of numbness in both legs.
- Mary Black is the 44-year-old wife of Louis Black. She was admitted 1 hour ago with multiple abrasions and ecchymotic areas. She is scheduled to go to surgery at 0900 for an open reduction of a left ankle fracture. Current vital signs are T 37.2°C (99°F), P 90 bpm, R 26/min, and BP 134/88 mmHg. She is requesting pain medication and wants to see her children, who were admitted to the pediatric unit, before going to surgery.
- John Linzer, age 67, was admitted 1 week ago in the terminal stages of colon cancer. Vital signs are T 36°C (96.8°F), P 54 bpm, R 10/min, and BP 88/68 mmHg. The family is requesting that a nurse check on Mr. Linzer as they feel that death is imminent. Mr. Linzer has signed a do-not-resuscitate order.
- Paul Goetz, age 47, was admitted 3 days ago due to being found unconscious in his car. On admission his alcohol level was 0.45. Current vital signs are T 37.8°C (100°F), P 110 bpm, R 30/min, and BP 168/94 mmHg. He is diaphoretic, disoriented, and complaining of nausea and seeing spiders on the wall. Mr. Goetz has a 5-year history of alcohol abuse.

CLINICAL REASONING

1. Why is it essential that the nurse immediately follow up on Mr. Black's new complaint of numbness in both legs?

Priority Setting

2. With his history of alcoholism, which is the priority nursing intervention in the plan of care for Mr. Goetz?
   A. Identify maladaptive behaviors that may contribute to the alcoholism.
   B. Encourage patient participation in therapeutic group activities.
   C. Teach the patient the effects of alcohol use on his body.
   D. Use a respectful, nonjudgmental approach to gain the patient's trust.

Nursing Process

3. Besides obtaining vital signs, what diagnosis-specific assessment data should be collected for each patient?
   A. _____
   B. _____
   C. _____
   D. _____

4. Mrs. Black understands the postoperative teaching done by the nurse when she states which of the following?
   A. "Since my surgery is on my ankle, I will need to stay still in the bed to prevent pain."
   B. "I will need to cough frequently to remove fluids from my lungs."
   C. "Since I will have a PCA machine for pain medication, I will not have to ask for pain medication."
   D. "I will be able to eat and drink as soon as I return from surgery."

Health Promotion

5. The nurse has provided dietary instruction to Mrs. Black in order to ensure proper healing of her fractured ankle. The nurse determines that the patient has understood the teaching if she orders which of the following meals?
   A. hamburger, french fries, and a cola beverage
   B. tossed salad, chocolate pudding, and iced tea
   C. baked chicken, broccoli and cheese, and lemonade
   D. salmon patty, rice, and milk

Communication

6. What information should be communicated with the pediatric unit nurses prior to Mrs. Black being allowed to visit her children before she has surgery on her ankle?

Delegation

7. What nursing interventions for each patient can be delegated to a certified nursing assistant (CNA)?

A. _____
B. _____
C. _____
D. _____

Interprofessional Care

8. The nurse collaborates with the healthcare provider regarding Mr. Goetz, who is diaphoretic, disoriented, nauseated, and seeing spiders on the wall. Which of the following interventions should the nurse anticipate being prescribed?

A. Application of limb restraints
B. Oxygen by nasal cannula at 2 L/min
C. Administration of metoclopramide (Reglan) 10 mg. I.V.P. stat
D. Administration of lorazepam (Ativan) 1 mg. I.V.P. every 6 hours

Continuity of Care

9. Why should hospice care be discussed with Mr. Linzer's family?

Safety

10. Identify the three key elements of the Universal Protocol.

A. _____
B. _____
C. _____

Quality Improvement

11. Mrs. Black is scheduled for an open reduction for a left ankle fracture. Which of the following would be included in the perioperative plan of care to be in accordance with the Surgical Care Improvement Project (SCIP)?

A. Shave the entire left lower extremity.
B. Administer warmed intravenous fluids to increase body temperature.
C. Apply a pneumatic compression device to the nonoperative leg.
D. Administer prophylactic antibiotic 2 hours before incision time.

Nursing Ethics

12. Mr. Goetz asks you to bring him some beer. He says, "You can smuggle it in and no one will know." How will you respond?

Informatics

13. On a medical-surgical unit, the nurse may encounter patients with diagnoses that are unfamiliar. What computerized resources may be widely available to provide quick access to information about evidence-based care standards?

A. unit-based quality improvement data
B. basic nursing orientation module
C. National Guidelines Clearinghouse
D. general Internet search

8 Genetic Implications of Adult Health Nursing

LEARNING OUTCOMES

1. Discuss the role of genetic concepts in health promotion and health maintenance.
2. Apply knowledge of the principles of genetic transmission and risk factors for genetic disorders.
3. Describe the significance of delivering genetic education and counseling follow-up in a professional manner.
4. Explain the implications of genetic advances on the role of nurses with particular attention to spiritual, cultural, ethical, legal, and social issues.
5. Identify the significance of recent advances in human genetics and the effect on healthcare delivery.

CLINICAL COMPETENCIES

1. Integrate genetic assessment and the use of a pedigree family history into delivery of nursing care.
2. Identify patients or families with actual or potential genetic conditions and initiate referrals to a genetics professional.
3. Prepare patients and their families for a genetic evaluation and facilitate the genetic counseling process.
4. Integrate basic genetic concepts into patient and family education with consideration of cultural and personal preferences and values of the family and the reinforcement of information provided to patients by genetic professionals.

MAJOR CHAPTER CONCEPTS

- Nurses are responsible for basic genetic knowledge and for delivering the expected standard of genetic nursing care. Nurses must be aware of the social, ethical, cultural, and spiritual issues related to the delivery of genetic nursing care.
- Basic genetic nursing care involves family risk assessment through a detailed family history, integration of genetic concepts into a physical assessment, and initiation of a referral to a genetic specialist.
- Genetic concepts can be applied to health promotion and health maintenance. Knowledge of the principles of inheritance allows the nurse to not only offer and reinforce genetic information to patients and their families but also to assist them in managing their care and in making reproductive decisions.

Ongoing research in genetics has enhanced our understanding of the causes of disease, its natural course, and the factors that increase risk for the development of many diseases. Genetics research is focused not only on traditional genetic disorders, but also on common complex diseases such as heart disease, stroke, diabetes, and several kinds of cancer. The knowledge gained from the Human Genome Project (Box 8–1) and the continued efforts of scientists and clinicians has and will continue to have a profound impact on the prevention, diagnosis, and treatment of genetic disorders and complex diseases (Figure 8–1 ■).

INTEGRATING GENETICS INTO NURSING PRACTICE

Genetic knowledge will continue to revolutionize how individuals perceive themselves, their health status, and their health potential. Therefore, nurses must integrate genetics into nursing practice. The *Statement on the Scope and Standards of Genetics Clinical Nursing Practice* from the American Nurses Association and the International Society of Nurses in Genetics (ANA/ISONG) defines the role of all nurses regardless of practice setting, thus emphasizing the importance of genetics in every arena of healthcare. According

BOX 8–1 Human Genome Project

In 1986, the U.S. Department of Energy (USDOE) announced the Human Genome Initiative, and in 1990 the USDOE joined with the National Institutes of Health (NIH) to develop the Human Genome Project (HGP). The ultimate goal was to sequence the **human genome** and identify all human genes. The completion of a high-quality reference sequence was announced in April 2003. Information obtained through the sequencing of the human genome has had a tremendous impact on finding the genes associated with human disease. Future research will now be directed toward understanding the complex functions of cellular regulation, human variation, and the interplay of genes and environment and how all the cell organelles, genes, and proteins work together in life's functions (USDOE Genome Programs, 2008).

to the ANA/ISONG (2007), all registered nurses must have an understanding of genetics to identify, support, and care for patients who have or who may transmit genetic conditions.

Nurses must have basic genetic knowledge to care for the needs of patients and their families with known or suspected genetic disease. Basic interventions that meet the standards of genetic nursing include the following:

- Identify simple risk factors by completing a genetics-focused family history.
- Perform an accurate and thorough physical assessment.
- Apply concepts of health promotion and health maintenance to assist the patient and family in making informed decisions while facilitating autonomy.
- Be a patient advocate and provide patients with information about available resources and services.
- Provide patient education and make referrals when appropriate.
- Complete an evaluation of the plan of care for the patient.
- Apply knowledge of the ethical, legal, cultural, and social implications of genetic information.

Nurses can improve the nursing care provided to patients by applying fundamental genetic concepts to their practice.

GENETIC BASICS

Life starts as a single cell, but the developed human body is made up of many cells. These cells share common features such as a nucleus that contains 46 chromosomes, and organelles such as mitochondria (refer to Figure 8–1). Many different types of specialized cells throughout the body function differently depending on their location. For example, pancreatic cells have a very different function than that of nerve cells.

All human cells, except mature red blood cells, contain a complete set of deoxyribonucleic acid (DNA) molecules. DNA molecules consist of long sequences of nucleotides or bases represented by the letters A, T, G, and C. The order of these bases gives the exact instructions for the functioning of that particular cell. Writing the correct order of the bases using the abbreviations represents the sequence of the bases in DNA. Together, the total sum of DNA in a human cell is referred to as the human *genome*, or the complete set of inheritance

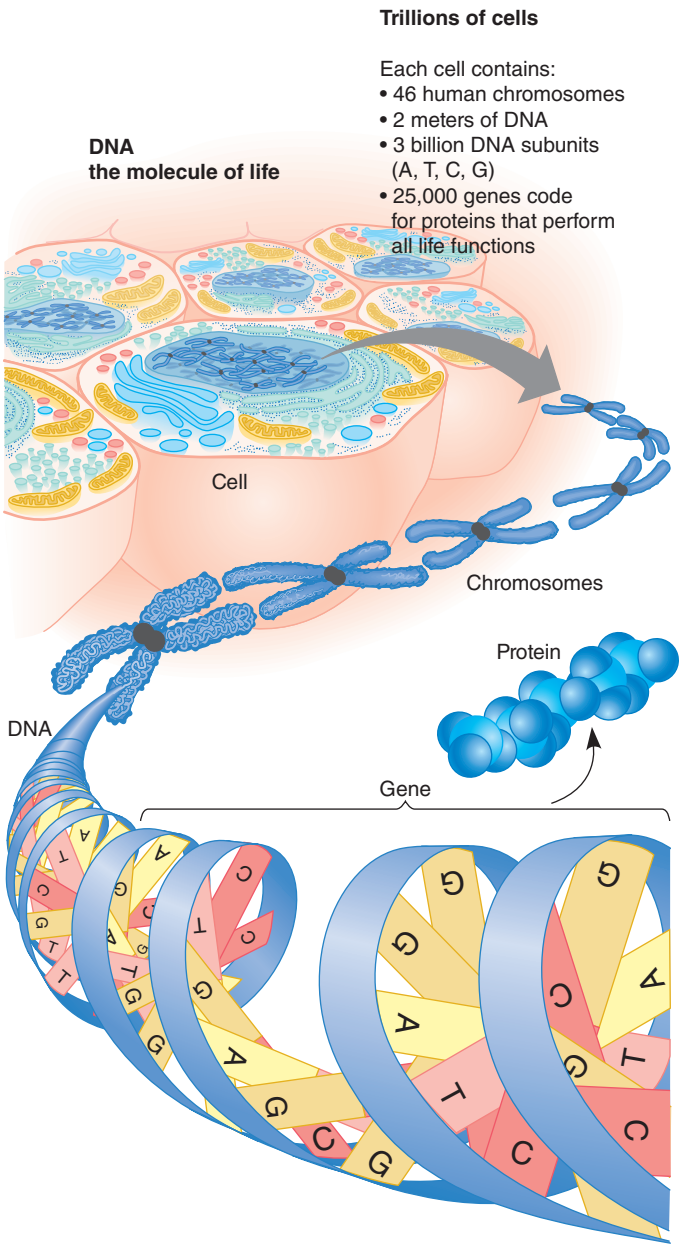

Figure 8–1 ■ Each cell nucleus throughout the body contains the genes, DNA, and chromosomes that make up the majority of an individual's genome. The remaining portion of the human genome is in the mitochondria.

Source: From Ball, Jane W., Bindler, Ruth McGillis W., and Cowen, Kay J., *Child Health Nursing: Partnering with Children and Families*, 3rd, © 2014 Pearson Prentice Hall. Reproduced by permission of Pearson Education, Inc., Upper Saddle River, New Jersey.

for an individual. The human genome includes the DNA in the cell nucleus as well as the DNA found in the mitochondria, which will be discussed later in this section. Each individual's genome is unique. Identical (monozygotic) twins are the exception because they develop from only one fertilized ovum and share identical DNA.

The cell nucleus contains about 6 feet of DNA that is tightly wound and packaged into 23 pairs of chromosomes, making a complete set of 46 **chromosomes**. The structure and number of chromosomes can be shown by a karyotype, or picture, of an individual's chromosomes (Figure 8–2 ■). There are two copies of each chromosome. One copy, or half of the complete set of these 46 chromosomes, is inherited from the mother and the other copy, or the other half of

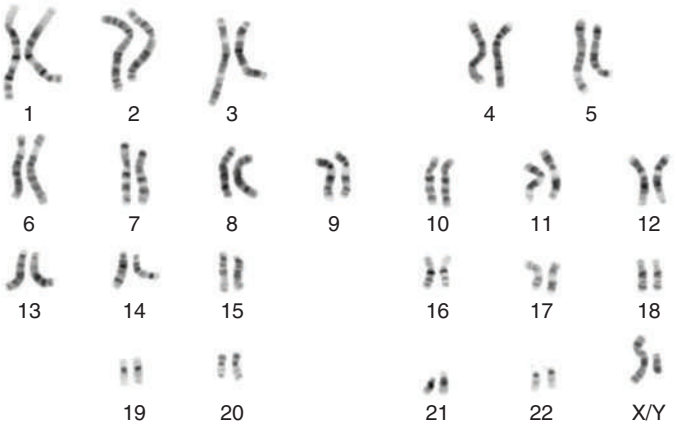

Figure 8–2 ■ A karyotype is a picture of an individual's chromosomes. It shows the chromosomal structure and number of the 22 pairs of autosomes and the sex chromosomes.
Source: Medical-On-Line/Alamy.

the 46 chromosomes, is inherited from the father. For example, an individual will have two copies of chromosome 1, one inherited from his or her mother and one inherited from his or her father. These two copies or pairs of inherited chromosomes are called homologous (the same) chromosomes. Chromosomes are numbered according to size (largest to smallest), with chromosome 1 being the largest. The first 22 pairs of chromosomes, known as **autosomes**, are alike in males and females. The 23rd pair, the **sex chromosomes**, determines an individual's gender. A female has two copies of the X chromosome (one copy inherited from each parent), and a male has one X chromosome (inherited from his mother) and one Y chromosome (inherited from his father).

Cell Division

Mitosis and meiosis are the two types of cell division in human cells. **Mitosis** is the process of making new cells and it takes place in the **somatic**, or tissue, **cells** of the body. Cell division through mitosis results in two cells called *daughter cells* that are genetically identical to the original cell (*mother cell*), and to each other. Cell division through mitosis heals wounds and replaces cells lost daily on skin surfaces and in the lining of gastrointestinal and respiratory tracts. In addition, mitosis is responsible for human development. The mitotic activity of the zygote and its daughter cells is the foundation for a human's growth and development. The zygote undergoes mitosis to form a multicellular embryo, then fetus, then infant.

Meiosis is also known as the reduction division of the cell. Meiosis occurs only in the sex cells of the testes and ovaries and results in the formation of the sperm and oocyte (gametes). Meiosis is very similar to mitosis in that it is a form of cell division; however, through a series of complex mechanisms, the amount of genetic material is reduced in half (23 chromosomes). This is very important because when the two sex cells combine during fertilization, the total number of chromosomes (46) is present in the offspring's cells. Meiosis has three purposes: (1) to produce gametes, (2) to reduce the number of chromosomes by half, and (3) to make new combinations of genetic material from crossing over and independent assortment processes, which allows diversity in the human population.

Chromosomal Alterations

Alterations in chromosomes often occur during cell division and are classified as either alterations in the number of chromosomes or structural alterations. They involve either part of or the whole chromosome. The clinical consequences of number and structural changes in the chromosomes in an individual vary depending on the amount and type of DNA affected by the alterations.

ALTERATIONS IN CHROMOSOME NUMBER

An increase or decrease in chromosomal numbers can occur during meiosis or mitosis (Box 8–2). Alterations occur often during meiosis because meiosis is a highly specific and complex process and each new daughter cell must contain exactly one chromosome from each pair of chromosomes. During meiosis, the paired chromosomes may fail to separate, resulting in an egg or sperm cell with either two copies or no copies of a particular chromosome. This is known as *nondisjunction*. When these egg or sperm cells are fertilized by a normal gamete that contains 23 copies of all of the chromosomes, a zygote that is monosomic (one member of the chromosome pair is missing) or trisomic (having three chromosomes instead of the usual two) results. These circumstances produce such conditions as *monosomy* of the sex chromosomes in a female (Turner syndrome) or *trisomy* of autosomes, of which **trisomy 21** (Down syndrome) is one of the more commonly known.

ALTERATIONS IN CHROMOSOME STRUCTURE

Alterations in chromosome structure include inversions, deletions, duplications, and translocations. In a chromosomal inversion a segment of a chromosome is reversed, changing the DNA sequence for that portion of the chromosome. It occurs when a chromosome breaks in two places and the piece between the breaks turns upside down and reattaches within the same chromosome. The clinical consequences of an inversion depend on how much chromosomal material is involved, where the inversion occurs, and what type of inversion is present.

A chromosomal alteration that includes a missing (deletion) or additional (duplication) whole chromosome or segment of a chromosome is an unbalanced rearrangement. An unbalanced rearrangement can result in missing genes, confusing directions from the genes, or too much gene product, which often results in a condition that is not compatible with life or in altered physical and/or mental

BOX 8–2 Terminology and Variations in Chromosomal Number

Euploidy—the presence of the normal number of 46 chromosomes
Aneuploidy—the condition in which extra or missing chromosomes exist; in affected living individuals, physical abnormalities and/or mental retardation are common
Monosomy—the loss of a single chromosome from a pair; for example, Turner syndrome (45,XO)
Trisomy—the gain of a single chromosome, making a total of three copies of a certain chromosome, for example, trisomy 21 or Down syndrome
Polyploidy—the condition in which more than two pairs of all the chromosomes are present

development. An example is *cri-du-chat* syndrome (mental retardation, crying that sounds like a cat mewing, and low-set ears), which results from a large deletion on 5p (the short arm of chromosome 5).

Translocation (chromosomal reshuffling) occurs when a segment of a chromosome transfers or moves and attaches itself to another chromosome. An example is the reciprocal translocation that is found in 95% of patients with chronic myelogenous leukemia (CML) (National Cancer Institute, 2012). The contributing translocation occurs between chromosomes 9 and 22 and is known as the Philadelphia chromosome. The translocation that occurs between chromosomes 9 and 22 is not inheritable. However, this is not true for all translocations. About 4% of trisomy 21 cases are caused by a translocation; of these, half can be attributed to a translocation inherited from a parent (Mayo Clinic, 2011). The parent remains unaffected because although he or she has extra material, his or hers is a balanced chromosomal rearrangement.

Genes

A **gene** is a small portion (segment) of the nucleotide (base) sequence of a chromosome that provides specific directions for a particular function or characteristic. Each chromosome contains numerous genes arranged in a linear order. The specific sequence of nucleotides (the genes and the variations therein) is referred to as the individual's **genotype**. Researchers currently believe there are about 20,000 to 30,000 genes in the human genome (Jameson & Kopp, 2012; Lister Hill National Center for Biomedical Communications, 2014).

With the exception of the genes on the sex chromosomes (X and Y) present in males, all genes come in pairs called **alleles**. All genes have a specific location on a specific chromosome. This is known as the *genetic locus*. For example, one of the many genes located on chromosome 19 is a gene for eye color. There may be slight variations or different forms of a gene, for instance, green versus blue eye color. When an individual has two identical forms (alleles) of a gene they are said to be **homozygous** (homo = same). If an individual has two different forms (alleles) of the gene, they are said to be **heterozygous** (hetero = different). Genes can be described as *altered* or *mutated* when a change has taken place, or *expressed* when the gene has an impact on the outward appearance of an individual and/or the functioning of cells. The observable, outward expression of an individual's entire physical, biochemical, and physiologic makeup, as determined by his or her genotype (alleles) and environmental factors, is referred to as **phenotype**.

FUNCTION AND DISTRIBUTION OF GENES

One function of genes is to provide directions for how to make proteins. These protein-directing genes are very important to life and functioning as a human. They are responsible for transmitting messages between cells, fighting infection, directing genes to turn "on" or "off," forming structures, as well as sensing light, taste, and smell (U.S. National Library of Medicine, 2012). Some gene activities change from moment to moment in response to tens of thousands of intra- and extracellular environmental signals. An example of this is the feedback mechanism that stimulates a cell to produce insulin after eating a candy bar. After eating, a gene on chromosome 11 directs pancreatic cells to produce, modify, and secrete insulin. Although the gene for producing insulin is present in all nucleated cells of the body, it is only functional in insulin-secreting pancreatic cells.

MITOCHONDRIAL GENES

Chromosomes in the cell nucleus are not the only site where genes reside. Several dozen that are involved in energy metabolism are located in the cell mitochondria (the powerhouse of the cell). *Mitochondria* are concerned with energy production and metabolism. Some cells contain more mitochondria than others, but each mitochondrion contains its own copies of DNA identified as mitochondrial DNA (mtDNA). Because ova contain many mitochondria and sperm do not (most mitochondria are located in the tail of the sperm, which detaches after fertilization), mtDNA is primarily inherited from the mother. Therefore, mitochondrial genes and any diseases due to DNA alterations on those genes are transmitted through the mother in a matrilineal pattern. This pattern of inheritance is very different from the pattern of inheritance of genes found in the nucleus of the cell. Thus, an affected female will pass the mtDNA mutation to all of her children; however, an affected male will not pass the mtDNA mutation to any of his children (John et al., 2010; Nussbaum et al., 2007). Manifestations of conditions due to mitochondrial gene alterations primarily involve high-energy tissues and organs such as skeletal muscle, heart muscle, the liver, kidney, brain, and nerve cells. The ears, eyes, and endocrine system are also affected. Symptoms develop over years as unhealthy or dying cells are not replaced. Hypertrophic cardiomyopathy, heart block, seizures, and deafness are associated with mtDNA gene alterations (John et al., 2010; Nussbaum et al., 2007).

GENE ALTERATIONS AND DISEASE

Today, we know that gene alterations are responsible for approximately 6000 hereditary diseases (Nussbaum et al., 2007). However, different genetic alterations within a particular gene can result in a wide variety of signs and symptoms. For example, the *CFTR* gene for cystic fibrosis is a very large gene located on chromosome 7. More than 1500 different mutations of the CFTR gene have been reported to be associated with disease (Ferraguti et al., 2011). The area of the CFTR gene that controls mucous production can have more than 300 different alterations, resulting in a variety of symptoms ranging from no symptoms at all to mild or severe (U.S. National Library of Medicine, 2012). Gene alterations, not the genes themselves, cause genetic diseases and conditions.

GENE ALTERATIONS THAT DECREASE RISK OF DISEASE

Although it is common to associate gene mutations with disease, it is important to remember that gene mutations can also be helpful in decreasing the risk of disease. Gene alterations and genetic variations may also have a protective role in the expression of diseases. A common example is the protective value of the gene alteration that causes sickle cell disease. Those individuals with this gene alteration have protection against malaria. Another example is the *APOE* gene. The APOE gene provides instructions for making a protein called apolipoprotein E. This protein combines with fats (lipids) in the body to form molecules called lipoproteins that are responsible for packaging cholesterol and other fats and carrying them through the

bloodstream. There are at least three slightly different versions (alleles) of the APOE gene. The major alleles are called e2, e3, and e4. Research has shown that a person who inherits at least one e4 allele will have a greater chance of developing Alzheimer's disease. However, inheriting the e2 allele seems to indicate that a person is less likely to develop Alzheimer's (Genin et al., 2011).

SINGLE NUCLEOTIDE POLYMORPHISMS

Greater than 99% of human DNA sequences are the same (HGP, 2008b). **Polymorphisms** are natural variations in gene DNA sequences in which each possible sequence is present in at least 1% of people, usually having no adverse effect on the individual. *Single nucleotide polymorphisms* (SNPs, or "snips") are the most common type of genetic variation among humans and are one-letter (base-pair) variations in the DNA sequence that serve as biologic markers. **Biologic markers** are important for the construction of chromosome maps and are easily tracked, stable segments of DNA. Scientists are hopeful that information gained from SNPs will provide information on how subtle differences in humans impact their response to drugs and the environment, thus making medical treatment and pharmacologic management more individualized.

PRINCIPLES OF INHERITANCE

Knowledge of inheritance allows the nurse to provide genetic information to patients and their families to assist them in managing their care and in making reproductive decisions. The basic underlying principles of inheritance that nurses can apply to inheritance risk assessment and teaching include (1) all genes are paired, (2) only one gene of each pair is transmitted (passed on) to an offspring, and (3) one copy of each gene in the offspring comes from the mother and the other copy comes from the father. Understanding the Mendelian patterns of inheritance is made easier by relating these principles.

Mendelian Pattern of Inheritance

Conditions that are caused by a mutation or alteration of a single gene are known as *monogenic* or *single-gene disorders*. The most common gene alterations that result in genetic disorders are predictably passed on from generation to generation following Mendelian inheritance patterns (Mendel's laws of inheritance). These single-gene mutations follow an **autosomal dominant**, **autosomal recessive**, **X-linked recessive**, or X-linked dominant inheritance pattern. The first three of these patterns are the most common. Modes of transmission or inheritance for thousands of conditions resulting from monogenic alterations have been identified (U.S. National Library of Medicine, 2012).

AUTOSOMAL DOMINANT

Autosomal dominant (AD) conditions are the result of an altered gene on any of the 22 autosomes or non–sex chromosomes (Figure 8–3 ■). More than half of the known Mendelian conditions are autosomal dominant. In AD conditions, disease occurs in spite of the fact that one unaltered or normal gene exists. Homozygous dominant conditions (the individual has inherited dominant altered genes from both parents) are generally much more severe than heterozygous dominant conditions and are often lethal. Because homozygous dominant conditions are usually lethal and would result from both parents being affected, the nurse should consider an individual exhibiting an autosomal dominant condition as heterozygous. See Box 8–3 for characteristics of an AD pattern of inheritance.

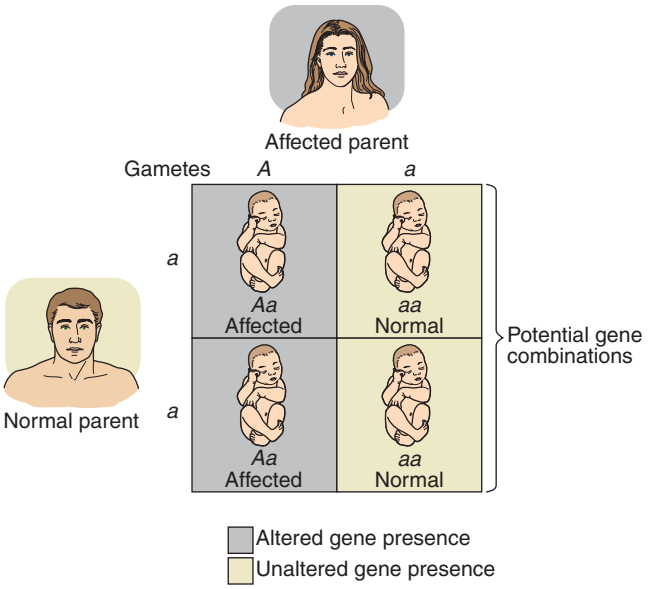

Figure 8–3 ■ This Punnett square shows potential gene combinations (genotypes) and resulting phenotypes of children from parent genotypes with an autosomal dominant altered gene. Phenotypes are expressed (affected) when a male *or* female has one copy of the gene alteration.

Source: From Ball, Jane W., Bindler, Ruth McGillis W., Cowen, Kay J., *Child Health Nursing: Partnering with Children and Families*, 3rd, © 2014. Reproduced by permission of Pearson Education, Inc., Upper Saddle River, New Jersey.

AUTOSOMAL RECESSIVE

A gene or genetic condition is considered recessive when two copies of altered genes are needed to express the condition. Autosomal recessive (AR) conditions are the result of an altered gene on any of the 22 autosomes or non–sex chromosomes (Figure 8–4 ■). An individual with a recessive condition has inherited one altered gene from his mother and one from his father. In most cases, each of the parents has a single gene alteration on one chromosome of a pair and the normal, wild-type or unaltered form of the gene on the other chromosome. These parents would be known as *carriers* of the condition

BOX 8–3 Autosomal Dominant Mendelian Inheritance Characteristics

(Examples: neurofibromatosis, breast and ovarian cancer, autosomal dominant polycystic kidney disease, Marfan syndrome, Huntington disease, familial hypercholesterolemia)

When gathering a family history, the nurse should assess for any of the following characteristics of autosomal dominant inheritance:

1. Both males and females are affected.
2. Males and females are usually affected in equal numbers.
3. An affected child will have an affected parent and/or all generations will have an affected individual (appearing as a vertical pattern of affected individuals on the family pedigree).
4. Unaffected children of an affected parent will have unaffected offspring.
5. A significant proportion of isolated cases are due to a new mutation.

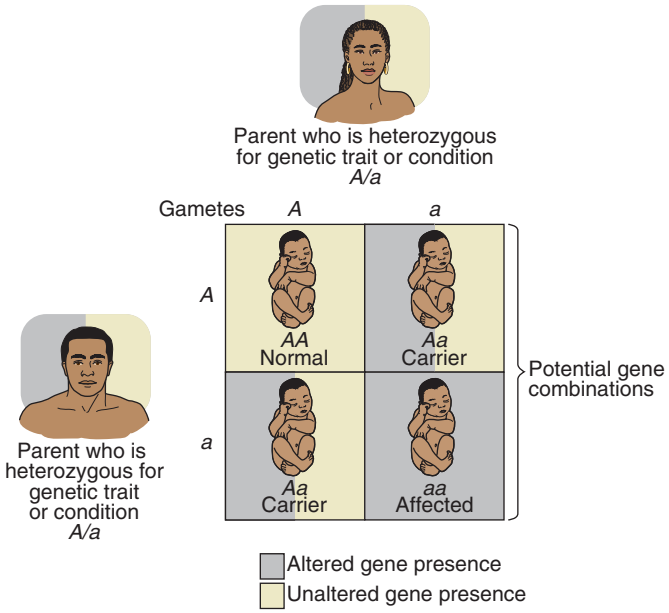

Figure 8–4 ■ This Punnett square shows potential gene combinations (genotypes) and resulting phenotypes of children from parent genotypes with an autosomal recessive altered gene. Phenotypes are expressed (affected) when a male *or* female has two copies of the gene alteration.

Source: From Ball, Jane W.; Bindler, Ruth McGillis W.; Cowen, Kay J., *Child Health Nursing: Partnering with Children and Families*, 3rd, © 2014. Reproduced by permission of Pearson Education, Inc., Upper Saddle River, New Jersey.

and they do not usually exhibit any manifestations of the condition. Because the gene alteration occurs on a non–sex chromosome, both males and females have an equal chance of inheriting the altered gene from their parent. See Box 8–4 for characteristics of an AR pattern of inheritance.

X-LINKED RECESSIVE

X-linked conditions are the result of an altered gene on the X chromosome. Unlike the autosomes, the sex chromosome, X, is unevenly distributed to males and females. The female has two X chromosomes and the male has only one. If any of the genes on the X chromosome inherited by a male are altered, an unaltered counterpart is not present to override the altered functioning gene, and it becomes the copy that provides direction for those particular functions of these genes.

The family history and pattern of inheritance has a characteristic distribution pattern among the males and females in the family (Figure 8–5 ■). The consequences of the altered gene on an X chromosome will be expressed in all males who receive that X chromosome from their mother. Females, on the other hand, will have two copies and the unaltered gene generally compensates for the altered gene, making the female a carrier. The male receives an X chromosome from his mother and his Y chromosome from his father. The female offspring receives an X chromosome from each of her parents. Thus, all affected males will pass on the altered X chromosome to all of their daughters who will be carriers of the altered gene. A male can never transmit an altered gene on the X chromosome to his sons because the male will transmit only the Y chromosome to his sons. Because of these transmission patterns, the most commonly occurring transmission of an X-linked condition is through a female who is a carrier of an altered gene. See Box 8–5 for characteristics of an X-linked recessive pattern of inheritance.

X-LINKED DOMINANT

X-linked dominant conditions also exist, but they are very rare. If a male is affected, the condition is severe and often lethal. A family history of multiple male miscarriages may be a sign of an X-linked dominant condition. An example of a viable X-linked dominant condition is vitamin D–resistant rickets, also known as hypophosphatemic rickets.

Variability in Classic Mendelian Patterns of Inheritance

Along with understanding the classic Mendelian inheritance patterns, several other concepts are also important for families to understand when the nurse is assisting patients with or at risk for inheriting a genetic disorder. These include the following exceptions or variations to the traditional Mendelian patterns of inheritance.

PENETRANCE

Penetrance is the probability that a gene will be expressed phenotypically. It is an "all-or-none" concept in that either the gene will be expressed (even if mildly expressed) or it will not be expressed at all. Penetrance can be measured in the following way. In a certain group

BOX 8–4 Autosomal Recessive Mendelian Inheritance Characteristics

(Examples: hemochromatosis type 1, cystic fibrosis, phenylketonuria, sickle cell disease)

When gathering a family history, the nurse should assess for any of the following characteristics of autosomal recessive inheritance:

1. Both males and females are affected.
2. Males and females are usually affected in equal numbers.
3. An affected child will have an unaffected parent but may have affected siblings (appearing as a horizontal pattern of affected individuals on the family pedigree).
4. The condition may appear to skip a generation.
5. The parents of the affected child may be consanguineous (close blood relatives).
6. The family may be descendants of a certain ethnic group that is known to have a more frequent occurrence of a certain genetic condition. For example, Tay-Sachs disease is an autosomal recessive, progressive neurodegenerative disorder that is more common among Ashkenazi Jews than other ethnic groups.

BOX 8–5 X-Linked Recessive Mendelian Inheritance Characteristics

(Examples: hemophilia A, Duchenne muscular dystrophy)

When the nurse gathers a family history, he or she should assess for any of the following characteristics of X-linked recessive inheritance:

1. More males will be affected than females; rarely seen in females.
2. An affected male will have all carrier daughters.
3. There is no male-to-male inheritance.
4. Affected males are related by carrier females.
5. Females may report varying milder symptoms of the condition.
6. A new sporadic case could be due to a new mutation.

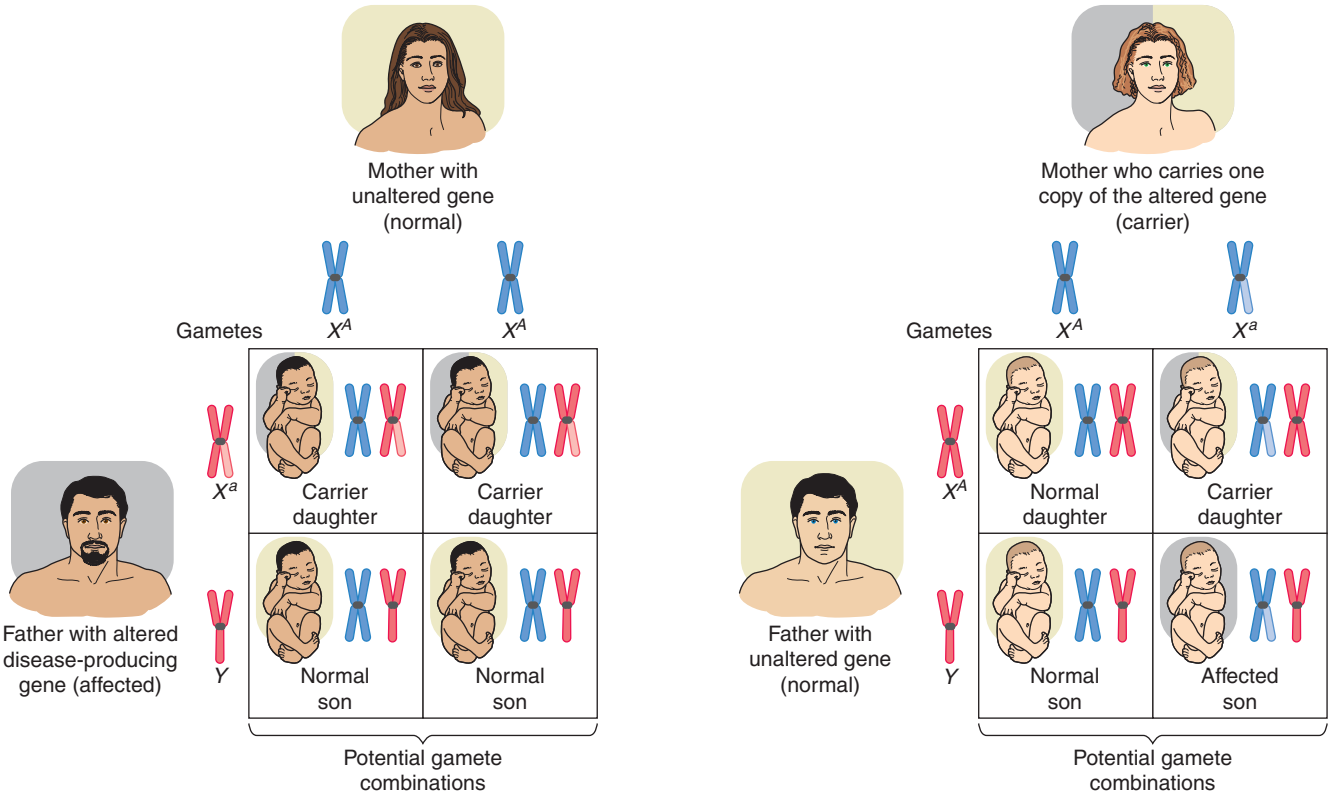

Figure 8–5 ■ These Punnett squares show potential gene combinations (genotypes) and resulting phenotypes of children from different parent genotypes with an X-linked recessive altered gene. Phenotypes are expressed (affected) in a male with only one copy of the gene alteration and in a female with two copies of the altered gene.

Source: From Ball, Jane W.; Bindler, Ruth McGillis W.; Cowen, Kay J., *Child Health Nursing: Partnering with Children and Families*, 3rd, © 2014. Reproduced by permission of Pearson Education, Inc., Upper Saddle River, New Jersey.

of individuals with the same genotype, what percentage of them will exhibit at least some manifestations of the condition? If the number is less than 100%, then that condition is said to show reduced penetrance. For example, the gene alterations that cause achondroplasia (dwarfism) exhibit 100% penetrance and all individuals with one copy of the gene alteration will exhibit signs and symptoms of the condition (Daly et al., 2010; Nussbaum et al., 2007).

NEW MUTATION

When there is no previous history of a condition including even subtle manifestations of the disease in any other immediate or distant family member, the disease may be caused by a spontaneous new mutation. This case is usually called a *de novo* mutation. New mutations of a gene are most frequently recognized in autosomal dominant conditions because one copy of an altered gene is all that is necessary to elicit a state of altered health. Autosomal dominant conditions known to have high mutation rates include neurofibromatosis, achondroplasia, and Marfan syndrome. New mutations are also possible in autosomal recessive diseases although rarely expressed because two altered genes are necessary for signs and symptoms to appear. Finally, new mutations are often seen in X-linked recessive disorders, such as hemophilia A, because the male with just one altered gene will express the disease phenotype.

ANTICIPATION

Anticipation occurs when successive generations of a family exhibit more severe manifestations of certain diseases and the disease often has an earlier onset. An example of a condition where this occurs is fragile X. Fragile X is the most common cause of inherited mental impairment, caused by a mutation in a gene known as *FMR-1*, which is located on the X chromosome. The mutation is a "genetic stutter" in which a small section within the gene is repeated too many times. A person who does not have fragile X has between 6 and 45 repeats (trinucleotide repeats). Individuals with 55 to 200 repeats have a premutation that can possibly expand when passed on to offspring. When this mutation is greater than 200 repeats, an individual has a full mutation. See Box 8–6 for more information about fragile X.

VARIABLE EXPRESSIVITY

The term *expressivity* is used to describe the severity of the *gene expression* of a phenotype. When people with the same genetic makeup (genotype) exhibit signs and/or symptoms with varying degrees of severity, the phenotype is described as *variable expression* (Nussbaum et al., 2007). Variable expression is common in the autosomal dominant condition neurofibromatosis. The diagnosis of neurofibromatosis is based on clinical criteria established by the 1987 Consensus Development Conference of the National Institutes of Health. Manifestations include café au lait spots, optic gliomas, neurofibromas, and bone lesions to name a few. Although neurofibromatosis has 100% penetrance, variable expressivity can occur within family members, meaning they all have the condition but not the same clinical manifestations.

BOX 8–6 Fragile X and Anticipation

Fragile X syndrome is transmitted in an X-linked dominant pattern (Genetics Home Reference, 2012). This syndrome affects intellect, learning, behavior and social skills, speech and language, and sensory perception. It affects about 1 in 4000 males and 1 in 8000 females (NICHD, 2013). In general, boys with fragile X syndrome are more severely affected than girls. Physical manifestations of the disorder, which develop during puberty, include a narrow face, large head and ears, flexible joints, and flat feet.

Fragile X syndrome is caused by mutations in the *FMR1* gene on the X chromosome. In nearly all cases of fragile X syndrome, a certain DNA segment within this gene is repeated more than 200 times.

- *Normal number of repeats:* Individuals with a normal number of repeats (5 to 40) do not have fragile X syndrome and cannot pass it on to their offspring.
- *Intermediate number of repeats or gray zone:* Individuals who have between about 40 and 55 repeats are considered to be in a gray zone. The number of repeats can sometimes expand slightly when passed from parent to child.
- *Premutation:* Individuals with between 55 and 200 repeats have what is called a premutation (Abrams et al., 2012). About 1 in 150 women and 1 in 450 men carry the premutation. Women with the premutation have a 50% chance of passing along the abnormal gene to her baby during each pregnancy and are at risk for having a child with fragile X syndrome (NICHD, 2014).

  Some children who inherit the abnormal gene have a permutation and no symptoms of fragile X syndrome. However, the number of repeats often expands when the gene is passed from mother to child. As a result, some children of carrier mothers. Inherit the full mutation (more than 200 repeats) and show symptoms of fragile X syndrome. A male with the premutation passes it on to all of his daughters but to none of his sons. The daughters generally are carriers of a premutation and may pass it on to their children. The premutation does not usually expand in size when passed from fathers to their daughters.
- *Full mutation:* Individuals with more than 200 repeats have the full mutation. A woman with a full fragile X mutation has a 50% chance of passing along the full mutation in each pregnancy. For reasons that are not understood, the full mutation shrinks back to a permutation in sperm. If a man with a full mutation has children, he will pass the permutation on to all of his daughters. His sons are not at risk because they do not inherit the X chromosome from their father.

Multifactorial (Polygenic or Complex) Disorders

Many birth defects such as cleft lip and palate, as well as many adult-onset conditions such as cancer, mental illness, asthma, diabetes, obesity, heart disease, and Alzheimer's disease, have a multifactorial cause. *Multifactorial conditions* occur as a result of genetic variations and lifestyle and environmental influences that work together. Often, multiple genes contribute to the disorder (*polygenic*). The polygenic concept is illustrated with the multiple genes involved in an individual's susceptibility for breast cancer. These genes have been identified on chromosomes 6, 11, 13, 14, 15, 17, and 22. Exactly which genes interrelate and how many environmental influences are enough to cause the presentation of many of the common complex diseases or conditions is not known.

Multifactorial conditions do not follow the characteristic Mendelian patterns of inheritance seen with single-gene conditions. The risks of inheriting multifactorial conditions vary. Type 2 diabetes mellitus, for example, shows a strong inheritance pattern, with impaired glucose tolerance or diabetes present in 40% of an affected individual's siblings and 30% of that person's children. For diseases such as asthma, cardiovascular disease, and colon cancer, having two or more affected first-degree relatives is known to increase an individual's risk by two to five times that of someone without this strong family history (Miesfeldt & Jameson, 2012). A patient considered as high risk for an inheritable condition should be referred for a genetics consultation.

●○● INTERPROFESSIONAL CARE

Many health professionals work together in the screening, diagnosis, identification, and treatment of genetic disorders. The goals of interprofessional care are early diagnosis through testing and assessment and development of an effective treatment plan. Psychosocial support to enhance coping and referral to a genetic specialist when needed are critical elements of the plan.

Genetic Testing

Genetic testing involves the analysis of DNA, RNA, chromosomes, and serum levels of specific enzymes or metabolites. Genetic tests can be classified into two categories: screening and diagnostic. A positive screening genetic test result indicates an increased risk or probability but must always be confirmed by diagnostic testing. Screening genetic tests are most commonly completed in prenatal, newborn, and carrier circumstances. In contrast, a diagnostic test can definitively validate or eliminate a genetic disorder in the symptomatic patient and then guide clinical management. Box 8–7 lists some of the benefits and potential negative outcomes of genetic testing. Several categories of genetic tests follow:

- *Newborn screening* can identify children who have an increased risk for a genetic disease such as phenylketonuria, sickle cell disease, or maple syrup urine disease. Several states now screen for more than 30 conditions (expanded newborn screen) as part of routine newborn care.
- *Carrier testing* is completed on asymptomatic individuals who may be carriers of a gene alteration that can be transmitted to offspring in an autosomal recessive or X-linked pattern of inheritance. This may be part of a couple's premarriage or preconception planning if they belong to an ethnic group with known risk for genetic disorders such as sickle cell disease and Tay-Sachs disease. It may be necessary to determine the exact gene mutation from an affected family member prior to carrier testing. This is often completed through lineage analysis.
- *Preimplantation genetic diagnosis (PGD)* allows detection of disease-causing gene alterations in human embryos before implantation in the uterus, thus providing an opportunity for preselection of unaffected embryos for implantation. This type of genetic testing is most often used by parents who are both carriers of a single-gene recessive disorder and who wish to implant into the uterus only the embryo(s) without the disease-causing gene alteration. It has also been used to determine tissue type

BOX 8–7 Outcomes Related to Genetic Testing

BENEFITS OF GENETIC TESTING

Provide for:

- Early screening and preventive measures
- Future planning and life preparation
- Lifestyle adaptations
- Decreased confusion and anxiety
- Psychologic stress relief
- Reproductive choices
- Informed immediate/extended family members
- Early medical and/or surgical intervention
- Cost of medical follow-up potentially reduced with confirmation or refuting of a diagnosis

POSSIBLE NEGATIVE OUTCOMES OF GENETIC TESTING

- Survivor guilt
- Loss of identity
- No treatment may exist
- Employability and insurability affected
- Confusion about accessing healthcare and resources
- Risk for invasion of confidentiality and privacy
- Social stigmatization

Sources: Badzek, L., Henaghan, M., Turner, M., & Monsen, R. (2013). Ethical, legal, and social issues in the translation of genomics into health care. *Journal of Nursing Scholarship, 45*(1), 5–14; and American Cancer Society. (2012). *Genetic testing for cancer: What you need to know.* Retrieved from http://www.cancer.org/acs/groups/cid/documents/webcontent/002548-pdf.pdf.

for donation of tissue such as bone marrow to a sibling or parent. PGD is usually not covered by insurance, is very costly, and is available at only a small number of centers and for only a small number of disorders (U.S. National Library of Medicine, 2012).

- *Predictive genetic testing* is usually made available to the asymptomatic individual and includes both predispositional and presymptomatic testing. A positive predispositional testing result indicates an increased risk that the individual might eventually develop the disease. Common examples include breast cancer and hereditary nonpolyposis colorectal cancer. A presymptomatic test is performed when development of the disease is certain if the gene alteration is present. These tests are medically indicated when the seriousness and mortality of the disease can be reduced with knowledge of the gene alteration. An example of this would be hereditary hemochromatosis or familial hypercholesterolemia. Life planning and lifestyle choices can be influenced by predictive testing.
- Other uses of genetic testing include organ transplantation tissue typing and pharmacogenetic testing. Pharmacogenetic testing involves predicting or studying the patient's response to particular medications. For example, 20% of Caucasians have a polymorphism on the cytochrome P450 *CYP2C9* gene and consequently metabolize warfarin more slowly and take longer to achieve therapeutic dosing (Johnson et al., 2011; Shahin & Johnson, 2013). These patients require significantly less warfarin and are two to three times more likely to have an adverse hemorrhagic event. Controversy remains as to whether genetic testing should be undertaken for every patient prior to initiating warfarin therapy; however, the U.S. Food and Drug Administration has revised the product label for warfarin to include information on the benefits of genetic testing to guide warfarin treatment.

DIAGNOSING CHROMOSOMAL ALTERATIONS

Chromosomal diagnostic examination can be accomplished with a blood, skin, or buccal cell sampling. A karyotype is completed in a cytogenetics laboratory. Chromosomes can be identified by their size and unique light and dark banding patterns. The pairs of autosomal chromosomes are arranged from 1 to 22 according to each chromosome's size, unique banding patterns, and *centromere* position. The sex chromosomes complete the picture, with the X chromosome(s) first, then the Y chromosome (if present). The karyotype shows all of the chromosome pairs lined up and positioned on a piece of paper allowing for visual chromosomal analysis (refer to Figure 8–2). The final karyotype report contains numerical data that includes the total number of chromosomes present.

Guidelines for writing results of karyotyping are determined by the International System of Human Cytogenetic Nomenclature (ISCN). These guidelines allow for use of a standardized universal language by cytogenetic laboratories and in medical publications. For example, a normal female karyotype is written as 46, XX, whereas a karyotype of a female with trisomy 21 is written as 47, XX, +21. In the second example, the (+) symbol signifies an additional copy of chromosome 21, whereas a (−) would signify a deletion (Shaffer et al., 2012).

DIAGNOSING GENE ALTERATIONS

More than 1000 tests are available from several laboratories, with some tests only available by a small number of sites. *DNA-based tests* involve sophisticated technology that permits the examination of the DNA itself. DNA-based genetic testing can be performed on blood, bone marrow, amniotic fluid, fibroblast cells of the skin, or buccal cells from the mouth. These tests can look for common mutation(s) associated with a specific disorder or a mutation previously identified in a family member. Newborn screening for conditions such as galactosemia are biochemical tests that look at enzyme levels. Genotyping must be done to confirm the diagnosis, identify the specific type of galactosemia, and to provide more accurate genetic counseling for family planning. A third type of DNA-based test is a complete gene sequence that may be utilized when only one mutation can be found in a symptomatic patient or when none of the common mutations were found (U.S. National Library of Medicine, 2012).

●○● NURSING CARE

The Role of the Nurse in Genetic Testing

Although confidentiality and privacy are integral parts of delivery of care for all nurses, this issue is of even more concern as it relates to genetic information. Results of genetic tests can affect employment and insurance options. Will the results affect the patient's ability to obtain and/or maintain insurance coverage? Can an employer refuse to hire or promote an individual because of genetic testing results? Can genetic information be released to the courts, military, schools, or adoption agencies? Would a patient with a known gene alteration for Huntington disease be offered a college scholarship to the best law school? There is debate over whether genetic privacy is different from medical privacy. The nurse should inform patients of their rights and responsibility to know who will have access to the genetic test results. Those providing the genetic tests must provide the patient with assurance that the results will be handled confidentially, and that there will be no access to the

genetic information by a third party without written permission of the individual being tested.

All genetic testing should be voluntary. It is the nurse's responsibility to ensure that the informed consent process includes discussion of the risks and benefits of the test, including any physical harm as well as potential psychologic and societal injury by stigmatization, discrimination, and emotional stress. Healthcare providers are legally liable to maintain that confidence. However, exceptions to the individual's privacy may be made when genetic test results indicate a significant probability of irreversible harm to a family member that can be prevented by knowledge of the threat (Bradzek et al., 2013).

Psychosocial Issues

Although family and individual anxiety may be decreased with a negative test result, the nurse must be prepared to address potential problems. Concerns about carrier status may interfere with development of intimacy and interpersonal relationships. Nonpaternity may be revealed through genetic testing. For example, the parents of a child born with an autosomal recessive condition will be considered carriers of the altered gene the majority of the time. To counsel the parents about future pregnancies, the parents would be tested to confirm their genotype, and nonpaternity may become an issue. A positive test result may lead to feelings of unworthiness, confusion, anger, depression, and self-image disturbance. Survivor guilt may affect adults with negative results if their siblings are positive. The individual carrying a gene alteration for a late-onset disease may have an increased tendency for risky behaviors and may choose not to be a positive member of society. Relatives of an individual affected with a genetic disorder may be very frightened when they realize what their own future might be. The individual who has inherited an altered disease-producing gene may foster deep resentment toward the parent who carries the altered gene. Parents and older generations may feel tremendous guilt for passing the altered gene to their children and grandchildren.

Economic Issues

The nurse should consider the cost of genetic tests, which can range from hundreds to thousands of dollars, depending on the size of the gene being tested. Most insurance companies do not cover genetic tests, but if there is insurance coverage the individual must weigh the cost of allowing the insurance company to have access to the genetic information (Bradzek et al., 2013). Additionally, depending on the information that will be gained from obtaining the test, the family may wish to defer testing if it does not provide better outcomes or a change in treatment strategy for the patient.

Health Promotion

With knowledge of genetic conditions, the nurse can ensure health teaching and early detection of complications from genetic conditions with emphasis on primary and secondary care interventions. Consider the following examples:

- A woman with a strong family history and/or mutations in the *BRCA1* and *BRCA2* tumor suppressor genes should have screening clinical breast exams and mammographies at an earlier age than the general population.
- A man with a strong family history and/or mutations in the *BRCA1* and *BRCA2* tumor suppressor genes should report any mass, tenderness, or swelling in the breast tissue and maintain early screening for prostate cancer.
- Colonoscopy screening every 1 to 2 years beginning at age 25 is important for the individual with a positive family history and/or mutations in the *MLH1/MSH2* gene, which increases the risk for hereditary nonpolyposis colorectal cancer.

Patients receiving early intervention and health promotion focused care can live longer and with a much better quality of life than those who do not. The nurse must be able to identify both community-based and genetic-based resources that are available to assist the patient in strategies to support both health promotion and health maintenance activities. The following are reliable sources of information that can be used by professionals and consumers:

- U.S. Department of Health and Human Services, Surgeon General's Family Health History Initiative.
- Genetics Home Reference is a consumer friendly website providing information on the effects of genetic variations on human health (U.S. National Library of Medicine, 2012).

Assessment

Patient Intake and History

Family history has long been a part of nursing assessment, but the relative importance of obtaining a family history has recently increased as our knowledge of the interaction of genes and the environment has expanded. In fact, it is an inexpensive first genetic screen, often underused by healthcare professionals. Professionals in primary care and other specialties share some of the responsibility for obtaining this information and making appropriate referrals.

Pedigrees

A pedigree is a pictorial representation or diagram of the medical history of a family (typically three generations). Multiple symbols are utilized to present this picture (Figure 8–6 ■) and the finished pedigree presents a family's medical data and biologic relationship information at a glance (Figure 8–7 ■). A pedigree provides the nurse, genetic counselor, or geneticist with a clear, visual representation of relationships of affected individuals to the immediate and extended family. It can identify other individuals in the family who might benefit from a genetic consultation. It also can identify a single-gene alteration pattern of inheritance or a cluster of multifactorial conditions. A referral and/or reproductive risk teaching for the individual and family can result. A family's learning can be enhanced by the visual teaching contribution a pedigree can provide. A pedigree can also clarify any inheritance misunderstandings or misconceptions.

By simply integrating into practice the genetic aspects of assessment, observation, and history gathering, the nurse can improve the standard of care delivered and have a positive effect on the patient. The nurse does not need to be a genetic expert, but with heightened awareness, appropriate inquiries and referrals to genetic specialists can be completed.

Diagnoses, Outcomes, and Interventions

Nurses are responsible for comprehensively delivering the correct standard of care to patients, but must also be aware of the limitations of their own knowledge and expertise. In addition to integration of genetic aspects into assessments of the individual and family history,

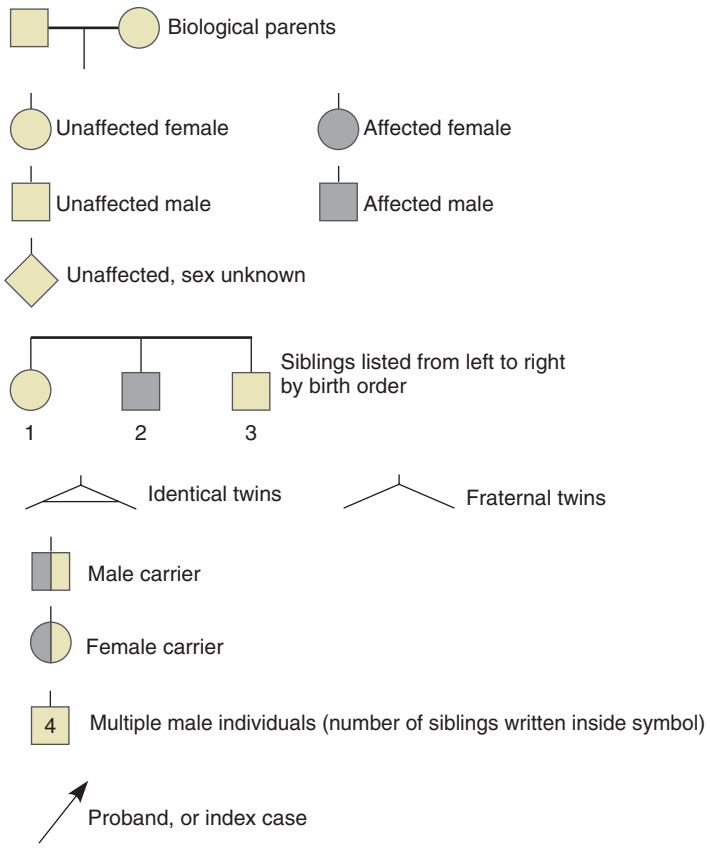

Figure 8–6 ■ Selected standardized symbols for use in drawing a pedigree.
Source: From Ball, Jane W.; Bindler, Ruth McGillis W.; Cowen, Kay J., *Child Health Nursing: Partnering with Children and Families*, 3rd, © 2014. Reproduced by permission of Pearson Education, Inc., Upper Saddle River, New Jersey.

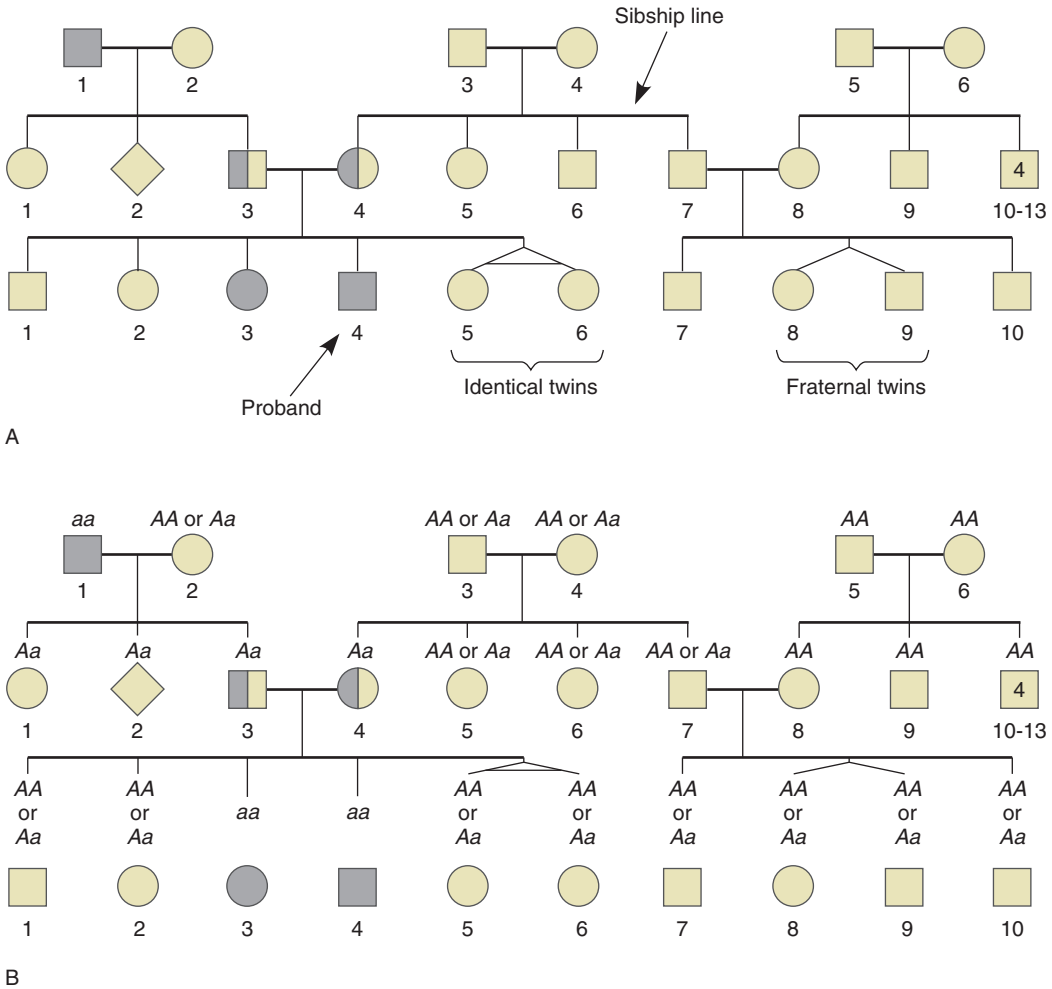
nurses are also responsible for carrying out interventions that include initiating referrals to genetic specialists and delivering care to the individual or family in any of the ways discussed in this section. Nursing diagnoses to consider include the following:

- *Grieving*
- *Anxiety*
- *Disturbed Body Image*
- *Ineffective Coping*
- *Decisional Conflict*
- *Interrupted Family Processes*
- *Ineffective Health Maintenance*
- *Deficient Knowledge*
- *Powerlessness*
- *Spiritual Distress*

Genetic Referrals and Counseling

Referral of a patient with a suspected genetic problem to a geneticist, genetic clinical nurse specialist, or genetic clinic is an expected nursing responsibility in the same way as referrals to a dietitian or a social worker are made. After gathering assessment data that incorporate genetic concepts, the nurse is able to initiate a referral to genetic specialists if there are indicators for a genetic referral (Box 8–8). The nurse should provide the patient with information about the advantages of a referral to genetic specialists, explain the disadvantages of not following through with the referral, and provide anticipatory guidance as to what to expect from his or her visit (Box 8–9).

Usually before the first visit for genetic evaluation, the patient will be contacted to provide a detailed medical and family history. The patient should be prepared to give as exact a family history as possible so that a detailed three-generation pedigree can be constructed. The patient should be informed that a genetic consultation usually lasts several hours. During the appointment, a genetic clinical nurse, genetic counselor, and/or a physician will perform an initial interview with the patient. A geneticist will examine the patient in order to establish an accurate diagnosis. Tests may be ordered. These



BOX 8–8 Indicators for a Referral to a Genetic Specialist

HISTORY ASSESSMENT DATA CONCERNS

- Several closely related individuals affected with the same or related conditions:
  - Breast and ovarian cancer
  - Colon and endometrial cancer
  - Diabetes
  - Hypertension
  - Coronary heart disease
  - Thyroid cancer
  - Colon polyps
- A common disorder with earlier age of onset than typical (increase concern if it occurs in more than one family member):
  - Breast cancer: <45–50 years of age or premenopausal
  - Colon cancer: <45–50 years of age
  - Prostate cancer: <45–60 years of age
  - Vision loss: <55 years of age
  - Hearing loss: <50–60 years of age
  - Dementia: <60 years of age
  - Heart disease: <40–60 years of age
  - Stroke: <60 years of age
- A sudden or unexpected death in someone who seemed healthy:
  - Renal disease
  - Asthma
  - Suicide

AN INDIVIDUAL WITH

- Two or more conditions
- A medical condition and *dysmorphic* (abnormal or misshapen) features
- Developmental delay with dysmorphic features and/or physical birth anomalies
- Learning disabilities
- Behavioral problems
- Unexplained:
  - Movement disorders
  - Seizures
  - Hypotonia
  - Ataxia
  - Infertility
- Disproportionate tall or short stature
- Proportionate short stature with dysmorphic features
- Atypical sexual development
- Premature ovarian failure

(A) A representative pedigree for a single character or genetic condition through three generations.
(B) The most probable genotypes of each individual in the pedigree for an autosomal recessive condition, represented by AA, Aa, or aa.

Figure 8–7 ■ Sample three-generation pedigree.

Source: Fig. 3.13, p. 63 from *Concepts of Genetics*, 7th ed. by William S. Klug and Michael R. Cummings. Copyright © 2003 by William S. Klug and Michael R. Cummings. Reproduced by permission of Pearson Education, Inc.

may include chromosome (cytogenetic) analysis, DNA-based testing, x-rays, biopsy, biochemical tests, and genome sequencing (Conley et al., 2013; U.S. National Library of Medicine, 2012). After the exam and the completion of any applicable testing, the geneticist and/or genetic counselor will discuss the findings with the patient and make recommendations. The discussion will include the natural history of the condition, the inheritance patterns, the current preventive or treatment options, and the risks to the patient and/or family. The visit will also include opportunities for questions and answers as well as the assessment and evaluation of the patients' understanding. Poor retention of information is typical for a patient facing a new genetic diagnosis. This makes it imperative for the nurse to take advantage of opportunities to reinforce genetic concepts at a later time when the patient is ready.

As the visit concludes, the patient can expect appropriate referrals to be made, discussion of available services or research studies, and possible scheduling of a follow-up visit. A summary of the information is usually sent to the patient. The patient's healthcare provider will receive a report if requested by the patient.

Genetic healthcare providers present the patient with information to promote informed decisions. They are also sensitive to the importance of protecting the individual's autonomy. A challenge during any visit to a genetic specialist is providing nondirective counseling. Patients should be permitted to make decisions that are not influenced by any biases or values from the nurse, counselor, or geneticist. Many patients are accustomed to practitioners and nurses providing direction and guidance in their decision making. Patients

BOX 8–9 Genetic Information Nondiscrimination Act of 2008 (GINA)

After 13 years of debate, on May 21, 2008, President George W. Bush signed into law the Genetic Information Nondiscrimination Act of 2008 (GINA) (National Human Genome Research Institute, 2012). The purpose of this federal law is to protect consumers from discrimination by employers and health insurance companies based on genetic information. Examples of protected tests are *BRCA1/BRCA2* (breast cancer), Huntington disease, and carrier screening for cystic fibrosis, sickle cell disease, and Tay-Sachs disease. GINA does not include considerations regarding life, disability, or long-term care insurance, nor members of the military.

may be uncomfortable with the nurse's approach to providing education, however it is imperative for the nurse to remain unbiased and leave decision making to the patient. The patient may believe that the nurse or healthcare provider is withholding very bad news. The nurse should discuss the positives and negatives of each decision and present as many options as possible through the use of therapeutic listening and communication skills.

Patient Teaching and Support

The nurse must be aware of available genetic resources and participate in patient education about genetic disorders. The cultural and religious beliefs and values of patients must be assessed prior to teaching. Are the gene alterations viewed as uncontrollable and believed to be occurring secondary to cultural belief such as a stranger looking at the patient? Or, are the gene alterations considered a form of punishment? Obtaining educational materials in the native language of the patient will also help facilitate the teaching–learning experience. Also, identifying and dealing with barriers to learning, such as denial, anxiety, or guilt, will enable teaching to be more useful and effective for the patient and family.

Nurses should encourage open discussions and the expression of fears and concerns. Reinforce to patients that genetic alterations are caused by changes within a gene and not by religious, superstitious, or cultural beliefs. However, it is important to remember that everyone has superstitions or beliefs and the nurse must remain nonjudgmental. The nurse is responsible for assessing the patient's coping mechanisms as well as available family, spiritual, cultural, and community support systems. Genetic conditions can cause a permanent strain on family dynamics and relationships. The nurse may need to help the patient reaffirm his or her self-worth- and value (Calzone et al., 2010).

Growth and development and meeting adult developmental milestones can be altered by actual or potential genetic disorders. Especially unique is the potential or actual inheritance of a late-onset condition such as Huntington disease. The patient with this altered gene may not achieve the developmental tasks in moving through adulthood. The patient may be worried about future goals and aspirations. The nurse must identify the impact of genetic knowledge on daily living activities but also achievement of developmental milestones. Both patient and family strengths need to be identified.

The nurse can refer the patient to a support group. However, the nurse must have permission from the patient to provide a support group with the patient's name and contact information.

Another key role for the nurse is to help patients with the often difficult task of communicating genetic information such as inheritance patterns to extended family members. Cultural values of autonomy and privacy affect a patient's decision whether to communicate genetic information to extended family members who may also carry the altered gene. The history of a genetic alteration that may or may not cause disease can be extensive within a family, affecting multiple family members. Family members often have difficulty understanding that some genetic conditions have variable expressivity. Members of the extended family often are shocked and feel a profound sense of guilt that they are the one who has carried the gene alteration that caused their loved one to have a genetic condition.

Careful self-assessment of feelings is essential for the nurse. The nurse must continually advocate for patients and support their decisions even if the decisions conflict with the nurse's own ideals and morals. Coping with genetic revelations and making genetic-related treatment decisions are difficult. The nurse must remember that patients will need resources and support, and also help in gathering information about reproductive options.

Evaluation

Expected outcomes of delivering nursing care with a genetic focus include the following:

- The patient will make informed and voluntary decisions related to genetic health issues.
- The patient will accurately identify the following:
  - Basic genetic concepts and simple inheritance risk probabilities
  - What to expect from a genetic referral
  - The influence of genetic factors in health promotion and health maintenance
  - Differences between medical and genetic tests
  - Social, legal, and ethical issues related to genetic testing.

VISIONS FOR THE FUTURE

Nurses are often the primary caregivers to whom patients turn for information, guidance, and clarification of ideas. This nursing role is essential not only in providing direct nursing care but as a member of the community. As more information about the genetic revolution becomes available to consumers—in areas such as pharmacogenomics, gene transfer, ethics, genetic engineering, and stem cell research—the role of nurses remains not only vital but grows enormously. Nurses should remain educated, informed, knowledgeable, and ready to discuss trends and changes with patients and their families.

CHAPTER HIGHLIGHTS

- **Nurses are responsible for basic genetic knowledge and for delivering the expected standard of genetic nursing care. Nurses must be aware of the social, ethical, cultural, and spiritual issues related to the delivery of genetic nursing care.**
- When cell division does not occur as expected, chromosomal alterations on the autosomes or sex chromosomes can result. Chromosomal alterations can be seen in a human karyotype.
- An individual may be identified as heterozygous or homozygous for a single gene. Some gene alterations cause disease and some are protective from disease. Multifactorial inheritance does not follow Mendelian inheritance patterns.
- Many types of genetic tests are available. All genetic tests have social, financial, ethical, and legal implications. Genetic healthcare providers are obligated to present the individual and his or her family with information to promote informed decisions.
- **Basic genetic nursing care involves family risk assessment through a detailed family history, integrating genetic concepts into a physical assessment, and initiating a referral to a genetic specialist.**
- **Genetic concepts can be applied to health promotion and health maintenance with the nurse taking into consideration cultural and spiritual influences on health decisions. Knowledge of the principles of inheritance allows the nurse to not only offer and reinforce genetic information to patients and their families but also to assist them in managing their care and in making reproductive decisions.**

TEST YOURSELF NCLEX-RN® REVIEW

1. A patient learns that she has a health problem caused by an autosomal recessive gene. What should the nurse include when explaining the transmission of this disorder?
   1. The health problem can be lethal without adequate treatment.
   2. The health problem is transmitted through a sex chromosome.
   3. The health problem was inherited from both the mother and the father.
   4. The patient's parents have yet to be diagnosed with the same health problem.

2. A male patient is diagnosed with an X-linked recessive health problem. What should the nurse emphasize when teaching the patient about this health problem?
   1. All male offspring of the patient will be carriers of the disorder.
   2. All female offspring of the patient will be carriers of the disorder.
   3. All female offspring of the patient will be affected by the disorder.
   4. The health problem can only be transmitted through direct blood contact.

3. The nurse is providing information regarding genetic testing to a couple who believe they are carriers of an autosomal recessive gene alteration. Which statement by the nurse is appropriate?
   1. "Newborn screening will reveal if your child is affected."
   2. "Chromosomal studies will reveal if you are actually a carrier."
   3. "During the genetic evaluation, you will be asked to provide at least a three-generation family history."
   4. "If both of you are carriers, all of your sons will be affected and all of your daughters will be carriers."

4. When analyzing a family pedigree, the nurse notes the pedigree demonstrates that successive generations contain affected individuals, both males and females are affected, and there is no father-to-offspring inheritance. What is the most likely pattern of inheritance?
   1. mitochondrial
   2. X-linked recessive
   3. autosomal recessive
   4. autosomal dominant

5. When beginning a health history, the patient questions the need to discuss family members' health problems. What should the nurse explain about the purpose of a family history?
   1. It is an inexpensive first genetic screen for the patient.
   2. It helps the nurse to focus on specific body systems to assess.
   3. It serves as a predictor of what health problems the patient will face in the future.
   4. It validates information collected by Health and Human Services on family health.

6. The nurse notes that a teaching session for a patient with a newly diagnosed genetic disorder has been scheduled for an hour. What is the purpose of this extra time?
   1. The information is complex and high level.
   2. Many patients do not want to know this information.
   3. Retention of information is typically low at this time.
   4. Genetic disorders frequently are accompanied by learning difficulty.

7. A patient scheduled for a genetic screening asks the nurse what will happen during the appointment. What should the nurse explain as likely to be included in a genetic referral? (Select all that apply.)
   1. Complete chromosomal studies.
   2. Ask to see photographs of relatives.
   3. Provide direction for important decision making.
   4. Prescribe medication to treat the genetic disorder.
   5. Provide information about the natural history of the condition.

8. After genetic testing a patient learns that she has the gene that causes breast cancer. Which nursing diagnosis should the nurse use to guide this patient's care?
   1. *Ineffective Coping*
   2. *Deficient Knowledge*
   3. *Disturbed Body Image*
   4. *Interrupted Family Processes*

9. A young male has a strong family history for coronary heart disease. What should the nurse recommend for this patient?
   1. hematocrit levels every 3 months
   2. genetic testing to identify the MLH/MLH2 gene
   3. lifestyle changes to reduce heart disease risk
   4. statin therapy to reduce blood cholesterol levels

10. A patient with a suspected genetic anomaly does not want to have genetic testing because of the fear of losing employment based on the results. What should the nurse explain to the patient about the Genetic Information Nondiscrimination Act (GINA)?

1. It protects against gender bias in the workplace.
2. It provides guidelines for specific sexual harassment activities.
3. It mandates genetic testing for all government employees and their children.
4. It protects against discrimination by employers based on genetic information.

9 Nursing Care of Patients in Pain

LEARNING OUTCOMES

1. Explain the neurophysiology of pain.
2. Compare and contrast definitions and characteristics of acute, chronic, central, and phantom, pain.
3. Discuss factors affecting individualized responses to pain.
4. Describe interprofessional care for the patient in pain, including medications, surgery, transcutaneous electrical nerve stimulation, and complementary therapies.

CLINICAL COMPETENCIES

1. Use clinical reasoning to provide individualized nursing care for patients experiencing pain.
2. Assess patients' pain intensity, quality, location, pattern, intensifiers, relievers; side effects of analgesics; and effect on function and mood.
3. Determine patient's expressed desire, values, preference, and support for pain management.
4. In collaboration with the healthcare team, intervene with appropriate evidence-based nursing measures to promote patient comfort and include pharmacologic and nonpharmacologic methodologies.
5. Revise plan of care according to patient's response to interventions and need for control.
6. Use equianalgesia tables to select and transition among opioid analgesics.
7. Teach patients about safe and effective self-management of pain.
8. Evaluate effectiveness of interventions to relieve pain and promote comfort; retreat or adjust doses of medication and interventions as necessary.

MAJOR CHAPTER CONCEPTS

- Nurses play a pivotal role in managing pain for patients in all healthcare settings.
- Completion of a comprehensive assessment and development of an individualized and patient-centered plan lead to effective pain management.
- Pain management involves pharmacologic and nonpharmacologic interventions.

nociceptors, *153*
pain, *151*
titrate, *165*

Pain is a subjective response to both physical and psychologic stressors. All people experience pain at some point during their lives. Prevalence of chronic pain continues to rise and the Institute of Medicine (IOM) (2011) estimates that 100 million adult Americans live with chronic pain. Low back pain is one of the most common types of chronic pain, along with migraine and severe headache and joint pain. Eighty percent of patients undergoing surgery report they experience postoperative pain, and fewer than half indicate they experience adequate pain relief (IOM, 2011). Whether the pain is acute, chronic, severe, or mild to moderate, the experience is pervasive and common in all healthcare settings and is associated with increased healthcare costs, loss of productivity, and an adverse effect on the quality of life.

Although pain usually is experienced as uncomfortable and unwelcome, it also serves a protective role, warning of potentially health-threatening conditions. For this reason, pain is referred to as the *fifth vital sign*, with recommendations to assess pain with each vital sign assessment. The Joint Commission (Berry & Dahl, 2000) established pain standards that identify the relief of pain as a patient right. Joint Commission standards require healthcare facilities to implement specific procedures for, and provider education on, pain assessment and management.

Pain is a distinct and personal experience influenced by genetic, physiologic, psychologic, cognitive, sociocultural, cultural, and spiritual factors. It is the symptom most associated with describing oneself as ill, and it is the most common reason for seeking healthcare. The International Association for the Study of Pain defines pain as an unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage.

FAST FACTS

- More than 25% of adults report low back pain lasting at least a day within the past 3 months (IOM, 2011).
- For 60% of patients visiting the emergency department with acute painful conditions who receive analgesics (IOM, 2011):
  - The median time to receive pain medication was 90 minutes.
  - Nearly 75% of emergency department patients were discharged in moderate to severe pain.
- For the 62% of U.S. nursing home residents who reported pain (IOM, 2011):
  - Arthritis is the most common painful condition.
  - Seventeen percent have substantial daily pain.

Although there are many definitions and descriptors of pain, the one most relevant for nurses is that pain is "whatever the person experiencing it says it is, and existing whenever the person says it does" (McCaffery, 1979, p. 11). This definition acknowledges the patient as the only person who can accurately define and describe his or her own pain and serves as the basis for nursing assessment and care of patients in pain. It also supports the values and beliefs about pain necessary for holistic nursing care, including the following:

- Only the person affected can experience pain; that is, pain has a personal meaning.
- If the patient says he or she has pain, the patient is in pain. All pain is real.
- Pain has physical, emotional, cognitive, sociocultural, and spiritual dimensions.
- Pain affects the whole body, usually negatively.
- Pain may serve as both a response to and a warning of actual or potential trauma.

MYTHS AND MISCONCEPTIONS ABOUT PAIN

Myths and misconceptions about pain and its management are common in both healthcare providers and patients. Some of the most common of these myths are listed here:

- ***Pain is a result, not a cause.*** According to the traditional view of pain, pain is a symptom, not a condition. Pain is now recognized as having both immediate and long-term effects, such as immobility, anger, and anxiety; pain may also delay healing and rehabilitation.
- ***Chronic pain is really a masked form of depression.*** Serotonin plays a chemical role in pain transmission and is the major modulator of depression. Therefore, pain and depression are chemically related, not mutually exclusive. It is common to find them coexisting.
- ***Narcotic medication is too risky to be used in chronic pain.*** This common misconception often deprives patients of the most effective source of pain relief. Opioid (narcotic) analgesics are recognized as an appropriate strategy for managing chronic pain unrelieved by other strategies.
- ***It is best to wait until a patient has pain before giving medication.*** Relieving pain before it escalates is widely accepted as having a noticeable effect on the amount of pain a patient experiences.
- ***Many patients lie about the existence or severity of their pain.*** Very few patients lie about their pain.
- ***Pain relief interferes with diagnosis.*** Effective pain management with analgesics in the emergency department (ED) has been shown to have no impact on physical assessment findings or diagnosis (IOM, 2011).

NEUROPHYSIOLOGY OF PAIN

The peripheral nervous system has two types of neurons: sensory and motor. The pain experience involves both sensory stimulation and perception. Pain stimuli are generated and transmitted through the sensory neurons, perceived within the central nervous system (CNS), and responded to through the motor neurons. Connections or synapses occur within the spinal cord and again within the brain, where interpretation of the painful stimulus leads to a response. A pain stimulus may prompt an immediate reflex response that precedes awareness of the pain.

Pain Theories

Several theories explain the response to pain and the diversity of human experiences with pain. The meaning or perception of pain can be modified by past experiences, motivation, attention, suggestion, personality, and culture. *Specificity* and *pattern* theories describe nerve impulses of varying intensity terminating in pain centers in the forebrain. These theories provide explanations of the neurophysiologic basis of pain. In 1965, Melzack and Wall postulated the *gate-control theory* (Helms & Barone, 2008). According to this theory, activation of large-diameter, faster-propagating fibers by a tactile stimulus (e.g., massaging the elbow after hitting it on a sharp object) activates a gating mechanism that then blocks impulses from smaller pain fibers (Grossman & Porth, 2014). This mechanism was thought to exist at the segmental spinal cord level (Figure 9–1 ■).

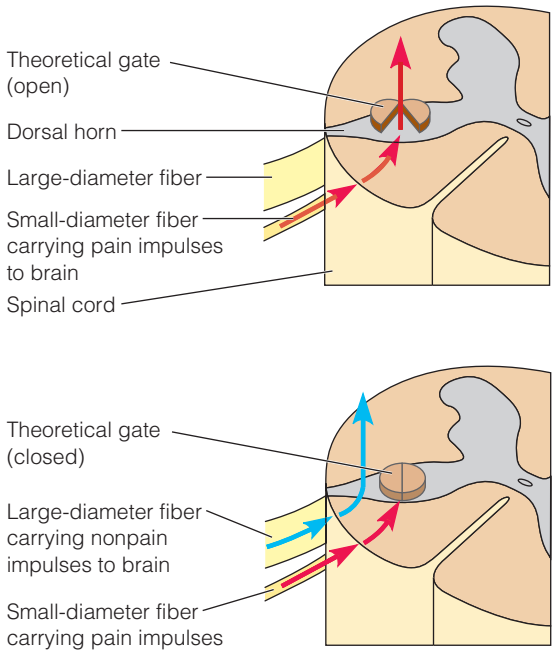

Figure 9–1 ■ The spinal cord component of the gate-control theory. Pain transmission by small-diameter fibers is blocked when large-diameter fibers carrying touch impulses dominate, closing the gate in the dorsal horn of the spinal cord.

Ongoing research demonstrates that the control and modulation of pain is much more complex than the description in the gate-control theory, which served as a base for further research about pain-modulating systems. Tactile information is now known to be transmitted by both large- and small-diameter fibers, and interaction between sensory neurons is known to occur at multiple levels of the CNS. Melzack subsequently developed the *neuromatrix* theory of pain to integrate cultural and genetic factors with basic neurophysiologic function. This theory is consistent with, but more complex than, the gate-control theory. According to the neuromatrix theory, the brain contains a *body-self neuromatrix*, a widely distributed network of neurons that is affected by both genetic factors and sensory experiences. The neuromatrix integrates multiple sources of input in addition to the stimuli of pain and touch. The pain experience for the individual is affected by inputs from other sensory systems that help interpret the stimuli (e.g., seeing a wound); factors such as attention, expectation, personality, and culture; innate pain modulation systems; and components of stress-regulation systems (Grossman & Porth, 2014).

One pain theory that is quite significant in clinical terms describes the effect of sensitizing the central and peripheral nervous system to painful stimuli. According to this theory, painful signals create a cascade of changes in the nervous system that increase the responsiveness of the peripheral and central neurons. These changes, in turn, increase the response to future signals and amplify pain. Sensitization occurs from nociceptive barrage and from the inflammation that follows an injury or incision. In adults this theory indicates the value of preventing sensitization as well as treating perceived pain with multimodal pain therapy. Local and regional anesthesia used in combination with central anesthesia prior to incision to diminish sensitization of these pathways results in significantly reduced consumption of intravenous morphine via patient-controlled analgesia (PCA) following surgery (D'Arcy, 2011b).

Physiology

Nerve receptors for pain are called **nociceptors** (Figure 9–2 ■). These free nerve endings are woven throughout all the tissues of the body except the brain. Nociceptors are especially numerous in the skin and muscles. Pain occurs when the tissue containing nociceptors is subjected to a noxious insult. The intensity and duration of the stimuli determine the sensation. Long-lasting, intense stimulation produces greater pain than brief, mild stimulation.

Nociceptors respond to several different types of noxious stimuli: chemical, mechanical, or thermal. Some nociceptors respond to only a single type of stimulus, whereas others respond to all three types of stimuli (Table 9–1). The perception of pain in different parts of the body is affected by this variation in sensitivity to type of stimulus and the distribution of nociceptors in various tissues.

Tissue trauma, inflammation, and ischemia prompt the release of a number of biochemicals. These biochemicals have several effects. Chemicals such as bradykinin, histamine, serotonin, and potassium ion directly stimulate nociceptors, producing pain. These

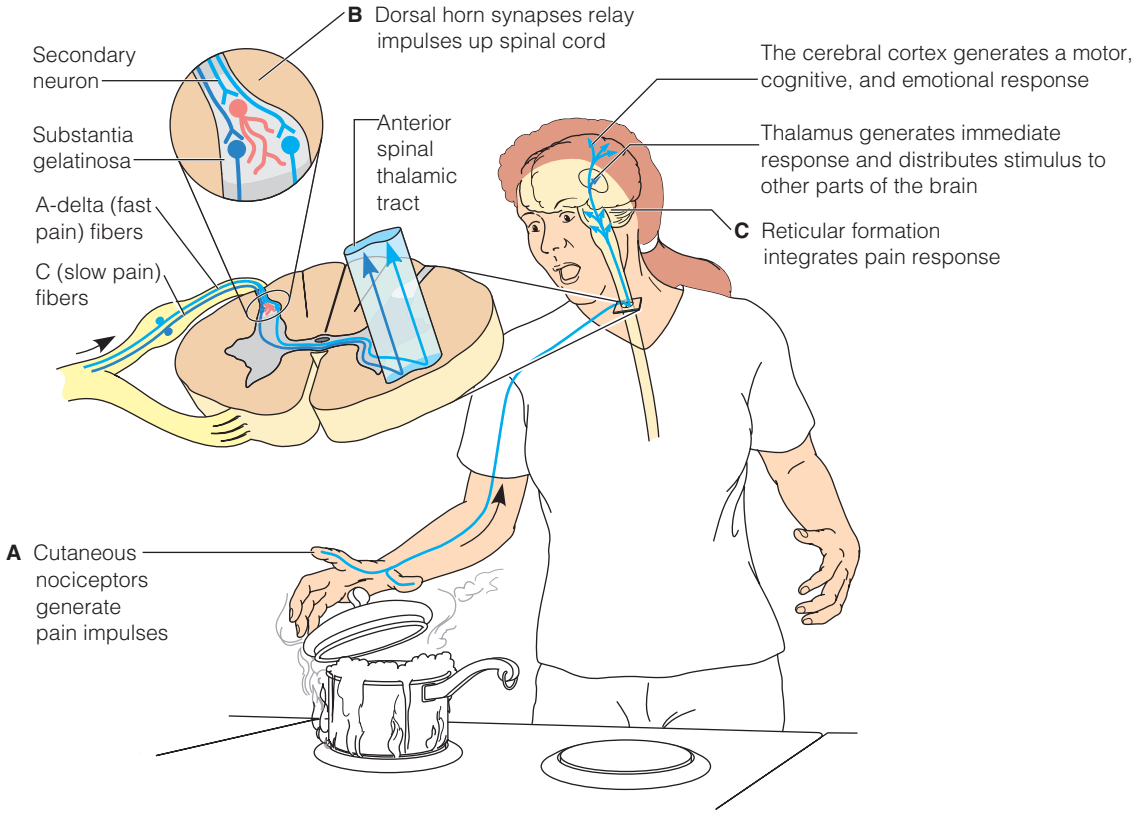

Figure 9–2 ■ A, Touching the hot lid activates nociceptors in the skin, generating pain impulses that travel via fast Aδ and slower C fibers to the spinal cord. B, Secondary neurons in the dorsal horn pass impulses across the spinal cord to the anterior spinothalamic tract. C, Pain impulses ascend to the thalamus and, from there, to the cerebral cortex and the reticular and limbic systems in the brainstem, which integrate the emotional, cognitive, and autonomic responses to pain.

TABLE 9–1 Painful Stimuli

Stimulus	Examples
Chemical	• Ischemia (e.g., angina, bowel infarct) • Tissue trauma • Inflammation, inflammatory mediators such as histamine, prostaglandins
Mechanical	• Spasm (ureteral colic, gallstones) • Compression (e.g., mechanical or by a tumor, carpal tunnel syndrome, or compartment syndrome) • Extreme muscle stretch or contraction (e.g., following a fracture)
Thermal	• Contact with extreme heat or cold

chemicals and others (such as ATP and prostaglandins) sensitize nociceptors, intensifying the pain response and causing normally innocuous stimuli (such as touch) to be perceived as pain. Chemical mediators act to perpetuate inflammation, which, in turn, causes release of additional chemicals that stimulate pain receptors. Furthermore, so-called *silent nociceptors* (e.g., sensory receptors in the gut that normally do not respond to mechanical or thermal stimuli) can become sensitive to mechanical stimuli in the presence of inflammatory mediators, leading to severe and debilitating pain and tenderness (Longo et al., 2013).

Pain Pathways

The neural pathways of pain illustrated earlier in Figure 9–1 can be summarized as follows:

1. A noxious stimulus is translated by nociceptors into an action potential that then is transmitted through small A-delta (Aδ) and even smaller C nerve fibers to the spinal cord. Aδ fibers are myelinated and transmit impulses rapidly. They produce what is called *fast pain* or first pain—sharp, well-defined pain sensations, such as those that result from cuts, electric shocks, or the impact of a blow. Aδ fibers are associated with acute pain from mechanical or thermal injury. C fibers are not myelinated and thus transmit pain impulses more slowly. Pain transmitted by C fibers may be described as *slow-wave pain* or second pain because it is slower to develop and lasts longer. This pain is more often prompted by chemical stimuli or persistent mechanical or thermal stimuli (Grossman & Porth, 2014). The pain from deep body structures (such as muscles and viscera) is primarily transmitted by C fibers, producing diffuse burning or aching sensations. C fibers are associated with chronic pain. Both Aδ and C fibers are involved in most injuries. For example, if an individual bangs an elbow, Aδ fibers transmit this pain stimulus within 0.1 second, and can actually prompt reflex withdrawal from the stimulus before pain is perceived. The person feels this pain as a sharp, localized, smarting sensation. One or more seconds after the blow, the person experiences a duller, aching, diffuse sensation of pain impulses carried by the C fibers.
2. The sensory neuron enters the spinal cord via the dorsal root and terminates in the dorsal horn of the spinal cord. Here it synapses with spinal (or second-order) neurons that transmit the pain signal to the brain. Several chemical neurotransmitters, including glutamate, norepinephrine, and substance P, carry the pain signal from the sensory neuron to the spinal neurons. Each neuron contacts many spinal neurons, and each spinal neuron receives input from many peripheral neurons. This accounts for the phenomenon of referred pain (discussed under types of pain). Spinal neurons transmit the impulses via axons that cross over to the spinothalamic tract.
3. The impulses ascend the spinothalamic tracts and pass through the medulla and midbrain to the thalamus.
4. From the thalamus, the pain signal is distributed via third-order neurons to several areas of the cerebral cortex. The somatosensory area of the cerebral cortex localizes the pain and interprets its intensity and quality. Other thalamic neurons reach areas of the frontal lobe, generating an emotional or affective response to pain. Connections to the reticular and limbic systems of the brain also are involved in the emotional and autonomic responses to painful stimuli. Pain signals to these areas can activate the fight-or-flight response, stress responses, and cardiovascular changes. A noxious impulse becomes pain when the sensation reaches conscious levels and is perceived and evaluated by the person experiencing the sensation.

Pain Modulation

No two people experience pain from an identical stimulus in the same way or at the same intensity; furthermore, the same person may perceive pain from the same stimulus differently on different occasions. A number of neural and chemical responses explain some of these differences.

Neural circuits that are thought to arise in the cerebral cortex link with the hypothalamus, midbrain, and medulla. These circuits interact with peripheral sensory axon terminals in the dorsal horn of the spinal cord to selectively control neurons that transmit pain signals. As a result, that pain response can be modified, that is, changed, increased, or dampened. Neurons within this circuit produce *endogenous opioids*, naturally occurring morphine-like neuropeptides. They also contain opioid receptors sensitive to endorphins and opioid drugs. Four types of endogenous opioids have been identified: enkephalins, endorphins, dynorphins, and endomorphins. They are hormones that act like neurotransmitters, binding with opioid receptors to block transmission of painful stimuli (Figure 9–3 ■). These substances also have been linked to a general sense of well-being (Pasero & Portenoy, 2011).

Chemicals such as peptides and neurotransmitters also affect responses to pain stimuli. Locally, inflammatory mediators (e.g., prostaglandins, nitric oxide, histamine) lower the threshold for pain perception and tend to augment pain. ATP, substance P, and other peptides promote the local spread of pain and contribute to vasodilation and vascular permeability, increasing discomfort (Pasero & Portenoy, 2011). In contrast, substances such as serotonin, norepinephrine, and others inhibit pain impulse transmission in the spinal cord and brain.

TYPES AND CHARACTERISTICS OF PAIN

Pain typically is described and characterized in several ways: by its duration (acute or chronic), its source or location, and referral.

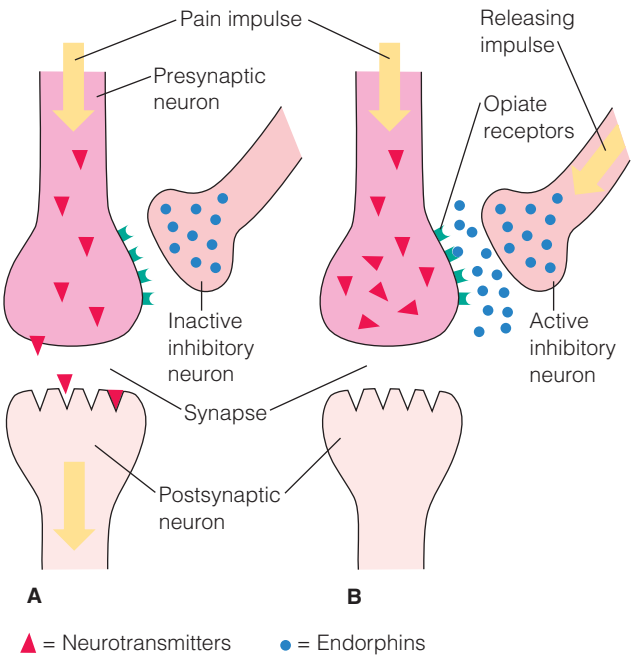

Figure 9–3 ■ A, Pain impulse causes presynaptic neuron to release burst of neurotransmitters across synapse. These bind to postsynaptic neuron and propagate impulse. B, Inhibitory neuron releases endorphins, which bind to presynaptic opiate receptors. Neurotransmitter release is inhibited, and pain impulse is interrupted.

Acute Pain

Acute pain has a sudden onset, is usually self-limited, and is localized. The cause of acute pain generally can be identified ("I tripped and twisted my ankle; now it really hurts"). The onset is usually sudden, most often resulting from tissue injury from trauma, surgery, or inflammation. The pain is usually sharp and localized, although it may radiate. Tissue healing relieves the pain. The three major types of acute pain are:

- *Cutaneous and deep somatic pain*, which arises from nerve receptors originating in the skin (e.g., from a laceration), subcutaneous tissues, or deep body structures such as periosteum, muscles, tendons, joints, and blood vessels (acute pain from a fracture or sprain, for example). Somatic pain may be either sharp and well localized, or dull and diffuse.
- *Visceral pain*, which arises from body organs. Visceral pain is dull and poorly localized because of the low number of nociceptors. The viscera are sensitive to stretching, inflammation, and ischemia but relatively insensitive to cutting and temperature extremes. Visceral pain often radiates or is referred. It may be described as deep cramping, splitting or stabbing pain, intermittent pain, or colicky pain. A kidney stone passing through the ureter to the bladder causes severe, acute visceral pain.
- *Referred pain* is pain that is perceived in an area distant from the site of the stimuli. It commonly occurs with pain that originates in thoracic or abdominal viscera. Visceral sensory fibers synapse at the level of the spinal cord, close to fibers innervating other subcutaneous tissue areas of the body (Figure 9–4 ■). For example,

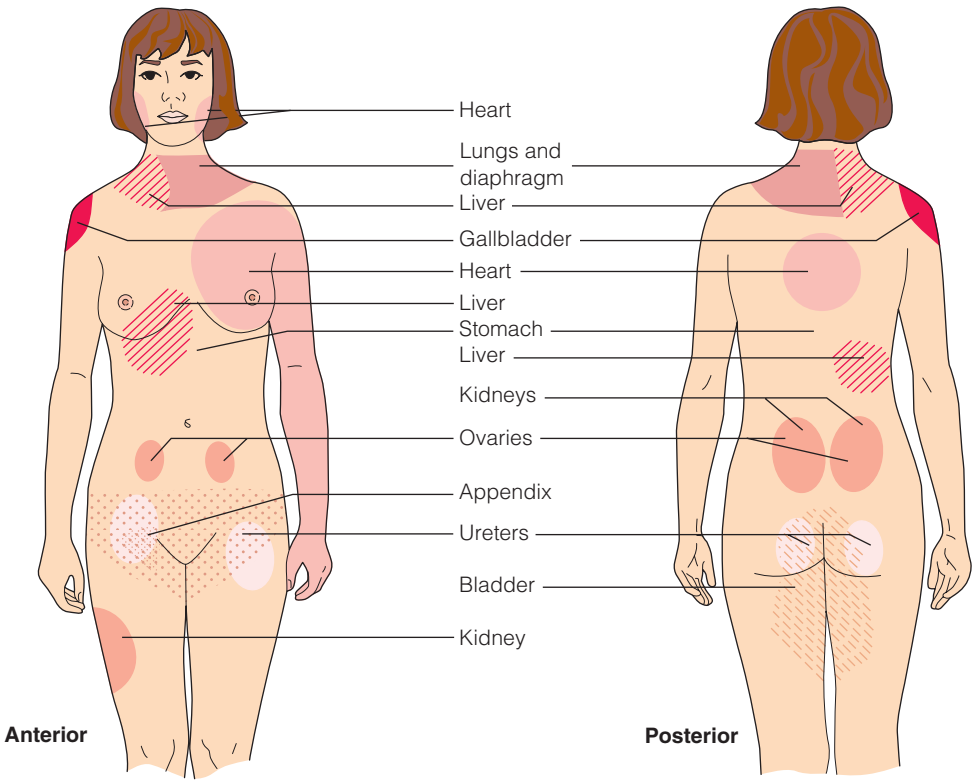

Figure 9–4 ■ Referred pain results from the convergence of sensory nerves from certain areas of the body within the spinal cord. For example, a toothache may be felt in the ear, pain from inflammation of the diaphragm may be felt in the shoulder, and pain from ischemia of the heart muscle (angina) may be felt in the left arm.

PATHOPHYSIOLOGY LINKAGE

Acute Pain and Associated Manifestations

Manifestation	Related Pathophysiology
Localized, sharp, burning pain	Nociceptors transmit pain stimulus along myelinated Aδ fibers to spinal cord, where it travels via the neospinothalamic tract to the thalamus. From the thalamus, the stimulus is distributed to the somatosensory cortex (perception and interpretation), the limbic system (emotional responses to pain), and brainstem centers (autonomic nervous system responses).
Diffuse, dull, aching pain	Transmission of nociceptive stimuli along unmyelinated C fibers to the spinal cord, and from there to the thalamus via the paleospinothalamic tract. Stimuli are distributed from the thalamus to the somatosensory cortex, limbic system, and brainstem centers.
Increased heart rate, stroke volume, and blood pressure; pupil dilation	Activation of the sympathetic nervous system (SNS) with release of catecholamines, which stimulate receptors in the heart and blood vessels.
Nausea, vomiting	SNS activation causes decreased blood flow to the gut, with decreased gastric acid secretion and intestinal motility; pain, anxiety cause stimulation of the vomiting center in the medulla.
Muscle tension	Protective responses initiated by higher brain centers to reduce nociceptive stimuli.
Anxiety, fear	Emotional responses to pain stimuli generated by limbic system.

the phrenic nerve, which innervates the central part of the diaphragm, enters the spinal cord at the C_3 to C_5 level; pain originating in the diaphragm or the parietal peritoneum lining it (e.g., peritonitis) may be perceived as shoulder pain. Sites of referred pain are determined during embryologic development.

Acute pain warns of actual or potential injury to tissues. As a stressor, it initiates the fight-or-flight autonomic stress response. Characteristic physical responses include tachycardia, rapid and shallow respirations, increased blood pressure, dilated pupils, sweating, and pallor. The pain may be accompanied by nausea and vomiting. Secondary reflex muscle spasms may develop, intensifying the pain. The person experiencing acute pain responds to this threat with anxiety and fear. This psychologic response may further increase the physical responses to acute pain. The accompanying Pathophysiology Linkage box describes manifestations of pain and gives an abbreviated explanation of the pathophysiology underlying the manifestation.

Chronic Pain

Chronic pain is prolonged pain, or pain that persists after the condition causing it has resolved. Although the cause may be identifiable (e.g., arthritis, cancer, migraine headache, diabetic neuropathy), chronic pain does not always have an identifiable cause. In some cases, pain may be perpetuated by disease-caused damage that persists after the disease has resolved (e.g., sensory nerve damage or reflex muscle contraction). In others, an imbalance of pain modulation mechanisms is thought to cause the persistent pain. This imbalance may relate to changes in the peripheral nervous system such as increased neuronal sensitivity to stimuli (a lower pain threshold) or spontaneous impulse generation by damaged neurons. Changes in the dorsal root, spinal cord, and brain also affect pain modulation. Repeated stimulation of peripheral nerves leads to a progressive buildup of electrical response in the CNS, leading to more intense and prolonged pain.

Unlike acute pain, chronic pain has much more complex and poorly understood neurophysiology and purpose. Persistent chronic pain often serves no useful function. The pain itself becomes the problem, creating physical, psychosocial, and economic stresses on the affected individual and his or her family. Furthermore, emotional and psychologic factors can cause the pain itself or make it worse. There is a clear association between chronic pain and depression. Depletion of serotonin (a neurotransmitter) and endorphins, found in both chronic pain and in depression, suggest a common physiology in these disorders (Grossman & Porth, 2014).

Chronic pain can be subdivided into three categories:

- *Recurrent acute pain*, characterized by relatively well-defined episodes of pain interspersed with pain-free episodes. Migraine headache is an example of recurrent acute pain.
- *Chronic malignant pain*, caused by advance of a life-threatening disease or associated with treatment. Cancer pain is a type of chronic malignant pain.
- *Chronic nonmalignant pain*, non–life-threatening pain that nevertheless persists beyond the expected time for healing. Chronic lower back pain, a major cause of suffering and lost work time, falls into this category.

Patients with chronic pain often do not have the same physiologic responses to pain as are seen in acute pain. The heart and respiratory rates and blood pressure may remain within the normal range. Other autonomic nervous system responses such as nausea, vomiting, pallor, or sweating may not occur with persistent pain. The patient with chronic pain often is depressed, may have difficulty sleeping, and may be preoccupied with the pain. Table 9–2 compares acute and chronic pain.

The most common chronic pain condition is lower back pain. Other common chronic pain conditions include the following (IOM, 2011):

- *Myofascial pain syndromes* are marked by injury to or disease of muscle and fascia. They include myositis, fibrositis, myofibrositis, myalgia, and muscle strain. Pain results from muscle spasm, stiffness, and collection of lactic acid in the muscle. The pain

TABLE 9–2 Characteristics of Acute and Chronic Pain

Characteristic	Acute Pain	Chronic Pain
Purpose	Signals actual or potential tissue damage	May serve no useful function.
Onset and duration	Sudden; relieved by healing	Persists after acute problem is resolved.
Cause	Actual or potential tissue damage	May not be readily identifiable. May result from nerve damage or pain modulation mechanism imbalance.
Associated symptoms	Sympathetic nervous system responses (increased pulse and respiratory rates, increased blood pressure, sweating, nausea) Muscle spasms Anxiety, fear	Depression is common. Insomnia is present. Patient may experience a preoccupation with pain.

leads to *guarding* (a defensive tensing of the muscle) and limited motion, which, in turn, leads to weakness, stiffness, and spasm—and more pain.

- Cancer often produces chronic pain, usually due to factors such as a tumor growth that presses on nerves or other structures, stretching of viscera, obstruction of ducts, or metastasis to bones. The malignant tumor may mechanically stimulate pain or the production of biochemicals that cause pain. Pain also may be associated with treatments such as chemotherapy and radiation therapy.
- Chronic postoperative pain is uncommon, but may occur following incisions in the chest wall, radical mastectomy, radical neck dissection, and surgical amputation.

BREAKTHROUGH PAIN

Breakthrough pain is pain that exceeds baseline chronic or persistent pain. It is often described as a sudden flare that exceeds the analgesic effect of long-acting pain medications. Whether the pain is malignant or nonmalignant in origin, treated or untreated, breakthrough pain is temporary and can be debilitating. The onset and intensity of breakthrough pain vary; its unpredictability and inconsistency are distressing to the patient and can make it difficult to manage.

Incident pain is a subtype of breakthrough pain. Incident or *episodic pain* is predictable, precipitated by an event or activity such as coughing, changing position, or being touched. Pain associated with a fractured bone is a good example of incident pain. When the patient remains still and the fracture is aligned and supported, little pain is experienced. Movement of the affected part, however, can precipitate sharp, intense pain.

Nociceptive Pain

Nociceptive pain is pain caused by stimulation of peripheral or visceral pain receptors. It generally is localized and responsive to treatment. Nociceptive pain may be either acute or chronic, resulting from disease processes (e.g., arthritis), tissue trauma, and medical treatment (e.g., surgery).

Neuropathic Pain

Neuropathic pain was recently redefined as "Pain arising as a consequence of a lesion or disease affecting the somatosensory system" (D'Arcy, 2011a, p. 61). This definition better defines the origin of the pain as the result of disease instead of the result of hyperactive nociceptive stimulation (Haanpää et al., 2011). Although neuropathic pain may be acute (e.g., the pain associated with shingles [herpes zoster]), usually it is chronic, associated with conditions such as diabetic neuropathy or postherpetic neuralgia. The pain may be described as gnawing, electric shock-like, burning, shooting, or tingling. Pain may occur with a stimulus such as touch that normally does not produce pain (*allodynia*), or its intensity may be disproportionate to the stimulus (*hyperalgesia*) (Haanpää et al., 2011; Huether & McCance, 2012).

CENTRAL PAIN

Central pain is caused by a lesion or damage in the brain or spinal cord. This damage leads to spontaneous generation of impulses that are perceived as pain. An infarction, tumor, trauma, or disorder such as multiple sclerosis or epilepsy may cause central pain. Central pain is constant, of moderate to severe intensity, and difficult to treat. The location of the pain depends on the area of the CNS affected. The pain may be described as burning, pressing, lacerating, or aching. Pins and needles sensations may be experienced along with the underlying pain. Affected areas may have decreased sensation (numbness). Thalamic pain, a type of central pain, may cause hyperesthesia (an abnormal sensitivity to touch, pain, or other sensory stimuli) on the side of the body opposite to the thalamic lesion.

COMPLEX REGIONAL PAIN SYNDROMES

Complex regional pain syndromes (CRPS) cause extremity pain that is severe, diffuse, and burning. The pain is accompanied by vasomotor changes that affect skin color and temperature. Initially the affected extremity has typical inflammatory symptoms, with redness, warmth, and swelling. Later, it is cool, cyanotic, and edematous; skin and nail changes may be seen (Huether & McCance, 2012). The cause of CRPS is unclear; there may, in fact, be several causes, including damage to the central or peripheral nervous system, or a disrupted healing or immune process. In CRPS, pain receptors in the affected part of the body become sensitized to catecholamines, neurotransmitters associated with sympathetic nervous system activity.

PHANTOM LIMB PAIN

Phantom limb pain is a pain syndrome that occurs following amputation of a body part. The patient experiences pain that may be described as burning, cramping, or shooting, in the missing body part. Phantom limb pain more frequently affects people who had pain in the amputated limb prior to its removal than those who did not. Several theories for phantom limb pain have been developed. These include regeneration of severed peripheral nerves and abnormal impulses generated by spinal cord neurons that no longer receive normal sensory input from the body (Grossman & Porth, 2014). Adequate management of postoperative pain after an amputation will help

prevent the development of phantom limb pain. Select medications shown to be effective for neuropathic pain are also used to treat phantom limb pain and include opioids, calcitonin/N-methyl-D-aspartate receptor antagonists, and ketamine, gabapentin, pregabalin, tricyclic antidepressants, and muscle relaxants. Encourage the patient to move the affected extremity, which helps the brain reconnect with the remaining portion of the limb. Movement will promote circulation and reduce edema, thereby reducing pain. Ongoing pain assessment is important to monitor the patient's pain status. Assist the patient in documenting ongoing pain assessment and encourage the patient to report his or her pain assessment to the physician.

ADVERSE EFFECTS OF PAIN

Acute pain has a defined purpose: to warn of injury to body tissues. Although often attributable to a defined disorder (such as arthritis, migraine, or cancer), chronic pain often serves no useful purpose, becoming instead part of the problem. Physiologic responses to pain extend beyond the muscle spasm and fight-or-flight response (increased blood pressure, heart rate, and cardiac output, decreased gastric and intestinal motility), and can have adverse effects on the patient's health. Pain interferes with sleep quantity and quality, leading to exhaustion and possible disorientation. Metabolism and myocardial oxygen demand are increased. Catabolism (breakdown of body tissues) increases, and healing is impaired. Immune function is suppressed, increasing the risk for infection. Research shows a clear link between chronic pain and depression.

FACTORS AFFECTING RESPONSES TO PAIN

Responses to pain stimuli are as individualized as the person experiencing the stimulus. The previous discussion focused on types of pain and physiologic responses to pain stimuli. The individualized response to pain is shaped not only by physiologic responses, but by multiple and interacting factors, including genetics, age, gender, sociocultural influences, emotional state, past experiences with pain, the source and meaning of the pain, and knowledge base.

The *pain threshold* is the point at which a stimulus elicits a response. Although the pain threshold is relatively consistent, meaning that a given pain stimulus will elicit pain perception among most people, it can be affected by factors such as the presence of chronic pain (which tends to lower the threshold) or more intense pain at another site (which tends to raise the threshold).

Pain tolerance is the amount (duration, intensity) of pain an individual can endure before outwardly responding to it (Pasero, Portenoy, & McCaffery, 2011). Pain tolerance varies significantly among individuals and within an individual over time. It is influenced by culture, expectations, emotions, and psychosocial factors. The ability to tolerate pain may be decreased by repeated episodes of pain, fatigue, anger, anxiety, and sleep deprivation. Medications, alcohol, hypnosis, warmth, distraction, and spiritual practices may increase pain tolerance.

Age

Age influences a person's perception and expression of pain. There is, however, no evidence that nociception is altered by age. When compared with younger adults, pain stimulus transmission relies more on C fibers in older adults than on Aδ fibers. As a result, pain stimulus transmission is slower, and pain more frequently may be described as burning, dull, or aching. Central processing often is slowed, resulting in a slower response time to pain. Referred pain is less typical in older adults, and visceral pain may present as less severe than in younger adults. The older adult may report vague complaints of pain, or may present with manifestations such as delirium rather than subjective reports of pain (D'Arcy, 2011b; Tabloski, 2013).

Many older adults experience both acute and chronic pain related to disorders such as arthritis or peripheral neuropathy. While peripheral vascular disease or diabetes may lead to neuropathy and interfere with normal nerve impulse transmission, neuropathy can manifest as hyperesthesias as well as hypoesthesias. Both of these manifestations cause discomfort. Pain tolerance decreases with aging, perhaps related to the prevalence of chronic pain in this population. Studies of older adults found that 45% to 85% of nursing home residents report daily persistent pain. Studies show that 25% to 50% of community-dwelling older adults experience persistent or frequent episodes of pain (Tabloski, 2013). Effective assessment and management of pain in older adults can be challenging. Patients and healthcare professionals (including nurses) may believe that pain and discomfort are unavoidable aspects of aging. Individuals in this age group may fail to acknowledge pain, believing that pain is inevitable or fearing dependency if they alarm their loved ones. Patients and healthcare professionals may have misconceptions about the use of analgesics, including opioid medications, fearing adverse effects (such as respiratory depression) or **addiction**. Sensory impairments (e.g., impaired hearing) or cognitive impairments can interfere with the patient's ability to report pain and the healthcare professional's ability to assess pain. The Nursing Care of the Older Adult table lists some age-related changes and their effects on pain.

Gender

Clinical and animal studies show that women have a lower pain threshold and experience higher intensity of pain than men (D'Arcy, 2011b). It has long been held that sociocultural factors account for these recognized differences in the pain experience. Research has recently provided evidence of physiologic differences in pain responses and the analgesic effect of opioid medications. These physiologic responses appear to be genetically encoded, involving the sex hormones and the activity of opioid receptors in the brain. Fluctuating estrogen levels associated with the menstrual cycle affect perceived pain intensity. The circuits that mediate the pain response differ in men and women, the opioid pain modulatory system in particular. Because of these differences, women and men may respond differently to opioid analgesics such as morphine (D'Arcy, 2011b).

Sociocultural Influences

Each person's response to pain is strongly influenced by the family, community, and culture. Sociocultural influences affect pain behavior, dictating appropriate and inappropriate expressions of pain. People acquire beliefs about pain and norms for expressing response to pain over a lifetime of varying experiences that are influenced by social and culture factors. Whether they perceive pain as a sign of impending damage or disability, a short-term or permanent condition, or controllable or uncontrollable will influence their response (IOM, 2011). For example, if the patient's culture teaches that people should tolerate pain stoically, the patient may

NURSING CARE OF THE OLDER ADULT

Age-Related Changes in Pain Perception and Response

Age-Related Factor	Effects
Decreased Aδ fiber transmission, greater reliance on C fiber transmission	Pain perceived as dull, aching, more diffuse rather than sharp, localized
Slowed central processing	Slower motor or avoidance responses
Reduced norepinephrine levels	Reduced sympathetic nervous system responses to pain (pulse, blood pressure, papillary dilation)
Decreased referred pain	May not exhibit classic manifestations of such disorders as myocardial infarction, acute abdomen
Reduced neurotransmitter levels	Increased risk of depression related to chronic pain

appear withdrawn and refuse (or not request) pain medication. If the cultural norm encourages open and intense emotional expression, the patient may cry freely and appear comfortable requesting pain medication.

Cultural standards also teach an individual how much pain to tolerate, what types of pain to report, to whom to report the pain, and what kind of treatment to seek. For example, patients of northern European ancestry may value "being a good patient," which may cause them to avoid complaining about their pain, whereas patients of Jewish ancestry may value seeking information about their pain, which may cause them to discuss their pain often and in detail. Note, however, that behaviors vary greatly within a culture and from generation to generation. The nurse should approach each patient as an individual, observing the patient carefully, taking the time to ask questions, and avoiding assumptions. Although considering the meaning of pain and how a patient expresses pain from a cultural perspective is important, the nurse must avoid applying culturally based generalizations and instead treat the individual's response to pain from a patient-centered perspective.

The nurse also has a set of sociocultural values and beliefs about pain. If these values and beliefs differ from those of the patient, the assessment and management of pain may be based on the values of the nurse rather than on the needs of the patient. The nurse must be familiar with ethnic and cultural diversity in pain expression and management and respect cultural differences. It is particularly important to remember that pain behaviors are not an objective indicator of the amount of pain present for any individual. Most experts agree that cultural differences in the expression of, response to, and interpretation of the meaning of pain need further research.

Psychologic Influences

The intensity of perceived pain has been shown to be affected by psychologic variables such as attention, expectation, and suggestion. The sensation of pain may be blocked by intense concentration (during sports activities, for example) or may be increased by anxiety or fear. Pain often is increased when it occurs in conjunction with other illnesses or physical discomforts such as nausea or vomiting. The presence or absence of support people or caregivers that genuinely care about pain management also may alter emotional status and the perception of pain. The placebo effect, a positive patient response to an inactive substance, has been demonstrated through both observational studies and brain MRI studies (Longo et al., 2013).

Anxiety may increase the perception of pain, and pain in turn may cause anxiety. In addition, the muscle tension common with anxiety can create its own source of pain. This association explains why nonpharmacologic interventions such as relaxation or guided imagery are helpful in relieving or decreasing pain.

Fatigue, lack of sleep, and depression also are related to pain experiences. Pain interferes with a person's ability to fall asleep and stay asleep and thus induces fatigue. In turn, fatigue can lower pain tolerance. Depression is clearly linked to pain: Serotonin, a neurotransmitter, is involved in the modulation of pain in the CNS. In clinically depressed people, serotonin is decreased, leading to an increase in pain sensations. The reverse is also true: In the presence of pain, depression is common.

The meaning associated with the pain influences the experience of pain. For example, the pain of labor to deliver a baby is experienced differently from the pain following removal of a major organ for cancer. Because pain is the major signal for health problems, it is strongly linked to all associated meanings of health problems, such as disability, loss of role, and death. A lack of understanding of the source, outcome, and meaning of the pain can contribute negatively to the pain experience. For this reason, it is important to explain to patients the etiology and prognosis for the pain assessed.

If the patient perceives the pain as deserved (e.g., "just punishment for sins"), the patient may actually feel relief that the "punishment" has commenced. If the patient believes that the pain will relieve him or her of an unrewarding job, dangerous military service, or even stressful social obligations, there may similarly be a feeling of relief. In contrast, pain that is perceived as meaningless—for example, chronic low back pain or the unrelieved pain of arthritis—can cause anxiety and depression.

●○● INTERPROFESSIONAL CARE

Effective pain relief results from collaboration among the patient and all members of the healthcare team. Acute pain management may be straightforward, accomplished though short-term analgesia and management of the underlying problem. Chronic pain, on the other hand, frequently requires a multidisciplinary approach. Pain clinics are centers staffed by a team of healthcare professionals who use traditional pharmacologic agents and complementary therapies such as herbs, vitamins, and other dietary supplements; nutritional counseling; psychotherapy; biofeedback; hypnosis; acupuncture; massage; and other treatments. Hospices for dying patients also provide a

multifaceted approach to pain management. Chapter 5 provides information about pain management during end-of-life care.

MEDICATIONS

Medication is the most common approach to pain management. Management of acute pain often is relatively straightforward, relying on **analgesic** (pain-relieving) drugs such as acetaminophen, nonsteroidal anti-inflammatory drugs (NSAIDs), and opioid analgesics. Recent practice guidelines suggest using a multimodal approach to pain management for postoperative care (D'Arcy, 2011b). Multiple studies show that the use of adjuvant medications such as gabapentin and ketamine (administered IV) and regional pain management techniques such as peripheral nerve catheters improve postoperative pain control and reduce the use of opioids (D'Arcy, 2011b). Chronic pain presents additional challenges that may require use of a broader range of drug classes, including antidepressant medications, anticonvulsants, and long-term opioids.

In addition to administering the prescribed medications, the nurse may act interdependently in selecting the appropriate dosage and timing. The Joint Commission approves the use of range orders when appropriate policies and procedures are in place and nurses are educated in appropriate implementation (Rosier, 2012). The nurse is also responsible for assessing the side effects of medications, evaluating medication effectiveness, and providing patient teaching. The nurse's role in pain relief is that of patient advocate as well as direct caregiver.

The World Health Organization (WHO) (2013) "ladder of analgesia" effectively guides the use of medications for patients with malignant pain (Figure 9–5 ■). Aspirin and NSAIDs are initially used, followed by the addition of mild opioid analgesics and then strong opioids until pain is relieved, reflecting the interactive nature of these two types of analgesics. Adjuvant drugs are used to manage fear and anxiety. This approach also emphasizes administering analgesics by the clock, rather than on demand, to maintain comfort.

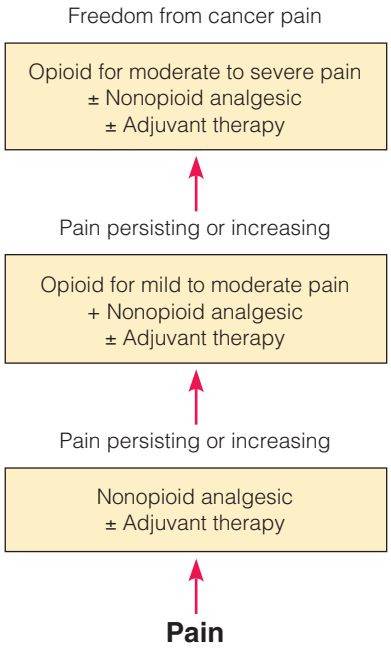

Figure 9–5 ■ The WHO analgesic ladder illustrates the process for selection of analgesic medications for pain management.

ASPIRIN, ACETAMINOPHEN, AND NSAIDS Nonopioid analgesics such as acetaminophen (Tylenol), aspirin, and NSAIDs produce analgesia and reduce fever. They are used to treat mild to moderate pain, and are particularly effective for treating headache and musculoskeletal pain.

Acetaminophen appears to act on the CNS to relieve pain. Its exact mechanism of action is unknown, but it is believed to raise the pain threshold by acting on receptors in pain pathways. Acetaminophen is often combined with opioid analgesics to allow effective pain relief with a lower opioid dose (e.g., Percocet, Tylenol #3, Vicodin). It is important to remember that acetaminophen is toxic to the liver and is the number one cause of acute hepatic failure in the United States (Adams et al., 2014). Hepatotoxicity is a particular risk in patients who are malnourished or who have a history of alcohol abuse or are immunosuppressed (Adams et al., 2014). As the patient develops tolerance to the opioid, increasing doses may be required to achieve effective analgesia, resulting in acetaminophen doses that increase the risk for hepatotoxicity.

Aspirin and NSAIDs act on peripheral nerve endings and minimize pain by interfering with two enzymes necessary for prostaglandin synthesis, cyclooxygenase type 1 (COX-1) and cyclooxygenase type 2 (COX-2). Examples include ibuprofen, indomethacin (Indocin), and ketorolac (Toradol). The NSAIDs have anti-inflammatory, analgesic, and antipyretic actions. NSAIDs are the treatment of choice for mild to moderate pain and continue to be effective when combined with narcotics for moderate to severe pain. NSAIDs are increasingly used in a *multimodal* approach to analgesic therapy; that is, in combination with opioid and adjunctive pain relief measures.

As a class, aspirin and NSAIDs are associated with gastric irritation. As cyclooxygenase (COX) inhibitors, they interfere with prostaglandin production. While this accounts for their anti-inflammatory effects, prostaglandins are necessary to maintain the gastric mucosal barrier. The gastric mucosal barrier (composed of mucus and bicarbonate) protects gastric mucosa from the irritating effects of ingested substances. NSAIDs, therefore, are not only irritating to gastric mucosa, they interfere with its protection as well. The risk for resultant gastrointestinal bleeding is greatest with aspirin, because it interferes with platelets and blood clotting (Adams et al., 2014).

NSAIDs also increase blood pressure in many patients and, with long-term use, may be toxic to the kidneys. With the exception of aspirin, NSAIDs have been shown to have an associated increased cardiovascular risk (Pasero, Polomano, et al., 2011). They are not recommended for use in people with kidney or liver disease, bleeding disorders, peptic ulcer disease, pregnancy, or a history of hypersensitivity to aspirin or other NSAIDs. Nursing implications for NSAIDs are found in the Medication Administration box on page 162. For more information about doses and precautions for specific NSAIDs, see Table 40–5 on page 1294.

OPIOID ANALGESICS *Opioid* (also called *narcotic*) analgesics are derivatives of the opium plant. These drugs (and their synthetic forms) are the most potent pain-relieving drugs available, and they are the treatment of choice for acute moderate-to-severe pain. Examples are morphine, codeine, and fentanyl (Duragesic, Actiq). Opioid analgesics produce analgesia by binding to opioid receptors both within and outside the CNS. They differ from one another in potency, speed of onset, duration of action, and preferred route of

administration. Opioid *agonists* such as morphine produce their effect by stimulating the receptor they bind with. Drugs with a mixed *agonist–antagonist* effect block the activity of some receptors (mu receptors) while activating others (kappa receptors). This mixed agonist–antagonist activity can actually intensify pain responses in some patients. Buprenorphine (Buprenex), butorphanol (Stadol), nalbuphine (Nubain), and pentazocine (Talwin) are examples of opioids with mixed agonist–antagonist effects.

A summary of **equianalgesic** or approximate equivalent doses of selected opioid analgesics used to treat moderate to severe pain, their peak effect and duration, and nursing implications is provided in Table 9–3.

TABLE 9–3 Equianalgesic Drug Chart

Analgesic	Dosage (mg)	Peak (min)	Duration (h)	Nursing Considerations
Morphine sulfate	10 Subcut, IV 30–60 PO	30–60 min 60–90 min	3–4 h 3–6 h	PO dose is 3–6 times the IV dose. Oral modified release will have a longer peak time. A lower dose may be appropriate for older patients with chronic pain. Smaller doses (e.g., 2–5 mg) may be administered more frequently when using IV route.
Codeine	130 IM, Subcut 200 PO	30–60 min 60–90 min	3–4 h 3–4 h	PO dose is about 1.5 times the parenteral dose. IM absorption unpredictable. Analgesic potency about one-sixth that of morphine. Often given in combination with aspirin or acetaminophen for mild to moderate pain. Also used for its antitussive (cough suppressant) effect.
Fentanyl (Duragesic, Sublimaze, Actiq)	50–100 mcg IV/IM 25 mcg/hour every 3 days transdermal 200 mcg stick lozenge (Actiq only) for breakthrough pain.	3–5 min 24 h	2–5 h 48–72h	100 mcg/h parenteral or transdermal is equivalent to 4 mg/h of parenteral morphine. Rapid onset and short half-life; tissue storage can prolong half-life and effect with longer-term use. Transdermal fentanyl not recommended for acute pain management. Available by oral transmucosal route (lozenge on a stick).
Hydrocodone (as in Vicodin, Lortab)	30 mg	60–90 min	4–6 h	Available PO only.
Hydromorphone HCl (Dilaudid)	1.5 IM, Subcut, IV 7.5 PO, Rectal	30–90 min 10–20 min 30–90 min	3–4 h 3–4 h 3–4 h	PO dose is 5 times IM dose. Shorter acting than morphine.
Levorphanol (Levo-Dromoran)	2 IM, Subcut, IV 4 PO	60–90 min 15–30 min 90–120 min	4–6 h 4–6 h 4–5 h	Longer acting than morphine when given in repeated, regular doses. Accumulates, so analgesic effect may increase over time.
Meperidine (Demerol)	75 IM, Subcut, IV 300 PO	15–30 min 10–15 min 60–90 min	2–4 h 2–4 h	Not recommended as first-line opioid for acute or chronic pain. Metabolized to normeperidine, which is toxic to the CNS. Not recommended for older adults, patients with impaired kidney function, or for administration by continuous IV infusion.
Methadone HCl (Dolophine)	10 IM, Subcut, IV 20 PO	60–120 min 90–120 min	6–8 h 6–8 h	Initial PO dose is twice IM dose. Accumulates, so analgesic effect may increase over time. Initial doses lower in opioid-tolerant patients. Also used for heroin detoxification and temporary maintenance.
Oxycodone (Percocet, OxyContin)	20 PO (NA parenteral)	60–90 min	3–4 h	Used in combination with nonopioid analgesic (Percocet, Tylox) for moderate pain. Available as a single-entity product in immediate- or controlled-release forms (OxyContin) for severe pain. Has faster onset and higher peak effect than most PO narcotics, equivalent to oral morphine.
Oxymorphone (Numorphan)	1–1.5 IM, Subcut, IV 10 PO or PR	30–90 min 15–30 min	3–6 h 3–4 h	Also available as rectal suppository (10 mg equianalgesic). Used for moderate to severe pain.
Tramadol (Ultram, Zydol)	100 PO	120–180 min	3–6 h	Used for moderate to moderately severe pain. Causes less respiratory depression than morphine.

Note: Morphine sulfate 10 mg IM is the analgesic dose to which all other parenteral and PO doses in this table are considered equianalgesic.

MEDICATION ADMINISTRATION

Nonsteroidal Anti-Inflammatory Drugs

EXAMPLES OF NSAIDS

aspirin (acetylsalicylic acid)
celecoxib (Celebrex)
diflunisal (Dolobid)
fenoprofen calcium (Nalfon)
ibuprofen (Advil, Motrin)
indomethacin (Indocin)
ketoprofen (Orudis)
ketorolac tromethamine (Toradol)
nabumetone (Relafen)
naproxen (Aleve, Naprosyn)
piroxicam (Feldene)
sulindac (Clinoril)
tolmetin (Tolectin)

The NSAIDs have anti-inflammatory, analgesic, and antipyretic effects. It is believed that they inhibit the enzyme COX, thereby decreasing synthesis of prostaglandins. These drugs provide analgesic effects by reducing inflammation and by perhaps blocking the generation of noxious impulses.

Nursing Responsibilities

- Do not administer aspirin with other NSAIDs.
- Assess and document if the patient is taking a hypoglycemic agent or insulin; the NSAIDs may increase the hypoglycemic effect.
- Administer with meals, milk, or a full glass of water to decrease gastric irritation.
- Assess patients who are also taking anticoagulants for bleeding; the NSAIDs increase this risk.

Health Education for the Patient and Family

- Drugs may cause gastrointestinal bleeding (report nausea, vomiting of blood, dark stools), visual disturbances (report blurred or diminished vision), increased blood pressure, hearing problems, dizziness, skin rash, and kidney problems (report weight gain or edema).
- Take medications with meals to decrease gastric irritation.
- Avoid drinking alcohol or taking any over-the-counter drug unless approved by the healthcare provider.
- The desired effects may not appear for 3–5 days, and the full effects may not appear for 2–4 weeks.
- Maintain regular healthcare appointments.

Note: Drugs identified in *italics* are among the 200 most commonly prescribed medications in the U.S.

Opioid analgesics tend to have similar unintended effects. They are CNS and respiratory depressants. They commonly produce sedation, drowsiness, and dizziness. All should be avoided or used with caution in patients with chronic obstructive lung disease (COPD) or who are experiencing an acute asthma attack because these drugs can suppress respirations. Nausea and vomiting are common adverse effects, as is constipation. All opioid analgesics have the potential to cause physical and psychologic dependence, particularly when taken at high doses for an extended time (McCaffery et al., 2011).

A common myth among healthcare professionals is that using opioids for pain treatment poses a real threat of addiction. Actually, when the medications are used as recommended, there is little to no risk of addiction. Rather, if pain is not adequately treated, the patient may seek more and more analgesic relief, thus increasing the risk of an adversarial relationship with the provider and a weakening of the trust relationship between patient and provider (Box 9–1).

Opioid analgesics commonly are used to treat chronic malignant pain (refer to Figure 9–5). Because of their potency and efficacy, they also may be used to treat chronic nonmalignant pain. Oral preparations of a fixed combination of an opioid and acetaminophen are used with caution. Tolerance can lead to higher required doses of the opioid, increasing the risk for hepatoxicity due to the increasing dose of acetaminophen. Nursing implications for opioid analgesics are found in the Medication Administration box on page 164.

Certain opioid analgesics, while still available, are not recommended for use because of toxic effects or their potential for abuse. As previously noted, the metabolite of meperidine (Demerol) is toxic to the CNS. While a single dose of meperidine may be used to relieve acute pain (e.g., migraine), it is not recommended for continued use (Pasero, Quinn, et al., 2011). Propoxyphene (Darvon, Darvocet, Balacet), a synthetic opioid analgesic for mild to moderate pain has a high potential for abuse, with significant risk for psychologic dependence. The risk of fatal overdose is significant with propoxyphene (Pasero, Quinn, et al., 2011), and it should not be taken concurrently with any other CNS depressant such as alcohol. Furthermore, clinical studies have shown propoxyphene to be no more effective as an analgesic than acetaminophen.

ANTIDEPRESSANTS Antidepressants, particularly those within the tricyclic and related chemical groups, are useful for treating chronic pain. Tricyclic antidepressants act on the production and retention of serotonin in the CNS, thus inhibiting pain sensation. The dose to provide analgesia is lower than that required to treat depression. These drugs potentiate the effects of opioid analgesics, and may be used to help manage severe persistent or malignant pain. They also promote normal sleeping patterns, further alleviating the suffering of the patient in pain. They are particularly useful in treating neuropathic pain. Tricyclic antidepressants are not without adverse effects, however. They may cause orthostatic hypotension, drowsiness, urinary retention, constipation, and impaired memory. These effects can limit their usefulness in older adults in particular. Antidepressants from other classes such as serotonin norepinephrine reuptake inhibitors (venlafaxine [Effexor], duloxetine [Cymbalta]) appear to have an analgesic effect similar to that of tricyclic antidepressants with fewer adverse effects (Longo et al., 2013).

ANTICONVULSANTS Similar to antidepressants, some seizure medications such as gabapentin (Neurontin), pregabalin (Lyrica), and carbamazepine (Tegretol) are useful with neuropathic pain, including shingles (herpes zoster), migraine headaches, and diabetic neuropathy and are frequently used with opioids in multimodal postoperative pain control (D'Arcy, 2011b). These drugs reduce pain and sleep disruption. Drugs that are primarily used to treat epilepsy (seizures) have been used to treat nerve pain conditions and migraine

BOX 9–1 Pain Management, Addiction, and Regulation

The goals of pain control are to minimize discomfort and promote normal functioning. Although these goals often can be achieved through use of nonpharmacologic strategies and nonnarcotic analgesics, opioid medications currently provide the only effective option for pain associated with acute trauma, surgery, cancer, and some chronic conditions.

Crude opium has been available for thousands of years. Abuse of opium and its derivatives (e.g., heroin, morphine) increased dramatically with development of the hypodermic syringe. International efforts to control narcotic trafficking and abuse while ensuring availability for medical and scientific purposes began in the early 20th century.

The WHO estimates more than 80% of people with severe pain are inadequately treated (IOM, 2011). Despite significant data showing very little addiction as the result of treating pain with adequate analgesia, prescribers still tend to undertreat chronic nonmalignant pain (IOM, 2011). The American Society for Pain Management Nursing has recently updated its position statement on pain management in patients with substance abuse disorders. The position statement emphasizes every patient's right to be treated with dignity and respect and to receive high-quality pain assessment and management (Oliver et al., 2012). Addiction is a neurophysiologic disease, separate and distinct from physical dependence and tolerance. See the following list for definitions of relevant terms.

Substance use is common in our society and illicit use of controlled substances is the leading category of medication misuse (Oliver et al., 2012). The development of highly effective oral opioid analgesics such as oxycodone (OxyContin) and hydrocodone (Vicodin) has resulted in increased reports of illicit substance use and an increase in individuals meeting diagnostic criteria for a drug use disorder. The abuse/misuse of prescribed medications occurs in all age groups and experts predict that as the population ages, drug abuse among older adults will rise significantly (Oliver et al., 2012). This has led to calls for legislation to limit the use and availability of these drugs, an option that concerns palliative care specialists.

Opioid analgesics are among the most effective, highly regulated, and significantly abused drugs available today. Treating patients in pain who have become addicted to drugs is complex and often involves an interprofessional approach that includes the expertise of a pain control specialist or pain treatment team. Patients with drug addictions frequently require large doses of medication to control their pain. Although addiction is a public health concern, so is undertreatment of pain (IOM, 2011; Oliver et al., 2012). Patients with substance use disorders must be treated with respect and dignity and their pain should be assessed and managed using the same standards as all other patients (Oliver et al., 2012). Clearly, there are no simple answers to the problems associated with drug trafficking, abuse, addiction, and adequate pain management for patients with substance abuse disorders.

The following list of definitions help to discern the difference between tolerance to opioids, physical dependence on opioids, and addiction to opioids. These three terms are sometimes confused and lead to poor patient outcomes.

- *Addiction:* A primary, chronic neurobiologic, treatable disease characterized by compulsive use of a substance despite negative consequences, such as health threats or legal problems.
- *Drug abuse:* The use of any chemical substance for other than a medical purpose.
- *Physical drug dependence:* Is not the same as addiction. Physical dependence is an expected physical response to a number of drug classes (such as opioids and benzodiazepines) that produces a drug class-specific withdrawal/abstinence syndrome with specific symptoms.
- *Psychologic drug dependence:* A psychologic need for a substance. If the substance is not supplied, psychologic withdrawal symptoms occur.
- *Drug tolerance:* Physical adaptation to the drug resulting in its diminished effects over time.
- *Equianalgesic:* Having the same pain-killing effect when administered to the same individual. Drug dosages are equianalgesic if they have the same effect as morphine sulfate 10 mg administered parenterally.
- *Pseudoaddiction:* An iatrogenic syndrome associated with undertreatment of pain and characterized by problematic behaviors that mimic abuse. Pseudoaddiction can be distinguished from true addiction in that behaviors resolve when pain is adequately treated.

headache for several decades. Many anticonvulsant drugs have been shown in clinical studies to be effective in managing chronic pain (Pasero et al., 2011).

LOCAL ANESTHETICS Drugs such as benzocaine and lidocaine are part of a large group of substances that block the initiation and transmission of nerve impulses in a local area, thus blocking pain as well. Local anesthetics can be delivered by a variety of methods, including via transdermal patch to treat focal neuropathic pain (Pasero & Portenoy, 2011). They are sometimes used to enable a patient to begin moving and using a painful area to diminish long-term pain.

Local anesthetics can be delivered directly to the sheath of a nerve through a peripheral nerve catheter. During surgery, a soaker type catheter can be inserted along a surgical incision to deliver local relief; this method may decrease the need for opioids and allow the patient to resume activity sooner (D'Arcy, 2011b).

ANALGESIC ADMINISTRATION

The ideal drug, route of administration, and dosing schedule to provide optimal pain relief vary, depending on such factors as the type of pain, its intensity and duration, and the individual patient. Each drug has a unique absorption and duration of action. The nurse must understand that no drug will have a totally predictable effect, because each person absorbs, metabolizes, and excretes medications at different dosage levels. The only way to obtain reliable data about the effectiveness of the medication for the individual is to assess how that patient responds. Therefore, the best choice is to individualize the drug, route, and schedule.

Giving analgesics before the pain occurs or increases prevents some of the untoward effects of pain. This holds true for both acute and chronic pain: Poorly managed acute pain is one of the leading causes of persistent pain syndrome. Additional benefits of a preventive approach to pain can be summarized as follows:

- The patient may spend less time in pain. Pain has been shown to have a negative effect on healing; poorly relieved pain is associated with longer hospital stays.
- Inadequate relief of acute pain has been shown to be a significant contributing factor to chronic pain (Pasero & Portenoy, 2011).
- Frequent analgesic administration may allow for smaller doses and less analgesic administration.
- Smaller doses will in turn mean fewer side effects.

MEDICATION ADMINISTRATION

Opioid Analgesics

EXAMPLES OF OPIOID ANALGESICS

buprenorphine HCl (Buprenex)
codeine
fentanyl (Duragesic)
hydrocodone (Hycodan, Vicodin)
hydromorphone HCl (Dilaudid)
levorphanol (Levo-Dromoran)
morphine sulfate
nalbuphine HCl (Nubain)
oxycodone (OxyContin)
oxymorphone HCl (Numorphan)
pentazocine (Talwin)

Opioid analgesics are used to treat severe pain. The drugs in this category include morphine, codeine, opium derivatives, and synthetic substances with activity similar to natural opioids. Morphine and codeine are pure chemical substances isolated from opium. These drugs decrease the awareness of the sensation of pain by binding to opiate receptors in the brain and spinal cord. It is also believed that they diminish the transmission of pain impulses by altering cell membrane permeability to sodium and by affecting the release of neurotransmitters for efferent nerves sensitive to noxious stimuli. Opioid analgesics affect the CNS, causing analgesia, euphoria, drowsiness, mental clouding, and lethargy. They have various other effects. Depending on the drug used, they can depress respirations, stimulate the vomiting center, suppress the cough reflex, induce peripheral vasodilation (resulting in hypotension), constrict the pupils, and decrease intestinal peristalsis (Pasero & Portenoy, 2011). Opioid analgesics have the potential to cause tolerance and psychologic and physical dependence.

Nursing Responsibilities

- Opioids are regulated by federal law; the nurse must record the date, time, patient name, type and amount of the drug used, and sign the entry in a narcotic inventory sheet or use an automated medication dispensing device such as Pyxis. If the drug must be wasted after it is signed out, the act must be witnessed and the nurse and the witness must both document. Computerized narcotic documentation methods are frequently integrated into the electronic health system documentation system.
- Keep an opioid antagonist, such as naloxone, immediately available to treat respiratory depression.
- Assess allergies or adverse effects from opioids previously experienced by the patient.
- Assess for respiratory disorders (e.g., asthma or COPD), neuromuscular disorders (e.g., multiple sclerosis), and other conditions that might increase the risk associated with respiratory depression.
- Assess the characteristics of the pain and the effectiveness of drugs that have been previously used to treat the pain.
- Take and record baseline vital signs before administering the drug.
- Administer the drugs, following established guidelines.
- Monitor vital signs and respiratory status, level of consciousness, papillary response, nausea, bowel function, urinary function, and effectiveness of pain management at regular intervals and as indicated.
- Provide for patient safety.
- Report adverse effects such as continued nausea, vomiting, or itching.
- Employ protocols or prn orders as needed to promote bowel function and prevent constipation.
- Meperidine (Demerol) is associated with CNS toxicity and thus involves significant patient risk (Pasero, Quinn, et al., 2011). Monitor any patient who is receiving more than one dose for nervousness, restlessness, tremors, twitching, shakiness, myoclonic jerks, diaphoresis, changes in level of awareness, agitation, disorientation, confusion, delirium, hallucinations, violent shivering, and/or seizures. Toxicity can occur with any route of administration or any dosing regimen. The risk is increased in patients with decreased renal function (including normal changes with aging). Report these manifestations to the physician. Oral administration is not recommended.
- Teach noninvasive methods of pain management for use in conjunction with opioid analgesics.

Health Education for the Patient and Family

- The use of opioid analgesics to treat severe pain is unlikely to cause addiction (IOM, 2011).
- Do not drink alcohol while taking these drugs.
- Do not take over-the-counter medications unless approved by the healthcare provider.
- Increase intake of fluids and fiber in the diet to prevent constipation. Contact your provider if additional measures (such as laxatives) are needed to manage constipation.
- The drugs often cause dizziness, drowsiness, and impaired thinking; use caution when driving or making decisions.
- Report adverse effects or decreasing effectiveness to the physician.

Note: Drugs identified in *italics* are among the 200 most commonly prescribed medications in the U.S.

- The patient's fear and anxiety about the return of pain will decrease.
- Pain relief allows the patient to be more physically active and avoid complications of immobility.

Analgesics may be given either around-the-clock (ATC) or as necessary (prn, meaning *pro re nata*, Latin for "as circumstances may require"). ATC administration is recommended for the first 48 hours for acute pain related to surgery or traumatic injury. It also is appropriate for pain that has a predictable intensity and pattern. For pain that is not predictable or constant, prn administration is appropriate and should be given as soon as the pain begins. Breakthrough pain occurs in patients receiving long-acting analgesics for chronic pain. It is a transitory experience of moderate to severe pain often precipitated by coughing or movement but that may occur spontaneously. Breakthrough pain is managed using short-acting opioid analgesics in addition to ATC medications.

Maintaining effective pain relief while minimizing the adverse effects of a medication can be challenging. Within a prescribed range, the nurse can choose the correct dose according to the patient's response. It is the role of the nurse to notify the physician if the prescribed dosage does not meet the patient's needs or causes excessive drowsiness, unsteadiness, or significant adverse effects.

ROUTES OF ADMINISTRATION

The route of administration significantly affects how much of a medication is needed to relieve pain. For example, because of differences

in absorption and distribution, oral doses of some opioids must be up to five times greater than parenteral doses to achieve the same degree of pain relief. In addition, the potency of opioid analgesics varies. Consulting an equianalgesic chart when converting from one route of administration to another or from one drug to another helps ensure an equivalent effect for the patient. The analgesic effect of 10 mg of parenteral morphine is used as the base to which other opioids and routes of administration are compared. Table 9–3 earlier in this chapter is an example of an equianalgesic chart.

ORAL The simplest route for both patient and nurse is the oral (PO) route. Unless contraindicated, the oral route is preferred for most patients. Special nursing care is still required, because some medications must be given with food, some are irritating to the gastrointestinal system, and some patients have trouble swallowing pills. Liquid and timed-release forms are available for special applications.

Some analgesics, such as fentanyl, are available in alternative forms, including a buccal tablet, a lozenge, or a lollipop. The buccal route provides a rapid onset of action, because the medication is absorbed directly into the circulation, bypassing the gastrointestinal tract and first-pass liver metabolism. These delivery systems are particularly helpful for managing breakthrough pain. Special precautions must be taken in storing the lozenge and lollipop forms, because children and pets may mistake these for candy.

RECTAL The rectal route is helpful for patients who are unable to swallow or who are experiencing nausea and vomiting. Acetaminophen, aspirin, and some NSAIDs and opioid analgesics are available in this form. The rectal route is effective and simple, but the patient and family may not accept it. To be effective, any rectal medication must be placed above the rectal sphincter.

TRANSDERMAL The transdermal, or patch, form of medication is increasingly being used because it is simple, painless, and delivers a continuous level of medication. Transdermal medications are easy to store and apply. Reapplication every 72 hours enhances compliance. Additional short-acting medication may be needed for breakthrough pain. As with any route of administration, overdosage can occur. It is important to start with a low dose and **titrate** (increase or decrease a dose in small increments) to the effective level. Medication administered transdermally is in a lipid-soluble form, and may be stored in fat cells longer than expected. Monitor level of sedation and respiratory effort.

A transdermal patch is applied to a clean, dry area on the upper torso. If hair is present, it should be clipped before applying the patch. Apply the patch immediately after opening the package, ensuring complete contact with the skin, especially around the edges. The patch is effective for about 72 hours. When replaced, the new patch should be applied on a different site. When transdermal therapy is initiated, approximately 12 to 24 hours is necessary for the therapeutic level to be absorbed. Similarly, when discontinuing, expect a gradual decline in level because of the medication reservoir in the skin. Fever or inflammation of the skin, exercise, and use of electric blankets or heating pads all increase or enhance absorption.

PARENTERAL Once the most popular route for pain medication administration, the intramuscular (IM) route is no longer preferred. Its disadvantages include uneven absorption from the muscle, discomfort on administration, and time consumed to prepare and administer the medication. Subcutaneous administration may be used, primarily when continuous analgesic administration via a parenteral route is required.

Figure 9–6 ■ PCA units allow the patient to self-manage acute pain. The units may be portable or mounted on intravenous poles. *Source:* Roy Ramsey/Pearson Education.

INTRAVENOUS The intravenous (IV) route provides the most rapid onset of effect, usually ranging from 1 to 15 minutes. Medication can be given by drip, bolus, or patient-controlled analgesia (PCA). PCA uses a pump with a control mechanism that allows the patient to self-manage pain (Figure 9–6 ■). The advantages of PCA are dose precision, timeliness, and convenience. The patient does not have to wait for a nurse to assess the need for pain medication, then procure and deliver the analgesia. Respiratory depression and sedation are minimized when plasma levels of opioids are steady. PCA, especially with basal dosing (continuous infusion of a very small dose), facilitates frequent small dosing. Several drugs can be administered by this route. The disadvantages are the nursing care needed for any intravenous line, the potential for infection, and the cost of disposable supplies. In addition, the risk for a serious medication error requiring interventions in response has been shown to be greater with PCA than when other methods of analgesic delivery are used. Adverse events associated with PCA errors include depressed respirations, inadequate pain relief, and even patient death (D'Arcy, 2011b). Risk factors for respiratory depression include the use of basal infusion; age greater than 70; obesity; sleep apnea; concurrent use of CNS depressants; upper abdominal or thoracic surgery; renal hepatic, pulmonary, or cardiac impairment; and a PCA bolus of more than 1 mg morphine without a basal rate. Additionally, increased risk is attributed to the complexity of the systems involved when PCA is used to provide analgesia. The PCA method of administration requires close attention by the physician, pharmacist, and nurse, as well as careful patient teaching and monitoring.

SAFETY ALERT

Recommendations for nurses caring for at-risk patients on PCA include careful monitoring of respiratory rate and oxygen saturation and sedation levels.

INTRASPINAL The intraspinal (intrathecal or epidural) route is invasive and requires more extensive nursing care. Intraspinal analgesia

is used to manage chronic intractable malignant pain and postoperative pain. The use of the intraspinal route has decreased in acute care with improved peripheral nerve catheters that deliver local anesthesia postoperatively. However, intraspinal delivery may provide better analgesia and postoperative recovery than intravenous delivery for some patients. Many patients experience better pain relief, earlier bowel recovery, and earlier mobility when a combination of local anesthetics and opioids are infused by the epidural route. The risk for respiratory depression and failure is lower with epidural analgesia than with administration by other parenteral routes. Other complications can occur, however, including hypotension, development of an epidural hematoma or abscess, and neurologic damage.

NERVE BLOCKS In a nerve block, a local anesthetic, sometimes in combination with steroidal anti-inflammatory drugs, is injected by a physician or nurse anesthetist into or near a nerve, usually in an area between the nociceptor and the dorsal root. The procedure may be performed to determine the precise location of the source of the pain: Pain relief indicates that the injection site is the site of the source of the pain.

Temporary (local) nerve blocks may give the patient enough relief to (1) develop a more hopeful attitude that pain relief is possible, (2) allow local procedures to be performed without causing discomfort, or (3) exercise and move the affected part. A temporary nerve block may be particularly useful for such painful conditions as fractured ribs, allowing the patient to deep breathe, cough, and move with more ease during healing. Nerve blocks may also be performed to predict the results of neurosurgery. For long-term pain relief, a permanent neurolytic agent is used. Neurolytic blocks usually are reserved for terminally ill patients because of the risks of weakness, paralysis, and bowel and bladder dysfunction.

SAFETY ALERT

When you are caring for patients receiving frequent or continuous opioids, ensure that naloxone, an opioid antagonist, is immediately available to reverse respiratory depression if necessary.

- Monitor the effectiveness of the pain management. Administer supplemental analgesics as ordered, and notify the physician if analgesia is inadequate (patient rates pain at 4 or higher on a scale of 0 to 10).
- Monitor intake and output. Narcotics may block the micturition reflex, causing urinary retention and necessitating intermittent catheterization or placement of an indwelling urinary catheter.
- Use sterile technique to care for the intraspinal catheter.

SURGERY

As a pain relief measure, surgery usually is considered only after all other methods have failed. Surgical intervention typically is reserved for patients experiencing nerve pain, for example, the pain of trigeminal neuralgia, complex regional pain syndrome, or pain associated with spinal nerve or spinal cord injury. Patients need thorough knowledge of the implications of the use of surgery for pain relief. For example, motor function loss is an unwelcome side effect of some surgeries. Surgical procedures used to relieve pain are shown in Figure 9–7 ■. Some surgical procedures can be accomplished through minimally invasive techniques (e.g., percutaneously); others require an open surgical procedure. Surgical approaches to pain relief may include the following:

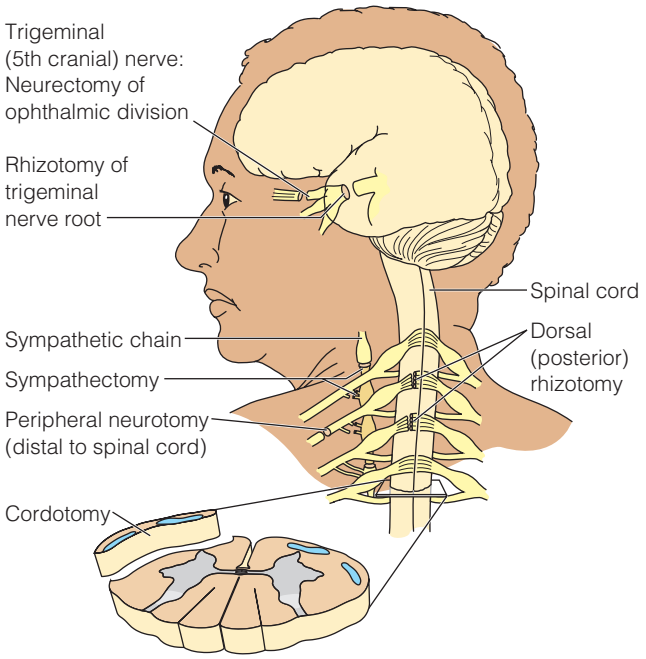

Figure 9–7 ■ Surgical procedures may be used to treat severe pain that does not respond to other types of management. They include cordotomy, neurectomy, sympathectomy, and rhizotomy.

CORDOTOMY A *cordotomy* is an incision into the anterolateral tracts of the spinal cord to interrupt the transmission of pain. Because it is difficult to isolate the nerves responsible for upper body pain, this surgery is most often performed for pain in the abdominal region and legs, including severe pain from terminal cancer. A percutaneous cordotomy produces lesions of the anterolateral surface of the spinal cord by means of a radio-frequency current.

NEURECTOMY A *neurectomy* is the removal or destruction of a nerve. It is sometimes used for pain relief, for example, to relieve the pain of trigeminal neuralgia. The nerve may be destroyed through several different methods, including injection of glycerol into the nerve, using radio-frequency–generated heat, or by compressing the nerve using a balloon. When an open approach is used, the nerve is exposed and severed. A peripheral neurectomy is the severing of a nerve at any point distal to the spinal cord.

SYMPATHECTOMY The sympathetic nerves play an important role in producing and transmitting the sensation of pain. A *sympathectomy* involves destruction by injection or incision of the ganglia of sympathetic nerves, usually in the lumbar region or the cervicodorsal region at the base of the neck.

RHIZOTOMY *Rhizotomy* is surgical severing of the dorsal spinal roots. It is most often performed to relieve the pain of cancer of the head, neck, or lungs. A rhizotomy may be performed by surgically cutting the nerve fibers, by injecting a chemical such as alcohol or phenol into the subarachnoid space, or by using a radio-frequency current to selectively destroy pain fibers.

TRANSCUTANEOUS ELECTRICAL NERVE STIMULATION (TENS)

Transcutaneous electrical nerve stimulation (TENS) is the application of electrical current through the skin to control acute or chronic pain.

Figure 9–8 ■ The TENS unit is used to assist with acute and chronic pain management. Electrodes deliver low-voltage electrical stimuli through the skin to block transmission of pain stimuli.
Source: Gary Ombler/DK Images.

A TENS unit consists of a battery-operated low-voltage transmitter connected to the skin using two or more electrodes (Figure 9–8 ■). Electrodes may be placed by the patient or by the physical therapist. The TENS unit generates a high- or low-frequency electrical pulse. With high-frequency application, pulse intensity is low and does not cause muscle contraction; low-frequency applications produce an intensity that does produce muscle contraction. The patient experiences a gentle tapping or vibrating sensation over the electrodes. He or she can adjust the voltage to achieve maximum pain relief.

TENS controls pain in several ways. It activates opioid receptors in the spinal cord and medulla. It also affects release of both excitatory and inhibitory neurotransmitters, reducing the transmission of pain signals within the CNS. Furthermore, TENS stimulates large-diameter A-beta touch fibers to close the gate controlling pain transmission within the spinal cord. Low-frequency TENS stimulates serotonin release, activates serotonin receptors, and prompts endorphin release.

A TENS unit is most commonly used to relieve chronic benign pain, neuropathic pain, and acute postoperative pain. Their use during obstetric care (labor in particular) is increasing, as is their use in treating orthopedic conditions. In any case, thorough patient teaching is essential, including an explanation of manufacturer's directions, instructions on where to place the electrodes, and the importance of placing the electrodes on clean, unbroken skin. The patient should assess the skin daily for signs of irritation. Patients who have a cardiac pacemaker or implanted cardioverter-defibrillator should not use TENS.

TENS offers several advantages: avoidance of drug side effects, patient control, and good interaction with other therapies. Disadvantages are its cost and the need for expert training for initiation. Note also that TENS is not effective in relieving all types of pain or for all patients.

COMPLEMENTARY THERAPIES

The benefit of complementary and adjunctive therapies (or *CAM*—complementary and alternative medicine) as part of a comprehensive pain management strategy is increasingly recognized. According to the IOM report (2011) about 44% of adults in the United States with pain or neurologic conditions are using some form of CAM. See the accompanying Focus on Cultural Diversity box for the prevalence of CAM use among people of various cultures.

Musculoskeletal aches and headaches are the most common conditions that prompt adults to use CAM. A number of CAM therapies are used to treat pain, including acupuncture, chiropractic and osteopathic medicine, massage, and relaxation. Discussion of some of the more commonly used therapies follows.

ACUPUNCTURE Acupuncture is an ancient Chinese system involving the stimulation of certain specific points on the body to enhance the flow of vital energy (chi) along pathways called meridians. Acupuncture points can be stimulated by inserting and withdrawing needles, applying heat, massage, laser, electrical stimulation, or a combination of these methods. Only care providers with training in acupuncture techniques can use this method. Acupuncture is becoming a more widely accepted therapy, although evidence of its effectiveness in treating pain is mixed. Acupuncture has been shown to enhance traditional analgesia when used after abdominal surgery. The effectiveness of acupuncture in relieving chronic musculoskeletal pain has been extensively studied, with a beneficial effect shown in relieving chronic pain in the neck, lower back, or shoulder.

BIOFEEDBACK Biofeedback is a method for learning to control physiologic responses of the body. Physiologic responses such as brain waves, muscle contraction, and skin temperature are measured electronically, "feeding" this information back to the patient. Biofeedback units use electrodes placed on the skin to transform data into visual cues, such as colored lights. The patient thus learns to recognize stress-related responses and to replace them with relaxation responses. Eventually, the patient learns to repeat independently those actions that produce the desired brain wave effect.

Biofeedback gives the patient a measure of control over the response to pain. It has been studied as a CAM therapy for migraine, fibromyalgia, traumatic brain injury, and temporomandibular disorder (TMD). In all studies, a beneficial effect was found, for example, reduced frequency of migraine headache or reduced intensity of pain associated with fibromyalgia and TMD (Fontaine, 2011).

CHIROPRACTIC Chiropractic uses hands-on therapy, focusing on the relationship between body structure and function. This relationship between structure (primarily that of the spine) and function and its effect on health is a key concept of chiropractic medicine. Chiropractic therapy is directed at normalizing the relationship between structure and function to promote the body's innate ability to self-heal (Fontaine, 2011). The practice of chiropractic in the United States is limited to those who earn a doctor of chiropractic degree from an accredited college. Chiropractic is among the 10 most commonly used CAM procedures, with an estimated 20% of Americans receiving chiropractic care at some point during their lives. Most often, it is used in conjunction with conventional medical services.

Spinal manipulation has been demonstrated to be as effective for relieving mild-to-moderate low back pain as conventional treatments (NCCAM, 2014a). Chiropractic generally is safe, with discomfort of the treated area, headache, and fatigue the most common adverse effects. Chiropractors may combine treatments such as application of heat or ice, electrical stimulation, exercise prescriptions, counseling, and dietary supplements with spinal manipulation.

FOCUS ON CULTURAL DIVERSITY

Use of CAM Therapies

Although about 38% of adults in the United States use CAM therapies, the number of people using CAM varies among different cultural groups. The National Center for Complementary and Alternative Medicine (NCCAM, 2014b) estimates that in 2007 CAM was used by the following:

50.3% of American Indian/Alaska Natives
43.1% of non-Hispanic White Americans
39.9% of Asian Americans
25.5% of Black Americans
23.7% of Hispanic Americans.

DISTRACTION Distraction involves redirecting attention away from the pain and onto something that the patient finds more pleasant. Examples of distracting activities are practicing focused breathing, listening to music, or doing some form of rhythmic activity to music. For example, the patient using recorded music for distraction may sing along with the song, tap out the rhythm with the fingers or foot, clap to the music, conduct the music, or add harmony.

Participating in an activity that promotes laughter, such as reading a joke book or viewing a comedy, has been found to be highly effective in pain relief. Laughing for 20 minutes or more is known to produce an increase in endorphins that may continue pain relief even after the patient stops laughing.

HYPNOTHERAPY AND GUIDED IMAGERY Hypnotherapy is the use of hypnosis, a trance state in which the mind becomes extremely responsive to suggestion, to address a specific problem such as pain. Guided imagery is similar, helping patients achieve a state of focused attention. During hypnotherapy or guided imagery, the patient enters a trance state in which he or she is aware of the surroundings without focusing on them. The patient may go through three trance levels: superficial trance, in which awareness of the surroundings is maintained; alpha trance, a deeper trance state during which the heart rate, blood pressure, and respirations fall; and somnambulism, the level believed to be most beneficial. The patient's muscles relax, alpha brain waves predominate, and the patient experiences a sense of well-being and the ability to accept new ideas. During this state, the therapist may make suggestions to encourage pain relief. It is possible to achieve complete anesthesia or to modify pain in a variety of ways through hypnotism. For the technique to work, however, the patient must be fully relaxed and must want to be hypnotized.

Guided imagery, also called creative visualization, is use of the mind to create a scene or sensory experience that relaxes the muscles and moves the attention of the mind away from the pain experience. The therapist may create imagery to help the patient modify physical responses to stressors such as pain. To use guided imagery, the patient must be able to concentrate, use the imagination, and follow directions. The nurse can facilitate this technique by asking the patient for some descriptions of what the patient finds most relaxing. The nurse then speaks to the patient in a calm, soothing voice about those places or situations. Imagery can cause changes in vital signs, brain wave patterns, blood flow, and hormone and neurotransmitter levels (Fontaine, 2011).

Advantages of hypnotherapy and guided imagery include patient control and lack of side effects. Disadvantages include the need for a skilled practitioner and a willing patient. However, some patients can learn to enter into a trance state without assistance from a practitioner to achieve pain relief.

MASSAGE Massage therapy often is employed as a CAM therapy to relieve pain and promote relaxation. In massage therapy, muscles and soft tissues of the body are manipulated with the intent of relaxing soft tissues; increasing warmth, blood flow, and oxygen delivery to the area; and decreasing pain. There are over 80 different types of massage therapy. Among the most common are Swedish massage, deep tissue massage, trigger point massage, and shiatsu massage. Massage therapy carries very little risk, but should be used appropriately and performed by a licensed or certified massage professional.

NATURAL PRODUCTS Natural products are the most frequently employed CAM therapy overall, used by nearly 80% of the world's population (Fontaine, 2011). A number of products, including herbals, natural oils, and other natural substances, are available. Natural products have been studied for the relief of pain associated with migraine and other musculoskeletal conditions such as fibromyalgia and rheumatoid arthritis with mixed results (Fontaine, 2011).

RELAXATION Relaxation involves learning activities that deeply relax the body and mind. Relaxation distracts the patient's focus from the pain, lessens the effects of stress from pain, increases pain tolerance, increases the effectiveness of other pain relief measures, and increases perception of pain control. Examples of relaxation activities include the following:

- *Diaphragmatic breathing* can relax muscles, improve oxygen levels, and provide a feeling of release from tension. This technique is more effective when the patient either lies down or sits comfortably, remains in a quiet environment, and keeps the eyelids closed. Inhaling and exhaling slowly and regularly are also helpful.
- *Progressive muscle relaxation* may be used alone or in conjunction with deep breathing to help manage pain. The patient is taught to tighten one group of muscles (such as those of the face), hold the tension for a few seconds, and then relax the muscle group completely, repeating these actions for all parts of the body. This method is also more effective when the patient lies or sits comfortably, is in a quiet environment, and keeps the eyelids closed. Tapes are available to help the patient with this relaxation process.
- *Meditation* is a process whereby the patient empties the mind of all sensory data and, typically, concentrates on a single object, word, or idea. This activity produces a deeply relaxed state in which oxygen consumption decreases, muscles relax, and endorphins are produced. At its deepest level, the meditative state may resemble a trance state. A variety of exercises can induce the meditative state, and all are relatively easy to learn. Many books and tapes are available commercially.
- *Music therapy* uses music and the therapeutic relationship to reduce pain, anxiety, and depression. Music provides a familiar sensory stimulus that can provoke favorable responses such as muscle relaxation and reduced heart rate and blood pressure. Studies on

the efficacy of music therapy to reduce pain perception in an acute care setting show a positive impact on pain. Music therapy is a simple and easy intervention that has minimal to no side effects and has been shown to be an effective adjuvant for pain control in multiple studies (Cole & LoBiondo-Wood).

●○● NURSING CARE

Nursing care of the patient with pain presents perhaps more of a challenge than almost any other type of illness or injury. Regardless of the type of pain, the goal of nursing care is to assist the patient to achieve optimal control of the pain. See the accompanying Case Study & Nursing Care Plan.

Health Promotion

Health promotion activities related to pain focus on providing effective relief of acute pain to avoid the negative consequences of inadequately managed pain. Evidence points to the existence of pain circuits established when acute pain is inadequately treated that perpetuate pain and contribute to chronic pain. Furthermore, pain has a negative effect on quality of life, resulting in decreased job performance, exercise, socialization, and activity-of-daily-living performance. Longer-term effects include depression, isolation, and loss of self-esteem (American Academy of Pain Management, 2009).

Assessment

Pain assessment varies by the acuity of the pain and circumstances surrounding the patient's entry into the healthcare setting. Identifying the location, intensity, and triggering event may be the most appropriate initial assessment for a patient experiencing acute pain related to trauma. The approach to a patient experiencing acute pain without known trauma (e.g., acute chest, flank, or abdominal pain) may still be very focused due to the acuity of the situation. Additional information regarding the quality and timing of the pain and also the patient's health history often provide valuable clues about the underlying cause. When pain is chronic, a comprehensive approach to pain assessment is essential to ensure adequate and appropriate interventions. The four essential areas to assess are patient perceptions, physiologic responses, behavioral responses, the patient's attempts to manage the pain, in addition to the effectiveness of these pain management strategies.

Patient Perceptions

The most reliable indicator of the presence and degree of pain is the patient's own statement about the pain.

CASE STUDY & NURSING CARE PLAN A Patient Experiencing Chronic Pain

Susan Akers, age 37, is currently being seen at an outpatient clinic for chronic nonmalignant pain. She works at a local paper factory. She has a 3-year history of neck and shoulder pain that usually is accompanied by headaches. She believes the pain is related to lifting objects at work, but it is now precipitated by activities of daily living. Susan is absent from work approximately three times a month and states that the absences are due to her pain and headaches. She has been seeking care in the local emergency department on the average of twice monthly for injections for pain. She does not regularly use medications but does take Percocet-5 as needed (usually two to three times a day). Ms. Akers is divorced and has two children. She states that she has several friends in the area, but her parents and siblings live in another part of the United States.

ASSESSMENT

During the nursing history, Ms. Akers rates her pain during an acute episode as a 7 on a scale of 1 to 10. She states that lifting objects and moving her hands and arms above shoulder level precipitate sharp pain. The pain never really goes away, but it does decrease with upper extremity rest. She says that when she lifts a lot at work, she has difficulty sleeping that night. She takes two Percocet-5 tablets every 6 hours when the pain is severe, but does not get complete relief.

DIAGNOSES

- *Chronic Pain* related to muscle inflammation

EXPECTED OUTCOMES

Ms. Akers will:

- Return for follow-up visits with a journal of activities and pain experiences.
- After 3 to 5 days on regularly scheduled doses of pain medication, report a decrease in the level of pain from 7 to 3 or 4 on a scale of 1 to 10.
- Decrease number of absences from work.
- Modify activities at work and at home, especially when pain is intense.

PLANNING AND IMPLEMENTATION

- Encourage discussion of pain, and acknowledge belief in Ms. Akers' report of pain.
- Consult with a physician for an appropriate nonsteroidal anti-inflammatory analgesic with a minimum of side effects, and instruct in maintaining regular dosing schedules.
- For episodes of acute pain, take opioid analgesic as soon as the pain begins and every 6 hours while continuing the dosage of NSAID analgesic.
- Teach one relaxation technique that is personally useful.
- Explore distraction techniques such as listening to music, watching comedies, or reading.
- Provide clinic phone number and instruct to call if pain is unrelieved with opioid and NSAID analgesics.

EVALUATION

Ms. Akers returns for scheduled follow-up visits with a completed journal of her activities and associated pain. She reports that taking oral opioid analgesics has relieved her pain and that within 3 weeks regular use, NSAID analgesics brought her pain under control. She also reports that her supervisor has reassigned her to a position that requires no lifting. She now rates her pain at 2 or 3 on a scale of 1 to 10. She has missed only 1 day of work in the last 3 months and reports that her children and friends have helped with her household tasks when she has requested they do so.

Clinical Reasoning in Patient Care

1. Describe three factors that support the statement "Pain is a personal experience."
2. Ms. Akers asks you how often she should take her pain medications. You tell her to (a) take them on a regular basis or (b) wait until she experiences pain. Which action would you choose, and why?
3. Develop a care plan for Ms. Akers for the nursing diagnosis of *Risk for Constipation*. Why is this necessary?

See Evaluating Your Response in Appendix B.

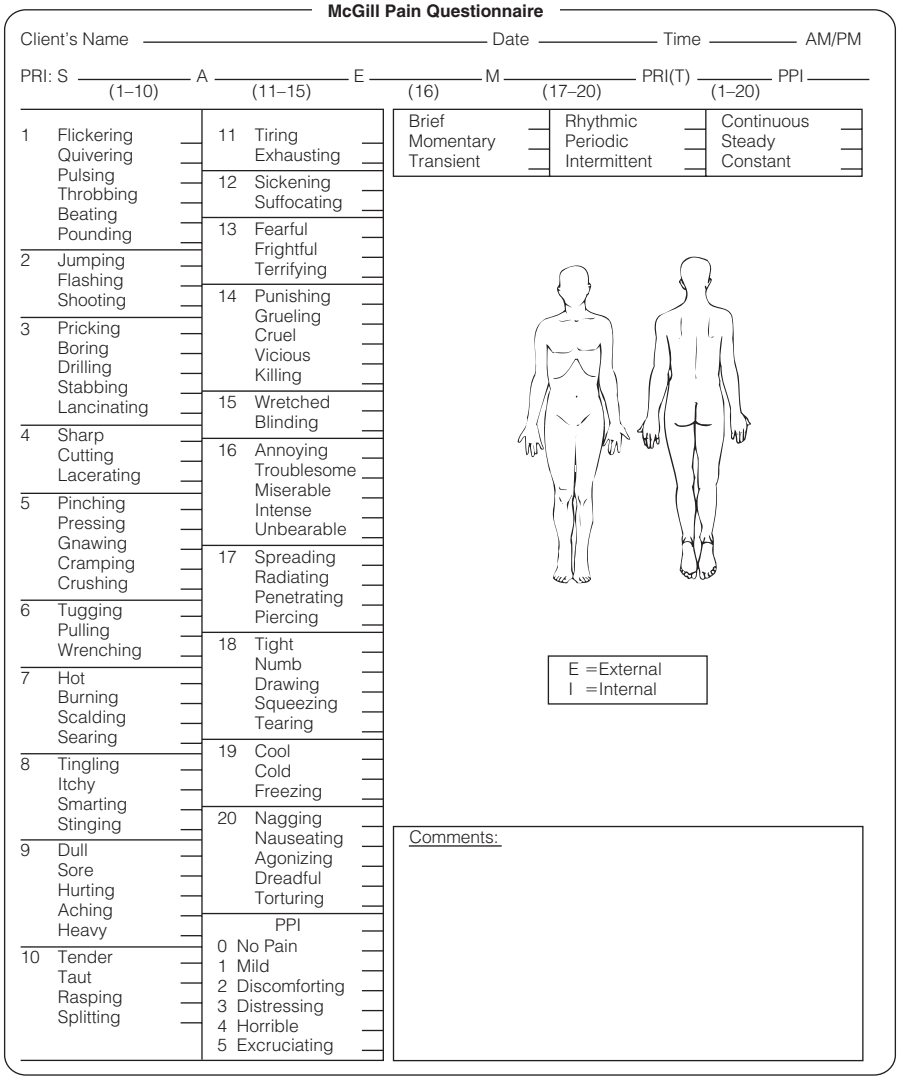

Figure 9–9 ■ The McGill Pain Questionnaire. The descriptors fall into four major groups: sensory (1–10), affective (11–15), evaluative (16), and miscellaneous (17–20). The rank value for each descriptor is based on its position in the word set; the sum of the rank values is the pain rating index (PRI). The present pain intensity (PPI) is based on a scale of 0 to 5.

MEMORY CUE

The PQRST mnemonic provides a useful tool for conducting a focused pain assessment:

P = What **p**recipitated (triggered, stimulated) the pain? Has anything relieved the pain? What is the pattern of the pain (constant, episodic)?
Q = What are the **q**ualities of the pain? How would you describe the pain (sharp, stabbing, aching, burning, stinging, deep, crushing, viselike, gnawing)?
R = What is the **r**egion (location) of the pain? Can you put your finger on where the pain is? Does the pain radiate to other areas of the body?
S = What is the **s**everity or intensity of the pain?
T = What is the **t**iming of the pain? When does it begin, how long does it last, and how is it related to other events in the patient's life?

The McGill Pain Questionnaire is a useful tool in assessing the subjective pain experience. It asks the patient to locate the pain and to describe its quality and intensity using terms that describe its sensory, affective, evaluative, and miscellaneous components. Additional components of the questionnaire address the pattern and timing of the pain (Figure 9–9 ■).

The most common method to assess the severity of pain is a pain rating scale. Pain rating scales can be used even in the most emergent situations. Several scales are illustrated in Figure 9–10 ■. For patients who do not understand English or numerals, a scale using colors (e.g., light blue for no pain through bright red for worst possible pain) or the Faces Pain Scale–Revised (FPS-R) may be helpful. The following guidelines will help the nurse effectively use a pain rating scale:

- To ensure consistent communication, explain the specific pain rating scale being used. If a word descriptor scale is used, verify that the patient can read the language being used. If a numerical scale is used, be sure the patient can count to 10. Discuss the definition of the word *pain* to ensure that the patient and the provider are communicating on the same level. It is often helpful to use the patient's own words when describing the pain.
- Explain that the report of pain is important for promoting recovery, not just for achieving temporary comfort.

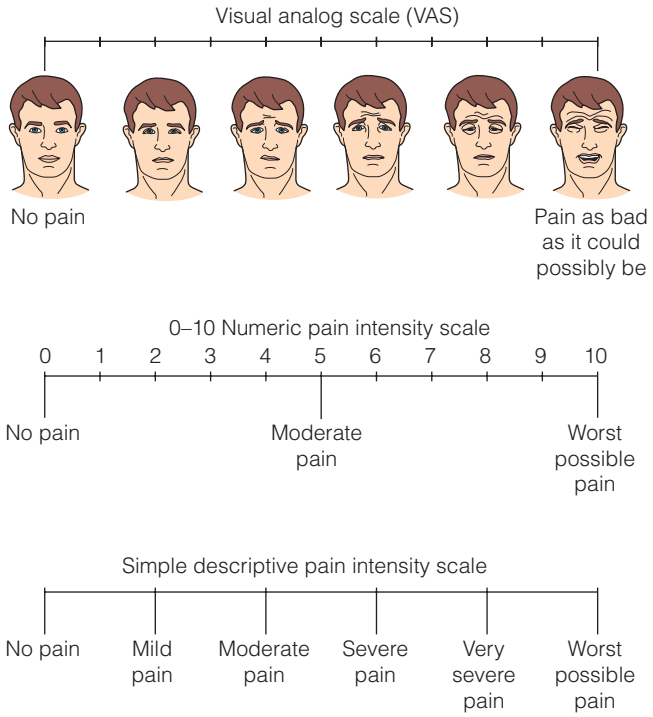

Figure 9–10 ■ Examples of commonly used pain scales.

- Ask the patient to establish a comfort-function goal. This is a level of pain that does not interfere with or prevent the performance of essential activities of recovery or living. Often, pain assessment is made while a patient is sedentary. In this state the patient may experience less pain than when active and falsely estimate tolerable pain ratings. Provide guidelines for setting goals. Researchers found that pain ratings higher than 3 (scale of 0–10) interfered significantly with patients' activities, and scores of 6 and 7 decrease quality of life (IOM, 2011).
- Use the same scale across shifts and between institutions to promote accurate assessment in transitional care situations (Herr, 2010).

Research has shown the numeric rating, verbal descriptor, and faces rating scales to be effective with young, middle, and older adults. Studies show that the Iowa Pain Thermometer is an effective scale to use for older adults representing a variety of ethnic and cultural backgrounds (Herr, 2010). These scales also are effective for use with older adults who have cognitive impairments, although the faces scale was the preferred tool.

Physiologic Responses

Predictable physiologic changes occur in the presence of acute pain. These may include muscle tension; tachycardia; rapid, shallow respirations; increased blood pressure; dilated pupils; sweating; and pallor. Over time, however, the pain stimulus triggers less of a sympathetic nervous system response, and these physiologic changes may be extinguished in patients with chronic pain.

Behavioral Responses

Some behaviors are so typical of people in pain that the behaviors are referred to as *pain behaviors*. They include facial grimacing, bracing or guarding the painful part, taking medication, crying, moaning, withdrawing from activity and socialization, becoming immobile, talking about pain, holding the painful area, breathing with increased effort, exhibiting a sad facial expression, and being restless.

Behavioral responses to pain may or may not coincide with the patient's report of pain and are not always reliable cues to the pain experience. Discrepancies between the patient's report of pain and behavioral responses may be the result of cultural factors, coping skills, fear, denial, or the utilization of relaxation or distraction techniques.

Patients may deny pain for a variety of reasons, including fear of injections, fear of drug/narcotic addiction, misinterpretation of terms (the patient may not think that aching, soreness, or discomfort qualify as pain), or the misconception that healthcare providers know when patients experience pain. Some patients may deny pain as part of an attempt to deny that there is something wrong with them. Other patients, by contrast, may think that "as-needed" medications will be given only if their pain rating is high. Patients may also use pain as a mechanism to gain attention from family and healthcare providers.

Patients with Advanced Dementia

Behavior cues are critical for assessing pain intensity in patients with advanced dementia (unable to respond to simple yes or no questions) or who are nonverbal. The Pain Assessment in Advanced Dementia (PAINAD) scale uses five behavioral indicators of pain. Once trained, the nurse can use the scale by observing patient behaviors related to breathing (normal, labored, hyperventilation), vocalization (moaning, calling out, crying), facial expression (smiling or without expression, sad, frowning, grimacing), body language (relaxed, tense, rigid or striking out), and consolability (distractible, reassured, or unable to console) (Herr, 2010).

Self-Management of Pain

The patient's attempts to manage pain are useful additions to the assessment database. This information is individualized and patient specific, including many factors such as culture, age, and patient knowledge. Get detailed descriptions of actions the patient or significant others took, when and how these measures were applied, and how well they worked.

Diagnoses, Outcomes, and Interventions

The primary nursing diagnoses for patients in pain are acute pain and chronic pain.

Acute Pain

Expected Outcome: Patient will demonstrate pain control through appropriate and established pain assessment scale.

Assess the characteristics of the pain by asking the patient to do the following:

- Point to the pain location or mark the pain location on a figure drawing. *Pain location provides information about the etiology of the pain and the type of pain being experienced.*
- Rate the intensity of the pain by using an evidence-based pain scale (refer to Figure 9–10). Use the same scale with each assessment. *Pain and its intensity is a subjective experience. Consistently using the same scale to rate pain intensity allows evaluation of intervention effectiveness.*
- Identify and use the most appropriate evidence-based pain scale based on patients' individual cognitive ability. *Do not assume that*

the older patient or the patient with a cognitive impairment is not having pain or is unable to identify its intensity. Many cognitively impaired patients are able to use a pain scale such as faces, numeric rating, or verbal descriptor (Herr, 2010).

- Describe the quality of the pain, saying, for example, "Describe what your pain feels like." If necessary, suggest word descriptors for the patient to select. *Descriptive terms provide insight into the nature and cause of the pain.*
- Describe the pattern of the pain, including time of onset, duration, persistence, and times without pain. Ask whether the pain is worse at regular times of the day and about its relationship to activity. *The pattern of pain provides clues about cause and location.*
- Describe any precipitating or relieving factors. *Precipitating factors provide clues to any underlying pathophysiology of the pain; relieving factors provide information that can be used when planning nursing interventions for pain management.*
- Monitor manifestations of pain by taking vital signs; assessing skin temperature and moisture; observing pupils; observing facial expressions, position in bed, guarding of body parts; and noting restlessness. *Autonomic responses to pain may result in an increased blood pressure, tachycardia, rapid respirations, perspiration, and dilated pupils. Other responses to pain include grimacing, clenching the hands, muscle rigidity, guarding, restlessness, and nausea.*
- Consider pain the fifth vital sign and assess patients for pain every time you check temperature, pulse, respirations, and blood pressure. *The Joint Commission requires frequent assessment of pain as a standard of practice. Studies show introducing the philosophy of pain as the fifth vital sign improves the quality of pain assessment and management (Purser et al., in press)*
- Communicate belief in the patient's pain. *Verbally acknowledge the presence of the pain, listen carefully to the description of pain, and act to help the patient manage the pain. Because pain is a personal, subjective experience, the nurse must convey belief in the patient's pain. By conveying belief in the patient's pain, the nurse reduces anxiety and thereby lessens pain.* See the accompanying Moving Evidence into Action box.
- Administer prescribed analgesics, determining the preferred route of administration. Provide pain-relieving measures for severe pain on a regular around-the-clock basis or by self-administration (such as with a PCA pump). *The patient is a part of the decision-making process and can exert some control over the situation by choosing the administration route. Analgesics are usually most effective when they are administered before pain occurs or becomes severe. Around-the-clock administration has been proven to provide better pain management for both acute and chronic pain.*

SAFETY ALERT

Use extreme care to ensure the correct patient, medication, and dose when setting up and monitoring PCA for analgesia. Programming issues accounted for 71% of adverse events for patients with PCA. Consider PCA to be a process, not just a machine.

- To reduce the risk of medication errors associated with PCA, work with administration to develop the following strategies:
  - Select patients who are good candidates for PCAs. Confused patients are not good candidates.
  - Use a single brand or type of pump within a facility to reduce programming and use complexity for caregivers.

Moving Evidence into Action

The Patient Experiencing Pain

Pain that is not adequately managed is the focus of regulatory agencies, professional healthcare organizations, and consumer groups. Developing an individualized pain management plan addresses the QSEN competency for providing *patient-centered care.* Despite well-defined guidelines for pain management, there is a gap between guideline standards of care and implementation of care. A number of studies have compared nurses' perceptions of pain management with the experience related by patients. In a study by Lewthwaite et al. (2011), 324 nurses were surveyed to assess their knowledge, skills, and attitudes related to providing adequate pain management. A nurse's age, experience, and level of education significantly affected the survey scores. Results indicate pain management continues to be a challenge in all healthcare settings and found a lack of knowledge among nurses as one of the main reasons for inadequate pain control. Nurses lacked adequate knowledge in the area of pharmacology in particular. A qualitative study explored nurses' responses to patients in acute care settings with chronic pain (Siedlecki, 2013). Findings show some nurses did not perceive the importance of addressing chronic pain in relation to the patients' acute illness, citing more pressing clinical issues were the priority of care. The study revealed the nurse characteristics of knowledge, attitude, and discernment. Discernment was defined as the nurse's ability to interpret subtle signs related to chronic pain. The study also identified nurses' expressed frustration related to physicians' knowledge and commitment to effectively managing chronic pain in acute care settings. Recommendations include the implementation of organizational policies addressing adequate management of chronic pain and interprofessional education.

Implications for Nursing

Appropriate pain management is increasingly recognized as a critical component of care, with increasing attention given to patients' self-reported pain scores. These studies provide valuable information to guide nursing practice. Communication among nurses, physicians, and patients is key to pain relief. Developing and maintaining caregiver competence in the effective use of pharmacologic and nonpharmacologic pain management is critical. Pain management is an important component of professional nursing; nurses should be supported in their efforts to address pain with compassion and efficiency.

Moving Knowledge into Action

1. Reflect on your own experiences with pain. How will those experiences facilitate or hinder your assessments and interventions for patients in pain?
2. You are caring for a young man who has multiple injuries from a motorcycle crash. He tells you his pain is so bad that "he just wants to die." How would you respond?
3. You are caring for an 80-year-old man with diabetes who has had his left foot amputated for gangrene. He is restless and moaning. Another nurse tells you to only give one-half of the ordered dose of narcotics because "he is old and there is a danger of respiratory depression." What would you do?
4. Why do you think nurses tend to underestimate and undermedicate pain?

- Use standard prescription sets and standard medication concentrations.
- Maintain proficiency with PCA machines, know how to enter a prescription correctly, and use independent nurse checks to confirm dosages.
- Use bar codes and electronic medical records to reduce errors that involve the wrong medication.
- Develop and use easily understood and standardized forms for PCA.

  The complexity of activities required to safely program PCA pumps, the use of different medications and concentrations, confusion of medical orders, and variations in documentation related to PCA are identified as contributing factors to PCA medication errors (D'Arcy, 2011b).

- Evaluate and monitor the effects of analgesics and other pain-relieving measures. Teach family members or significant others to be alert for adverse reactions to pain medications. Sedation, constipation, nausea, and dizziness are common side effects of opioid analgesics. *Opioid analgesics stimulate mu receptors, leading to common adverse effects such as respiratory depression, nausea, and constipation.*
- Provide for safety of the patient receiving opioid analgesics:
  - Check respiratory rate and oxygen saturation every 2 hours at the beginning of opioid therapy and after increasing dosage. Reduce the dose and notify the physician if the respiratory rate falls to eight per minute (or lower) or if the oxygen saturation falls. *Excessive sedation can progress to significant respiratory depression.*
  - Use a sedation scale to monitor sedation levels consistently. *Using a scale will support a standardized approach to monitoring level of sedation.*
  - Prevent falls that may result from sedation or dizziness. *Opioid analgesics can affect balance and judgment, increasing the risk for falls, particularly in older adults.*
  - Administer an opioid antagonist such as naloxone (Narcan) if the patient develops symptoms of excessive opioid dosage. Administer prescribed dose (0.4 to 2 mg) by direct intravenous push over 10 to 15 seconds or by intravenous infusion. Titrate infusion or repeat direct IV push every 2 to 3 minutes (up to a total of 10 mg) to reverse respiratory depression or excessive sedation. Continue to monitor respiratory status and sedation, repeating naloxone as necessary. *The opioid agonist causing excessive sedation and respiratory depression may have a longer half-life than naloxone, leading to a fall in respiratory rate and decreased LOC after the initial dose of naloxone has been substantially eliminated. Administration of excessive naloxone may cause acute withdrawal and failure of pain relief. It may take considerable time to reestablish a therapeutic comfort level.*
- Teach the patient and family nonpharmacologic methods of pain management, such as relaxation, distraction, and cutaneous stimulation. *These techniques are especially useful when used in conjunction with pain medications. They can be beneficial for patients experiencing either acute or chronic pain.*
- Provide comfort measures, such as changing positions, back massage, oral care, skin care, and changing bed linens. *Basic comfort measures for personal cleanliness, skin care, and mobility promote physical and psychosocial well-being, lessening the perception of pain.*
- Provide patient and family teaching, and make referrals if necessary to assist with coping, financial resources, and home care. *The patient (and family) with pain requires information about medications, noninvasive techniques for pain management, and sources of assistance with home-based care. The patient with acute pain requires information about the expected course of pain resolution.*

NURSING CARE OF THE OLDER ADULT

Pain Management for the Older Adult

Older adults often have medical conditions associated with pain, such as arthritis, peripheral vascular disease, and diabetes. Many older adults have multiple health disorders causing them to experience both acute and chronic pain.

The nursing standard of care calls for older adults to be pain free or have their pain controlled to an acceptable level that allows the highest possible level of functioning (Herr, 2010). Achieving this standard requires comprehensive assessment of the patient, including the patient's history, subjective reports of pain, nonverbal and behavioral responses, and information from family members about the patient's pain experiences.

In addition to frequent and ongoing assessment, nursing care guidelines call for the nurse to anticipate and treat pain before, during, and after painful procedures and treatments. The nurse should educate the patient, family, and other clinicians about prophylactic analgesic use, using analgesics on a regular basis, and how to avoid allowing pain to escalate. Teaching must include information about the medications themselves, their side and adverse effects, and issues about addiction, dependence, and tolerance. Finally, the nurse teaches the patient, family, and other healthcare providers about nonpharmacologic pain management strategies such as relaxation, massage, and application of heat or cold (Herr, 2010).

Chronic Pain

The patient who has chronic pain may not demonstrate the same physiologic and behavioral responses to pain as are seen in the patient with acute pain. The intensity of the pain, however, may be as high or even higher than acute pain. Furthermore, chronic pain, whether of malignant or nonmalignant origin, has a negative effect on the patient's physical, psychosocial, emotional, and functional status. In addition to the nursing assessments and interventions identified for

Evidence for Nursing Care

The Patient with Acute Pain

Selected resources that nurses may find helpful when planning evidence-based nursing care follow.

- Faigeles, B., Howie-Esquivel, J., Miaskowski, C., Stanik-Hutt, J., Thompson, C., White, C., . . . Puntillo, K. (2013). Predictors and use of nonpharmacologic interventions for procedural pain associated with turning among hospitalized adults. *Pain Management Nursing, 14*(2), 85–93.
- Martic, L., Kelly, M. J., & Roosa, K. (2012). Multidisciplinary approach to improving pain management. *Critical Care Nursing Quarterly, 35*(3), 268–271.
- Samuels, J., & Bliss, R. (2012). Analyzing variability in pain management using electronic health record data. *Journal of Nursing Care Quality, 27*(4), 316–324.
- Willens, J. S., Jungquist, C., R., Cohen, A., & Polomano, R. (2013). ASPMN survey—Nurses' practice patterns related to monitoring and preventing respiratory depression. *Pain Management Nursing, 14*(1), 60–65.

acute pain, consider the following interventions for the patient experiencing chronic pain:

Expected Outcome: Patient will verbalize pain level at acceptable level using agency-specific pain scale, demonstrate ability to maintain optimal level of functioning, and report ability to maintain role performance and interpersonal relationships.

- Ask the patient to describe the pain and its meaning, including its effects on lifestyle, self-concept, roles, and relationships. *Pain is a stressor that may affect the patient's coping ability. Chronic pain often interferes with sleep quality, job performance, personal relationships, and social interactions. The patient may have concerns about addiction to pain medication and costs as well.*
- Assess for depression using an accepted depression screening tool. *Chronic pain and depression commonly occur concurrently* (*Longo et al., 2013*).
- If the underlying cause of chronic pain has not been identified, advocate for consultations, diagnostic testing, or other means of establishing an accurate diagnosis. *Guidelines for chronic pain management call for treatment of the underlying cause whenever it can be identified* (*WHO, 2008b*).
- Administer prescribed NSAIDs, opioid and nonopioid analgesics, and other medications around the clock and as ordered. Whenever possible, the oral or transdermal routes should be used. *Around-the-clock analgesic administration helps maintain pain within an acceptable range within which the patient remains comfortable and functional. As-needed medications may be required for breakthrough pain.*
- Do not crush, break, or allow patients to chew controlled-release oral preparations. *Crushing, breaking, or chewing controlled-release oral preparations may lead to overdose. Capsules containing controlled-release pellets can be opened and sprinkled over soft food. See the accompanying Nursing Care of the Older Adult box for more information about standards of pain management in older adults.*
- Teach the patient, family, and caregivers how to manage side and adverse effects of prescribed medications. Advise about the importance of taking NSAIDs with food to reduce the risk of gastrointestinal irritation and bleeding. Provide information about appropriate laxatives for the patient taking opioid analgesics. Instruct when to contact the prescribing care provider should adverse effects become problematic. *Many analgesics, while effective, have adverse effects that may limit the patient's willingness to continue therapy. In most cases, appropriate management of these effects allows continued use of the medication.*

Evidence for Nursing Care

The Patient with Chronic Pain

Selected resources that nurses may find helpful when planning evidence-based nursing care follow.

- City of Hope brief summary of select pain assessment tools. Retrieved from http://prc.coh.org/html/brief_pain.htm
- Herr, K. (2010). Pain in the older adult: An imperative across all health care settings. *Pain Management Nursing, 11*(2), S1–S10.
- Stefanacci, R. G., & Haimowitz, D. (2012). Taking the pain out of pain management. *Geriatric Nursing, 33*(5), 391–397.

- Encourage and advocate for a multimodal approach to pain management, teaching about the use of heat, cold, and CAM therapies, providing for referrals to healthcare providers (e.g., physical therapists, chiropractic physicians, massage therapists, acupuncturists) and chronic pain clinics as appropriate. *Using a multimodal approach to management of chronic pain improves the patient's perception of control over the pain and its effect on lifestyle. This also may result in less dependence on opioid and nonopioid analgesics.*

Continuity of Care

Teaching for the patient and family includes the following:

- Specific drugs to be taken, including the frequency, potential side effects, possible drug interactions, and any special precautions to be taken (such as taking with food or avoiding alcohol)
- How to take or administer the drugs ordered for managing chronic malignant or nonmalignant pain (Box 9–2)
- The importance of taking pain medications before the pain becomes severe
- An explanation that the risk of addiction to pain medications is very small when they are used for pain relief and management
- Discussion about physical tolerance and the importance of contacting the prescriber should medications become less effective
- The importance of scheduling periods of rest and sleep
- Use of CAM therapies to supplement or enhance traditional approaches to pain management.
- In addition, suggest the following resources:
  - Pain clinics
  - Community support groups
  - American Cancer Society
  - American Pain Society.

BOX 9–2 Opioids for Long-Term Analgesia for Chronic Pain

Drug	Route	Nursing Implications
Oxycodone (OxyContin)	Oral	Available in a timed-release formulation for 12-hour dosing and as fast-acting formulations (OxyIR, OxyFAST) for breakthrough pain.
Morphine (Kadian)	Oral	Formulated of timed-release particles in a capsule. If patient can't swallow the capsule, may be sprinkled over food or given by nasogastric or gastric tube.
Fentanyl (Duragesic)	Transdermal	Absorbed slowly through the skin; allows 72-h dose schedule. Up to 14 h to achieve therapeutic level; when discontinued therapeutic effect will decay slowly.
Fentanyl citrate (Actiq)	Transmucosal	A lozenge formulation used to treat breakthrough cancer pain in opioid-tolerant patients.

CHAPTER HIGHLIGHTS

- **Nurses play a pivotal role in managing pain for patients in all healthcare settings.**
- **Completion of a comprehensive assessment and development of an individualized and patient-centered plan lead to effective pain management.**
- **Pain management involves pharmacologic and nonpharmacologic interventions.**
- Pain is transmitted by the peripheral and central nervous systems and perceived in the CNS. Opioids and other analgesics block the perception of pain; NSAIDs and most nonpharmacologic interventions block or decrease the transmission of pain from the periphery to the CNS.
- There are many types of pain and treatment varies according to the type and combination of types. Acute pain, which may be cutaneous or deep somatic, visceral, or referred, usually decreases as healing progresses. Chronic pain may be episodic, experienced as recurrent acute pain, or may be persistent pain of either malignant or nonmalignant origin. Breakthrough pain is that which exceeds the baseline or persistent level of pain. Phantom limb pain is a type of neuropathic pain that occurs after amputations. Central pain and complex regional pain syndrome also are types of neuropathic pain.
- Culture and gender impact pain perception and behavior. A patient's emotional state, past experiences with pain, and the underlying cause and meaning of the painful experience also affect responses to pain. Important components of the assessment include the location, intensity, and character (quality) of the pain; its onset, duration, and timing; factors that aggravate or relieve the pain; associated symptoms; and measures taken to treat the pain or its cause.
- Behavioral assessment of pain intensity is less accurate than a patient's report of pain intensity, particularly when pain is chronic. Behavioral responses may be used to assess pain in patients who are significantly cognitively impaired. Older adults perceive pain as intensely as younger adults, but may hesitate to report pain for fear of losing independence. Physical tolerance develops with long-term opioid use, necessitating dose increases to achieve the same effect. Although patients who are addicted to opioids need greater doses of opioid analgesics to control pain because of tolerance, treating physicians and nurses providing care often withhold or use lower doses of opioid analgesics, leading to inadequate pain relief.
- Pain management includes assessment, intervention, and evaluation. It is important to verify that interventions have been effective. If not, interventions must be identified that bring pain down to a level of intensity with which the patient feels satisfied.

TEST YOURSELF NCLEX-RN® REVIEW

1. During an assessment, the nurse learns that a patient has had lower back pain for 9 months. For which type of pain will the nurse plan care?
   1. chronic pain
   2. somatic pain
   3. visceral pain
   4. neuropathic pain

2. A patient who smashed a finger in the car door relates that the pain initially was sharp but now it is dull and throbbing. What should the nurse recall as the reason for the current type of pain that the patient is experiencing?
   1. It is an example of the gate theory of pain transmission.
   2. Transmission of pain stimuli occurs via unmyelinated C fibers.
   3. Indicates that the injury is less severe than initially perceived.
   4. It is the result of interpretation of the pain stimulus by the thalamus.

3. A patient with arthritis has been taking over-the-counter NSAIDs for several years. Which questions should the nurse ask the patient while completing the health history? (Select all that apply.)
   1. "Tell me how and when you take this drug."
   2. "Do you have your blood pressure checked regularly?"
   3. "Have you noticed any problems with your breathing?"
   4. "Have you ever vomited blood or had very dark stools?"
   5. "Do you know that you may become addicted to this drug?"

4. What should the nurse include when teaching a patient about a transdermal pain medication?
   1. When reapplying the patch, place it on the anterior thigh.
   2. Replace this patch every 24 hours, applying it to clean, dry skin.
   3. Contact the physician if this medication causes excessive sleepiness.
   4. This medication should be effective within 2 to 4 hours; contact the physician if the pain is not at an acceptable level after that.

5. Which statement should the nurse use to determine the quality of a patient's pain?
   1. "Tell me where it hurts."
   2. "Rate the pain on a scale of 0 to 10."
   3. "Describe what the pain feels like."
   4. "Tell me how this pain affects sleeping."

6. A patient recovering from surgery rates pain as being 7 on a scale of 0 to 10 but the nurse notes the patient is relaxed, smiling, and visiting with friends. Which action should the nurse take?
   1. Administer the prescribed analgesic dose.
   2. Reassess the patient's pain after his friends have left.
   3. Document your assessment but take no further action.
   4. Note that the patient is developing tolerance to the prescribed opioid analgesic.

7. What information should the nurse include when teaching a patient with chronic malignant pain about opioid analgesics?
   1. "This drug may cause itching and rash; take diphenhydramine (Benadryl) as needed."
   2. "This drug may interfere with urination; contact your physician if that becomes a problem."
   3. "Increase fluid and fiber intake; you may need a stool softener or laxative to prevent constipation."
   4. "There is a risk of addiction with this drug; stop the drug if you find that it no longer provides the degree of pain relief necessary."

8. What approach should the nurse use to assess pain in a patient who is moderately cognitively impaired?
   1. Ask the patient to rate the pain using the faces pain scale.
   2. Have the family evaluate the intensity of the patient's pain.
   3. Administer the prescribed analgesic on an around-the-clock basis.
   4. Use only behavioral cues such as grimacing, pacing, or agitation.

9. A patient asks if glucosamine should be taken for knee pain. Which information should the nurse use to base a response to this patient's question?
1. There is no evidence that natural products such as glucosamine are effective for treating any type of pain.
2. Chronic pain such as that associated with osteoarthritis is best treated with NSAIDs and acetaminophen.
3. When combined with chondroitin, glucosamine has been effective in relieving moderate to severe knee pain in some patients.
4. Although no studies have shown a benefit from taking glucosamine, other CAM therapies such as acupuncture are effective for treating pain.

10. A patient who recently took up running to lose weight asks why she feels better after running when she should be tired and sore. Which nursing response would be the most accurate?
1. Natural narcotic-like substances are released during physical activities like running.
2. Activities such as running activate a natural "gate" in the spinal cord, blocking pain signals.
3. Engaging in activities that actively use large muscle groups change pain circuits in the brain, reducing the perception of pain.
4. With repeated stimulation through activities such as running, nociceptors in deep tissues become less sensitive to stimuli.

10 Nursing Care of Patients with Altered Fluid, Electrolyte, and Acid–Base Balance

LEARNING OUTCOMES

1. Describe the functions and regulatory mechanisms that maintain water, electrolyte, and acid–base balance in the body.
2. Compare and contrast the causes, pathophysiology, effects, and care of the patient with fluid volume or electrolyte imbalance.
3. Describe the causes, effects, and management of acid–base imbalances.

CLINICAL COMPETENCIES

1. Recognize patients at risk for fluid, electrolyte, or acid–base imbalances.
2. Assess and monitor fluid, electrolyte, and acid–base balance, communicating findings with appropriate interprofessional team members.
3. Demonstrate effective use of individualized and patient-centered strategies to reduce the risk of fluid, electrolyte, or acid–base imbalances.
4. Effectively communicate and function within the interprofessional team to plan and provide care to patients with altered fluid, electrolyte, and acid–base balance.
5. Administer fluids, medications, and other prescribed therapies knowledgeably and safely, using guidelines or protocols as appropriate.
6. Adapt individual cultural values, expressed needs and preferences, and available evidence into the plan of care to provide knowledgeable and safe care to patients with fluid, electrolyte, or acid–base imbalances.
7. Use assessed data, patient values, and evidence to provide patient and family teaching about strategies to promote, restore, and maintain fluid, electrolyte, and acid–base balance.
8. Document care in the electronic medical record and use information management tools to monitor outcomes of care.
9. Participate in studies and projects to improve the quality and safety of care for patients with fluid, electrolyte, or acid–base disorders.

MAJOR CHAPTER CONCEPTS

- Homeostasis is dependent on a balance of body fluids, electrolytes, and acids and bases. This balance is maintained through physiologic processes that regulate the intake, output, and distribution of fluids and the solutes they contain.
- Fluid and electrolyte imbalances result from excess or inadequate intake of water or the involved electrolyte, excess loss or retention of water or an electrolyte, or a shift in the distribution of fluid or electrolytes. Age, diet, exercise, and environmental factors can affect fluid and electrolyte balance, as can manifestations (e.g., nausea, diarrhea), disease processes (e.g., kidney disorders), and treatment (e.g., medications, nasogastric suction).
- Acid–base disorders are broadly classified as acidosis or alkalosis, and generally result from an excess or loss of physiologic acids (e.g., hydrochloric acid, lactic acid) or bases (e.g., bicarbonate) or disrupted function of the renal or respiratory systems.
- The nurse provides teaching for patients, families, and caregivers to prevent fluid, electrolyte, and acid–base imbalances in at-risk patients. Within the interprofessional team, the nurse plays a key role in identifying imbalances and monitoring the effects of treatment. The nurse also recognizes responses and potential responses to imbalances, providing care to reduce the risk of harm associated with these responses.

Normal physiologic processes depend on **homeostasis** (the ability to maintain internal equilibrium by adjusting physiologic processes) in the internal environment of the body. The fluid volume, electrolyte composition, and pH of both intracellular and extracellular spaces must remain constant within a relatively narrow range to maintain health and life. Changes in the normal distribution and composition of body fluids often occur in response to illness and trauma. These changes affect fluid balance of the intracellular and extracellular compartments of the body, the concentration of electrolytes within fluid compartments, and the body's hydrogen ion concentration (pH). Fluid and electrolyte imbalances occur in all adult age groups, and in all healthcare settings.

Changes in the normal volume of fluids, their composition, distribution, and relative acidity or alkalinity have the potential to disrupt most functional health patterns. Imbalances of fluids, electrolytes, and pH affect the ability to maintain activities of daily living (activity-exercise), think clearly (cognitive-perceptual), and engage in self-care (health perception–health management). Conversely, alterations in a number of health patterns affect the ability to maintain homeostasis. Alterations in the nutritional-metabolic pattern affect the ability to consume adequate food and fluids. Disruptions of the elimination pattern may lead to retention or loss of excess amounts of fluids and electrolytes. Disrupted heart or respiratory function, which falls within the activity-exercise pattern, has the potential to affect fluid, electrolyte, and acid–base balance.

The goal in managing fluid, electrolyte, and acid–base imbalances is to reestablish and maintain homeostasis. Nursing care includes identifying and assessing patients who are likely to develop imbalances, monitoring patients for early manifestations, and implementing interprofessional and nursing interventions to prevent or correct imbalances. Effective nursing interventions require an understanding of the multiple processes that maintain fluid, electrolyte, and acid–base balance and an understanding of the causes and treatment of imbalances that occur. This chapter contains many references to disease processes that are discussed throughout the book and is most useful as a reference when learning about those disorders.

OVERVIEW OF FLUID AND ELECTROLYTE BALANCE

Fluid and electrolyte balance in the body involves regulatory mechanisms that maintain the composition, distribution, and movement of fluids and electrolytes.

Body Fluid Composition

Body fluid is composed of water and various dissolved substances (solutes).

WATER

Water is the primary component of body fluids and functions in several ways to maintain normal cellular function. Water provides a medium for the transport and exchange of nutrients and other substances such as oxygen, carbon dioxide, and metabolic wastes to and from cells; provides a medium for metabolic reactions within cells; and assists in regulating body temperature through the evaporation of perspiration.

Total body water constitutes about 60% of the total body weight of a young adult male and 50% of that of a young adult female. The amount varies with age, gender, and the amount of body fat. Total body water decreases to about 45% of total body weight in older adults (Marieb & Hoehn, 2011). Adipose tissue contains comparatively little water: In the person who is obese, the proportion of water to total body weight is less than in the person of average weight; an individual who is very thin has a higher proportion of water to total body weight. Adult females have a greater ratio of fat to lean tissue mass than adult males; therefore, they have a lower percentage of total body water.

TABLE 10–1 24-Hour Fluid Gain and Loss for an Adult

	Source	Amount (mL)
Gain	Fluids taken orally	1200
	Water in food	1000
	Water as by-product of food metabolism	300
		↓
	Total	2500
		↑
Loss	Urine	1500
	Feces	200
	Perspiration	500
	Respiration	300

To maintain normal fluid balance, body water intake and output should be approximately equal. The average fluid intake and output is about 2500 mL over a 24-hour period. Most water gain is from the intake of foods and fluids; carbohydrate metabolism and other metabolic processes produce an additional small amount. Urine production and excretion account for most water loss. The average daily urine output is 1200 to 1500 mL in adults. About 500 mL of urine per day is required to excrete metabolic wastes produced by the body (Marieb & Hoehn, 2011). Insensible water loss occurs through the skin, lungs, and feces. These losses, while normally small, can increase significantly during exercise, when environmental temperatures are high, and during illness that increases the respiratory rate, perspiration, or gastrointestinal (GI) losses (particularly diarrhea). Table 10–1 shows the sources of fluid gain and loss.

ELECTROLYTES

Body fluids contain both water molecules and chemical compounds. These chemical compounds can either remain intact in solution or dissociate into discrete particles. Electrolytes are substances that dissociate in solution to form charged particles called ions. Cations are positively charged electrolytes; anions are negatively charged electrolytes. Electrolytes have many functions, including assisting with the regulation of water balance, regulating and maintaining acid–base balance, and contributing to enzyme reactions. They are also essential for neuromuscular activity.

Body Fluid Distribution

Body fluid is classified by its location inside or outside of cells. Intracellular fluid (ICF) is found within cells (Figure 10–1 ■). ICF is essential for normal cell function, providing a medium for metabolic

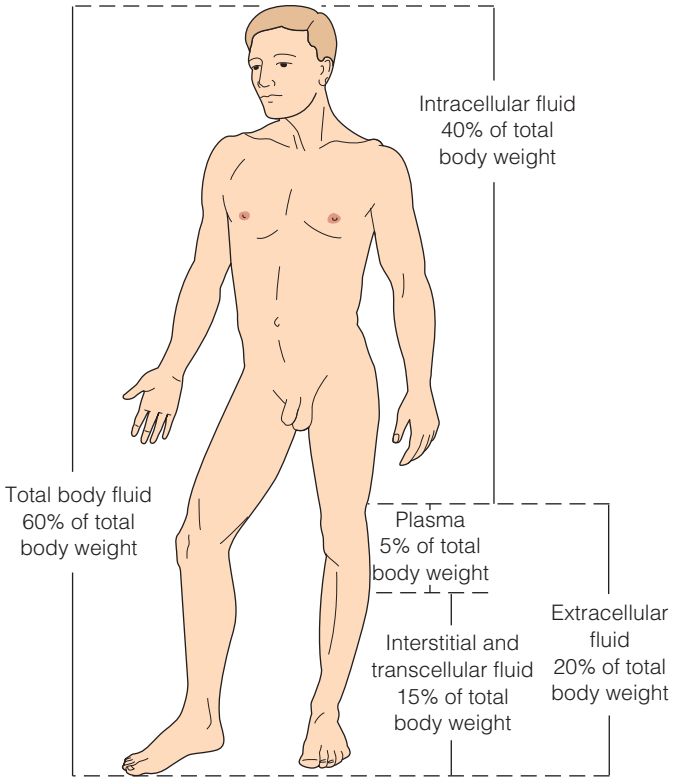

Figure 10–1 ■ The major fluid compartments of the body.

processes. Extracellular fluid (ECF) is located outside of cells and is further classified by location:

- Interstitial fluid is located in the spaces between most of the cells of the body.
- Intravascular fluid, called *plasma*, is contained within the arteries, veins, and capillaries.
- Transcellular fluid includes urine; digestive secretions; perspiration; and cerebrospinal, pleural, synovial, intraocular, gonadal, and pericardial fluids.

SOLUTES

Although the overall concentration of solutes in ICF and ECF is nearly identical, the concentration of specific electrolytes differs significantly between these compartments, as shown in Figure 10–2 ■. ICF contains high concentrations of potassium (K^+), magnesium (Mg^{2+}), and phosphate (PO_4^{2-}), as well as other solutes such as glucose and oxygen. Sodium (Na^+), chloride (Cl^-), and bicarbonate (HCO_3^-) are the principal extracellular electrolytes. The high sodium concentration in ECF is essential to regulating body fluid volume. The concentration of potassium in ECF is low. There is a minimal difference in electrolyte concentration between plasma and interstitial fluid. Normal values for electrolytes in plasma are shown in Table 10–2.

The body fluid compartments are separated by cell membranes and epithelial membranes. The cell membrane is selectively permeable; that is, it allows the passage of water, oxygen, carbon dioxide, and small water-soluble molecules, but bars proteins and other intracellular colloids (Figure 10–3 ■). Capillary membranes separate

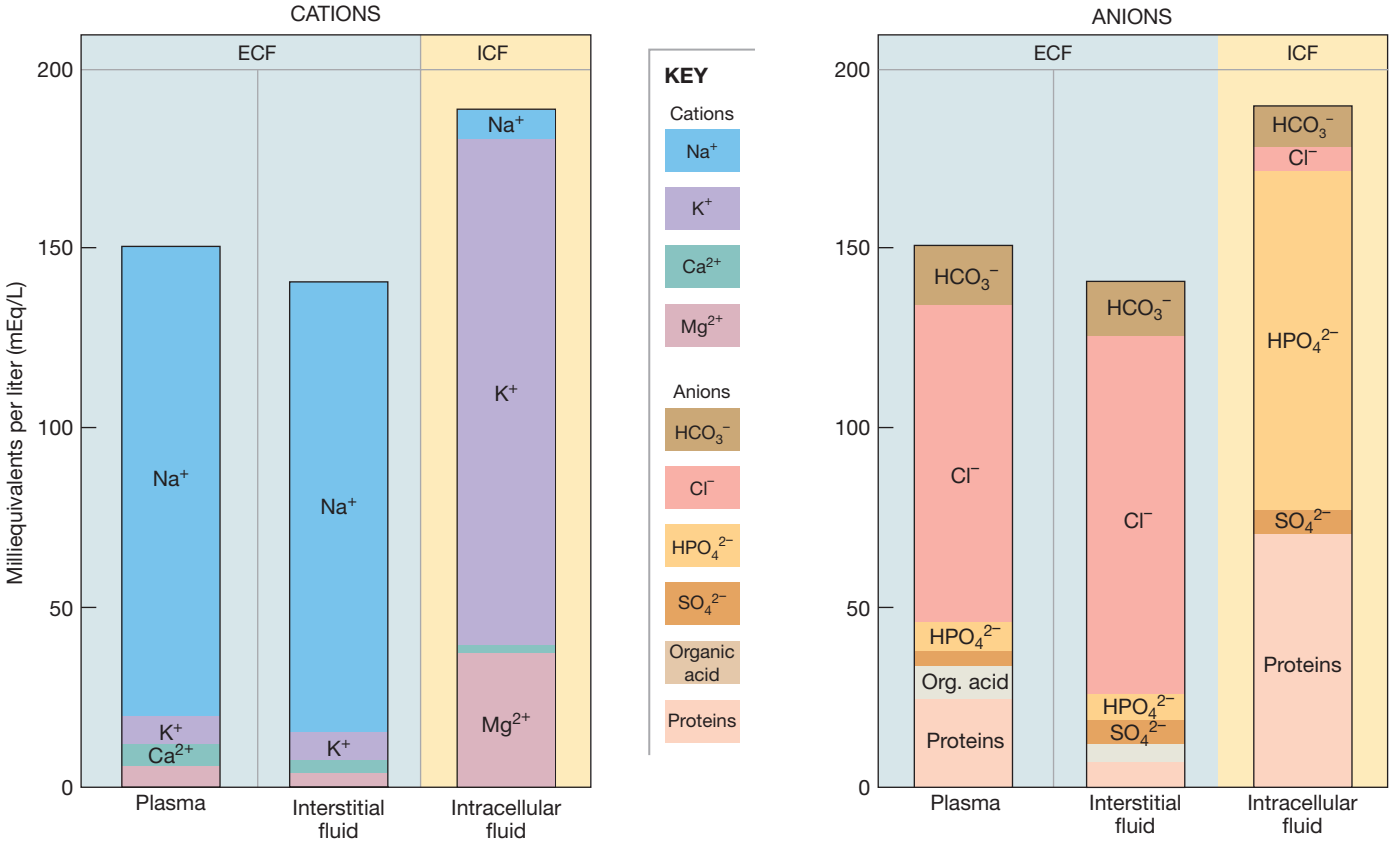

Figure 10–2 ■ Electrolyte composition (cations and anions) of body fluid compartments.

TABLE 10–2 Normal Values for Electrolytes and Serum Osmolality

	Values	
Serum Component	**Conventional**	**SI**
Electrolytes		
Sodium (Na^+)	135–145 mEq/L	135–145 mmol/L
Chloride (Cl^-)	95–105 mEq/L	95–105 mmol/L
Bicarbonate (HCO_3^-, total carbon dioxide)	22–30 mEq/L	22–30 mmol/L
Calcium (Ca^{2+}) (total)	4.5–5.5 mEq/L (9–11 mg/dL)	2.3–2.8 mmol/L
Potassium (K^+)	3.5–5.3 mEq/L	3.5–5.0 mmol/L
Phosphate/inorganic phosphorus (PO_4^{2-})	1.7–2.6 mEq/L (2.5–4.5 mg/dL)	0.8–1.5 mmol/L
Magnesium (Mg^{2+})	1.5–2.5 mEq/L (1.8–3.0 mg/dL)	0.8–1.3 mmol/L
Serum osmolality	280–300 mOsm/kg	275–295 mmol/kg

Source: Values used in this table and throughout the chapter are from Kee, J. (2013). *Pearson handbook of laboratory & diagnostic tests with nursing implications* (7th ed.). Upper Saddle River, NJ: Pearson.

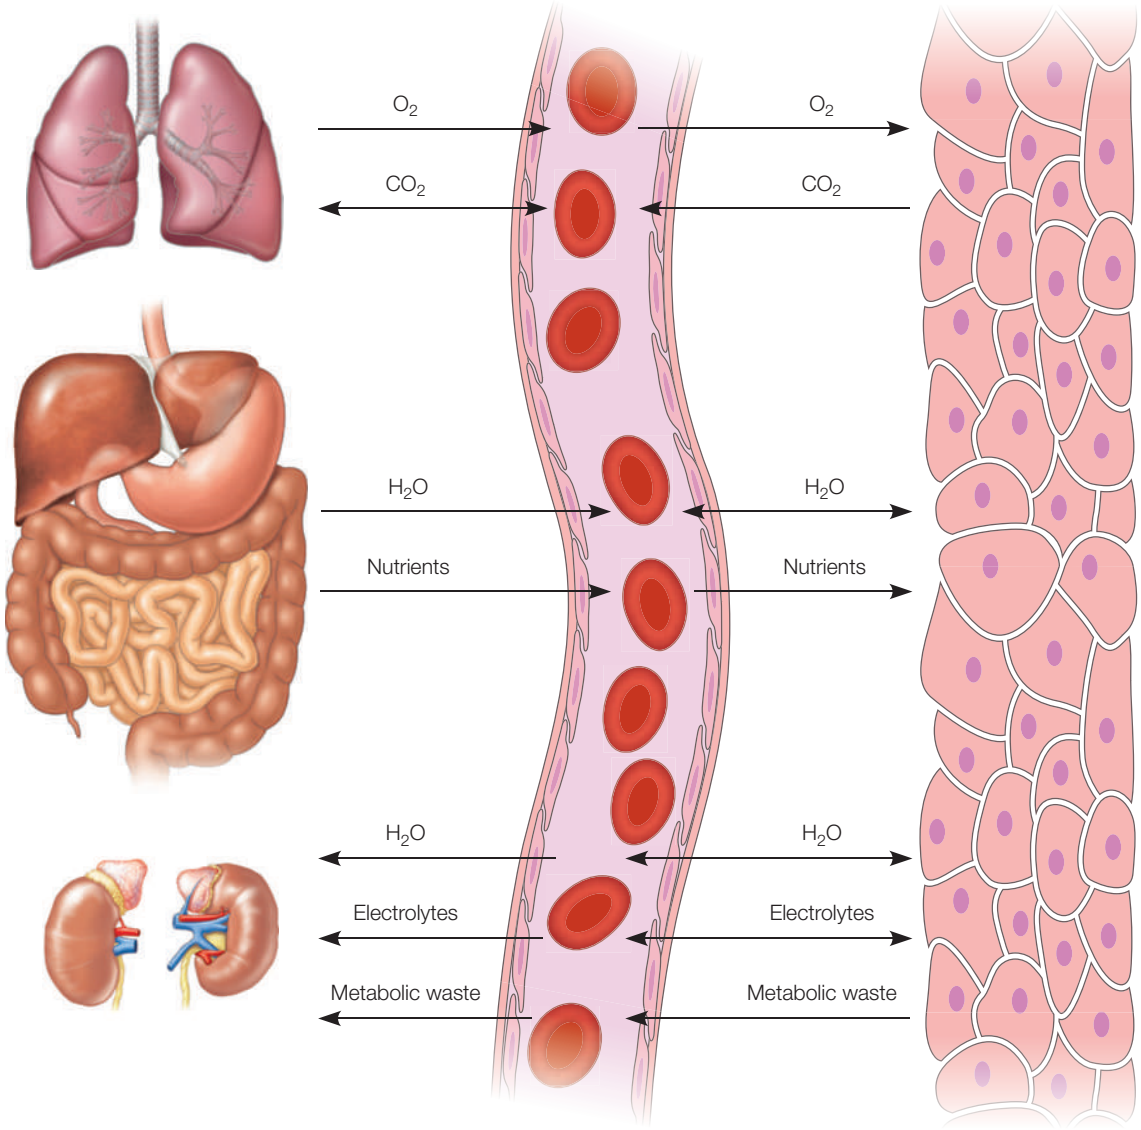

Figure 10–3 ■ Exchange of gases, nutrients, water, and wastes between the three fluid compartments of the body.

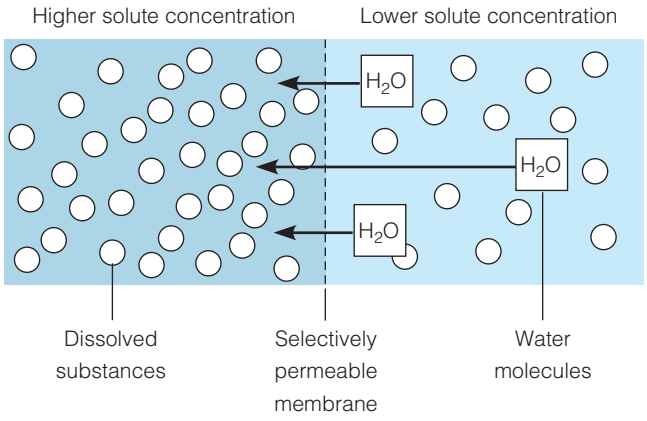

Figure 10–4 ■ Osmosis. Water molecules move through a selectively permeable membrane from an area of low solute concentration to an area of high solute concentration.

plasma from interstitial fluid. The capillary membrane separating the plasma from the interstitial space is made of squamous epithelial cells. Pores in the membrane allow solute molecules (such as glucose and sodium), dissolved gases, and water to cross the membrane. Epithelial membranes separate transcellular fluid from interstitial fluid and plasma. These membranes include the mucosa of the stomach, intestines, and gallbladder; the pleural, peritoneal, and synovial membranes; and the tubules of the kidney.

Body Fluid Movement

Four chemical and physiologic processes control the movement of fluid, electrolytes, and other molecules across membranes between the intracellular and interstitial space and the interstitial space and plasma. These processes are osmosis, diffusion, filtration, and active transport.

OSMOSIS

Osmosis is the process by which water moves across a selectively permeable membrane from an area of lower solute concentration to an area of higher solute concentration (Figure 10–4 ■). A selectively permeable membrane allows water molecules to cross but is relatively impermeable to dissolved substances (solutes). Osmosis continues until the solute concentration on both sides of the membrane is equal. For example, if pure water and a sodium chloride solution are separated by a selectively permeable membrane, then water molecules will move across the membrane to the sodium chloride solution. Osmosis is the primary process that controls body fluid movement between the ICF and ECF compartments.

OSMOLALITY Osmolality, or concentration of a solution, refers to the number of solutes per kilogram of water (by weight); it is reported in milliosmoles per kilogram (mOsm/kg). The osmolality of the ECF depends chiefly on sodium concentration. Serum osmolality may be estimated by doubling the serum sodium concentration (approximately 140 mEq/L). Glucose and urea contribute to the osmolality of ECF, although to a lesser extent than sodium.

OSMOTIC PRESSURE AND TONICITY The power of a solution to draw water across a membrane is known as the *osmotic pressure* of the solution. The composition of interstitial fluid and intravascular plasma is essentially the same except for a higher concentration of proteins in the plasma. These proteins (especially albumin) exert colloid osmotic pressure (also called *oncotic pressure*), pulling fluid from the interstitial space into the intravascular compartment. Because the osmolalities of intravascular and interstitial fluid are essentially identical, the osmotic activity of plasma proteins is important in maintaining fluid balance between the interstitial and intravascular spaces, helping hold water within the vascular system.

Tonicity refers to the effect a solution's osmotic pressure has on water movement across the membrane of cells within that solution. Isotonic solutions have the same concentration of solutes as plasma. Cells placed in an isotonic solution will neither shrink nor swell because there is no net gain or loss of water within the cell, and no change in cell volume (Figure 10–5A ■). Normal saline (0.9% sodium chloride solution) is an example of an isotonic solution.

Hypertonic solutions have a greater concentration of solutes than plasma. In their presence, water is drawn out of a cell, causing it to shrink (Figure 10–5B). A 3% sodium chloride solution is hypertonic. Hypotonic solutions (such as 0.45% sodium chloride) have a lower solute concentration than plasma (Figure 10–5C). When red blood cells are placed in a hypotonic solution, water moves into the cells, causing them to swell; rupture (hemolysis) of cells may occur with extremely hypotonic solutions.

The concepts of osmotic draw and tonicity are important in understanding the pathophysiologic changes that occur with fluid and electrolyte imbalances, as well as treatment measures. For example, an increased sodium concentration of extracellular fluid pulls water from the ICF compartment into the ECF compartment, causing cells to shrink. In this case, administering a hypotonic IV solution to reduce the sodium concentration and osmolality of ECF will facilitate water movement back into the cells.

DIFFUSION

Diffusion is the process by which solute molecules move from an area of high solute concentration to an area of low solute concentration to

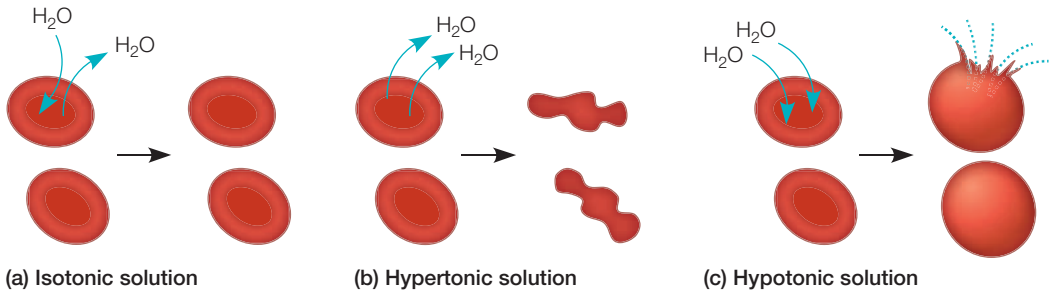

Figure 10–5 ■ The effect of tonicity on red blood cells. A, In an isotonic solution, RBCs neither gain nor lose water, retaining their normal biconcave shape. B, In a hypertonic solution, cells lose water and shrink in size. C, In a hypotonic solution, cells absorb water and may burst (hemolysis).

become evenly distributed. The two types of diffusion are simple and facilitated diffusion. *Simple diffusion* occurs by the random movement of particles through a solution. Water, carbon dioxide, oxygen, and solutes move between plasma and the interstitial space by simple diffusion through the capillary membrane. Water and solutes move into the cell by passing through protein channels or by dissolving in the lipid cell membrane. *Facilitated diffusion*, also called *carrier-mediated diffusion*, allows large water-soluble molecules, such as glucose and amino acids, to diffuse across cell membranes. Proteins embedded in the cell membrane function as carriers, helping large molecules cross the membrane. The rate of diffusion is influenced by a number of factors, such as the concentration of solute and the availability of carrier proteins in the cell membrane. The effect of both simple and facilitated diffusion is to establish equal concentrations of the molecules on both sides of a membrane.

FILTRATION

Filtration is the process by which water and dissolved substances (solutes) move from an area of high hydrostatic pressure to an area of low hydrostatic pressure. This usually occurs across capillary membranes. Hydrostatic pressure is created by the pumping action of the heart and gravity against the capillary wall. Filtration occurs in the glomerulus of the kidneys, as well as at the arterial end of capillaries.

A balance of hydrostatic (filtration) pressure and osmotic pressure regulates the movement of water between the intravascular and interstitial spaces in the capillary beds of the body. Hydrostatic pressure within the arterial end of the capillary pushes water into the interstitial space. At the venous end of the capillary, the osmotic force of plasma proteins draws fluid back into the capillary (Figure 10–6 ■).

ACTIVE TRANSPORT

Active transport allows molecules to move across cell membranes and epithelial membranes against a concentration gradient. This movement requires energy (adenosine triphosphate [ATP]) and a carrier mechanism to maintain a higher concentration of a substance on one side of the membrane than on the other. The sodium-potassium pump is an important example of active transport (Figure 10–7 ■). High concentrations of potassium in intracellular fluids and of sodium in extracellular fluids are maintained because cells actively transport potassium from interstitial fluid into intracellular fluid.

Body Fluid Regulation

Homeostasis requires several regulatory mechanisms and processes to maintain the balance between fluid intake and excretion. These include thirst, the kidneys, the renin–angiotensin–aldosterone mechanism, antidiuretic hormone, and atrial natriuretic peptide. These mechanisms affect the volume, distribution, and composition of body fluids.

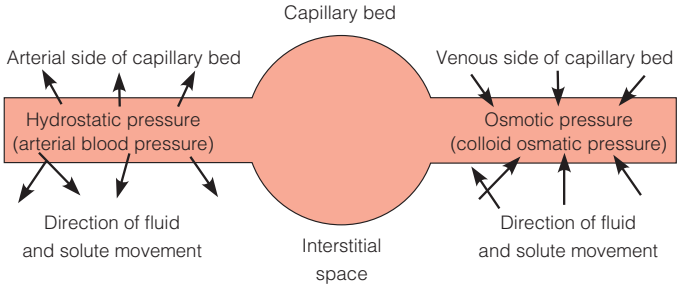

Figure 10–6 ■ Fluid balance between the intravascular and interstitial spaces is maintained in the capillary beds by a balance of filtration at the arterial end and osmotic draw at the venous end.

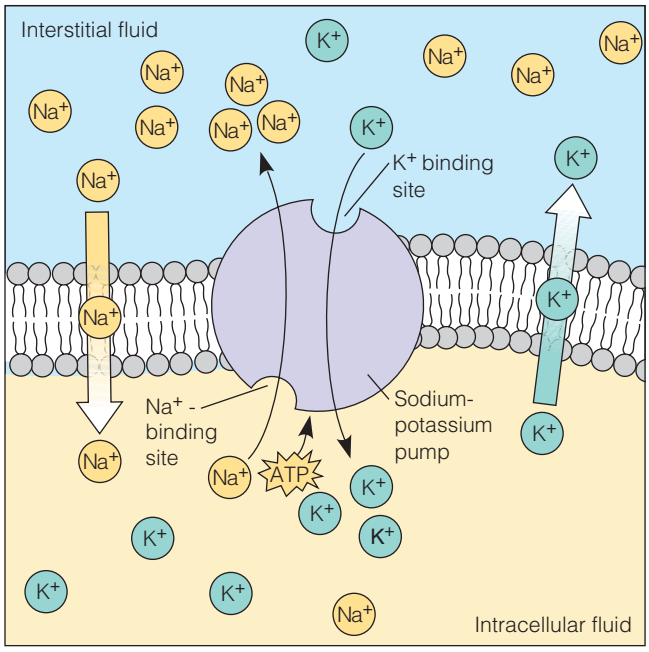

Figure 10–7 ■ The sodium-potassium pump. Sodium and potassium ions are moved across the cell membranes against their concentration gradients. This active transport process is fueled by energy from ATP.

THIRST

Thirst is the primary regulator of water intake. Thirst plays an important role in maintaining fluid balance and preventing dehydration. The thirst center, located in the hypothalamus, is stimulated when the blood volume drops because of water losses or when serum osmolality increases. The thirst mechanism is highly effective in regulating extracellular sodium levels. Increased sodium in ECF increases serum osmolality, stimulating the thirst center. Fluid intake in turn reduces the sodium concentration of ECF and lowers serum osmolality. Conversely, a drop in serum sodium and low serum osmolality inhibit the thirst center.

PRACTICE ALERT!

The thirst mechanism declines with aging, making older adults more vulnerable to dehydration and hyperosmolality. Patients with an altered level of consciousness or who are unable to respond to thirst, such as intubated patients and artificially fed patients, are also at risk.

KIDNEYS

The kidneys are primarily responsible for regulating fluid volume and electrolyte balance in the body. They regulate the volume and osmolality of body fluids by controlling the excretion of water and electrolytes. In adults, about 170 L of plasma are filtered through the glomeruli every day. By selectively reabsorbing water and electrolytes, the kidneys maintain the volume and osmolality of body fluids. About 99% of the glomerular filtrate is reabsorbed, and only about 1500 mL of urine is produced over a 24-hour period.

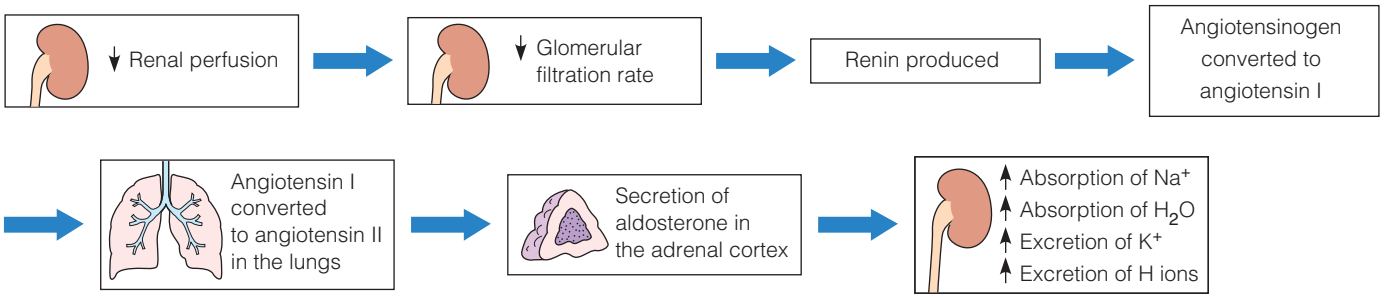

Figure 10–8 ■ The renin–angiotensin–aldosterone system. Decreased blood volume and renal perfusion set off a chain of reactions leading to release of aldosterone from the adrenal cortex. Increased levels of aldosterone regulate serum K^+ and Na^+, blood pressure, and water balance through effects on the kidney tubules.

RENIN–ANGIOTENSIN–ALDOSTERONE SYSTEM

The renin–angiotensin–aldosterone system helps to maintain intravascular fluid balance and blood pressure. A decrease in blood flow or blood pressure to the kidneys stimulates specialized receptors in the juxtaglomerular cells of the nephrons to produce renin, an enzyme. Renin converts angiotensinogen (a plasma protein) in the circulating blood into angiotensin I. Angiotensin I travels through the bloodstream to the lungs where it is converted to angiotensin II by angiotensin-converting enzyme (ACE). Angiotensin II is a potent vasoconstrictor; it raises the blood pressure. It also stimulates the thirst mechanism to promote fluid intake and acts directly on the kidneys, causing them to retain sodium and water. Angiotensin II stimulates the adrenal cortex to release aldosterone. Aldosterone promotes sodium and water retention in the distal nephron of the kidney, restoring blood volume (Figure 10–8 ■).

ANTIDIURETIC HORMONE

Antidiuretic hormone (ADH, also known as vasopressin), released by the posterior pituitary gland, regulates water excretion from the kidneys. Osmoreceptors in the hypothalamus respond to increases in serum osmolality and decreases in blood volume, stimulating ADH production and release. ADH acts on the distal tubules of the kidney, making them more permeable to water and thus increasing water reabsorption. With increased water reabsorption, urine output falls, blood volume is restored, and serum osmolality drops as the water dilutes body fluids (Figure 10–9 ■). Increased amounts of ADH are also released in response to stress situations such as nausea, pain, surgery and anesthesia, narcotics, and nicotine. Its release is inhibited by alcohol and medications such as phenytoin, as well as by increased blood volume and decreased serum osmolality.

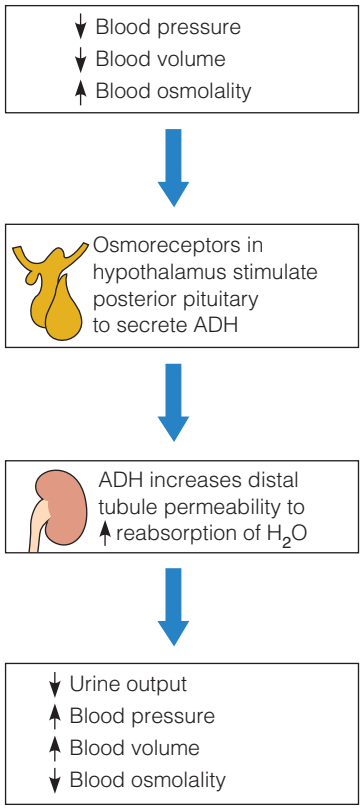

Figure 10–9 ■ Antidiuretic hormone release and effect. Increased serum osmolality or a fall in blood volume stimulates the release of ADH from the posterior pituitary. ADH increases the permeability of distal tubules, promoting water reabsorption.

ATRIAL NATRIURETIC PEPTIDE

Atrial natriuretic peptide (ANP) is a hormone released by atrial muscle cells in response to distention from fluid overload. ANP affects several body systems, including the cardiovascular, renal, neural, GI, and endocrine systems, but it primarily opposes the renin–angiotensin–aldosterone system by inhibiting renin secretion and blocking the secretion and sodium-retaining effects of aldosterone. As a result, ANP promotes sodium wasting and increased urine output.

Fluid and Electrolyte Imbalances

FLUID IMBALANCE

The Patient with a Fluid Volume Deficit

Fluid volume deficit (FVD) is a decrease in intravascular, interstitial, and/or intracellular fluid in the body. Fluid volume deficits may be the result of excessive fluid losses, insufficient fluid intake, or failure of regulatory mechanisms and fluid shifts within the body. FVD is a relatively common problem that may exist alone or in combination with other electrolyte or acid–base imbalances. The term **dehydration** refers to loss of water alone, even though it often is used interchangeably with fluid volume deficit.

NURSING CARE OF THE OLDER ADULT

Fluid Volume Deficit

Changes in the normal aging process affect homeostasis in several ways. In older adults, the percentage of total body water is about 10% lower than in younger or middle-aged adults, and thus they have less body reserve. Lean muscle mass is lower in older adults, and the percentage of body fat is higher; as a result, water accounts for about 50% of the total body weight (TBW) of an older man and about 45% TBW of an older woman. Sodium and water regulation become less efficient with aging. Renal blood flow and glomerular filtration decline with aging; the kidneys are less able to effectively concentrate the urine and conserve sodium and water. The perception of thirst decreases, interfering with the thirst mechanism. Consequently, the older adult may become dehydrated without being aware of the need to increase fluid intake.

Undetected fever in older adults can increase the total body need for water with every degree of temperature. Dehydration can cause a fever and further compound dehydration in the older adult. Older adults who have self-care deficits, or who are confused, depressed, tube fed, on bed rest, or taking medications (such as sedatives, tranquilizers, diuretics, and laxatives) are at greatest risk for fluid volume imbalance. Older adults without air conditioning are at risk during extremely hot weather. In addition, functional changes and illnesses can affect fluid balance. For example, fear of incontinence can lead to self-limiting of fluid intake; physical disabilities associated with age-related illnesses, such as arthritis or stroke, may limit access to fluids; and cognitive impairments can interfere with recognition of thirst and the ability to respond to it.

Manifestations of fluid volume deficit may be more difficult to recognize in the older adult. A change in mental status, memory, or attention may be an early manifestation. Skin turgor is less reliable as an indicator of dehydration, although assessing turgor over the sternum or on the inner aspect of the thigh may be more effective. Dry oral mucous membranes, increased tongue furrows, subnormal temperature, tachycardia, and a pinched facial expression are also indicative of dehydration. Orthostatic vital signs may not demonstrate typical changes in the dehydrated older adult.

PATHOPHYSIOLOGY

The most common cause of fluid volume deficit is excessive loss of GI fluids from vomiting, diarrhea, GI suctioning, intestinal fistulas, and intestinal drainage. Other causes of fluid losses include diuretics, renal disorders, endocrine disorders, excessive exercise, hot environment, hemorrhage, and chronic abuse of laxatives and/or enemas. Other factors involved in inadequate fluid intake include inability to access fluids, inability to request or to swallow fluids, oral trauma, or altered thirst mechanisms. Older adults are at particular risk for fluid volume deficit (see the Nursing Care of the Older Adult box above).

Fluid volume deficit can develop slowly or rapidly, depending on the type of fluid loss. Loss of extracellular fluid volume can lead to **hypovolemia**, decreased circulating blood volume. Electrolytes often are lost along with fluid, resulting in an isotonic fluid volume deficit. When both water and electrolytes are lost, the serum sodium level remains normal, although levels of other electrolytes such as potassium may fall. Fluid is drawn into the vascular compartment from the interstitial spaces as the body attempts to maintain tissue perfusion. This eventually depletes fluid in the intracellular compartment as well.

Hypovolemia stimulates regulatory mechanisms to maintain circulation. The sympathetic nervous system is stimulated, as is the thirst mechanism. ADH and aldosterone are released, prompting sodium and water retention by the kidneys. Severe fluid loss, as in hemorrhage, can lead to shock and cardiovascular collapse.

MOVING KNOWLEDGE INTO ACTION

On a warm summer day, the following patients present in the urgent care clinic:

- An 87-year-old female with mild dementia, who lives in an apartment without air conditioning presents with a fever.
- A 29-year-old female is complaining of urinary frequency, urgency, and cloudy, malodorous urine.
- A 45-year-old male construction worker has had symptoms of nausea and diarrhea for the past 24 hours since "eating some bad food."

Who will you assess first and why?

THIRD SPACING **Third spacing** is a shift of fluid from the vascular space into an area where it is not available to support normal physiologic processes. Fluid may be sequestered in the bowel, in a serous cavity such as the pleural or peritoneal space, or within soft tissues due to sepsis or following trauma or burns. The trapped fluid is unavailable to support cardiovascular or renal function, thus it represents a volume loss.

Increased vascular permeability or decreased protein levels can trigger third spacing (Longo et al., 2012). Stress hormones released in response to tissue trauma or sepsis (catecholamines in particular) promote redistribution of blood to vital organs (the heart and brain). Renal blood flow falls, stimulating the renin–angiotensin–aldosterone system. This promotes sodium and water retention to maintain intravascular volume. The blood vessel and tissue damage caused by trauma or sepsis stimulate the release of inflammatory mediators such as histamine and prostaglandins. These substances lead to local vasodilation and increased capillary permeability, allowing fluid to accumulate in interstitial tissues. Hypoproteinemia (low plasma protein levels) affects the balance of hydrostatic pressure to osmotic pressure in capillary beds, allowing fluid to accumulate within serous cavities and interstitial tissues.

Assessing the extent of FVD resulting from third spacing is difficult. Fluid trapped within the body is not apparent as output, and the patient's weight remains stable (Metheny, 2012). Delays in recognition and treatment can lead to irreversible shock and multiorgan system failure (Perrin, 2012).

MANIFESTATIONS

With a rapid fluid loss (such as hemorrhage or uncontrolled vomiting), manifestations of hypovolemia develop rapidly. When the loss of fluid occurs more gradually, the patient's fluid volume may fall to a very low level before manifestations develop. See the Multisystem Effects of Fluid Volume Deficit feature on page 186.

Rapid weight loss is a good indicator of fluid volume deficit. Each liter of body fluid weighs about 1 kg (2.2 lb). The severity of the fluid volume deficit can be estimated by the percentage of rapid weight loss: A loss of 2% of body weight represents a mild FVD; 5%, moderate FVD; and 8% or greater, severe FVD (Metheny, 2012). Loss of interstitial fluid causes skin turgor to diminish. When pinched, the skin of a patient with FVD tents, remaining elevated in

TABLE 10–3 Comparison of the Manifestations of Fluid Imbalance

Assessment	Fluid Deficit	Fluid Excess
Blood pressure	Decreased systolic postural hypotension	Increased
Heart rate	Increased	Increased
Pulse amplitude	Decreased	Increased
Respirations	Normal	Moist crackles Wheezing
Jugular vein	Flat	Distended
Edema	Rare	Dependent
Skin turgor	Loose, poor turgor	Taut
Output	Low, concentrated	May be low or normal
Urine specific gravity	High	Low
Weight	Loss	Gain

the pinched position. Postural or orthostatic hypotension is a sign of hypovolemia. A drop of more than 15 mmHg in systolic blood pressure when changing from a lying to standing position often indicates loss of intravascular volume. Venous pressure falls as well, causing flat neck veins, even when the patient is recumbent. Compensatory mechanisms to conserve water and sodium and maintain circulation account for many of the manifestations of fluid volume deficit, such as tachycardia; pale, cool skin (vasoconstriction); and decreased urine output. The specific gravity of urine increases as water is reabsorbed in the tubules. Table 10–3 compares manifestations of fluid imbalances.

●○● INTERPROFESSIONAL CARE

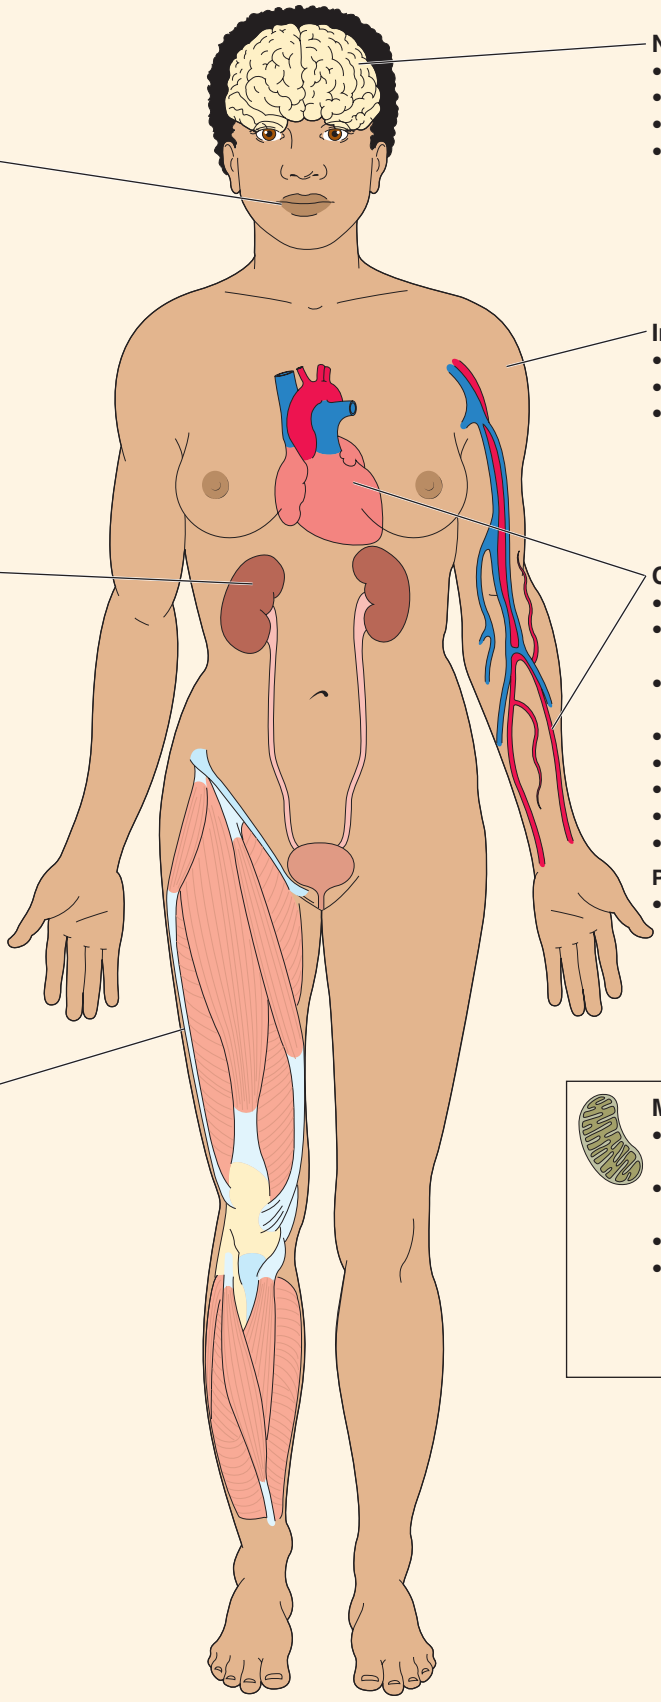
The primary goals of care are to prevent deficits in patients at risk and to correct deficits and their underlying causes. Depending on the acuity of the imbalance, treatment may include replacement of fluids and electrolytes by the IV, oral, or enteral route. When possible, the oral or enteral route is preferred for administering fluids. In acute situations, however, IV fluid administration is necessary.

DIAGNOSIS

Laboratory and diagnostic tests may be ordered when fluid volume deficit is suspected. Such tests measure the following:

- ***Serum electrolytes.*** In an isotonic fluid deficit, sodium levels are within normal limits; when the loss is water only, sodium levels are high. Decreases in potassium are common.
- ***Serum osmolality.*** Measurement of serum osmolality helps to differentiate isotonic fluid loss from water loss. With water loss, osmolality is high; it may be within normal limits with an isotonic fluid loss.
- ***Hemoglobin and hematocrit.*** The hematocrit often is elevated due to loss of intravascular volume and hemoconcentration.
- ***Urine specific gravity and osmolality.*** As the kidneys conserve water, both the specific gravity and osmolality of urine increase.
- ***Hemodynamic pressures.*** The mean arterial pressure (MAP), central venous pressure (CVP), right atrial pressure (RAP), and pulmonary artery wedge pressure (PAWP) are decreased in severe FVD (Perrin, 2012).

FLUID MANAGEMENT



Oral rehydration is the safest and most effective treatment for fluid volume deficit in alert patients who are able to take in and retain oral fluids. Adults require a minimum of 1500 mL of fluid per day or approximately 30 mL per kilogram of body weight (ideal body weight is used to calculate fluid requirements for patients who are obese) for maintenance. Fluids are replaced gradually, particularly in older adults, to prevent rapid rehydration of the cells.

For mild fluid deficits in which a loss of electrolytes has been minimal (e.g., moderate exercise in warm weather), water alone may be used for fluid replacement. When the fluid deficit is more severe and when electrolytes have also been lost (e.g., due to vomiting and/or diarrhea, strenuous exercise for longer than an hour or two), a carbohydrate/electrolyte solution such as a sports drink, ginger ale, or a rehydrating solution (e.g., Pedialyte or Rehydralyte) is more appropriate. These solutions provide sodium, potassium, chloride, and calories to help meet metabolic needs.

IV THERAPY When the fluid deficit is severe or the patient is unable to ingest fluids, the IV route is used to administer replacement fluids. Table 10–4 describes commonly administered IV fluids with nursing implications. Isotonic electrolyte solutions (0.9% NaCl or Ringer's solution) are used to expand plasma volume in hypotensive patients or to replace abnormal losses, which are usually isotonic in nature. These solutions provide additional electrolytes such as potassium, a buffer (lactate or acetate) as needed, and water (Wells et al., 2012). Normal saline (0.9% NaCl) tends to remain in the vascular compartment, increasing blood volume. When administered rapidly, however, this solution can precipitate acid–base imbalances, so balanced electrolyte solutions such as lactated Ringer's solution are preferred to expand plasma volume.

Five percent dextrose in 0.45% saline (D_5 1/2NS) or 0.45% NaCl is given to provide water to treat total body water deficits. D_5W, although isotonic in the bag, is not used for fluid resuscitation because the dextrose is rapidly metabolized and the subsequent fluid is hypotonic. Saline solution (0.45% NaCl with or without added electrolytes) or 5% dextrose in 0.45% sodium chloride is used as a maintenance solution (Metheny, 2012). The addition of dextrose also provides a minimal number of calories.

MULTISYSTEM EFFECTS OF
Fluid Volume Deficit

Neurologic
- Altered mental status
- Anxiety, restlessness
- Diminished alertness/cognition
- Possible coma (severe FVD)

Mucous Membranes
- Dry; may be sticky
- ↓ tongue size, longitudinal furrows ↑

Integumentary
- Diminished skin turgor
- Dry skin
- Pale, cool extremities

Urinary
- ↓ urine output
- Oliguria (severe FVD)
- ↑urine specific gravity

Cardiovascular
- Tachycardia
- Orthostatic hypotension (moderate FVD)
- Falling systolic/diastolic pressure (severe FVD)
- Flat neck veins
- ↓venous filling
- ↓pulse volume
- ↓capillary refill
- ↑hematocrit

Potential Complication
- Hypovolemic shock

Musculoskeletal
- Fatigue

Metabolic Processes
- ↓body temperature (isotonic FVD)
- ↑body temperature (dehydration)
- Thirst
- Weight loss
  2–4% mild FVD
  5–7% moderate FVD
  ≥8% severe FVD

TABLE 10–4 Commonly Administered IV Fluids with Nursing Implications

I. ISOTONIC SOLUTIONS	
0.9% sodium chloride (normal saline [NS]) Lactated Ringer's solution Plasma-Lyte 148 5% dextrose in water (D_5W)	• Monitor for fluid overload; if manifestations occur, discontinue fluids and notify the healthcare provider. • Do not administer lactated Ringer's solution to patients with severe liver disease because the lactate may not convert to bicarbonate, leading to acidosis. Do not administer if the patient has a blood pH of >7.50. • If administering lactated Ringer's solution, monitor potassium levels and cardiac rhythm; if abnormal, notify the healthcare provider.
II. HYPOTONIC SOLUTIONS	
0.45% sodium chloride (1/2NS) 0.225% sodium chloride (1/4NS)	• Monitor for inflammation and infiltration at IV insertion site because hypotonic solutions may cause cell lysis, including at the insertion site. • Monitor plasma sodium levels. • Do not administer to patients at risk for increased intracranial pressure (e.g., head trauma, stroke, neurosurgery). • Do not administer to patients at risk for third-space shifts (burns, trauma, liver disease, malnutrition).
III. HYPERTONIC SOLUTIONS	
D_5 NS D_5 in lactated Ringer's solution 10% dextrose in water ($D_{10}W$) 3% sodium chloride 5% sodium chloride Parenteral nutrition solutions	• Monitor for inflammation and infiltration at IV insertion site because hypertonic solutions cause cells to shrink, exposing the basement membrane of the vein. • Monitor plasma sodium levels. • Monitor for circulatory overload. • Do not administer to patients with diabetic ketoacidosis or impaired cardiac or kidney function.

Clinical Alert: **Hypertonic solutions should be administered through a central venous access device to reduce the risk of vessel damage.**

●○● NURSING CARE

Nurses are responsible for identifying patients at risk for fluid volume deficit, initiating and carrying out interventions to prevent and treat fluid volume deficit, and monitoring the effects of therapy.

Health Promotion

Health promotion activities focus on teaching to prevent fluid volume deficit. Discuss the importance of maintaining adequate fluid intake, particularly when exercising and during hot weather. Advise patients to use commercial sports drinks to replace both water and electrolytes when exercising during warm weather. Instruct patients to maintain fluid intake when ill, particularly during periods of fever or when diarrhea is a problem.

Carefully monitor the intake and output of patients at risk for abnormal fluid losses through vomiting, diarrhea, nasogastric suction, increased urine output, fever, or draining wounds. Monitor fluid intake in patients with decreased level of consciousness, disorientation, nausea, anorexia, and physical limitations. See the accompanying Moving Evidence into Action feature for a discussion about determining fluid intake requirements for residents of long-term care facilities.

Assessment

Collect assessment data through the health history interview and physical examination:

- ***Health history:*** risk factors such as medications, acute or chronic renal or endocrine disease; precipitating factors such as hot weather, extensive exercise, lack of access to fluids, recent illness (especially if accompanied by fever, vomiting, and/or diarrhea); onset and duration of manifestations
- ***Physical assessment:*** weight; vital signs including orthostatic blood pressure and pulse; peripheral pulses and capillary refill; jugular neck vein distention; skin color, temperature, turgor; level of consciousness and mentation; urine output. Allow the older adult to stand quietly for a full minute before rechecking blood pressure and pulse when measuring orthostatic vital signs.

Priorities of Care

Restoration of adequate fluid volume is critical to support tissue perfusion and organ function. Concurrently, the nurse employs measures to prevent injury associated with FVD.

Diagnoses, Outcomes, and Interventions

Nursing diagnoses and interventions for the patient with fluid volume deficit focus on managing the effects of the deficit and preventing complications.

Deficient Fluid Volume

Patients with a fluid volume deficit due to abnormal losses, inadequate intake, or impaired fluid regulation require close monitoring as well as immediate and ongoing fluid replacement.

Expected Outcome: Patient's fluid volume and balance will be restored as evidenced by weight within previous parameters and balanced intake and output.

Moving Evidence into Action

Determining Fluid Needs in Long-Term Care

Residents of long-term care facilities are at significant risk for developing fluid volume deficit. Most are elderly, many have some degree of dementia, and a significant number are dependent on caregivers to provide fluids. Dehydration, when it occurs, can be a sentinel health event leading to serious and potentially life-threatening secondary problems (Gaspar, 2011). Various standards for determining the amount of fluid a resident requires have been developed. These standards vary in complexity from a simple 30 mL fluid per kilogram of body weight to a formula that uses body surface area to determine fluid needs. A retrospective study by Gaspar (2011) compared four different formulas, ultimately recommending a formula based on the height and weight of the resident to determine fluid intake.

Implications for Nursing

As noted at the beginning of this chapter, the percentage of total body water varies with age and the amount of lean body tissue to adipose tissue. Likewise, fluid requirements of residents in long-term care facilities vary, necessitating attention to the needs of the individual. Furthermore, caregivers are more likely to attend to an individualized plan for a resident's fluid intake than to a generalized recommendation to "push fluids." This plan should include not only the target amount of daily fluid intake but also residents' preferences for the type, temperature, and timing of fluid intake.

Moving Knowledge into Action

1. Why are older adults more vulnerable to dehydration and fluid volume deficit than younger adults?
2. Identify factors in long-term care settings that increase the risk for fluid volume deficit. Consider the setting, the residents, and caregivers.
3. Develop a teaching plan about resident fluid intake for caregivers in a long-term care facility.

- Assess intake and output accurately, monitoring fluid balance. In acute situations, hourly intake and output may be indicated. *Urine output should normally be 30 to 60 mL per hour. Urine output of less than 30 mL per hour in adults indicates inadequate renal perfusion and an increased risk for acute renal failure and inadequate tissue perfusion* (Perrin, 2012).

PRACTICE ALERT!

Report a urine output of less than 30 mL per hour to the patient's healthcare provider.

- Assess vital signs, CVP, and peripheral pulse volume at least every 4 hours. *Hypotension, tachycardia, low CVP, and weak, easily obliterated peripheral pulses indicate hypovolemia.*
- Weigh daily under standard conditions (time of day, clothing, and scale). *In most instances (except third spacing), changes in weight accurately reflect fluid balance.*
- Administer and monitor the intake of oral fluids as prescribed. Identify beverage preferences and provide these on a schedule. *Oral fluid replacement is preferred when the patient is able to drink and retain fluids.*
- Administer IV fluids as prescribed using an infusion pump. Monitor for indicators of fluid overload if rapid fluid replacement is ordered: dyspnea, tachypnea, tachycardia, increased CVP, jugular vein distention, and edema. *Rapid fluid replacement may lead to hypervolemia, resulting in pulmonary edema and cardiac failure, particularly in patients with compromised cardiac and renal function.*
- Monitor laboratory values: electrolytes, serum osmolality, blood urea nitrogen (BUN), and hematocrit. *Rehydration may lead to changes in serum electrolytes, osmolality, BUN, and hematocrit. In some cases, electrolyte replacement may be necessary during rehydration.*

Ineffective Tissue Perfusion

A fluid volume deficit can lead to decreased perfusion of renal, cerebral, and peripheral tissues. Inadequate renal perfusion can lead to acute kidney injury. Decreased cerebral perfusion leads to changes in mental status and cognitive function, causing restlessness, anxiety, agitation, excitability, confusion, vertigo, fainting, and weakness.

Expected Outcome: Patient will not develop any manifestations of impaired tissue and organ perfusion.

- Monitor for changes in level of consciousness and mental status. *Restlessness, anxiety, confusion, and agitation may indicate inadequate cerebral blood flow and circulatory collapse.*
- Monitor serum creatinine, BUN, and cardiac enzymes, reporting elevated levels to the physician. *Elevated levels may indicate impaired renal function or cardiac perfusion related to circulatory failure.*
- Turn at least every 2 hours. Provide good skin care and monitor for evidence of skin or tissue breakdown. *Impaired circulation to peripheral tissues increases the risk of skin breakdown. Turn frequently to relieve pressure over bony prominences. Keep skin clean, dry, and moisturized to help maintain integrity.*

Risk for Injury

The patient with fluid volume deficit is at risk for injury because of dizziness and loss of balance resulting from decreased cerebral perfusion secondary to hypovolemia.

Expected Outcome: Patient will be free of injury.

- Institute safety precautions, including keeping the bed in a low position and slowly raising the patient from supine to sitting or sitting to standing position. *Using safety precautions and allowing time for the blood pressure to adjust to position changes reduce the risk of injury.*
- Teach patient and family members how to reduce orthostatic hypotension:
  a. Move from one position to another in stages; for example, sit on the side of the bed for a few minutes before standing.
  b. Avoid prolonged standing.
  c. Rest in a recliner rather than in bed during the day.
  d. Use assistive devices to pick up objects from the floor rather than stooping.

  Teaching measures to reduce orthostatic hypotension reduces the patient's risk for injury. Prolonged standing allows blood to pool in the legs, reducing venous return and cardiac output.

Delegating Nursing Care Activities

As appropriate and allowed by designated duties and responsibilities of assistive personnel, the nurse may delegate nursing care activities such as measuring fluid intake and output, collecting vital signs

(including orthostatic vital signs), encouraging oral or enteral fluid intake, and skin care.

Continuity of Care

Depending on the severity of the fluid volume deficit, the patient may be managed in the home or long-term care facility, or may be admitted as a hospital inpatient. Assess the patient's understanding of the cause of the deficit and the fluids necessary for providing replacement. Address the following topics when preparing the patient and family for home care:

- The importance of maintaining adequate fluid intake (at least 1500 mL per day; more if extra fluid is being lost through perspiration, fever, or diarrhea)
- Manifestations of fluid imbalance, and how to monitor fluid balance
- How to prevent fluid deficit:
  - Avoid exercising during extreme heat.
  - Increase fluid intake during hot weather.
  - If vomiting, take small frequent amounts of ice chips or clear liquids, such as weak tea, flat cola, or ginger ale.
  - Reduce intake of coffee, tea, and alcohol, which increase urine output and can cause fluid loss.
- Replacement of fluids lost through diarrhea with fruit juices or bouillon, rather than large amounts of tap water
- Alternate sources of fluid (such as gelatin, frozen juices, or ice cream) for effective replacement of lost fluids.

The Patient with a Fluid Volume Excess

Fluid volume excess results when both water and sodium are retained in the body. Fluid volume excess may be caused by fluid overload (excess water and sodium intake) or by impairment of the mechanisms that maintain homeostasis. The excess fluid can lead to excess intravascular fluid (**hypervolemia**) and excess interstitial fluid (**edema**).

PATHOPHYSIOLOGY

Fluid volume excess usually results from conditions that cause retention of both sodium and water. These conditions include heart failure, cirrhosis of the liver, renal failure, adrenal gland disorders, corticosteroid administration, and stress conditions causing the release of ADH and aldosterone. Other causes include an excessive intake of sodium-containing foods, drugs that cause sodium retention, and the administration of excess amounts of sodium-containing IV fluids (such as 0.9% NaCl or Ringer's solution). This *iatrogenic* (induced by the effects of treatment) cause of fluid volume excess primarily affects patients with impaired regulatory mechanisms.

In fluid volume excess, both water and sodium are gained in about the same proportions as normally exist in extracellular fluid. The total body sodium content is increased, which in turn causes an increase in total body water. Because the increase in sodium and water is isotonic, the serum sodium and osmolality remain normal, and the excess fluid remains in the extracellular space.

Stress responses activated before, during, and immediately after surgery commonly lead to increased ADH and aldosterone levels, leading to sodium and water retention. In the immediate postoperative period, however, this additional fluid tends to be sequestered in interstitial tissues and unavailable to support cardiovascular and renal function (see the earlier Third Spacing section in this chapter). This sequestered fluid is reabsorbed into the circulation within about 48 to 72 hours after surgery. Although it is then normally eliminated through a process of diuresis, patients with heart or kidney failure are at risk for developing fluid overload.

MANIFESTATIONS

Excess extracellular fluid leads to hypervolemia and circulatory overload. Excess fluid in the interstitial space causes peripheral or generalized edema. The manifestations of fluid volume excess relate to both the excess fluid and its effects on circulation. Manifestations of fluid volume excess with related pathophysiology are described in the Pathophysiology Linkage feature on the following page.

COMPLICATIONS

Congestive heart failure (CHF) is not only a potential cause of fluid volume excess, but it is also a potential complication of the condition if the heart is unable to increase its workload to handle the excess blood volume. Severe fluid overload and CHF can lead to pulmonary edema, a medical emergency.

●○● INTERPROFESSIONAL CARE

Managing fluid volume excess focuses on prevention in patients at risk, treating its manifestations, and correcting the underlying cause. Management includes limiting sodium and water intake and administering diuretics.

DIAGNOSIS

The following laboratory tests may be ordered:

- *Serum electrolytes* and *serum osmolality* are measured, but usually remain within normal limits.
- *Serum hematocrit* and *hemoglobin* often are decreased due to plasma dilution from excess extracellular fluid.

Additional tests of *renal* and *liver function* (such as serum creatinine, BUN, and liver enzymes) may be ordered to help determine the cause of fluid volume excess.

MEDICATIONS

Diuretics are commonly used to treat fluid volume excess. They inhibit sodium and water reabsorption, increasing urine output. The three major classes of diuretics, each of which acts on a different part of the kidney tubule, are as follows:

- Loop diuretics act in the ascending loop of Henle.
- Thiazide-type diuretics act on the distal convoluted tubule.
- Potassium-sparing diuretics affect the distal nephron.

The nursing implications for diuretics are outlined in the following Medication Administration box.

TREATMENTS

FLUID MANAGEMENT Fluid intake may be restricted in patients who have fluid volume excess. The amount of fluid allowed per day is prescribed by the primary care provider. All fluid intake must be

PATHOPHYSIOLOGY LINKAGE

Fluid Volume Excess

Manifestations	Related Pathophysiology
Peripheral edema, or if severe, anasarca (severe, generalized edema)	Excess fluid in the interstitial spaces, usually resulting from conditions that cause retention of both sodium and water (e.g., heart failure, renal failure, and stress responses causing the release of ADH and aldosterone, such as surgery)
Full bounding pulse, distended neck and peripheral veins, increased central venous and right atrial pressures, cough, dyspnea (labored or difficult breathing), **orthopnea** (difficult breathing when supine)	Circulatory overload from increased water and sodium retention
Dyspnea at rest	Mobilization (reabsorption) of fluid from peripheral tissues increases circulatory fluid volume
Tachycardia and hypertension	Increased circulatory fluid volume
Reduced oxygen saturation	As fluid increases in the interstitial spaces and alveoli, gas exchange is impaired, leading to hypoxia and hypercapnia
Moist crackles on auscultation of the lungs, pulmonary edema	Excess fluid in pulmonary interstitial spaces and alveoli
Increased urine output (polyuria)	Increased circulatory volume and increased perfusion of the renal arteries increases amount of filtrate produced in glomerulus
Ascites (excess fluid in the peritoneal cavity)	Increased filtration pressure due to hypervolemia
Decreased hematocrit and BUN	Dilutional effect of increased circulatory volume
Altered mental status and anxiety	Pressure on the cerebral cortex from cerebral hypertension and edema causes decreased oxygenation (hypoxia) of neurons
Pulmonary edema	Elevation of left-sided filling pressures from increased circulatory volume and heart failure increase pressures in pulmonary vascular system

MEDICATION ADMINISTRATION

Diuretics for Fluid Volume Excess

Diuretics increase urinary excretion of water and sodium. They are used to enhance renal function and to treat vascular fluid overload and edema. Common side effects include orthostatic hypotension, dehydration, electrolyte imbalance, and possible hyperglycemia. Patient education is important to reduce the risk of these adverse effects (Harvey & Jordan, 2010). Diuretics should be used with caution in the older adult. Examples of each major type follow.

LOOP DIURETICS

furosemide (Lasix)
ethacrynic acid (Edecrin)
bumetanide (Bumex)
torsemide (Demadex)

Loop diuretics inhibit sodium and chloride reabsorption in the ascending loop of Henle. As a result, loop diuretics promote the excretion of sodium, chloride, potassium, and water.

THIAZIDE AND THIAZIDE-LIKE DIURETICS

bendroflumethiazide (Naturetin)
chlorothiazide (Diuril)
hydrochlorothiazide (HydroDIURIL, Oretic)
metolazone (Zaroxolyn)
polythiazide (Renese)
chlorthalidone (Hygroton)
trichlormethiazide (Naqua)
indapamide (Lozol)

Thiazide and thiazide-like diuretics promote the excretion of sodium, chloride, potassium, and water by decreasing absorption in the distal tubule.

POTASSIUM-SPARING DIURETICS

spironolactone (Aldactone)
amiloride HCl (Midamor)
triamterene (Dyrenium)

Potassium-sparing diuretics promote excretion of sodium and water by inhibiting sodium-potassium exchange in the distal tubule.

Health Education for the Patient and Family

- The drug will increase the amount and frequency of urination.
- The drugs must be taken even when you feel well.
- Take the drugs in the morning and afternoon to avoid having to get up at night to urinate.
- Change position slowly to avoid dizziness.
- Report the following to your primary healthcare provider: dizziness; trouble breathing; or swelling of face, hands, or feet.
- Weigh yourself every day, and report sudden gains or losses.
- Avoid using the salt shaker when eating.
- If the drug increases potassium loss, consume foods high in potassium, such as orange juice and bananas.
- Do not use salt substitute if you are taking a potassium-sparing diuretic.

Note: Drugs identified in *italics* are among the 200 most commonly prescribed medications in the U.S.

BOX 10–1 Fluid Restriction Guidelines

- Subtract required fluids (e.g., ordered IV fluids, fluid used to dilute IV medications) from total daily allowance.
- Divide remaining fluid allowance—daytime: 50% of total; evening: 25% to 33% of total; nighttime: remainder.
- Explain the fluid restriction to the patient and family members.
- Identify preferred fluids and intake pattern of patient.
- Place allowed amounts of fluid in small glasses (gives perception of a full glass).
- Offer ice chips (when melted, ice chips are approximately half the frozen volume).
- Provide frequent oral care.
- Provide sugarless chewing gum (if allowed) to reduce thirst sensation.

calculated, including meals and that used to administer medications orally or IV. Box 10–1 provides guidelines for hospitalized patients with a fluid restriction.

PRACTICE ALERT!

Maintaining moisture of the oral cavity and lips is an important comfort measure for patients unable to provide self-care, particularly those on restricted fluids. Guidelines from the John A. Hartford Foundation Centers of Geriatric Nursing Excellence include the following recommendations for palliative oral care:

- Brush teeth, gums, and tongue with prescription-strength fluoridated toothpaste or gel to protect from caries.
- Use moisturizing products such as Biotine to reduce dryness and relieve oral discomfort. Use KY Jelly or Biotene gel on oral mucous membranes for lubrication and protection. Lanolin may be applied to the lips.
- Use an oral chlorhexidine gluconate (0.12%) rinse to prevent superinfection and help control plaque.
- Avoid hydrogen peroxide-, thymol-, and alcohol-containing products and lemon and glycerine swabs because they can further dry and damage oral tissues (Johnson & Chalmers, 2011).

DIETARY MANAGEMENT Because sodium retention is a primary cause of fluid volume excess, a sodium-restricted diet often is prescribed. This is particularly important for patients with a history of heart failure or renal failure (Baraz et al., 2010; Son et al., 2011). The primary dietary sources of sodium are the salt shaker, processed foods, and foods themselves.

A mild sodium restriction can be achieved by instructing the patient and primary food preparer in the household to reduce the amount of salt in recipes by half, avoid using the salt shaker during meals, and avoid foods that contain high levels of sodium (either naturally or because of processing). In moderate and severely sodium-restricted diets, salt is avoided altogether, as are all foods containing significant amounts of sodium. A mild to moderate sodium restriction, perceived by many patients as less difficult to follow, may actually promote compliance (Nieuwenhuis et al., 2011). Examples of foods high in sodium include lunch meat, bacon, cheese, dry cereal, canned soup, popcorn, ketchup, pickles, and seafood.

●○● NURSING CARE

Nursing care focuses on preventing fluid volume excess in patients at risk and on managing problems resulting from its effects.

Evidence for Nursing Care

Fluid Volume Excess

Selected resources that nurses may find helpful when planning evidence-based nursing care follow.

- Baraz, S., Parvardeh, S., Mohammadi, E., & Broumand, B. (2010). Dietary and fluid compliance: An educational intervention for patients having haemodialysis. *Journal of Advanced Nursing, 66*(1), 60–68.
- Nieuwenhuis, M., van der Wall, M., & Jaarsma, T. (2011). The body of knowledge on compliance in heart failure patients: We are not there yet. *Journal of Cardiovascular Nursing, 26*(1), 21–28.
- Son, Y., Lee, Y., & Song, E. (2011). Adherence to a sodium-restricted diet is associated with lower symptom burden and longer cardiac event-free survival in patients with heart failure. *Journal of Clinical Nursing, 20*(21/22), 3029–3038.

Health Promotion

Health promotion related to fluid volume excess focuses on teaching preventive measures to patients who are at risk (e.g., patients who have heart disease or kidney failure). Discuss the relationship between sodium intake and water retention. Provide guidelines for a low-sodium diet, and teach patients to carefully read food labels to identify sodium in processed foods. Instruct patients at risk to weigh themselves on a regular basis, using the same scale, and to notify their primary care provider if they gain more than 5 lb in a week or less.

Assessment

Collect assessment data through the health history interview and physical examination:

- ***Health history:*** risk factors such as medications; heart failure; acute or chronic renal or endocrine disease; precipitating factors such as a recent illness, change in diet, or change in medications; recent weight gain; complaints of persistent cough, shortness of breath, swelling of feet and ankles, or difficulty sleeping when lying down.
- ***Physical assessment:*** weight; vital signs; peripheral pulses and capillary refill; jugular neck vein distention; edema; lung sounds (crackles or wheezes), dyspnea, cough, and sputum; urine output; mental status.

Priorities of Care

Supporting cardiovascular and respiratory function are priority nursing responsibilities for the patient with fluid volume excess, particularly when severe or accompanied by heart failure or dyspnea.

Diagnoses, Outcomes, and Interventions

Fluid Volume Excess

Nursing care for the patient with excess fluid volume includes collaborative interventions such as administering diuretics and maintaining a fluid restriction, as well as monitoring the status and effects of the excess fluid volume. This is particularly critical in older patients because of the age-related decline in cardiac and renal compensatory responses.

Expected Outcome: Patient will eliminate excess fluid volume as evidenced by weight within usual parameters, balanced fluid intake and output, and laboratory test results.

- Assess vital signs, heart sounds, and peripheral pulse amplitude (strength). *Hypervolemia can cause hypertension, bounding peripheral pulses, and a third heart sound (S_3) due to the volume of blood flow through the heart.*
- Assess for the presence and extent of edema, particularly in the lower extremities and the back, sacral, and periorbital areas. *Initially, edema affects the dependent portions of the body—the lower extremities of ambulatory patients and the sacrum in bedridden patients. Periorbital edema indicates more generalized edema.*
- Assess urine output hourly. Maintain accurate intake and output records. Note urine output of less than 30 mL per hour or a positive fluid balance on 24-hour total intake and output calculations. *Heart failure and inadequate renal perfusion may result in decreased urine output and fluid retention.*
- Obtain daily weights at the same time of day, using approximately the same clothing and a balanced scale. *Daily weights are one of the most important gauges of fluid balance. Acute weight gain or loss represents fluid gain or loss. Weight gain of 2.2 lbs is equivalent to 1 L of fluid gain.*
- Administer oral and parenteral fluids cautiously, adhering to any prescribed fluid restriction. Discuss the restriction with the patient and significant others, including the total volume allowed, the rationale, and the importance of reporting all fluid taken. *All sources of fluid intake, including ice chips, are recorded to avoid excess fluid intake.*
- Provide oral hygiene at least every 2 hours. *Oral hygiene contributes to patient comfort and keeps mucous membranes intact; it also helps relieve thirst if fluids are restricted.*
- Teach patient and significant others about the sodium-restricted diet (see Box 10–2), and emphasize the importance of checking before bringing foods to the patient. *Excess sodium promotes water retention; a sodium-restricted diet is ordered to reduce water gain.*
- Administer prescribed diuretics as ordered, monitoring the patient's response to therapy. *Loop or high-ceiling diuretics such as furosemide can lead to rapid fluid loss and manifestations of hypovolemia and electrolyte imbalance.*
- Promptly report significant changes in serum electrolytes or osmolality or abnormal results of tests done to determine contributing factors to the fluid volume excess. *Gradual correction of serum electrolytes and osmolality is expected; however, aggressive diuretic therapy can lead to overcorrection.*

BOX 10–2 Patient Teaching: Low-Sodium Diet

- Reducing sodium intake will help the body excrete excess sodium and water.
- The body needs less than one-tenth of a teaspoon of salt per day.
- Approximately one-third of sodium intake comes from salt added to foods during cooking and at the table; one-fourth to one-third comes from processed foods; and the rest comes from food and water naturally high in sodium.
- Read labels. Sodium compounds are used in foods as preservatives, leavening agents, and flavor enhancers.
- Many nonprescription drugs (such as analgesics, cough medicine, laxatives, and antacids) as well as toothpastes and mouthwashes contain high amounts of sodium.
- Low-sodium salt substitutes are not really sodium free and may contain half as much sodium as regular salt.
- Use salt substitutes sparingly; larger amounts often taste bitter instead of salty.
- The preference for salt will eventually diminish.
- Salt, monosodium glutamate, baking soda, and baking powder contain substantial amounts of sodium.
- In place of salt or salt substitutes, use herbs, spices, lemon juice, vinegar, and wine as flavoring when cooking.

Risk for Impaired Skin Integrity

Tissue edema decreases oxygen and nutrient delivery to the skin and subcutaneous tissues, increasing the risk of injury.

Expected Outcome: Patient's skin will remain intact without evidence of injury.

- Frequently assess skin, particularly in pressure areas and over bony prominences. *Skin breakdown can progress rapidly when circulation is impaired.*
- Reposition the patient at least every 2 hours. Provide skin care with each position change. *Frequent position changes minimize tissue pressure and promote blood flow to tissues.*
- Provide an egg-crate mattress or alternating pressure mattress, foot cradle, heel protectors, and other devices to reduce pressure on tissues. *These devices, which distribute pressure away from bony prominences, reduce the risk of skin breakdown.*

Impaired Gas Exchange

With fluid volume excess, gas exchange may be impaired by edema of pulmonary interstitial tissues. Acute pulmonary edema is a serious and potentially life-threatening complication of pulmonary congestion.

Expected Outcome: Patient's gas exchange will not be compromised as indicated by clear lung sounds and mental status, absence of dyspnea, and oxygen saturation and blood gas values within usual parameters.

- Auscultate lungs for presence or worsening of crackles and wheezes; auscultate heart for extra heart sounds. *Crackles and wheezes indicate pulmonary congestion and edema. A gallop rhythm (S_3) may indicate diastolic overloading of the ventricles secondary to fluid volume excess.*

PRACTICE ALERT!

Place in Fowler's position if dyspnea or orthopnea is present. Fowler's position improves lung expansion by decreasing the pressure of abdominal contents on the diaphragm.

- Monitor oxygen saturation levels and **arterial blood gases (ABGs)** for evidence of impaired gas exchange ($SaO_2 < 92\%$ to 95%; $PaO_2 < 80$ mmHg). Administer oxygen as indicated. *Edema of interstitial lung tissues can interfere with gas exchange and delivery to body tissues. Supplemental oxygen promotes gas exchange across the alveolar-capillary membrane, improving tissue oxygenation.*

Delegating Nursing Care Activities

As appropriate, the nurse may delegate nursing care activities such as measuring intake and output, obtaining daily weights, and providing oral and skin care for the patient with excess fluid volume to assistive personnel.

Continuity of Care

Teaching for continuing care focuses on managing the underlying cause of fluid volume excess and preventing future episodes of excess fluid volume. Address the following topics when preparing the patient and family or caregivers for continuing care:

- Manifestations of excess fluid and when to contact the care provider
- Prescribed medications: when and how to take, intended and adverse effects, what to report to care provider
- Recommended or prescribed diet; ways to reduce sodium intake; how to read food labels for salt and sodium content; use of salt substitutes, if allowed
- If restricted, the amount and type of fluids to take each day; how to balance intake over 24 hours
- Monitoring weight; changes reported to care provider
- Ways to decrease dependent edema:
  - Change position frequently.
  - Avoid restrictive clothing.
  - Avoid crossing the legs when sitting.
  - Wear support stockings or hose.
  - Elevate feet and legs when sitting.
- How to protect edematous skin from injury:
  - Do not walk barefoot.
  - Buy properly fitted shoes; shop in the afternoon when feet are more likely to be swollen.
- Using additional pillows or a recliner to sleep, to relieve orthopnea.

SODIUM IMBALANCE

Sodium is the most plentiful electrolyte in ECF, with normal serum sodium levels ranging from 135 to 145 mEq/L. Sodium is the primary regulator of the volume, osmolality, and distribution of ECF. It also is important in maintaining neuromuscular activity. Due to the close interrelationship between sodium and water balance, disorders of fluid volume and sodium balance often occur together. Sodium imbalances affect the osmolality of ECF and water distribution between the fluid compartments. When sodium levels are low (hyponatremia), water is drawn into the cells of the body, causing them to swell. In contrast, high levels of sodium in ECF (hypernatremia) draw water out of body cells, causing them to shrink.

Most of the body's sodium comes from dietary intake. Although a sodium intake of 500 mg per day is usually sufficient to meet the body's needs, and the American Heart Association recommends that all Americans limit their intake to 1500 mg per day (about 3/4 teaspoon), the average intake of sodium by adults in the United States is about 3300 mg per day (Appel et al., 2011; Centers for Disease Control and Prevention, 2012). Other sources of sodium include prescription drugs and some self-prescribed remedies.

The kidney is the primary regulator of sodium balance in the body. The kidney excretes or conserves sodium in response to changes in vascular volume. A fall in blood volume prompts several mechanisms that lead to sodium and water retention:

- The renin–angiotensin–aldosterone system (refer to Figure 10–8) is stimulated. Angiotensin II prompts the renal tubules to reabsorb sodium. It also causes vasoconstriction, slowing blood flow through the kidney and reducing glomerular filtration. This further reduces the amount of sodium excreted. Angiotensin II promotes the release of aldosterone from the adrenal cortex. In the presence of aldosterone, more sodium is reabsorbed in the cortical collecting tubules of the kidney, and more potassium is eliminated in the urine.
- ADH is released from the posterior pituitary (refer to Figure 10–9). ADH promotes sodium and water reabsorption in the distal tubules of the kidney, reducing urine output and expanding blood volume.

TABLE 10–5 Manifestations of Sodium Imbalances

Hyponatremia	Hypernatremia
• Plasma sodium < 135 mEq/L • Decreased serum osmolality • Muscle cramps, weakness • Headache • Irritability, lethargy • Hyperflexia, seizures • Anorexia, nausea, vomiting • Hypotension, shock	• Plasma sodium > 145 mEq/L • Increased serum osmolality • Increased thirst, oliguria, increased urine specific gravity • Dry skin and mucous membranes, decreased skin turgor, furrowed tongue, dry mouth • Headache, restlessness • Seizures, coma • Tachycardia, hypotension, vascular collapse

In contrast, when blood volume expands, more sodium and water are eliminated by the kidneys:

- The glomerular filtration rate increases, allowing more water and sodium to be filtered and excreted.
- The hormone ANP is released by cells in the atria of the heart. ANP increases renal blood flow and glomerular filtration rate and also inhibits the aldosterone secretion to increase sodium excretion by the kidneys.
- ADH release from the pituitary gland is inhibited by ANP. In the absence of ADH, the distal tubule is relatively impermeable to water, allowing more to be excreted in the urine.

Table 10–5 summarizes the manifestations of sodium imbalances.

The Patient with Hyponatremia

Hyponatremia is a serum sodium level of less than 135 mEq/L. Hyponatremia usually results from a loss of sodium from the body, but it may also be caused by water gains that dilute ECF.

PATHOPHYSIOLOGY

Excess sodium loss can occur through the kidneys, GI tract, or skin. Diuretics, kidney diseases, or adrenal insufficiency with impaired aldosterone and cortisol production can lead to excessive sodium excretion in urine. Vomiting, diarrhea, and GI suction are common causes of excess sodium loss through the GI tract. Neurologic conditions, such as stroke, cerebral hemorrhage, trauma, or surgery can cause cerebral salt wasting (Tocco, 2010). Excessive sweating, loss of skin surface (as with an extensive burn), and third spacing can also cause excessive sodium loss.

Hyponatremia causes a decrease in serum osmolality. Water shifts from ECF into the intracellular space, causing cells to swell. Many of the manifestations of hyponatremia can be attributed to cellular edema, cerebral edema in particular. Water gains that can lead to hyponatremia may occur with systemic diseases such as heart failure, renal failure, or cirrhosis of the liver; syndrome of inappropriate secretion of antidiuretic hormone (SIADH); excessive administration of hypotonic IV fluids; and self-induced water intoxication.

MANIFESTATIONS

The manifestations of hyponatremia depend on the rapidity of onset, the severity, and the cause of the imbalance. If the condition develops slowly, manifestations are usually not experienced until the serum sodium levels reach 125 mEq/L. In addition, the manifestations of hyponatremia vary, depending on extracellular fluid volume. Early manifestations of hyponatremia include muscle cramps, weakness, and fatigue from its effects on muscle cells. Gastrointestinal function is affected, causing anorexia, nausea and vomiting, and abdominal cramping.

As sodium levels continue to decrease, the brain and nervous system swell, causing cerebral edema. Neurologic manifestations progress rapidly when the serum sodium level falls below 120 mEq/L and include headache, depression, dulled sensorium, personality changes, irritability, lethargy, hyperreflexia, muscle twitching, and seizures. If serum sodium falls to very low levels, coma is likely to occur. When hyponatremia is associated with decreased ECF volume, the manifestations are those of hypovolemia (*hypovolemic hyponatremia*). In dilutional hyponatremia, associated with fluid volume excess, manifestations include those of hypervolemia.

●○● INTERPROFESSIONAL CARE

Interprofessional management of hyponatremia focuses on restoring normal blood volume and serum sodium levels.

DIAGNOSIS

The following laboratory tests may be ordered:

- *Serum sodium* and *osmolality* are decreased in hyponatremia.
- A *24-hour urine specimen* is obtained to evaluate sodium excretion. In conditions associated with normal or increased extracellular volume (such as SIADH), urinary sodium is increased; in conditions resulting from losses of isotonic fluids (e.g., sweating, diarrhea, vomiting, and third-space fluid accumulation), by contrast, urinary sodium is decreased.

MEDICATIONS

When both sodium and water have been lost (hyponatremia with hypovolemia), sodium-containing fluids are given to replace both water and sodium. Isotonic Ringer's solution or isotonic saline (0.9% NaCl) solution may be administered. Cautious administration of IV 3% NaCl solution may be necessary in patients who have very low plasma sodium levels (110 to 115 mEq/L).

PRACTICE ALERT!

Carefully monitor patients receiving sodium-containing IV solutions for manifestations of hypervolemia (increased blood pressure, bounding pulses, tachypnea, tachycardia, gallop rhythm [S_3 and/or S_4 heart sounds], shortness of breath, crackles). Hypertonic saline solutions can lead to hypervolemia, particularly in patients with cardiovascular or renal disease.

Loop diuretics (e.g., furosemide) are administered to patients who have hyponatremia with normal or excess ECF volume. Loop diuretics promote an isotonic diuresis and fluid volume loss without hyponatremia. Oral salt tablets are given concurrently to correct the sodium loss associated with diuresis (Mount, 2012). In addition, drugs to treat the underlying cause of hyponatremia may be administered.

FLUID AND DIETARY MANAGEMENT

If hyponatremia is mild (serum sodium 130 mEq/L or higher), increasing the intake of foods high in sodium may restore normal sodium balance. Fluids often are restricted to help reduce ECF volume and correct hyponatremia (refer to Box 10–1 for fluid restriction guidelines).

●○● NURSING CARE

Nursing care of the patient with hyponatremia focuses on identifying patients at risk and managing problems resulting from the systemic effects of the disorder.

Health Promotion

People at risk for mild hyponatremia include those who participate in activities that increase fluid loss through excessive perspiration (diaphoresis) and then replace those losses by drinking large amounts of water or drinks with high sugar content. This includes athletes, people who do heavy labor in high environmental temperatures, and older adults living in non–air-conditioned settings during hot weather. Teach the following to patients who are at risk:

- Manifestations of mild hyponatremia, including headache, nausea, abdominal cramps, and muscle weakness
- The importance of drinking liquids containing sodium and other electrolytes at frequent intervals when perspiring heavily, when environmental temperatures are high, and/or if watery diarrhea persists for several days.

Assessment

Assessment data related to hyponatremia include the following:

- ***Health history:*** current manifestations, including nausea and vomiting, abdominal discomfort, muscle weakness, headache, other manifestations; duration of manifestations and any precipitating factors such as heavy perspiration, vomiting, or diarrhea; chronic diseases such as heart or renal failure, cirrhosis of the liver, or endocrine disorders; current medications
- ***Physical assessment:*** mental status and level of consciousness; vital signs including orthostatic vital signs and peripheral pulses; presence of edema or weight gain.

Priorities of Care

Cerebral edema and impaired neurologic function present the greatest dangers in hyponatremia; thus restoring sodium and water balance and preventing complications of cerebral edema are priority nursing actions.

Diagnoses, Outcomes, and Interventions

Risk for Imbalanced Fluid Volume

Because of its role in maintaining fluid balance, sodium imbalances often are accompanied by water imbalances. In addition, treatment of hyponatremia can affect the patient's fluid balance.

Expected Outcome: Patient's fluid and electrolyte balance will be restored without adverse effects of treatment.

- Monitor intake and output, weigh daily, and calculate 24-hour fluid balance. *Fluid excess or deficit may occur with hyponatremia.*

- Use an infusion pump to administer hypertonic saline (3% NaCl) solutions; carefully monitor flow rate and response. *Hypertonic solutions can increase the risk of pulmonary and cerebral edema due to water retention. Careful monitoring is vital to prevent these complications and possible permanent damage.*
- If fluids are restricted, explain the reason for the restriction, the amount of fluid allowed, and how to calculate fluid intake. *Teaching increases the patient's sense of control and compliance.*

For additional nursing interventions that may apply to the patient with hyponatremia, review the discussions of fluid volume deficit and fluid volume excess.

Risk for Ineffective Cerebral Tissue Perfusion

The patient with severe hyponatremia experiences fluid shifts that increase the intracellular fluid volume. This can cause brain cells to swell, increasing pressure within the cranial vault.

Expected Outcome: Patient's neurologic function will remain intact as evidenced by level of consciousness (LOC), orientation, mental status, and muscle strength and tone.

- Monitor serum electrolytes and serum osmolality. Report abnormal results to the healthcare provider. *As serum sodium and osmolality levels fall, the manifestations and neurologic effects of hyponatremia become increasingly severe.*
- Assess for neurologic changes, such as lethargy, altered LOC, confusion, and convulsions. Monitor mental status and orientation. Compare baseline data with continuing assessments. Institute seizure precautions as indicated. *If serum sodium levels continue to fall, the patient may become increasingly less responsive.*
- Assess muscle strength and tone, and deep tendon reflexes. *Increased muscle weakness and decreased deep tendon reflexes are manifestations of increasing hyponatremia.*

Delegating Nursing Care Activities

As appropriate and allowed by the designated duties and responsibilities of assistive personnel, the nurse may delegate nursing care activities such as measuring intake and output and obtaining daily weights for the patient with hyponatremia.

Continuity of Care

Teaching for home care focuses on the underlying cause of the sodium deficit and prevention. Teach patients about the following:

- Manifestations of mild and more severe hyponatremia to report to the primary care provider
- The importance of regular serum electrolyte monitoring if taking a potent diuretic or on a low-sodium diet
- Types of foods and fluids to replace sodium orally if dietary sodium is not restricted
- Older adults' increased risk for hyponatremia from the effects of medications and potential fluid imbalances.

The Patient with Hypernatremia

Hypernatremia is a serum sodium level greater than 145 mEq/L. It usually develops when water is lost in excess of sodium, but may also occur when excessive sodium is ingested or administered. Older adults with diminished thirst or who have limited access to water are at particular risk for hypernatremia (Mount, 2012).

PATHOPHYSIOLOGY

Two regulatory mechanisms protect the body from hypernatremia: Excess sodium in ECF stimulates the release of ADH so more water is retained by the kidneys, and the thirst mechanism is stimulated to increase the intake of water. These two factors increase extracellular water, diluting the excess sodium and restoring normal levels.

Hypernatremia causes hyperosmolality of the ECF. As a result, water is drawn out of cells, leading to cellular dehydration. The most serious effects of cellular dehydration are seen in the brain. As brain cells contract, neurologic manifestations develop. The brain itself shrinks, causing mechanical traction on cerebral vessels. These vessels may tear and bleed. Although the brain rapidly adapts to hyperosmolality to minimize the water loss, acute hypernatremia can cause coma and seizures (Grossman & Porth, 2014).

Water deprivation is a cause of hypernatremia in patients who are unable to respond to thirst due to altered mental status or physical disability. Excess water loss may also occur with watery diarrhea or increased water losses from fever, hyperventilation, or massive burns. Osmotic diuresis, such as that caused by hyperglycemia or an osmotic diuretic, can lead to excess water loss via the kidneys. Excess sodium intake can result from ingestion of excess salt or hypertonic IV solutions. Patients who experience near-drowning in seawater are at risk for hypernatremia, as are patients with heatstroke.

MANIFESTATIONS

Thirst is the first manifestation of hypernatremia. If thirst is not relieved, the primary manifestations relate to altered neurologic function (refer to Table 10–5). Initial lethargy, weakness, and irritability can progress to seizures, coma, and death in severe hypernatremia. Both the severity of the sodium excess and the rapidity of its onset affect the manifestations of hypernatremia.

●○● INTERPROFESSIONAL CARE

Treatment of hypernatremia depends on its cause. Hypernatremia is corrected slowly (over a 48-hour period) to avoid development of cerebral edema secondary to a shift of water into the brain cells.

DIAGNOSIS

The following laboratory and diagnostic tests may be ordered:

- *Serum sodium levels* are greater than 145 mEq/L in hypernatremia.
- *Serum osmolality* is greater than 295 mOsm/kg in hypernatremia.

MEDICATIONS

The principal treatment for hypernatremia is oral, enteral, or IV water replacement. Hypotonic IV fluids such as 0.45% NaCl solution or 5% dextrose in water (which is isotonic when administered, but becomes hypotonic and provides pure water when the glucose is metabolized) may be administered to correct the water deficit. Diuretics may also be given to increase sodium excretion (Lukitsch, 2012).

●○● NURSING CARE

The primary focus of nursing care related to hypernatremia is prevention. Measures to prevent hypernatremia include identifying risk factors, teaching patients and caregivers, monitoring laboratory test results, and collaborating with the interprofessional team to reduce the potential for hypernatremia.

Health Promotion

Patients at risk for hypernatremia, as well as their caregivers, need teaching to prevent this electrolyte disorder. Instruct caregivers of debilitated patients who are unable to perceive thirst or unable to respond to it to offer fluids at regular intervals. If the patient is unable to maintain adequate fluid intake, contact the healthcare provider about an alternate route for fluid intake (e.g., a feeding tube). Teach caregivers the importance of providing adequate water for patients receiving tube feedings (many of which are hypertonic).

Assessment

Assessment data related to hypernatremia include the following:

- ***Health history:*** duration of manifestations and any precipitating factors such as water deprivation, increased water loss due to heavy perspiration, temperature or rapid breathing, diarrhea, excess salt intake, diabetes mellitus or insipidus; current medications; perception of thirst
- ***Physical assessment:*** vital signs, mucous membranes; mental status or level of consciousness; manifestations of fluid volume excess or fluid volume deficit.

Priorities of Care

Mental status and brain function may be affected by hypernatremia itself or by rapid correction of the condition that leads to cerebral edema. In either case, precautions to reduce the risk of injury are a priority.

Diagnoses, Outcomes, and Interventions

Risk for Injury

Expected Outcome: Patient will remain free of injury.

- Monitor and maintain fluid replacement to within the prescribed limits. Monitor serum sodium levels and osmolality; report rapid changes to the care provider. *Rapid water replacement or rapid changes in serum sodium or osmolality can increase the risk of bleeding or cerebral edema.*
- Monitor neurologic function, including mental status, level of consciousness, and other manifestations such as headache, nausea, vomiting, hypertension, and bradycardia. *Both hypernatremia and rapid correction of hypernatremia affect cerebral function. Careful monitoring is vital to detect changes in mental status that may indicate cerebral bleeding or edema.*
- Institute safety precautions as necessary: Keep the bed in its lowest position, side rails up and padded, and an airway at bedside. *Patients with sodium disorders are at risk for injury due to seizure activity and changes in mental status.*
- Orient to time, place, and circumstances as needed. Allow significant others to remain with the patient as much as possible. *An unfamiliar environment and altered thought processes can further increase the patient's risk for injury. Significant others provide a sense of security and reduce the patient's anxiety.*

Delegating Nursing Care Activities

As appropriate and allowed within the designated duties, the nurse may enlist assistive personnel in monitoring and recording vital signs and intake and output; obtaining daily weights; promoting safety; and providing oral and skin care for the patient with hypernatremia.

Continuity of Care

When preparing the patient who has experienced hypernatremia for continuing care, discuss the following topics with the patient and caregivers:

- The importance of responding to thirst and consuming adequate fluids (If the patient is dependent on a caregiver, stress to the caregiver the importance of regularly offering fluids.)
- If prescribed, guidelines for following a low-sodium diet (refer to Box 10–2)
- The importance of following a schedule for regular monitoring of serum electrolyte levels and reporting manifestations of imbalance to healthcare provider.

POTASSIUM IMBALANCE

Potassium, the primary intracellular cation, plays a vital role in cell metabolism and cardiac and neuromuscular function. The normal serum (ECF) potassium level is 3.5 to 5.3 mEq/L. To maintain balance, potassium must be replaced daily through diet. Virtually all foods contain potassium, although some foods and fluids are richer sources of this element than others.

Most potassium in the body is found within the ICF, which has a concentration of 140 to 150 mEq/L. This significant difference in the potassium concentrations of ICF and ECF helps maintain the resting membrane potential of nerve and muscle cells. Potassium imbalances affect transmission and conduction of nerve impulses, maintenance of normal cardiac rhythms, and contraction of skeletal and smooth muscle. The higher intracellular potassium concentration is maintained by the sodium-potassium pump. Potassium constantly shifts into and out of the cells. This movement between ICF and ECF can significantly affect the serum potassium level. For example, potassium shifts into or out of the cells in response to changes in hydrogen ion concentration (pH, discussed later in this chapter) as the body strives to maintain a stable acid–base balance.

Aldosterone helps regulate potassium elimination by the kidneys. An increased potassium concentration in ECF stimulates aldosterone production by the adrenal gland. The kidneys respond to aldosterone by increasing potassium excretion. Changes in aldosterone secretion can profoundly affect the serum potassium level.

The Patient with Hypokalemia

Hypokalemia is an abnormally low serum potassium level (less than 3.5 mEq/L). It usually results from excess potassium loss, although hospitalized patients may be at risk for hypokalemia because of inadequate potassium intake.

PATHOPHYSIOLOGY

Hypokalemia may result from inadequate intake of potassium; excessive renal or intestinal losses; or redistribution between the ICF and ECF. An intake of a minimum of 40 to 50 mEq/day is needed to compensate for urinary losses (Grossman & Porth, 2014). The kidneys are the main source of potassium excretion. Infectious diarrhea is the most common cause of hypokalemia worldwide (Cho, 2012).

Renal and gastrointestinal losses deplete total potassium stores in the body, as can loss of potassium in perspiration.

- Excess potassium loss through the kidneys often is secondary to drugs such as potassium-wasting diuretics, corticosteroids,

amphotericin B, and large doses of some antibiotics. Hyperaldosteronism, a condition in which the adrenal glands secrete excess aldosterone, also causes excess elimination of potassium through the kidneys. Renal losses of potassium also occur from stress, trauma, metabolic acidosis, and a magnesium deficit.

- Gastrointestinal losses of potassium are usually the result of loss of intestinal fluids through diarrhea or ileostomy drainage.

Transcellular potassium shifts (from the ECF to the ICF) occur in conditions such as metabolic alkalosis and treatment of diabetic ketoacidosis with insulin (insulin increases the movement of potassium into the cells).

Potassium intake may be inadequate in patients who are unable or unwilling to eat for prolonged periods. Hospitalized patients are at risk, especially those on extended parenteral fluid therapy with solutions that do not contain potassium. Patients with anorexia nervosa or alcoholism may develop hypokalemia due to both inadequate intake and loss of potassium through vomiting, diarrhea, or laxative or diuretic use.

MANIFESTATIONS

Hypokalemia affects the transmission of nerve impulses, interfering with the contractility of smooth, skeletal, and cardiac muscle, as well as the regulation and transmission of cardiac impulses. Carbohydrate metabolism is affected by hypokalemia. Insulin secretion is suppressed, as is the synthesis of glycogen in skeletal muscle and the liver.

See the Pathophysiology Linkage box for manifestations of hypokalemia. Manifestations of hypokalemia are more pronounced when potassium losses occur acutely. When hypokalemia develops gradually, potassium shifts out of the cells, helping maintain the ratio of intracellular to extracellular potassium. As a result, the neuromuscular manifestations of hypokalemia are less severe. See the Multisystem Effects of Hypokalemia feature.

●○● INTERPROFESSIONAL CARE

The management of hypokalemia focuses on preventing a deficiency and treating imbalances.

DIAGNOSIS

The following laboratory and diagnostic tests may be ordered:

- *Serum potassium* (K^+) is used to monitor potassium levels in patients who are at risk for or who are being treated for hypokalemia.
- *Serum electrolytes (Na^+, Ca^{2+}, HCO_3^-, and Mg^{2+})* are evaluated because imbalances often occur concurrently.
- *Arterial blood gases (ABGs)* are measured to determine acid–base status. An increased pH (alkalosis) often is associated with hypokalemia. (See Table 10–9 later in this chapter for normal ABG values.)
- *Renal function studies*, such as *serum creatinine* and *blood urea nitrogen (BUN)*, may be ordered to evaluate for potential causes or effects of hypokalemia.
- *ECG recordings* are obtained to evaluate the effects of hypokalemia on the cardiac conduction system.

MEDICATIONS

Oral and/or parenteral potassium supplements are given to prevent and, as needed, treat hypokalemia. To prevent hypokalemia in the patient taking nothing by mouth, potassium chloride is added to IV fluids. The dose used to treat hypokalemia includes the daily maintenance requirement, replacement of ongoing losses (e.g., gastric suction), and additional potassium to correct the existing deficit. Several days of therapy may be required. Commonly prescribed potassium supplements, their actions, and nursing implications are described in the Medication Administration box.

PATHOPHYSIOLOGY LINKAGE

Hypokalemia

Manifestations	Related Pathophysiology
Muscle weakness and leg cramps, initially affecting lower extremities, then trunk and upper extremities	Low potassium levels affect the resting membrane potential and intracellular enzymes in skeletal muscle cells. Muscle effects of hypokalemia are magnified when serum calcium levels are high.
Nausea and vomiting, anorexia, decreased bowel sounds, ileus	Low potassium levels have the same effects as above on smooth muscle cells, slowing peristalsis of the GI tract.
Electrocardiogram (ECG) changes include flattened T waves, the development of U waves, and a depressed ST segment (see Figure 10–10B on page 201); atrial and ventricular dysrhythmias (abnormal rhythms)	Low potassium levels interfere with the regulation and transmission of cardiac impulses, which maintain normal cardiac rhythms.
Decreased cardiac output	Low potassium levels interfere with the contractility of cardiac muscle. Decreased strength of cardiac contractions and dysrhythmias in turn cause cardiac output to fall.
Increased risk of digoxin toxicity	Decreased competition between potassium and digoxin occurs at shared binding sites in cardiac muscle (Mount, 2012).
Polyuria, altered kidney function	Decreased sensitivity to ADH affects ability to concentrate urine. Severe hypokalemia can lead to rhabdomyolysis with release of myoglobin, a body protein toxic to the kidneys.

NUTRITION

A diet high in potassium-rich foods is recommended for patients at risk for developing hypokalemia or to supplement drug therapy. Examples of foods high in potassium include bananas, oranges, avocados, spinach, potatoes, tomatoes, meat, seafood, milk, and yogurt.

●○● NURSING CARE

Health Promotion

When providing general health education, discuss using balanced electrolyte solutions (e.g., Pedialyte or sports drinks) to replace abnormal fluid losses (excess perspiration, vomiting, or severe diarrhea). Discuss the necessity of preventing hypokalemia with patients at risk. Provide diet teaching and refer patients with anorexia nervosa for counseling. Stress the potassium-losing effects of diuretics. Encourage a diet rich in high-potassium foods, as well as regular monitoring of serum potassium levels.

Assessment

Assessment data related to hypokalemia include the following:

- ***Health history:*** current manifestations, including anorexia, nausea and vomiting, abdominal discomfort, muscle weakness or cramping, other manifestations; duration of manifestations and any precipitating factors such as diuretic use, prolonged vomiting or diarrhea; chronic diseases such as diabetes, hyperaldosteronism, or Cushing's syndrome; current medications
- ***Physical assessment:*** mental status; vital signs including orthostatic vitals, apical and peripheral pulses; bowel sounds, abdominal distention; muscle strength and tone.

Priorities of Care

The effects of hypokalemia on cardiac impulse transmission and cardiac and skeletal muscle function are the highest priorities for nursing care.

Diagnoses, Outcomes, and Interventions

Decreased Cardiac Output

Hypokalemia affects the strength of cardiac contractions and can lead to dysrhythmias that further impair cardiac output. Hypokalemia also alters the response to cardiac drugs, such as digitalis and the antidysrhythmics.

Expected Outcome: Patient will maintain adequate cardiac output as evidenced by clear mentation, stable vital signs, pink and warm skin, and urine output greater than 30 mL/h.

- Monitor serum potassium levels in patients at risk for hypokalemia (those with excess losses due to drug therapy, GI losses, or who are unable to consume a normal diet). Report abnormal levels to the healthcare provider. *Potassium must be replaced daily because the body is unable to conserve it. Either lack of intake or abnormal losses of potassium in the urine or gastric fluids can lead to hypokalemia.*
- Monitor vital signs, including orthostatic vitals and peripheral pulses. *As cardiac output falls, the pulse becomes weak and thready. Orthostatic hypotension may be noted with decreased cardiac output.*

PRACTICE ALERT!

Severe hypokalemia (serum potassium < 2.5 mEq/L) can cause life-threatening dysrhythmias. Place a cardiac monitor on patients with severe hypokalemia and closely monitor cardiac rhythm. Observe for characteristic ECG changes of hypokalemia (ST segment depression, flattened T waves, and U waves). Report rhythm changes immediately.

MEDICATION ADMINISTRATION

Hypokalemia

POTASSIUM SOURCES

Potassium acetate (Tri-K)

Potassium bicarbonate (K + Care ET)

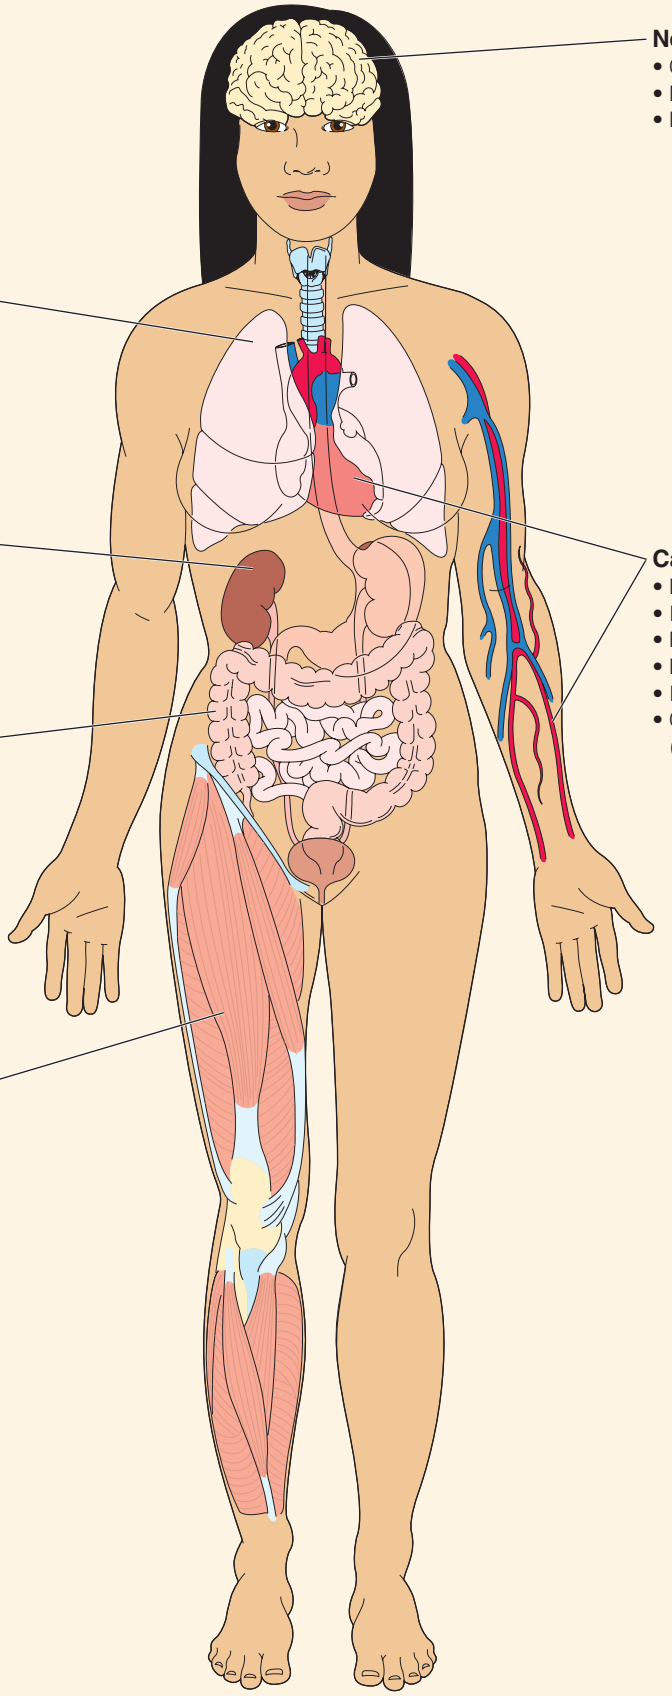
Potassium citrate (K-Lyte)

Potassium chloride (K-Lease, Micro-K 10, Apo-K)

Potassium gluconate (Kaon Elixir, Royonate)

Potassium is rapidly absorbed from the GI tract; potassium chloride is the agent of choice, because low chloride often accompanies low potassium. Potassium is used to prevent and/or treat hypokalemia (e.g., with parenteral nutrition and potassium-wasting diuretics, and prophylactically after major surgery).

Nursing Responsibilities



- When giving oral forms of potassium:
  a. Dilute or dissolve effervescent, soluble, or liquid potassium in fruit or vegetable juice or cold water.
  b. Chill to increase palatability.
  c. Give with food to minimize GI effects.
- When giving parenteral forms of potassium (KCl):
  a. Infuse at a rate not to exceed 10 mEq/h.
  b. Do **NOT** administer IV push, and do not add to fluids already hanging.
  c. Do **NOT** administer undiluted.
  d. Assess injection site frequently for manifestations of pain and inflammation. Discontinue and restart in another vein at first sign of infiltration.
  e. Use an infusion pump.
  f. Use cardiac monitoring if high doses are administered.
- Assess for abdominal pain, distention, GI bleeding; if present, do not administer medication. Notify healthcare provider.
- Monitor fluid intake and output.
- Assess for manifestations of hyperkalemia: weakness, feeling of heaviness in legs, mental confusion, hypotension, cardiac dysrhythmias, changes in ECG, increased serum potassium levels.

Health Education for the Patient and Family

- Do not take potassium supplements if you are also taking a potassium-sparing diuretic.
- When parenteral potassium is discontinued, eat potassium-rich foods.
- Do not chew enteric-coated tablets or allow them to dissolve in the mouth; this may affect the potency and action of the medications.
- Take potassium supplements with meals.
- Do not use salt substitutes when taking potassium (most salt substitutes are potassium based).

Note: Drugs identified in *italics* are among the 200 most commonly prescribed medications in the U.S.

MULTISYSTEM EFFECTS OF Hypokalemia

Neurologic
- Confusion
- Depression
- Lethargy

Respiratory
- Respiratory arrest (severe hypokalemia)

Urinary
- Dilute urine
- Polyuria
- Polydipsia

Cardiovascular
- Dysrhythmias
- Irregular pulse
- Postural hypotension
- ECG (conduction) abnormalities
- Increased risk of digitalis toxicity
- Cardiac arrest (severe hypokalemia)

Gastrointestinal
- Nausea and vomiting
- Anorexia
- Diarrhea
- Decreased bowel sounds
- Ileus

Musculoskeletal
- Fatigue
- Leg cramps
- Muscle weakness
- Poor muscle tone
- Paresthesias, paralysis

- Monitor patients taking digitalis for toxicity (such as fatigue, weakness, confusion, dizziness, hypotension, nausea). Monitor response to antidysrhythmic drugs. *Hypokalemia potentiates digitalis effects and increases resistance to certain antidysrhythmics.*
- Dilute IV potassium as prescribed and administer using an infusion pump. Closely monitor IV flow rate and response to potassium replacement (Metheny, 2012). *Rapid potassium administration is dangerous and can lead to hyperkalemia and cardiac arrest.*

SAFETY ALERT

Never administer undiluted potassium directly into the vein.

Activity Intolerance

Muscle cramping and weakness are common early manifestations of hypokalemia. The lower extremities are usually affected first. This muscle weakness can cause the patient to fatigue easily, particularly with activity.

Expected Outcome: Patient will resume and tolerate usual activities.

- Monitor skeletal muscle strength and tone, which are affected by moderate hypokalemia. *Increasing weakness, paresthesias, or paralysis of muscles or progression of affected muscles to include the upper extremities or trunk can indicate a further drop in serum potassium levels.*
- Monitor respiratory rate, depth, and effort; heart rate and rhythm; and blood pressure at rest and following activity. *Tachypnea, dyspnea, tachycardia, and/or a change in blood pressure may indicate decreasing ability to tolerate activities. Report changes to the healthcare provider.*
- Assist with self-care activities as needed. *Increasing muscle weakness can lead to fatigue and affect the ability to meet self-care needs.*

Risk for Imbalanced Fluid Volume

Expected Outcome: Patient will maintain fluid balance.

- Maintain accurate intake and output records. *Gastrointestinal fluid losses can lead to significant potassium losses.*
- Monitor bowel sounds and abdominal distention. *Hypokalemia affects smooth muscle function and can lead to slowed peristalsis and paralytic ileus.*

Delegating Nursing Care Activities

As appropriate, the nurse may delegate nursing care activities such as obtaining vital signs, measuring intake and output, and assisting the patient with self-care activities to assistive personnel.

Continuity of Care

The focus in teaching the patient with or at risk for hypokalemia is prevention by self-care practices. Include the following topics when preparing the patient and family for home care:

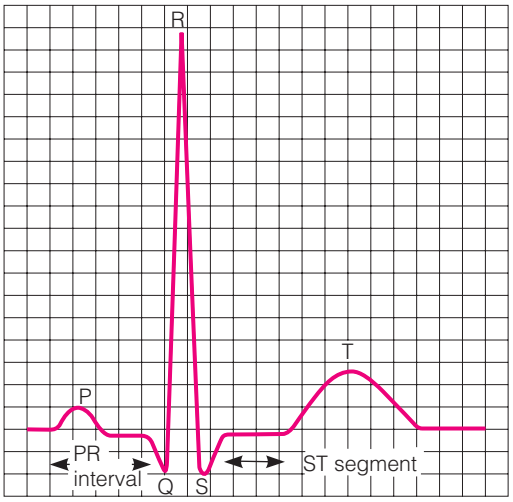
- Recommended diet, including a list of potassium-rich foods
- Prescribed medications and potassium supplements, their use, and desired and unintended effects
- Using salt substitutes (if recommended) to increase potassium intake; avoiding substitutes if taking a potassium supplement or potassium-sparing diuretic
- Manifestations of potassium imbalance (hypokalemia or hyperkalemia) to report to healthcare provider
- Recommendations for monitoring serum potassium levels
- If taking digoxin, manifestations of digoxin toxicity to report to healthcare provider
- Managing GI disorders that cause potassium loss (vomiting, diarrhea, ileostomy drainage) to prevent hypokalemia.

Moving Knowledge into Action

Rose Ortiz is a 72-year-old widow who has mild heart failure and is being treated with digoxin (Lanoxin) 0.125 mg, furosemide (Lasix) 40 mg PO daily, and a sodium-restricted diet (1500 mg daily). She reveals that she occasionally takes an extra water pill when she eats something salty and her ankles swell. Ms. Ortiz is now complaining that she feels weak and sometimes faint, light-headed, and dizzy. Serum electrolytes reveal a potassium level of 2.4 mEq/L. Potassium chloride (K-dur 20 mEq) PO twice daily is prescribed.

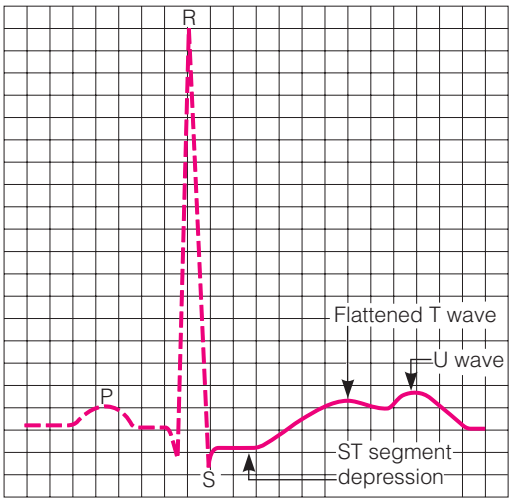
1. Describe the pathophysiology causing Ms. Ortiz's muscle weakness and dizziness. How did taking an occasional extra furosemide tablet contribute to her symptoms?
2. Ms. Ortiz identifies herself as White Hispanic. How might this affect your teaching regarding potassium-rich foods to include in her diet?
3. Ms. Ortiz says she is reluctant to take potassium because her neighbor complains that his potassium tablets upset his stomach. What information does Ms. Ortiz need about her prescribed medications and their potential interactions?

The Patient with Hyperkalemia



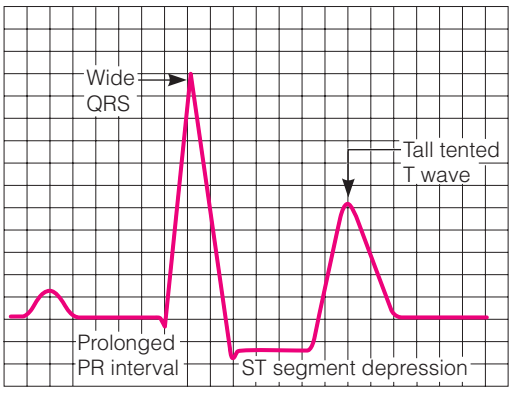
Hyperkalemia is an abnormally high serum potassium (greater than 5.3 mEq/L). Hyperkalemia can result from inadequate excretion of potassium, excessively high intake of potassium, or a shift of potassium from the ICF to the ECF. Hyperkalemia affects neuromuscular and cardiac function.

PATHOPHYSIOLOGY



Impaired renal excretion of potassium is a primary cause of hyperkalemia. Untreated renal failure, adrenal insufficiency (e.g., Addison's disease or inadequate aldosterone production), and medications (such as potassium-sparing diuretics, ACE inhibitors, or angiotensin-receptor blockers [ARBs]) impair potassium excretion by the kidneys (Mount, 2012).

Rapid IV administration of potassium or transfusion of aged blood can lead to hyperkalemia. A shift of potassium ions from the ICF can occur in acidosis, with severe tissue trauma, during chemotherapy, and due to starvation. In acidosis, excess hydrogen ions enter the cells, displacing potassium and causing it to shift into the extracellular space. The extent of this shift is greater with metabolic acidosis than with respiratory acidosis (see the Acid–Base Disorders section later in this chapter).



Hyperkalemia alters the cell membrane potential, affecting the heart, skeletal muscle function, and the GI tract. The most harmful consequence of hyperkalemia is its effect on cardiac function. The cardiac conduction system is affected first, with slowing of the heart rate, possible heart blocks, and prolonged depolarization. ECG changes include peaked T waves, a prolonged PR interval, and widening of the QRS complex (Figure 10–10 ■). Ventricular dysrhythmias develop, and cardiac arrest may occur, especially in severe hyperkalemia

A Normal ECG

B ECG in hypokalemia

C ECG in hyperkalemia

Figure 10–10 ■ The effects of changes in potassium levels on an ECG. A, Normal ECG. B, ECG in hypokalemia. C, ECG in hyperkalemia.

(serum K^+ greater than 8 mEq/L). Severe hyperkalemia decreases the strength of cardiac and skeletal muscle contractions.

MANIFESTATIONS

The manifestations of hyperkalemia result from its effects on the heart, skeletal, and smooth muscles. Early manifestations include diarrhea, colic (abdominal cramping), anxiety, paresthesias, irritability, and muscle tremors and twitching. As serum potassium levels increase, muscle weakness develops, progressing to flaccid paralysis. The lower extremities are affected first, progressing to the trunk and upper extremities. The heart rate may be slow (bradycardia) and irregular. See the accompanying Pathophysiology Linkage feature.

●○● INTERPROFESSIONAL CARE

The management of hyperkalemia focuses on returning the serum potassium level to normal by treating the underlying cause and avoiding additional potassium intake. The choice of therapy for existing hyperkalemia is based on the severity of the hyperkalemia.

DIAGNOSIS

The following laboratory and diagnostic tests may be ordered:

- *Serum electrolytes* show a serum potassium level greater than 5.3 mEq/L. Low calcium and sodium levels may increase the effects of hyperkalemia; therefore, these electrolytes are usually measured as well.
- *ABGs* are measured to determine if acidosis is present.
- An *ECG* is obtained and *continuous ECG monitoring* is instituted to evaluate the effects of hyperkalemia on cardiac conduction and rhythm.

MEDICATIONS

Medications are administered to lower the serum potassium and to stabilize the conduction system of the heart. If renal function is normal, diuretics such as furosemide are given to promote potassium excretion. For moderate to severe hyperkalemia, calcium gluconate is given IV to counter the effects of hyperkalemia on the cardiac conduction system. Although the effect of calcium gluconate lasts for only 1 hour, it allows time to initiate measures to lower serum potassium levels. To rapidly lower these levels, regular insulin and 50 g of glucose are administered. Insulin and glucose promote potassium uptake by the cells, shifting potassium out of ECF. In addition to insulin and glucose, a β_2-agonist such as albuterol may be given by nebulizer to enhance potassium movement into the cells.

To remove potassium from the body, sodium polystyrene sulfonate (SPS Suspension, Kayexalate), a resin that binds potassium in the GI tract, may be administered orally or rectally. Commonly prescribed drugs, their actions, and nursing implications are listed in the accompanying Medication Administration box.

DIALYSIS

When renal function is severely limited, either peritoneal dialysis or hemodialysis may be implemented to remove excess potassium. These measures are invasive and typically used only when other measures are ineffective.

●○● NURSING CARE

Nursing care interventions related to hyperkalemia include identifying patients at risk, preventing hyperkalemia, and addressing problems resulting from the systemic effects of hyperkalemia. See the Case Study & Nursing Care Plan for a patient with hyperkalemia on page 204.

PATHOPHYSIOLOGY LINKAGE

Hyperkalemia

Manifestations	Related Pathophysiology
Cardiac manifestations: • ECG changes: peaked T waves, prolonged PR and QRS intervals	Mild increases in serum K^+ levels affect the repolarization phase of the cardiac action potential; further increases slow the cardiac conduction system.
• Dysrhythmias (bradycardia, heart blocks, ventricular tachycardia)	Slowed conduction and impaired repolarization allow development of abnormal rhythms.
• Possible cardiac arrest	Severe hyperkalemia (levels higher than 8 mEq/L) can lead to ventricular fibrillation or asystole, with no effective ventricular contractions and cardiac arrest.
Neuromuscular: • Paresthesias • Muscle tremors, twitching, and weakness • Ascending paralysis • Dyspnea; possible respiratory failure	Excess potassium in ECF interferes with the membrane potentials of cells, increasing the threshold needed to generate an action potential. This impairs neuromuscular function, affecting skeletal, smooth, and cardiac muscle. Effects initially are seen in lower extremities, progressing upward. If the diaphragm is affected, respiratory failure can result.
Gastrointestinal: • Abdominal cramping, ileus • Nausea, vomiting, diarrhea	The effect of hyperkalemia on smooth muscle can impair intestinal peristalsis.

Health Promotion

Patients at the greatest risk for developing hyperkalemia include those taking potassium supplements (prescribed or over the counter), using potassium-sparing diuretics or salt substitutes, and experiencing renal failure. Athletes participating in competition sports such as body building and those using anabolic steroids, muscle-building compounds, or energy drinks also may be at risk for hyperkalemia.

Teach all patients to carefully read food and dietary supplement labels. Discuss the importance of taking prescribed potassium supplements as ordered, and not increasing the dose unless prescribed by the care provider. Advise patients taking a potassium supplement or potassium-sparing diuretic to avoid salt substitutes, which usually contain potassium. Discuss the importance of maintaining an adequate fluid intake (unless a fluid restriction has been prescribed) to maintain renal function to eliminate potassium from the body.

Assessment

Assessment data related to hyperkalemia include the following:

- ***Health history:*** current manifestations, including numbness and tingling, nausea and vomiting, abdominal cramping, muscle weakness, palpitations; duration of manifestations and any precipitating factors such as use of salt substitutes, potassium supplements, or reduced urine output; chronic diseases such as renal failure or endocrine disorders; current medications
- ***Physical assessment:*** apical and peripheral pulses; bowel sounds; muscle strength in upper and lower extremities; ECG pattern.

Priorities of Care

The effects of excess potassium on the electrical conduction and contractility of the heart are the highest priority for nursing care, particularly when the serum potassium level is 6.5 mEq/L or higher.

Diagnoses, Outcomes, and Interventions

Risk for Decreased Cardiac Output

Hyperkalemia affects depolarization of the atria and ventricles of the heart. Severe hyperkalemia can cause dysrhythmias with ventricular fibrillation and cardiac arrest. The cardiac effects of hyperkalemia are more pronounced when the serum potassium level rises rapidly. Low serum sodium and calcium levels, high serum magnesium levels, and acidosis contribute to the adverse effects of hyperkalemia on the heart muscle.

Expected Outcome: Patient's cardiac output will remain within expected range for patient, as evidenced by clear mentation; warm, dry skin; and stable vital signs and urine output consistent with patient norms.

PRACTICE ALERT!

Monitor the ECG pattern for development of peaked, narrow T waves, prolongation of the PR interval, depression of the ST segment, widened QRS interval, and loss of the P wave (refer to Figure 10–10). Notify the physician of changes. Progressive ECG changes from a peaked T wave to loss of the P wave and widening of the QRS complex indicate an increasing risk of dysrhythmias and cardiac arrest (Metheny, 2012).

- Closely monitor the response to IV calcium gluconate, particularly in patients taking digitalis. *Calcium increases the risk of digitalis toxicity.*

Risk for Activity Intolerance

Both hypokalemia (low serum potassium levels) and hyperkalemia (high serum potassium levels) affect neuromuscular activity and the function of cardiac, smooth, and skeletal muscles. Hyperkalemia can cause muscle weakness and even paralysis.

Expected Outcome: Patient will resume normal activity without evidence of weakness, fatigue, or shortness of breath.

- Monitor skeletal muscle strength and tone. *Increasing weakness, muscle paralysis, or progression of affected muscles to affect the upper*

MEDICATION ADMINISTRATION

Hyperkalemia

DIURETICS
Potassium-wasting diuretics, such as furosemide (Lasix), may be used to enhance renal excretion of potassium.

Nursing Responsibilities
- Monitor serum electrolytes.
- Monitor and record weight at regular intervals under standard conditions (same time of day, balanced scale, same clothing).
- Monitor intake and output.

INSULIN, HYPERTONIC DEXTROSE, AND SODIUM BICARBONATE
Insulin, hypertonic dextrose (10% to 50%), and possibly sodium bicarbonate are used in the emergency treatment of moderate to severe hyperkalemia (serum potassium > 6.0 to 6.5 mEq/L). Insulin promotes the movement of potassium into the cell, and glucose prevents hypoglycemia. The onset of action of insulin and hypertonic dextrose occurs within 30 minutes and is effective for approximately 4 to 6 hours.

Sodium bicarbonate elevates the serum pH; potassium is moved into the cell in exchange for hydrogen ion. Sodium bicarbonate is used in the patient with metabolic acidosis (Perrin, 2012). Onset of effects occurs within 15 to 30 minutes and is effective for approximately 2 hours.

Nursing Responsibilities
- Administer IV insulin and dextrose over prescribed interval of time using an infusion pump.
- Administer sodium bicarbonate as prescribed. It may be administered as an IV bolus or added to a dextrose-in-water solution and given by infusion.
- In patients receiving sodium bicarbonate, monitor for sodium overload, particularly in patients with hypernatremia, heart failure, and renal failure.
- Monitor the ECG pattern closely.
- Monitor serum electrolytes (K^+, Na^+, Ca^{2+}, Mg^{2+}) frequently during treatment.

CALCIUM GLUCONATE AND CALCIUM CHLORIDE
IV calcium gluconate or calcium chloride is used as a temporary emergency measure to counteract the toxic effects of potassium on myocardial conduction and function.

Nursing Responsibilities
- Closely monitor the ECG of the patient receiving IV calcium, particularly for bradycardia.
- Calcium should be used cautiously in patients receiving digitalis, because calcium increases the cardiotonic effects of digitalis and may precipitate digitalis toxicity, leading to dysrhythmias.

SODIUM POLYSTYRENE SULFONATE (SPS, KAYEXALATE)
Sodium polystyrene sulfonate (SPS Suspension, Kayexalate) is used to treat moderate or severe hyperkalemia. Categorized as a cation exchange resin, SPS exchanges sodium or calcium for potassium in the large intestine. A laxative such as lactulose is given with SPS to promote bowel elimination. SPS may be administered orally, through a nasogastric tube, or rectally as a retention enema.

Nursing Responsibilities
- Because SPS contains sodium, monitor patients with heart failure and edema closely for water retention.
- Monitor serum electrolytes (K^+, Na^+, Ca^{2+}, Mg^{2+}) frequently during therapy.
- Restrict sodium intake in patients who are unable to tolerate increased sodium load (e.g., those with CHF or hypertension).
- SPS should not be given to patients at risk for intestinal necrosis, including patients who are postoperative, have a history of bowel obstruction, have ischemic bowel disease, or who have had a renal transplant.

extremities or trunk can indicate increasing serum potassium levels (Metheny, 2012).
- Monitor respiratory rate and depth. Regularly assess lung sounds. *Muscle weakness due to hyperkalemia can impair ventilation. In addition, medications such as sodium bicarbonate or sodium polystyrene sulfonate can cause fluid retention and pulmonary edema in patients with preexisting cardiovascular disease.*
- Assist with self-care activities as needed. *Increasing muscle weakness can lead to fatigue and affect the ability to meet self-care needs.*

Delegating Nursing Care Activities

As appropriate and allowed by the designated duties and responsibilities of assistive personnel, the nurse may delegate care activities such as measuring intake and output, obtaining daily weights, and assisting with self-care activities for the patient with hyperkalemia.

Continuity of Care

Preventing future episodes of hyperkalemia is the focus when preparing the patient for home care. Include the family, a significant other, or a caregiver when teaching the following topics:

- Recommended diet and any restrictions including salt substitutes and foods high in potassium
- Medications to be avoided, including over-the-counter and fitness supplements
- Early manifestations of hyperkalemia to be reported to the care provider.

CALCIUM IMBALANCE

Calcium is one of the most abundant ions in the body. The normal adult total serum calcium concentration is 9 to 11 mg/dL (4.5 to 5.5 mEq/)L. Calcium is obtained from dietary sources, although only about 20% of the calcium ingested is absorbed into the blood. The remainder is excreted in feces. Extracellular calcium is excreted by the kidneys. Approximately 99% of the total calcium in the body is bound to phosphorus to form the minerals in bones and teeth. The remaining 1% is in extracellular fluid. About half of this extracellular calcium is ionized (free); it is this ionized calcium that is physiologically active. The remaining extracellular calcium is bound to protein or other ions. Ionized calcium is essential to a number of processes: stabilizing cell membranes, regulating muscle contraction and relaxation, maintaining cardiac function, and blood clotting.

Serum calcium levels are regulated by the interaction of three hormones: parathyroid hormone (PTH), calcitonin, and calcitriol (a metabolite of vitamin D). When serum calcium levels fall, the parathyroid glands secrete PTH, which mobilizes skeletal calcium

CASE STUDY & NURSING CARE PLAN A Patient with Hyperkalemia

Montigue Longacre, a 51-year-old African American male, has end-stage renal failure. He arrives at the emergency clinic complaining of shortness of breath on exertion and extreme weakness.

ASSESSMENT

Mr. Longacre tells the nurse, Janet Allen, RN, that he normally receives dialysis three times a week. He missed his last treatment, however, to attend his father's funeral. During the past several days, he has eaten a number of fresh oranges he received as a gift. Physical assessment findings include T 37.3°C (99.2°F), P 100 bpm, R 28/min, BP 168/96 mmHg, 2+ pretibial edema, and a 3.6-kg (6-lb) weight gain since his last hemodialysis treatment 4 days ago. Laboratory and diagnostic tests show the following abnormal results:

- K^+: 6.5 mEq/L (normal 3.5 to 5.3 mEq/L)
- BUN: 118 mg/dL (normal 7 to 18 mg/dL)
- Creatinine: 14 mg/dL (normal 0.7 to 1.3 mg/dL)
- HCO_3^-: 17 mEq/L (normal 22 to 30 mEq/L)
- Peaked T wave noted on ECG.

Mr. Longacre is placed on continuous ECG monitoring, and the physician prescribes hemodialysis. As an interim measure to lower the serum potassium, the physician prescribes $D_{50}W$ (25 g of dextrose), one ampule, to be administered IV with 10 units of regular insulin over 30 minutes.

DIAGNOSES

- *Risk for Decreased Cardiac Output* related to hyperkalemia
- *Risk for Ineffective Health Maintenance* related to inadequate knowledge of recommended diet
- *Fluid Volume Excess* related to renal failure

EXPECTED OUTCOMES

- Patient will gradually resume usual physical activities.
- Patient will maintain serum potassium level within normal range.
- Patient will verbalize causes of hyperkalemia, the importance of having hemodialysis treatments as scheduled, and the role of diet in preventing hyperkalemia.

PLANNING AND IMPLEMENTATION

- Monitor intake and output.
- Monitor serum potassium and ECG closely during treatment.
- Teach causes of hyperkalemia and the relationship between hemodialysis and hyperkalemia.
- Discuss the importance of avoiding foods high in potassium to prevent or control hyperkalemia.

EVALUATION

Following treatment, Mr. Longacre's ECG and serum potassium level have returned to normal. His muscle strength has returned, and he verbalizes an understanding of his prescribed hemodialysis regimen. Janet Allen provides verbal and written information about hyperkalemia, the importance of complying with the hemodialysis regimen, and the importance of limiting intake of dietary sources of potassium in renal failure. She furnishes a list of foods high in potassium and cautions against using potassium-containing salt substitutes.

Clinical Reasoning in Patient Care

1. What information given by Mr. Longacre indicated that he might be experiencing hyperkalemia?
2. Why was continuous ECG monitoring instituted as an emergency measure?
3. What additional emergency measures might have been instituted if Mr. Longacre's serum potassium level had been 8.5 mEq/L and his ECG had showed changes in impulse conduction?
4. Develop a care plan for Mr. Longacre for the nursing diagnosis of *Readiness for Enhanced Coping.*

See Evaluating Your Response in Appendix B.

stores, increases calcium absorption in the intestines, and promotes calcium reabsorption by the kidneys (Figure 10–11 ■). Calcitriol facilitates this process by stimulating calcium release from the bones, absorption in the intestines, and reabsorption by the kidneys. Calcitonin is secreted by the thyroid gland in response to high serum calcium levels. Its effect on serum calcium levels is the opposite of PTH: It inhibits the movement of calcium out of bone, reduces intestinal absorption of calcium, and promotes calcium excretion by the kidneys.

Serum calcium levels are also affected by acid–base balance. When hydrogen ion concentration falls and the pH rises (alkalosis), more calcium binds with protein. While the total serum calcium remains unchanged, less calcium is available in the ionized, active form. Conversely, when hydrogen ion concentration increases and the pH falls (acidosis), calcium is released from protein, making more ionized calcium available.

Finally, the total amount of calcium in blood plasma fluctuates with plasma protein levels, particularly the albumin level. As the albumin level falls, the total amount of plasma calcium declines. Table 10–6 summarizes the manifestations of calcium imbalances.

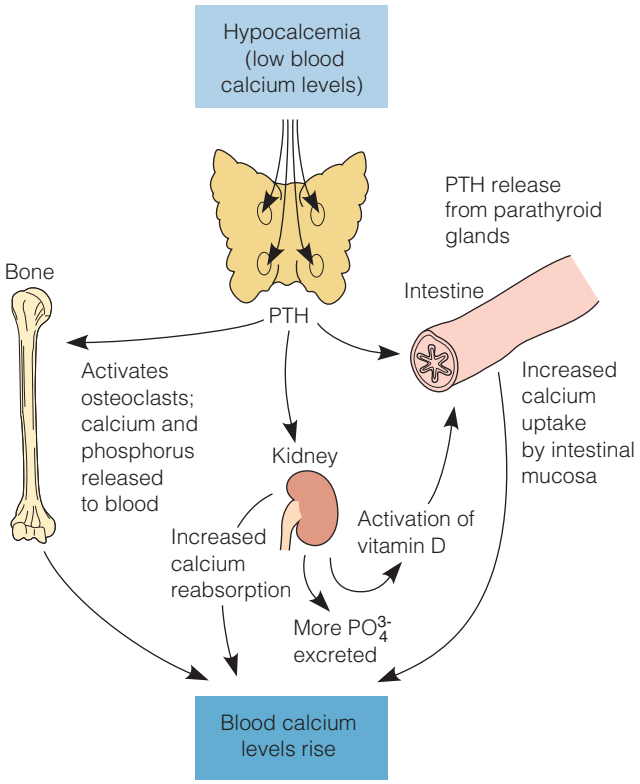


Figure 10–11 ■ Low calcium levels (hypocalcemia) trigger the release of parathyroid hormone (PTH), increasing calcium ion levels through stimulation of bones, kidneys, and intestines.

The Patient with Hypocalcemia

Hypocalcemia is a total serum calcium level of less than 9 mg/dL. Hypocalcemia can result from decreased total body calcium stores or low levels of extracellular calcium with normal amounts of calcium stored in bone. The systemic effects of hypocalcemia are caused by decreased levels of ionized calcium in extracellular fluid.

TABLE 10–6 Manifestations of Calcium Imbalances

Hypocalcemia	Hypercalcemia
• Serum calcium level < 9 mg/dL (<4.5 mEq/L) • Numbness and tingling • Muscle cramping • Hyperactive reflexes • Tetany • Carpopedal and laryngeal spasms • Positive Chvostek and Trousseau signs (see Figure 10–12) • Decreased blood pressure • Ventricular dysrhythmias • Bone pain, fractures (chronic form)	• Serum calcium level > 11.0 mg/dL (5.5 mEq/L) • Increased thirst and urine output • Anorexia • Nausea, vomiting • Constipation • Muscle weakness • Increased blood pressure • AV block • Lethargy • Coma

RISK FACTORS

Certain people are at greater risk for hypocalcemia: those who have had a parathyroidectomy (removal of the parathyroid glands), older adults (especially women), people with lactose intolerance, and those who have alcoholism. Patients who have undergone bariatric surgery for weight loss are at risk due to decreased food intake and malabsorption (Dewey & Heuberger, 2011). Older adults often consume less milk and fewer milk products (good sources of calcium) and may have decreased exposure to the sun (a source of vitamin D). Older adults also may be less active, promoting calcium loss from bones. They are more likely to be taking drugs that interfere with calcium absorption or promote calcium excretion (e.g., furosemide). Older women are at particular risk after menopause because of reduced estrogen levels. Intolerance to lactose (found in milk and milk products) causes diarrhea and often limits the intake of milk and milk products, leading to possible calcium deficiency. Ethanol, or drinking alcohol, has a direct effect on calcium balance, reducing intestinal absorption and interfering with other processes involved in regulating serum calcium levels.

PATHOPHYSIOLOGY

Common causes of hypocalcemia are hypoparathyroidism resulting from surgery (parathyroidectomy, thyroidectomy, radical neck dissection) and acute pancreatitis. In the patient who has undergone surgery, manifestations of hypocalcemia usually occur within the first 24 to 48 hours, but may be delayed.

PRACTICE ALERT!

Carefully monitor patients who have undergone neck surgery for manifestations of hypocalcemia. Check serum calcium levels, and document and report changes.

Additional causes of hypocalcemia include other electrolyte imbalances (such as hypomagnesemia or hyperphosphatemia), alkalosis, malabsorption disorders that interfere with calcium absorption in the bowel, and inadequate vitamin D (due to lack of sun exposure or malabsorption). Hyperphosphatemia often occurs in renal failure, with reciprocal hypocalcemia. Massive transfusion of banked blood can lead to hypocalcemia. Citrate is added to blood to prevent clotting and as a preservative. When blood is administered faster than the liver can metabolize the citrate, it can bind with calcium, temporarily removing ionized calcium from circulation. Many drugs increase the risk for hypocalcemia, including loop diuretics (such as furosemide [Lasix]), anticonvulsants (such as phenytoin [Dilantin] and phenobarbital), phosphates (including phosphate enemas), and drugs that lower serum magnesium levels (such as cisplatin [Platinol]).

Extracellular calcium acts to stabilize neuromuscular cell membranes. This effect is reduced in hypocalcemia, increasing neuromuscular irritability. The threshold of excitation of sensory nerve fibers is lowered as well, leading to paresthesias (altered sensation). The nervous system becomes more excitable, and muscle spasms develop. In the heart, this change in cell membranes can lead to dysrhythmias such as ventricular tachycardia and cardiac arrest. Hypocalcemia decreases the contractility of cardiac muscle fibers, leading to decreased cardiac output.

MEMORY CUE

Remember, calcium has a stabilizing or sedative effect on neuromuscular transmission. Therefore:

Hypocalcemia → Increased neuromuscular excitability, muscle twitching, spasms, and possible tetany

Hypercalcemia → Decreased neuromuscular excitability, muscle weakness, and fatigue

MANIFESTATIONS AND COMPLICATIONS

The most serious manifestations of hypocalcemia are **tetany** (tonic muscular spasms) and convulsions. Numbness and tingling around the mouth (circumoral) and in the hands and feet develop. Muscle spasms of the face and extremities occur, and deep tendon reflexes become hyperactive. Chvostek's sign, contraction of the facial muscles produced by tapping the facial nerve in front of the ear (Figure 10–12A ■), and Trousseau's sign, carpal spasm induced by inflating a blood pressure cuff on the upper arm to above systolic blood pressure for 2 to 5 minutes (Figure 10–12B), indicate increased neuromuscular excitability in patients without obvious manifestations. Tetany can also cause bronchial muscle spasms, simulating an asthma attack, and visceral muscle spasms, producing acute abdominal pain. Cardiovascular manifestations include hypotension, possible bradycardia (slow heart rate), and ventricular dysrhythmias.

Serious complications of hypocalcemia include airway obstruction and possible respiratory arrest from laryngospasm, ventricular dysrhythmias, prolonged QT intervals, cardiac arrest, heart failure, and convulsions.

●○● INTERPROFESSIONAL CARE

Management of hypocalcemia is directed toward restoring normal calcium balance and correcting the underlying cause.

DIAGNOSIS

The following laboratory and diagnostic tests may be ordered when hypocalcemia is known or suspected:

- *Total serum calcium,* the amount of ionized (active) calcium available, usually is estimated. In critically ill patients, however, *ionized calcium* may be directly measured using ion-selective electrodes. Direct measurement of ionized calcium requires special handling of the blood specimen, including placing the specimen on ice and analyzing it immediately.
- *Serum albumin,* because the albumin level affects serum calcium results. When the albumin level is low (hypoalbuminemia), the

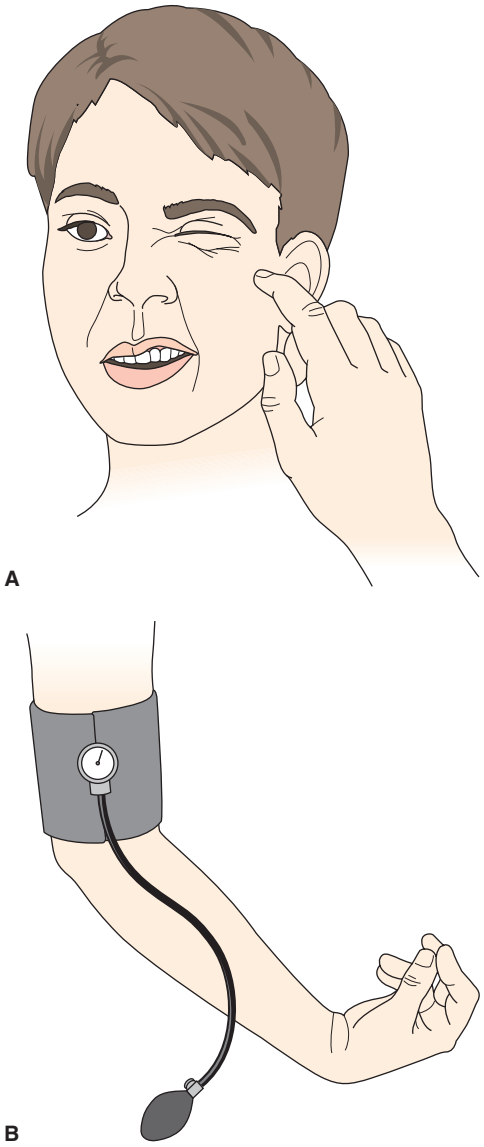

Figure 10–12 ■ A, Positive Chvostek's sign. B, Positive Trousseau's sign.

amount of ionized calcium may remain normal even though the total calcium level is low.

- *Serum magnesium,* because hypocalcemia is often associated with hypomagnesemia (serum magnesium < 1.8 mg/dL). In this case, normal magnesium levels must be restored to correct the hypocalcemia.
- *Serum phosphate,* because hyperphosphatemia (serum phosphate > 4.5 mg/dL) can lead to hypocalcemia due to the inverse relationship between phosphorus and calcium (as phosphate levels rise, calcium levels fall).
- *Parathyroid hormone (PTH),* to identify the possible diagnosis of hyperparathyroidism.
- An *ECG,* to evaluate the effects of hypocalcemia on the heart, such as a prolonged ST segment.

MEDICATIONS

Hypocalcemia is treated with oral or IV calcium. The patient with severe hypocalcemia is treated with IV calcium to prevent life-threatening problems such as airway obstruction. The most common IV calcium preparations include calcium chloride and calcium gluconate. Although calcium chloride contains more elemental calcium than calcium gluconate, it also is more irritating to the veins and may cause venous sclerosis (hardening of the vein walls) if given into a peripheral vein. See the accompanying Medication Administration box for further information about calcium administration.

SAFETY ALERT

IV calcium preparations can cause necrosis and sloughing of tissue if they infiltrate into subcutaneous tissue. Rapid drug administration can lead to bradycardia and possible cardiac arrest due to overcorrection of hypocalcemia with resulting hypercalcemia.

Oral calcium preparations (calcium carbonate, calcium gluconate, or calcium lactate) are used to treat chronic, asymptomatic hypocalcemia. Calcium supplements may be combined with vitamin D, or vitamin D may be given alone to increase GI absorption of calcium.

NUTRITION

A diet high in calcium-rich foods may be recommended for patients with chronic hypocalcemia or with low total body stores of calcium. Foods high in calcium include dairy products, canned salmon, broccoli, spinach, and tofu.

●○● NURSING CARE

Health Promotion

Because of the large stores of calcium in bones, most healthy adults have a very low risk of developing hypocalcemia. However, a deficit of total body calcium is often associated with aging, increasing the risk of osteoporosis, fractures, and disability. Women have a higher risk for developing osteoporosis than men due to lower bone density and hormonal influences. Teach women of all ages the importance of maintaining adequate calcium intake through diet and, as needed, calcium supplements. Stress the relationship between weight-bearing exercise and bone density, and encourage women to engage in a regular aerobic and weight-training exercise regime. Recommend screening for bone density in older women.

Assessment

Assessment data related to hypocalcemia include the following:

- ***Health history:*** current manifestations, including numbness and tingling around mouth and of hands and feet, abdominal pain, shortness of breath; acute or chronic diseases such as pancreatitis, liver or kidney disease; current medications
- ***Physical assessment:*** muscle spasms; deep tendon reflexes; Chvostek's sign and Trousseau's sign; vital signs and apical pulse; presence of convulsions.

Priorities of Care

The effect of hypocalcemia on neuromuscular irritability, with the risk for muscle spasm and convulsions, is the highest priority for nursing care of the patient.

MEDICATION ADMINISTRATION

Calcium Salts

CALCIUM SALTS

Calcium carbonate (BioCal, Calsan, Caltrate, Os-Cal, Tums, others)

Calcium chloride

Calcium citrate (Citracal)

Calcium glubionate

Calcium gluceptate

Calcium gluconate (Kalcinate)

Calcium lactate

Calcium salts are given to increase calcium levels when there is a deficit (a total body deficit or inadequate levels of extracellular calcium). Calcium is necessary to maintain bone structure and for multiple physiologic processes including neuromuscular and cardiac function as well as blood coagulation. In the presence of vitamin D, calcium is well absorbed from the GI tract. Severe hypocalcemia is treated with IV calcium preparations.

Nursing Responsibilities

Oral calcium salts:

- Administer 1 to 1.5 hours after meals and at bedtime.
- Give calcium tablets with a full glass of water.

IV calcium salts:

- Assess IV site for patency. Do not administer calcium if there is a risk of leakage into the tissues.
- May be given by slow IV push (dilute with sterile NS for injection prior to administering) or added to compatible parenteral fluids such as NS, lactated Ringer's solution, or D_5W.
- Administer into the largest available vein; use a central line if available.
- Do not administer with bicarbonate or phosphate because a precipitate (insoluble salt) will form (Metheny, 2012).
- Continuously monitor ECG when administering IV calcium to patients taking digitalis due to increased risk of digitalis toxicity.
- Frequently monitor serum calcium levels and response to therapy.

Health Education for the Patient and Family

- Take calcium tablets with a full glass of water 1 to 2 hours after meals. Do not take with food or milk. If possible, do not take within 1 to 2 hours of other medications.
- Maintain adequate vitamin D intake through diet or exposure to the sun to promote calcium absorption.
- Calcium carbonate can cause constipation. Eat a high-fiber diet and maintain a generous fluid intake to prevent constipation.

Diagnoses, Outcomes, and Interventions

Risk for Injury

The patient with hypocalcemia is at risk for injury from possible laryngospasm, cardiac dysrhythmias, or convulsions. In addition, too rapid administration of IV calcium or infiltration of the medication into subcutaneous tissues can lead to injury.

Expected Outcome: Patient will remain free of injury or complications of hypocalcemia.

- Frequently monitor airway and respiratory status, including oxygen saturation levels. Report changes such as respiratory stridor (a high-pitched, harsh inspiratory sound indicative of upper airway obstruction) or increased respiratory rate or effort to the physician. *These changes may indicate laryngeal spasm due to tetany.*

PRACTICE ALERT!

Laryngeal spasm is a respiratory emergency, requiring immediate intervention to maintain ventilation and gas exchange.

- Monitor cardiovascular status including heart rate and rhythm, blood pressure, and peripheral pulses. *Hypocalcemia decreases myocardial contractility, causing reduced cardiac output and hypotension. It also can cause bradycardia or ventricular dysrhythmias. Cardiac arrest may occur in severe hypocalcemia.*
- Continuously monitor ECG in patients receiving IV calcium preparations, especially if the patient also is taking digitalis. *Rapid administration of calcium salts can lead to hypercalcemia and cardiac dysrhythmias. Calcium administration increases the risk of digitalis toxicity and resultant dysrhythmias.*
- If the patient has tetany, provide a quiet environment and institute seizure precautions such as raising the side rails and keeping an airway at bedside. *A quiet environment reduces central nervous system stimuli and the risk of convulsions in the patient with tetany.*

Continuity of Care

In preparing the patient with hypocalcemia for home or continuing care, consider the circumstances leading to low serum calcium levels. Discuss risk factors for hypocalcemia specific to the patient, and provide information about managing these risk factors to avoid future episodes of hypocalcemia. Teach about prescribed medications, including calcium supplements. Provide a list of foods high in calcium, as well as sources of vitamin D if recommended. Discuss manifestations to report to the healthcare provider, and stress the importance of follow-up care as scheduled.

The Patient with Hypercalcemia

Hypercalcemia is a serum calcium value greater than 11.0 mg/dL. Excess ionized calcium in ECF can have serious widespread effects.

PATHOPHYSIOLOGY

Hypercalcemia usually results from increased resorption of calcium from the bones. The two most common causes of bone resorption are hyperparathyroidism and malignancies. In hyperparathyroidism, excess PTH is produced. This causes calcium to be released from bones, as well as increased calcium absorption in the intestines and retention of calcium by the kidneys. Hypercalcemia is a common complication of malignancies. It may develop as a result of bone destruction by the tumor or due to hormone-like substances produced by the tumor itself. Prolonged immobility and lack of weight bearing also cause increased resorption of bone with calcium release into extracellular fluids. Self-limiting hypercalcemia may follow successful kidney transplant. Levels of parathyroid hormone may be altered in chronic renal failure, leading to increased serum calcium levels.

Increased intestinal absorption of calcium also can lead to hypercalcemia. This may result from excess vitamin D, overuse of calcium-containing antacids, or excessive milk ingestion. Renal

failure and some drugs such as thiazide diuretics and lithium can interfere with elimination of calcium by the kidneys, causing high serum calcium levels.

The effects of hypercalcemia largely depend on the degree of serum calcium elevation and the length of time over which it develops. In general, higher serum calcium levels are associated with more serious effects. Calcium has a stabilizing effect on the neuromuscular junction; hypercalcemia decreases neuromuscular excitability, leading to muscle weakness and depressed deep tendon reflexes. Gastrointestinal motility is reduced as well. In the heart, calcium exerts an effect similar to digoxin, strengthening contractions and reducing the heart rate. Hypercalcemia affects the conduction system of the heart, leading to bradycardia and heart blocks. The ability of the kidneys to concentrate urine is impaired by hypercalcemia, causing excess sodium and water loss and increased thirst.

High serum calcium levels affect mental status. This is thought to be due to increased calcium in cerebrospinal fluid. Behavioral effects range from personality changes to confusion, impaired memory, and acute psychoses.

MANIFESTATIONS AND COMPLICATIONS

Manifestations of hypercalcemia may be subtle, particularly when it is mild and develops over time. Decreased neuromuscular excitability causes muscle weakness and fatigue, as well as GI manifestations such as anorexia, nausea, vomiting, and constipation. Central nervous system (CNS) effects may include difficulty concentrating, confusion, lethargy, behavior or personality changes, and coma. Cardiovascular effects include dysrhythmias, ECG changes, and possible hypertension. Hypercalcemia causes polyuria and, as a result, increased thirst (refer to Table 10–6).

Complications of hypercalcemia can affect several different organ systems. Peptic ulcer disease may develop due to increased gastric acid secretion. Pancreatitis can occur as a result of calcium deposits in pancreatic ducts. Excess calcium can precipitate out of urine to form kidney stones. Hypercalcemic crisis, an acute increase in the serum calcium level, can lead to cardiac arrest.

●○● INTERPROFESSIONAL CARE

The management of hypercalcemia focuses on correcting the underlying cause and reducing the serum calcium level. Treatment is particularly important in patients who have one or more of the following: serum calcium levels greater than 12 mg/dL, overt manifestations of hypercalcemia, compromised renal function, and inability to maintain an adequate fluid intake.

DIAGNOSIS

The laboratory and diagnostic tests that may be ordered are as follows:

- *Serum electrolytes* show a total serum calcium greater than 11.0 mg/dL.
- *Serum PTH levels* are measured to identify or rule out hyperparathyroidism as the cause of hypercalcemia.
- *ECG* changes in hypercalcemia include a shortened QT interval, shortened and depressed ST segment, and widened T wave. Bradycardia or heart block may be identified on the ECG.
- *Bone density scans* may be done to monitor bone resorption and the effects of treatment measures on mineralization of bone.

MEDICATIONS

Measures to promote calcium elimination by the kidneys and reduce calcium resorption from bone are used to treat hypercalcemia. In acute hypercalcemia, IV fluids are given with a loop diuretic such as furosemide (Lasix) to promote elimination of excess calcium.

A number of drugs that inhibit bone resorption are available. The bisphosphonates (zoledronic acid [Reclast, Zometa], pamidronate [Aredia], and etidronate [Didronel]) are commonly used to treat hypercalcemia associated with malignancies. These drugs also are used to prevent and treat osteoporosis. Nursing implications for bisphosphonate drugs are presented in the Medication Administration boxes in Chapter 40. Rapid reversal of hypercalcemia in emergency situations may be accomplished by IV administration of sodium phosphate or potassium phosphate. Calcium binds to phosphate, thus decreasing serum calcium levels. Paradoxically, complications of this therapy can include fatal hypocalcemia resulting from binding of the ionized calcium and soft tissue calcifications.

Other drug therapies include the use of IV plicamycin (Mithramycin) to inhibit bone resorption. Glucocorticoids (cortisone), which compete with vitamin D, and a low-calcium diet may be prescribed to decrease GI absorption of calcium, to inhibit bone resorption, and to increase urinary calcium excretion. Also, calcitonin may be prescribed to decrease skeletal mobilization of calcium and phosphorus and to increase renal output of calcium and phosphorus. See Chapter 19 for more information about and nursing implications of glucocorticoid therapy.

FLUID MANAGEMENT

IV fluids, usually isotonic saline, are administered to patients with severe hypercalcemia to restore vascular volume and promote renal excretion of calcium. Isotonic saline is used because sodium excretion is accompanied by calcium excretion. Careful assessment of cardiovascular and renal function is done prior to fluid therapy; the patient is carefully monitored for evidence of fluid overload during treatment.

●○● NURSING CARE

Health Promotion

Identify and monitor patients at risk for hypercalcemia. Promote mobility in patients when possible. Assist hospitalized patients to ambulate as soon as possible. In the home setting, discuss the benefits of regular weight-bearing activity with patients, families, and caregivers. Encourage a generous fluid intake of up to 3 to 4 quarts per day. Encourage patients at risk to limit their intake of milk and milk products, as well as calcium-containing antacids and supplements. In addition, patients with prolonged immobility or hypercalcemia are encouraged to consume fluids that increase the acidity of urine (which inhibits calcium stone formation), such as cranberry or prune juice.

Assessment

Assessment data related to hypercalcemia include the following:

- ***Health history:*** current manifestations, including weakness or fatigue, abdominal discomfort, nausea or vomiting, increased urination and thirst; changes in memory or thinking; duration of

manifestations and any risk factors such as excess intake of milk or calcium products, prolonged immobility, malignancy, renal failure, or endocrine disorders; current medications
- ***Physical assessment:*** mental status and level of consciousness; vital signs including apical pulse; bowel sounds; muscle strength of upper and lower extremities; deep tendon reflexes.

Priorities of Care

The patient with hypercalcemia is at risk for injury due to changes in mental status, muscle weakness, cardiac dysrhythmias, and loss of calcium from bones, making safety the priority of care.

Diagnoses, Outcomes, and Interventions

Risk for Injury

Expected Outcome: Patient will be free of injury, including complications of hypercalcemia.

- Institute safety precautions if confusion or other changes in mental status are noted. *Changes in mental status may impair judgment and the patient's ability to maintain his or her own safety.*

PRACTICE ALERT!

Hypercalcemia can cause bradycardia, various heart blocks, and cardiac arrest. Immediate treatment may be necessary to preserve life. Monitor cardiac rate and rhythm, treating and/or reporting dysrhythmias as indicated. Prepare for possible cardiac arrest; keep emergency resuscitation equipment readily available.

- Observe for manifestations of digoxin toxicity (if administered), including vision changes, anorexia, and changes in heart rate and rhythm. Monitor serum digoxin levels. *Hypercalcemia increases the risk of digoxin toxicity.*
- Promote fluid intake to keep the patient well hydrated and maintain dilute urine. Encourage fluids such as prune or cranberry juice to help maintain acidic urine. *Acidic, dilute urine reduces the risk of calcium salts precipitating out to form kidney stones.*
- If excess bone reabsorption has occurred, use caution when turning, positioning, transferring, or ambulating. *Bones that have lost excess calcium may fracture with minimal stress or trauma (pathologic fractures).*

Risk for Fluid Volume Excess

Large amounts of isotonic IV fluid often are administered to help correct acute hypercalcemia, leading to a risk for hypervolemia. Patients with preexisting cardiac or renal disease are at particular risk. Loop diuretics may be prescribed to help eliminate excess fluid and calcium.

Expected Outcome: Patient's fluid balance will be maintained.

- Closely monitor intake and output. *A loop diuretic such as furosemide may be necessary if urinary output does not keep up with fluid administration.*
- Frequently assess vital signs, respiratory status, and heart sounds. *Increasing pulse rate, dyspnea, adventitious lung sounds, and an S_3 on auscultation of the heart may indicate excess fluid volume and potential heart failure.*
- Place in semi-Fowler's to Fowler's position. *Elevating the head of the bed improves lung expansion and reduces the work of breathing.*

Delegating Nursing Care Activities

Although the nurse retains responsibility for conducting initial and ongoing assessment of the patient, nursing care activities such as obtaining vital signs, measuring intake and output, helping promote fluid intake, and assisting with positioning and ambulation for the patient with hypercalcemia may be delegated to assistive personnel with appropriate education and documented competency.

Continuity of Care

Discuss the following topics when preparing the patient for discharge:

- Avoid excess intake of calcium-rich foods and antacids.
- Use prescribed drugs to prevent excess calcium resorption. Discuss their dose, use, and desired and possible adverse effects.
- Increase fluid intake to 3 to 4 quarts per day; increase the intake of foods that help acidify urine (meats, fish, poultry, eggs, cranberries, plums, prunes); increase dietary fiber and fluid intake to prevent constipation.
- Maintain weight-bearing physical activity to prevent hypercalcemia.

MAGNESIUM IMBALANCE

Only about 1% of the magnesium in the body is in extracellular fluid; the rest is found within the cells and in bone. The normal serum concentration of magnesium ranges from 1.8 to 3.0 mg/dL (1.5 to 2.5 mEq/L).

Magnesium is obtained through the diet (it is plentiful in green vegetables, grains, nuts, meats, and seafood) and excreted by the kidneys. Magnesium is vital to many intracellular processes, including enzyme reactions and synthesis of proteins and nucleic acids. Magnesium exerts a sedative effect on the neuromuscular junction, decreasing acetylcholine release. It is an essential ion for neuromuscular transmission and cardiovascular function. The physiologic effects of magnesium are affected by both potassium and calcium levels.

The Patient with Hypomagnesemia

Hypomagnesemia is a magnesium level of less than 1.8 mg/dL. It is a common problem in critically ill patients. Hypomagnesemia may be caused by deficient magnesium intake, excessive losses, or a shift between the intracellular and extracellular compartments.

RISK FACTORS

Loss of GI fluids, particularly from diarrhea, an ileostomy, or intestinal fistula is a major risk factor for hypomagnesemia. Disruption of nutrient absorption in the small intestine also increases the risk. Multiple factors associated with alcoholism contribute to hypomagnesemia: deficient nutrient intake, increased GI losses, impaired absorption, and increased renal excretion. Other risk factors for hypomagnesemia include protein-calorie malnutrition or starvation; diabetic ketoacidosis; kidney disease; drugs such as loop or thiazide diuretics, aminoglycoside antibiotics, and cyclosporine; and rapid administration of citrated blood.

PATHOPHYSIOLOGY

Magnesium deficiency usually occurs along with low serum potassium and calcium levels. The effects of hypomagnesemia relate not only to the magnesium deficiency but also to hypokalemia and hypocalcemia.

TABLE 10–7 Manifestations of Magnesium Disorders

Hypomagnesemia	Hypermagnesemia
• Serum magnesium level < 1.8 mg/dL (<1.5 mEq/L) • Changes in personality • Nystagmus (lateral twitching of eyeballs) • Positive Babinski, Chvostek, and Trousseau signs • Hypertension • Tachycardia • Cardiac dysrhythmias	• Serum magnesium level > 3.0 mg/dL (2.5 mEq/L) • Confusion and lethargy • Hypotension • Cardiac dysrhythmias • Coma • Cardiac arrest

Hypomagnesemia causes increased neuromuscular excitability, with muscle weakness and tremors. The accompanying hypocalcemia contributes to this effect. In the central nervous system, this increased neural excitability can lead to seizures and changes in mental status. Deficient intracellular magnesium in the myocardium increases the risk of cardiac dysrhythmias and sudden death. Hypokalemia increases this risk. Hypomagnesemia also increases the risk of digoxin toxicity. Chronic hypomagnesemia may contribute to hypertension, probably due to increased vasoconstriction. Severe hypomagnesia is strongly linked to low serum calcium levels because both are associated with renal and GI losses.

MANIFESTATIONS AND COMPLICATIONS

Neuromuscular manifestations of hypomagnesemia include tremors, hyperreactive reflexes, positive Chvostek's and Trousseau's signs (refer to Figure 10–12), tetany, paresthesias, and seizures. CNS effects include confusion, mood changes (apathy, depression, agitation), hallucinations, and possible psychoses. An increased heart rate and ventricular dysrhythmias are common, especially when hypokalemia is present or the patient is taking digitalis. Cardiac arrest and sudden death may occur. Table 10–7 summarizes manifestations of magnesium imbalances.

●○● INTERPROFESSIONAL CARE

Hypomagnesemia is diagnosed by measuring serum electrolyte levels. The ECG shows a prolonged PR interval, widened QRS complex, and depression of the ST segment with T-wave inversion. Treatment is directed toward prevention and identification of an existing deficiency. Magnesium is added to parenteral nutrition solutions to prevent hypomagnesemia.

In patients able to eat, a mild deficiency may be corrected by increasing the intake of foods rich in magnesium (such as green leafy vegetables, seafood, milk, bananas, citrus fruits, and chocolate), or with oral magnesium supplements. Oral magnesium supplements may cause diarrhea, however, limiting their use.

Patients with manifestations of hypomagnesemia are treated with parenteral magnesium sulfate. Treatment is continued for several days to restore intracellular magnesium levels. Magnesium may be given IV or by deep IM injection. Renal function is evaluated prior to administration, and serum magnesium levels are monitored during treatment. The IV route is used for severe magnesium deficiency or if neurologic changes or cardiac dysrhythmias are present. See the following Medication Administration box for the nursing implications of parenteral magnesium sulfate administration.

●○● NURSING CARE

Health Promotion

Discuss the importance of maintaining adequate magnesium intake through a well-balanced diet, particularly with patients at risk (people with alcoholism, malabsorption, or bowel surgery). Many hospitalized patients are at risk for hypomagnesemia due to protein-calorie malnutrition and other disorders. Monitor serum magnesium levels, reporting changes to the healthcare provider.

Assessment

In addition to asking questions related to risk factors for hypomagnesemia, assess for manifestations of hypokalemia and hypocalcemia. Monitor diagnostic studies such as serum electrolytes, serum albumin levels, and the ECG. Monitor GI function, including bowel sounds and abdominal distention.

Priorities of Care

As is the case with many electrolyte imbalances, maintaining patient safety and preventing complications of the imbalance or its treatment are nursing care priorities.

Diagnoses, Outcomes, and Interventions

Nursing care for patients with hypomagnesemia focuses on careful monitoring of manifestations and responses to treatment, promoting safety, patient and family teaching, and administering prescribed medications. Monitor serum electrolytes, including magnesium, potassium, and calcium. Initiate cardiac monitoring, reporting and treating (as prescribed) ECG changes and dysrhythmias. In patients receiving digoxin, monitor for digoxin toxicity. Assess deep tendon reflexes frequently during IV magnesium infusions and prior to each IM dose. Depressed tendon reflexes indicate a high serum magnesium level. Institute seizure precautions and maintain a quiet, darkened environment to reduce neuromuscular and CNS irritability.

Continuity of Care

Prior to discharge, instruct the patient to increase dietary intake of foods high in magnesium and provide information about magnesium supplements. In addition, if alcohol abuse has precipitated a magnesium deficit, discuss alcohol treatment options, including support groups such as Alcoholics Anonymous, Al-Anon, and/or Alateen.

The Patient with Hypermagnesemia

Hypermagnesemia is a serum magnesium level greater than 3.0 mg/dL (2.5 mEq/L). It is much less common than hypomagnesemia. Hypermagnesemia can develop in renal failure, particularly if magnesium is administered parenterally or orally (e.g., magnesium-containing antacids or laxatives). Older adults are at risk for hypermagnesemia as renal function declines with aging and they may be more likely to use over-the-counter laxatives and other preparations that contain magnesium.

MEDICATION ADMINISTRATION

Magnesium Sulfate

Magnesium sulfate is used to prevent or treat hypomagnesemia. It may be given IV or by IM injection.

Nursing Responsibilities

- Assess serum magnesium levels and renal function tests (BUN and serum creatinine) prior to administering. Notify the care provider if magnesium levels are above normal limits or renal function is impaired.
- Frequently monitor neurologic status and deep tendon reflexes during therapy. Withhold magnesium and notify the care provider if deep tendon reflexes are hypoactive or absent.
- Monitor intake and output.
- Administer IM doses deep into the ventral or dorsal gluteal sites.
- IV magnesium sulfate may be given by direct IV push or by continuous infusion.
  - Solutions with a concentration of 20% or lower may be administered undiluted by direct IV injection at a rate of not faster than 150 mg/min.
  - When administering by infusion, give required dose over 4 hours, but no faster than 150 mg/min (Wilson et al., 2013).

Health Education for the Patient and Family

- Explain purpose and duration of treatment.
- Discuss reason for frequent neurologic and reflex assessments.

PATHOPHYSIOLOGY AND MANIFESTATIONS

Elevated serum magnesium levels interfere with neuromuscular transmission and depress the central nervous system. Hypermagnesemia also affects the cardiovascular system, potentially causing hypotension, flushing, sweating, and bradydysrhythmias.

Predictable manifestations occur with increasing serum magnesium levels. With lower levels, nausea and vomiting, hypotension, facial flushing, sweating, and a feeling of warmth occur. As levels increase, manifestations of CNS depression appear (weakness, lethargy, drowsiness, weak or absent deep tendon reflexes). Marked elevations cause respiratory depression, coma, and compromised cardiac function (ECG changes, bradycardia, heart block, and cardiac arrest).

●○● INTERPROFESSIONAL CARE

The management of hypermagnesemia focuses on identifying and treating the underlying cause. All medications or compounds containing magnesium (such as antacids, IV solutions, or enemas) are withheld. In the patient with renal failure, hemodialysis or peritoneal dialysis is instituted to remove the excess magnesium.

Calcium gluconate is administered IV to reverse the neuromuscular and cardiac effects of hypermagnesemia. The patient may require mechanical ventilation to support respiratory function, and a pacemaker to maintain adequate cardiac output.

●○● NURSING CARE

Nursing care includes instituting measures to prevent and identify hypermagnesemia in patients at risk, monitoring for critical effects of hypermagnesemia, and providing measures to ensure the patient's safety. Consider the following nursing diagnoses for the patient with hypermagnesemia:

- Decreased Cardiac Output
- Ineffective Breathing Pattern
- Risk for Injury

PHOSPHATE IMBALANCE

Although most phosphate (85%) is found in bones, it is the primary intracellular anion. About 14% is in intracellular fluid, and the remainder (1%) is in extracellular fluid. The normal serum phosphate (or phosphorus) level in adults is 2.5 to 4.5 mg/dL (1.7 to 2.6 mEq/L). Phosphorus levels vary with age, gender, and diet.

Overview of Normal Phosphate Balance

Phosphate is essential to intracellular processes such as the production of ATP, the fuel that supports muscle contraction, nerve cell transmission, and electrolyte transport. Phosphate is vital for red blood cell function and oxygen delivery to tissues; nervous system and muscle function; and the metabolism of fats, carbohydrates, and protein. It also assists in maintaining acid–base balance.

Phosphorus is ingested in the diet, absorbed in the jejunum, and primarily excreted by the kidneys. When phosphate intake is low, the kidneys conserve phosphorus, excreting less. An inverse relationship exists between phosphate and calcium levels: When one increases, the other decreases. Regulatory mechanisms for calcium levels (parathyroid hormone, calcitonin, and vitamin D) also influence phosphate levels. The manifestations of phosphate imbalances are summarized in Table 10–8.

The Patient with Hypophosphatemia

Hypophosphatemia is a serum phosphorus of less than 2.5 mg/dL. Low serum phosphate levels may indicate a total body deficit of phosphate or a shift of phosphate into the intracellular space, the most common cause of hypophosphatemia. Decreased GI absorption of phosphate or increased renal excretion of phosphate also can cause low phosphate levels. Hypophosphatemia often is iatrogenic (related

TABLE 10–8 Manifestations of Phosphate Imbalances

Hypophosphatemia	Hyperphosphatemia
• Serum phosphate level < 2.5 mg/dL (<1.7 mEq/L)	• Serum phosphate level > 4.5 mg/dL (>2.6 mEq/L)
• Intention tremor, paresthesias	• Paresthesias
• Confusion, stupor	• Muscle weakness
• Bone pain	• Nausea and vomiting
• Joint stiffness	• Dysphagia
• Bleeding disorders (platelet dysfunction)	• Tetany
• Impaired white blood cell function	• Decreased blood pressure
• Seizures	• Cardiac dysrhythmias

to treatment). Selected causes of hypophosphatemia include the following:

- Refeeding syndrome can develop when malnourished patients are started on enteral or parenteral nutrition. Glucose in the formula or solution stimulates insulin release, which promotes the entry of glucose and phosphate into the cells, depleting extracellular phosphate levels.
- Medications frequently contribute to hypophosphatemia, including IV glucose solutions, antacids (aluminum- or magnesium-based antacids bind with phosphate), anabolic steroids, and diuretics.
- Alcoholism affects both the intake and absorption of phosphate.
- Hyperventilation and respiratory alkalosis cause phosphate to shift out of extracellular fluids into the intracellular space.
- Other causes include diabetic ketoacidosis with excess phosphate loss in the urine, stress responses, and extensive burns.

PATHOPHYSIOLOGY AND MANIFESTATIONS

Most effects of hypophosphatemia result from depletion of ATP and impaired oxygen delivery to the cells due to a deficiency of the red blood cell enzyme 2,3-DPG. Severe hypophosphatemia affects virtually every major organ system:

- ***Central nervous system:*** Reduced oxygen and ATP synthesis in the brain causes neurologic manifestations such as irritability, apprehension, weakness, paresthesias, lack of coordination, confusion, seizures, and coma.
- ***Hematologic:*** Oxygen delivery to the cells is reduced. Hemolytic anemia (excessive RBC destruction) may develop due to lack of ATP in red blood cells.
- ***Musculoskeletal:*** Decreased ATP causes muscle weakness and release of creatinine phosphokinase (CPK, a muscle enzyme); acute rhabdomyolysis (muscle cell breakdown) can develop. Muscle cell destruction, in turn, can lead to acute kidney injury as myoglobin, a muscle cell protein, exerts a toxic effect on the kidney tubule.
- ***Cardiovascular:*** Hypophosphatemia decreases myocardial contractility; decreased oxygenation of the heart muscle can cause chest pain and dysrhythmias.
- ***Gastrointestinal:*** Anorexia can occur, as well as dysphagia (difficulty swallowing), nausea and vomiting, decreased bowel sounds, and possible ileus due to reduced GI motility.

●○● INTERPROFESSIONAL CARE

Treatment for hypophosphatemia is directed at prevention, treating the underlying cause of the disorder, and replacing phosphate. An improved diet and oral phosphate supplement (such as Neutra-Phos or Neutra-Phos K capsules) may restore normal phosphate levels in patients with a mild to moderate deficiency. IV phosphate (sodium phosphate or potassium phosphate) is given when serum phosphate levels are less than 1 mg/dL.

●○● NURSING CARE

Nurses can be instrumental in identifying patients at risk for phosphate deficiency and preventing it from developing. Nurses should closely monitor serum electrolyte values in patients at risk, including those who are malnourished, receiving IV glucose solutions or total parenteral nutrition, or being treated with diuretic therapy or antacids that bind with phosphate. Teach the patient and family about the causes and manifestations of hypophosphatemia. Discuss the importance of avoiding phosphorus-binding antacids, unless prescribed. Stress a well-balanced diet to maintain an adequate intake of phosphate.

The Patient with Hyperphosphatemia

Hyperphosphatemia is a serum phosphate level greater than 4.5 mg/dL. As with other electrolyte imbalances, it may be the result of impaired phosphate excretion, excess intake, or a shift of phosphate from the intracellular space into extracellular fluids.

- Acute or chronic renal failure is the primary cause of impaired phosphate excretion.
- Rapid administration of phosphate-containing solutions, including phosphate enemas, can increase serum phosphate levels. In addition, excess vitamin D increases phosphate absorption and can lead to hyperphosphatemia in patients with impaired renal function.
- A shift of phosphate from the intracellular to extracellular space can occur during chemotherapy, from sepsis or hypothermia, or because of extensive trauma or heat stroke.
- Because phosphate levels are affected by serum calcium concentrations, disruption of the mechanisms that regulate calcium levels (e.g., hypoparathyroidism, hyperthyroidism, or vitamin D intoxication) can lead to hyperphosphatemia.

PATHOPHYSIOLOGY AND MANIFESTATIONS

Excessive serum phosphate levels cause few specific manifestations. The effects of high serum phosphate levels on nerves and muscles (muscle cramps and pain, paresthesias, tingling around the mouth, muscle spasms, tetany) are more the result of hypocalcemia that develops secondary to an elevated serum phosphorus level. The phosphate in the serum combines with ionized calcium, and the ionized serum calcium level falls.

●○● INTERPROFESSIONAL CARE

Treatment of the underlying disorder often corrects hyperphosphatemia. When this is not feasible, phosphate-containing drugs are eliminated and intake of phosphate-rich foods such as organ meats and milk and milk products is restricted. Agents that bind with phosphate in the GI tract (such as calcium-containing antacids) may be prescribed. If renal function is adequate, IV normal saline may be given to promote renal excretion of phosphate. Dialysis may be necessary to reduce phosphate levels in patients with renal failure.

●○● NURSING CARE

When providing nursing care for the patient with hyperphosphatemia, monitor the laboratory data for an excess of phosphorus and a deficit of calcium, as well as the manifestations of hypocalcemia. Discuss the risk of hyperphosphatemia related to using phosphate preparations as laxatives or enemas, particularly with patients who have other risk factors for the disorder (e.g., chronic kidney disease, endocrine disorders). When preparing the patient for discharge, teach about the use of phosphate-binding preparations as ordered and dietary phosphate restrictions.

Acid–Base Disorders

Homeostasis and optimal cellular function require maintenance of the hydrogen ion (H^+) concentration of body fluids within a relatively narrow range. Hydrogen ions determine the relative acidity of body fluids. **Acids** release hydrogen ions in solution; **bases** (or **alkalis**) accept hydrogen ions in solution. The hydrogen ion concentration of a solution is measured as its pH. The relationship between hydrogen ion concentration and pH is inverse; that is, as hydrogen ion concentration increases, the pH falls, and the solution becomes more acidic. As hydrogen ion concentration falls, the pH rises, and the solution becomes more alkaline or basic. The pH of body fluids is slightly basic, with the normal pH ranging from 7.35 to 7.45 (a pH of 7 is neutral).

REGULATION OF ACID–BASE BALANCE

A number of mechanisms work together to maintain the pH of the body within normal range. Metabolic processes in the body continuously produce acids, which fall into two categories: volatile acids and nonvolatile acids. Volatile acids can be eliminated from the body as a gas. Carbonic acid (H_2CO_3) is the only volatile acid produced in the body. It dissociates into carbon dioxide (CO_2) and water (H_2O); the carbon dioxide is then eliminated from the body through the lungs. All other acids produced in the body are nonvolatile acids that must be metabolized or excreted from the body in fluid. Lactic acid, hydrochloric acid, phosphoric acid, and sulfuric acid are examples of nonvolatile acids. Most acids and bases in the body are weak; that is, they neither release nor accept a significant amount of hydrogen ion.

Three systems work together in the body to maintain the pH despite continuous acid production: buffers, the respiratory system, and the renal system.

Buffer Systems

Buffers are substances that prevent major changes in pH by removing or releasing hydrogen ions. When excess acid is present in body fluid, buffers bind with hydrogen ions to minimize the change in pH. If body fluids become too basic or alkaline, buffers release hydrogen ions, restoring the pH. Although buffers act within a fraction of a second, their capacity to maintain pH is limited. The major buffer systems of the body are the bicarbonate-carbonic acid buffer system, phosphate buffer system, and protein buffers.

The bicarbonate-carbonic acid buffer system can be illustrated by the following equation:

$$CO_2 + H_2O \leftrightarrow H_2CO_3 \leftrightarrow H^+ + HCO_3^-$$

Bicarbonate (HCO_3^-) is a weak base; when an acid is added to the system, the hydrogen ion in the acid combines with bicarbonate, and the pH changes only slightly. Carbonic acid (H_2CO_3) is a weak acid produced when carbon dioxide dissolves in water. If a base is added to the system, it combines with carbonic acid, and the pH remains within the normal range. Although the amounts of bicarbonate and carbonic acid in the body vary to a certain extent, as long as a ratio of 20 parts bicarbonate (HCO_3^-) to 1 part carbonic acid (H_2CO_3) is maintained, the pH remains within the 7.35 to 7.45 range (Figure 10–13 ■).

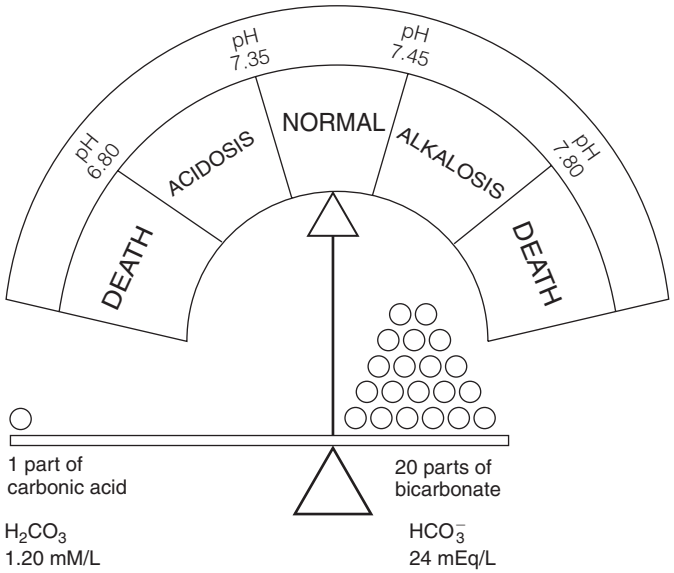

Figure 10–13 ■ The normal ratio of bicarbonate to carbonic acid is 20:1. As long as this ratio is maintained, the pH remains within the normal range of 7.35 to 7.45.

The normal serum bicarbonate level is 24 mEq/L, and that of carbonic acid is 1.2 mEq/L. Thus, the ratio of bicarbonate to carbonic acid is 20:1. It is this ratio that maintains the pH within the normal range. Adding a strong acid to extracellular fluid depletes bicarbonate, changing the 20:1 ratio and causing the pH to drop below 7.35. This is known as **acidosis**. Addition of a strong base depletes carbonic acid as it combines with the base. The 20:1 ratio again is disrupted and the pH rises above 7.45, a condition known as **alkalosis**.

Intracellular and plasma proteins also serve as buffers. Plasma proteins contribute to buffering of extracellular fluids. Proteins in intracellular fluid provide extensive buffering for organic acids produced by cellular metabolism. In red blood cells, hemoglobin acts as a buffer for hydrogen ions when carbonic acid dissociates. Inorganic phosphates also serve as extracellular buffers, although their roles are not as important as those of the bicarbonate-carbonic acid buffer system. Phosphates are, however, important intracellular buffers, helping to maintain a stable pH within the cells.

Respiratory System

The respiratory system (and the cerebral respiratory center) regulates carbonic acid in the body by eliminating or retaining carbon dioxide. Carbon dioxide is a potential acid; when combined with water, it forms carbonic acid (see the previous equation), a volatile acid. Acute increases in either carbon dioxide or hydrogen ions in the blood stimulate the respiratory center in the brain. As a result, both the rate and depth of respiration increase. The increased rate and depth of lung ventilation eliminate carbon dioxide from the body, and carbonic acid levels fall, bringing the pH to a more normal range. Although this compensation for increased hydrogen ion concentration occurs within minutes, it becomes less effective over time. Patients with chronic lung disease may have consistently high carbon dioxide levels in their blood.

Alkalosis, by contrast, depresses the respiratory center. Both the rate and depth of respiration decrease, and carbon dioxide is retained. The retained carbon dioxide then combines with water to restore carbonic acid levels and bring the pH back within the normal range.

Renal System

The renal system is responsible for the long-term regulation of acid–base balance in the body. The kidneys normally eliminate excess nonvolatile acids produced during metabolism. The kidneys also regulate bicarbonate levels in extracellular fluid by regenerating bicarbonate ions as well as reabsorbing them in the renal tubules. Although the kidneys respond more slowly to changes in pH (over hours to days), they can generate bicarbonate and selectively excrete or retain hydrogen ions as needed. In acidosis, when excess hydrogen ion is present and the pH falls, the kidneys excrete hydrogen ions and retain bicarbonate. In alkalosis, the kidneys retain hydrogen ions and excrete bicarbonate to restore acid–base balance.

Assessing Acid–Base Balance

Acid–base balance is evaluated primarily by measuring arterial blood gases. Arterial blood is used because it reflects acid–base balance throughout the entire body better than venous blood. Arterial blood also provides information about the effectiveness of the lungs in oxygenating blood. The elements measured are pH, the $PaCO_2$, the PaO_2, and bicarbonate level.

The abbreviations $PaCO_2$ and PaO_2 are used interchangeably with PCO_2 and PO_2. The *P* stands for partial pressure, the pressure exerted by the gas dissolved in the blood. The *a* indicates that the sample is arterial blood. Because these measurements rarely are done on venous blood, the *a* often is deleted from the abbreviation.

The $PaCO_2$ measures the pressure exerted by dissolved carbon dioxide in the blood. It reflects the respiratory component of acid–base regulation and balance, and is regulated by the lungs. The normal value is 35 to 45 mmHg. A $PaCO_2$ of less than 35 mmHg is known as *hypocapnia*; a $PaCO_2$ greater than 45 mmHg is *hypercapnia*.

The PaO_2 is a measure of the pressure exerted by oxygen that is dissolved in the plasma. Only about 3% of oxygen in the blood is transported in solution; most is combined with hemoglobin. However, it is the dissolved oxygen that is available to the cells for metabolism. As dissolved oxygen diffuses out of plasma into the tissues, more is released from hemoglobin. The normal value for PaO_2 is 80 to 100 mmHg. A PaO_2 of less than 80 mmHg is indicative of hypoxemia. The PaO_2 is valuable for evaluating respiratory function, but is not used as a primary measurement in determining acid–base status.

The **serum bicarbonate** (HCO_3^-) reflects the renal regulation of acid–base balance. It is often called the metabolic component of arterial blood gases. The normal HCO_3^- value is 22 to 26 mEq/L.

The **base excess (BE)** is a calculated value also known as *buffer base capacity*. The base excess measures substances that can accept or combine with hydrogen ion. It reflects the degree of acid–base imbalance by indicating the status of the body's total buffering capacity. It represents the amount of acid or base that must be added to a blood sample to achieve a pH of 7.4. This is essentially a measure of increased or decreased bicarbonate. The normal value for base excess for arterial blood is −3.0 to +3.0. Normal ABG values are summarized in Table 10–9.

TABLE 10–9 Normal Arterial Blood Gas Values

Value	Normal Range	Significance
pH	7.35–7.45	Reflects hydrogen ion (H^+) concentration • <7.35 = acidosis • >7.45 = alkalosis
$PaCO_2$	35–45 mmHg	Partial pressure of carbon dioxide (CO_2) in arterial blood • <35 mmHg = hypocapnia • >45 mmHg = hypercapnia
PaO_2	80–100 mmHg	Partial pressure of oxygen (O_2) in arterial blood • <80 mmHg = hypoxemia
HCO_3^-	22–26 mEq/L	Bicarbonate concentration in plasma
BE	−3 to +3	Base excess; a measure of buffering capacity

ABGs are analyzed to identify acid–base disorders and their probable cause, to determine the extent of the imbalance, and to monitor treatment. When analyzing ABG results, it is important to use a systematic approach. First evaluate each individual measurement, then look at the interrelationships to determine the patient's acid–base status (see Box 10–3).

ACID–BASE IMBALANCE

Acid–base imbalances fall into two major categories: acidosis and alkalosis. Acidosis occurs when the hydrogen ion concentration increases above normal (pH below 7.35). Alkalosis occurs when the hydrogen ion concentration falls below normal (pH above 7.45).

Acid–base imbalances are further classified as metabolic or respiratory disorders. In metabolic disorders, the primary change is in the concentration of bicarbonate. In metabolic acidosis, the amount of bicarbonate is decreased in relation to the amount of acid in the body (Figure 10–14 ■ on page 216). It can develop as a result of abnormal bicarbonate losses or because of excess nonvolatile acids in the body. The pH falls below 7.35 and the bicarbonate concentration is less than 22 mEq/L. Metabolic alkalosis, by contrast, occurs when there is an excess of bicarbonate in relation to the amount of hydrogen ion (Figure 10–15 ■). The pH is above 7.45 and the bicarbonate concentration is greater than 26 mEq/L.

In respiratory disorders, the primary change is in the concentration of carbonic acid. Respiratory acidosis occurs when carbon dioxide is retained, increasing the amount of carbonic acid in the body (Figure 10–16 ■). As a result, the pH falls to less than 7.35, and the $PaCO_2$ is greater than 45 mmHg. When too much carbon dioxide is "blown off," carbonic acid levels fall and respiratory alkalosis develops (Figure 10–17 ■). The pH rises to above 7.45 and the $PaCO_2$ is less than 35 mmHg.

Acid–base disorders are further defined as *primary* (simple) and *mixed*. Primary disorders usually are due to one cause. For example, respiratory failure often causes respiratory acidosis due to retained

BOX 10–3 Interpreting Arterial Blood Gases

1. Look at the pH:
   - pH < 7.35 = acidosis
   - pH > 7.45 = alkalosis
2. Look at the $PaCO_2$:
   - $PaCO_2$ < 35 mmHg = hypocapnia; more carbon dioxide is being exhaled than normal
   - $PaCO_2$ > 45 mmHg = hypercapnia; carbon dioxide is being retained
3. Evaluate the pH–$PaCO_2$ relationship for a possible respiratory problem:
   - If the pH is < 7.35 (acidosis) and the $PaCO_2$ is > 45 mmHg (hypercapnia), retained carbon dioxide is causing increased H^+ concentration and *respiratory acidosis*.
   - If the pH is > 7.45 (alkalosis) and the $PaCO_2$ is < 35 mmHg (hypocapnia), low carbon dioxide levels and decreased H^+ concentration are causing *respiratory alkalosis*.
4. Look at the bicarbonate:
   - If the HCO_3^- is < 22 mEq/L, bicarbonate levels are lower than normal.
   - If the HCO_3^- is > 26 mEq/L, bicarbonate levels are higher than normal.
5. Evaluate the pH, HCO_3^-, and BE for a possible metabolic problem:
   - If the pH is < 7.35 (acidosis), the HCO_3^- is < 22 mEq/L, and the BE is < −3 mEq/L, then low bicarbonate levels and high H^+ concentrations are causing *metabolic acidosis*.
   - If the pH is > 7.45 (alkalosis), the HCO_3^- is > 26 mEq/L, and the BE is > +3 mEq/L, then high bicarbonate levels are causing *metabolic alkalosis*.
6. Look for compensation:
   - *Renal compensation:*
     - In respiratory acidosis (pH < 7.35, $PaCO_2$ > 45 mmHg), the kidneys retain HCO_3^- to buffer the excess acid, so the HCO_3^- is > 26 mEq/L.
     - In respiratory alkalosis (pH > 7.45, $PaCO_2$ < 35 mmHg), the kidneys excrete HO_3^- to minimize the alkalosis, so the HCO_3^- is < 22 mEq/L.
   - *Respiratory compensation:*
     - In metabolic acidosis (pH < 7.35, HCO_3^- < 22 mEq/L), the rate and depth of respirations increase, increasing carbon dioxide elimination, so the $PaCO_2$ is < 35 mmHg.
     - In metabolic alkalosis (pH > 7.45, HCO_3^- > 26 mEq/L), respirations slow, carbon dioxide is retained, so the $PaCO_2$ is > 45 mmHg.
7. Evaluate oxygenation.
   - PaO_2 < 80 mmHg = hypoxemia; possible hypoventilation
   - PaO_2 > 100 mmHg = hyperventilation

carbon dioxide; renal failure usually causes metabolic acidosis due to retained hydrogen ion and impaired bicarbonate production. Table 10–10 summarizes primary acid–base imbalances with common causes of each. Mixed disorders occur from combinations of respiratory and metabolic disturbances. For example, a patient in cardiac arrest develops a mixed respiratory and metabolic acidosis due to lack of ventilation (and retained CO_2) and hypoxia of body tissues that leads to anaerobic metabolism and acid by-products (excess nonvolatile acids).

FAST FACTS

- Simple acid–base imbalances are more commonly seen than mixed imbalances. Common causes of simple acid–base imbalances include the following:
  - Diabetic ketoacidosis (metabolic acidosis)
  - Chronic obstructive lung disease (respiratory acidosis)
  - Anxiety-related (psychogenic) hyperventilation (respiratory alkalosis).
- Critically ill patients are at higher risk for mixed acid–base imbalances.

Compensation

With primary acid–base disorders, compensatory changes in the other part of the regulatory system occur to restore a normal pH and homeostasis. In metabolic acid–base disorders, the change in pH affects the rate and depth of respirations. This, in turn, affects carbon dioxide elimination and the $PaCO_2$, helping restore the carbonic acid:bicarbonate ratio. The kidneys compensate for simple respiratory imbalances. The change in pH affects both bicarbonate conservation and hydrogen ion elimination (refer to Table 10–10).

Compensatory changes in respirations occur within minutes of a change in pH. These changes, however, become less effective over time. The renal response takes longer to restore the pH, but is a more effective long-term mechanism. If the pH is restored to within normal limits, the disorder is said to be fully compensated. When these changes are reflected in ABG values but the pH remains outside normal limits, the disorder is said to be partially compensated.

The Patient with Metabolic Acidosis

Metabolic acidosis (bicarbonate deficit) is characterized by low pH (<7.35) and low bicarbonate (<22 mEq/L) values. It may be caused by excess acid in the body or loss of bicarbonate from the body. When metabolic acidosis develops, the respiratory system attempts to return the pH to normal by increasing the rate and depth of respirations. Carbon dioxide elimination increases, and the $PaCO_2$ falls (<35 mmHg) (refer to Figure 10–14).

RISK FACTORS

Metabolic acidosis rarely is a primary disorder; it usually develops during the course of another disease:

- Acute lactic acidosis usually results from tissue hypoxia due to shock or cardiac arrest.
- Patients with type 1 diabetes mellitus are at risk for developing diabetic ketoacidosis. (See Chapter 20 for more information about diabetes and its complications.)
- Acute or chronic renal failure impairs the excretion of metabolic acids.
- Diarrhea, intestinal suction, or abdominal fistulas increase the risk for excess bicarbonate loss.

Other common causes of metabolic acidosis are listed in Table 10–10.

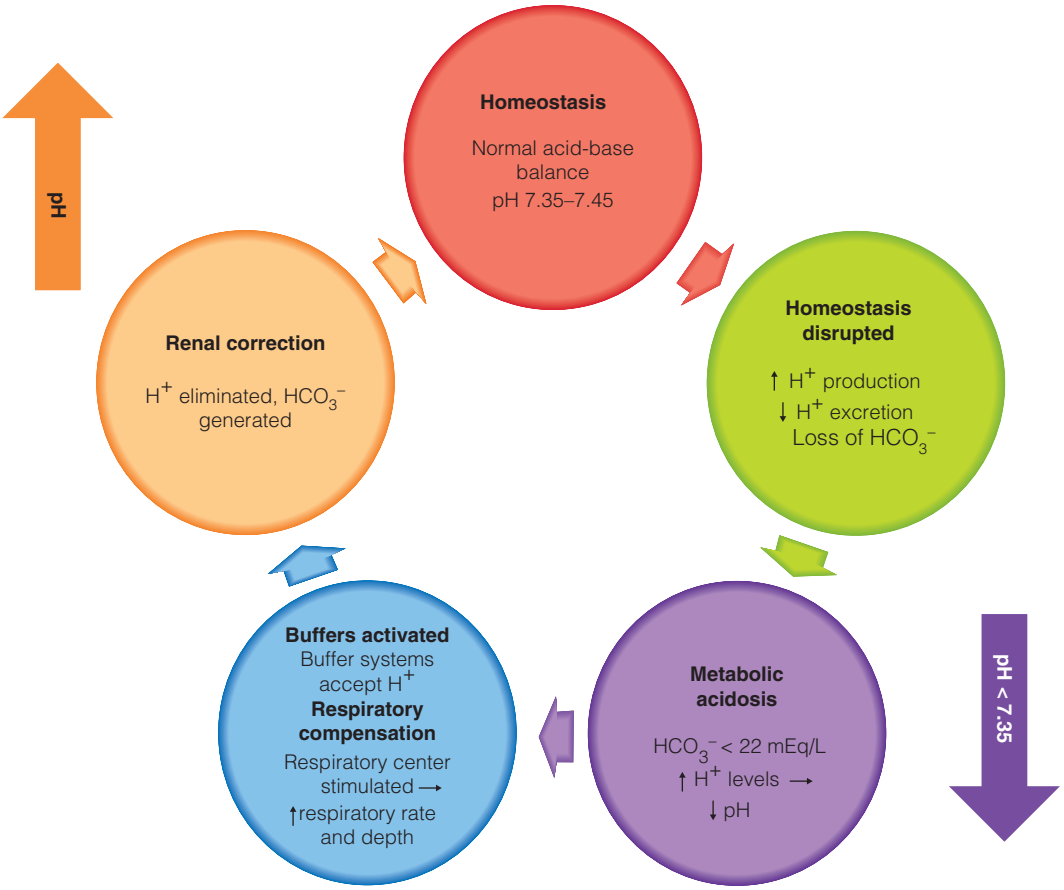

Figure 10–14 ■ Metabolic acidosis. Excess nonvolatile acids such as ketones or lactic acid or a loss of bicarbonate ions increases H^+ levels in body fluids, causing the pH to fall.

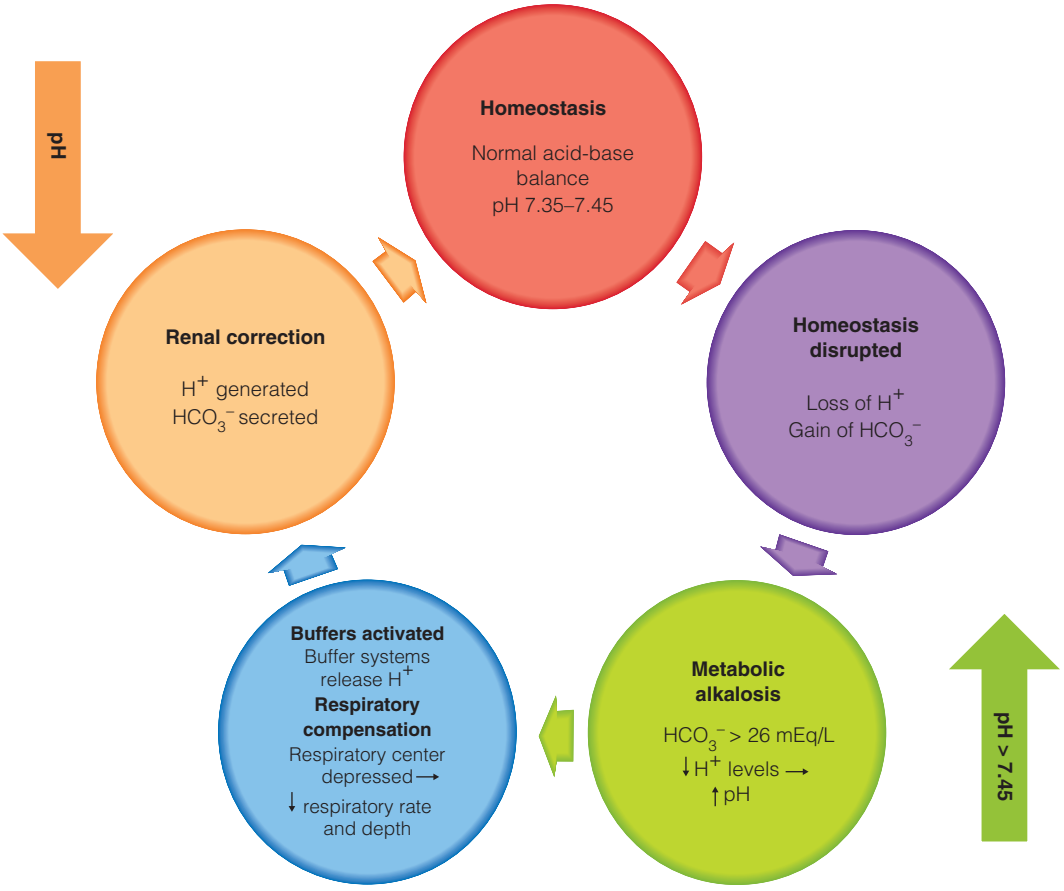

Figure 10–15 ■ Metabolic alkalosis. Loss of acids (for example, loss of stomach acid with vomiting) or excess bicarbonate ingestion decreases H^+ levels in body fluids, causing the pH to rise.

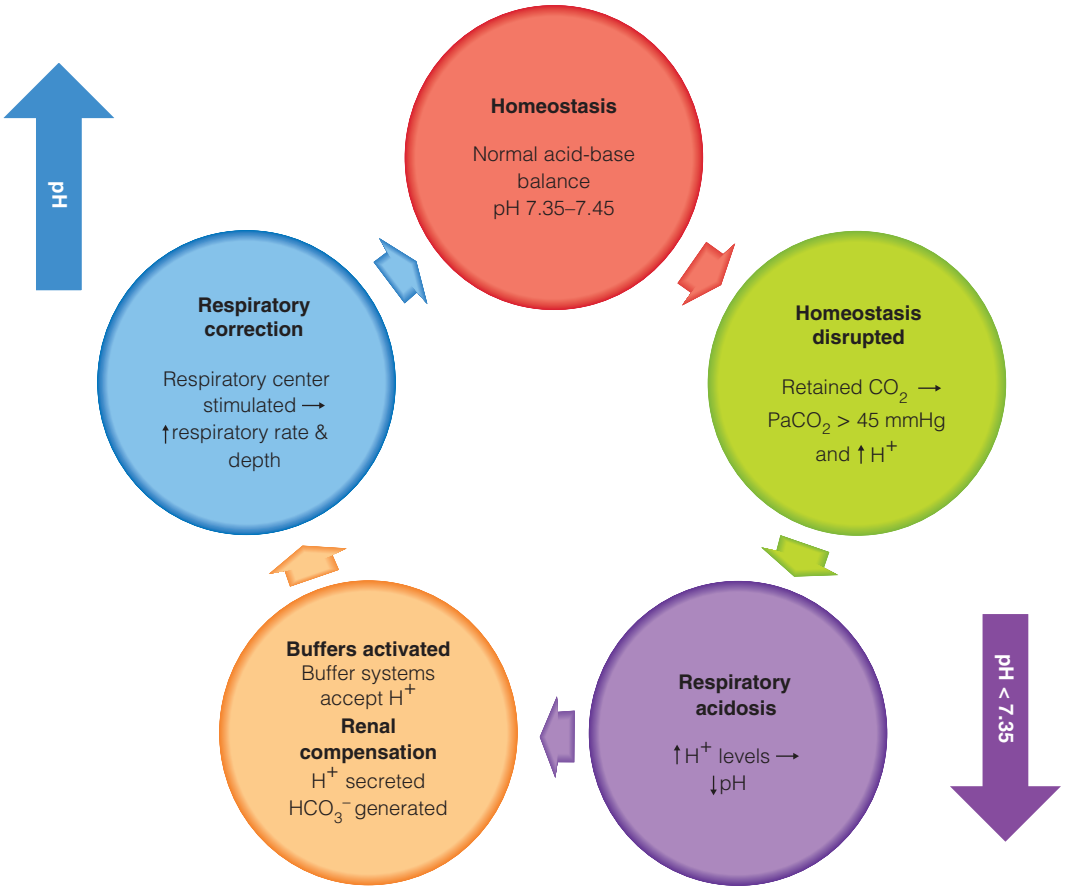

Figure 10–16 ■ Respiratory acidosis. Hypoventilation and retained CO_2 (increased $PaCO_2$) increase H^+ levels in body fluids, causing the pH to fall.

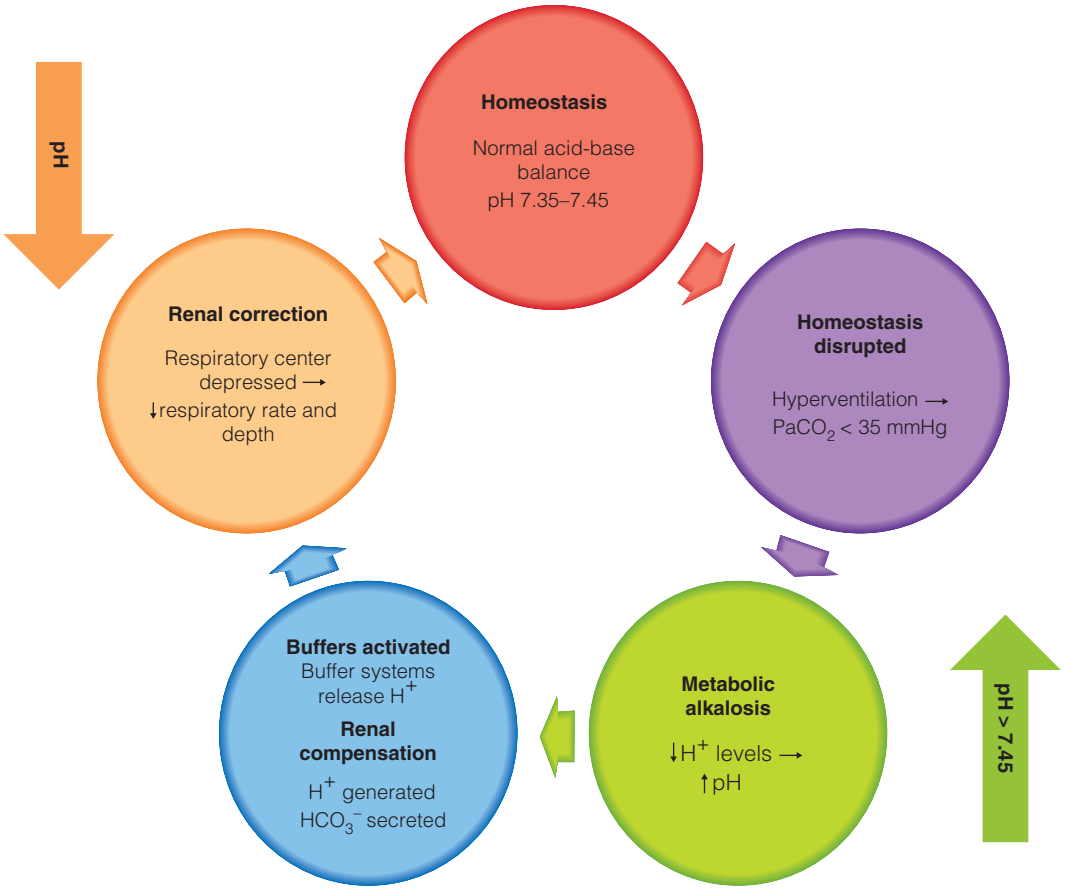

Figure 10–17 ■ Respiratory alkalosis. Hyperventilation and excess CO_2 elimination (decreased $PaCO_2$) decrease H+ levels in body fluids, causing the pH to rise.

TABLE 10–10 Common Causes of and Compensation for Primary Acid–Base Imbalances

Imbalance	Common Causes	Compensation
Metabolic acidosis **pH < 7.35** **HCO_3^- < 22 mEq/L** Critical values pH < 7.20 HCO_3^- < 10 mEq/L	Increased acid production • Lactic acidosis • Ketoacidosis related to diabetes, starvation, or alcoholism Decreased acid excretion • Renal failure Increased bicarbonate loss • Diarrhea, ileostomy drainage, intestinal fistula • Biliary or pancreatic fistulas Increased chloride • Sodium chloride IV solutions • Renal tubular acidosis	Rate and depth of respirations increase, eliminating additional CO_2.
Metabolic alkalosis **pH > 7.45** **HCO_3^- > 26 mEq/L** Critical values pH > 7.60 HCO_3^- > 40 mEq/L	Increased acid loss or excretion • Vomiting, gastric suction • Hypokalemia Increased bicarbonate • Alkali ingestion (bicarbonate of soda) • Excess bicarbonate administration	Rate and depth of respirations decrease, retaining CO_2.
Respiratory acidosis **pH < 7.35** **$PaCO_2$ > 45 mmHg** Critical values pH < 7.2 $PaCO_2$ > 77 mmHg	Acute respiratory acidosis • Acute respiratory conditions (pulmonary edema, pneumonia, acute asthma) • Opiate overdose • Chest trauma Chronic respiratory acidosis • Chronic respiratory conditions (COPD, cystic fibrosis) • Multiple sclerosis, other neuromuscular diseases	Kidneys conserve bicarbonate to restore carbonic acid:bicarbonate ratio of 1:20
Respiratory alkalosis **pH > 7.45** **$PaCO_2$ < 35 mmHg** Critical values pH > 7.60 $PaCO_2$ < 20 mmHg	• Anxiety-induced hyperventilation (e.g., anxiety) • Fever • Early salicylate intoxication • Hyperventilation with mechanical ventilator	Kidneys excrete bicarbonate and conserve H^+ to restore carbonic acid:bicarbonate ratio

PATHOPHYSIOLOGY

Three basic mechanisms that can cause metabolic acidosis are as follows:

- Accumulation of metabolic acids
- Excess loss of bicarbonate
- An increase in chloride levels.

An accumulation of metabolic acids can result from excess acid production or impaired elimination of metabolic acids by the kidney. Lactic acidosis develops due to tissue hypoxia and a shift to anaerobic metabolism by the cells. Lactate and hydrogen ions are produced, forming lactic acid. Both oxygen and glucose are necessary for normal cell metabolism. When intracellular glucose is inadequate due to starvation or a lack of insulin to move it into cells, the body breaks down fatty tissue to meet its metabolic needs. In this process, fatty acids are released, which are converted to ketones; ketoacidosis develops. Substances such as aspirin, methanol (wood alcohol), and ethylene (contained in antifreeze and solvents) cause a toxic increase in body acids by either breaking down into acid products (salicylic acid) or stimulating metabolic acid production (Grossman & Porth, 2014). Renal failure impairs the body's ability to excrete excess hydrogen ions and form bicarbonate.

Excess metabolic acids increase the hydrogen ion concentration of body fluids. The excess acid is buffered by bicarbonate, leading to what is known as a high anion gap acidosis (see Box 10–4).

The pancreas secretes bicarbonate-rich fluid into the small intestine. Intestinal suction, severe diarrhea, ileostomy drainage, or fistulas can lead to excess losses of bicarbonate. Hyperchloremic acidosis can develop when excess chloride solutions (such as NaCl or ammonium chloride) are infused, causing a rise in chloride concentrations. It also may be related to renal disease or administration of carbonic anhydrate inhibitor diuretics. The anion gap remains normal in metabolic acidosis due to bicarbonate loss or excess chloride.

Acidosis depresses cell membrane excitability, affecting neuromuscular function. It also increases the amount of free calcium in ECF by interfering with protein binding. Severe acidosis (pH of 7.0 or less) depresses myocardial contractility, leading to a fall in cardiac output. If kidney function is normal, acid excretion and ammonia production increase to eliminate excess hydrogen ions.

Acid–base imbalances also affect electrolyte balance. In acidosis, potassium is retained as the kidney excretes excess hydrogen ions. Excess hydrogen ions also enter the cells, displacing potassium from the intracellular space to maintain the balance of cations and anions within the cells. The effect of both processes is to increase

BOX 10–4 Unraveling the Anion Gap

Calculation of the anion gap can help identify the underlying mechanism in metabolic acidosis if it is unclear.

The number of cations (positively charged ions) and anions (negatively charged ions) in ECF normally is equal (refer to Figure 10–2). Not all of these ions, however, are measured in laboratory testing (e.g., organic acids and proteins). The anion gap is calculated by subtracting the sum of two measured anions, chloride and bicarbonate, from the concentration of the major cation, sodium (see the accompanying figure). The normal anion gap is 8 to 12 mEq/L.

Excess acids in ECF are buffered by bicarbonate, reducing serum bicarbonate levels and the total measured concentration of anions. This increases the anion gap (**B** in figure). When bicarbonate is lost from the body or chloride levels increase, however, the anion gap remains within normal limits (**C** in figure). This occurs because an increase or decrease in one of these negatively charged ions causes a corresponding change in the other to maintain balance (e.g., $\downarrow HCO_3^- \leftrightarrow \uparrow Cl^-$), and there is no change in the amount of unmeasured anions.

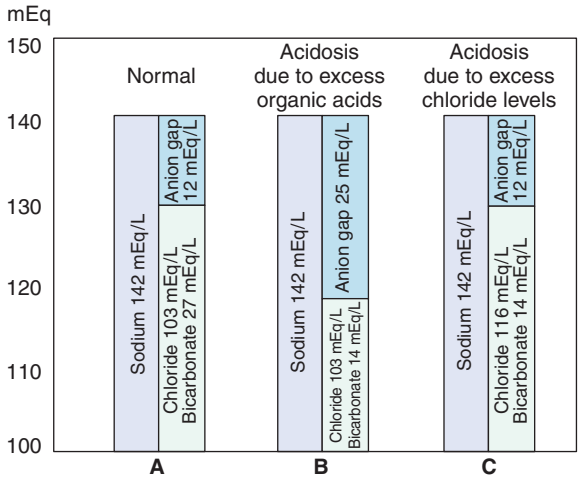

Illustration of the anion gap in metabolic acidosis. A, Normal anion gap. B, High anion gap caused by excess acids. C, Normal anion gap with hyperchloremia.

serum potassium levels. Also in acidosis, calcium is released from its bonds with plasma proteins, increasing the amount of ionized (free) calcium in the blood. Magnesium levels may fall in acidosis.

MANIFESTATIONS

Metabolic acidosis affects the function of many body systems. Its general manifestations include weakness and fatigue, headache, and general malaise. Gastrointestinal function is affected, causing anorexia, nausea, vomiting, and abdominal pain. The level of consciousness declines, leading to stupor and coma. Cardiac dysrhythmias develop, and cardiac arrest may occur. The skin is often warm and flushed. Manifestations of compensatory mechanisms are seen. The respirations, known as **Kussmaul's respirations**, are labored, deep, and rapid. The patient may complain of shortness of breath or dyspnea. See the Manifestations box below.

●○● INTERPROFESSIONAL CARE

Management of metabolic acidosis focuses on treating the underlying cause of the disorder and correcting the acid–base imbalance.

DIAGNOSIS

The following laboratory and diagnostic tests may be ordered:

- *ABGs* generally show a pH of less than 7.35 and a bicarbonate level of less than 22 mEq/L. A compensatory decrease in $PaCO_2$ to less than 35 mmHg is usually present.
- *Serum electrolytes* demonstrate elevated potassium levels and possible low magnesium levels. The total calcium may remain unchanged, although more physiologically active ionized calcium is available. Sodium, chloride, and bicarbonate levels are used to calculate the anion gap.
- The *ECG* may show changes that reflect both the acidosis (particularly when severe) and the accompanying hyperkalemia.
- Other diagnostic studies such as blood glucose and renal function studies may be ordered to identify the underlying cause of metabolic acidosis.

MANIFESTATIONS OF METABOLIC ACIDOSIS

- Anorexia, nausea and vomiting
- Abdominal pain
- Weakness and fatigue
- General malaise
- Decreasing levels of consciousness
- Dysrhythmias, bradycardia
- Warm, flushed skin
- Hyperventilation (Kussmaul's respirations)

MEDICATIONS

An alkalinizing solution such as bicarbonate may be given for severe acidosis (pH less than 7.1) to reduce the effects of the acidosis on cardiac function. Sodium bicarbonate is the most commonly used alkalinizing solution; others include lactate, citrate, and acetate solutions (which are metabolized to bicarbonate). Alkalinizing solutions are given IV for severe acute metabolic acidosis. In chronic metabolic acidosis, the oral route is used.

The patient treated with bicarbonate must be carefully monitored. Rapid correction of the acidosis may lead to metabolic alkalosis and hypokalemia. Hypernatremia and hyperosmolality may develop as well, leading to water retention and fluid overload.

PRACTICE ALERT!

As metabolic acidosis is corrected, potassium shifts back into the intracellular space. This can lead to hypokalemia and cardiac dysrhythmias. Carefully monitor serum potassium levels during treatment.

Treatment for diabetic ketoacidosis includes IV insulin and fluid. Alcoholic ketoacidosis is treated with saline solutions and glucose. Treatment for lactic acidosis from decreased tissue perfusion (e.g., shock or cardiac arrest) focuses on correcting the underlying problem and improving tissue perfusion. Patients with chronic renal failure and mild or moderate metabolic acidosis may or may not require treatment, depending on the pH and bicarbonate levels.

When metabolic acidosis is due to diarrhea, treatment includes correcting the underlying cause and providing fluid and electrolyte replacement.

●○● NURSING CARE

Nurses frequently provide care for patients with metabolic acidosis, although the focus of care often is the disorder underlying the acidosis (e.g., diabetes mellitus, renal failure) rather than the acidosis itself. For this reason, it is vital for the nurse to be aware of the effects of the acidosis and its implications for nursing care.

Health Promotion

To promote health in patients at risk for metabolic acidosis, discuss management of their underlying disease process (e.g., type 1 diabetes or renal failure) to prevent complications such as diabetic ketoacidosis and metabolic acidosis. Because early manifestations of metabolic acidosis (e.g., fatigue, general malaise, anorexia, nausea, abdominal pain) resemble those of common viral disorders such as the flu, stress the importance of promptly seeking treatment if these manifestations develop.

Assessment

Assessment data related to metabolic acidosis include the following:

- ***Health history:*** current manifestations, including anorexia, nausea, vomiting, abdominal discomfort, fatigue, lethargy, other manifestations; duration of manifestations and any precipitating factors such as diarrhea, ingestion of a toxin such as aspirin, methanol, or ethylene; chronic diseases such as diabetes or renal failure, cirrhosis of the liver, or endocrine disorders; current medications
- ***Physical assessment:*** mental status and level of consciousness; vital signs; apical and peripheral pulses; skin color and temperature; abdominal contour and distention; bowel sounds; urine output.

Priorities of Care

While interprofessional management of the patient with metabolic acidosis focuses on correcting the imbalance and the underlying condition causing it, monitoring for adverse effects of the imbalance and treatment instituted is the priority for nursing management.

Diagnoses, Outcomes, and Interventions

Decreased Cardiac Output

Metabolic acidosis affects cardiac output by decreasing myocardial contractility, slowing the heart rate, and increasing the risk for dysrhythmias. The accompanying hyperkalemia increases the risk for decreased cardiac output as well (see the earlier discussion about hyperkalemia). As the acidosis is corrected, potassium shifts back into ICF, placing the patient at risk for hypokalemia.

Expected Outcome: Patient's cardiac output will remain within expected range as evidenced by clear mentation; normal color; warm, dry skin; stable vital signs; and urine output greater than 30 mL/h.

- Monitor vital signs, including peripheral pulses and capillary refill. *Hypotension, diminished pulse strength, and slowed capillary refill may indicate decreased cardiac output and impaired tissue perfusion. Poor tissue perfusion can increase the risk for lactic acidosis.*
- Monitor the ECG pattern for dysrhythmias and changes characteristic of potassium imbalances (hyperkalemia or hypokalemia). Notify the physician of changes. *Progressive ECG changes such as widening of the QRS complex indicate an increasing risk of dysrhythmias and cardiac arrest. Dysrhythmias further decrease cardiac output, possibly intensifying the degree of acidosis.*
- Monitor laboratory values, including ABGs, serum electrolytes, and renal function studies (serum creatinine and BUN). *Frequent monitoring of laboratory values allows evaluation of the effectiveness of treatment as well as early identification of potential problems.*

PRACTICE ALERT!

Apply firm pressure to the puncture site for 2–5 minutes after the needle is withdrawn following aspiration of arterial blood to measure ABGs to prevent bleeding into the surrounding tissues. Pressure may need to be applied longer for patients receiving anticoagulation medications.

Risk for Fluid Volume Excess

Administering bicarbonate to correct severe acidosis increases the risk for hypernatremia, hyperosmolality, and fluid volume excess.

Expected Outcome: Patient's fluid balance will be maintained as evidenced by balanced intake and output, stable weight and vital signs, and laboratory values within expected ranges.

- Monitor and maintain fluid replacement as ordered. Monitor serum sodium levels and osmolality. *Bicarbonate administration can cause hypernatremia and hyperosmolality, leading to water retention.*
- Monitor heart and lung sounds, hemodynamic pressures, and respiratory status. *Increasing dyspnea, adventitious lung sounds and a high venous or atrial pressure reading, and a third heart sound (S_3) due to the volume of blood flow through the heart are indicative of hypervolemia and should be reported to the healthcare provider.*
- Assess for edema, particularly in the back, sacral, and periorbital areas. *Initially, edema affects dependent tissues—the back and sacrum in patients who are bedridden. Periorbital edema indicates more generalized edema.*
- Assess urine output hourly. Maintain accurate intake and output records. Note urine output less than 30 mL/h or a positive fluid balance on 24-hour total intake and output calculations. *Heart failure and inadequate renal perfusion may lead to decreased urine output.*
- Obtain daily weights using consistent conditions. *Daily weights are an accurate indicator of fluid balance.*
- Administer prescribed diuretics as ordered, monitoring the patient's response to therapy. *Loop or high-ceiling diuretics such as furosemide (Lasix) can lead to further electrolyte imbalances, especially hypokalemia. This is a significant risk like that seen during correction of metabolic acidosis.*

Risk for Injury

Mental status and brain function are affected by acidosis, increasing the risk for injury.

Expected Outcome: Patient will remain free of injury.

- Monitor neurologic function, including mental status, level of consciousness, and muscle strength. *As the pH falls, mental functioning declines, leading to confusion, stupor, and a decreasing level of consciousness.*

- Institute safety precautions as necessary: Keep the bed in its lowest position, use a position alarm as needed. *These measures help protect the patient from injury resulting from confusion or disorientation.*
- Keep clocks, calendars, and familiar objects at bedside. Orient to time, place, and circumstances as needed. Allow significant others to remain with the patient as much as possible. *An unfamiliar environment and altered thought processes can further increase the risk for injury. Significant others provide a sense of security and reduce anxiety.*

Delegating Nursing Care Activities

As appropriate and allowed by the designated duties and responsibilities of assistive personnel, the nurse may delegate nursing care activities such as measuring intake and output, obtaining daily weights, and assisting with safety precautions and reorientation for the patient with metabolic acidosis.

Continuity of Care

Discharge planning and teaching focus on the underlying cause of the imbalance. The patient who has developed ketoacidosis as a result of diabetes mellitus, starvation, or alcoholism needs interventions and teaching to prevent future episodes of acidosis. Diet, medication management, and alcohol dependency treatment are vital teaching areas. When metabolic acidosis is related to renal failure, the patient should be referred for management of the renal failure itself. Patients who have experienced diarrhea or excess ileostomy drainage leading to bicarbonate loss need information about appropriate diarrhea treatment strategies and when to call their primary care provider.

The Patient with Metabolic Alkalosis

Metabolic alkalosis (bicarbonate excess) is characterized by a high pH (>7.45) and a high bicarbonate (>26 mEq/L). It may be caused by loss of acid or excess bicarbonate in the body. When metabolic alkalosis develops, the respiratory system attempts to return the pH to normal by slowing the respiratory rate (refer to Figure 10–15). Carbon dioxide is retained, and the $PaCO_2$ increases (>45 mmHg).

RISK FACTORS

As is the case with other acid–base imbalances, metabolic alkalosis rarely occurs as a primary disorder. Risk factors include hospitalization, hypokalemia, and treatment with alkalinizing solutions (e.g., bicarbonate).

PATHOPHYSIOLOGY

Hydrogen ions may be lost via gastric secretions, through the kidneys, or because of a shift of H^+ into the cells. Metabolic alkalosis due to loss of hydrogen ions usually occurs because of vomiting or gastric suction. Gastric secretions are highly acidic (pH 1 to 3). When these are lost through vomiting or gastric suction, both H^+ and chloride are lost. Chloride is the major anion in ECF; when it is lost, bicarbonate is retained as a replacement anion. As a result, the alkalinity of body fluids increases.

Increased renal excretion of hydrogen ions can be prompted by hypokalemia as the kidneys try to conserve potassium, excreting hydrogen ion instead. Hypokalemia contributes to metabolic alkalosis in another way as well. When potassium shifts out of cells to maintain extracellular potassium levels, hydrogen ions shift into the cells to maintain the balance between cations and anions within the cell.

Excess bicarbonate usually occurs as a result of ingesting antacids that contain bicarbonate (such as soda bicarbonate or Alka-Seltzer) or overzealous administration of bicarbonate to treat metabolic acidosis. Common causes of metabolic alkalosis are summarized in Table 10–10.

In alkalosis, more calcium combines with serum proteins, reducing the amount of ionized (physiologically active) calcium in the blood. This accounts for many of the common manifestations of metabolic alkalosis. Alkalosis also affects potassium balance: Hypokalemia not only can cause metabolic alkalosis (see the earlier discussion), but it also can result from metabolic alkalosis. Hydrogen ions shift out of the intracellular space to help restore the pH, prompting more potassium to enter the cells and depleting ECF potassium. The high pH depresses the respiratory system as the body retains carbon dioxide to restore the carbonic acid:bicarbonate ratio.

MANIFESTATIONS AND COMPLICATIONS

Manifestations of metabolic alkalosis (see the following box) occur as a result of decreased calcium ionization and are similar to those of hypocalcemia, including numbness and tingling around the mouth, fingers, and toes; dizziness; Trousseau's sign; and muscle spasm. As the respiratory system compensates for metabolic alkalosis, respirations are depressed and respiratory failure with hypoxemia and respiratory acidosis may develop.

●○● INTERPROFESSIONAL CARE

Interprofessional management of metabolic alkalosis focuses on diagnosing and correcting the underlying cause.

DIAGNOSIS

The following laboratory and diagnostic tests may be ordered:

- *ABGs* show a pH greater than 7.45 and bicarbonate level greater than 26 mEq/L. With compensatory hypoventilation, carbon dioxide is retained, and the $PaCO_2$ is greater than 45 mmHg.
- *Serum electrolytes* often demonstrate hypokalemia (serum K^+ < 3.5 mEq/L) and decreased chloride (<95 mEq/L) levels. The serum bicarbonate level is high. Although the total serum calcium may be normal, the ionized fraction of calcium is low.
- *Urine pH* may be low (pH 1 to 3) if metabolic alkalosis is caused by hypokalemia. The kidneys selectively retain potassium and excrete hydrogen ion to restore ECF potassium levels. Urinary chloride levels may be normal or greater than 250 mEq/24 hours.

MANIFESTATIONS OF METABOLIC ALKALOSIS

- Confusion
- Decreasing level of consciousness
- Hyperreflexia
- Tetany
- Dysrhythmias
- Hypotension
- Seizures
- Respiratory failure

- The *ECG pattern* shows changes similar to those seen with hypokalemia. These changes may be due to hypokalemia or to the alkalosis.

MEDICATIONS

Treatment of metabolic alkalosis includes restoring normal fluid volume and administering potassium chloride and sodium chloride solution. The potassium restores serum and intracellular potassium levels, allowing the kidneys to more effectively conserve hydrogen ions. Chloride promotes renal excretion of bicarbonate. Sodium chloride solutions restore fluid volume deficits that can contribute to metabolic alkalosis. In severe alkalosis, an acidifying solution such as dilute hydrochloric acid or ammonium chloride may be administered. In addition, drugs may be used to treat the underlying cause of the alkalosis.

●○● NURSING CARE

Health Promotion

Health promotion activities focus on teaching patients the risks of using sodium bicarbonate as an antacid to relieve heartburn or gastric distress. Stress the availability of other effective antacid preparations and the need to seek medical evaluation for persistent gastric manifestations. In the hospital setting, carefully monitor laboratory values for patients at risk for developing metabolic alkalosis, particularly patients undergoing continuous gastric suction.

Assessment

Focused assessment data related to metabolic alkalosis include the following:

- ***Health history:*** current manifestations, such as numbness and tingling, muscle spasms, dizziness, other manifestations; duration of manifestations and any precipitating factors such as bicarbonate ingestion, vomiting, diuretic therapy, or endocrine disorders; current medications
- ***Physical assessment:*** vital signs including apical pulse and rate and depth of respirations; muscle strength; deep tendon reflexes.

Priorities of Care

The risk for impaired gas exchange as a compensatory response to metabolic alkalosis is a priority problem, especially when the alkalosis is severe, or when the patient's respiratory status is compromised by underlying lung disease.

Diagnoses, Outcomes, and Interventions

Risk for Impaired Gas Exchange

Respiratory compensation for metabolic alkalosis depresses the respiratory rate and reduces the depth of breathing to promote carbon dioxide retention. As a result, the patient is at risk for impaired gas exchange.

Expected Outcome: Patient's rate and depth of respirations and oxygen saturation levels will remain within normal range for patient.

- Monitor respiratory rate, depth, and effort. Monitor oxygen saturation continuously, reporting an oxygen saturation level of less than 95% (or as ordered). *The depressed respiratory drive associated with metabolic alkalosis can lead to hypoxemia and impaired oxygenation of tissues. Oxygen saturation levels of less than 90% indicate significant oxygenation problems.*
- Assess skin color; note and report cyanosis around the mouth. *Central cyanosis, seen around the mouth and oral mucous membranes, indicates significant hypoxia.*
- Monitor mental status and level of consciousness (LOC). Report decreasing LOC or behavior changes such as restlessness, agitation, or confusion. *Changes in mental status or behavior may be early manifestations of hypoxia.*
- Place in semi-Fowler's or Fowler's position as tolerated. *Elevating the head of the bed facilitates alveolar ventilation and gas exchange.*
- Schedule nursing care activities to allow rest periods. *The patient who is hypoxemic has limited energy reserves, necessitating frequent rest and limited activities.*
- Administer oxygen as ordered or necessary to maintain oxygen saturation levels. *Supplemental oxygen can help maintain blood and tissue oxygenation despite depressed respirations.*

Deficient Fluid Volume

Patients with metabolic alkalosis often have an accompanying fluid volume deficit.

Expected Outcome: Patient's fluid balance will be maintained as evidenced by stable vital signs and weight, balanced intake and output, and laboratory values within expected ranges.

- Assess vital signs, CVP, and peripheral pulse volume at least every 4 hours. *Hypotension, tachycardia, a low CVP, and weak, easily obliterated peripheral pulses indicate hypovolemia.*
- Weigh daily under standard conditions (time of day, clothing, and scale). *Rapid weight changes accurately reflect fluid balance.*
- Administer IV fluids as prescribed using an infusion pump. Monitor for indicators of fluid overload if rapid fluid replacement is ordered: dyspnea, tachypnea, tachycardia, increased CVP, jugular vein distention, and edema. *Rapid fluid replacement may lead to hypervolemia, resulting in pulmonary edema and cardiac failure, particularly in patients with compromised cardiac and renal function.*
- Monitor serum electrolytes, osmolality, and ABG values. *Rehydration and administration of potassium chloride will affect both acid–base and fluid and electrolyte balance. Careful monitoring is important to identify changes.*

Delegating Nursing Care Activities

Under the direction of the nurse, nursing care activities such as positioning, measuring vital signs and intake and output, obtaining daily weights, and providing hygiene measures for the patient with metabolic alkalosis may be performed by assistive personnel.

Continuity of Care

When preparing the patient with metabolic alkalosis for discharge or continuing care, consider the cause of the alkalosis and any underlying factors. For example, provide teaching about the following:

- Using appropriate antacids for heartburn and gastric distress
- Using potassium supplements as ordered or eating high-potassium foods to avoid hypokalemia if taking a potassium-wasting diuretic or if aldosterone production is impaired
- Contacting the primary care provider if uncontrolled or extended vomiting develops.

The Patient with Respiratory Acidosis

Respiratory acidosis is caused by an excess of dissolved carbon dioxide, or carbonic acid. It is characterized by a pH of less than 7.35 and a $PaCO_2$ greater than 45 mmHg (refer to Figure 10–16). Respiratory acidosis may be either acute or chronic. In chronic respiratory acidosis, the bicarbonate is higher than 26 mEq/L as the kidneys compensate by retaining bicarbonate.

RISK FACTORS

Acute or chronic lung disease (e.g., pneumonia or chronic obstructive pulmonary disease [COPD]) is the primary risk factor for respiratory acidosis. Other conditions that depress or interfere with ventilation, such as opioid (narcotic) overdose, airway obstruction, or neuromuscular disease, also are risk factors for respiratory acidosis. Selected causes of respiratory acidosis are listed in Table 10–10.

PATHOPHYSIOLOGY

Both acute and chronic respiratory acidosis result from carbon dioxide retention caused by alveolar hypoventilation. Hypoxemia (low oxygen in the arterial blood) frequently accompanies respiratory acidosis.

ACUTE RESPIRATORY ACIDOSIS Acute respiratory acidosis occurs as the result of a sudden failure of ventilation. Chest trauma, aspiration of a foreign body, acute pneumonia, and overdoses of narcotic or sedative medications can lead to this condition. Because acute respiratory acidosis occurs with the sudden onset of hypoventilation—for example, with cardiac arrest—the $PaCO_2$ rises rapidly and the pH falls markedly. A pH of 7 or lower can occur within minutes (Metheny, 2012). The serum bicarbonate level initially is unchanged because the compensatory response of the kidneys occurs over hours to days.

Hypercapnia (increased carbon dioxide levels) affects neurologic function and the cardiovascular system. Carbon dioxide rapidly crosses the blood–brain barrier. Cerebral blood vessels dilate and, if the condition continues, intracranial pressure increases and papilledema (swelling and inflammation of the optic nerve where it enters the retina) develops. Peripheral vasodilation also occurs, and the pulse rate increases to maintain cardiac output.

CHRONIC RESPIRATORY ACIDOSIS Chronic respiratory acidosis is associated with chronic respiratory or neuromuscular conditions such as COPD, asthma, cystic fibrosis, or multiple sclerosis. These conditions affect alveolar ventilation because of airway obstruction, structural changes in the lung, or limited chest wall expansion. Most patients with chronic respiratory acidosis have COPD with chronic bronchitis and emphysema. In chronic respiratory acidosis, the $PaCO_2$ increases over time and remains elevated. The kidneys retain bicarbonate, increasing bicarbonate levels, and the pH often remains close to the normal range.

The acute effects of hypercapnia may not develop because carbon dioxide levels rise gradually, allowing compensatory changes to occur. When carbon dioxide levels are chronically elevated, the respiratory center becomes less sensitive to the gas as a stimulant of the respiratory drive. The PaO_2 provides the primary stimulus for respirations. Patients with chronic respiratory acidosis are at risk for developing carbon dioxide narcosis, with manifestations of acute respiratory acidosis, if the respiratory center is suppressed by administering excess supplemental oxygen.

PRACTICE ALERT!

Carefully monitor neurologic and respiratory status in patients with chronic respiratory acidosis who are receiving oxygen therapy. Immediately report a decreasing LOC or depressed respirations.

MANIFESTATIONS

The manifestations of acute and chronic respiratory acidosis differ (see the following box). In acute respiratory acidosis, the rapid rise in $PaCO_2$ levels causes manifestations of hypercapnia. Cerebral vasodilation causes manifestations such as headache, blurred vision, irritability, and mental cloudiness. If the condition continues, the level of consciousness progressively decreases. Rapid and dramatic changes in ABGs can lead to unconsciousness and ventricular fibrillation, a potentially lethal cardiac dysrhythmia. The skin of the patient with acute respiratory acidosis may be warm and flushed, and the pulse rate is elevated.

The manifestations of chronic respiratory acidosis include weakness and a dull headache. Sleep disturbances, daytime sleepiness, impaired memory, and personality changes also may be manifestations of chronic respiratory acidosis.

●○● INTERPROFESSIONAL CARE

Patients with acute respiratory failure usually require treatment in the emergency department or intensive care unit. The focus is on restoring adequate ventilation and gas exchange. Hypoxemia often accompanies acute respiratory acidosis, so oxygen is administered as well. Supplemental oxygen is administered with caution to patients with chronic respiratory acidosis.

DIAGNOSIS

The following laboratory and diagnostic tests may be ordered:

- *ABGs* show a pH of less than 7.35 and a $PaCO_2$ of more than 45 mmHg. In acute respiratory acidosis, the bicarbonate level is initially within normal range but increases to greater than 26 mEq/L as the kidneys generate bicarbonate if the condition persists. In chronic respiratory acidosis, both the $PaCO_2$ and the HCO_3^- may be significantly elevated.
- *Serum electrolytes* may show hypochloremia (chloride level < 98 mEq/L) in chronic respiratory acidosis.

MANIFESTATIONS OF RESPIRATORY ACIDOSIS

ACUTE RESPIRATORY ACIDOSIS
- Headache
- Warm, flushed skin
- Blurred vision
- Irritability, altered mental status
- Decreasing level of consciousness
- Cardiac arrest

CHRONIC RESPIRATORY ACIDOSIS
- Weakness
- Dull headache
- Sleep disturbances with daytime sleepiness
- Impaired memory
- Personality changes

Additional diagnostic tests may be done to identify the underlying cause of the respiratory acidosis. *Chest x-ray* and *sputum studies* (cytology and culture) may be ordered to identify an acute or chronic lung disorder. If drug overdose is suspected, serum levels of the drug may be obtained. Pulmonary function tests may be done to determine if chronic lung disease is the cause of the respiratory acidosis.

MEDICATIONS

Bronchodilator drugs may be administered to open the airways and antibiotics prescribed to treat respiratory infections. If excess narcotics or anesthetic has caused acute respiratory acidosis, drugs to reverse their effects (such as naloxone) may be given.

RESPIRATORY SUPPORT

Treatment of respiratory acidosis, either acute or chronic, focuses on improving alveolar ventilation and gas exchange. Pulmonary hygiene measures, such as breathing treatments or percussion and drainage, may be instituted. Adequate hydration is important to promote removal of respiratory secretions. In patients with chronic respiratory acidosis, oxygen is administered cautiously to avoid carbon dioxide narcosis.

HIGH-ACUITY CARE

Patients with severe respiratory acidosis and hypoxemia may require intubation and mechanical ventilation. The $PaCO_2$ level is lowered slowly to avoid complications such as cardiac dysrhythmias and decreased cerebral perfusion. In patients with chronic respiratory acidosis, mechanical ventilation allows administration of a higher percentage of oxygen because the ventilator can maintain adequate respirations should the respiratory center be depressed.

●○● NURSING CARE

See the Case Study & Nursing Care Plan for a patient with acute respiratory acidosis on page 225.

Health Promotion

Health promotion activities related to respiratory acidosis focus on identifying, monitoring, and teaching patients at risk. Carefully monitor patients receiving anesthesia, narcotic analgesics, or sedatives for manifestations of respiratory depression. Monitor the response of patients with a history of chronic lung disease to oxygen therapy. Teach patients who have an identified risk for respiratory acidosis (such as people using narcotic analgesia for cancer pain and people with chronic lung disease) and their families about early manifestations of respiratory depression and acidosis, and instruct them to immediately contact their care provider if manifestations develop.

Assessment

Assessment data related to respiratory acidosis include the following:

- ***Health history:*** current manifestations, including headache, irritability or lethargy, difficulty thinking, blurred vision, and other manifestations; duration of manifestations and any precipitating factors such as drug use or respiratory infection; chronic diseases such as cystic fibrosis or COPD; current medications
- ***Physical assessment:*** mental status and level of consciousness; vital signs; skin color and temperature; rate and depth of respirations, pulmonary excursion, lung sounds; examination of optic fundus for possible papilledema.

Priorities of Care

Restoring effective alveolar ventilation and gas exchange is the priority of interprofessional and nursing care for patients with respiratory acidosis.

Diagnoses, Outcomes, and Interventions

Impaired Gas Exchange

Expected Outcome: Patient's gas exchange will be restored as evidenced by oxygen saturation and ABGs within normal ranges for patient.

- Frequently assess respiratory status, including rate, depth, effort, and oxygen saturation levels. *Decreasing respiratory rate and effort along with decreasing oxygen saturation levels may signal worsening respiratory failure and respiratory acidosis.*
- Frequently assess level of consciousness. *A decline in LOC may indicate increasing hypercapnia and the need for increasing ventilatory support (such as intubation and mechanical ventilation).*
- Promptly evaluate and report ABG results to the physician and respiratory therapist. *Rapid changes in carbon dioxide or oxygen levels may necessitate modification of the treatment plan to prevent complications of overcorrection of respiratory acidosis.*
- Place in semi-Fowler's to Fowler's position as tolerated. *Elevating the head of the bed promotes lung expansion and gas exchange.*
- Administer oxygen as ordered. Carefully monitor response. Reduce the oxygen flow rate or percentage and immediately report increasing somnolence. *Supplemental oxygen can suppress the respiratory drive in patients with chronic respiratory acidosis.*

Ineffective Airway Clearance

Expected Outcome: Effective ventilation will be restored as evidenced by clear lung sounds and a respiratory rate and depth that is normal for patient.

- Frequently auscultate breath sounds (whether on or off a mechanical ventilator). *Increasing adventitious sounds or decreasing breath sounds (faint or absent) may indicate worsening airway clearance due to obstruction or fatigue.*
- Encourage the patient with chronic respiratory acidosis to use pursed-lip breathing. *Pursed-lip breathing helps maintain open airways throughout exhalation, promoting carbon dioxide elimination.*
- Frequently reposition and encourage ambulation as tolerated. *Repositioning, sitting at the bedside, and ambulation promote airway clearance and lung expansion.*
- Encourage fluid intake of up to 3000 mL per day as tolerated or allowed. *Fluids help liquefy secretions and hydrate respiratory mucous membranes, promoting airway clearance.*
- Administer medications such as inhaled bronchodilators as ordered. *Inhaled bronchodilators help relieve bronchial spasm, dilating airways.*
- Provide percussion, vibration, and postural drainage as ordered. *Pulmonary hygiene measures such as these help loosen respiratory secretions so they can be coughed out of airways.*

Delegating Nursing Care Activities

As appropriate and allowed by the designated duties and responsibilities of assistive personnel, the nurse may delegate nursing care activities such as measuring intake and output, obtaining vital signs

and daily weights, repositioning and assisting with ambulation, and providing oral care.

Continuity of Care

Planning and teaching for home or continuing care focuses on the health problem that caused the patient to develop respiratory acidosis. The patient who developed acute respiratory acidosis as a result of acute pneumonia or chest trauma may only require teaching to prevent future problems. If acute respiratory acidosis occurred secondary to a narcotic overdose, determine if the drug was prescribed for pain or if it was an illicit street drug. Provide teaching to the patient who requires narcotic medication on a continuing basis. Refer the patient using illicit drugs to a substance abuse counselor, treatment center, or Narcotics Anonymous as appropriate.

For patients with chronic lung disease, discuss ways to avoid future episodes of acute respiratory failure. Encourage the patient to be immunized against pneumococcal pneumonia and influenza. Discuss ways to avoid acute respiratory infections and measures to take when respiratory status is further compromised.

The Patient with Respiratory Alkalosis

Respiratory alkalosis is characterized by a pH $>$ 7.45 and a $PaCO_2$ $<$ 35 mmHg. It is always caused by hyperventilation leading to a carbon dioxide deficit (refer to Figure 10–17).

RISK FACTORS

Anxiety with hyperventilation is the most common cause of respiratory alkalosis; therefore, anxiety disorders increase the risk for this acid–base imbalance. In the patient who is critically ill, mechanical ventilation is a risk factor for respiratory alkalosis.

PATHOPHYSIOLOGY

In acute respiratory alkalosis, the pH rises rapidly as the $PaCO_2$ falls. Because the kidneys are unable to rapidly adapt to the change in pH, the bicarbonate level remains within normal limits. Anxiety-based hyperventilation is the most common cause of acute respiratory alkalosis. Other physiologic causes of hyperventilation include high fever, hypoxia, gram-negative bacteremia, and thyrotoxicosis. Early salicylate intoxication (aspirin overdose), encephalitis, and high progesterone levels in pregnancy directly stimulate the respiratory center, potentially leading to hyperventilation and respiratory alkalosis. Hyperventilation also can occur during anesthesia or mechanical ventilation if the rate and tidal volume (depth) of ventilations are excessive.

If hyperventilation continues, the kidneys compensate by eliminating bicarbonate to restore the carbonic acid:bicarbonate ratio. The bicarbonate level is lower than normal in chronic respiratory alkalosis, and the pH may be close to the normal range.

Alkalosis increases binding of extracellular calcium to albumin, reducing ionized calcium levels. As a result, neuromuscular excitability increases and manifestations similar to hypocalcemia develop. Low carbon dioxide levels in the blood cause vasoconstriction of cerebral vessels, increasing the neurologic manifestations of the disorder.

MANIFESTATIONS

The manifestations of respiratory alkalosis include light-headedness, a feeling of panic and difficulty concentrating, circumoral and

CASE STUDY & NURSING CARE PLAN A Patient with Acute Respiratory Acidosis

Marlene Hitz, age 76, is eating lunch when she suddenly begins to choke and is unable to breathe. After several minutes of trying, an attendant at the senior center successfully dislodges some meat caught in Ms. Hitz's throat by using the Heimlich maneuver. Ms. Hitz is taken by ambulance to the emergency department for follow-up.

ASSESSMENT

Ms. Hitz is placed in an observation room. Oxygen is started at 4 L/min per nasal cannula. David Love, the nurse admitting Ms. Hitz, makes the following assessments: T 38.8°C (98.2°F), P 102 bpm, R 36/min and shallow, BP 146/92 mmHg, O_2 sat 92%. Skin is warm and dry. Alert but restless and not oriented to time or place; responds slowly to questions. Stat ABGs are drawn, a chest x-ray is done, and D_5 1/2NS is started IV at 50 mL/h.

The chest x-ray shows no abnormality. ABG results are pH 7.32 (normal: 7.35 to 7.45), $PaCO_2$ 48 mmHg (normal: 35 to 45 mmHg), PaO_2 92 mmHg (normal: 80 to 100 mmHg), and HCO_3^- 24 mEq/L (normal: 22 to 26 mEq/L).

DIAGNOSES

- *Impaired Gas Exchange* related to temporary airway obstruction
- *Anxiety* related to emergency hospital admission
- *Risk for Injury* related to confusion

EXPECTED OUTCOMES

- Patient will regain normal gas exchange and ABG values.
- Patient will be alert and oriented to time, place, and person.
- Patient will remain free of injury.

PLANNING AND IMPLEMENTATION

- Monitor ABGs, to be redrawn in 2 hours.
- Monitor vital signs and respiratory status (including oxygen saturation) every 15 minutes for the first hour, then every hour.
- Assess color of skin, nail beds, and oral mucous membranes every hour.
- Assess mental status and orientation every hour.
- Monitor anxiety level as evidenced by restlessness and agitation.
- Maintain a calm, quiet environment.
- Provide reorientation and explain all activities.

EVALUATION

Ms. Hitz remains in the emergency department for 6 hours. Her ABGs are still abnormal, and David now notes the presence of respiratory crackles and wheezes. She is less anxious and responds appropriately when asked who and where she is. Because she has not regained normal gas exchange, Ms. Hitz is admitted to the hospital for continued observation and treatment.

Clinical Reasoning in Patient Care

1. Describe the pathophysiologic process that leads to acute respiratory acidosis in Ms. Hitz.
2. Describe the effect of acidosis on mental function.
3. The emergency department physician provides the following orders on Ms. Hitz's admission to the ED: continuous cardiac monitoring; O_2 at 4 L/min per nasal cannula; IV of D_5 1/2NS at 50 mL/h; stat chest x-ray, ABGs, CBC, and serum electrolytes; 12-lead ECG; NPO until fully alert; keep in Fowler's position. How would you prioritize these orders for implementation?
4. What teaching would you provide to Ms. Hitz to prevent future episodes of choking?

See Evaluating Your Response in Appendix B.

MANIFESTATIONS OF RESPIRATORY ALKALOSIS

- Dizziness
- Numbness and tingling around mouth, hands, and feet
- Palpitations
- Dyspnea
- Chest tightness
- Anxiety/panic
- Tremors
- Tetany
- Seizures, loss of consciousness

distal extremity paresthesias, tremors, and positive Chvostek's and Trousseau's signs. The patient also may experience tinnitus, a sensation of chest tightness, and palpitations (cardiac dysrhythmias). Seizures and loss of consciousness may occur. (See the Manifestations box.)

●○● INTERPROFESSIONAL CARE

Management of respiratory alkalosis focuses on correcting the imbalance and treating the underlying cause.

DIAGNOSIS

ABGs generally show a pH greater than 7.45 and a $PaCO_2$ of less than 35 mmHg. In chronic hyperventilation, there is a compensatory decrease in serum bicarbonate to less than 22 mEq/L and the pH may be near normal.

MEDICATIONS

A sedative or antianxiety agent may be necessary to relieve anxiety and restore a normal breathing pattern. Additional drugs to correct underlying problems other than anxiety-induced hyperventilation may be ordered.

RESPIRATORY THERAPY

The usual treatment for anxiety-related respiratory alkalosis involves instructing the patient to breathe more slowly and having the patient breathe into a paper bag or rebreather mask. This allows rebreathing of exhaled carbon dioxide, increasing $PaCO_2$ levels, and reducing the pH. If excessive ventilation by a mechanical ventilator is the cause of respiratory alkalosis, ventilator settings are adjusted to reduce the respiratory rate and tidal volume as indicated. When hypoxia is the underlying cause of hyperventilation, oxygen is administered.

●○● NURSING CARE

Health Promotion

Identify patients at risk in the hospital (e.g., patients on mechanical ventilation or who have a fever or infection), and monitor assessment data and ABGs to identify early manifestations of hyperventilation and respiratory alkalosis.

Diagnoses, Outcomes, and Interventions

Ineffective Breathing Pattern

The usual cause of hyperventilation and respiratory alkalosis is psychologic, although physiologic disorders also can lead to hyperventilation. It is important to not only address the hyperventilation, but also to identify the underlying cause.

Expected Outcome: Patient's respiratory rate and depth and ABG values will be within normal ranges.

- Assess respiratory rate, depth, and ease. Monitor vital signs (including temperature) and skin color. *Assessment data can help identify the underlying cause, such as a fever or hypoxia.*
- Obtain subjective assessment data such as circumstances leading up to the current situation, current health and recent illnesses or medication use, and current manifestations. *Subjective data provide cues to the cause and circumstances of the hyperventilation response.*
- Reassure the patient that he or she is not experiencing a heart attack and that manifestations will resolve when breathing returns to normal. *Manifestations of hyperventilation and respiratory alkalosis such as dyspnea, chest tightness or pain, and palpitations can mimic those of a heart attack.*
- Instruct the patient to maintain eye contact and breathe with you to slow the respiratory rate. *These measures help to make the patient aware of respirations and provide a sense of support and control.*
- Have the patient breathe into a paper bag or apply a rebreather mask. *This allows the patient to rebreathe exhaled carbon dioxide, increasing the $PaCO_2$ and decreasing the pH.*
- Protect the patient from injury. *If hyperventilation continues to the point at which the patient loses consciousness, respirations will return to normal, as will acid–base balance.*

Continuity of Care

Planning and teaching for home care is directed toward the underlying cause of hyperventilation. If anxiety precipitated the episode, discuss anxiety management strategies with the patient. Refer the patient and family to a counselor if appropriate. Teach the patient to identify a hyperventilation reaction, and how to breathe into a paper bag to manage it at home.

CHAPTER HIGHLIGHTS

- **The volume and composition of body fluid is normally maintained by a balance of fluid and electrolyte intake; elimination of water, electrolytes, and acids by the kidneys; and hormonal influences. Changes in any of these factors can lead to a fluid, electrolyte, or acid–base imbalance that adversely affects health.**
- **Fluid, electrolyte, and acid–base imbalances can affect all body systems, especially the cardiovascular system, the central nervous system, and the transmission of nerve impulses. Conversely, primary disorders of the respiratory, renal, cardiovascular, endocrine, or other body systems can lead to an imbalance of fluids, electrolytes, or acid–base status.**
- Fluid and sodium imbalances are related; both affect serum osmolality.
- Potassium imbalances are commonly seen in patients with acute or chronic illnesses. Both hypokalemia and hyperkalemia affect cardiac conduction and function. Carefully monitor cardiac rhythm and status in patients with very low or very high potassium levels.
- Calcium imbalances primarily affect neuromuscular transmission: Hypocalcemia increases neuromuscular irritability; hypercalcemia depresses neuromuscular transmission. Magnesium imbalances have a similar effect.
- Acid–base imbalances may be caused by either metabolic or respiratory health problems. Simple acid–base imbalances (respiratory or metabolic acidosis or alkalosis) are more commonly seen than mixed imbalances.
- Buffers, lungs, and kidneys work together to maintain acid–base balance in the body. Buffers respond to changes almost immediately; the lungs respond within minutes; the kidneys require hours to days to restore normal acid–base balance.
- The lungs compensate for metabolic acid–base imbalances by excreting or retaining carbon dioxide. This is accomplished by increasing or decreasing the rate and depth of respirations.
- The kidneys compensate for respiratory acid–base imbalances by producing and retaining or excreting bicarbonate, and by retaining or excreting hydrogen ions.
- **The nurse provides teaching for patients, families, and caregivers to prevent fluid, electrolyte, and acid–base imbalances in at-risk patients. Careful monitoring of respiratory and cardiovascular status, mental status, neuromuscular function, and laboratory values is an important nursing responsibility for all patients with fluid, electrolyte, or acid–base imbalances and those who are at risk for these imbalances.**

TEST YOURSELF NCLEX-RN® REVIEW

1. A patient is admitted to the emergency department with hypovolemia. Which IV solution should the nurse anticipate administering?
   1. 3% sodium chloride
   2. 10% dextrose in water
   3. 0.45% sodium chloride
   4. lactated Ringer's solution
2. Which manifestations should the nurse expect to assess in a patient with fluid volume deficit?
   1. headache and muscle cramps
   2. dyspnea and respiratory crackles
   3. increased pulse rate and blood pressure
   4. orthostatic hypotension and flat neck veins
3. The nurse is planning care for a patient with acute hypernatremia. What should the nurse include in this patient's plan of care? (Select all that apply.)
   1. Maintain IV access.
   2. Limit length of visits.
   3. Restrict fluids to 1500 mL per day.
   4. Conduct frequent neurologic checks.
   5. Orient to time, place, and person every 2 hours.
4. A patient's serum potassium level is 2.2 mEq/L. Which nursing action is the highest priority for this patient?
   1. Start oxygen at 2 L/min.
   2. Initiate cardiac monitoring.
   3. Initiate seizure precautions.
   4. Keep the patient on bed rest.
5. The nurse instructs a patient on calcium supplement therapy. Which statement indicates that the patient understands how to take calcium supplementation?
   1. "I will take the calcium with meals."
   2. "I will take the calcium with a full glass of water."
   3. "I will take these supplements as needed for tremulousness."
   4. "I will take these supplements all at one time in the morning."
6. A patient is demonstrating confusion, hallucinations, and a positive Chvostek's sign. Which medication(s) should the nurse prepare to provide to this patient?
   1. calcium chloride
   2. magnesium sulfate
   3. insulin and glucose
   4. sodium bicarbonate
7. A patient's arterial blood gas results are pH 7.21, PaO_2 98 mmHg, $PaCO_2$ 32 mmHg, and HCO_3^- 17 mEq/L. Which acid–base imbalance do these results indicate to the nurse?
   1. metabolic acidosis
   2. metabolic alkalosis
   3. respiratory acidosis
   4. respiratory alkalosis
8. A patient diagnosed with a suspected heroin overdose has a respiratory rate of 5 to 6 per minute. Which additional data should the nurse expect to collect on this patient? (Select all that apply.)
   1. pH 7.29
   2. $PaCO_2$ 54 mmHg
   3. HCO_3^- 32 mEq/L
   4. alert and oriented
   5. skin warm and flushed

9. The nurse is caring for a patient undergoing gastric decompression. For which potential acid–base balance should the nurse plan interventions?
1. metabolic acidosis
2. metabolic alkalosis
3. respiratory acidosis
4. respiratory alkalosis

10. A patient being mechanically ventilated after a severe chest wall injury and flail chest complains of chest tightness, anxiety, and air hunger. The patient fears that a heart attack is pending. What should the nurse do first?
1. Notify the physician.
2. Obtain arterial blood gases.
3. Administer prescribed analgesic.
4. Contact respiratory therapy to evaluate ventilator settings.

See Test Yourself answers in Appendix B.

11 Nursing Care of Patients Experiencing Trauma and Shock

LEARNING OUTCOMES

1. Define the word *trauma*.
2. Define the components and types of trauma.
3. Describe the result of energy transfer to the human body.
4. Discuss causes, effects, and initial management of trauma.
5. Discuss diagnostic tests used in assessing patients experiencing trauma and shock.
6. Describe collaborative interventions for patients experiencing trauma and shock, including medications, blood transfusion, and intravenous fluids.
7. Discuss organ donation and forensic implications of traumatic injury or death.
8. Discuss cellular homeostasis and basic hemodynamics.
9. Discuss the risk factors, etiologies, and pathophysiology of hypovolemic shock, cardiogenic shock, obstructive shock, and distributive shock.
10. Use the nursing process as a framework for providing individualized care to patients experiencing trauma and shock.

CLINICAL COMPETENCIES

1. Describe steps of the primary survey to diagnose and manage life-threatening injuries.
2. Obtain initial subjective and objective data of the trauma patient to include history taking, assessment, review of past medical history, and communication with prehospital and other healthcare providers and family members.
3. Evaluate patient response to medical and surgical interventions for patients sustaining multiple trauma and shock.
4. Provide essential ongoing written communication for patient care and continuity of the trauma patient.
5. Describe the role of the nurse in trauma prevention education and develop a plan of care to restore the functional health status of trauma patients.
6. Communicate significant data and changes in the condition of the patient who has sustained trauma.
7. Identify nursing diagnoses based on signs and symptoms recognized during the nursing assessment.
8. Develop a plan of care for the trauma patient based on scientific knowledge and patient diversity that addresses the nursing diagnosis.
9. Document quality of care issues associated with the trauma patient.
10. Advocate for the patient's rights as indicated by documents that address end-of-life issues.
11. Comply with guidelines related to the Uniform Anatomical Gift Act.

MAJOR CHAPTER CONCEPTS

- Trauma is the global term used to describe injury to human tissues and organs caused by energy transfer from the environment. It is the primary cause of death for persons between 1 and 44 years of age.
- Trauma can affect all parts of the body and organ systems. The team approach is used in the care and management of the trauma patient, starting with prehospital care.
- Shock is a clinical syndrome of an imbalance between oxygen supply and demand, leading to life-threatening cellular dysfunction. Seven types of shock have been identified based on the underlying cause.

KEY TERMS

abrasion, *234*
brain death
  criteria, *239*
contusion, *234*
laceration, *234*
pneumothorax, *232*
puncture wound, *234*
shock, *244*
tension pneumothorax, *232*
transfusion, *237*
trauma, *230*

Management of shock focuses on correcting the underlying cause, maintaining oxygenation, and improving perfusion. Shock management is a high-acuity situation best conducted by a multidisciplinary healthcare team.

THE PATIENT EXPERIENCING TRAUMA

Trauma is defined as injury to human tissues and organs resulting from the transfer of energy from the environment. In the past the term *trauma* has been associated with the word *accident*. *Accident* means that the injury occurred without intent, a result of random chance. We now know that a considerable number of injuries are preventable and not of random chance. Intentional and nonintentional trauma encompasses a variety of injuries resulting from motor vehicle crashes, pedestrian injuries, gunshot wounds, falls, violence toward others, or self-inflicted violence. The injuries, disabilities, and deaths resulting from these acts constitute a major healthcare challenge.

FAST FACTS

- Trauma kills more people between the ages of 1 and 44 than any other disease or illness.
- Forty-three percent of all deaths from ages 1 to 4 are due to trauma.
- Forty-eight percent of all deaths from ages 5 to 14 are due to trauma.
- Sixty-two percent of all deaths from ages 15 to 24 are due to trauma.

Source: Centers for Disease Control and Prevention [CDC], 2009

Trauma usually occurs suddenly, leaving the patient and family with little time to prepare for its consequences. Nurses provide a vital link in providing both physical and psychosocial care to the injured patient and family. In caring for the patient who has experienced trauma, nurses must consider not only the initial physical injury, but also its long-term consequences, including rehabilitation. Trauma may alter the patient's previous way of life, potentially affecting independence, mobility, cognitive thinking, and appearance.

Components of Trauma

Trauma results from an abnormal exchange of energy between a host and a mechanism in a predisposing environment. The host is the person or group at risk of injury. Multiple factors influence the host's potential for injury: age, sex, race, economic status, preexisting illnesses, and use of substances such as street drugs and alcohol.

The mechanism is the source of the energy transmitted to the host. The energy exchanged can be mechanical, gravitational, thermal, electrical, physical, or chemical. Table 11–1 lists the most common mechanisms for each type of energy. Mechanical energy is the most common type of energy transferred to a host in trauma. The most common mechanical source of injury in all adult age groups is the motor vehicle.

Guns are another common mechanical source of injury. Trauma from gunshot wounds has steadily increased during the past 20 years and remains a major reason for emergency department and trauma center admissions, especially in large cities (Firearm and Injury Center at Penn, 2011).

TABLE 11–1 Common Mechanisms of Injury by Energy Source

Energy Source	Common Mechanisms of Injury
Mechanical	Motor vehicles Firearms Machines
Gravitational	Falls
Thermal	Heating appliances Fire Freezing temperatures
Electrical	Wires, sockets, and other electrical objects Lightning
Physical	Fists, feet, and other body parts (as in physical assault) Sharp objects, such as knives Ultraviolet radiation Ionizing radiation Water (drowning) Other submersion agents (e.g., grain) Explosions
Chemical	Drugs Poisons Industrial chemicals

When describing a traumatic injury, intention is included as a component. Most gunshot and stab wounds are examples of intentional injuries. It is important to remember, however, that some gunshot wounds are unintentional, such as those that occur when children play with their parents' guns. Other common unintentional injuries result from motor vehicle crashes, falls, drowning, fires, and hunting accidents.

The final component of trauma is the environment. For example, a road that has become slippery after a snowstorm is a physical environment that may contribute to an injury. Occupation is another important environmental factor to consider. Those in certain occupations face a high risk of trauma; examples include police officers, firefighters, professional athletes, racecar drivers, and taxi cab drivers. One's social environment also influences risk for injury, such as the presence of gangs and neighborhood violence. (See the Meeting Individualized Needs box for one such example, intimate partner violence.)

Types of Trauma

Minor trauma causes injury to a single part or system of the body and is usually treated in a physician's office or in the hospital emergency department. A fracture of the clavicle, a small second-degree burn, and a laceration requiring sutures are examples of minor trauma. Major or multiple trauma involves serious single-system injury (such as the traumatic amputation of a leg) or multiple-system injuries. Multiple trauma is most often the result of a motor vehicle crash.

Trauma is further classified as either blunt or penetrating. Blunt trauma occurs when there is no communication between the damaged tissues and the outside environment. Blunt trauma is the term for an injury caused by five types of force, including deceleration (a decrease in the speed of a moving object), acceleration (an increase in the speed of a moving object), shearing (forces occurring across a plane, with structures slipping across each other), compression (acute

Meeting Individualized Needs

Assessing Intimate Partner Violence (IPV)

Most IPV incidents are not reported, thus it is believed that the available data greatly underestimate the true magnitude of the problem. In 2005, it was reported that 329 males and 1181 females were murdered by an intimate partner. It is estimated that between 1 to 33 million women (many millions go unreported) are beaten by their intimate partner every year, resulting in 2 million injuries. Women make up about 84% of domestic violence victims. One out of every 6 American women has been a victim of an attempted or completed rape in her lifetime. Among men, 2.78 million have been victims of sexual assault or rape. IPV is the single largest cause of injury to women in the United States. This is a widespread problem that occurs regardless of age, sex, race, socioeconomic status, or education. IPV is also referred to as partner abuse or spousal abuse (CDC, 2012). In 2009, intimate partner violence made up 20% of violent crime against women. The same year, intimate partners committed 3% of all violent crimes against men.

The United Nations Development Fund for Women estimates that at least one of every three women globally will be beaten, raped, or otherwise abused during her lifetime. In most cases, the abuser is a member of her own family (Futures without Violence, 2011).

VIOLENCE IN OLDER ADULTS

Elder abuse is defined as anything that endangers the life of an older adult. This can range from physical or emotional assault to intimidation, neglect, or financial exploitation. In addition, willful deprivation of food or medical care is included. Persons 80 years of age and older experienced abuse and neglect at a rate of two to three times their proportion of the older population. The perpetrator is a family member in 90% of the cases (National Center on Elder Abuse, 2013).

The general approach to diagnosis in abuse situations is challenging and many times hidden. As with spousal, older adult, or child abuse, the task of identification is complex. The following are clues to identify violence-related injuries:

- Injuries that do not correlate with the history
- Injuries that suggest a defensive posture
- Injuries during pregnancy
- Pattern injuries
- Pattern burns
- Sexual abuse/rape
- Unusual or unexplained fractures
- Signs of confinement
- Unusual interaction between patient and caregiver
- Lack of medical attention; immunizations not up to date, poor dental health
- Unexplained dehydration or malnutrition.

tissue pressure resulting in increased density), or crushing (high force that results in tissue destruction). Blunt forces often cause multiple injuries that may affect the head, spinal cord, bones, thorax, and abdomen. Blunt trauma is frequently caused by motor vehicle crashes, falls, assaults, and sports activities.

Penetrating trauma occurs when a foreign object enters the body, causing damage to body structures. Structures commonly affected include the brain, lungs, heart, liver, spleen, the intestines, and the vascular system. Examples of penetrating trauma are gunshot or stab wounds and impalement.

Other types of trauma include inhalation injuries from gases, smoke, or steam, burn or freezing injuries, and blast injuries from explosions. Blast injuries result from the temperature and velocity of air movement and the force of projectiles from the explosion. Blast injuries are more severe in water than in air since blast waves travel farther and faster in water. Trauma from blast injuries includes pulmonary edema and hemorrhage, damage to abdominal organs, burns, penetrating injuries, and ruptured tympanic membranes.

Outcome studies show a correlation between survival rates of multiple trauma victims and rapid response times by prehospital providers, coupled with appropriate decision making with regards to transporting victims to a facility capable of treating their injuries (American College of Emergency Physicians, 2013). As a result, a system was devised to assist prehospital providers to make the appropriate decisions. Trauma patients are classified as Class 1, 2, or 3 based on factors including mechanism of injury, vehicle speed, height of falls, and location of penetrating injuries. Class 3 trauma is the least severe. An example would be a same-level fall without loss of consciousness or significant injury. Class 1 trauma involves life-threatening injuries likely to require medical specialists or immediate surgical intervention. Although any hospital emergency department should be capable of caring for Class 3 trauma patients, patients meeting Class 1 or 2 criteria should be transported to a designated trauma center when possible. Facilities designated as trauma centers have medical specialists and surgical coverage available or on call 24 hours a day.

Effects of Traumatic Injury

Death is a common result of serious traumatic injury, and falls into one of three categories related to the time span between injury and death: immediate, early, or late. Immediate death happens within minutes at the scene from such injuries as a torn thoracic aorta or decapitation. Early death occurs during what is called the "Golden Hour" (the first hour following the injury) from major abdominal or thoracic injuries or progression of intracranial hemorrhage. Appropriate care during this time has been shown to improve survival. Late death generally occurs days or weeks after the injury and results from multiple organ failure, sepsis, and coagulopathies.

Because of the serious consequences of trauma, it is important to rapidly identify the patient's injuries and institute appropriate interventions quickly. Following are common results of trauma and interventions necessary for good outcomes.

HEAD AND NECK EFFECTS—AIRWAY OBSTRUCTION

Maintenance of the airway and cervical spine are the highest priority in the trauma patient. Other distracting injuries may take the inexperienced practitioner away from the airway, but if the airway is not patent and the patient is unable to deliver oxygen to vital organs, all other interventions are futile.

Assessment includes determining airway patency. If the patient is unresponsive, manual opening of the airway using a jaw-thrust maneuver is necessary. The jaw thrust is recommended in patients with actual and potential C-spine injury. Once the airway is opened, the practitioner must identify any potential obstruction from the tongue,

loose teeth, foreign bodies, bleeding, secretions, vomitus, or edema. If the patient is responsive and can vocalize, that is a good indication that the airway is clear.

Any time the nurse performs an intervention it is important that you reassess the effectiveness of the intervention. For example, if you suction the airway to remove vomitus, you would reassess the airway after suctioning to determine if that intervention was successful or if you have to resuction the airway a second time.

All trauma patients should receive high-flow oxygen until stabilized. Assessment of breathing effectiveness is paramount. Assessment should include determining if the patient has spontaneous breathing, good rise and fall of the chest, good skin color, general rate and depth of respirations, abdominal or accessory muscle use, position of the trachea, observation of chest wall integrity and presence of jugular vein distention, bilateral breath sounds, and the presence of any surface trauma. Consider pulse oximetry and cardiac monitoring as well.

In addition to suctioning, other airway adjuncts available include oral or nasal pharyngeal airways, oxygen delivery devices, laryngeal mask airway, Combitube, and endotracheal intubation (Figure 11–1 ■). Intubation is the preferred method of airway management if the patient is unable to maintain oxygenation or an open airway.

Trauma patients may exhibit several aspects of airway management that are unique and require special preparation and precautions, as discussed next.

CLOSED HEAD INJURY Changes in hemodynamics, oxygenation, and ventilation should be minimized in order to maintain adequate cerebral perfusion pressure. Laryngoscopy causes a marked increase in intracranial pressure (ICP).

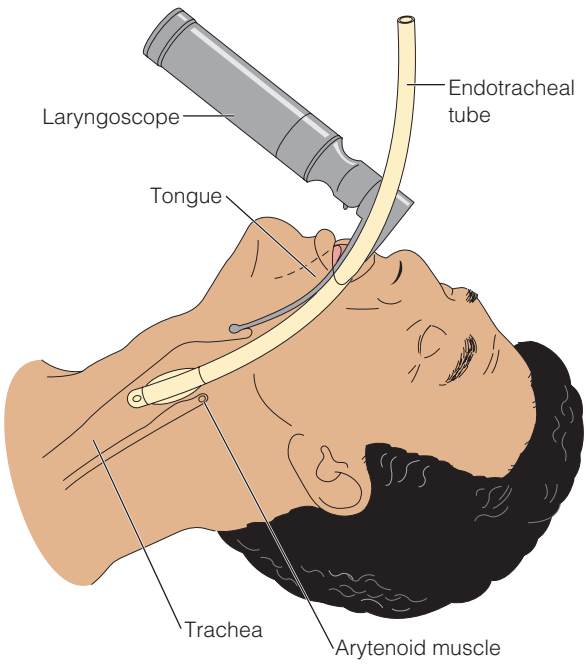

Figure 11–1 ■ Placement of an oral endotracheal tube (ETT) for intubation. When the ETT is in place, air or oxygen can be blown into the external opening of the tube and enter the trachea.

The goal is to maintain a $PaCO_2$ of 30 to 35 mmHg. Lidocaine administered 3 to 5 minutes prior to intubation can blunt an increase in ICP that is secondary to laryngeal stimulation. In a normotensive patient, beta blockers are given 2 to 3 minutes prior to intubation to attenuate the sympathetic response. Effective induction agents such as etomidate or thiopental have not been shown to increase ICP (Turner et al., 2005).

MAXILLOFACIAL TRAUMA Significant distortion of normal anatomy in facial trauma and respiratory compromise is not uncommon. Even in patients who present with mild respiratory compromise, rapid deterioration from edema or hemorrhage can occur. A surgical airway may be the only alternative.

DIRECT AIRWAY TRAUMA Penetrating trauma to the neck is associated with a high degree of morbidity and mortality. Airway involvement includes dyspnea, cyanosis, subcutaneous emphysema, hoarseness, or air bubbling from the wound. Orotracheal intubation with rapid sequence intubation is the technique of choice. The key is early identification of the need for intubation before the patient has no airway at all. Tracheobronchial injury occurs in approximately 10% to 20% of patients with penetrating neck injuries.

CERVICAL SPINE INJURY In the presence of a presumed C-spine injury, precautions for securing an airway are consistently applied. Approximately 1.5% to 3% of major trauma victims have clinically significant C-spine injuries (Desjardins, 2013). Oral intubation with manual in-line axial head and neck stabilization (MIAS) is a safe method for securing an airway. There is a decreased probability of C-spine injury if the following criteria are met:

- Absence of midline cervical spine tenderness
- Normal alertness
- Absence of intoxication
- Absence of a painful distracting injury
- No focal neurologic defects.

BURNS Burn patients with airway compromise require aggressive management. Upper airway edema associated with inhalation or enclosed-space fires can progress during the post-burn phase. Securing an airway sooner rather than later is the goal. See Chapter 17 for the nursing care of the patient with burns.

THORACIC EFFECTS

TENSION PNEUMOTHORAX A **pneumothorax** results when air enters the potential space between the parietal and visceral pleura. The thorax is completely filled by the lungs. Surface tension between the pleural surfaces holds the lungs to the chest wall. Air present in the pleural space will eventually collapse the lungs. A **tension pneumothorax** is life threatening and requires immediate intervention. On inspiration air enters the pleural space, does not escape on expiration, and increases the intrapleural pressure. This pressure collapses the injured lung and shifts the mediastinal contents, compressing the heart, great vessels, trachea, and eventually the uninjured lung. In turn, this causes the following signs and symptoms:

- Severe respiratory distress
- Hypotension

- Jugular vein distention
- Tracheal deviation toward the uninjured side
- Cyanosis.

The immediate short-term lifesaving intervention is a needle thoracostomy, inserting a large-bore over the needle catheter into the second intercostal space at the midclavicular line (MCL). See Figure 11–2 ■.

FLAIL CHEST Flail chest is the fracture of two or more ribs in two or more separate locations, leading to an unstable thoracic wall segment. Paradoxical movement of the chest wall is seen with the area sinking into the chest cavity with inspiration and protrusion with expiration. The area must be supported quickly to reestablish the thoracic bellows effect.

THORACIC CONTUSION AND RUPTURE Bruising of thoracic tissue is referred to as contusion. Pulmonary contusion is the most common traumatic chest injury. As a shock wave of force travels through the parenchyma, diffuse hemorrhage and alveolar edema develop, impairing gas exchange. Motor vehicle crashes are the most common cause of pulmonary contusions. Diaphragmatic rupture is a rare traumatic injury but can result in herniation of abdominal contents into the thoracic cavity, causing respiratory compromise.

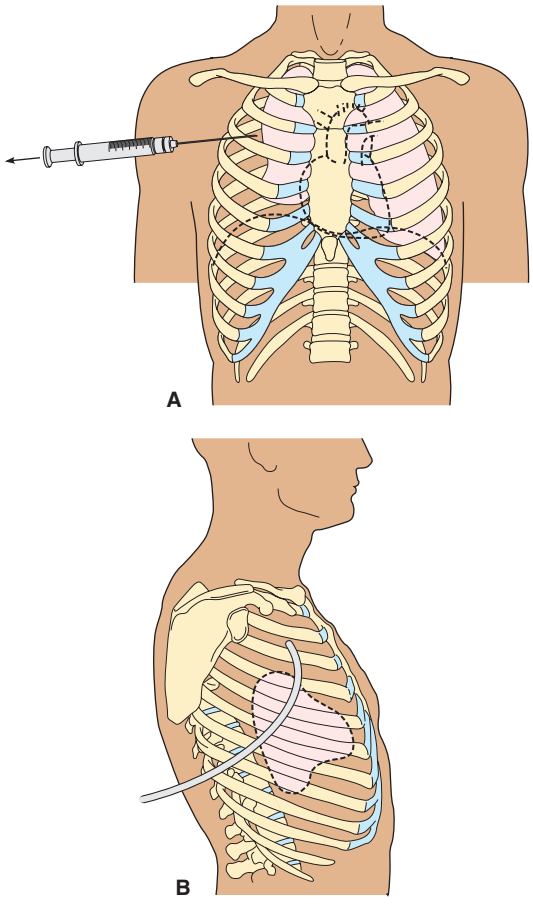

Figure 11–2 ■ A needle thoracostomy may be used in the emergency treatment of a tension pneumothorax. A, A large-gauge needle is introduced, and air and fluid are aspirated. B, Alternatively, a chest tube may be inserted and connected to a chest drainage system.

Myocardial contusion results in extravasation of red blood cells into myocardial fibers. As myocardial cells are injured, it is believed that cardiac output diminishes due to reductions in contractile strength. Myocardial rupture is an acute traumatic tear of any structures of the heart. Although rare, myocardial rupture is usually fatal with atrial rupture having the best chance for survival.

Cardiac tamponade occurs when blood or fluid collects in the pericardial sac. Resulting in myocardial compression, this condition is potentially life threatening and should be addressed immediately with pericardiocentesis. (See Chapter 31 for a discussion of nursing management of this condition.)

Aortic rupture (transection) can result in acceleration-deceleration injury or blunt chest trauma. This injury is commonly fatal due to profuse bleeding. Aortic rupture is the second most common cause of trauma death after traumatic brain injury.

HEMORRHAGE

When a patient has suffered an injury that causes external hemorrhage, such as severing of an artery, the bleeding must be controlled immediately. This may be done by applying direct pressure over the wound and applying pressure over arterial pressure points (Figure 11–3 ■).

Internal hemorrhage may result from either blunt or penetrating traumatic injury. Discovering the cause and location of the injury, as well as the extent of related blood loss, are the most important concerns. Several potential spaces in the body can accommodate large amounts of blood that may accumulate (called *third spacing*) following injury. For example, bleeding into the pleural space may occur with chest trauma (*hemothorax*), and bleeding into the abdominal

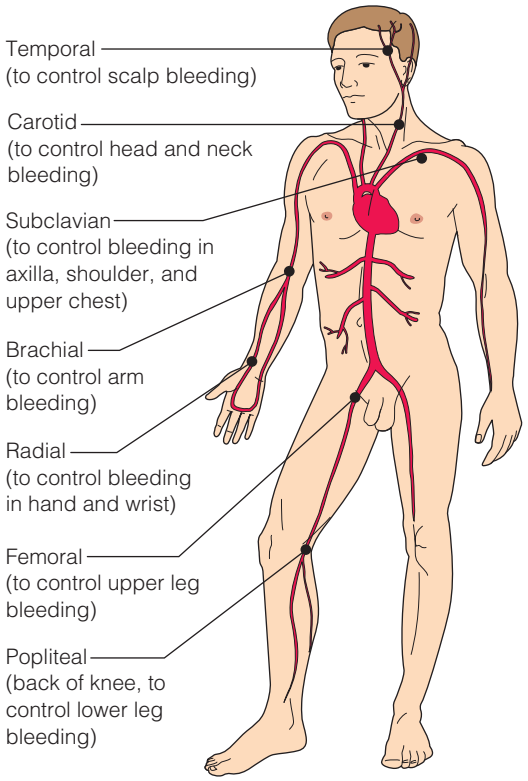

Figure 11–3 ■ The major pressure points used for the control of bleeding.

cavity may occur with abdominal trauma. A pelvic fracture may cause massive hemorrhage in the retroperitoneal region. Once the source of internal hemorrhage has been recognized, interventions are initiated, including operative control of bleeding and continual assessment of the patient. Hemorrhage may result in hypovolemic shock (discussed later in the chapter).

INTEGUMENTARY EFFECTS

Injuries to the integument generally are not as serious as other injuries, with the exception of burns (see Chapter 17). The primary organ involved in integumentary trauma is the skin; however, underlying structures may also be injured. Injuries may result from either blunt or penetrating sources. It is important to evaluate all injuries to the integument, because they may indicate a more serious injury such as an open fracture. Additionally, large wounds may contribute to significant blood loss.

Five specific injuries to the integument are contusions, abrasions, puncture wounds, lacerations, and full-thickness avulsion injuries (Figure 11–4 ■). **Contusions**, or superficial tissue injuries, result from blunt trauma that causes the breakage of small blood vessels and bleeding into the surrounding tissue. **Abrasions**, or partial-thickness denudations of an area of integument, generally result from falls or scrapes. **Puncture wounds** occur when a sharp or blunt object penetrates the integument. **Lacerations** are open wounds that result from sharp cutting or tearing. Injuries to the integument are at risk for contamination from dirt, debris, or foreign objects. Infection may cause further physical stress to the patient with multiple injuries. Full-thickness avulsion injuries are injuries that result in loss of all of the layers of the skin, causing fat and muscle to be exposed. The size of the wound impacts both the length of time necessary for healing to take place as well as the risk for infection. These types of injuries are treated by either, allowing new skin to grow from the edges, by stitching the wound together, by reattaching avulsed skin, or by skin grafting.

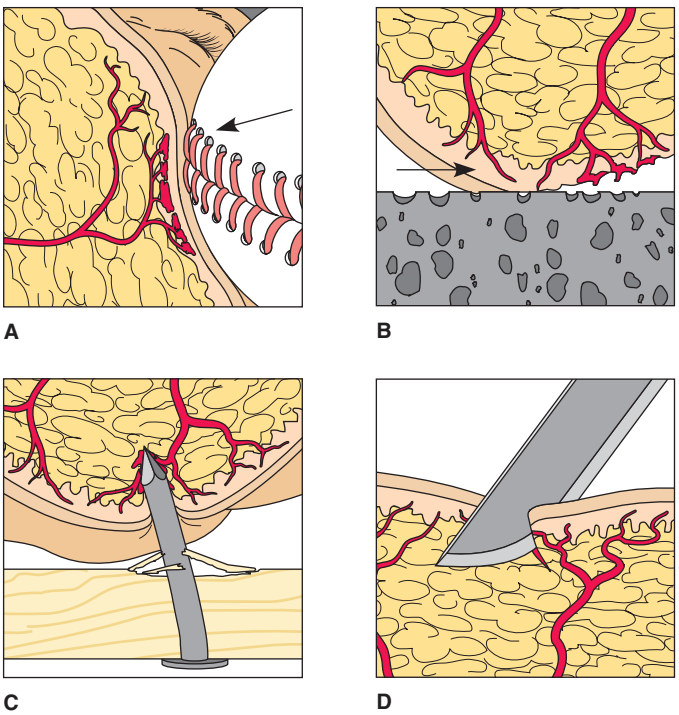

Figure 11–4 ■ Traumatic injuries to the skin: A, Contusion. B, Abrasion. C, Puncture wound. D, Laceration.

ABDOMINAL EFFECTS

The abdomen contains both solid organs (liver, spleen, and pancreas) and hollow organs (stomach and intestines). Direct trauma to the abdomen can lacerate and compress the solid organs and cause burst injuries to the hollow organs. Blood vessels may be torn and organs may be displaced from their blood supply, producing life-threatening hemorrhage. Damage to the mesenteric vessels supplying the bowel can result in bowel ischemia and infarction. Injury to the stomach, pancreas, and small bowel may allow digestive enzymes to leak out into the abdominal cavity. Rupture of the large bowel results in escape of feces, which causes peritonitis. The immediate threat following abdominal trauma is hemorrhage; the later threat is peritonitis.

MUSCULOSKELETAL EFFECTS

Musculoskeletal injuries may occur alone or with multiple injuries as the result of blunt or penetrating trauma. Musculoskeletal injuries usually are not considered a high priority in the care of the patient with multiple injuries. Exceptions are the life- or limb-threatening musculoskeletal injury, such as a dislocated hip, pulseless extremity, or significant blood loss such as from a femur or pelvic fracture. Other exceptions include fractures or dislocations with neurovascular compromise, open fractures, or compartment syndromes. Musculoskeletal injuries may provide clues to the presence of other serious injuries; for example, a fractured clavicle may indicate an associated thoracic injury. Care of the patient who has experienced a musculoskeletal injury is discussed in Chapter 39.

NEUROLOGIC EFFECTS

Head injuries are a common type of injury sustained as the result of trauma. Injuries to the spinal cord, resulting in loss of neurologic function, are devastating outcomes of trauma, but they are much less common than head injuries. Most head and spinal cord injuries result from blunt trauma and are sustained in motor vehicle crashes. Falls, sports injuries, and assaults are other sources of neurologic injury. Care of the patient with a neurologic injury is discussed in Chapters 41, 42, and 43.

MULTIPLE ORGAN DYSFUNCTION SYNDROME

Multiple organ dysfunction syndrome (MODS) is a common complication of severe injury and a frequent cause of death in intensive care units. It is a progressive impairment of two or more organ systems. This is the result of an uncontrolled inflammatory response to severe injury or illness.

Patients at risk for MODS are those with a disturbance in homeostasis resulting from one or a combination of the following conditions:

- Infection
- Injury
- Inflammation
- Ischemia
- Immune response
- Intoxication of substances
- Iatrogenic factors.

The primary organ systems involved in MODS are the respiratory, renal, hepatic, hematologic, cardiovascular, gastrointestinal,

and neurologic systems. Supportive therapy depends on the identification of correctable causes and may involve one or a combination of several therapies. Surgical intervention, antibiotic administration, corticosteroid administration, or correction coagulopathies are some therapies used for this condition. MODS following injuries produces more than half of the late mortality following trauma (Frink et al., 2011).

EFFECTS ON THE FAMILY

Trauma usually occurs suddenly and with little warning. It may result in death or cause injury serious enough to alter both the patient's and the family's lives. The suddenness and seriousness of the event are precipitating factors in the development of a psychologic crisis. During the past decade, some emergency departments have instituted policies that allow families to be present during resuscitation. This type of policy is not without controversy, but it should be considered when appropriate.

●○● INTERPROFESSIONAL CARE

Interprofessional care of the trauma patient depends on a team approach. Providing trauma care with a team focus helps each team member know his or her role. Prompt delegation of tasks and responsibilities improves the patient's chances for survival and decreases the morbidity that may result from traumatic injuries.

PREHOSPITAL CARE

The major functions of prehospital care include injury identification, critical interventions, and rapid transport.

INJURY IDENTIFICATION Emergency care of the patient experiencing trauma is based on rapid assessment to identify injuries and begin appropriate interventions. Injuries that indicate the need for trauma center care include the following:

- Penetrating injuries to the abdomen, pelvis, chest, neck, or head
- Spinal cord injuries with deficit
- Crushing injuries to the abdomen, chest, or head
- Major burns
- Injuries leading to airway compromise or obstruction.

Many methods help healthcare providers determine the seriousness of patients' injuries and the potential for survival. Scoring systems such as the Champion Revised Trauma Scoring System can be helpful (Table 11–2). A primary trauma assessment follows an alphabet mnemonic:

- **A** is airway assessment (with C-spine immobilization) to determine if the airway is patent, maintainable, or nonmaintainable.
- **B** is breathing evaluation for spontaneous respirations or ventilatory impedance such as by rib fractures or a collapsed lung.
- **C** is circulatory assessment to palpate peripheral and central pulses; to assess capillary refill, skin color, and temperature; and to identify any external sources of bleeding.
- **D** is disability and refers to the neurovascular status. Assessment includes level of consciousness, pupillary function, and response to verbal or painful stimuli.
- **E** is expose/environment where a whole body assessment is completed while ensuring that hypothermia does not occur (i.e., heated blankets, warmed intravenous fluids).

TABLE 11–2 Champion Revised Trauma Scoring System

Test	Score	Coded Value
Glasgow Coma Scale*	13–15	4
	9–12	3
	6–8	2
	4–5	1
	3	0
Systolic blood pressure	>89	4
	76–89	3
	50–75	2
	1–49	1
	0	0
Respiratory rate	10–29	4
	>29	3
	6–9	2
	1–5	1
	0	0
	Total score:	_____

The highest possible total score is 12. The lowest possible score is 0. The higher the total score, the greater the chance of survival.

** See Chapter 41 for instructions for using the Glasgow Coma Scale.*

Source: Centers for Disease Control and Prevention. (2009). Guidelines for field triage of injured patients. *Morbidity and Mortality Weekly Report, 58*(RR-1), 15. Retrieved from http://www.cdc.gov/mmwr/pdf/rr/rr5801.pdf.

Secondary assessment usually begins while the primary assessment is under way. This assessment extends the alphabetical mnemonic:

- **F** is full set of vital signs. F can also stand for having family members present during treatment.
- **G** is giving comfort measures for both physical and emotional comfort for the patient and family.
- **H** is head-to-toe assessment and medical history that includes visual and manual assessment as well as appropriate auscultation.
- **I** is inspection of posterior surfaces for any injuries.

The Glasgow Coma Scale is another scoring system that is used to quantify the level of consciousness following traumatic brain injury. See Chapter 41.

CRITICAL INTERVENTIONS As life-threatening problems are identified during the primary assessment, appropriate on-the-scene interventions must be performed immediately. These include providing life support, immobilizing the cervical spine, managing the airway, and treating hemorrhage and shock.

Immobilization of the patient's cervical spine is a primary intervention. The patient is placed on a spine board, and a cervical collar and head immobilizer applied (Figure 11–5 ■). The cervical spine may also be immobilized by logrolling the patient onto a board, placing towel rolls or a head immobilizer along the sides of the patient's head, and securing the patient to the board. If the patient was wearing a helmet at the time of injury, the helmet should remain on until the patient arrives at the hospital, unless the patient's airway is at risk. If

Figure 11–5 ■ Immobilization of the cervical spine at the scene of the accident is essential to preventing further injury to the spinal cord. The combined use of a hard cervical collar, head blocks, and tape best restricts flexion, extension, rotation, and lateral bending of the neck.
Source: Michal Heron/Pearson Education.

necessary, healthcare personnel at the scene will remove the helmet by manipulating it over the patient's nose and ears while holding the patient's head and neck immobile; safe removal requires at least two people. Improper removal of a helmet risks injury or additional injury to the spinal cord.

If the patient's airway is patent, oxygen is administered. Ventilations may be assisted with a bag-valve-mask resuscitator until airway management is achieved. Active external bleeding is controlled by direct pressure. Measures to reverse shock (discussed later in the chapter) are initiated.

RAPID TRANSPORT Patients who have multiple injuries must be transported as soon as possible to a regional trauma center. The most common modes of rapid transport are ground ambulance and air ambulance, which includes specially staffed and equipped helicopters to care for trauma victims. Figure 11–6 ■ shows a flight nurse assessing a patient. Stable patients within access of a ground ambulance are best transported by ground. Unstable patients and those injured in the wilderness or other areas in which ground access is difficult may best be transported by air. When these transport systems are unavailable, the patient is transported by any possible means.

EMERGENCY DEPARTMENT CARE

DIAGNOSIS The diagnostic tests ordered once the patient reaches the hospital depend on the type of injury the patient has sustained. Tests that may be ordered for victims of trauma include the following:

- *Blood type and crossmatch* involves typing the patient's blood for ABO antigens and Rh factor, screening the blood for antibodies, and crossmatching the patient's serum and donor red blood cells.
- *Complete blood count* evaluates the components of blood including red blood cell count and white blood cell count.
- *Arterial blood gas* evaluates oxygenation, acid–base balance, and the presence of metabolic or respiratory compensatory mechanisms.
- *Blood alcohol level* measures the amount of alcohol in a patient's blood. It has been found that between 20% and 50% of people who are injured may be intoxicated. Alcohol alters the patient's level of consciousness and response to pain.
- *Urine drug screen* may also be ordered. Like alcohol, such drugs as cocaine alter the patient's level of consciousness and overall response to the primary survey.
- *Pregnancy test* for any woman of childbearing age rules out the potential for pregnancy and fetal injury.
- *Focused assessment by sonography in trauma (FAST)* primarily focuses on evaluating the identification of blood in body cavities where it is not supposed to be. Primary focus is on the peritoneum. It is also helpful in identification of blood in the pleura and pericardium.
- *Diagnostic peritoneal lavage* determines the presence of blood in the peritoneal cavity, which may indicate abdominal injury. The test is generally done in the emergency department. A local anesthetic (such as lidocaine) is injected subcutaneously, and a small incision is made in the lower abdomen. A catheter is placed into the peritoneal cavity, and any free blood is aspirated. If 10 mL of blood is found, the patient is taken to the operating room for exploratory surgery. If no free blood is aspirated, 1 L of a warm isotonic solution (Ringer's solution or normal saline) is rapidly infused into the peritoneal cavity and then allowed to drain by gravity. If the solution returns pink and is found to have a red blood cell count of 100,000 mm^3; a white blood cell count of $\geq$ 500; or

Figure 11–6 ■ Flight nurses provide initial assessment, stabilization, and support for patients with trauma.
Source: © ZUMA Press, Inc./Alamy.

bile, food, or feces, the test is considered positive and the patient is taken to the operating room for exploratory surgery. This procedure is used less with the inception of the FAST exam. This test does not detect retroperitoneal injuries (injuries of the kidneys, pancreas, great vessels, duodenum, or portions of the ascending or descending colon).
- *Computerized tomography (CT) scans* can reveal injuries to the brain, skull, spine, spinal cord, chest, and abdomen.
- *Magnetic resonance imaging (MRI) scans* can reveal injuries to the brain and spinal cord.

MEDICATIONS

Medications used to treat the patient who has experienced trauma depend on the type and severity of the injuries, as well as the degree of traumatic shock that is present. The following general categories of medications may be used:

- Blood components and crystalloids are administered intravenously in the initial treatment of traumatic shock to replace intravascular volume.
- Inotropic drugs (drugs that increase myocardial contractility) are given to increase cardiac output and improve tissue perfusion. These drugs, administered only after fluid volume restoration, include dopamine (Dopastat, Intropin), dobutamine (Dobutrex), and isoproterenol (Isuprel).
- Vasopressors may be administered in conjunction with fluid replacement to treat neurogenic, septic, or anaphylactic shock. Examples of vasopressors include dopamine (Dopastat), epinephrine (Adrenalin), norepinephrine (Levophed), and phenylephrine (Neo-synephrine).
- Opioids, administered by bolus or continuous infusion, are used to treat pain as soon as possible. However, the effects of the pain medications may alter patient responses to injury, cause hypotension and respiratory depression, and mask potential injuries. If pain medications are administered, they must be carefully regulated, and the patient must be closely monitored.
- Immunization: If the patient has penetrating and open wounds, tetanus immunization status must be determined. If the patient is unable to remember when the last tetanus immunization was given, is unable to answer, or has not received a tetanus immunization within the past 5 years, then tetanus prophylaxis is given.

These drugs and their administration are covered later in the chapter in the discussion of the collaborative care of the patient in shock.

BLOOD TRANSFUSIONS

Blood and blood components are initially produced in the body and then donated for use by another person through a **transfusion** (an infusion of blood or blood components). A patient may be given whole blood, packed red blood cells (RBCs), platelets, plasma, albumin, clotting factors, prothrombin, or cryoprecipitate (Table 11–3). Blood and blood components increase the amount of hemoglobin available to carry oxygen to the cells, improve hemoglobin and hematocrit levels during active bleeding, increase intravascular volume, and replace deficient substances such as platelets and clotting factors.

Each person has one of four blood types: A, B, AB, or O. The blood group antigens A and B, present on RBC membranes, form the basis for the ABO blood categorization. The presence or absence of these inherited antigens determines one's blood type. People with blood type A have A antigens, those with type B have B antigens, those with type AB have both antigens, and those with neither antigen have blood type O (called a *universal donor*).

FAST FACTS

- Type AB blood is the universal recipient.
- Type O blood is the universal donor.

ABO antibodies develop in the serum of people whose RBCs lack the corresponding antigen; these antibodies are called anti-A and anti-B. The person with blood type B has A antibodies, the person with type A has B antibodies, the person with type O has both types of antibodies, and the person with blood type AB has no antibodies (called a *universal recipient*).

A third antigen on the RBC membrane is D. People who are Rh positive have the D antigen, whereas people who are Rh negative do not. These antigens and antibodies may cause ABO and Rh incompatibilities. Rh factor is referred to as positive (+) or negative (−) and is used as a descriptor with the blood type, for example, O+ or AB−.

A transfusion of incompatible blood causes hemolysis (breakdown) of the RBCs and agglutination of erythrocytes. (Agglutination is the clumping of cells that results from their interaction with specific antibodies.) The ABO blood group names and compatibilities are listed in Table 11–4.

Before RBCs or whole blood can be administered, a series of procedures determine donor and recipient ABO types and Rh groups. These procedures, called *a type and crossmatch*, are performed by mixing the donor cells with the recipient's serum and watching for agglutination. If none occurs, the blood is considered compatible.

Despite meticulous procedures for matching blood types and antigens, blood transfusion reactions may still occur. The most common is a febrile reaction. Antibodies within the patient receiving the blood are directed against the donor's white blood cells, causing fever and chills. Febrile reactions typically begin during the first 15 minutes of the transfusion. Using leukocyte-poor blood avoids future febrile reactions.

Hypersensitivity reactions result when antibodies in the patient's blood react against proteins, such as immunoglobulin A, in the donor blood. Hypersensitivity reactions may appear during or after the transfusion. The manifestations of hypersensitivity reaction include *urticaria* (the appearance of reddened wheals of various sizes on the skin) and itching.

Hemolytic reactions, the most dangerous transfusion reactions, usually result from an ABO incompatibility. Clumping RBCs block capillaries, decreasing blood flow to vital organs. In addition, macrophages engulf the clumped RBCs, releasing free hemoglobin into the circulating blood; the hemoglobin is then filtered by the kidneys and may block the renal tubules, causing renal failure. Hemolytic reactions usually begin after infusion of 100 to 200 mL of incompatible blood. Manifestations of a hemolytic reaction include flushing of the face, a burning sensation along the vein, headache, urticaria, chills, fever, lumbar pain, abdominal pain, chest pain, nausea and vomiting, tachycardia, hypotension, and dyspnea. If any of these manifestations appear, the blood transfusion must be immediately discontinued.

Other risks to patients receiving blood include circulatory overload, electrolyte imbalances, and infectious diseases such as hepatitis or cytomegalovirus.

TABLE 11–3 Volume Resuscitation Therapies

Component	Indications	Advantages	Disadvantages
Ringer's lactate	• Restoration of circulating volume • Replacement of electrolyte deficits	• Ready availability • Safe to use • Low cost • Aids in buffering acidosis	• Rapid movement from the intravascular to the extravascular space, leading to three or more times requirement for replacement
Normal saline	• Restoration of circulating volume • Vehicle compatible with administration of blood	• Good availability • Low cost • Safe to use	• Hyperchloremic acidosis associated with prolonged use of sodium solutions
Whole blood	• Replaces blood volume and oxygen-carrying capacity in hemorrhage and shock	• Contains RBCs, plasma proteins, clotting factors, and plasma	• Contains few platelets or granulocytes; deficient in clotting factors V and VII • Greatest risks are for incompatibility or circulatory overload • Risk of transmitting bloodborne pathogens
Packed RBCs	• Restoration of intravascular volume • Replacement of oxygen-carrying capacity	• One unit of RBCs should increase the hemoglobin of a 70-kg (154-lb) adult by approximately 1 g/dL in the absence of volume overload or continuing blood loss	• Red cells require compatibility testing • Risk of transmitting bloodborne pathogens • Should be warmed to prevent hypothermia • Contains little or no clotting factors
Platelets	• Significant thrombocytopenia (platelet count less than 20,000–50,000 per mm^3) • Continued hemorrhage	• Compatibility testing is not required • Typical platelet transfusion should raise the platelets of a 70-kg (154-lb) adult approximately 30,000–50,000/μL	• Postexposure prophylaxis with anti-Rh immune globulin should be considered following Rh+ platelet transfusion to an Rh– woman • Risk of transmitting bloodborne pathogens
Albumin	• Expands blood volume in shock and trauma	• Good availability	• Is not a substitute for whole blood • Risk of hypersensitivity reactions • Risk of transmitting bloodborne pathogens
Fresh frozen plasma (FFP)	• Documented coagulopathy • Restoration of clotting factors • Supplies plasma proteins	• Crossmatching and Rh compatibility is not required	• Must be thawed in a 37°C (98.6°F) water bath for approximately 30 min • Should be ABO compatible • Risk of transmitting bloodborne pathogens
Cryoprecipitate	• Coagulopathy with low fibrinogen • Restoration of fibrinogen	• Rh type not important	• Risk of transmitting bloodborne pathogens • Contains hemagglutinins • If large volumes of ABO-incompatible cryoprecipitate are administered, intravascular hemolysis can occur

TABLE 11–4 Blood Group Types and Compatibilities

Blood Group	RBC Agglutinogens	Serum Agglutinogens	Compatible Donor Blood Groups	Incompatible Donor Blood Groups
A	A	Anti-B	A, O	B, AB
B	B	Anti-A	B, O	A, AB
AB	A, B	None	A, B, AB, O	None
O	None	Anti-A, anti-B	O	A, B, AB

Patients who have experienced trauma of any severity have had substantial blood loss and are usually in hypovolemic shock. Blood replacement is the treatment of choice to restore oxygen-carrying capacity. Patients in severe shock with active bleeding are given universal, type O red blood cells immediately. Patients with less severe injuries or bleeding may be stabilized with other types of fluids until type-specific or crossmatched blood is available.

Some emergency departments and trauma centers use autotransfusion to provide blood for transfusions for a patient with multiple injuries and/or severe shock. Autotransfusion is a method of blood administration in which special equipment collects and returns the patient's own blood. The chest cavity is the typical source of blood to be autotransfused.

Nursing considerations for blood transfusion therapy are described in the following Medication Administration box.

EMERGENCY SURGERY

Immediate surgical intervention is indicated when the patient remains in shock despite resuscitation and there is no obvious external sign of blood loss. Abdominal and chest x-rays, ultrasound studies, diagnostic peritoneal lavage, or CT scan may be performed to help identify the potential source of the blood loss. It is important for the emergency or trauma nurse to speak with the family as soon as possible to keep everyone informed about what is happening to a family member. Unfortunately, the need for emergency surgery may not allow time for family members or significant others to see their loved one before transfer to the operating room.

ORGAN DONATION

The Uniform Anatomical Gift Act (1968, 1987) requires that people be informed about their options for organ donation. Under this act, consent for organ donation may be given not only by the donor but also by a spouse, adult children, parents, adult siblings, guardian, or any adult authorized to do so. The act also encourages people to carry donor cards.

The increased success of organ transplant has made it a more common and valuable method of prolonging and improving life; however, many people are still waiting for organs, and many people who may be suitable organ donors die each year from trauma. Organs and tissues that may be transplanted include bones, eyes, liver, lungs, skin, muscles and tendons, pancreas, intestines, kidneys, heart, and heart valves.

The organ donation process begins with identification of the potential organ donor. Most people are potential organ donors. Exceptions include those who

- Currently abuse intravenous drugs
- Have preexisting untreated infections, such as septicemia
- Have any malignancy other than a primary brain tumor
- Have active tuberculosis.

HIV-positive patients continue to be excluded as donors in the United States. In 2013, Bill 297-301, the HIV Organ Policy Equity (HOPE) Act, was introduced but it has not yet been passed.

The family needs to be made aware of the patient's prognosis and presented with the option of donating the patient's organs. Both the family's and the patient's feelings about organ donation must be explored. Even if the patient carries an organ donation card, many institutions will not remove any organs without a signature from a family member or other authorized person. The nurse must always respect the family's concerns and feelings in this process. Organ procurement agencies employ specially trained personnel who oversee organ donor identification and procurement. These professionals are trained to approach families regarding potential organ donation. Box 11–1 lists **brain death criteria**. Once brain death has been confirmed, the family must also understand the diagnosis and be allowed time to accept the patient's death.

BOX 11–1 Brain Death Criteria

CLINICAL SIGNS
- Irreversible condition
- Apnea with a $PaCO_2$ greater than 60 mmHg
- No response to deep stimuli
- No spontaneous movement (some spinal cord reflexes may be present)
- No gag or corneal reflex
- No oculocephalic or oculovestibular reflex
- Absence of toxic or metabolic disorders

CONFIRMATORY TESTS
- Cerebral blood flow study
- Electroencephalogram

When caring for an adult patient who is an organ donor, the nurse carries out the following:

- Maintain systolic blood pressure of 90 mmHg to keep the patient's organs perfused until removal.
- Maintain urine output at more than 30 mL per hour. This is usually accomplished by administering fluids and/or inotropic agents such as dopamine.
- Maintain oxygen saturation at 90% or greater.

FORENSIC CONSIDERATIONS

Injuries often happen under circumstances that require legal investigation. Many injuries, particularly penetrating trauma, may involve criminal activity. Therefore, the nurse must recognize the need to identify, store, and properly transfer potential evidence for medical–legal investigations.

Each item of clothing removed from a patient must be placed in a breathable container, such as a paper bag, and documented appropriately. Bullets or knives should be labeled, with their source specified, and given to the proper authorities. Holes found in clothing should not be disturbed. When it is necessary to cut off clothing, these areas should be avoided and never cut through if at all possible.

The patient's hands may yield important evidence, such as powder burns or residue on the skin, or tissue or hair samples beneath the fingernails. In the case of death, it is recommended that paper bags be placed over the patient's hands if the presence of evidence is suspected; otherwise, the evidence should be collected by nail clippings.

Identify all wounds and document these findings with pictures, diagrams, or written descriptions. Once the evidence has been collected, identified, and properly stored, ensure that it is given to the appropriate authorities. A chain of custody needs to be maintained throughout the entire process. All evidence must be identified and labeled, and documentation procedures must chronicle where and in whose possession the evidence has been. For the chain of custody to remain intact, the evidence must remain in the continuous possession of identified people and be marked and sealed in tamper-proof containers.

●○● NURSING CARE

Nursing care of the patient who has been injured begins with a primary assessment and the initiation of collaborative interventions for any life-threatening injuries. Nursing care is directed toward the patient's specific responses to trauma.

MEDICATION ADMINISTRATION

Blood Transfusion

The risk for and seriousness of blood transfusion reactions require that extreme caution be taken when blood is administered. Most fatal transfusion reactions are the result of human error. Although general guidelines are provided here, each institution has specific policies and procedures that must be followed. Prior to beginning the transfusion, the nurse must determine that typed and crossmatched blood is available and collect the needed equipment: a Y-tubing blood administration set with a filter, a large-bore intravenous catheter (usually 18 or 19 gauge), and normal saline solution. Only normal saline is used with a blood transfusion. Dextrose causes clumping of RBCs, and distilled water causes hemolysis.

Nursing Responsibilities

- Obtain patient consent.
- Assess for any previous reactions to blood.
- Explain the procedure to the patient, and answer any questions.
- Prepare the intravenous equipment. Shut off one side of the Y tubing, and attach the other side to the saline solution. Flush the tubing and filter with the saline.
- If venous access is not already in place, insert the intravenous needle (following body substance precautions), and begin administering the saline.
- Using institutional procedure, obtain the blood from the blood bank or laboratory. Administer the blood immediately; if this is not possible, return it to the blood bank or laboratory.
- Check and document that the donor and recipient blood have been tested and are compatible. This usually involves two nurses, each verifying the following:
  a. An order for blood has been written.
  b. A type and crossmatch has been done.
  c. The name of the patient and the name on the blood bag are identical.
  d. The number assigned to the unit of blood is identical to the one on the requisition for the blood.
  e. The blood type and Rh factor are compatible.
  f. The blood has not exceeded its expiration date.
  g. The unit of blood is intact and has no bubbles or discoloration.
- Identify the patient by reading the armband and asking the patient to tell you his or her name. Check the armband against the unit of blood.
- Gently invert the blood bag several times to mix the plasma and RBCs.
- Take and record vital signs as a baseline.
- Attach the open side of the Y tubing to the blood unit, and begin the transfusion at a slow rate of about 2 mL per minute. (Some trauma patients may have blood infused at a rapid rate. If blood is infused rapidly, it may need to be warmed prior to administration to prevent hypothermia.) Stay with the patient for at least the first 15 minutes of the transfusion, monitoring for manifestations of a reaction and taking the patient's vital signs.
- Continue to monitor the patient during the transfusion, assessing for manifestations of hypersensitivity or hemolytic reactions and taking and recording vital signs as directed by institutional policy.
- After the first 15 minutes, the rate of infusion is increased. If there is no danger of fluid volume overload, most patients can tolerate an infusion of a unit of blood (ranging from 250 to 500 mL, depending on the blood component administered) in 2 hours. The unit of blood should be administered within 3 to 4 hours; after this time, it has warmed and begins to deteriorate.
- Take the following actions if manifestations of a reaction occur:
  a. Stop the infusion of blood immediately, and notify the physician. Continue to infuse the saline.
  b. Take vital signs and assess manifestations.
  c. Compare the blood slip with the unit of blood to ensure that an identification error was not made.
  d. Save the blood bag and any remaining blood for return to the laboratory for further tests to determine the cause of the reaction.
  e. Follow institutional policy for collecting urine and venous blood samples.
  f. Continue to monitor the patient and provide prescribed interventions to treat hypersensitivity or hemolytic manifestations.

Health Education for the Patient and Family

- The possible risks of blood transfusions include infectious diseases and acquired immune deficiency syndrome (AIDS). However, because of careful handling and storage of blood, bacterial contamination is rare. Although hepatitis may be transmitted by contaminated blood, new tests for hepatitis antibodies in the donor blood are reducing this risk. Many people are afraid of contracting AIDS from blood; however, donor screening and HIV-antibody testing of donor blood has virtually eliminated the transmission of HIV by blood transfusion. A new risk that has been identified is the transmission of West Nile Virus through blood transfusions. Screening for this risk is asking potential donors about the presence of symptoms indicative of West Nile Virus.
- During the transfusion, immediately report any warm feelings, chills, itching, feelings of weakness or fainting, or difficulty breathing.
- Report any signs of a delayed transfusion reaction: chills, fever, cough, difficulty breathing, hives, itching, or changes in circulation, and seek medical care immediately.
- Discuss any religious or cultural considerations related to blood transfusions.

Health Promotion

Prevention efforts can reduce the incidence and severity of trauma. Areas of health promotion and trauma prevention interventions for individuals and communities include the following:

- ***Motor vehicle safety:*** seat belts, air bags, helmets, driving under the influence of alcohol or drugs, reckless driving, visual or cognitive deficits in the older adult, cell phone use, driver fatigue
- ***Home safety:*** snow and ice removal, electrical wiring, falls, burns, drowning
- ***Farm safety:*** operating heavy equipment, safe storage of chemicals such as fertilizers
- ***Work safety:*** operating work equipment, wearing safety equipment, removal of jewelry
- ***Relationships:*** domestic violence, child abuse, older adult abuse, or neglect
- ***Communities:*** gun control, gangs, condition of streets, neighborhood safety.

In providing information about trauma prevention to members of the community, the nurse serves as a healthcare educator, political activist, and safety advocate.

Assessment

See the Interprofessional Care section for assessment of the patient experiencing trauma.

Priorities of Care

The nurse collaborates with the interprofessional team to ensure adequate treatment of the underlying injury while providing care that supports oxygenation and perfusion. Teaching the patient and, as appropriate, caregivers strategies to prevent injuries and optimize safe home and work environments should be considered priority nursing actions. The nurse also focuses on promoting comfort and maintaining asepsis for all interruptions of the integument.

Diagnoses, Outcomes, and Interventions

The trauma patient has many complex and interrelated actual or potential alterations in health. The nursing care in this section focuses on patient and family problems with respirations, infection, immobility, and spirituality. Nursing interventions for decreased cardiac output and altered perfusion are discussed in the section of the chapter on nursing care of the patient in shock. See the accompanying Case Study & Nursing Care Plan on page 243.

Ineffective Airway Clearance

The patient with multiple injuries is at great risk for developing airway obstruction and apnea. Facial injuries, loose teeth, blood, and vomitus increase the risk for aspiration and obstruction. Neurologic injuries and cerebral edema alter the patient's respiratory drive and ability to keep the airway clear.

Expected Outcome: Patient's airway will remain patent.

- Assess if airway is patent, maintainable, or unable to be maintained. Assess for manifestations of airway obstruction: stridor, tachypnea, bradypnea, cough, cyanosis, dyspnea, decreased or absent breath sounds, changes in oxygen levels, and changes in level of consciousness. *Assessing the airway and initiating interventions are the first steps in managing the patient with multiple injuries.*
- Monitor oxygen saturation by applying a pulse oximeter. Adjust oxygen flow to maintain oxygen saturation from 94% to 100%. *Changes in oxygen saturation as measured by the pulse oximeter indicate the effectiveness of the patient's airway. Pulse oximetry in patients who have been exposed to carbon monoxide (i.e., house fires) is unreliable since it cannot differentiate carboxyhemoglobin from oxyhemoglobin.*
- Monitor level of consciousness. *An early sign of an ineffective airway is a change in the patient's behavior. If the patient becomes restless, anxious, combative, or unresponsive, the effectiveness of the airway needs to be immediately evaluated and appropriate interventions initiated.*

Risk for Infection

Traumatic injuries are considered dirty wounds. Projectiles enter the body through dirty surfaces and clothing, carrying dirt and debris into the wound. Open fractures provide a portal for the entry of bacteria and dirt. Even with surgical intervention, the wounds often remain contaminated.

Expected Outcome: Patient will avoid getting an infection as much as possible through careful hygiene and the use of correct aseptic technique and universal precautions.

Evidence for Nursing Care

The Patient with Brain Death

Selected resources that nurses may find helpful when planning evidence-based nursing care follow.

Moving Evidence into Action

The Care of ICU Patients Sustaining Multiple Trauma

Ventilator-associated pneumonia (VAP) is an important patient safety issue in critically injured patients. The Association for Professionals in Infection Control and Epidemiology (APIC) published an evidence-based clinical guideline for the prevention and elimination of VAP in 2009 [APIC, 2009]. The association recommends the use of a facility-wide VAP infection prevention and control program and overall infection prevention and antimicrobial stewardship. The guideline describes the critical topics of problem identification, surveillance and how it is defined, risk assessment, and the development and use of a surveillance plan and prevention strategies. The guideline also provides examples of documents and reminders that can be used to provide systematic surveillance and management strategies.

Implications for Nursing

The APIC evidence-based guidelines recommend elements related to VAP prevention:

- Prevention of complications in ventilated patients focusing on positioning specific to reduce VAP
- Educational programs for healthcare personnel focusing on VAP prevention
- Use of quality improvement projects with VAP prevention focus
- Organizational issues related to leadership, staffing, and informatics which can impact patient outcomes
- Setting a target of zero VAP cases
- Key prevention strategies related to unit and institutional processes, supportive early innovators, consistent communication, connecting actions to outcomes, and review of deviation from practice standards

Moving Knowledge into Action

1. Considering the information from this guideline, how would you communicate the recommendations to the medical staff for the patient with mechanical ventilation?
2. What is the rationale behind the preceding recommendations?

- Use careful hand hygiene practices. *Hand hygiene remains the single most important factor in preventing the spread of infection.*
- Use strict standard precautions and aseptic technique when caring for wounds. *Standard precautions are essential to protect the patient and the nurse from infection.* In addition:
  - Monitor wounds for odor, redness, heat, swelling, and copious or purulent drainage.
  - Monitor hidden wounds, such as those under casts, by asking the patient whether the pain has increased and observing for increased drainage and heat over the area of the wound.
  - Ensure that cross-contamination between wounds does not occur. Collect drainage in ostomy bags if it is copious.

  The skin is the first line of defense against infection. Wounds provide a portal of entry for organisms. Risk factors for wound infection include contamination, inadequate wound care, and the condition of the wound at the time of closure. Aseptic techniques used in applying and changing dressings reduce the entry of organisms.
- Take and record vital signs, including temperature, every 2 to 4 hours. *Abnormal vital signs, particularly an elevated body temperature, can indicate the presence of an infection.*
- Provide adequate fluids and nutrition. *Adequate fluids, calories, and protein are essential to wound healing.*
- Assess for manifestations of gas gangrene: fever, pain, and swelling in traumatized tissues; drainage with a foul odor. *Gas gangrene is usually caused by the organism* Clostridium perfringens. *This bacterium is found in the soil and can be introduced into the body during a traumatic injury. The organism grows in the tissues, causing necrosis; hydrogen and carbon dioxide are released, with resultant swelling of tissues. If the infection continues, tissues are progressively destroyed, and sepsis and death may result.*
- Assess for development of potentially life-threatening conditions such as necrotizing fasciitis where flesh-eating bacteria infect subcutaneous and dermal layers, spreading to the fascial plane. Many types of bacteria can cause necrotizing fasciitis; however, methicillin-resistant *Staphylococcus aureus* is occurring with increasing frequency.
- Assess the status of tetanus immunization and administer tetanus toxoid or human toxin-antitoxin (TAT) as prescribed. *Tetanus is caused by an exotoxin produced by* Clostridium tetani, *usually introduced through an open wound. The organism is commonly found in the soil.*
- Use strict aseptic technique when inserting catheters, suctioning, administering parenteral medications, or performing any other invasive procedure. *Using aseptic technique during invasive procedures reduces the risk of entry of organisms.*

Impaired Physical Mobility

The patient with trauma injuries is often unable to change positions independently and is at risk for complications of the integumentary, cardiovascular, gastrointestinal, respiratory, musculoskeletal, and renal systems. Patients at greatest risk are those who have had multiple injuries, spinal cord injuries, peripheral nerve injuries, and traumatic amputations. Collaborate with the physical therapist and occupational therapist (if available) to determine the most effective types and schedule of exercises and assistive devices.

Expected Outcome: Patient will maintain joint range of motion, avoid development of contractures, and avoid pulmonary complications such as atelectasis with appropriate pulmonary hygiene.

- If active bleeding or edema is not present, provide active or passive exercises to affected and unaffected extremities at least once every 8 hours. *Exercise improves muscle tone, maintains joint mobility, improves circulation, and prevents contractures.*
- Help the patient turn, cough, and deep breathe and use the incentive spirometer at least every 2 hours. *Changing positions, coughing, deep breathing, and incentive spirometry reduce the risk of integumentary and respiratory complications.*
- If the patient is unable to be moved and positioned, consider a specialty bed, such as the kinetic continuous rotation bed (Figure 11–7 ■). *The kinetic continuous rotation bed allows continuous turning of the patient; the motion decreases pulmonary complications, venous stasis, postural hypotension, urinary stasis, muscle wasting, and bone demineralization.*
- Monitor the lower extremities each day for manifestations of deep venous thrombosis: heat, swelling, and pain. Measure and record the circumference of the thigh and calf each day. If antiemboli stockings or intermittent compression stockings are used, remove them for 1 hour during each shift and assess the skin. *Venous stasis results when surrounding muscles are unable to contract and help move the blood through the veins. Thrombus (clot) formation in deep veins is a major risk for pulmonary embolism.*

Spiritual Distress

Trauma generally strikes without warning and carries potentially devastating consequences, including severe alterations in the lives of the victim and family, and death. The traumatic death of a loved one

Figure 11–7 ■ A kinetic continuous rotation bed provides a means of turning the patient with multiple injuries to decrease the hazards of immobility.

Source: Photo of the RotoRest® Critical Care Therapy System is copyrighted and used by permission of ArjoHuntLeigh Inc.

may be the most difficult event a family will ever experience. The decision to cease life support systems or to donate organs challenges the family's belief systems and psychologic stability.

Expected Outcome: The patient and/or family, as appropriate, will express feelings of grief and lack of control over the traumatic situation.

Nursing care of the family (or patient) experiencing spiritual distress includes the following:

- Offer referral to a spiritual adviser if needed. *Most hospitals have chaplain programs.*
- Give the family information about the option to donate the patient's organs. *The decision to donate organs needs to be based on information about the patient's condition, prognosis, and criteria by which brain death is determined. It is important to convey to family members that organ donation is only an option and that they should not feel they are obligated to consent or are doing something wrong if they do not consent.*
- Encourage the family to ask questions and express any feelings about the traumatic event and/or organ donation. *Allowing families to express their feelings may help prevent long-term consequences such as guilt.*
- Refer the family for follow-up care. Long-term follow-up is important for the family facing the sudden death of a loved one. *Grieving is not an overnight process, and providing the family with resources that may be used in the future may help prevent future crises and dysfunction.* (For more information, see Chapter 5.)

Post-Traumatic Stress Disorder

Post-traumatic stress disorder is an intense, sustained emotional response to a disastrous event. It is also referred to as post-trauma syndrome. It is characterized by emotions that range from anger to fear and by flashbacks or psychic numbing. In the initial stage, the patient may be calm or may express feelings of anger, disbelief, terror, and shock. In the long-term phase, which begins anywhere from a few days to several months after the event, the patient often experiences flashbacks and nightmares of the traumatic event. The patient may call on ineffective coping mechanisms, such as alcohol or drugs, and withdraw from relationships.

Expected Outcome: Patient will verbalize feelings and fears as they move through the traumatic experience. Patient will report development or occurrence of flashbacks to appropriate healthcare personnel.

- Assess emotional responses while providing physical care. Observe for crying, sleep problems, suspiciousness, and fear during the initial phase of treatment. If the patient is unconscious, encourage family members and friends to express their feelings. *These assessments provide valuable information about the patient's ability to cope with the trauma.*

CASE STUDY & NURSING CARE PLAN A Patient with Multiple Injuries

Jane Souza is a 25-year-old married woman with two children who provides day care for preschool children in her home. As she is driving the interstate at 65 miles per hour, a car crosses the median and strikes her vehicle head-on. Mrs. Souza, who is not wearing a seat belt, is thrown forward against the steering wheel. Her lower extremities are entrapped by the dashboard structure of her car, which was crushed in by the car that struck hers.

After extensive efforts to extricate her from the car, Mrs. Souza is transported to the local trauma center. She is still conscious, is receiving high-flow oxygen by mask, and has one intravenous line in place. Her vital signs are a palpable systolic blood pressure of 80, a pulse rate of 120, and a respiratory rate of 36. On arrival, she states that she is having difficulty breathing.

ASSESSMENT

- Airway: Maintainable with high-flow oxygen in place.
- Breathing: Respiratory rate of 36, multiple bruising and abrasions on right side of her chest, decreased breath sounds on the right side.
- Circulation: No palpable radial pulses; palpable brachial pulses. Monitor shows sinus tachycardia. No active external bleeding noted. Skin color pale, cool to the touch, and diaphoretic. One intravenous line already established.
- Neurologic: Moved her fingers when asked; complains of difficulty breathing; denies that she is hurt. Pupils 4 mm, equal, and react to light. Has a broken right arm and an open fracture of the left ankle; because of these injuries, extremity movement is limited.

Because of Mrs. Souza's respiratory distress, she is intubated and ventilated with 100% oxygen. Another intravenous line is inserted and O-negative blood administered. It is determined that Mrs. Souza has sustained a pneumothorax in the right side and a chest tube is inserted.

DIAGNOSES

- *Ineffective Breathing Pattern* related to multiple bruises and abrasions on the right side of the chest, and respiratory difficulty
- *Deficient Fluid Volume* related to acute internal blood loss (presumed because no active bleeding can be found)
- *Risk for Injury* related to trauma resuscitation

EXPECTED OUTCOMES

- Patient will maintain adequate oxygenation.
- Patient will maintain adequate circulating blood volume.

PLANNING AND IMPLEMENTATION

- Monitor airway and assist in any needed airway management.
- Explain all procedures.
- Monitor the effects of fluid and blood administration, including any changes in blood pressure and pulse.
- Prepare for transfer to the operating room for emergency surgery.
- Keep family informed about her condition.

EVALUATION

Mrs. Souza is transferred to the operating room, where it is determined that she has a ruptured spleen and a serious pelvic fracture. Her treatment continues in the operating room.

Clinical Reasoning in Patient Care

1. Is the nursing diagnosis *Deficient Fluid Volume* appropriate for Mrs. Souza? Why or why not?
2. The assessment of a patient who has experienced trauma is, in order, A = airway, B = breathing, and C = circulation. What is the rationale for this sequence?
3. Following surgery, Mrs. Souza is moved to the surgical intensive care unit. She is very anxious and restless. What methods of assessments would help you identify the cause of her restlessness?
4. Infection is a common complication for the trauma patient. Describe five risks for infection that are present from the time of injury to the time of hospital discharge.

See Evaluating Your Response in Appendix B.

- Be available if the patient wishes to talk about the trauma, and encourage expression of feelings. *The patient may initially deny negative feelings; this denial is a coping mechanism in the initial phase of recovery.*
- Teach relaxation techniques, such as deep breathing, progressive muscle relaxation, or imagery (see Chapter 4). *These techniques often help patients cope when thoughts of the trauma recur.*
- Refer the patient and family members for counseling, psychotherapy, or support groups as appropriate. *Continued therapy may be necessary in assisting the patient and family to resolve the acute and long-term effects of trauma.*

Delegating Nursing Care Activities

As appropriate and allowed by the designated duties and responsibilities of assistive personnel, the nurse may delegate nursing care activities such as measuring fluid intake and output, collecting vital signs (including orthostatic vital signs), encouraging oral or enteral fluid intake, and skin care.

Continuity of Care

Address the following topics to prepare the patient and family for home care:

- The type of home environment to which the patient will be returning, including any changes that will be required to let the patient function in that environment
- Medications, dressings, wound care, equipment, and supplies
- Special diet, if needed
- Rehabilitation plan and its effect on the patient's family
- Follow-up appointments with the physician or at the trauma clinic
- Emotional changes that the patient may undergo as a result of the trauma
- Helpful resources:
  - Home healthcare
  - Community support groups
  - National Institute of Neurological Disorders and Stroke.

THE PATIENT EXPERIENCING SHOCK

Shock is a clinical syndrome characterized by a systemic imbalance between oxygen supply and demand. This imbalance results in a state of inadequate blood flow to body organs and tissues, causing life-threatening cellular dysfunction.

Overview of Cellular Homeostasis and Hemodynamics

To maintain cellular metabolism, cells of all body organs and tissues require a regular and consistent supply of oxygen and the removal of metabolic wastes. This homeostatic regulation is maintained primarily by the cardiovascular system and depends on four physiologic components:

1. A cardiac output sufficient to meet bodily requirements
2. An uncompromised vascular system, in which the vessels have a diameter sufficient to allow unimpeded blood flow and have good tone (the ability to constrict or dilate to maintain normal pressure)
3. A volume of blood sufficient to fill the circulatory system, and a blood pressure adequate to maintain blood flow
4. Tissues that are able to extract and use the oxygen delivered through the capillaries.

In a healthy person, these components function as a system to maintain tissue perfusion. During shock, however, one or more of these components are disrupted. An understanding of basic hemodynamics is necessary to understand the pathophysiology of shock:

- Stroke volume (SV) is the amount of blood pumped into the aorta with each contraction of the left ventricle.
- Cardiac output (CO) is the amount of blood pumped per minute into the aorta by the left ventricle. CO is determined by multiplying the SV by the heart rate (HR): CO = SV × HR.
- Systemic vascular resistance (SVR) is the resistance offered by the peripheral circulation.

PRACTICE ALERT!

Cardiac Output (CO) = Stroke Volume (SV) × Heart Rate (HR)

- Mean arterial pressure (MAP) is the product of cardiac output and SVR: MAP = CO × SVR. It can also be calculated as MAP = [(2 × diastolic BP) + systolic BP] / 3. When CO, SVR, or total blood volume rises, MAP and tissue perfusion increase. Conversely, when CO, SVR, or total blood volume falls, MAP and tissue perfusion decrease. A MAP of 70 to 110 is normal. A MAP of 60 mmHg is required to maintain adequate perfusion to the brain, heart, and kidneys.
- The sympathetic nervous system maintains the smooth muscle surrounding the arteries and arterioles in a state of partial contraction called sympathetic tone. Increased sympathetic stimulation increases vasoconstriction and SVR; decreased sympathetic stimulation allows vasodilation, which decreases SVR.

Pathophysiology

When one or more cardiovascular components do not function properly, the body's hemodynamic properties are altered. Consequently, tissue perfusion may be inadequate to sustain normal cellular metabolism. The result is the clinical syndrome known as shock. The manifestations of shock result from the body's attempts to maintain vital organs (heart and brain) and to preserve life following a drop in cellular perfusion. However, if the injury or condition triggering shock is severe enough or of long enough duration, cellular hypoxia and cellular death occur.

Shock is triggered by a sustained drop in mean arterial pressure. This drop can occur after a decrease in cardiac output, a decrease in the circulating blood volume, or an increase in the size of the vascular bed due to peripheral vasodilation. If intervention is timely and effective, the physiologic events that characterize shock may be stopped; if not, shock may lead to death.

STAGE 1: EARLY, REVERSIBLE, AND COMPENSATORY SHOCK

The initial stage of shock begins when baroreceptors in the aortic arch and the carotid sinus detect a sustained drop in MAP of less than 10 mmHg from normal levels. The circulating blood volume may

decrease (usually to less than 500 mL), but not enough to cause serious effects.

The body reacts to the decrease in arterial pressure. The cerebral integration center initiates the body's response systems, causing the sympathetic nervous system to increase the heart rate and the force of cardiac contraction, thus increasing cardiac output. Sympathetic stimulation also causes peripheral vasoconstriction, resulting in increased systemic vascular resistance and a rise in arterial pressure. The net result is that the perfusion of cells, tissues, and organs is maintained. Symptoms are almost imperceptible during the early stage of shock. The pulse rate may be slightly elevated. If the injury is minor or of short duration, arterial pressure is usually maintained, and no further symptoms occur.

Compensatory shock begins after the MAP falls 10 to 15 mmHg below normal levels (Pollack, 2011). The circulating blood volume is reduced by 25% to 35% (1000 mL or more), but compensatory mechanisms are able to maintain blood pressure and tissue perfusion to vital organs, thereby preventing cell damage.

- Stimulation of the sympathetic nervous system results in the release of epinephrine from the adrenal medulla and the release of norepinephrine from the adrenal medulla and the sympathetic fibers. Both hormones rapidly stimulate the alpha- and beta-adrenergic fibers. Stimulated alpha-adrenergic fibers cause vasoconstriction in the blood vessels supplying the skin and most of the abdominal viscera. Perfusion of these areas decreases. Stimulated beta-adrenergic fibers cause vasodilation in vessels supplying the heart and skeletal muscles ($beta_1$ response), and increase the heart rate and force of cardiac contraction ($beta_2$ response). Further, blood vessels in the respiratory system dilate, and the respiratory rate increases ($beta_2$ response). Thus, stimulation of the sympathetic nervous system results in increased cardiac output and oxygenation of these tissues.
- The renin–angiotensin response occurs as the blood flow to the kidneys decreases. Renin released from the kidneys acts on angiotensinogen to form angiotensin I. This is converted by angiotensin-converting enzyme in the lungs to angiotensin II, which causes vasoconstriction and stimulates the adrenal cortex to release aldosterone. Aldosterone causes the kidneys to reabsorb water and sodium and to lose potassium. The absorption of water maintains circulating blood volume, while increased vasoconstriction increases SVR, maintaining central vascular volume and raising blood pressure.
- The hypothalamus releases adrenocorticotropic hormone (ACTH), causing the adrenal glands to secrete aldosterone. Aldosterone promotes the reabsorption of water and sodium by the kidneys, preserving blood volume and pressure.
- The posterior pituitary gland releases antidiuretic hormone (ADH), which increases renal reabsorption of water to increase intravascular volume. The combined effects of hormones released by the hypothalamus and posterior pituitary glands work to conserve central vascular volume.
- As MAP falls in the compensatory stage of shock, decreased capillary hydrostatic pressure causes a fluid shift from the interstitial space into the capillaries. The net gain of fluid raises the blood volume.

Working together, these compensatory mechanisms can maintain MAP for only a short period of time. During this period, the perfusion and oxygenation of the heart and brain are adequate. If effective treatment is provided, the process is arrested, and no permanent damage occurs. However, unless the underlying cause of shock is reversed, these compensatory mechanisms soon become harmful, and shock perpetuates shock.

STAGE 2: INTERMEDIATE OR PROGRESSIVE SHOCK

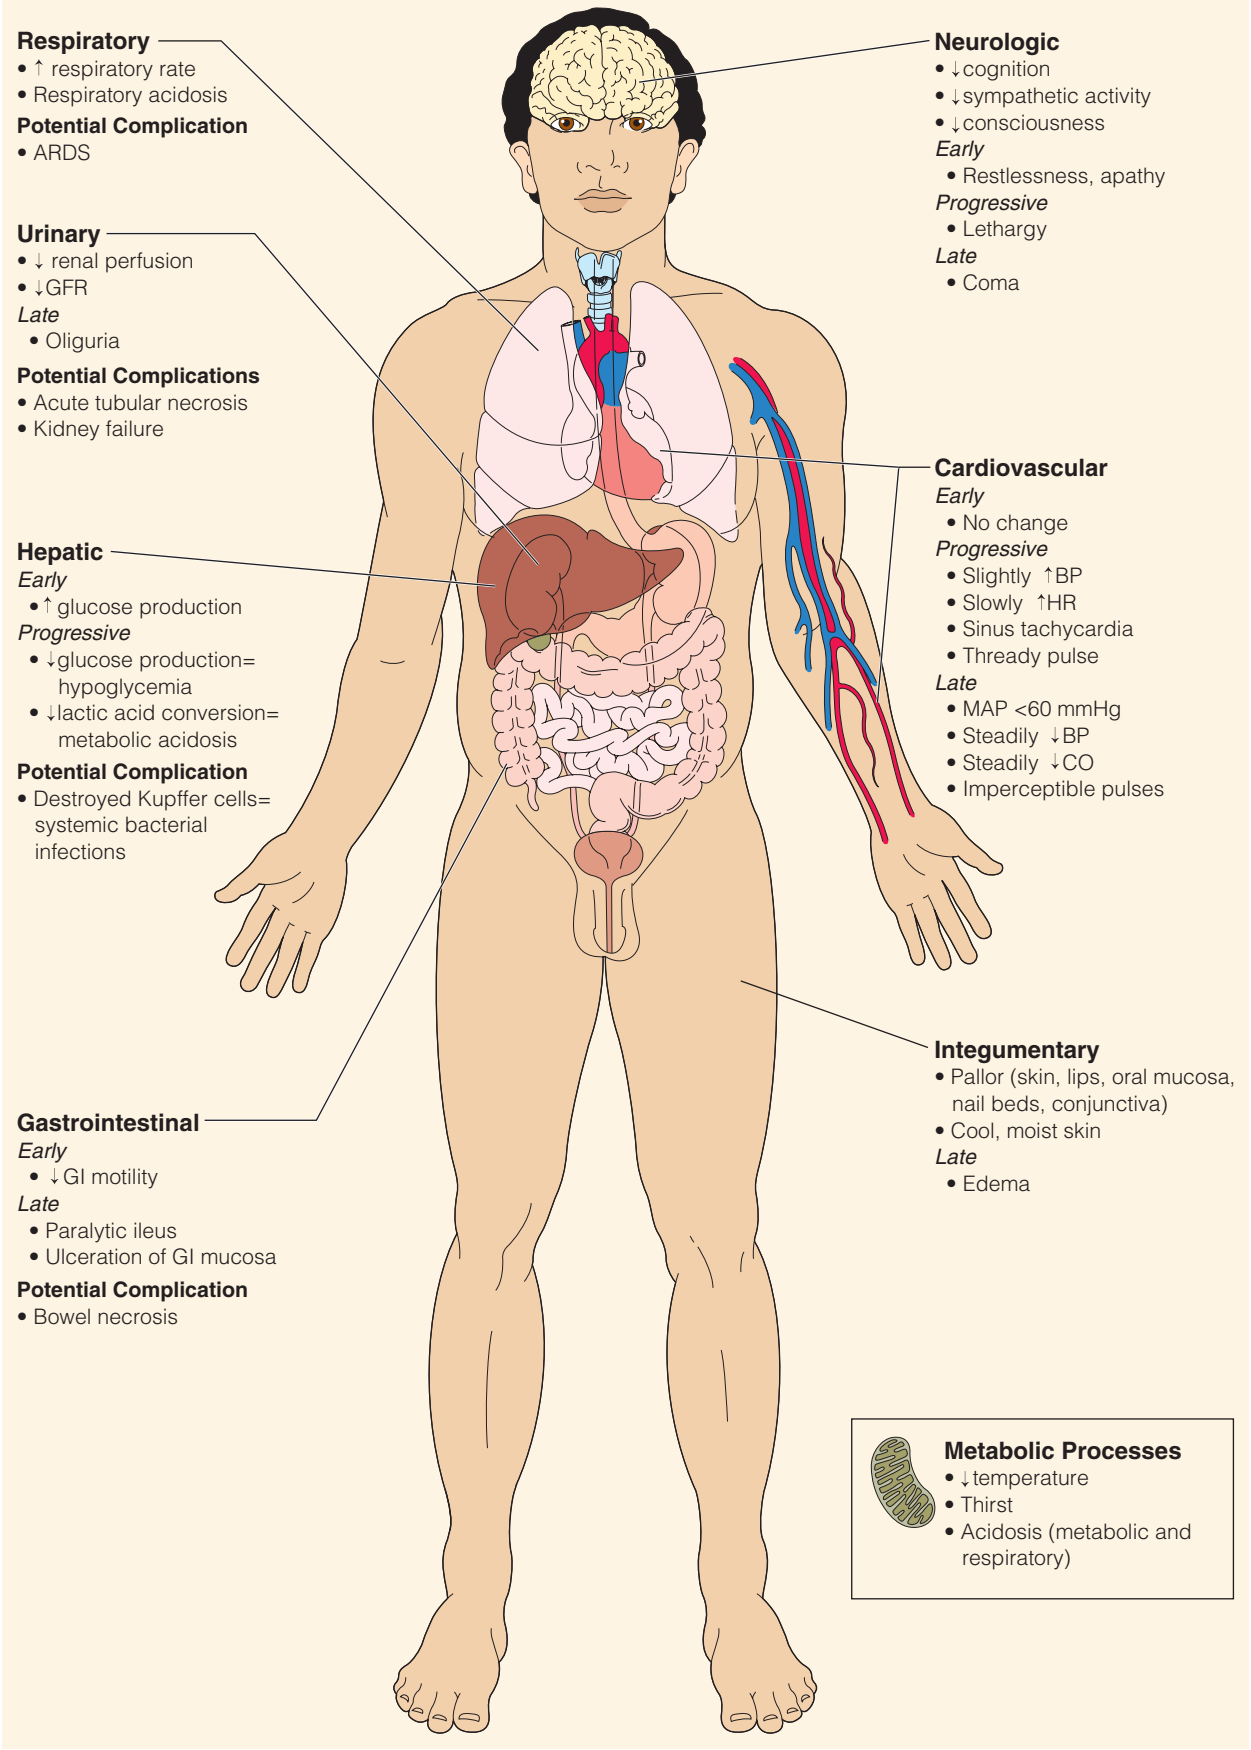
The progressive stage of shock occurs after a sustained decrease in MAP of 20 mmHg or more below normal levels and a fluid loss of 35% to 50% (1800 to 2500 mL of fluid) (Pollack, 2011). Although the compensatory mechanisms in the previous state remain activated, they are no longer able to maintain MAP at a level sufficient to ensure perfusion of vital organs.

The vasoconstriction response that first helped sustain MAP eventually limits blood flow to the point that cells become oxygen deficient. To remain alive, the affected cells switch from aerobic to anaerobic metabolism. The lactic acid formed as a by-product of anaerobic metabolism contributes to an acidotic state at the cellular level. As a result, adenosine triphosphate (ATP), the source of cellular energy, is produced inefficiently. Lacking energy, the sodium-potassium pump fails. Potassium moves out of the cell, while sodium and water move inward. As this process continues, the cell swells, cell membrane integrity is lost, and cell organelles are damaged. Lysosomes within the cell spill out their digestive enzymes, which disintegrate any remaining organelles. Some enzymes spread to adjacent cells, where they erode and rupture cell membranes.

The acid by-products of anaerobic metabolism dilate the precapillary arterioles and constrict the postcapillary venules. This causes increased hydrostatic pressure within the capillary, and fluid shifts back into the interstitial space. The capillaries also become increasingly permeable, allowing serum proteins to shift from the vascular space into the interstitium. The buildup of plasma proteins increases the osmotic pressure in the interstitium, further accelerating the fluid shift out of the capillaries.

Throughout this period, the heart rate and vasoconstriction increase; however, perfusion of the skin, skeletal muscles, kidneys, and gastrointestinal organs is greatly diminished. Cells in the heart and brain become hypoxic, while other body cells and tissues become ischemic and anoxic. A generalized state of acidosis and hyperkalemia ensues (see Chapter 10). Unless this stage of shock is treated rapidly, the patient's chances of survival are poor.

STAGE 3: REFRACTORY OR IRREVERSIBLE SHOCK



If shock progresses to the irreversible stage, tissue anoxia becomes so generalized and cellular death so widespread that no treatment can reverse the damage. Even if MAP is temporarily restored, too much cellular damage has occurred to maintain life. Death of cells is followed by death of tissues, which results in death of organs. Death of vital organs contributes to subsequent death of the body.

EFFECTS OF SHOCK ON BODY SYSTEMS

Whatever its causes, shock produces predictable effects on the body's organ systems. (See the Multisystem Effects of Shock feature on page 246.)

CARDIOVASCULAR SYSTEM The perfusion and oxygenation of the heart are adequate in the early stages of shock. As shock

MULTISYSTEM EFFECTS OF Shock

progresses, myocardial cells become hypoxic, and myocardial muscle function diminishes. Initially, the blood pressure may be normal or even slightly elevated (as a result of compensatory mechanisms) and the heart rate only slightly increased. Sympathetic stimulation increases the heart rate (a sinus tachycardia of 120 bpm is common) in an effort to increase cardiac output. As a result of vasoconstriction and decreased blood volume, the palpated pulse is rapid, weak, and thready; as shock progresses, peripheral pulses are usually nonpalpable.

Tachycardia reduces the time available for left ventricular filling and coronary artery perfusion, further reducing cardiac output. With progressive shock, altered acid–base balance, hypoxia, and hyperkalemia damage the heart's electrical systems and contractility. Consequently, cardiac dysrhythmias may develop. Decreased blood volume with decreased venous return also decreases cardiac output, and blood pressure falls.

The blood pressure changes produced by shock are characterized by a progressive decrease in both systolic and diastolic pressures and a narrowing pulse pressure. Auscultation of blood pressure is often difficult or impossible and is an inaccurate reflection of blood pressure status. For this reason, hemodynamic monitoring is usually instituted to follow the patient's cardiovascular status accurately.

RESPIRATORY SYSTEM During shock, impaired oxygen delivery to cells may occur due to a drop in circulating blood volume or, in the case of blood loss, by an insufficient number of red blood cells that carry oxygen. Although the respiratory rate increases because of compensatory mechanisms that promote oxygenation, the number of alveoli that are perfused decreases, and gas exchange is impaired. As a result, oxygen levels in the blood decrease, and carbon dioxide levels increase. As perfusion of the lungs diminishes, carbon dioxide is retained, and respiratory acidosis occurs.

A complication of decreased perfusion of the lungs is acute respiratory distress syndrome (ARDS), or "shock lung." (ARDS is discussed in detail in Chapter 37.) The exact mechanism that produces ARDS is unknown, but some contributing factors have been identified. This potentially lethal form of respiratory failure may result from any condition that causes hypoperfusion of the lungs, but it is more common in shock caused by hemorrhage, severe allergic responses, trauma, and infection.

GASTROINTESTINAL AND HEPATIC SYSTEMS The gastrointestinal organs normally receive 25% of the cardiac output through the splanchnic circulation. Shock constricts the splanchnic arterioles and redirects arterial blood flow to the heart and brain. Consequently, gastrointestinal organs become ischemic and may be irreversibly damaged.

Gastric mucosa tends to ulcerate when it becomes ischemic. Lesions of the gastric and duodenal mucosa (called *stress ulcers*) can develop within hours of severe trauma, sepsis, or burns (Huether & McCance, 2013). Gastrointestinal ulcers may hemorrhage within 2 to 10 days following the original cause of shock. In addition, the permeability of damaged mucosa increases, allowing bacterial translocation to occur. During this process, enteric bacteria or their toxins enter the abdominal cavity, progress to the circulation, and can eventually result in sepsis.

Gastric and intestinal motility is impaired during shock, and paralytic ileus may result. If the episode of shock is prolonged, necrosis of the bowel may occur. In many cases, alterations in the structure and function of the gastrointestinal tract impair absorption of nutrients, such as protein and glucose.

Shock also alters the metabolic functions of the liver. Initially, *gluconeogenesis* (the process of forming glucose from noncarbohydrate sources) and *glycogenolysis* (the breakdown of glycogen into glucose) increase. This process allows blood glucose levels to increase as the body attempts to respond to the stressor; however, as shock progresses, liver functions are impaired, and hypoglycemia develops. Metabolism of fats and protein is impaired, and the liver can no longer effectively remove lactic acid, contributing to the development of metabolic acidosis.

The destruction of the liver's reticuloendothelial Kupffer cells (phagocytes that destroy bacteria) causes a further problem. Bacteria may proliferate within the circulatory system, causing overwhelming bacterial infection and toxicity.

NEUROLOGIC SYSTEM The primary effects of shock on the neurologic system involve changes in mental status and orientation. Cerebral hypoxia produces altered levels of consciousness, beginning with apathy and lethargy and progressing to coma. A common early symptom of cerebral hypoxia is restlessness. Continued ischemia of brain cells eventually causes swelling, resulting in cerebral edema, neurotransmitter failure, and irreversible brain cell damage.

As cerebral ischemia worsens, the sympathetic activity and vasomotor centers are depressed. This leads to a loss of sympathetic tone, causing systemic vasodilation and pooling of blood in the periphery. As a result, venous return and cardiac output further decrease.

PRACTICE ALERT!

An early sign of shock is a change in the level of consciousness. Late signs of shock are mental status changes, hypotension, and marked tachycardia.

RENAL SYSTEM Blood that normally perfuses the kidneys is shunted to the heart and brain during the progressive stage of shock, resulting in renal hypoperfusion. The drop in renal perfusion is reflected in a corresponding decrease in the glomerular filtration rate. Urine output is reduced, and the urine that is produced is highly concentrated. Oliguria of less than 20 mL per hour indicates progressive shock.

Healthy kidneys can tolerate a drop in perfusion for only about 20 minutes; thereafter, acute tubular necrosis develops (Huether & McCance, 2013). As tubular necrosis occurs, epithelial cells slough off and block the tubules, disrupting nephron function. The accumulating loss of functional nephrons eventually causes renal failure. Without normal renal function, metabolic waste products are retained in the plasma.

If treatment restores renal perfusion, the kidneys can regenerate the lost epithelial cells in the tubules, and renal function usually returns to normal. However, in the older or chronically ill patient or in the patient with sustained shock, loss of renal function may become permanent.

EFFECTS ON SKIN, TEMPERATURE, AND THIRST In most types of shock, blood vessels supplying the skin are vasoconstricted, and the sweat glands are activated. As a result, changes in skin color occur. The skin of Caucasian patients becomes pale. In people with

darker skin (such as those of African, Hispanic, or Mediterranean descent), shock-related skin color changes may be assessed as paleness of the lips, oral mucous membranes, nail beds, and conjunctiva. The skin is usually cool and moist and, in the later stages of shock, often edematous.

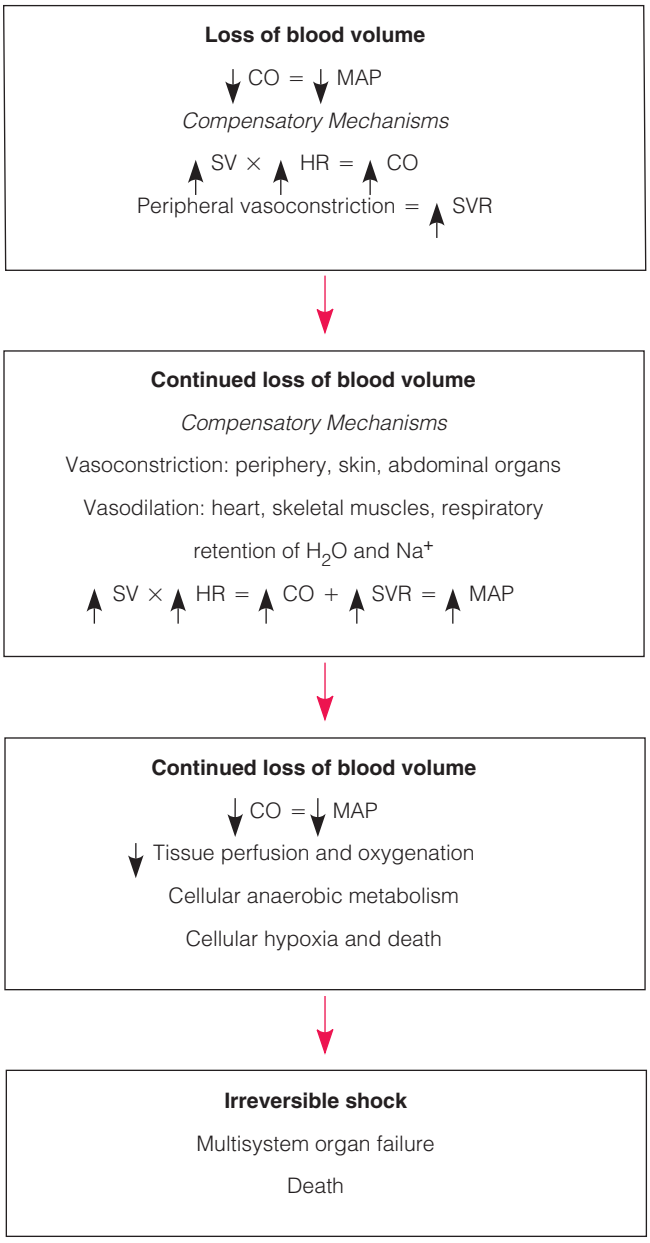
The body temperature decreases as shock progresses, the result of a decrease in overall body metabolism. Some people in shock become thirsty, probably a response to decreased blood volume and increased serum osmolality (Huether & McCance, 2013).

Types of Shock

Shock is identified according to its underlying cause. All types of shock progress through the same stages and exert similar effects on body systems. Any differences are noted in the following discussion.

HYPOVOLEMIC SHOCK

Hypovolemic shock is caused by a decrease in intravascular volume of 15% or more (Huether & McCance, 2013). In hypovolemic shock, the venous blood returning to the heart decreases, and ventricular filling drops. As a result, stroke volume and cardiac blood pressure decrease. Hypovolemic shock is the most common type of shock, and it often occurs simultaneously with other types.



The decrease in circulating blood volume that triggers hypovolemic shock may result from the following:

- Loss of blood volume from hemorrhage (from surgery, trauma, gastrointestinal bleeding, blood coagulation disorders, ruptured esophageal varices)
- Loss of intravascular fluid from the skin due to injuries such as burns (see Chapter 17)
- Loss of intravascular volume from severe dehydration
- Loss of body fluid from the gastrointestinal system due to persistent and severe vomiting or diarrhea, or continuous nasogastric suctioning
- Renal losses of fluid due to the use of diuretics or to endocrine disorders such as diabetes insipidus
- Conditions causing fluid shifts from the intravascular compartment to the interstitial space
- Third spacing due to such disorders as liver diseases with ascites, pleural effusion, or intestinal obstruction.

Hypovolemic shock affects all body systems. Its effects vary depending on the patient's age, general state of health, extent of injury or severity of illness, length of time before treatment is provided, and the rate of volume loss.

The manifestations of hypovolemic shock result directly from the decrease in circulating blood volume and the initiation of compensatory mechanisms (Figure 11–8 ■). The loss of circulating blood volume reduces cardiac output by decreasing venous return to the heart. As a result, blood pressure drops. The carotid and cardiac baroreceptors sense the decrease in blood pressure and communicate it to the vasomotor centers in the brainstem. The vasomotor centers then induce the sympathetic compensatory responses. If the fluid loss is less than 500 mL, activation of the sympathetic response is generally adequate to restore cardiac output and blood pressure to near normal, although the heart rate may remain elevated.

With a sustained loss of blood volume (1000 mL or more), the shock stage progresses. Heart rate and vasoconstriction increase, and blood flow to the skin, skeletal muscles, kidneys, and abdominal organs decreases. Several renal mechanisms and a decline in capillary pressure help conserve blood volume. Eventually, the amount of blood flowing to cells is too low to oxygenate them and sustain production of cellular energy. Anaerobic metabolism begins, producing an acidotic environment for cells. As a result, cells lose their physical integrity. If untreated, shock causes multiple organ failure, and death results. Manifestations of various stages of hypovolemic shock are listed in an accompanying box.

Key CO: Cardiac output
HR: Heart rate
MAP: Mean arterial pressure
SV: Stroke volume
SVR: Systemic vascular resistance

Figure 11–8 ■ The stages of hypovolemic shock.

OLDER ADULTS EXPERIENCING HYPOVOLEMIA With aging comes a relative decrease in sympathetic activity in relation to the cardiovascular system. Cardiac compliance also decreases with age.

Atherosclerosis affects many vital organs' sensitivity to even the slightest reduction in blood flow. Many older patients experience secondary volume depletion due to chronic diuretic use or malnutrition. Also, patients prescribed beta-blockers may not present with tachycardia as an early indicator of shock. This important sign can be masked due to beta-adrenergic blockade. These patients will require early invasive monitoring in order to avoid excessive or inadequate volume restoration. This should be considered early in the treatment phase.

CARDIOGENIC SHOCK

Cardiogenic shock occurs when the heart's pumping ability is compromised to the point that it cannot maintain cardiac output and adequate tissue perfusion. Cardiac disorders are discussed in Chapters 30 and 31; this section focuses only on the effects of shock caused by these disorders.

The loss of the pumping action of the heart may be caused by the following conditions:

- Myocardial infarction
- Cardiac tamponade
- Restrictive pericarditis
- Cardiac arrest
- Dysrhythmias, such as fibrillation or ventricular tachycardia
- Pathologic changes in the valves
- Cardiomyopathies from hypertension, alcohol, bacterial or viral infections, or ischemia
- Complications of cardiac surgery
- Electrolyte imbalances (especially changes in normal potassium and calcium levels)
- Drugs affecting cardiac muscle contractility
- Head injuries causing damage to the cardioregulatory center

Myocardial infarction is the most common cause of cardiogenic shock. Patients admitted to the hospital for treatment of myocardial infarction or cardiac surgery are at risk for cardiogenic shock. The severity and progression of shock are related to the amount of myocardial damage.

Whatever the cardiogenic cause, the decrease in cardiac output causes a decrease in MAP. Heart rate may increase in response to compensatory mechanisms. However, tachycardia increases myocardial oxygen consumption and decreases coronary perfusion. The myocardium becomes progressively depleted of oxygen, causing further myocardial ischemia and necrosis. The typical sequence of shock is essentially unchanged in cardiogenic shock.

Cyanosis, however, is more common in cardiogenic shock because stagnating blood increases extraction of oxygen from the hemoglobin at the capillary beds. As a result, the skin, lips, and nail beds may appear cyanotic. As cardiac failure (and cardiogenic shock) progresses, left ventricular end-diastolic pressure increases. The increase is transmitted to the pulmonary capillary bed, and pulmonary edema may occur. Retention of blood in the right side of the heart increases right atrial pressure, which leads to jugular venous distention as a result of backflow through the vena cava. Manifestations of cardiogenic shock are listed in an accompanying box.

OBSTRUCTIVE SHOCK

Obstructive shock is caused by an obstruction in the heart or great vessels that either impedes venous return or prevents effective cardiac pumping action. The causes of obstructive shock are impaired diastolic filling (e.g., pericardial tamponade or pneumothorax), increased right ventricular afterload (e.g., pulmonary emboli), and increased left ventricular afterload (e.g., aortic stenosis, abdominal distention). The manifestations are the result of decreased cardiac output and blood pressure, with reduced tissue perfusion and cellular metabolism.

DISTRIBUTIVE SHOCK

Distributive shock (also called *vasogenic shock*) includes several types of shock that result from widespread vasodilation and decreased peripheral resistance. Because the blood volume does not change, relative hypovolemia results. Examples of distributive shock include septic, neurogenic, and anaphylactic shock. Treatment is based on the underlying pathogenesis.

MANIFESTATIONS OF HYPOVOLEMIC SHOCK

INITIAL STAGE

- Blood pressure: normal to slightly decreased
- Pulse: slightly increased from baseline
- Respirations: normal (baseline)
- Skin: cool, pale (in periphery), moist
- Mental status: alert and oriented
- Urine output: slight decrease
- Other: thirst, decreased capillary refill time

COMPENSATORY AND PROGRESSIVE STAGES

- Blood pressure: hypotension
- Pulse: rapid, thready
- Respirations: increased
- Skin: cool, pale (includes trunk); poor turgor with fluid loss, edematous with fluid shift
- Mental status: restless, anxious, confused, agitated
- Urine output: oliguria (less than 30 mL/h)
- Other: marked thirst, acidosis, hyperkalemia, decreased capillary refill time, decreased or absent peripheral pulses

IRREVERSIBLE STAGE

- Blood pressure: severe hypotension (often, systolic pressure is below 80 mmHg)
- Pulse: very rapid, weak
- Respirations: rapid, shallow; crackles and wheezes
- Skin: cool, pale, mottled with cyanosis
- Mental status: disoriented, lethargic, comatose
- Urine output: anuria
- Other: loss of reflexes, decreased or absent peripheral pulses

MANIFESTATIONS OF CARDIOGENIC SHOCK

- Blood pressure: hypotension, possible narrowing pulse pressures
- Pulse: rapid, thready; distention of veins of hands and neck
- Respirations: increased, labored; crackles and wheezes; pulmonary edema
- Skin: pale, cyanotic, cold, moist
- Mental status: restless, anxious, lethargic progressing to comatose
- Urine output: oliguria to anuria
- Other: dependent edema; elevated CVP; elevated pulmonary capillary wedge pressure; arrhythmias

SEPTIC SHOCK

Septic shock, the leading cause of death for patients in intensive care units, is one part of a progressive syndrome called systemic inflammatory response syndrome (SIRS). This condition is most often the result of gram-negative bacterial infections (i.e., *Pseudomonas*, *E. coli*, *Klebsiella*), but may also follow gram-positive infections from *Staphylococcus* and *Streptococcus* bacteria. Gram-negative sepsis has greatly increased in the past 10 years, with a 60% mortality rate despite treatment. The pathophysiology of septic shock is complex and not completely understood.

Patients at risk for developing infections leading to septic shock include those who are hospitalized, have debilitating chronic illnesses, or have poor nutritional status. The risk is heightened after invasive procedures or surgery. Other patients at risk of septic shock include older adults and those who are immunocompromised. Portals of entry for infection that may lead to septic shock are as follows:

- Urinary system: catheterizations, suprapubic tubes, cystoscopy
- Respiratory system: suctioning, aspiration, tracheostomy, endotracheal tubes, respiratory therapy, mechanical ventilators
- Gastrointestinal system: peptic ulcers, ruptured appendix, peritonitis
- Integumentary system: surgical wounds, intravenous catheters, intra-arterial catheters, invasive monitoring, decubitus ulcers, burns, trauma
- Female reproductive system: elective surgical abortion, ascending infections from transmission of bacteria during the intrapartal and postpartal periods, tampon use, sexually transmitted infections.

Septic shock begins with *septicemia* (the presence of pathogens and their toxins in the blood). As pathogens are destroyed, their ruptured cell membranes allow endotoxins to leak into the plasma. The endotoxins disrupt the vascular system, coagulation mechanism, and immune system and trigger an immune and inflammatory response. For this reason, the initial effects of septic shock differ from those of hypovolemic and cardiogenic shock; cardiac output is high and systemic vascular resistance is low.

Endotoxins directly damage the endothelial lining of small blood vessels first; the small blood vessels of the kidneys and lungs are most susceptible. Cellular damage stimulates the release of vasoactive proteins and activates coagulation factor XII. The vasoactive proteins stimulate peripheral vasodilation and increase capillary permeability; the activation of coagulation factors results in the production of multiple intravascular blood clots.

As a result of the increased capillary permeability and vasodilation, fluid shifts from the intravascular space to the interstitial space. Hypovolemia results as fluid volume is lost from the circulating blood. Hypovolemia and intravascular coagulation alter oxygenation and cellular metabolism, leading to anaerobic metabolism, lactic acidosis, and cellular death.

Septic shock has an early phase and a late phase. In early septic shock (sometimes called the *warm* phase), vasodilation results in weakness and warm, flushed skin, and the septicemia often causes high fever and chills. In late septic shock (sometimes called the *cold* phase), hypovolemia and activity of the compensatory mechanisms result in typical shock manifestations, including cold, moist skin; oliguria; and changes in mental status. Death may result from respiratory failure, cardiac failure, or renal failure. Manifestations of septic shock are listed in an accompanying box.

MANIFESTATIONS OF SEPTIC SHOCK

EARLY (WARM) SEPTIC SHOCK

- Blood pressure: normal to hypotension
- Pulse: increased, thready
- Respirations: rapid and deep
- Skin: warm, flushed
- Mental status: alert, oriented, anxious
- Urine output: normal
- Other: increased body temperature; chills; weakness; nausea, vomiting, diarrhea; decreased CVP

LATE (COLD) SEPTIC SHOCK

- Blood pressure: hypotension
- Pulse: tachycardia, arrhythmias
- Respirations: rapid, shallow, dyspneic
- Skin: cool, pale, edematous
- Mental status: lethargic to comatose
- Urine output: oliguria to anuria
- Other: normal to decreased body temperature; decreased CVP

Toxic shock syndrome is an especially virulent form of septic shock, occurring most frequently in menstruating women who use tampons. It is thought that bacterial toxins diffuse from the site of infection in the vagina into the circulation. The toxins then trigger a widespread inflammatory response and septic shock. The manifestations of toxic shock syndrome include extreme hypotension, hyperpyrexia, headache, myalgia, confusion, skin rash, vomiting, and diarrhea (Huether & McCance, 2013).

Disseminated intravascular coagulation (DIC), a generalized response to injury, is a potential risk in septic shock. This condition is characterized by simultaneous bleeding and clotting throughout the vasculature. Sepsis injures blood cells, causing platelet aggregation and decreased blood flow. As a result, blood clots form throughout the microcirculation. The clotting slows circulation further while stimulating excess fibrinolysis. As the body's stores of clotting factors are depleted, generalized bleeding begins. DIC is further discussed in Chapter 13.

NEUROGENIC SHOCK

Neurogenic shock is the result of an imbalance between parasympathetic and sympathetic stimulation of vascular smooth muscle. If parasympathetic overstimulation or sympathetic understimulation persists, sustained vasodilation occurs, and blood pools in the venous and capillary beds.

Neurogenic shock causes a dramatic reduction in systemic vascular resistance as the size of the vascular compartment increases. As systemic vascular resistance decreases, pressure in the blood vessels becomes too low to drive nutrients across capillary membranes, and cellular metabolism is impaired.

The following conditions can cause neurogenic shock by increasing parasympathetic stimulation or inhibiting sympathetic stimulation of the smooth muscle of blood vessels:

- Head injury
- Trauma to the spinal cord (Spinal shock, a form of neurogenic shock, is described in Chapter 43.)
- Insulin reactions (which cause hypoglycemia, decreasing glucose to the medulla)
- Central nervous system depressant drugs (such as sedatives, barbiturates, or narcotics)

MANIFESTATIONS OF NEUROGENIC SHOCK

- Blood pressure: hypotension
- Pulse: slow and bounding
- Respirations: vary
- Skin: warm, dry
- Mental status: anxious, restless, lethargic progressing to comatose
- Urine output: oliguria to anuria
- Other: lowered body temperature

- Anesthesia (spinal and general)
- Severe pain
- Prolonged exposure to heat.

Bradycardia occurs early, but tachycardia begins as compensatory mechanisms are initiated. Central venous pressure drops as veins dilate, venous return to the heart decreases, stroke volume decreases, and MAP falls. In early stages, the extremities are warm and pink (from the pooling of blood), but as shock progresses, the skin becomes pale and cool. Manifestations of neurogenic shock are listed in an accompanying box.

ANAPHYLACTIC SHOCK

Anaphylactic shock is the result of a widespread humorally mediated hypersensitivity reaction (called *anaphylaxis*). The pathophysiology in this type of shock includes vasodilation, pooling of blood in the periphery, and hypovolemia with altered cellular metabolism. These physiologic alterations occur when a sensitized person has contact with an *allergen* (a foreign substance to which an individual is hypersensitive). Many different allergens can cause anaphylactic shock, including medications, blood administration, latex, foods, snake venom, and insect stings.

Anaphylactic shock does not occur with the first exposure to an allergen. With the first exposure to a foreign substance (the *antigen*), the body produces specific immunoglobulin E (IgE) antibodies against this antigen. The person is thus sensitized to that specific antigen. With subsequent exposure, the antigen reacts with the already formed IgE antibodies, disrupting cellular integrity. In addition, large amounts of histamine and other vasoactive amines are released and distributed through the circulatory system. These substances cause increased capillary permeability and massive vasodilation, resulting in profound hypotension and eventual vascular collapse.

Histamine also causes constriction of smooth muscles in the bladder, uterus, intestines, and bronchioles. Respiratory distress, bronchospasm, laryngospasm, and severe abdominal cramping result. Serotonin (a neurotransmitter with vasoconstrictive properties) is released, further affecting respiratory status by increasing capillary permeability in the lungs. As a result, plasma leaks into the alveoli, gas exchange is impaired, and pulmonary edema may occur.

Anaphylactic shock begins and progresses rapidly. Manifestations may begin within 20 minutes of contact with an antigen. Unless appropriate intervention is provided, death can occur within a matter of minutes. Because anaphylaxis is rapid and potentially lethal, people with known allergies should carry some form of warning (such as a medical alert bracelet) informing others of their susceptibility. Some patients carry an *EpiPen* (epinephrine) to halt anaphylaxis. Healthcare providers should be extremely careful to assess and document allergies or previous drug reactions. Manifestations of anaphylactic shock are listed in an accompanying box. Similar, but not related, are anaphylactoid reactions that are not humorally mediated and do not require prior exposure to a trigger. These can have similar symptoms and are treated in a similar manner.

MANIFESTATIONS OF ANAPHYLACTIC SHOCK

- Blood pressure: hypotension
- Pulse: increased, dysrhythmias
- Respirations: dyspnea, stridor, wheezes, laryngospasm, bronchospasm, pulmonary edema
- Skin: warm, edematous (lips, eyelids, tongue, hands, feet, genitals)
- Mental status: restless, anxious, lethargic to comatose
- Urine output: oliguria to anuria
- Other: paresthesias; urticaria; pruritus; abdominal cramps, vomiting, diarrhea

●○● INTERPROFESSIONAL CARE

Medical care for the patient in shock focuses on treating the underlying cause, increasing arterial oxygenation, and improving tissue perfusion. Depending on the cause and type of shock, interventions include emergency care measures, oxygen therapy, fluid replacement, and medications. Emergency care is often the first course of collaborative action taken to arrest shock, as discussed earlier in this chapter. A *central venous catheter* may be used to aid in the differential diagnosis of shock and to provide information about the preload of the heart. A pulmonary artery catheter may be inserted to monitor cardiac dynamics, fluid balance, and the effects of vasoactive medications.

DIAGNOSIS

The following diagnostic tests can help identify the type of shock and assess the patient's physical status:

- *Blood hemoglobin* and *hematocrit*, to detect the concentration that usually occurs in hypovolemic shock. These changes reflect the underlying etiology. In hypovolemic shock resulting from hemorrhage, the hemoglobin and hematocrit concentrations are lower than normal; in hypovolemic shock resulting from intravascular fluid loss, by contrast, the hemoglobin and hematocrit concentrations are higher than normal.
- *Arterial blood gases (ABGs)*, to determine oxygen and carbon dioxide levels and pH. The effects of shock and of the body's compensatory mechanisms cause a decrease in pH (indicating acidosis), a decrease in the partial pressure of oxygen (PaO_2) and in total oxygen saturation, and an increase in the partial pressure of carbon dioxide ($PaCO_2$).
- *Serum electrolytes*, to monitor the severity and progression of shock. As shock progresses, glucose levels decrease, sodium levels decrease, and potassium levels increase.
- *Blood urea nitrogen (BUN), serum creatinine levels, urine specific gravity*, and *osmolality*, to check renal function. As perfusion of the kidneys is decreased and renal function is reduced, the BUN and creatinine levels increase as does urine specific gravity and osmolality.
- *Blood cultures*, to identify the causative organism in septic shock.

- *White blood cell count* and *differential*, in the patient with septic or anaphylactic shock. The total WBC count is increased in septic shock. Elevated neutrophils indicate acute infection, increased monocytes indicate a bacterial infection, and increased eosinophils indicate an allergic response.
- *Serum cardiac enzymes*, which are elevated in cardiogenic shock: creatine kinase (CK), myoglobin, and C-reactive protein. Troponin can be elevated if the cause of cardiogenic shock is acute MI.

Other diagnostic tests may be ordered to determine the extent of injury or damage or to locate the site of internal hemorrhage. These tests might include x-ray studies, computerized tomography (CT) scans, magnetic resonance imaging (MRI), endoscopic examinations, and echocardiograms. Newer diagnostic methods for hypoperfusion include gastric tonometry and sublingual PCO_2. Gastric tonometry measures the partial pressure of carbon dioxide in the gastric lumen. The measurement of sublingual carbon dioxide correlates well with decreased MAP.

MEDICATIONS

When fluid replacement alone is not sufficient to reverse shock, vasoactive drugs (drugs causing vasoconstriction or vasodilation) and inotropic drugs (drugs improving cardiac contractility) may be administered. When used to treat shock, these drugs increase venous return through vasoconstriction of peripheral vessels; they also improve the pumping ability of the heart by facilitating myocardial contractility and by dilating coronary arteries to increase perfusion of the myocardium.

Drugs used to treat shock are discussed in the Medication Administration box on page 253. Other drugs that may be administered to the patient in shock include the following:

- Diuretics to increase urine output after fluid replacement has been initiated
- Sodium bicarbonate to treat acidosis
- Calcium to replace calcium lost as a result of blood transfusions
- Antiarrhythmic agents to stabilize heart rhythm
- Broad-spectrum antibiotics to suppress organisms responsible for septic shock
- Epinephrine, antihistamines, and inhaled $beta_2$-agonists to treat anaphylactic shock
- Morphine to dilate veins and decrease anxiety.

OXYGEN THERAPY

Establishing and maintaining a patent airway and ensuring adequate oxygenation are critical interventions in reversing shock. All patients in shock (even those with adequate respirations) should receive oxygen therapy (usually by mask or nasal cannula) to maintain the PaO_2 at greater than 80 mmHg during the first 4 to 6 hours of care. If the patient's unassisted respiration cannot maintain PaO_2 at this level, ventilatory assistance may be necessary. Care of the patient requiring ventilatory assistance is discussed in Chapter 37.

FLUID RESUSCITATION

The most effective treatment for the patient in hypovolemic shock is the administration of intravenous fluids or blood. Fluids also treat septic and, more judiciously, neurogenic shock. However, the patient with cardiogenic shock may require either fluid replacement or restriction, depending on pulmonary artery pressure.

Evidence for Nursing Care

The Patient with Cardiogenic Shock

Selected current resources that nurses may find helpful when planning evidence-based nursing care follow.

- Mallet, J., Albarren, J. W., & Richardson, A. (2013). *Critical care manual of clinical procedures and competencies.* West Sussex, UK: John Wiley & Sons.
- National Guideline Clearinghouse. (2008). *Acute coronary syndromes: A national clinical guideline*. Retrieved from http://www.guideline.gov/summary/summary.aspx?doc_id=10585&nbr=005527&string=cardiogenic+AND+shock
- Unverzagt, S., Machemer, M. T., Solms, A., Thiele, H., Burkhoff, D., Seyfarth, M., . . . Prondzinsky, R. (2011). Intra-aortic balloon pump counterpulsation (IABP) for myocardial infarction complicated by cardiogenic shock. *Cochrane Database of Systematic Reviews, 6*(7), CD009398.

Various fluids may be administered alone or in combination as part of fluid replacement therapy in treating shock. Fluid replacements are administered in massive amounts through two large-bore peripheral lines or through a central line. Current fluid resuscitation protocols include rapid crystalloid infusion followed by blood transfusion. Fluid replacements, such as crystalloid and colloid solutions, increase circulating blood volume and tissue perfusion. Whole-blood or blood products increase the oxygen-carrying capacity of the blood and thus increase oxygenation of cells. However, these resuscitation fluids are not thought to minimize inflammation. Studies are under way to evaluate alternative resuscitation fluids such as an alternative colloid (hydroxyethyl starch [Hextend Biotime, Inc., Berkley, CA]), alternative crystalloid (Ringer's ethyl pyruvate), and hypertonic saline with dextran and polymerized hemoglobin.

CRYSTALLOID SOLUTIONS Crystalloid solutions contain dextrose or electrolytes dissolved in water; they are hypertonic, isotonic, or hypotonic. Hypertonic solutions include 3% saline. Isotonic solutions include normal saline (0.9%), lactated Ringer's solution, and Ringer's solution. Hypotonic solutions include one-half normal saline (0.45%) and 5% dextrose in water (D_5W).

Hypertonic crystalloid solutions pull fluid into the vascular space to promote excretion. Isotonic and hypotonic crystalloid solutions increase fluid volume in both the intravascular and the interstitial space. Of the total amount infused, only about 25% remains in the intravascular system; the remaining 75% moves into the interstitial space. Consequently, fluid volume is only minimally expanded and the potential for peripheral edema is increased when crystalloid solutions are used. However, Ringer's lactate (an electrolyte solution) and 0.9% saline are the fluids of choice in treating hypovolemic shock, especially in the emergency phase of care while blood is being typed and crossmatched. Large amounts of these solutions may be infused rapidly, increasing blood volume and tissue perfusion.

COLLOID SOLUTIONS Colloid solutions contain substances (colloids) that should not diffuse through capillary walls. Hence, colloids tend to remain in the vascular system and increase the osmotic pressure of the serum, causing fluid to move into the vascular compartment from the interstitial space. As a result, plasma volume expands. Colloid

MEDICATION ADMINISTRATION

The Patient in Shock

ADRENERGICS (SYMPATHOMIMETICS)

Vasoconstrictors
- epinephrine (Adrenalin)
- norepinephrine (Levophed)
- metaraminol (Aramine)
- vasopressin (Pitressin)

Inotropes
- dopamine (Intropin)
- dobutamine (Dobutrex)
- isoproterenol (Isuprel)

Adrenergic drugs (also called sympathomimetics) mimic the fight-or-flight response of the sympathetic nervous system, selectively stimulating alpha-adrenergic and beta-adrenergic receptors. Many of these drugs have both vasopressor (vasoconstricting) effects and positive inotropic effects. Stimulation of alpha-adrenergic receptors results in vasoconstriction and increased systemic blood pressure. Stimulation of beta-adrenergic receptors increases the force and rate of myocardial contraction.

The physiologic effect of these drugs includes improved perfusion and oxygenation of the heart, with increased stroke volume and heart rate, and increased cardiac output. Increased cardiac output in turn increases tissue perfusion and oxygenation. The major disadvantage is that increases in stroke volume and heart rate also increase the oxygen requirements of the myocardium. These drugs may be used in the early stages of shock, especially in types of shock characterized by vasodilation.

Nursing Responsibilities
- Carefully monitor responses in the older adult, who may be especially sensitive to sympathomimetics and require lower doses.
- When administering these drugs by the subcutaneous route, carefully aspirate the injection site to avoid injecting the drug directly into a blood vessel.
- Use the intravenous route only with continuous infusion pumps. Carefully adjust the dose to accommodate the patient's cardiovascular status (as ordered by the physician or by written protocol).
- Document lung sounds, vital signs, and hemodynamic parameters before starting the medication, and then according to institutional policy (usually every 5 to 15 minutes).
- Record and monitor urine output. Report output of less than 30 mL per hour.
- Be aware that the sympathomimetics are incompatible with sodium bicarbonate or alkaline solutions.
- When administering drugs that cause vasoconstriction, such as norepinephrine (Levophed) and metaraminol (Aramine), monitor the intravenous insertion site for infiltration. If infiltration does occur, stop the infusion and notify the physician immediately. (Infiltration may cause ischemia and necrosis of tissue.)

Patient Teaching
- Because these drugs mimic a physiologic reaction to stress, they may cause feelings of anxiety.
- Close monitoring to adjust the dose will be carried out by qualified nurses using written protocols.
- Report heart palpitations or chest pain immediately.

Vasodilators
- amrinone (Inocor)
- nitroglycerin (Tridil)
- nitroprusside (Nipride)

Drugs that cause vasodilation act directly on smooth muscle, affecting both arterioles and veins. Peripheral resistance, cardiac output, and pulmonary wedge pressure are all reduced as a result of the vasodilation. These effects decrease the oxygen need of the heart and decrease pulmonary congestion. Vasodilators are used primarily in the treatment of cardiogenic shock and may be combined with a sympathomimetic (e.g., dopamine).

Nursing Responsibilities
- Mix with D_5W or 0.9% saline.
- IV nitroglycerin must be mixed in glass bottles and infused through special, non-PVC tubing. Up to 40% to 80% of nitroglycerin can be absorbed by PVC bags or tubing.
- Infuse with an infusion pump, and use within 4 hours of reconstitution.
- Do not add other medications to the solution.
- Use cautiously in patients with increased intracranial pressure.
- Assess mental status, blood pressure, and pulse prior to initiating medication. Thereafter, assess blood pressure and pulse according to institutional policy (usually every 5 minutes initially, then every 15 minutes until stable, and then every hour).
- Monitor for confusion, dizziness, tachycardia, arrhythmias, hypotension, and adventitious breath sounds. Report these immediately if they occur, and slow infusion to a keep-open rate.
- Monitor patients receiving nitroprusside for signs of thiocyanate poisoning (nausea, disorientation, muscle spasms, decreased or absent reflexes) if infusion lasts longer than 72 hours.
- Keep patient in bed with side rails up.

Health Education for the Patient and Family
- It is important to stay in bed and change positions slowly to avoid dizziness.
- The blood pressure and pulse are taken frequently to adjust the dose of medication.
- Headache is a common side effect.

solutions used to treat shock include 5% albumin, 25% albumin, hetastarch, plasma protein fraction, and dextran.

Colloid products reduce platelet adhesiveness and have been associated with reductions in blood coagulation. Consequently, the patient's prothrombin time (PT), INR, platelet count, and activated partial thromboplastin time (APTT) should be monitored when these solutions are administered. Normal values are as follows:

PT	10–15 seconds
INR	1–1.2 seconds
Platelets	150,000–400,000
APTT	< 35 seconds

See the accompanying Medication Administration box for further information about colloid solutions and associated nursing responsibilities and patient teaching.

BLOOD AND BLOOD PRODUCTS If hypovolemic shock is due to hemorrhage, the infusion of blood and blood products may be indicated. The goal of blood administration is to keep the hematocrit at 30% to 35% and the hemoglobin level between 12.5 and 14.5 g/100 mL (World Health Organization, 1997). Available blood and blood products include fresh whole blood, stored whole blood, packed RBCs, platelet concentrate, fresh-frozen plasma, and cryoprecipitate. Often, packed RBCs are given to provide hemoglobin concentration

and are supplemented with crystalloids to maintain an adequate circulatory volume (see the discussion of blood administration earlier in the chapter).

●○● NURSING CARE

Nursing assessments and interventions to prevent shock are an essential part of the nursing care of every patient. The primary nursing interventions to prevent shock are assessment and monitoring.

Health Promotion and Assessment

Nursing assessments are critical in preventing shock. Identifying patients at risk and making focused assessments are essential. Although shock may occur at any age, physiologic changes with aging make the older adult a high-risk population (see the accompanying box).

- ***Hypovolemic shock:*** Patients who have undergone surgery, have sustained multiple traumatic injuries, or have been seriously burned are most likely to develop hypovolemic shock. Monitoring fluid status is essential in preventing shock and includes daily assessments of weight, fluid intake by all routes, measurable fluid loss (e.g., urine, vomitus, wound drainage, gastric drainage, and chest tube drainage), and fluid loss that must be estimated, such as profuse perspiration and wound drainage. Assessments for the critically ill patient are ongoing and include fluid balance, hemodynamic values, and vital signs.
- ***Cardiogenic shock:*** Patients with left anterior wall myocardial infarctions are at risk for developing cardiogenic shock. Nursing care to prevent the development of cardiogenic shock focuses on maintaining or improving myocardial oxygen supply by providing immediate pain relief, maintaining rest, and administering supplemental oxygen.
- ***Neurogenic shock:*** The risk of neurogenic shock is increased in patients who have spinal cord injuries and those who have received spinal anesthesia. Preventive nursing care includes maintaining immobility of patients with spinal cord trauma and elevating the head of the bed 15 to 20 degrees following spinal anesthesia. Elevations of more than 20 degrees, however, can potentiate headaches following spinal anesthesia and should be avoided.
- ***Anaphylactic shock:*** Prevent anaphylactic shock by collecting information about allergies and drug reactions during the health history. Note these allergies clearly on all documents and place a special armband on the patient. Careful and frequent assessments during blood administration may prevent serious reactions to blood or blood products.
- ***Septic shock:*** Patients who are hospitalized, debilitated, or chronically ill and those who have undergone invasive procedures or tube insertions are at high risk for septic shock. Nursing care to prevent septic shock includes careful and consistent hand hygiene, the use of aseptic techniques for procedures (e.g., catheterizations, suctioning, changing dressings, starting and maintaining intravenous fluids or medications), and monitoring for local and systemic manifestations (e.g., white blood cell and differential counts) of infection.

Priorities of Care

Supporting cardiovascular and respiratory function to maintain oxygenation and perfusion is the priority nursing responsibility for the patient in shock. Interprofessional interventions to ameliorate the precipitating injury are also care priorities.

MEDICATION ADMINISTRATION

Colloid Solutions (Plasma Expanders)

albumin 5% (Albuminar-5, Buminate 5%)
albumin 25% (Albuminar-25, Buminate 25%)
dextran 40 (Gentran 40)
dextran 70 (Gentran 70, Macrodex)
dextran 75 (Gentran 75)
hetastarch (Hespan [HES])
plasma protein fraction (Plasmanate, Plasma-Plex, Plasmatein, Protenate)

These solutions are blood volume expanders and are used to treat hypovolemic shock due to surgery, hemorrhage, burns, or other trauma. Albumin and plasma protein fraction are prepared from healthy blood donors. Dextran and hetastarch are synthetically prepared large molecules. The solutions promote circulatory volume and tissue perfusion by rapidly expanding plasma volume. Dextran solutions are infrequently used.

Nursing Responsibilities

- Before infusion begins, establish baseline for vital signs, lung sounds, heart sounds, and (if possible) CVP and pulmonary artery wedge pressure.
- Start administration of ordered intravenous fluids, using a large-gauge (18-gauge or larger) infusion needle.
- Obtain and record vital signs as required by institutional policy (usually every 15 to 60 minutes) and patient status.
- Obtain and record intake and output every 1 to 2 hours.
- Monitor for manifestations of congestive heart failure or pulmonary edema (dyspnea, cyanosis, cough, crackles, wheezes). If these manifestations appear, stop the fluids and notify the physician immediately.
- Monitor for bleeding from new sites; an increase in blood pressure may cause bleeding in severed vessels that did not bleed with decreased blood pressure.
- Monitor for manifestations of dehydration (dry lips; scant, dark-colored urine; loss of skin turgor). Increased intravenous fluids are usually ordered if the patient becomes dehydrated.
- Monitor for manifestations of circulatory overload (jugular vein distention, increase in CVP, increase in pulmonary capillary wedge pressure). If these manifestations occur, slow rate of infusion and notify physician.
- Monitor prothrombin time, partial thromboplastin time, and platelet counts.
- If administering dextran or plasma protein fraction, have epinephrine and antihistamines readily available for any manifestations of a hypersensitivity reaction (fever, chills, rash, headache, wheezing, flushing).
- Maintain patient on bed rest with side rails elevated.

Health Education for the Patient and Family

- The solutions are given to replace lost serum protein, which helps maintain the volume of blood.
- Vital signs are taken frequently to ensure the safety of the patient.

Evidence for Nursing Care

The Patient with Pneumothorax

Selected resources that nurses may find helpful when planning evidence-based nursing care follow.

- Ding, W., Shen, Y., Yang, J., He, X., & Zhang, M. (2011). Diagnosis of pneumothorax by radiography and ultrasonography: A meta-analysis. *Chest, 140*(4), 859–866.
- National Guidelines Clearinghouse. (2012). *Global strategy for the diagnosis, management, and prevention of chronic obstructive pulmonary disease.* Retrieved from http://www.goldcopd.com
- Robinson, P. D., Cooper, P., & Ranganathan, S. C. (2009). Evidence-based management of paediatric primary spontaneous pneumothorax. *Paediatric Respiratory Reviews, 10*(3), 110–117.

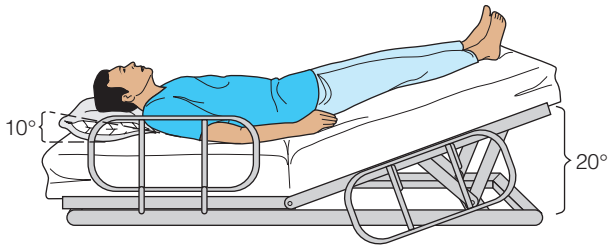


Figure 11–9 ■ The patient in shock should be positioned with the lower extremities elevated approximately 20 degrees (knees straight), trunk horizontal, and the head elevated about 10 degrees.

Diagnoses, Outcomes, and Interventions

Nursing care for the patient in shock focuses on assessing and monitoring overall tissue perfusion and on meeting the psychosocial needs of the patient and the family. This section discusses nursing diagnoses that are appropriate for the patient with hypovolemic shock. See the accompanying Case Study & Nursing Care Plan on page 256.

Decreased Cardiac Output

Decreased cardiac output is the primary problem for the patient in shock. Although much of the care related to this diagnosis is collaborative, many independent nursing interventions are critical to the care of the patient in shock.

Expected Outcome: Patient will maintain adequate cardiac output.

- Assess and monitor cardiovascular function via the following:
  - Blood pressure
  - Heart rate and rhythm
  - Pulse oximetry
  - Peripheral pulses
  - Hemodynamic monitoring of arterial pressures, pulmonary artery pressures, and central venous pressures (CVPs).
    A baseline assessment is necessary to establish the stage of shock. If palpable peripheral pulses and audible (to auscultation) blood pressure are lost, inserting central arterial, venous, and pulmonary artery catheters is essential to establish progression of shock accurately and to evaluate the patient's response to therapy.
- Measure and record intake and output (total output and urinary output) hourly. *A decrease in circulating blood volume with hypotension and the effect of the compensatory mechanisms associated with shock can cause renal failure. Urinary output of less than 30 mL per hour in an acutely ill adult indicates reduced renal blood flow.*
- Monitor bowel sounds, abdominal distention, and abdominal pain. *Decreased splanchnic blood flow reduces bowel motility and peristalsis; paralytic ileus may result.*
- Monitor for sudden sharp chest pain, dyspnea, cyanosis, anxiety, and restlessness. *Hemoconcentration and increased platelet aggregation may result in pulmonary emboli.*
- Maintain bed rest and provide (to the extent possible) a calm, quiet environment. Place in a supine position with the legs elevated to about 20 degrees, trunk flat, and head and shoulders elevated higher than the chest (the semi-Fowler position can also be used with mechanically ventilated patients) (Figure 11–9 ■). *Limiting activity and ensuring rest decreases the workload of the heart. The supine position with legs elevated increases venous return; however, this position should not be used for patients in cardiogenic shock. The Trendelenburg position is no longer recommended, because it causes the abdominal organs to press against the diaphragm (limiting respirations), decreases filling of the coronary arteries, and initiates aortic and carotid sinus reflexes.*

Altered Tissue Perfusion

As shock progresses, diminished tissue perfusion causes ischemia and hypoxia of major organ systems. As shock worsens, blood flow and oxygenation of the lungs, heart, and brain are also impaired. Hypoxia and ischemia result from decreased tissue perfusion in the kidneys, brain, heart, lungs, gastrointestinal tract, and the periphery.

Expected Outcome: Patient will regain adequate tissue perfusion as evidenced by skin characteristics and vital signs within normal limits.

- Monitor skin color, temperature, turgor, and moisture. *Decreased tissue perfusion is evidenced when the skin becomes pale, cool, and moist; as hemoglobin concentrations decrease, cyanosis occurs.*
- Monitor cardiopulmonary function by assessing/monitoring the following:
  - Blood pressure (by auscultation or by hemodynamic monitoring)
  - Rate and depth of respirations
  - Lung sounds
  - Pulse oximetry and arterial blood gases
  - Peripheral pulses (brachial, radial, dorsalis pedis, and posterior tibial); include presence, equality, rate, rhythm, and quality (If unable to palpate pulses, use a device such as a Doppler ultrasound flowmeter to assess peripheral arterial blood flow.)
  - Jugular vein distention
  - CVP measurements
    Baseline vital signs are necessary to determine trends in subsequent findings. As shock progresses, the blood pressure decreases, and the pulse becomes rapid, weak, and thready. As perfusion of the lungs decreases, crackles, wheezes, and dyspnea are commonly assessed. Capillary refill is prolonged, and peripheral pulses are weak or nonpalpable. Neck veins that cannot be seen when the patient is in the supine position indicate decreased intravascular volume. CVP is an accurate means of determining fluid status in the patient in shock; the findings will be low (5 to 15 cmH_2O or 2 to 6 mmHg is normal) in hypovolemic shock because of the decreased blood volume. (See Chapter 10 for a discussion of CVP.)
- Monitor body temperature. *An elevated body temperature increases metabolic demands, depleting reserves of bodily energy. It also*

CASE STUDY & NURSING CARE PLAN A Patient with Septic Shock

Huang Mei Lan is a 43-year-old unmarried female who lives alone in a major West Coast city. Ms. Huang came to America 15 years ago from China and now speaks English well. Her family still lives in China. She worked in a neighborhood sewing shop until 3 years ago, when she was diagnosed with breast cancer. Her treatment included mastectomy of the affected breast and follow-up chemotherapy.

Last month, Ms. Huang experienced a recurrence of cancer in the lymph glands of the affected side. Surgery to remove the glands was performed and chemotherapy started. Ms. Huang has a central line, a urinary catheter, and a surgical incision. She is underweight, weak, and depressed. Although she has multiple physical problems, she never complains or asks for any kind of medication.

ASSESSMENT

Ms. Huang's primary nurse, Robert O'Brien, enters her room early in the morning to make an initial assessment. He finds Ms. Huang huddled in the middle of the bed, shivering violently. Her vital signs are T 40°C (104°F), P 110 bpm, R 30/min, and BP 106/66 mmHg. Her skin is hot, dry, and flushed with poor turgor. She is alert and oriented, but is restless and appears anxious. Ms. Huang states she is nauseated and suddenly begins vomiting and is incontinent of liquid stool. Laboratory data indicate leukocytosis, respiratory alkalosis, and reduced platelet count. Blood cultures, as well as cultures of Ms. Huang's sputum, urine, and wound drainage, are conducted. She is diagnosed as having septic shock.

Hetastarch is ordered per intravenous line, and intravenous broad-spectrum antibiotics are begun until the organism and its portal of entry can be determined. Despite treatment, Ms. Huang's condition worsens. Her blood pressure continues to drop, her skin becomes cool and cyanotic, and she begins to have periods of disorientation. She is transferred to the critical care unit. As she is being prepared for the transfer, she begins to cry and asks, "Am I going to die?"

DIAGNOSES

- *Ineffective Breathing Pattern* related to rapid respirations and progression of septic shock
- *Ineffective Tissue Perfusion* related to progression of septic shock with decreased cardiac output, hypotension, and massive vasodilation
- *Deficient Fluid Volume* related to vomiting, diarrhea, high fever, and shift of intravascular volume to interstitial spaces
- *Anxiety* related to feelings that illness is worsening and is potentially life threatening, and the transfer to the critical care unit

EXPECTED OUTCOMES

- Patient will regain and maintain blood gas parameters within normal limits.
- Patient will maintain adequate circulating blood volume.
- Patient will regain and maintain stable hemodynamic levels.
- Patient will verbalize increased ability to cope with stressors.

PLANNING AND IMPLEMENTATION

- Monitor results of arterial blood gases, blood counts, clotting times, and platelet counts.
- Monitor respiratory status, including respiratory rate, rhythm, and breath sounds.
- Monitor neurologic status, including mental status and level of consciousness.
- Monitor cardiovascular status, including arterial blood pressure; rate, rhythm, and quality of pulses; central venous pressure; pulmonary artery pressure; and cardiac output.
- Monitor body temperature every 2 hours.
- Monitor urinary output hourly, reporting any output of less than 30 mL per hour.
- Monitor color and character of skin.
- Explain procedures and provide comfort measures (oral care, skin care, turning, positioning).

EVALUATION

Despite intensive nursing and medical care, Ms. Huang's condition remains critical. The interventions are continued.

Clinical Reasoning in Patient Care

1. Vasopressors may be used in the treatment of septic shock. Explain the rationale for their use.
2. While monitoring Ms. Huang's arterial blood gases, the nurse notes that her PaO_2 is < 60 mmHg and her $PaCO_2$ is > 50. What do these findings indicate, and why have they occurred?
3. Ms. Huang has been given large amounts of colloids intravenously. Hemodynamic monitoring indicates a higher than normal CVP and pulmonary artery pressure. What do these findings indicate? What physical assessments would you make to confirm the changes?

See Evaluating Your Response in Appendix B.

NURSING CARE OF THE OLDER ADULT

Variations in Assessment Findings—Shock

- Cardiac changes may include a thickened left ventricular wall, decreased elasticity of the myocardium, and more rigid valves. These changes result in a decreased stroke volume and cardiac output, thus decreasing responses to shock in general and increasing the risk of cardiogenic shock.
- Decreased arterial wall elasticity and vasomotor tone reduce the older adult's ability to respond to a decrease in oxygenation.
- Decreased elasticity and turgor of the skin make assessments of skin turgor more difficult.
- Previous medication and blood administration increase the risk of anaphylactic shock.
- Decreased immune system response increases the risk of septic shock.

increases myocardial oxygen demand and may place the patient with previous cardiac problems at even greater risk for hypoperfusion.

- Monitor urinary output per Foley catheter hourly, using a urimeter. *Urine output is a reliable indicator of renal perfusion.*
- Assess mental status and level of consciousness. *The appropriateness of the patient's behavior and responses reflects the adequacy of cerebral circulation. Restlessness and anxiety are common early in shock; in later stages, the patient may become lethargic and progress to a comatose state. Altered levels of consciousness are the result of both cerebral hypoxia and the effects of acidosis on brain cells.*

Anxiety

Many patients in hypovolemic shock have experienced some form of major trauma and may have multiple life-threatening injuries that result in emergency care and the potential for emergency surgery. Throughout this sequence of crisis events, treatment is invasive, and

contact with family is minimal. Patient and family responses to these situations of uncertainty, instability, and change include anxiety, fear, and powerlessness. These responses are affected by age, developmental level, cultural and ethnic group, combined with life experiences with illness and within the healthcare system, and support systems.

Expected Outcome: Patient and family, as appropriate, will identify anxiety-provoking situations and verbalize feelings related to such situations.

- Assess the cause(s) of the anxiety, and manipulate the environment to provide periods of rest. *Reducing stimuli that cause anxiety is calming and facilitates rest, which is necessary in the patient at risk for bleeding.*
- Administer prescribed pain medications on a regular basis and implement any applicable nonpharmacologic comfort measures. *Pain precipitates and/or aggravates anxiety.*
- Provide interventions to increase comfort and reduce restlessness:
  - Maintain a clean environment.
  - Provide skin and oral care.
  - Monitor the effectiveness of ventilation or oxygen therapy.
  - Eliminate all nonessential activities.
  - Remain with the patient during procedures.
  - Speak slowly and calmly, using short sentences.
  - Use touch to provide support.

  Unfamiliar sounds, sights, and odors can increase anxiety. Damp skin or a dry mouth increases discomfort. Inadequate gas exchange with a decrease in oxygen or an increase in carbon dioxide in the blood may cause the patient to experience a "feeling of doom." Activity increases the body's need for oxygen. Listening and touch provide support in an environment in which the patient often feels alone and abandoned. Severe anxiety interferes with the ability to understand others and to respond appropriately.
- Provide support for the patient and family:
  - Provide time, space, and privacy for family members.
  - Allow family members access to the patient when feasible.
  - Encourage the expression of feelings and concerns. Provide anticipatory guidance to prepare for recovery or death and to support realistic hope.
  - Acknowledge the beliefs, values, and expectations of the patient and family.

  Allowing the family access to the patient reduces anxiety and gives both the patient and the family some feeling of control. If prognosis is poor, access and involvement allow the family to begin the grieving process. If recovery is expected, contact provides the patient and family with a feeling of hope. Supporting the patient and family facilitates concrete problem solving, promotes acceptance of the illness and its implications, and helps them begin to establish ways of managing the illness experience.
- Provide information about the current setting to both the patient and family; give the family information about available resources (such as pastoral care, social services, temporary housing, meals). *Knowing what to expect and how to control the environment to meet basic needs reduces anxiety.*

Continuity of Care

Home care for the patient who has experienced shock is highly individualized, depending on the cause and the illness or injury that caused shock. Therefore, topics for consideration are not included in this section.

CHAPTER HIGHLIGHTS

- **Trauma is defined as injury to human tissues and organs resulting from the transfer of energy from the environment. Energy sources can be mechanical, gravitational, thermal, electrical, physical, or chemical.**
- Trauma types included minor trauma, which causes minimal damage to underlying tissues, or major/multiple trauma, which involves at minimum a serious single-system injury or multiple trauma. Trauma can also be categorized as blunt and penetrating trauma. Blunt trauma is caused by forces like deceleration, acceleration, shearing, compression, or crushing. Penetrating trauma is the entrance into the body of a foreign object.
- Maintenance of the airway and cervical spine are the highest priority in the trauma patient, with airway assessment superseding all other interventions.
- The primary assessment conducted by the nurse identifies all life-threatening injuries and performance of appropriate interventions. The secondary assessment is when the nurse identifies all injuries in order to prioritize care.
- **Shock is a clinical syndrome characterized by a systemic imbalance between oxygen supply and demand. This imbalance results in a state of inadequate blood flow to body organs and tissues, causing life-threatening cellular dysfunction.**
- The symptoms of shock arise from the body's attempts to maintain vital organs (heart and brain) and to preserve life following a drop in oxygen delivery to the cells.
- An important early sign of shock is a change in the level of consciousness with restlessness a common symptom of cerebral hypoxia.
- Shock is defined in three stages: compensatory (stage 1), an early and reversible stage; progressive (stage 2), occurring after a fluid loss of 35% to 50% (1800 to 2500 mL of fluid), where the affected cells switch from aerobic to anaerobic metabolism in order to stay alive; and the final stage, refractory/irreversible (stage 3), where tissue anoxia and death becomes widespread.
- Hypovolemic shock is the most common type of shock and is caused by a decrease in circulating blood volume by 15% or greater.
- Cardiogenic shock is caused when the pumping ability of the heart is compromised to the point where adequate cardiac output cannot be maintained.

- Obstructive shock is caused by an obstruction in the heart or great vessels that either impedes venous return or prevents effective cardiac pumping action. Causes can include cardiac tamponade, pneumothorax, pulmonary embolism, and aortic stenosis.
- Distributive shock includes several types of shock that result from widespread vasodilation and decreased peripheral resistance. Because the blood volume does not change, relative hypovolemia results, leading to altered cellular metabolism. Examples of distributive shock include septic, neurogenic, and anaphylactic shock.
- Septic shock is part of a progressive syndrome called systemic inflammatory response syndrome (SIRS), a condition most commonly caused by gram-negative infections.
- Anaphylactic shock is caused by a fulminating hypersensitivity reaction to a foreign substance.

TEST YOURSELF NCLEX-RN® REVIEW

1. A patient is brought to the emergency department after sustaining a mechanical trauma. What should the nurse remember as the most common mechanical source of injury in adults of all ages?
   1. firearms
   2. accidental fire
   3. motor vehicles
   4. swimming pools
2. The nurse is preparing to assess a patient with severe facial injuries caused by going through a windshield during a motor vehicle crash. For which complication should the nurse assess first?
   1. fractures
   2. hemorrhage
   3. airway obstruction
   4. shallow respirations
3. The nurse is caring for a 23-year-old female patient who sustained injuries after being thrown from a car during a motor vehicle crash. Which laboratory test should the nurse ensure is collected from this patient?
   1. pregnancy test
   2. serum electrolytes
   3. complete blood count
   4. blood type and crossmatch
4. The nurse is monitoring a blood transfusion being administered to a trauma patient experiencing shock. Which assessment finding indicates a dangerous transfusion reaction?
   1. increasing dyspnea
   2. increasing blood pressure
   3. multiple urticaric, pruritic skin lesions
   4. an increase in body temperature by 0.3 degree
5. A patient with traumatic injuries is experiencing widespread vasodilation and decreased peripheral resistance. For which type of shock should the nurse plan care for this patient?
   1. septic shock
   2. obstructive shock
   3. cardiogenic shock
   4. hypovolemic shock
6. A victim of multiple traumatic injuries is bleeding profusely from one arm and leg. What should the nurse use to help manage this bleeding?
   1. vessel clamps
   2. limb elevation
   3. tourniquet application
   4. direct pressure application
7. A patient is admitted with chest injuries from a motor vehicle crash. For what should the nurse assess to determine the patient's ultimate extent of the injury?
   1. recreational activities
   2. preexisting health problems
   3. psychosocial status before the traumatic event
   4. number and types of previous traumatic injuries
8. While monitoring the complete blood count of a patient recovering from traumatic injuries, the nurse becomes concerned because the hemoglobin level continues to fall. What should the nurse suspect is occurring with this client?
   1. liver lacerations
   2. intracranial bleeding
   3. gastrointestinal hemorrhage
   4. postoperative internal bleeding
9. A patient experiencing cardiogenic shock is prescribed nitroprusside (Nipride). What should the nurse ensure when providing the medication to this patient?
   1. Monitor for thiocyanate poisoning.
   2. Report urine output of less than 30 mL per hour.
   3. May be mixed with sodium bicarbonate solutions.
   4. Assess intravenous access site and apply ice if infiltration occurs.
10. The nurse is caring for a patient recovering from surgery. Which action should the nurse perform to prevent the onset of hypovolemic shock?
    1. Elevate the head of the bed.
    2. Provide immediate pain relief.
    3. Monitor strict intake and output.
    4. Practice careful and consistent hand hygiene.

12 Nursing Care of Patients with Infections

LEARNING OUTCOMES

1. Explain the components and functions of the immune system and the immune response.
2. Compare antibody-mediated and cell-mediated immune responses.
3. Describe the pathophysiology of wound healing, inflammation, and infection.
4. Identify factors responsible for and the implications of healthcare-associated infections.
5. Discuss the purposes, nursing implications, and health education for medications and treatments used to treat inflammations and infections.
6. Explain the nursing care necessary to prevent and/or monitor the status of infections.

CLINICAL COMPETENCIES

1. Apply standard precautions and evidence-based practices to prevent the spread of infection within the patient, to other patients in the facility, and to members of the interprofessional team and visitors.
2. Provide safe, effective, and respectful patient-centered care for patients with inflammation and infection.
3. Collaborate with the interprofessional care team to integrate care of patients with infections.
4. Promote therapeutic levels and complete dosage of anti-inflammatory and anti-infective medication through prompt administration and patient and family teaching.
5. Assess for hypersensitivities to anti-inflammatory and anti-infective medication prior to and during administration.
6. Participate in quality improvement processes to reduce the rates and risk of infection for a patient group or population.

MAJOR CHAPTER CONCEPTS

- Innate immunity, a nonspecific response to tissue injury, and the adaptive immune response, which directly targets invading microorganisms and abnormal cells, are critical components of the body's defenses. Supporting these defenses is a key nursing responsibility in promoting patient health.
- A fully immunized population is an important infection control strategy and a major factor in maintaining the health of individuals and the population as a whole.
- The inflammatory response that is part of innate immunity serves to isolate invading antigens. When it occurs in response to acute injury, inflammation produces discomfort but serves a protective role. Chronic inflammation, in contrast, can damage affected tissue and may serve no protective function.
- Nurses are instrumental in protecting vulnerable patients from infection, identifying early manifestations of infection, participating with the interprofessional team in treating infection, and educating patients and their families about effective treatment of infection.

vaccines, *274*

The human body is continually threatened by foreign substances, infectious agents, and abnormal cells. The immune system is the body's major defense mechanism against these threats. Recent years have seen the emergence of resistant microorganisms such as methicillin-resistant *Staphylococcus aureus* (MRSA) and altered strains of familiar diseases, such as multiple-drug-resistant tuberculosis. Other diseases have also emerged, including severe acute respiratory syndrome (SARS), *Clostridium difficile*, and human immunodeficiency virus (HIV). The critical

need to prevent healthcare-associated infections and their resulting impact on the patient and healthcare costs is an emerging theme as well.

A thorough knowledge of the immune system increases understanding of inflammatory responses, resistance to infectious disease, and the importance of immunization. This foundation can help the nurse promote patients' health by preventing and identifying infections and teaching patients and families about recommended treatment regimens.

OVERVIEW OF THE IMMUNE SYSTEM

The immune system is a complex and intricate network of specialized cells, tissues, and organs. Cells of the immune system seek out and destroy damaged cells and foreign tissue, yet recognize and preserve host cells. The immune system defends and protects the body from infection by pathogens; removes and destroys damaged or dead cells; and identifies and destroys malignant cells, thereby preventing their further development into tumors.

The immune system is activated by minor injuries, such as small lacerations or bruises, and by major insults, such as burns, surgeries, and systemic diseases (e.g., pneumonia). The immune response may be innate or adaptive. **Innate immunity** provides a nonspecific, generic response to harmful events. These responses prevent or limit the entry of invaders into the body, thereby limiting the extent of tissue damage and reducing the workload of the adaptive immune system. When the inflammatory process is unable to destroy invading organisms or toxins, a more specific response, called the **adaptive immune response**, is activated. Adaptive immunity provides a response that is specific to unique organisms. Adaptive immunity includes memory that hastens future responses to the organism.

Immune System Components

The immune system consists of molecules, cells, and organs that produce the immune response (Table 12–1). These components may be involved in the innate inflammatory response, the adaptive immune response, or both.

LEUKOCYTES

Leukocytes (white blood cells [WBCs]) are the primary cells involved in both innate and adaptive immune system responses. Like all blood cells, leukocytes derive from stem cells, the hemocytoblasts, in the bone marrow (Figure 12–1 ■). Leukocytes are not confined to the circulation; they use it for transport to the site of an inflammatory or immune response. As the mobile units of the immune system, leukocytes detect, attack, and destroy anything that is recognized as foreign. They are able to move through tissue spaces, locating damaged tissue and infection by responding to chemicals released by other leukocytes and damaged tissue.

The normal number of circulating leukocytes is 4,500 to 10,000 cells per cubic millimeter (mm^3) of blood. Many more leukocytes are marginated. *Margination* refers to adhesion of leukocytes to vascular epithelial cells along the vessel walls, in other tissue spaces, or in the lymph system. Marginated leukocytes migrate into injured areas or areas where pathogens infiltrate as part of the innate immune response. In the presence of an attack such as an infection, additional WBCs are released from the bone marrow, leading to *leukocytosis*,

TABLE 12–1 Cells and Tissues of the Immune System

Component	Location	Function
LEUKOCYTES		
Granulocytes		
Neutrophils	Circulation	Phagocytosis and chemotaxis
Eosinophils	Circulation, respiratory tract, and gastrointestinal tract	Phagocytosis Protection against parasites Involved in allergic response
Basophils	Circulation	Release of chemotactic substances
Monocytes and macrophages	Circulation (monocytes) and body tissue, such as skin (histiocytes), liver (Kupffer cells), alveoli, spleen, tonsils, lymph nodes, bone, bone marrow, brain	Trapping and phagocytizing of foreign substances and cellular debris Secretion of interleukin-1 to stimulate lymphocyte growth Activation of T and B cells
Lymphocytes		
T cells (mature in thymus gland)	Circulation, lymph system, tissues	Control of viral infections and destruction of cancer cells Involved in hypersensitivity reactions and graft tissue rejection
B cells (mature in bone marrow)	Circulation, spleen	Production of antibodies (immunoglobulins) to specific antigens
NK (natural killer) cells	Circulation	Cytotoxic; killing of tumor cells, fungi, viral-infected cells, and foreign tissue
LYMPHOID TISSUES		
Primary or central lymphoid structures	Bone marrow and thymus gland	Production of immune cells; sites for cell maturation
Secondary or peripheral lymphoid structures	Lymph nodes, spleen, tonsils, intestinal lymphoid tissue, lymphoid tissue in other organs	Sites for activation of immune cells by antigens

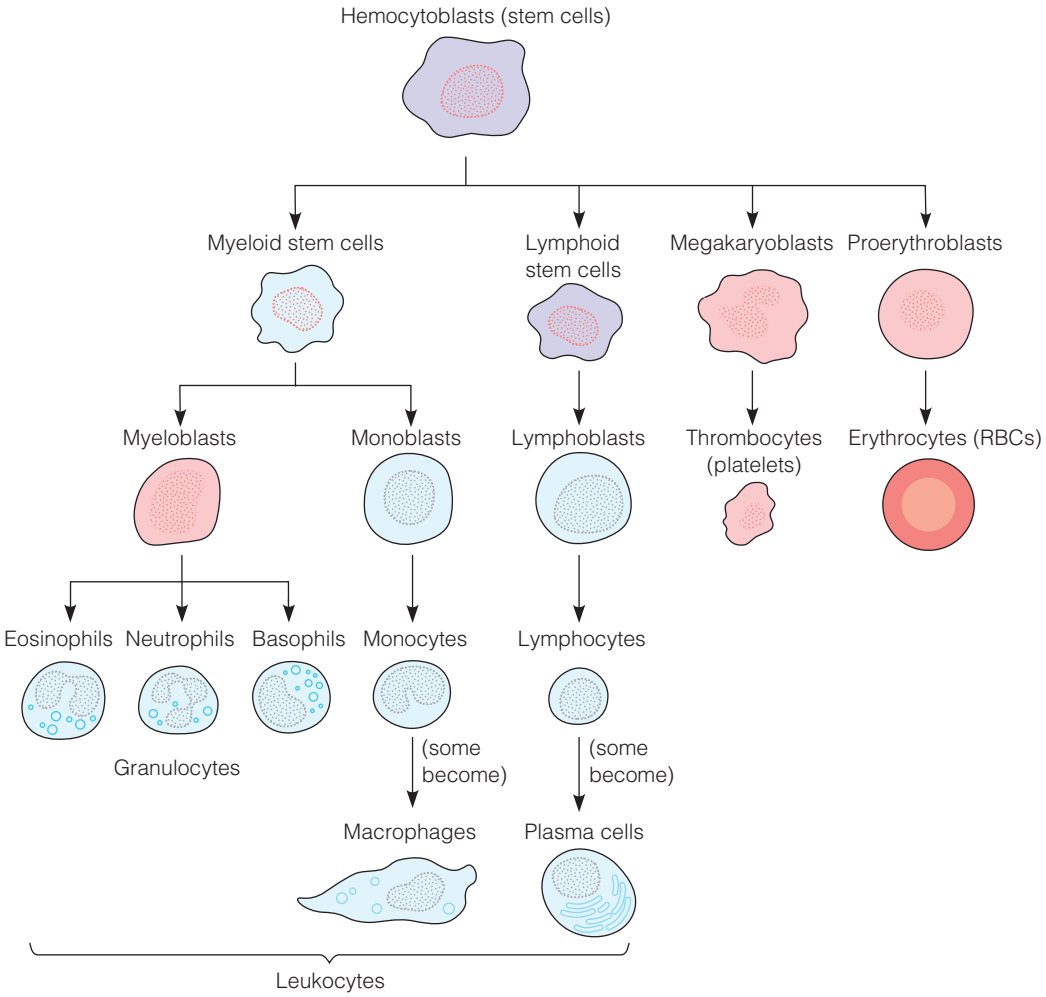

Figure 12–1 ■ The development and differentiation of leukocytes from hemocytoblasts.

a WBC count of greater than 10,000/mm^3. As WBCs move out of the bone marrow into the blood, the bone marrow increases its production of additional leukocytes. A decrease in the number of circulating leukocytes, known as *leukopenia*, occurs when bone marrow activity is suppressed or when leukocyte destruction increases.

Leukocytes are divided into three major groups: granulocytes, monocytes, and lymphocytes. The granulocytes and monocytes derive from the myeloid stem cells of the bone marrow and are instrumental in the inflammatory response. Lymphocytes derive from the lymphoid stem cells of the bone marrow and are the primary cells involved in the specific immune response. In laboratory tests, the WBC count indicates the total number of circulating leukocytes. The WBC differential identifies the portion of the total represented by each type of leukocyte.

GRANULOCYTES Granulocytes constitute 60% to 80% of the total number of normal circulating leukocytes. Their cytoplasm has a granular appearance, and their nuclei are distinctively multilobular (refer to Figure 12–1). Granulocytes have a short life span, measured in hours to days. Granulocytes play a key role in protecting the body from harmful microorganisms during acute inflammation and infection. There are three types of granulocytes: neutrophils, eosinophils, and basophils.

Neutrophils, also called polymorphonuclear leukocytes (PMNs or polys), are the most plentiful of the granulocytes, constituting 55% to 70% of the total number of circulating leukocytes. Neutrophils are *phagocytic* cells, responsible for engulfing and destroying foreign agents, particularly bacteria and small particles. Neutrophils are the first phagocytic cells to arrive at the site of invasion, drawn by chemicals released by damaged tissue and invading organisms.

Neutrophils are produced in the bone marrow and released into the circulation when they mature. Segmented neutrophils (or segs) are mature forms, and usually account for about 55% of total leukocytes. *Bands* are immature neutrophils and usually comprise 5% of leukocytes. As neutrophils mature, their nucleus changes from round to kidney bean shaped (banded) and then the nucleus separates into small, attached segments, thus the designations *banded* versus *segmented* neutrophils. It takes about 10 days for a neutrophil to mature and be released into the circulation. Once released, neutrophils have a circulating half-life of 6 to 10 hours. They cannot replicate and must be replaced constantly to maintain adequate numbers in the circulation. They do not return to the bone marrow.

Eosinophils account for 1% to 4% of the total number of circulating leukocytes. They mature in the bone marrow for 3 to 6 days before being released into the circulation. Eosinophils have a circulating half-life of 30 minutes and a tissue half-life of 12 days. They are phagocytic cells, but are less efficient at this process than neutrophils. Eosinophils are found in large numbers in the respiratory and gastrointestinal tracts, where they are thought to be responsible for protecting the body from parasitic worms, including tapeworms, flukes,

pinworms, and hookworms. Eosinophils surround the parasite and release toxic enzymes from their cytoplasmic granules. The parasite, although too large to be phagocytized, is destroyed. Eosinophils are also involved in a hypersensitivity response, inactivating some of the inflammatory chemicals released during the inflammatory response.

Basophils constitute about 0.5% to 1% of the circulating leukocytes. These cells are not phagocytic. Granules within basophils contain proteins and chemicals such as heparin, histamine, bradykinin, serotonin, and slow-reacting substance of anaphylaxis (leukotrienes). These substances are released into the bloodstream during an acute hypersensitivity reaction or stress response.

MONOCYTES, MACROPHAGES, AND DENDRITIC CELLS Monocytes, macrophages, and dendritic cells are the mediators of immunity. They recognize foreign matter (from molecules to cells) and initiate immune responses. *Monocytes* are the largest of the leukocytes and constitute 2% to 3% of circulating leukocytes. After their release from the bone marrow, monocytes circulate in the serum for 1 to 2 days. They then migrate throughout the body, attaching themselves to various tissues, where they remain for months or even years until they are activated. Monocytes mature into **macrophages** after settling into the tissues. Once they have migrated and matured, macrophages are differentiated by the tissues in which they reside. *Histiocytes* are tissue macrophages in loose connective tissue, *Kupffer cells* are found in the liver, *alveolar macrophages* in the lungs, and *microglia* in the brain. Tissue macrophages are also found in the spleen, tonsils, lymph nodes, and bone marrow. Dendritic cells are star-shaped cells that serve as intermediaries between the innate and adaptive immune systems. Dendritic cells capture antigens, transporting them to lymphoid organs such as regional lymph nodes (Grossman & Porth, 2014). Monocytes, macrophages, and dendritic cells are antigen-presenting cells (APCs), which activate immune responses in both B and T lymphocytes.

Monocytes, macrophages, and dendritic cells are actively phagocytic, with the capacity to phagocytize large foreign particles and cell debris. Like neutrophils, macrophages are drawn to an inflamed area by chemicals released from damaged tissue in a process known as *chemotaxis*. Once they are in the tissue, macrophages can multiply to encapsulate and trap foreign matter that cannot be phagocytized. Monocytes and macrophages activate the immune response against chronic infections such as tuberculosis, viral infections, and certain intracellular parasitic infections. Dendritic cells have long processes that can capture antigens and migrate to lymphoid tissue. They serve as sentinels for antigens in most organs including the heart, lungs, liver, kidney, and gastrointestinal tract. Dendritic cells activate T cells against cancer, assist B lymphocytes to produce antibodies, and downregulate the immune system.

LYMPHOCYTES **Lymphocytes** account for 20% to 40% of circulating leukocytes. Lymphocytes are the principal effector and regulator cells of specific immune responses that protect the body from microorganisms, foreign tissue, and cell mutations or alterations. Through a process known as immune surveillance, lymphocytes monitor the body for cancerous cells and eliminate or destroy them.

Like other leukocytes, lymphocytes derive from the stem cells in the bone marrow (Figure 12–2 ■). Lymphocytes have "homing"

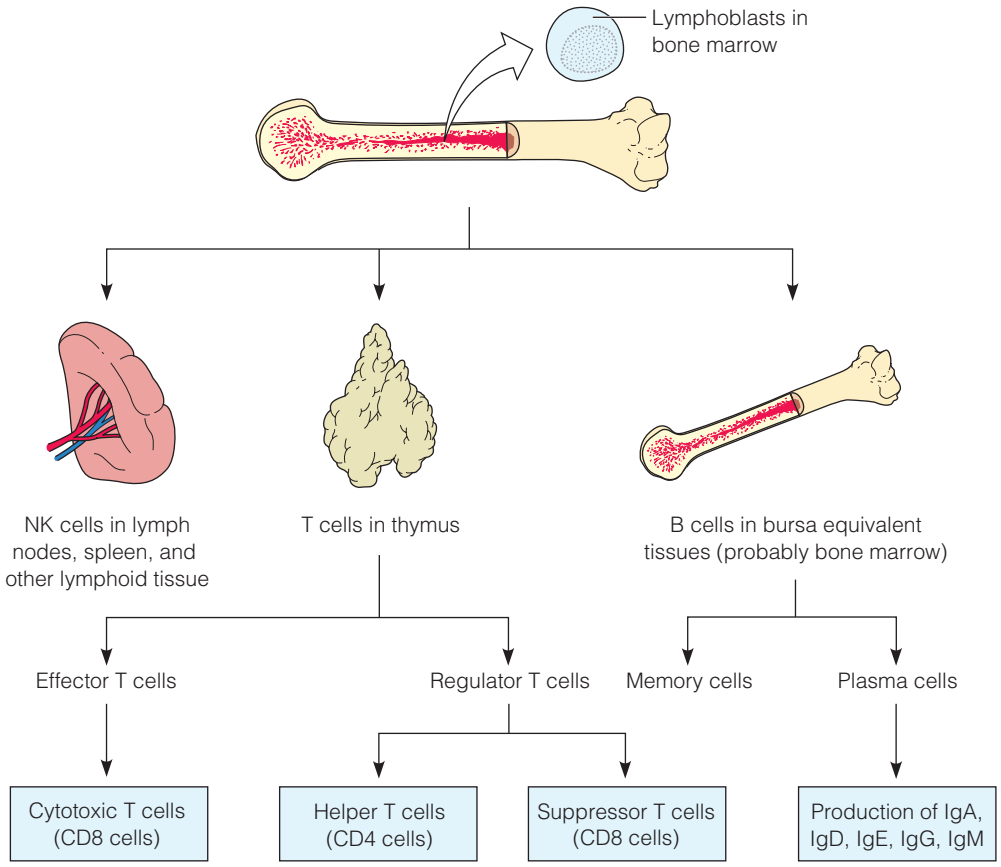

Figure 12–2 ■ The development and differentiation of lymphocytes from the lymphoid stem cell (lymphoblasts).

patterns: They constantly circulate, then return to concentrate in lymphoid tissues (the lymph nodes, spleen, thymus, tonsils, Peyer's patches in the submucosa of the distal ileum, and the appendix).

The three types of lymphocytes are **T lymphocytes (T cells)**, **B lymphocytes (B cells)**, and **natural killer cells (NK cells)**. None of these cells acts independently. Their functions are closely interrelated. T cells mature in the thymus gland, whereas B cells complete their maturation in the bone marrow. T cells and B cells are integral to the adaptive immune response. On contact with an antigen, B lymphocytes are activated and mature into either plasma cells, which secrete antibodies, or memory cells. On contact with APCs, T lymphocytes mature into active helper T (T_H) cells, cytotoxic T (T_C) cells, or memory T cells. Memory cells are inactive, sometimes for years, but activate immediately with subsequent exposure to the same antigen. They then proliferate rapidly, producing an intense immune response. Memory cells are responsible for providing acquired immunity.

NK cells are large, granular cells found in the spleen, lymph nodes, bone marrow, and blood. They constitute 15% of circulating lymphocytes. NK cells are part of the innate immune response. They provide immune surveillance, recognizing and destroying altered and abnormal host cells. Like B cells and T cells, NK cells are cytotoxic, but unlike T cells they do not require a specific antigen to become activated and kill cancer cells, virus-infected cells, and cells infected with microbes (Grossman & Porth, 2014). Fortunately, NK cells are inhibited when contact is made with normal host cells.

ANTIGENS Substances the immune system recognizes as foreign or "nonself" are called **antigens**. Antigens provoke a specific immune response when introduced into the body. Typically, antigens are large protein molecules found on the cell membrane or cell wall of microorganisms or tissues such as transplanted tissue or organs. Other potentially antigenic substances include pollens, insect venom, and the resin of poison ivy (Grossman & Porth, 2014).

Complete antigens, known as immunogens, have two characteristics: (1) *immunogenicity*, the ability to stimulate a specific immune response; and (2) *specific reactivity*, the stimulation of specific immune system components. In contrast, haptens are small molecules (e.g., chemical toxins or dust) that must link with proteins to evoke an antigenic response.

When an antigen is encountered in the body, generation of an effective immune response involves two major groups of cells: lymphocytes and antigen-presenting cells (APCs). Macrophages and dendritic cells function as APCs as they capture, process, and present antigens to the lymphocytes. Lymphocyte receptors recognize and respond to specific antigens, generating the immune response. Two separate but overlapping immune responses may occur, depending on the antigen itself and the type of immune cell activated by contact with the antigen. The B cell or humoral branch of the immune system mainly targets extracellular antigens such as bacteria, bacterial toxins, and free viruses through the production of **antibodies**, molecules that bind with the antigen and inactivate it. The five classes of antibodies are IgG, IgA, IgM, IgD, and IgE. These proteins make up the **antibody-mediated (humoral) immune response**. Intracellular pathogens, such as viral-infected cells, cancer cells, and foreign tissue, activate T lymphocytes, which are the primary agents of the **cell-mediated (cellular) immune response**. In this immune response, the lymphocytes themselves, in the form of helper T cells, cytotoxic T cells, and NK cells, inactivate the antigen, either directly or indirectly.

LYMPHOID SYSTEM

The *lymphoid system* consists of the lymph nodes, spleen, thymus, tonsils, lymphoid tissue scattered in connective tissues and mucosa, and bone marrow. The thymus and bone marrow, in which T cells and B cells mature, are considered central lymphoid organs. The spleen, lymph nodes, tonsils, and other peripheral lymphoid tissue are peripheral lymphoid organs (Figure 12–3 ■). The lymphoid system recovers proteins such as albumin for the vascular system and protects the bloodstream from invading organisms. Immune cells continuously circulate through lymphoid tissues and organs, identifying and destroying foreign antigens.

Lymph nodes, the most numerous elements of the lymphoid system, are small, round or bean-shaped encapsulated bodies that vary in size from 1 mm to 2 cm. Lymph nodes generally occur in groups at the junction of the lymphatic vessels. They can be found in the neck, axillae, abdomen, and groin.

Lymph nodes filter foreign products or antigens from the lymph and house and support proliferation of lymphocytes and macrophages. Lymph, a clear, protein-containing fluid transported within lymph vessels, enters the node through afferent lymphatic vessels. Inside the node, the lymph flows through sinuses in the cortex of the lymph node where T and B lymphocytes and macrophages are abundant, then through sinuses of the medulla of the lymph node, which contains macrophages and plasma cells. The presence of a foreign

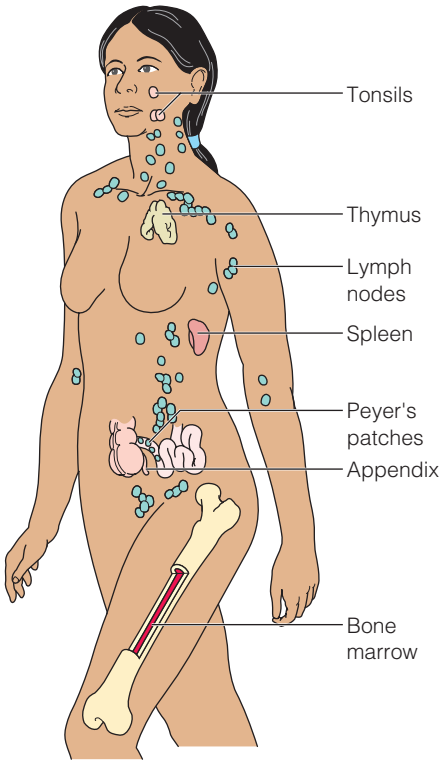

Figure 12–3 ■ The lymphoid system: the central organs of the thymus and bone marrow, and the peripheral organs, including the spleen, tonsils, lymph nodes, and Peyer's patches.

antigen stimulates lymphocytes and macrophages to proliferate in the lymph nodes. Macrophages destroy the antigen by phagocytosis. Immune cells and lymph then leave the lymph node through efferent vessels. An abundant blood supply to the node also facilitates lymphocyte movement.

The *spleen* is the largest lymphoid organ in the body and the only lymphoid organ that can filter blood. The spleen is located in the upper left quadrant of the abdomen. The spleen has two kinds of tissue, white pulp and red pulp. White pulp is lymphoid tissue that serves as a site for lymphocyte proliferation and immune surveillance. B cells predominate in the white pulp. Blood filtration occurs in the red pulp. In blood-filled venous sinuses, phagocytic cells dispose of damaged or aged RBCs and platelets. Other debris and foreign matter, such as bacteria, viruses, and toxins, are also removed from the blood. The spleen also stores blood and the breakdown products of RBCs for future use. The spleen is not essential for life. If it is removed because of disease or trauma, the liver and the bone marrow assume its functions.

The *thymus gland* is located in the superior anterior mediastinal cavity beneath the sternum. It reaches its maximum size at puberty, then begins to atrophy slowly. By adulthood it is difficult to differentiate from surrounding adipose tissue even though it remains active. In the older adult, the vast majority of thymus tissue has been replaced by adipose and fibrous connective tissue. During fetal life and childhood, the thymus serves as a site for the maturation and differentiation of thymic lymphoid cells, the T cells. Thymosin, an immunoregulatory hormone of the thymus, stimulates lymphopoiesis, the formation of lymphocytes or lymphoid tissue.

Bone marrow is soft organic tissue found in the hollow cavity of the long bones, particularly the femur and humerus, as well as the flat bones of the pelvis, ribs, and sternum. Bone marrow produces and stores hematopoietic stem cells, from which all cellular components of the blood are derived (refer to Figure 12–1).

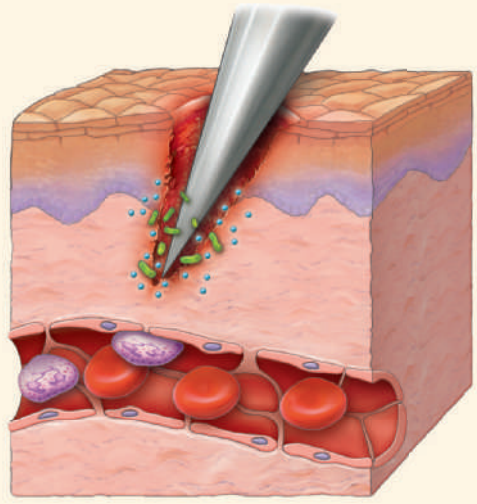
Lymphoid tissues are also located at key sites of potential invasion by microorganisms: the submucosa of the genitourinary, respiratory, and gastrointestinal tracts and the skin. Plasma cells in these lymphoid tissues defend the body against bacterial invasion at areas exposed to the external environment. In general, these tissues are known as *mucosa-associated lymphoid tissue* (MALT). Diffuse collections of lymphocytes, plasma cells, and phagocytes are scattered throughout the respiratory tract, concentrating at bifurcations of the bronchi and bronchioles. Peyer's patches, or *gut-associated lymphoid tissue* (GALT), comprises the largest collection of immune cells in the body. Ingestion and absorption of solid foodstuffs and liquids continually expose the lining of the gut to resident microflora and infectious pathogens. Unlike peripheral lymph nodes, which respond to pathogens with acute inflammatory responses, GALT processes common intestinal antigens without producing acute inflammation. Collections of immune cells make up the GALT. Intraepithelial lymphocytes fill the spaces between mucosal epithelial cells. Beneath the basement membrane of gut epithelium lie abundant T cells and mature plasma cells, which are sources of IgA. Peyer's patches hold dense collections of lymphocytes in lymphoid nodules. As naïve B and T cells migrate through Peyer's patches, they are sensitized to specific antigens. In mesenteric lymph nodes these sensitized cells proliferate and circulate throughout the vascular tree where they produce secretory IgA. Secretory IgA coats mucosal cells and prevents attachment of intraluminal bacteria in the intestine, upper respiratory tract, the bronchi, mammary ducts, and salivary glands. Thus, the GALT collection of immune cells effectively protects mucosa throughout the body that is exposed to resident and foreign pathogens.

Tonsils and adenoids protect the body from inhaled or ingested foreign agents. Skin-associated lymphoid tissue contains lymphocytes and dendritic cells such as Langerhans cells in the epidermis, which transport antigens to regional lymph nodes for destruction and development of specific immunity to the antigen.

Innate Immune Response

Innate or natural immunity is the first line of defense against infection. It is nonspecific and includes skin and mucosal barriers, vascular and cellular responses, and phagocytosis. Cells involved in innate immunity include phagocytic neutrophils and macrophages, and NK cells, which target intracellular pathogens. Soluble molecules such as opsonins, cytokines, acute-phase proteins (such as C-reactive protein), and the complement system also are involved in innate immunity.

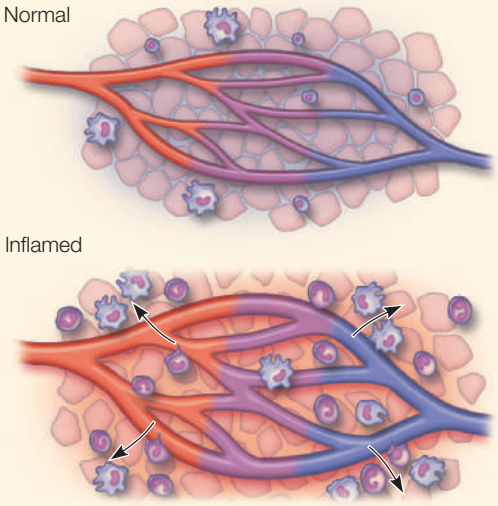
Barrier protection is the body's first defense against infection. Intact skin prevents invasion by external organisms. When the skin is damaged or lost (e.g., as a result of injury, surgery, or burns), infection is much more likely. A barrier of mucus, which traps microorganisms and other foreign substances, protects the membranes lining inner surfaces of the body. These can then be removed by other protective mechanisms, such as by ciliary movement or by the washing action of tears or urine. In addition, many body fluids contain bactericidal substances that provide barrier protection. These include acid in gastric fluid, zinc in prostatic fluid, and lysozyme in tears, nasal secretions, saliva, and sweat.



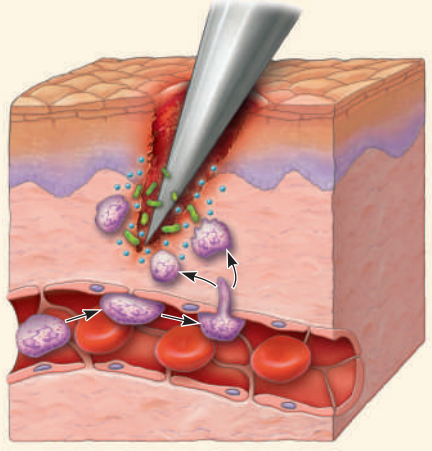
When these defenses are breached, the resulting tissue damage or foreign material entering the body induces inflammation, another innate defense mechanism. **Inflammation** is a response to injury that brings fluid, dissolved substances, and blood cells into the interstitial tissues where the invasion or damage has occurred. The response is nonspecific: The same events occur regardless of cause of the inflammatory process. Through the inflammatory reaction, the invader is neutralized and eliminated, destroyed tissue removed, and the process of healing and repair initiated. See Pathophysiology Illustrated Acute Inflammation on next page.

The inflammatory response has two stages: (1) a vascular response characterized by vasodilation and increased permeability of blood vessels, and (2) a cellular response. Phagocytosis sets the stage for healing (tissue repair).

VASCULAR RESPONSE

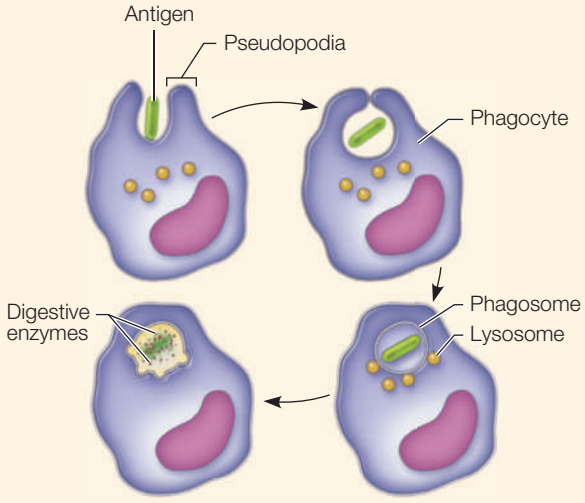


After tissue cells are damaged, local blood vessels briefly constrict. Vasodilation of the capillary arterioles and venules follows almost immediately as inflammatory mediators such as histamine and kinins are released from damaged tissue (Box 12–1). Increased blood flow causes vasocongestion at the injury site with resultant redness and heat. The congestion also increases local hydrostatic pressure. This, along with the increased vessel permeability that results from chemical mediators, moves fluid out of the capillaries and into the interstitial spaces of the tissue. The escaping fluid, called *fluid exudate*, contains large amounts of protein. This protein increases osmotic pressure in the interstitial spaces, which draws water and causes local edema. Fluid exudate provides protection for the injured tissue by transporting to the tissue certain nutrients needed for tissue healing, diluting bacterial



Acute Inflammation

1. Inflammation is a key component of innate immunity, the body's immediate response to tissue damage or invasion of the body by foreign material. The inflammatory response serves to contain, control, and eliminate damaged cells and tissue, microorganisms, and antigens.



2. Vascular Response. Tissue damage causes brief, initial vasoconstriction which is rapidly followed by vasodilation, with resulting redness and warmth. Inflammatory mediators (e.g., histamine, prostaglandins, bradykinins) released in the innate immune response and by damaged tissue dilate local blood vessels and increase the permeability of capillaries in the area. Protein-rich fluid (exudate) accumulates in interstitial spaces, causing swelling and pain. Resulting edema slows blood flow, and together with activation of clotting in the area, helps localize and prevent microorganisms from spreading.

3. Cellular Response. Within less than an hour after the injury, the cellular stage of the inflammatory process brings phagocytic blood cells into the damaged tissue. Loss of serous fluid from capillaries increases blood viscosity in the area and slows its flow. Leukocytes marginate, moving to vessel periphery and adhering to the capillary endothelium. As a result, endothelial cells separate, allowing leukocytes to transmigrate through vessel walls into the tissue spaces. Chemotactic signals draw the leukocytes to the site of the injury or infection.

4. Phagocytosis. Once attracted to the inflammatory site, phagocytes engulf the foreign agent or target cell by projecting pseudopodia ("false feet") in all directions around it. This produces a phagosome containing the antigen, which is ingested into the cytoplasm. Once engulfed, lysosomes fuse with the phagosome, killing any live organism and releasing digestive enzymes, which destroy the antigen.

BOX 12–1 Inflammatory Mediators

Many of the manifestations of inflammation are produced by chemicals released as a result of immunologic processes or tissue injury or damage. These inflammatory mediators are broadly classified as follows:

- Vasoactive substances (e.g., histamine, prostaglandins, leukotrienes, and platelet-activating factor) produce smooth muscle constriction, vasodilation, and increased capillary permeability.
- Chemotactic factors (e.g., complement fragments and chemokines) attract leukocytes to the damaged tissue.
- Plasma enzymes (proteases) activate the complement system, the clotting cascade, and the vasoactive kinins system, contributing to the vascular phase of the inflammatory response.
- Miscellaneous cell products (e.g., oxygen metabolites and lysosomal enzymes) damage surrounding tissue.

toxins, and transporting cells needed for phagocytosis. Exudate may range from *serous*, primarily plasma with some proteins, to *sanguineous*, containing large amounts of blood cells. *Fibrinous exudate* forms a thick, sticky meshwork of fibrinogen, in effect "walling off" inflamed tissues and preventing the spread of infection. In more severe or acute inflammation, the fluid contains fibrin, RBCs, and dead and live bacteria. This type of exudate, called *purulent exudate*, has an odor and color characteristic of the bacteria present.

Many of the outward manifestations of inflammation result from vasoactive substances such as *histamine*, *prostaglandins*, and *leukotrienes*. Stored in mast cells, basophils, and platelets, histamine is released when an injury occurs or with stimulation by the immune system. An important component of the early inflammatory response, histamine causes vasodilation and vascular permeability in the affected area. Histamine is also a key factor in many hypersensitivity reactions. The leukotrienes, collectively known as slow-reacting substance of anaphylaxis (SRS-A), play a significant vasoactive role in the later stages of the inflammatory response.

Prostaglandins are chemotactic substances that draw leukocytes to the inflamed tissue. In addition, they play a vasoactive role and are pain and fever inducers. Aspirin and other nonsteroidal anti-inflammatory drugs (NSAIDs), as well as the glucocorticoids, inhibit prostaglandin synthesis, thereby reducing fever, pain, and inflammation.

Plasma proteases activate the clotting cascade, kinin system, and complement system. With activation of the clotting cascade, bacteria and other foreign substances are trapped in the area of tissue damage. Fibrin, which has vasoactive by-products, is also released. Activation of the complement system causes vasodilation, increases vessel permeability, and facilitates the phagocytic process. Through the release of bradykinin, the kinin system has similar effects. Bradykinin also stimulates pain receptors.

Major chemical mediators of inflammation are summarized in Table 12–2.

The vascular response localizes invading bacteria and keeps them from spreading. Increased capillary permeability enhances the release of clotting factors such as fibrinogen, which converts to fibrin threads, entrapping the bacteria and walling them off from contact with the rest of the body.

CELLULAR RESPONSE

The cellular stage of the inflammatory process begins within less than an hour after an injury. This stage is marked by changes in the lining of blood vessels and movement of phagocytic blood cells into the damaged tissue.

As serous fluid escapes the capillaries, the viscosity of blood in the area increases and its flow becomes more sluggish. Leukocytes move to the edges of the blood vessels where they accumulate, their movement slows, and they begin to adhere to the capillary endothelium. This process is known as *margination*. Leukocyte adhesion causes separation of endothelial cells, allowing leukocytes to transmigrate through the blood vessel wall into the tissue spaces. Within hours, millions of leukocytes emigrate into the area of inflammation.

Once leukocytes have emigrated, they are drawn to the damaged or inflamed tissues by chemotactic signals. Infectious agents, damaged tissues, and activated plasma substances such as complement fractions provide chemotactic signals that attract an army of neutrophils, monocytes, and macrophages to the injury site.

The number of neutrophils around the site increases to about 15,000 to 25,000/mm^3, and they begin their role in phagocytosis within a few hours. Monocytes become transient macrophages to augment the activity of the fixed macrophages and dendritic cells; together they engulf dead cells, damaged tissue, nonfunctioning neutrophils, and invading bacteria.

PHAGOCYTOSIS

Phagocytosis is a process by which a foreign agent or target cell is recognized, engulfed, and destroyed. Neutrophils, monocytes, and macrophages, known as *phagocytes*, are the primary cells involved in phagocytosis. Once attracted to the inflammatory site, phagocytes select and engulf foreign material.

The following factors or processes help phagocytes differentiate foreign tissue from normal cells:

- ***Smooth surface.*** Normal tissue has a smooth surface that is resistant to phagocytosis, whereas the rough surface of a foreign agent or target cell promotes phagocytosis.

TABLE 12–2 Major Chemical Mediators of Inflammation

Factor	Source	Effect
Histamine	Mast cells, basophils, and platelets	Vasodilation and increased capillary permeability, producing tissue redness, warmth, and edema
Kinins (bradykinin and others)	Plasma proteins	Histamine-like effects; chemotaxis and pain inducers
Prostaglandins	Formed from arachidonic acid found in cell membranes	Histamine-like effects; chemotaxis, pain, and fever inducers
Leukotrienes	Formed from arachidonic acid	Smooth muscle constriction (especially bronchoconstriction), increased vascular permeability, chemotaxis

BOX 12–2 The Complement System

The complement system consists of approximately 20 complex plasma proteins that are activated by a tissue injury or antigen–antibody reaction. The complement system is involved in both innate and adaptive immune responses. Its activation results in the production of effector molecules that are involved in the processes of inflammation, phagocytosis, and cell lysis or destruction (Grossman & Porth, 2014). Specifically, complement activation leads to the following:

- *Mediation of the inflammatory response.* When the complement system is activated, chemical mediators such as histamine are released from mast cells and basophils, leading to smooth muscle contraction, increased vascular permeability and edema, and the attraction of leukocytes.
- *Opsonization (or coating) of microbes and antigen–antibody complexes.* Opsonization facilitates recognition of and binding to the antigen by the phagocyte, and activation of phagocytosis.
- *Alteration of the cell membrane or viral capsule.* Complement can alter cell membranes, forming pores that cause cell lysis and death. Bacteria and viruses are destroyed; certain normal cells, such as RBCs, that are damaged or old may also be destroyed through this process.

The complement system has three arms, or pathways, of protein and enzyme reactions. The *classic pathway* is activated by antibody-containing immunoglobulins and other substances, such as DNA and C-reactive protein. The *alternate* and *lectin pathways* function in innate immunity; they do not require antibodies but are activated by tissue injury, properties of the microbial antigen, and proteins produced in response to injury (for example, C-reactive protein) (Grossman & Porth, 2014). Complement activation results in mediation of the inflammatory process, attraction of phagocytes, facilitation of phagocytosis, and lysis of microbes.

- ***Surface charge.*** Healthy body cells present an electronegative surface charge that repels phagocytes. Cellular debris and foreign agents, by contrast, have an electropositive charge that attracts them.
- ***Opsonization.*** This immune process coats the surface of bacteria or target cells with soluble molecules (opsonins) such as complement, lectins, and other proteins. (See Box 12–2 for more information about the complement system.) Opsonization enables the phagocyte to bind tightly with the foreign tissue, facilitating phagocytosis.

Phagocytes engulf the foreign agent or target cell by projecting pseudopodia (*false feet*) in all directions around it. This produces a chamber called a *phagosome* containing the antigen, which is ingested into the cytoplasm. Once the phagosome has been engulfed, lysosomes fuse with the phagosome, releasing antibacterial molecules and digestive enzymes that destroy the antigen.

Phagocytes produce bactericidal agents that kill most pathogens. These agents include toxic oxygen and nitrogen radicals, such as nitric oxide, hydrogen peroxide, and hydroxyl ions, as well as digestive enzymes (e.g., lysozyme) that break down bacterial cell walls (Mayer, 2011). Finally, phagocytes can produce antimicrobial molecules known as *defensins* (Grossman & Porth, 2014). Some antigens, such as the tubercle bacillus, have coats or secrete substances that are resistant to lysosomal and bactericidal agents. To destroy such antigens, lysosomes release digestive enzymes into the phagosome. The lysosomes of neutrophils and macrophages contain an abundance of proteolytic (protein-destroying) enzymes that digest bacteria and other foreign protein components. The macrophage's lysosomes also contain lipases (fat-splitting enzymes) capable of digesting the thick lipid membranes of such bacteria as *Mycobacterium tuberculosis* and *Mycobacterium leprae*.

Once neutrophils have ingested toxic substances to their capacity, they in turn are destroyed. Neutrophils have the capacity to phagocytize 5 to 20 bacteria before they become inactive. Macrophages then digest the dead neutrophils. Monocytes or macrophages are capable of phagocytizing up to 100 bacteria. Because of their size, they can ingest larger particles than neutrophils can ingest, such as whole RBCs, necrotic tissue, cell fragments, malarial parasites, and dead neutrophils. Dendritic cells are also phagocytic and secrete IL-12, which is an important cytokine in the maturation of T_H cells. Macrophages have the ability to extrude (release) the toxic substances and lysosomal enzymes within their phagosomes. As a result, they can continue to function for months and even years.

HEALING

During the initial inflammatory process, particulate matter, bacteria, damaged cells, and inflammatory exudate are removed by phagocytosis. This process, called *debridement*, prepares the wound for healing. Adequate nutrition is essential for inflammation and healing to proceed. Protein, glucose, and oxygen are needed by leukocytes for chemotaxis, phagocytosis, and intercellular killings.

The second phase of the healing process, known as *reconstruction*, may overlap the inflammatory phase. The ideal result of the healing process is *resolution*, the restoration of the original structure and function of the damaged tissue. Simple resolution occurs when there is no destruction of the normal tissue and the body is able to neutralize and remove the offending agent through the inflammatory process.

Resolution may also occur when the damaged tissue is capable of regeneration. The ability to regenerate, or replace lost *parenchyma* (functional tissue) with new, functional cells varies by tissue and cell type.

- *Labile cells* continue to regenerate throughout life. These cells are found in tissues where there is a daily turnover of cells—namely, bone marrow and the epithelial cells of the skin, mucous membranes, cervix, gastrointestinal tract, and genitourinary tract.
- *Stable cells* normally stop replicating when growth ceases, but are capable of regeneration when stimulated by an injury. Osteocytes (which are found in bone) and parenchymal cells of the kidneys, liver, and pancreas are stable cells.
- *Permanent* or *fixed cells* are unable to regenerate. When these cells are destroyed, they are replaced by fibrous scar tissue. Nerve cells, skeletal muscle cells, and cardiac muscle cells are fixed cells.

When regeneration and complete resolution are not possible, healing occurs by replacement of the destroyed tissue with collagen scar tissue. This process is known as *repair*. Although tissue that has undergone repair lacks the physiologic function of the destroyed tissue, the scar fills the lesion and provides tensile tissue strength.

Adaptive Immune Response

The *adaptive immune response* is a more specific reaction to the introduction of antigens into the body than innate immunity. On the first exposure to an antigen, a change occurs in the host, allowing a specific and rapid response following subsequent exposures.

The adaptive immune response has the following distinctive properties:

- The immune response typically is directed against materials recognized as foreign (i.e., from outside the body) and is not usually directed against the self (i.e., cells or structures produced by the body). This property is known as *self-recognition*.
- The immune response is *specific*. It is initiated by and directed against particular antigens (such as a specific virus, bacterium, or transplanted tissue).
- Unlike a localized inflammatory response, the immune response is *systemic*. Immunity is not restricted to the initial site of infection or entry of foreign tissue.
- The immune response has *memory*. Repeated exposures to an antigen produce a more rapid response.

A patient whose immune system is able to identify antigens and effectively destroy or remove them is said to be **immunocompetent**.

There are two types of adaptive immune responses: humoral or antibody-mediated immunity, and cellular or cell-mediated immunity.

ANTIBODY-MEDIATED IMMUNE RESPONSE

The antibody-mediated (humoral) immune response is produced by B lymphocytes (B cells). B cells are constantly replaced through cell division and proliferation in the bone marrow. It is believed that B cells mature in the bone marrow and then migrate to the spleen to await activation. They normally constitute 10% to 15% of circulating lymphocytes.

B cells are activated by contact with an antigen and by T cells (discussed in the next section). Each B cell has receptor sites for a specific antigen or antigens. When the antigen is encountered, the activated B cell proliferates and differentiates into antibody-producing plasma cells and memory cells (Figure 12–4 ■). Plasma cells are short lived, lasting only about 1 day. While alive they can produce thousands of antibody molecules per second. Memory cells retain

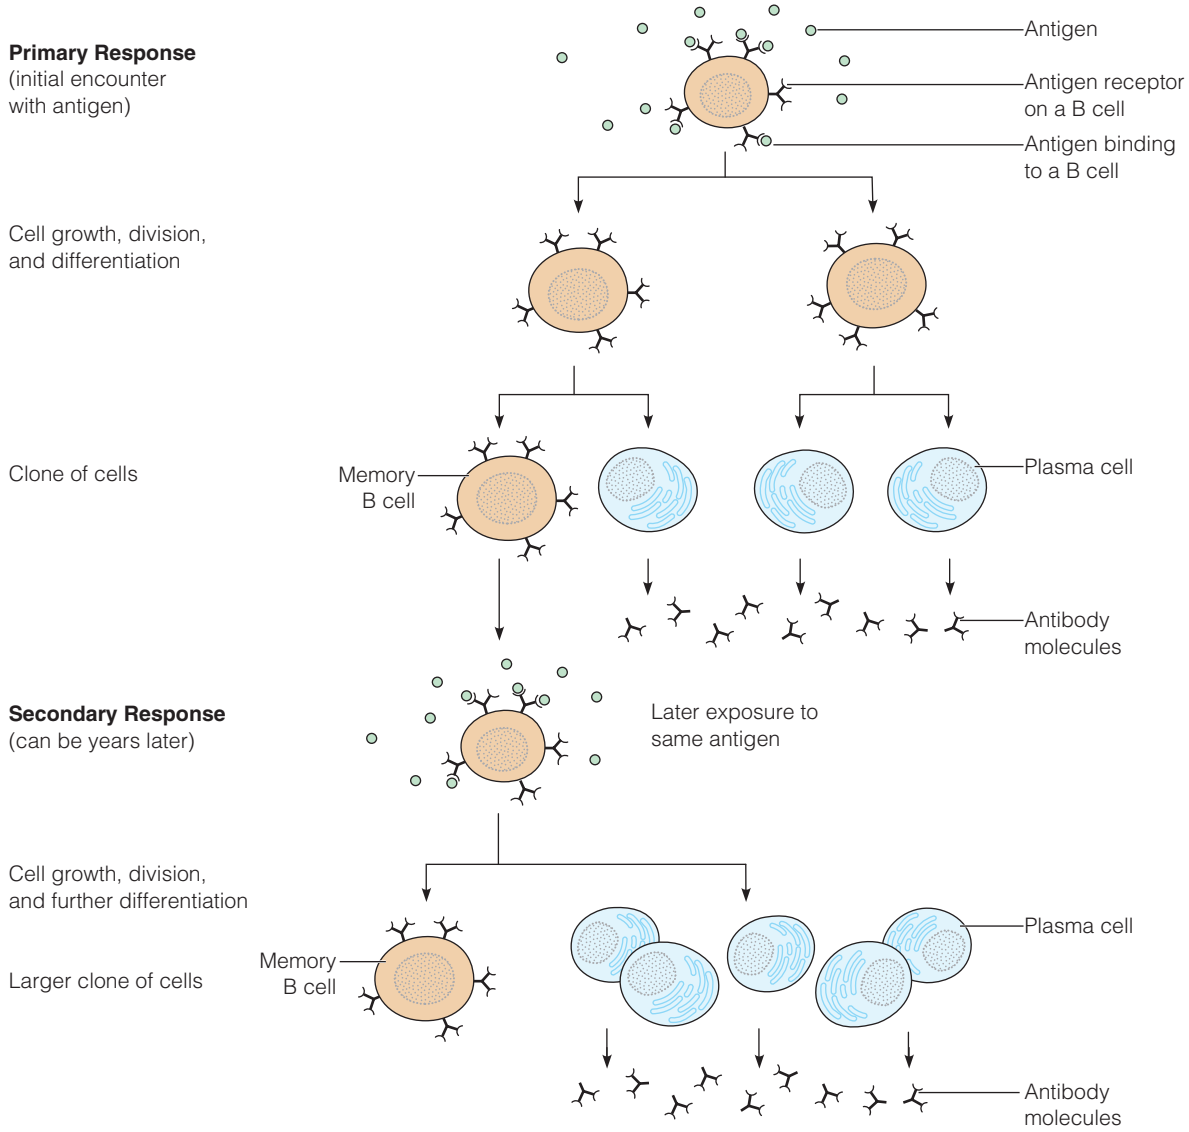


Figure 12–4 ■ Antibody-mediated (humoral) immunity. On initial exposure to the antigen, B cells with appropriate receptor sites are activated to become plasma cells, which produce antibodies or memory cells. This is known as the primary response. With subsequent exposures, memory cells respond rapidly with antibody production. This is known as the secondary response.

TABLE 12–3 Immunoglobulin Characteristics and Functions

Class	Percentage of Total	Characteristics and Function
IgG	75%	Most abundant Ig; also known as gamma globulin; found in blood, lymph, and intestines.
		Active against bacteria, bacterial toxins, and viruses.
		Activates complement and binds to macrophages.
		The only Ig to cross the placenta, providing immune protection to neonate.
IgA	10%–15%	Found in saliva; tears; and bronchial, gastrointestinal, prostatic, and vaginal secretions, as well as blood and lymph.
		Provides local protection on exposed mucous membrane surfaces and potent antiviral activity by preventing binding of the virus to epithelial cells.
		Levels decrease during stress.
IgM	5%–10%	Found in blood and lymph.
		First antibody produced with primary immune response.
		High concentrations early in infection, decreases within about a week.
		Mediates cytotoxic response and activates complement.
IgD	<1%	Found in blood, lymph, and surfaces of B cells.
		Exact function unknown; may be receptor-binding antigens to B-cell surface.
IgE	<0.1%	Found on mast cells and basophils.
		Involved in release of chemical mediators responsible for immediate hypersensitivity (allergic and anaphylactic) response and parasitic infections.

antibody-producing information, allowing a rapid response if the antigen is again encountered.

An antibody is an **immunoglobulin (Ig)** molecule with the ability to bind to and inactivate a specific antigen. Immunoglobulins fall into five classes: IgG, IgA, IgM, IgD, and IgE. Each has a slightly different structure and function. Their roles are summarized in Table 12–3.

Antibodies are Y-shaped molecules with two light and two heavy polypeptide chains (Figure 12–5 ■). The top portion of the Y, called the *Fab* or *antigen-binding fragment*, is chemically variable and specific to the antigen. The lower portion, the F_c, or *crystallized fragment*, is constant for its class of immunoglobulin and directs the biologic activity of the immunoglobulin (the manner in which it functions).

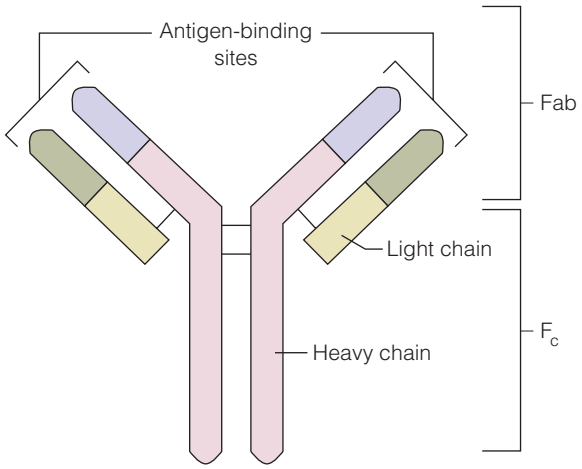

Figure 12–5 ■ An antibody molecule. The Fab section is unique, providing an antigen-specific binding site. The F_c section is common to each class of immunoglobulin (IgG, IgA, IgM, IgD, IgE).

For example, the lower portion of immunoglobulin molecules produced against hepatitis A and hepatitis B is the same (IgG), but the upper portion is different and specific to the virus.

The antibodies produced by B cells (refer to Figure 12–4) link with the antigen (Figure 12–6 ■) and inactivate it through one or more of the following processes:

- Covering the antigen with antibodies to attract phagocytes, including neutrophils, macrophages, and eosinophils
- Precipitation: combining with soluble antigens to form an insoluble complex or precipitate that can be captured and destroyed by phagocytes

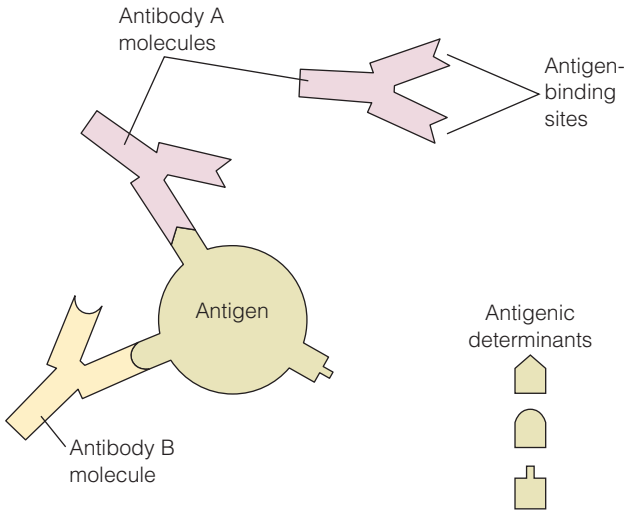

Figure 12–6 ■ Antigen–antibody binding. The unique Fab site on the antibody binds with specific receptor sites on the antigen. As shown, more than one kind of antibody may be produced to an antigen.

- Neutralization: combining with a virus or toxin to neutralize its effects by preventing it from attaching to cells and tissues; the antigen–antibody complex is then destroyed by the process of phagocytosis
- Complement activation and fixation to the antigenic cell surface, leading to cell lysis
- Agglutination (clumping) of insoluble antigens (e.g., a cell or virus) to form a large complex
- Opsonization: coating of the antigen with antibodies and complement, making them more susceptible to phagocytosis.

The complete antibody-mediated response occurs in two phases. With initial exposure to an antigen, the primary response develops. B cells are activated to proliferate and begin producing antibodies. There is a latency period of 3 to 6 days before antibodies become detectable in the blood. Levels then continue to rise, peaking at 10 to 14 days after the initial exposure. With many illnesses (e.g., chickenpox), this peak correlates with recovery.

Subsequent exposure to the same antigen elicits a secondary response. Memory cells (refer to Figure 12–4) formed during the primary response stimulate the production of plasma cells, and an almost immediate rise in antibody levels occurs (Figure 12–7 ■). This rapid secondary response is the basis of **acquired immunity** and is instrumental in preventing disease. It is also the mechanism through which vaccines provide protection from disease.

CELL-MEDIATED IMMUNE RESPONSE

Many antigens cannot stimulate the antibody-mediated response or are hidden from it because they live inside the body's cells (for example, viruses and mycobacteria). The cell-mediated immune response, also called *cellular immunity*, provides protection against these antigens. T lymphocytes (T cells) initiate this type of immune response.

Approximately 70% to 80% of circulating lymphocytes are T cells. T cells migrate to the thymus during fetal and early life, establishing the lifetime pool of cells. T cells have a life span measured in years, maintaining their numbers through proliferation, primarily in the lymph nodes. T cells are much more complex than B cells. There are two major populations of T cells, CD4 cells and CD8 cells, differentiated by their cell surface proteins (or markers). T cells are antigen specific; that is, each subset is activated by a particular antigen. The antigens that activate T cells must be presented on another cell surface, such as pieces of virus presented on the surface of an infected cell, or the histocompatibility locus antigen on a cell of transplanted tissue. When activated, T cells divide and proliferate, forming antigen-specific *clones* (Figure 12–8 ■). Activated T cells further differentiate to become *cytotoxic cells, helper cells,* or *suppressor cells*. *Memory cells* are also formed; these remain in reserve for future encounters with the antigen.

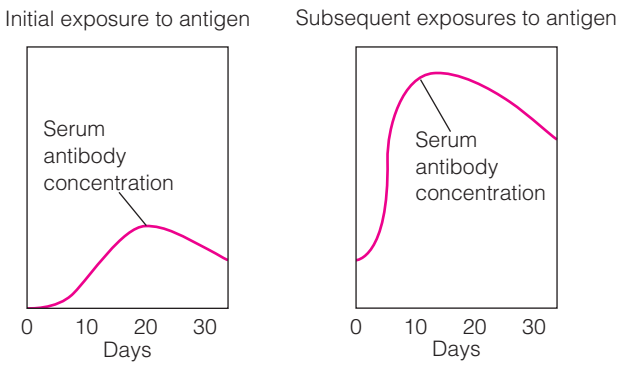

Figure 12–7 ■ Antibody production in the primary and secondary responses of the antibody-mediated immune response. Note the more rapid and effective production following subsequent exposure.

The *cytotoxic T cell* (T_C cell), an effector cell with the CD8 marker, seeks out and destroys abnormal cells and cells harboring anything foreign (e.g., viruses). Cytotoxic T cells bind with cell surface antigens on virus-infected or foreign cells. T_C cells destroy the identified cell by combining with it and then either destroying its cell membrane or releasing cytotoxic substances into the cell. They are vital in the control of viral and bacterial infections.

Helper T cells (T_H cells) develop from T-cell populations with the CD4 marker. T_H cells coordinate immune responses to an antigen. They stimulate the proliferation of other T cells, amplify the cytotoxic activity of T_C cells, and amplify the innate immune response. T_H cells interact directly with B cells to promote their multiplication and conversion into plasma cells capable of producing antibodies.

Suppressor T cells (T_S cells), a much smaller subgroup of T cells, are important regulators of immune responses. Suppressor T cells release inhibitory cytokines, which inhibit the activity of other T cells and B cells and limit the extent of the immune response to an antigenic stimulus.

On activation, both effector and regulator T cells synthesize and release soluble proteins known as **cytokines** (Box 12–3). Cytokines are important in amplifying innate immunity and specific immune responses. They stimulate:

- B cells to become plasma cells and produce antibodies
- Attraction and activation of macrophages to become aggressive phagocytes

BOX 12–3 Cytokines

Cytokines, essential components of an adequate immune response, are hormone-like polypeptides produced primarily by cells of the immune system. Cytokines are also produced in small quantities in many different tissues throughout the body. Cytokines act as messengers of the immune system, facilitating communication between the cells to adjust or vary the inflammatory reaction or to initiate immune cell proliferation and differentiation. The major cytokines and their functions are summarized in Table 12–4.

The inflammatory cytokines contribute to illness behaviors. Patients respond to increases in these chemicals with increased sleep, a need to seek warmth, and reduced energy output. These are considered adaptive responses to illness. Interventions to reduce or eliminate the production of certain cytokines are common. Aspirin or NSAIDs to reduce pain and fever are commonly used. Because some cytokines cross the blood–brain barrier, their increase may explain depression and anxiety experienced during illness.

Interferons are a class of cytokine with broad antiviral and anticancer effects. A number of different forms of interferon exist, broadly grouped as alpha, beta, and gamma interferons. Interferon is synthesized by cells infected with a virus and secreted into extracellular fluid. It then binds to specific receptors on uninfected neighboring cells, protecting them from infection. The spread of the virus is thus inhibited, and recovery from infection enhanced. It appears that interferons also moderate the activity of NK cells and may be involved in preventing the spread of abnormal malignant cells.

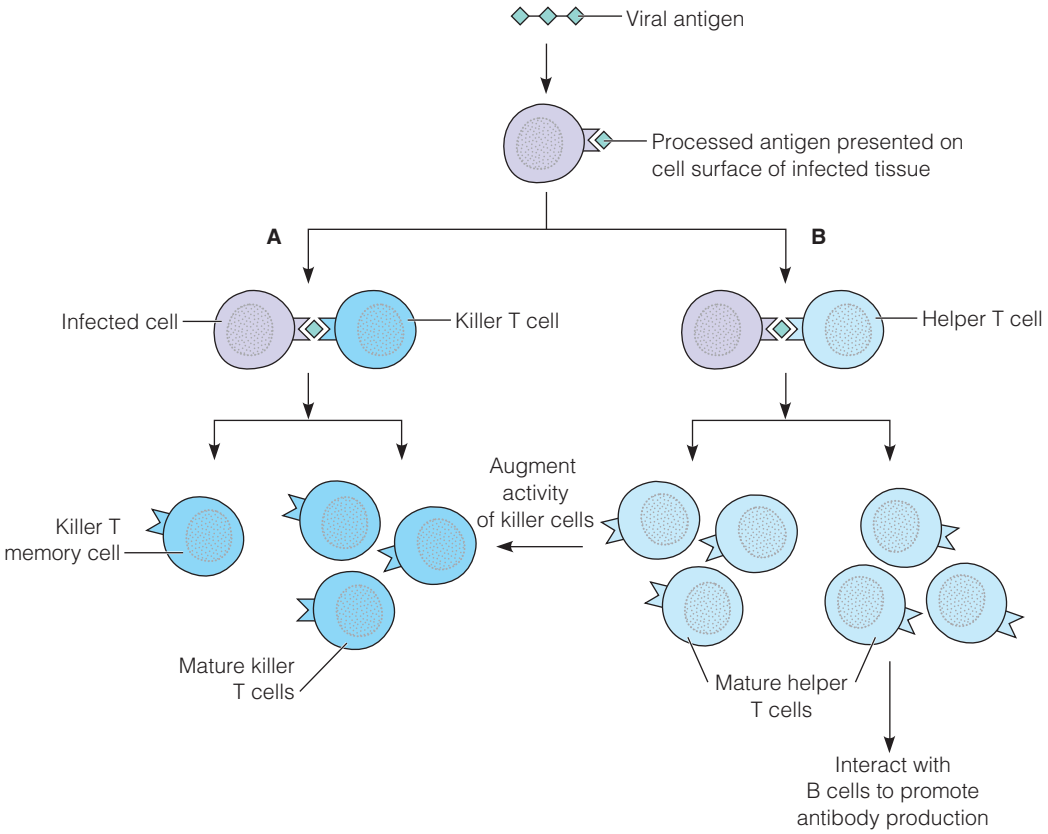

Figure 12–8 ■ Cellular immune response. *A,* An infected cell, abnormal cell, or phagocyte presents antigen on its surface that binds with a receptor site on a killer T cell or a helper T cell. The killer T cell is activated to proliferate into memory cells or mature cytotoxic cells. *B,* The helper T cell is activated to augment the cytotoxic response and stimulate the antibody-mediated immune response.

- Proliferation of cytotoxic T cells and memory helper T cells
- Stimulation of cytotoxic T cells to destroy abnormal cells and pathogens.

Although T cells are activated by specific antigens, much of the resulting effect is nonspecific—in other words, an enhanced inflammatory response. Like the antibody-mediated response, the cell-mediated response has memory. Subsequent exposures to an antigen result in a more rapid and effective inflammatory response and more effective phagocytosis by macrophages. This memory provides the basis for skin testing. For example, a patient previously exposed to tuberculosis develops a more pronounced inflammatory response when minute amounts of antigen are injected under the skin.

The Patient with Natural or Acquired Immunity

Immunity refers to the protection of the body from disease. Immunity to disease may be natural or acquired, active or passive.

Immunity develops from the activation of the body's immune response. Depending on the antigen, antibody-mediated or cell-mediated responses are activated. The immune response typically involves components of both. In the *immunocompetent* (having an immune system capable of responding to pathogens and tissue damage) patient, these responses inactivate and remove the antigen, allowing recovery to occur or preventing the development of disease. Patients with suppressed or impaired immune function are more susceptible to disease and require protection from exposure to environmental elements. Isolation techniques are employed to prevent the spread of disease and to protect immune-suppressed patients.

PATHOPHYSIOLOGY

The processes of antibody-mediated and cell-mediated immunity result in the development of **active immunity**. Active immunity occurs when the body produces antibodies or develops immune lymphocytes against specific antigens. Memory cells, which can produce an immediate immune response on reexposure to the antigen, provide long-term immunity. Active immunity can develop naturally, resulting from contact with the disease-producing antigen and subsequent development of the disease. For many diseases, however, the potential consequences of a single disease episode on the individual and society make prevention desirable, especially for highly contagious diseases capable of causing epidemics. In these instances, immunization or vaccination is used to provide artificially acquired active immunity. The purpose of vaccination is to establish adequate levels of antibody and/or memory cells to provide effective immunity. Vaccination introduces the disease-producing antigen into the body in a manner that will stimulate the immune system to form antibodies and memory cells but will not produce disease. Vaccines may be made of killed organisms or of live organisms that have been *attenuated* or modified to reduce their disease-producing capability. Typhoid is an example of a killed organism vaccine; measles-mumps-rubella (MMR) vaccine, by contrast, is made from attenuated organisms. Many newer vaccines use subunits of the antigen; these

TABLE 12–4 Major Cytokines and Their Functions

Cytokine	Where Produced	Primary Functions
Interleukin-1 (IL-1)	Monocytes, macrophages, and dendritic cells	Activates T and B cells. Induces fever and tissue catabolism. Enhances NK activity. Attracts neutrophils, macrophages, and lymphocytes. Stimulates bone marrow and endothelial cell growth, collagen, and collagenases.
Interleukin-2 (IL-2)	Helper T cells	Stimulates T- and B-cell proliferation; aids in discriminating between self and nonself. Activates killer T and NK cells.
Interleukin-3 (IL-3) Interleukin-4 (IL-4)	T cells	Stimulates growth and differentiation of bone marrow stem cells. Stimulates proliferation of T cells. Increases IgE secretion by B cells.
Interleukin-5 (IL-5)	T cells and activated mast cells	Promotes differentiation of B cells and eosinophils. Stimulates production of IgA.
Interleukin-6	T cells and macrophages	Is a pro-inflammatory and anti-inflammatory cytokine. Induces fever.
Interleukin-8	Macrophages	Mediates the innate immune response. Induces fever. Is angiogenic (stimulates vessel formation).
Gamma interferon	T and NK cells	Stimulates phagocytosis by neutrophils and macrocytes. Activates NK cells. Augments B-cell proliferation, enhancing both cellular and humoral immune responses.
Alpha and beta interferons	Virus-infected cells; macrophages	Activate macrophages and endothelial cells; beta interferon induces fever. Augment NK cell activity. Act at gene level to protect neighboring cells from invasion by intracellular parasites, such as viruses, rickettsia, and malaria.
Macrophage inflammatory proteins (MIP-1-4CC)	Macrophages, dendritic cells, and lymphocytes	Are chemokines (CC), which are small cytokines. Promote inflammatory response, chemotaxis, and homeostasis (control migration of cells in maintenance and development).
Tumor necrosis factor (TNF)	Activated macrophages, T cells, and NK cells	Is a major chemical mediator of inflammatory response. Stimulates T-cell activation, antibody production, and accumulation of leukocytes at inflammatory site. Is directly cytotoxic to some tumor cells Induces fever.

are portions of the organism that have antigenic properties but are unable to produce disease.

Passive immunity provides temporary protection against disease-producing antigens. Antibodies produced by other people or animals are the source of passive immunity. These acquired antibodies are used up; they either combine with the antigen or are naturally degraded by the body, and their protection is gradually lost. The transfer of maternal antibodies via the placenta and breast milk to the infant provides naturally acquired passive immunity. Rabies human immune globulin and hepatitis B immune globulin (HBIG) are examples of immunizations used to provide artificially acquired passive immunity. The types of active and passive immunity are summarized in Table 12–5.

TABLE 12–5 Types of Acquired Immunity

Type of Immunity		How Developed	Examples
Active immunity	Natural	Acquired by infection with a pathogen, resulting in the production of antibodies	Chickenpox
	Artificial	Acquired by immunization with an antigen, such as an attenuated live virus vaccine	MMR, polio, DPT, hepatitis B vaccines
Passive immunity	Natural	Acquired by transfer of maternal antibodies to the fetus or neonate via the placenta or breast milk	Neonate initially protected against MMR if mother immune
	Artificial	Acquired by administration of antibodies or antitoxins in immune globulin	Gamma globulin injection following hepatitis A exposure

●○● INTERPROFESSIONAL CARE

Interprofessional care is preventive, focusing primarily on assessing the patient's immune status and ensuring acquired immunity to prevent disease.

DIAGNOSIS

A number of diagnostic tests can be performed to assess the patient's immune status:

- *Serum protein* measures the total protein in the blood, including albumin and globulins. Normal total protein levels for the adult are 6 to 8 g/dL. Total protein levels, albumin, and globulin are decreased in malnutrition and liver disease. Decreased globulin levels are noted with immunologic deficiencies.
- *Protein electrophoresis* analyzes protein content, especially for albumin and gamma globulin, and is used to assess immune function. Albumin is approximately 60% (3.2 to 4.5 g/dL) of the total serum protein, and globulins are normally 2.3 to 3.4 g/dL. Gamma globulins subjected to further electrophoresis separate into immunoglobulins: IgA, IgD, IgE, IgG, and IgM (refer to Table 12–3). Analysis of specific levels of each provides clues about the immune status of the patient. IgG levels are increased during acute infection. Decreased levels of IgG, IgA, and IgM are found in malignancies.
- *Antibody testing* is ordered to determine if a patient has developed antibodies in response to an infection or immunization. Antibodies for hepatitis, HIV, rubella, varicella (chickenpox), and certain other diseases can be identified. An elevated titer for varicella and rubella indicates immunity. Antibody testing may also be used to determine if the patient has the disease.
- *Skin testing* can assess cell-mediated immunity. A known antigen such as tuberculin purified protein derivative (PPD) or candida is injected intradermally. The site is then observed for induration and erythema, which typically peaks at 24 to 48 hours. An induration of at least 10 mm in diameter is a positive reaction indicating previous exposure and sensitization to the antigen. No reaction to common antigens, or **anergy**, indicates depressed cell-mediated immunity.

IMMUNIZATIONS

Vaccines are suspensions of whole or fractionated bacteria or viruses that have been treated to make them nonpathogenic. Vaccines are given to induce an immune response and subsequent immunity. Although vaccine development has been a major factor in improving public health, no vaccine is completely effective or entirely safe. Table 12–6 outlines the vaccines recommended for the adult patient to maintain optimal health and immune status (Centers for Disease Control and Prevention [CDC], 2014).

Adults born before 1957 are generally considered to be immune to measles, mumps, and rubella by prior infection. Individuals born after 1956 should have documentation of one or more doses of MMR vaccine unless they have a medical contraindication to the vaccine or laboratory evidence of immunity to the three diseases (CDC, 2014). Adults who only received one dose of varicella (chickenpox) vaccine should receive a second dose. Adults ages 60 and older should receive zoster vaccine regardless of history of chickenpox or herpes zoster (shingles).

Tetanus and diphtheria (Td) toxoids are combined in a single immunization. The vaccine stimulates active immunity by inducing the production of antibodies and antitoxins. After an initial series of three immunizations, a booster injection is recommended every 10 years to maintain protection. Older patients, particularly those who never entered the workforce (e.g., older female adults), may have never received the initial series of Td vaccine. A resurgence of active cases of pertussis among adults and children has led the CDC to recommend that all adults under age 65 years and older adults (of any age) who have close contact with infants younger than 12 months receive one dose of tetanus/diphtheria/pertussis (Tdap) vaccine.

Hepatitis B (HB) vaccine is mandated by the Occupational Safety and Health Administration (OSHA) for healthcare workers and public safety workers. It also is recommended for people newly diagnosed with diabetes mellitus who are under age 60 years and for those in high-risk populations. High-risk populations include intravenous drug users, sexual partners of infected individuals, and patients with end-stage renal disease, HIV infection, or chronic liver disease.

Influenza vaccine is now recommended annually for all adults. The antigenic strains included in the influenza vaccine vary each year, according to the predicted predominant strains affecting the population; therefore, yearly reimmunization is required. Pneumococcal vaccine is recommended for older adults, people living with chronic disease or who are immunosuppressed, and individuals who smoke cigarettes. Revaccination 5 years after the initial dose of pneumococcal vaccine may be recommended for some people. Pneumococcal vaccine for all senior citizens is a U.S. public health and Medicare goal. The purpose of immunization is to prevent respiratory infections and hospitalizations.

Human papillomavirus (HPV) vaccine has been shown to significantly reduce the risk for cervical and other cancers. HPV is recommended for all previously unvaccinated men and women through age 26 years. Other vaccines such as hepatitis A and meningococcal vaccine may be given if other risk factors are present, for example, occupational risk factors.

In addition to routine immunizations, people traveling outside the United States and Canada should receive vaccines against diseases that are endemic in certain regions of the world.

Other immunologic substances may be administered as indicated. Immune globulins provide passive immunity as protection against a known or potential exposure to an antigen. Standard immune globulin is given to household contacts of patients with hepatitis A and individuals traveling to areas in which hepatitis A is endemic. HBIG contains higher titers of antibody to hepatitis B virus and is used for individuals exposed by blood or sexual contact. Following confirmed or suspected contact with a pathogen, selected vaccines may be administered to stimulate an immediate immune response.

For most vaccines, a sensitivity test should be performed prior to administration to detect sensitivity to substances such as horse serum or eggs. The substance is injected intradermally; if after 20 minutes there is no evidence of a reaction, the selected vaccine can be administered.

Moderate to severe local reactions may occur following administration of an immunization. Common reactions include redness, swelling, tenderness, and muscle ache. Administering the vaccine in the dominant arm of the patient helps minimize local reactions because use and movement of the arm facilitates absorption of the solution. Applying heat to the site is also beneficial. Occasionally

TABLE 12–6 Recommended Immunizations for Adults

Vaccine	Type	Dose	Indications	Precautions and Nursing Implications
Influenza	Inactivated virus or viral components	0.5 mL IM	Yearly for all adults	Do not administer to acutely ill patients or patients with history of anaphylactic reaction to egg protein.
Tetanus and diphtheria toxoids (Td); pertussis (Tdap)	Inactivated toxins	0.5 mL IM	Initial series of three injections (two doses, 4–6 weeks apart; third dose 6–12 months after dose 2) if never immunized; booster every 10 years; following a major or contaminated wound if more than 5 years since last booster. Replace one booster with Tdap.	Do not give during first 20 weeks of pregnancy or to patients with a history of anaphylactic reaction to horse serum; administer deep IM in deltoid of dominant arm.
Varicella	Live virus	0.5 mL subcutaneously (subcut)	All adults without evidence of immunity, particularly people at high risk for exposure, transmission, or severe disease	Two doses 4–8 weeks apart. Do not administer during pregnancy or to people with a history of life-threatening allergic reaction to the vaccine, gelatin, or neomycin. Use with caution in people who are immunocompromised (e.g., who have HIV disease or are taking immunosuppressant drugs).
Human papilloma virus (HPV)	Not a live virus	0.5 mL IM	Prior to exposure to HPV through sexual activity	Three doses for males and females ≤ 26 years; IM in deltoid.
Measles-mumps-rubella (MMR)	Live virus	0.5 mL subcut	All adults born after 1956, particularly those who are at risk for infection, such as college students, military recruits, and those working in a healthcare facility. Rubella vaccination recommended for all seronegative females.	As a live virus vaccine, should not be administered to pregnant women or immunocompromised patients. Do not administer to patients with a history of anaphylactic reaction to egg protein or neomycin. Give subcutaneously in fatty tissue over triceps.
Zoster (shingles)	Attenuated live virus	0.65 mL subcut	Adults ≥ 60 years including those who report having had shingles	Give in fatty tissue over triceps. Do not administer during pregnancy, or to immunocompromised or HIV-infected individuals. Cannot be used in children or in place of varicella vaccine.
Hepatitis A	Inactivated whole virus	1 mL IM	People with liver disease or who receive clotting factors; travel to areas with high endemicity; illicit drug use or men who have sex with men	Give IM in deltoid.
Hepatitis B (HB)	Inactive viral antigen	1.0 mL IM	Series of three doses: initial and at 1 and 6 months. Recommended for anyone at risk for exposure and for postexposure prophylaxis.	Use with caution in pregnant or lactating females, older patients, and patients with active infection; have epinephrine 1:1000 available on unit in case of anaphylaxis and laryngospasm.
Pneumococcal	Bacterial polysaccharides	0.5 mL IM or subcut	One dose for patients over age 65 and those at risk for pneumococcal pneumonia, including patients with chronic lung disease or other chronic diseases	Do not administer to pregnant women.
Meningococcal vaccine	Inactive bacterial antigens	0.5 mL IM	College students living in dormitories and military recruits	Give in deltoid muscle; individuals previously diagnosed with Guillain-Barré syndrome should not receive this vaccine.

local ulcerations occur; when they do, warm, wet pack, or sterile wet-to-dry dressings may be prescribed.

●○● NURSING CARE

Maintaining a population that is fully immunized against common, potentially epidemic, and devastating diseases is a major public health task for nursing. Nurses not only recommend and administer vaccines to individual patients and their families, but also plan and implement preventive care for whole communities.

Although this process may appear to be straightforward, multiple issues affect society's ability to immunize the entire population. For some people, for example, religious beliefs may preclude the use of immunizations to prevent disease. Also, people who are not

Moving Knowledge into Action

Outbreaks of pertussis have occurred in certain parts of the United States in the most recent decade. Routine vaccination of infants for pertussis had previously made this disease virtually unheard of in the United States for many years. The disease affects both young and old, causing a persistent, and often severe, cough. Infants, however, are at greatest risk for complications of pertussis.

1. Identify factors that are or may be contributing to these outbreaks. As you develop your response, consider population demographics, sociocultural, educational, political, and economic factors.
2. As a public health nurse in an urban or rural community, how might you approach the risk of a pertussis outbreak?

citizens and the medically indigent population have difficulty accessing immunization services. Lack of immunization not only puts the individual at increased risk for infectious disease, but also increases the cost of medical services and the possibility of exposing immunocompromised people to disease.

Health Promotion

In the public health setting, the nurse looks at the immunization needs and illness risk for an entire community. Communities include not only cities and localities but also groups of people, such as college populations and employees in a workplace. Public education needs may be met through presentations to groups of people, feature articles in newspapers and other local publications, advertising, radio presentations and public service announcements, and one-to-one discussion and teaching.

Assessment

Collect the following data through the health history and physical examination. Further focused assessments are described with nursing interventions in the next section.

- ***Health history:*** age, medication use (corticosteroids and antibiotics) and blood transfusion, nutrition, known allergies, pregnancy status, infection, immunizations, autoimmune disorders, chronic diseases such as asthma, diabetes mellitus, cancer, smoking history
- ***Physical assessment:*** skin lesions or rashes, breath sounds, respiratory rate.

Priorities of Care

Nursing care focuses on promoting immunity while preventing injury from the immunization and educating the patient. See the accompanying Case Study & Nursing Care Plan.

Diagnoses, Outcomes, and Interventions

Readiness for Enhanced Immunization Status

For individual patients and their families, nurses promote immunocompetence by assessing immune status, recommending appropriate

CASE STUDY & NURSING CARE PLAN A Patient with Acquired Immunity

Terry Adams is a 48-year-old executive who is planning a trip to central Africa. In preparation, he contacts his local healthcare provider to obtain the necessary immunizations. Jane Wong, the registered nurse in the clinic, obtains a nursing history of Mr. Adams.

ASSESSMENT

Mr. Adams's history reveals that he has always been very healthy and active, apart from mild asthma experienced during childhood. Mr. Adams has not seen a physician since recovering from an episode of hepatitis A more than 5 years ago and is unsure when he last received any immunizations. He does not know if he had all recommended childhood immunizations. His physical examination reveals an alert and healthy individual with no abnormalities noted. His vital signs are as follows: T 36.3°C (97.4°F), P 64 bpm, R 14/min, and BP 142/82 mmHg.

The physician orders the following immunizations for Mr. Adams:

- Measles-mumps-rubella (MMR)
- Combined tetanus and diphtheria toxoids with pertussis (Tdap)
- Yellow fever vaccine
- Typhoid vaccine
- Meningococcal meningitis vaccine.

DIAGNOSES

- *Readiness for Enhanced Immunization Status* related to impending international travel
- *Risk for Injury* related to adverse response to immunization

EXPECTED OUTCOMES

- Patient will obtain necessary immunizations.
- Patient will verbalize a schedule for maintaining up-to-date immunization status.
- Patient will experience no significant adverse effects from immunization.

PLANNING AND IMPLEMENTATION

- Administer MMR, Tdap, and meningococcal meningitis vaccines prior to discharge from clinic.
- Observe closely for 30 minutes following immunization for potential adverse responses.
- Schedule return visit in 1 week for typhoid vaccine.
- Provide referral to a registered vaccination center for yellow fever vaccine and documentation of vaccination.
- Provide instructions for comfort measures to relieve local and systemic adverse effects of vaccines.
- Provide written instructions on manifestations that should be reported to the physician.
- Document immunizations on a permanent record at the clinic and for the patient.

EVALUATION

Mr. Adams completes his prescribed immunizations without major adverse effects, although he does complain of mild fever, malaise, and general achiness for several days following the typhoid vaccination. His trip to Africa is successful, and he returns to the United States without contracting any infectious diseases.

Clinical Reasoning in Patient Care

1. Explain the concept of herd immunity and why it is important for adults to continue receiving immunizations throughout their life span.
2. If a patient says to you, "I don't believe in immunizations. I hear they are dangerous and cause autism in children," how would you respond?
3. What manifestations would cause a patient to contact his or her primary caregiver after receiving an immunization? What is the rationale for the need to do this?

See Evaluating Your Response in Appendix B.

immunizations, and administering vaccines as ordered or indicated. Once an individual reaches adulthood, routine immunizations often become a neglected part of healthcare.

Expected Outcome: Verbalizes understanding of the purposes for, risks of, and schedules of recommended immunizations based on health needs.

- Determine knowledge level, understanding, attitudes, and religious beliefs about immunization. *This provides a basis for further education and determines if religious beliefs may contraindicate immunization.*
- Discuss the value and reasons for recommended immunizations. *Understanding promotes adherence.*
- Reinforce positive health-seeking behaviors. *This will help promote future health maintenance activities.*
- Using recommended immunization schedules, develop a plan to attain optimal immunization status. *Adherence with recommended schedules for immunization is important in preventing disease and disability.*
- Do not administer influenza vaccine if the patient is allergic to eggs, or tetanus antitoxin if sensitive to horse serum. *Vaccines prepared from chicken or duck embryos are contraindicated in patients who are allergic to eggs. Tetanus antitoxin is prepared from horse serum. Both will cause a severe allergic reaction.*
- Withhold administration of active immunologic products in the presence of an upper respiratory infection or other infection. *Active immunizations can cause a greater inflammatory reaction in the presence of infections.*
- Do not administer oral polio vaccine, MMR, or any live virus vaccine to immunosuppressed patients or to patients who are in close household contact with an immunosuppressed person. *Live virus vaccines can cause disease in the immunosuppressed patient. The virus may be transmitted from close household contacts during the initial postvaccination period.*
- Do not administer vaccines such as MMR, pneumococcal, or varicella to women who are pregnant. *Although the risk to the developing fetus is greatest during the first trimester, these vaccines are avoided throughout pregnancy.*
- Do not administer live attenuated virus vaccines and passive immunizations such as gamma globulin simultaneously. *Passive antibodies interfere with the response of the live attenuated virus.*
- Prior to administering prescribed vaccine, check the expiration date and manufacturer's instructions. *Outdated vaccines cannot provide adequate immunization protection. Certain injection sites have better absorption than others.*
- Keep epinephrine 1:1000 readily available for subcutaneous injection when administering immunizations. *Epinephrine causes vasoconstriction and reduces laryngospasm; in acute anaphylaxis, it can be lifesaving.*

SAFETY ALERT

Observe the patient for 20 to 30 minutes following vaccine administration to monitor for possible adverse reactions.

Continuity of Care

Clinically important medical events including fever, injection-site hypersensitivity, unspecified rash, and injection-site edema that occur after vaccination should be reported to the Vaccine Adverse Event Reporting System (VAERS) by calling 1-800-822-7967 or by using the VAERS website. This report needs to be made even if the reporting person is not certain the event was caused by the vaccine. Approximately 10% to 15% of all reports describe serious adverse events, including life-threatening illness, hospitalization or prolongation of hospitalization, permanent disability, or death (CDC, 2013).

Helpful resources include state and county health departments, the CDC, and the National Institute of Allergy and Infectious Diseases.

Normal Immune Responses

THE PATIENT WITH TISSUE INFLAMMATION

Inflammation is a nonspecific response to injury that serves to destroy, dilute, or contain the injurious agent or damaged tissue. Inflammation may be either acute or chronic. Acute inflammation is a short-term reaction of the body to all types of tissue damage. It is immediate and aimed at protecting the body and preventing further invasion or injury. Acute inflammation usually lasts less than 1 to 2 weeks. Once the injurious agent is removed, the inflammation subsides. Healing with tissue repair or scar formation occurs, and the body functions in normal or near-normal capacity.

Chronic inflammation is slower in onset and may not have an acute phase. Its clinical manifestations occur over months or years. While the effects of some chronic inflammatory processes may be evident (such as the joint damage and destruction associated with rheumatoid arthritis), the role chronic inflammation plays in diseases such as asthma, obesity, and heart disease has only recently been recognized.

Pathophysiology and Manifestations

The tissue damage that evokes an inflammatory response may be caused by specific or nonspecific agents. These agents may be *exogenous*, from outside the body, or *endogenous*, from within the body. Causes of inflammation include the following:

- Mechanical injuries, such as cuts or surgical incisions
- Physical damage, such as burns
- Chemical injury from toxins or poisons
- Microorganisms, such as bacteria, viruses, or fungi
- Extremes of heat or cold
- Immunologic responses, such as hypersensitivity reactions
- Ischemic damage or trauma, such as a stroke or myocardial infarction.

ACUTE INFLAMMATION

Regardless of the cause, location, or extent of the injury, the acute inflammatory response follows the previously outlined sequence of vascular response, cellular and phagocytic response, and healing.

Many of the manifestations of inflammation are produced by inflammatory mediators, such as histamine and prostaglandins, which are released when tissue is damaged (refer to Box 12–1). The primary manifestations of inflammation include the following:

- Erythema (redness)
- Local heat caused by increased blood flow to the injured area (hyperemia)
- Swelling due to accumulated fluid at the site
- Pain from tissue swelling and chemical irritation of nerve endings
- Loss of function caused by swelling and pain.

The degree of functional loss depends on the location and extent of the injury. With increased tissue damage, more fluid exudate is formed, resulting in increased swelling, pain, and functional impairment. Pain may be immediate or delayed. Prostaglandins intensify and prolong the pain. Kinins cause irritation to the nerve endings and contribute to the pain sensation.

Dead neutrophils, necrotic tissue, and (if the tissue is infected) digested bacteria accumulate as a result of inflammation and phagocytosis, forming *pus*. Pus usually forms and remains until after the infection subsides. Pus may push itself to the surface of the body or become internalized. In the latter case, pus is gradually autolyzed (self-digested) by enzymes over a period of days. The end product is then absorbed by the body. On occasion, pus may remain after the infection is resolved. An **abscess**, or localized collection of pus, may form, necessitating *incision and drainage (I&D)*, surgical removal of the pus.

Systemic responses to inflammation include lymph node swelling (*lymphadenopathy*) due to the proliferation of macrophages within the nodes in response to microorganisms in the lymph. Enlarged lymph nodes are usually noted in the groin, axillae, and neck. Fever, often precipitated by inflammatory mediators or bacterial toxins, inhibits the growth of many microorganisms and increases tissue repair functions. Loss of appetite and fatigue may occur in the effort to conserve energy during the inflammatory process. Leukocytosis occurs with increased WBC production to support inflammation and phagocytosis.

CHRONIC INFLAMMATION

Whereas acute inflammation is a self-limiting process lasting less than 2 weeks, chronic inflammation tends to be self-perpetuating, lasting weeks to months or years. Chronic inflammation may develop when the acute inflammatory process has been ineffective in removing the offending agent. Persistent low-grade infection or irritation by chemicals, particulate matter, or physical irritants such as talc, asbestos, or silica may also result in chronic inflammation.

GRANULOMATOUS INFLAMMATION *Granulomatous inflammation* is characterized by dense infiltration of the site by lymphocytes and macrophages. The macrophages mass to surround the site; they, in turn are surrounded by lymphocytes and other immune cells, forming a lesion called a *granuloma*. The granuloma isolates the offending agent from the rest of the body; however, the infectious agent or irritant may not be destroyed and can survive within the granuloma for a long period of time. Chronic inflammation and granuloma formation are common with *Mycobacterium tuberculosis* infection. The granuloma formed in tuberculosis is called a tubercle. *M. tuberculosis* can survive for many years within the tubercle, emerging when the patient's immune system is no longer able to contain it.

NONSPECIFIC CHRONIC INFLAMMATION *Nonspecific chronic inflammation* is implicated in such disorders as pulmonary airway disease (asthma and chronic obstructive lung disease), cardiovascular disease, and autoimmune disorders such as inflammatory bowel disease (Reilkoff et al., 2011). This type of chronic inflammation is characterized by diffuse accumulation of macrophages and proliferation of fibroblasts in response to ongoing chemotaxis. The fibroblasts and fibrocytes, unique cells formed from monocytes, lead to formation of excessive fibrous connective tissue disrupting normal tissue function (Reilkoff et al., 2011). Inflammatory markers such as C-reactive protein, complement fractions, and inflammatory cytokines are present in nonspecific chronic inflammation and associated disorders (Bartunek & Vanderheyden, 2012; Engström, 2011; Pellizaro & Heuertz, 2010; Strowig et al., 2012).

Complications

Inflammation and wound healing are highly metabolic processes that may be affected by a number of factors. Without adequate nutrition, blood supply, and oxygenation, tissues cannot effectively complete the process. Impaired inflammatory and immune processes can interfere with phagocytosis and preparation of the wound for healing. Infection prolongs the inflammatory process and delays healing.

Chronic diseases may also impair healing. High blood glucose levels and small blood vessel disease associated with diabetes mellitus impair chemotactic and phagocytic function. Collagen formation and tensile strength of the wound are also impaired. Arterial and venous disorders impair the delivery of oxygen and nutrients to healing tissues, as well as the removal of toxins, bacteria, and other waste products from the area. Drug therapy, particularly corticosteroid medications, may suppress the immune and inflammatory responses, delaying healing. Other external factors, such as exposure to ionizing radiation and wound cleansing agents, can also affect healing. Table 12–7 summarizes major factors that affect the inflammatory process and wound healing.

Finally, there is growing evidence of the role chronic inflammation plays in diseases such as asthma, chronic obstructive lung disease, obesity, coronary heart disease, heart failure, and inflammatory bowel disease.

●○● INTERPROFESSIONAL CARE

Management of the patient with inflamed tissue focuses on promoting healing. Care is generally supportive, allowing the patient's own physiologic processes to remove foreign matter and damaged cells. Wound care may involve only simple cleaning, or may require irrigations and debridement. The patient is encouraged to rest, to increase fluid intake, and to eat a well-balanced, nutritious diet. Antibiotics may be prescribed to help eliminate infectious causes of inflammation.

DIAGNOSIS

The following diagnostic tests may be ordered to identify the source and extent of inflammation:

- *WBC with differential* provides information about the type and extent of inflammatory response. The differential count (the percentage of the total WBC made up by each type of leukocyte) provides further clues about inflammatory processes (Table 12–8).

TABLE 12–7 Factors That May Impair Healing

Factor	Effect
Malnutrition	
Protein deficit	Prolongs inflammation and impairs healing process.
Carbohydrate and kilocalorie deficit	Impairs metabolic processes and promotes catabolism; proteins are used for energy rather than for healing.
Fat deficit	Impairs cell membrane synthesis in tissue repair.
Vitamin deficits	
Vitamin A	Limits epithelialization and capillary formation.
B-complex	Inhibits enzymatic reactions that contribute to wound healing.
Vitamin C	Impairs collagen synthesis.
Tissue hypoxia	Increases the risk of infection and impaired healing, because oxygen is required to support cell function and collagen synthesis.
Impaired blood supply	Results in inadequate delivery of oxygen and nutrients to healing tissues and removal of waste products
Impaired inflammatory and immune processes	Result in decreased phagocytosis and wound debridement; increased risk of infection; delayed healing.

- *Erythrocyte sedimentation rate* (*ESR*) is a nonspecific test to detect inflammation. The rate at which RBCs fall to the bottom of a vertical tube is an indicator of inflammation. An increased ESR may indicate acute or chronic inflammation.
- *C-reactive protein (CRP) test* is used to detect this glycoprotein produced by the liver and excreted into the bloodstream during the acute phase of an inflammatory process. The expected result of this test is negative for CRP. A positive result indicates an acute or chronic inflammatory process.

In addition, blood and other body fluids may be cultured to determine if infection is the cause of inflammation.

MEDICATIONS

Although inflammation is a beneficial process to prepare acutely injured tissue for healing, its manifestations can be distressing. Chronic inflammation can lead to tissue damage and scarring, with resulting loss of function. Anti-inflammatory medications may be prescribed to manage these effects. Anti-inflammatory medications fall into three broad groups: salicylates, such as aspirin; other NSAIDs; and corticosteroids.

Aspirin (acetylsalicylic acid, or ASA) has antipyretic, analgesic, and antiplatelet effects. Its beneficial effects are largely dose related. Low doses (as little as 81 mg/day) inhibit platelet aggregation and normal blood clotting. A 650-mg dose of aspirin is an effective analgesic and antipyretic. To relieve pain, aspirin acts primarily on peripheral sensory nerves by inhibiting the synthesis of prostaglandins and kinins, which are chemical stimuli of sensory nerves. As an antipyretic, aspirin acts both centrally and peripherally. It inhibits the formation of pyrogenic substances that raise the hypothalamic thermostat. It also dilates peripheral blood vessels and promotes diaphoresis, increasing the dissipation of heat (Adams et al., 2014). Higher doses (650 to 1000 mg four to five times per day) are required to produce aspirin's anti-inflammatory effects. In therapeutic doses, aspirin mediates the inflammatory process by inhibiting the enzyme cyclooxygenase (COX) and preventing synthesis of prostaglandins. Inflammation is reduced, along with the swelling, redness, and impaired function that accompanies it.

The other NSAIDs have activity similar to that of aspirin. They inhibit COX and prostaglandin synthesis, reducing the inflammatory and pain response. Each NSAID has a slightly different mode of action; sometimes several different agents must be tried before the most effective is identified. Side effects also differ to a certain extent; however, all have a potential cross-sensitivity with aspirin, all irritate the gastrointestinal tract, and all are associated with an increased risk for cardiovascular events. NSAIDs also are more costly than aspirin, but

TABLE 12–8 The White Blood Cell Count and Differential

Cell Type and Normal Value	Increased	Decreased
Total WBCs: 4,000 to 10,000 per mm^3	*Leukocytosis:* infection or inflammation, leukemia, trauma or stress, tissue necrosis	*Leukopenia:* bone marrow depression, overwhelming infection, viral infections, immunosuppression, autoimmune disease, dietary deficiency
Neutrophils (segs, PMNs, or polys): 55% to 70%	*Neutrophilia:* acute infection or stress response, myelocytic leukemia, inflammatory or metabolic disorders	*Neutropenia:* bone marrow depression, overwhelming bacterial infection, viral infection, Addison's disease
Eosinophils (eos): 1% to 4%	*Eosinophilia:* parasitic infections, hypersensitivity reactions, autoimmune disorders	*Eosinopenia:* Cushing's syndrome, autoimmune disorders, stress, certain drugs
Basophils (basos): 0.5% to 1%	*Basophilia:* hypersensitivity responses, chronic myelogenous leukemia, chickenpox or smallpox, splenectomy, hypothyroidism	*Basopenia:* acute stress or hypersensitivity reactions, hyperthyroidism
Monocytes (monos): 2% to 8%	*Monocytosis:* chronic inflammatory disorders, tuberculosis, viral infections, leukemia, Hodgkin's lymphoma, multiple myeloma	*Monocytopenia:* bone marrow depression, corticosteroid therapy
Lymphocytes (lymphs): 20% to 40%	*Lymphocytosis:* chronic bacterial infection, viral infections, lymphocytic leukemia	*Lymphocytopenia:* bone marrow depression, immunodeficiency, leukemia, Cushing's syndrome, Hodgkin's lymphoma, renal failure

they have a longer duration of action; therefore, fewer daily doses are required to achieve the desired effect.

For acute hypersensitivity reactions, such as reactions to poison ivy, or for inflammation that cannot be managed using NSAIDs, corticosteroid therapy may be prescribed. The glucocorticoids are hormones produced by the adrenal cortex that have widespread effects on metabolism and the immune response. Glucocorticoids inhibit inflammation and may be lifesaving in acute or chronic progressive inflammation. When glucocorticoids are prescribed to manage inflammation, the smallest possible effective dose is used. Whenever possible, a local-acting preparation such as a topical agent, metered-dose inhaler, or intra-articular injection is prescribed to minimize systemic effects of the drug. The incidence of potentially harmful side effects increases with higher doses and prolonged therapy. Wound healing is impaired, and the metabolism of fats, proteins, and carbohydrates is altered. Blood glucose control is impaired. Fat distribution changes, producing a cushingoid appearance with a moon face, increased truncal fat, and "buffalo hump." Fluid retention and hypertension are potential problems, as are osteoporosis, gastrointestinal bleeding, and emotional disturbances.

Acetaminophen (Tylenol) may be administered to reduce the fever and pain associated with inflammation. It has no anti-inflammatory effect and will not reduce the inflammation, but can relieve associated manifestations such as fever and pain.

Antibiotics may be used either prophylactically to prevent infection from interfering with the healing process of damaged tissue, or therapeutically to treat the infection. If infection is present, the organism and its response or sensitivity to various antibiotics are used to guide therapy. Antibiotic therapy is discussed in the section of this chapter on infectious diseases.

NUTRITION

Healing depends on cell replication, protein synthesis, and the function of specific organs—the liver, heart, and lungs in particular. Malnutrition and protein depletion are risk factors for poor healing and wound complications. Even a few days of severely impaired nutritional intake can noticeably affect healing (Tucker & Dauffenbach, 2011). The patient with an inflammatory process or healing wound requires a well-balanced diet of sufficient kilocalories to meet the metabolic needs of the body (refer to Table 12–7). Inflammation often produces catabolism, a state in which body tissues are broken down. By contrast, healing is a process of anabolism or building up. Without sufficient kilocalories and nutrients, catabolism may dominate, impairing healing.

Adequate protein is necessary for tissue healing and the production of antibodies and WBCs. Lack of adequate protein increases the risk of infection. Complete protein sources, those that provide the essential amino acids, are preferred. Carbohydrates are important to meet energy demands, as well as to support leukocyte function. Care is taken to avoid hyperglycemia in patients with diabetes, however. Hyperglycemia interferes with oxygen delivery to the tissues as well as with the chemotactic and phagocytic function of neutrophils, impairing healing. Dietary fats are used in the synthesis of cell membranes.

Vitamins A, B complex, C, and K are also important to the healing process. Vitamin A is necessary for capillary formation and epithelialization. B-complex vitamins promote wound healing, and vitamin C is necessary for collagen synthesis. Vitamin K provides a vital component for the synthesis of clotting factors in the liver.

Although it has been established that minerals contribute to the inflammatory and healing processes, less is known about required amounts. Minerals serve important roles in maintaining normal cell function and as cofactors in enzyme reactions necessary for cell proliferation. Zinc, a micronutrient, is involved in cell growth and in T-cell development (Tucker & Dauffenbach, 2011).

Oxygen is another important element in healing. It is necessary for collagen synthesis. Phagocytes such as neutrophils and macrophages require oxygen to digest bacteria engulfed in the phagocytic process. Impaired oxygen delivery to the tissues slows healing and increases the risk for infection. Supplemental oxygen administered via nasal cannula or mask improves the oxygen saturation of hemoglobin and its availability to tissues. Hyperbaric oxygen delivery improves leukocyte and fibroblast function as well as the development of new blood vessels, and may be beneficial to promote healing of inflamed ischemic tissues (Bennett & Mitchell, 2012).

●○● NURSING CARE

Acute inflammation may be self-limiting or extensive and require hospitalization. Nursing care includes teaching patients with acute and chronic inflammatory conditions self-management at home.

Health Promotion

Health promotion activities to prevent inflammation focus on reducing the risk for accidents and exposure to harmful agents that can result in subsequent injury. It is important to educate the public about potential hazards in both the work and home environments. In addition, safety education guidelines such as not drinking and driving, wearing a protective helmet when riding a bicycle, and using a safety belt in the car are important areas for discussion. Because most injuries occur at home, it is also important to discuss ways to make the home safer.

Assessment

The following data are collected through the health history and physical examination. Further focused assessments are described with nursing interventions in the next section.

- ***Health history:*** risk factors, nutrition, medication use (anti-inflammatory and corticosteroids), location, duration, and type (redness, heat, pain, swelling, and impaired function) of manifestations
- ***Physical assessment:*** movement of injured area, pain, circulation, wounds, lymph nodes.

Priorities of Care

Nursing care priorities focus on relieving pain due to the inflammatory response, supporting tissue healing, and preventing infection.

Diagnoses, Outcomes, and Interventions

The nursing care needs of the patient with an inflammation are related to the manifestations of the inflammation and resulting altered tissue integrity.

Acute Pain

Along with redness, warmth, swelling, and impaired function, pain is one of the primary manifestations of inflammation. Depending

on the cause, affected area, and degree of inflammation, pain may be acute and immobilizing or chronic and demoralizing. It is important to remember that pain is a subjective experience and that patient responses to pain vary.

Expected Outcome: Patient's pain will be alleviated to an acceptable level of comfort as defined by the patient.

- Assess pain using a scale of 0 to 10, with 0 being no pain and 10 being the worst pain; note the character, location, and duration of the pain. *Because pain is subjective, the patient provides the most accurate information regarding his or her pain experience.*
- Use physical and nonverbal cues to further assess the level of pain. *This intervention is especially important if the patient is nonverbal or tends to underreport pain.*
- Administer anti-inflammatory medications as prescribed. *These medications help reduce the pain resulting from acute inflammation. Most NSAIDs also have analgesic and antipyretic effects, further promoting comfort* (Adams et al., 2014).
- Administer analgesic medications as prescribed. *Moderate to severe pain may require treatment with an analgesic (for example, an opioid drug). Acetaminophen and opioid analgesics act within the CNS to reduce pain. Opioids provide the most effective pain relief overall, activating pain-inhibitory neurons and inhibiting pain-transmission neurons* (Rathmell & Fields., 2012).

PRACTICE ALERT!

Because opioids can depress respirations, it is important to monitor oxygen saturation and encourage the patient to take deep breaths to keep oxygen saturation adequate.

- Provide comfort measures, such as back rubs, position changes, or relaxation techniques. *These measures reduce muscle tension, relieve areas of pressure, and provide distraction.*
- Encourage activities such as reading, watching television, and taking part in social interactions. *Such activities provide distraction from the pain experience.*
- Encourage rest. *Strenuous activity or exercising an inflamed body part may increase discomfort and tissue damage.*
- Provide cold or heat as pain relief measures, as ordered. *For an acute injury, cold reduces swelling and relieves pain; after the initial stage, heat increases blood flow to the affected tissue and relieves pain and swelling by promoting absorption of edema. Do not apply either heat or cold for more than 20 minutes at a time and ensure there is a covering between the patient and the application.*

SAFETY ALERT

Use heat or cold application cautiously in older patients who have fragile skin and are at risk for tissue injury.

- Elevate the inflamed area if possible. *Elevation promotes venous return and reduces swelling.*
- Teach about the appropriate use and expected effects of anti-inflammatory medications. *If the patient's pain continues after the initial doses of anti-inflammatory medication, he or she may become discouraged and stop taking the medication before it becomes fully effective.*

Impaired Tissue Integrity

The inflammatory response can either precipitate or result from impairment of the integrity of skin or other tissues.

Expected Outcome: Patient's tissue integrity will be maintained or restored.

- Assess general health and nutritional status. *Poor general health or chronic diseases such as diabetes mellitus or renal failure interfere with the healing processes and increase the risk of infection.*
- Assess circulation to the affected area. *Adequate tissue perfusion and oxygenation are necessary for healing* (Grossman & Porth, 2014).
- Monitor the skin and surrounding tissue for increased manifestations of inflammation. *Inflammation can spread to adjacent tissues leading to conditions such as cellulitis.*
- Provide protection and support for inflamed tissue. *This reduces discomfort and decreases the risk of further tissue damage.*
- Clean inflamed tissue gently; if possible, use water, normal saline, or nontoxic wound cleansers. *Soap and harsh cleansers such as povidone-iodine (Betadine) and hydrogen peroxide can cause further drying and tissue damage. Granulation tissue in a healing wound is fragile and easily damaged.*
- Keep the inflamed area dry, and expose it to air as much as possible. *This promotes healing and helps prevent infection.*
- Balance rest with activity. *Rest decreases metabolic demands and allows for cell regeneration, while mobility helps to promote oxygenation and perfusion of the tissues.*
- Provide supplemental oxygen as ordered. *Supplemental oxygen improves tissue oxygenation and reduces hypoxia.*
- Provide a well-balanced diet with adequate kilocalories to meet the body's metabolic and healing needs. If the patient is allowed nothing by mouth (NPO), suggest parenteral or enteral nutrition. For the patient who is unable to consume an adequate diet, consult with a dietitian for between-meal supplements and/or multivitamin supplements. *Careful attention to diet and nutrient intake is important to provide the nutrients necessary for immune function and healing and to prevent catabolism* (Tucker & Dauffenbach, 2011).

Risk for Infection

The inflammatory response often indicates that body defense mechanisms have been set in motion to protect against invading microorganisms. The patient with a healing wound is at particular risk for infection.

Expected Outcome: Patient will be free of manifestations of infection.

- Assess the wound for specific manifestations of infection, including purulent drainage, foul odor, and delayed healing. *The normal inflammatory response can indicate infection and, on occasion, mask its presence.*
- Evaluate complete blood counts for adequate WBC response. *Leukocytosis may indicate infection or healthy response to injury and protection from infection. Immune-impaired patients may not respond with increased WBCs; manifestations of inflammation may be diminished in those individuals.*
- Monitor vital signs at least every 4 hours. *In response to the inflammatory process the temperature rises, usually in the range of 37.2°C (99°F) to 38.2°C (100.9°F). A temperature of 38.3°C (101.0°F) or above indicates infection. Fever is usually accompanied by increased heart and respiratory rates.*

- Apply dry or moist heat to the affected area for no longer than 20 minutes several times a day. Monitor the temperature closely to prevent burns and further damage to the affected area. *Heat increases the circulation of blood to and from the inflamed tissue. Time is limited to prevent burns.*
- Provide and encourage fluid intake of 2500 mL/day as allowed. *Teach the purpose and importance of hydration to promote blood flow and nutrient supply to the tissues and also dilution and removal of waste products and heat from the body.*
- Ensure adequate nutrition. *Adequate nutrition enhances the function and production of T cells and B cells, which are important in the immune response.*
- Use good hand hygiene techniques consistently. *Hand hygiene removes transient microorganisms and is the best mechanism to prevent the spread of infection to a susceptible person.*
- Use aseptic technique when providing wound care. *Using sterile gloves and aseptic technique helps prevent further contamination of the wound and the spread of infection to other patients.*

Delegating Nursing Care Activities

As appropriate and allowed by the designated duties and responsibilities of assistive personnel, the nurse may delegate nursing care activities such as obtaining vital signs, assisting with positioning and activity, promoting food and fluid intake, and providing intact skin care for the patient with inflammation.

Continuity of Care

Patient and family teaching enhances understanding of the inflammatory process, its cause, and its management. Teaching is also important to prevent further compromise that could result in infection. Instructions, verbal and written, should include the following:

- Increase fluid intake to 2500 mL (approximately 2.5 quarts) per day.
- Eat a well-balanced diet high in vitamins and minerals and with adequate protein and kilocalories for healing.
- Use good hand hygiene, particularly when caring for wounds or inflamed tissue and after using the bathroom.
- Elevate the inflamed area to reduce swelling and pain.
- Apply heat or cold for no longer than 20 minutes at a time to reduce the risk of tissue damage from burns or frostbite.
- Take all medications as prescribed, notifying the physician if adverse effects or hypersensitivity responses are noted.
- Rest acutely inflamed tissue; do not engage in strenuous activity until the inflammation has subsided.

THE PATIENT WITH AN INFECTION

Microorganisms—including bacteria, viruses, fungi, and parasites—often invade the human body and proliferate if undetected and controlled or eliminated by inflammatory and immune responses. In most cases, contact between humans and microorganisms is incidental and may even be beneficial to both organisms. Resident bacteria of the skin, mucous membranes, and gastrointestinal tract are an important part of the body's defense system. However, many microorganisms are virulent; that is, they have the ability to cause disease. **Pathogens** are virulent organisms rarely found in the absence of disease. Some microorganisms, known as opportunistic pathogens, rarely, if ever, cause harm to individuals with intact immune systems, but are capable of producing infectious disease in the immunocompromised host.

To a certain extent, modern medicine has contributed to the development of infectious diseases caused by antibiotic-resistant strains of microorganisms. Tuberculosis is on the rise in many countries, partially because organisms have become resistant to standard therapies. Patients receive immunosuppressive therapy following organ or tissue transplant or in the treatment of neoplasms, making them more susceptible to infection. Metal and plastic prosthetic devices are implanted, providing potential sites for colonization by disease-producing organisms. It has also become apparent that many diseases long considered unrelated to microorganisms may actually be infectious; for example, colonization of the gastric mucosa with *Helicobacter pylori* is the predominant cause of peptic ulcer disease, and oncogenic viruses have the ability to transform normal cells into malignant cells.

Pathophysiology

Infection occurs when an organism is able to colonize and multiply within a host. The host can be any organism capable of supporting the nutritional and physical growth requirements of the microorganism—for example, humans. When the host experiences injury, pathologic changes, inflammation, or organ dysfunction in response to an infection or from intoxication by cellular poisons produced by a pathogen, the host is said to have an infectious disease.

For a microorganism to cause infection, it must have disease-causing potential (virulence), be transmitted from its reservoir, and gain entry into a susceptible host. This is known as the chain of infection (Figure 12–9 ■).

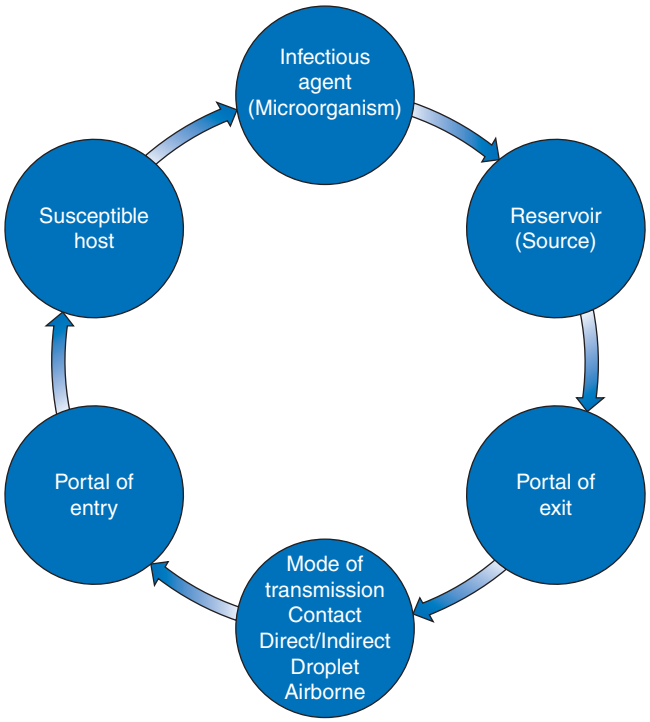

Figure 12–9 ■ The chain of infection.

PATHOGENS

Pathogens capable of infecting and causing disease in a susceptible host include bacteria, viruses, mycoplasma, rickettsia, chlamydia, fungi, and parasites such as protozoa, helminths (worms), and arthropods (Box 12–4). Each organism causes a different specific reaction in the host.

A number of different mechanisms have evolved in pathogens to facilitate their transmission and increase their ability to invade the host and cause disease. Factors influencing the transmission of an organism include resistance to drying and to variations in environmental temperature. For example, spore-forming organisms are extremely resistant to drying.

Adhesion factors produced by or incorporated into the cell wall or membrane of the pathogen improve its ability to attach to and colonize the host. Pathogens may also produce enzymes to enhance their spread to local tissues, chemicals to block specific immune processes or deplete neutrophils and macrophages, or extracellular capsules to discourage phagocytosis.

Pathogens are often capable of producing toxins that affect the normal function of host cells and promote colonization, proliferation, and invasion by the pathogen. Toxins can increase the disease-producing capability of the pathogen and, in some cases, are totally responsible for it; for example, cholera, tetanus, and botulism result from bacterial toxins, not from the direct effects of the infection. **Exotoxins** are soluble proteins secreted into surrounding tissue by the microorganism. Exotoxins are highly poisonous, causing cell death or dysfunction. **Endotoxins** are found in the cell wall of gram-negative bacteria and are released only when the cell is disrupted. Endotoxins have less specific effects than exotoxins, but they act as activators of many human regulatory systems, producing fever; inflammation; and potentially clotting, bleeding, or hypotension when released in large quantities.

RESERVOIR AND TRANSMISSION

The reservoir or source, where the pathogen lives and multiplies, may be either endogenous or exogenous. Organisms that reside on skin or mucosal surfaces of the host are endogenous. Exogenous sources can include other humans, animals, soil, water, an implanted device, or unclean equipment. Infectious diseases are usually transmitted from human sources, that is, people who have clinical disease or carriers with subclinical infection. Carriers harbor the pathogen without showing evidence of clinical disease. Pathogens exit human hosts via respiratory secretions, body fluids from the gastrointestinal and genitourinary tracts, skin or mucous membrane lesions, the placenta, and blood.

Organisms may be transmitted from the source to the susceptible host by direct or indirect contact, droplet or airborne transmission, or a vector. Direct contact includes person-to-person spread or contact with infected body fluids, as well as transmission from contaminated food or water. Indirect contact occurs when the infectious

BOX 12–4 Pathogenic Organisms

BACTERIA

Bacteria are single-celled organisms capable of autonomous reproduction. Relatively small and simple organisms, they contain a single chromosome. A flexible cell membrane and rigid cell wall surround their cytoplasm, giving them a distinctive shape; some also have an extracellular capsule for additional protection. Bacteria have different characteristics and growth requirements; the colonies formed by replicating bacteria differ from one another. *Aerobes* require oxygen for survival, whereas *anaerobes* cannot survive in the presence of oxygen; *gram-positive* bacteria stain purple when subjected to crystal violet stain, whereas *gram-negative* bacteria do not stain with crystal violet but turn red when subjected to safranin stain.

PRIONS

Prions are not independent organisms but small molecules that can modify host proteins. They primarily affect the neurologic system, causing neurologic degeneration in diseases such as mad cow disease (bovine spongiform encephalopathy) in animals and Creutzfeldt-Jacob disease in humans. These are slowly progressive, noninflammatory conditions leading to dementia, lack of coordination, and death. Prion entry into the neurologic cells makes them resistant to the host immune system and antibacterial and antiviral medications. They enter the host by injection, transplantation of contaminated tissue or medical devices, and possibly food. They are very resistant to disinfection, requiring special procedures for sterilizing instruments, especially those used in CNS surgeries (Prusiner & Miller, 2012; Rothrock, 2011).

VIRUSES

Viruses are obligate intracellular parasites that are incapable of reproducing outside of a living cell. Viruses consist of a protein coat around a core of either DNA or RNA. Some viruses are shed continuously from infected cell surfaces; others, after inserting their genetic material into that of the infected cell, remain latent until they are stimulated to replicate. Viruses may or may not cause lysis and death of the host cell during replication. Oncogenic viruses are able to transform normal cells into malignant cells.

MYCOPLASMA

Although similar to bacteria, mycoplasma are smaller and have no cell wall, making them resistant to antibiotics that inhibit cell wall synthesis (e.g., penicillins).

RICKETTSIA AND CHLAMYDIA

As obligate intracellular parasites with a rigid cell wall, rickettsia and *Chlamydia* have some features of both bacteria and viruses. Rather than depending on the host cell for reproduction, they use vitamins, nutrients, or products of metabolism (e.g., ATP) from the host. *Chlamydia* are transmitted by direct contact, whereas many rickettsiae infect the cells of arthropods (e.g., fleas, ticks, and lice) and are transmitted from these vectors to humans.

FUNGI

Fungi are prevalent throughout the world, but few are capable of causing disease in humans. Most fungal infections are self-limited, affecting the skin and subcutaneous tissue. Some fungi, such as *Pneumocystis jiroveci*, can cause life-threatening opportunistic infections in the immunocompromised host.

PARASITES

The term *parasite* is typically applied to members of the animal kingdom that infect and cause disease in other animals. Protozoa, helminths, and arthropods are considered parasites. Protozoa are single-celled organisms (for example, *Giardia lamblia* and *Trichomonas vaginalis*) transmitted via direct or indirect contact or an arthropod vector. Helminths are wormlike parasites: roundworms, tapeworms, and flukes are examples. They gain entry into humans primarily through ingestion of fertilized eggs or penetration of larvae through the skin or mucous membranes. Arthropod parasites, such as scabies (mites), lice, and fleas, typically infest external body surfaces, causing localized tissue damage and inflammation. Transmission is by direct contact with the arthropod or its eggs.

agent is contracted by use of inanimate objects, such as dirty eating utensils. Sneezing, talking, and coughing allow transmission by droplet contact when the host is within 2 to 3 feet of the source. Smaller respiratory particles that stay suspended in air and are carried via air currents allow airborne transmission. Vectors are insects and animals such as flies, mosquitoes, or rodents that act as intermediate hosts between the source and host. Microorganisms usually first colonize the portal of entry: nonintact skin; wounds; mucous membranes; and the respiratory, gastrointestinal, or genitourinary tracts.

HOST FACTORS

The susceptible host is the final link in the chain of infection. Exposure to pathogens does not automatically cause infection or infectious disease. The balance of microbial virulence and host resistance determines the outcome of contact with a pathogenic microorganism. Factors that can enable the host to resist infection include the following:

- Physical barriers, such as intact skin and mucous membranes
- The hostile environment created by acid stomach secretions, urine, and vaginal secretions
- Antimicrobial factors in saliva, tears, and prostatic fluid
- Respiratory defenses, including humidification, filtration, the mucociliary escalator, cough reflex, and alveolar macrophages
- Innate and adaptive immune responses to pathogenic invasion.

Stages of the Infectious Process

When infectious disease develops in the host, it typically follows a predictable course with stages based on the progression and intensity of manifestations.

The initial stage is the *incubation period*, during which the pathogen begins active replication but does not yet cause manifestations. Depending on the organism and host factors, the incubation period may last from hours, as with salmonella, to years, as with HIV infection.

The *prodromal stage* follows, during which manifestations first begin to appear. At this stage, manifestations are often nonspecific and include general malaise, fever, myalgias, headache, and fatigue.

Maximal impact of the infectious process is felt during the *acute phase* as the pathogen proliferates and disseminates rapidly. Toxic byproducts of microorganism metabolism and cell lysis, along with the immune response, produce tissue damage and inflammation during this stage (Grossman & Porth, 2014). Manifestations are more pronounced and specific to the infecting organism and site during the acute stage. Fever and chills may be significant during this phase. However, alcoholic patients and the very old may respond to severe infection by becoming hypothermic. The patient is often tachycardic and tachypneic because of increased metabolic demands. Localized manifestations include redness, heat, swelling, pain, and impaired function. When the infectious disease affects an internal organ, manifestations are related to inflammatory changes in that organ and surrounding tissue. The patient may experience tenderness to palpation over the site or show manifestations of impaired function, such as the hematuria and proteinuria characteristic of renal infections.

If the infectious process is prolonged, manifestations of the continuing immune response may become apparent. Catabolic and anorexic effects of the infection can lead to loss of body fat and muscle wasting. Immune complexes may be deposited at sites other than the primary infection, resulting in an inflammatory process. Glomerulonephritis (e.g., following strep throat) and vasculitis are possible results. Another possible consequence of prolonged infection and immune response is the triggering of an autoimmune disease process, such as rheumatic cardiomyopathy or celiac disease. As the infection is contained and the pathogen eliminated, the *convalescent stage* of the disease occurs. During this stage, affected tissues are repaired and manifestations resolve. Resolution of the infection is total elimination of the pathogen from the body without residual manifestations. If a balance between organism and host factors occurs with neither predominating, chronic disease may develop or the organism may be driven into a protected site, such as an abscess. A carrier state develops when host defenses eliminate the infectious disease but the organism continues to multiply on mucosal sites.

Complications

Multiple and varied complications are associated with infectious diseases. They are typically specific to the infecting organism and the body system affected.

Acute invasion of the blood by certain microorganisms or their toxins can result in septicemia and septic shock. Whereas *bacteremia*, the presence of bacteria in the blood, may not have serious effects, **septicemia** refers to systemic disease associated with their presence or toxins. Septic shock indicates a state of hypotension and impaired organ perfusion resulting from sepsis. Unless treated aggressively, septic shock leads to diffuse cell and tissue injury, and potentially to organ failure.

HEALTHCARE-ASSOCIATED INFECTIONS

Healthcare-associated infections (HAIs) are acquired in a healthcare setting, such as a hospital or nursing home. Also called *nosocomial infections*, HAIs are estimated to occur in 5% of all hospitalizations in the United States, affecting 1.7 million patients and contributing to an estimated 99,000 deaths annually (Heitz, 2013; U.S. Department of Health and Human Services, 2013; Weinstein, 2012). In 2009, the CDC estimated the annual direct medical costs of HAIs to be between $28 billion and $45 billion. HAIs add hospital days, reduce admissions by occupying available beds, and add to the cost of healthcare (CDC, 2010; Mirza, 2012). In an effort to reduce costs associated with HAIs, the Patient Protection and Affordable Care Act of 2010 limits or prohibits Medicare and Medicaid reimbursement to providers for treatment related to certain healthcare-associated conditions, including catheter-associated urinary tract infection (CAUTI) and surgical site infection following surgeries such as coronary artery bypass graft (CABG), bariatric surgery, and selected orthopedic procedures.

FAST FACTS

- Urinary tract infection is the most common type of HAI, usually associated with indwelling urinary catheters or urologic procedures.
- Other common HAIs are bloodstream infections, pneumonia, surgical wound infections, and *Clostridium difficile* colitis (CDC, 2011; Chin-Hong & Guglielmo, 2012).
- *Clostridium difficile*–associated diarrhea is an HAI linked with 14,000 deaths annually in the United States (CDC, 2012). The risk of acquiring this antibiotic-associated diarrhea increases with length of hospital stay, especially in an intensive care unit (ICU).
- Pathogens associated with HAI are often different than those causing community-acquired infections and frequently are multidrug resistant, necessitating treatment with multiple, broad-spectrum, and potentially toxic antibiotics (Chin-Hong & Guglielmo, 2012).

BOX 12–5 Interventions to Reduce Healthcare-Associated Infections

1. Central venous catheter infections have decreased by using chlorhexidine antiseptic for disinfection and maximal barrier precautions during insertion.
2. Ventilator-associated pneumonia is decreased by weaning patients off ventilators as soon as possible, limiting sedation of the patient, positioning patients with the head of the bed elevated to prevent gastric reflux and for maximal ventilation, and using proper hand hygiene and sterile technique for all ventilator-associated care.
3. Surgical site infections are reduced by administering a prophylactic antibiotic 1 hour before the incision and discontinuing it within 24 hours after surgery, limiting hair removal (no shaving), controlling perioperative glucose levels (especially in cardiac surgeries), and ensuring normothermia for the patient during the perioperative period (especially in colorectal surgeries).
4. Insert urinary catheters only when clearly indicated, using aseptic technique during insertion; minimize manipulation or opening of drainage systems (Weinstein, 2012).

Moving Knowledge into Action

You have recently taken a position as resident care manager (RCM) in a large, long-term care facility. On reviewing the records for your assigned residents, you note that five of the residents have been treated for urinary tract infections (UTIs) in the past 6 months; one of these residents required transport to and treatment in the emergency department for manifestations of sepsis.

1. What data will you collect to help identify factors contributing to UTIs in these patients?
2. Another RCM tells you that this is a normal infection rate for residents in this facility. What resources will you use to determine if this is true and what measures, if any, have been taken in response?
3. Based on data about UTI rates in comparable facilities, you decide the infection rate among your residents needs to be addressed. Identify sources for evidence-based best practices to prevent healthcare-associated urinary tract infections.
4. Based on the understanding that reducing UTIs may require modification of current care practices, what challenges should you anticipate in implementing a plan of action?

Many HAIs result from the use of invasive devices such as intravenous catheters, urinary catheters, and endotracheal tubes for ventilator support. Patients developing HAIs often are critically ill and among those least able to mount an effective immune defense against infection. Nosocomial infections also occur when antibiotic therapy has altered natural defenses and impaired resistance to harmful microorganisms. Endogenous organisms outside their normal habitats (such as in *Escherichia coli* in the urinary tract) become a threat to the patient. Other pharmacologic and therapeutic procedures such as chemotherapy, the use of corticosteroids, or radiation therapy also contribute to nosocomial infections. Surgical site infections rank second in frequency of healthcare-associated infections and add up to 7 to 10 extra days to postoperative hospitalization (CDC, 2010; Weinstein, 2012). Superficial or deep wounds may be contaminated by endogenous or exogenous sources. Infections in body cavities or those associated with prosthetics are difficult to diagnose and may necessitate removal of the prosthetic device. Box 12–5 lists interventions that should be used to prevent healthcare-associated infections.

Hospital-acquired (HA) pneumonia accounts for about 15% of HAIs. It is usually associated with ICU stays and mechanical ventilation. Organisms causing the infection are often resistant to many drugs, not responding to antibiotics usually effective in treating infections acquired outside the hospital. More deaths are associated with HA pneumonia than any other site of infection (Weinstein, 2012).

SAFETY ALERT

Since October 2002, alcohol-based hand rub has been recommended by the CDC as the preferred method for hand hygiene (CDC, 2002). Antiseptic soaps and detergents are the next most effective agents and nonantiseptic soaps are the least effective. A soap and water wash is recommended for visibly soiled hands. Wearing gloves does not eliminate the need to perform hand hygiene.

Prevention is the most important control measure for HAIs. Cross-infection, spread of pathogens from one patient to another on the inadequately cleaned hands of healthcare workers, is one of the primary sources of HAIs (Weinstein, 2012). *Effective hand hygiene is the single most important measure in infection control.* Although infections may also be transmitted by the airborne route, from contaminated equipment, or from the environment, these are less significant causes. Invasive procedures and equipment should be used only when absolutely necessary; for example, it is not appropriate to insert an indwelling catheter when the only indication is incontinence. Peripheral intravenous equipment and sites must be kept clean and inspected regularly: Palpate the site for tenderness daily and visually inspect it if a transparent dressing is used. If the patient is not receiving blood, blood products, or fat emulsions, continuously used administration sets should be replaced no more frequently than every 96 hours, but at least every 7 days or per agency guidelines (O'Grady et al., 2011).

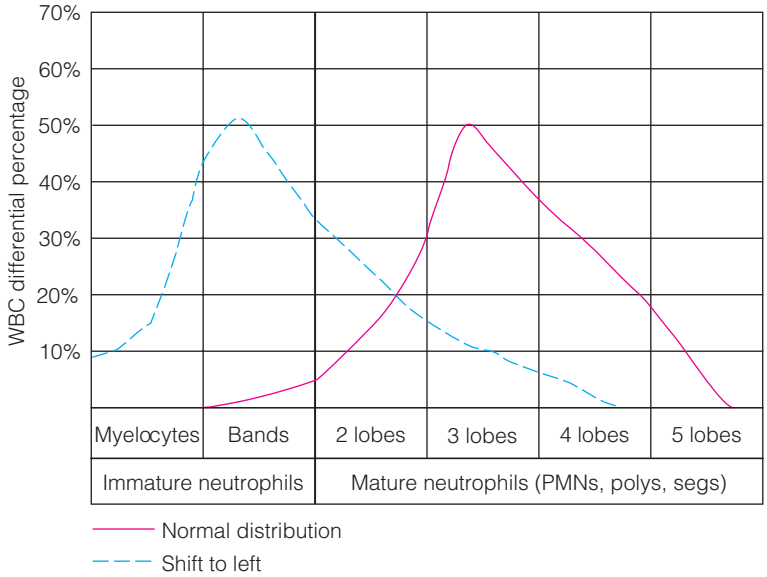
ANTIBIOTIC-RESISTANT MICROORGANISMS

Antibiotic-resistant microorganisms are increasing at an alarming rate primarily due to prolonged or inappropriate use of antibiotic therapy. Although antibiotic therapy is expected to eradicate all targeted microorganisms, sometimes a few bacteria survive, leading to bacteria that reproduce with antibiotic resistance already encoded into their genetic makeup. Other bacteria produce enzymes that inactivate drugs, change drug binding sites, or alter their cell membranes to prevent drug absorption. It is important for infectious agents to be identified and treated with effective antibiotics; culture and sensitivity analysis guides prescription of effective antimicrobials. These reports need to be reviewed carefully and appropriate action taken if drug-resistant pathogens are found.

Standard precautions, most importantly hand hygiene and the use of carefully selected antibiotics, are critical actions for stopping the spread of these diseases. Equipment such as stethoscopes, blood pressure cuffs, and thermometers should be restricted to use by each patient identified with one of these diseases. Personal protective gear, used and disposed of appropriately, are important safeguards.

●○● INTERPROFESSIONAL CARE

The goals of care for the patient with an infection are to identify the organ system affected by the infection; to identify the causative agent; and to achieve a cure by the least toxic, least expensive, and



most effective means. Fortunately, most infectious diseases are self-limiting and will resolve with little or no medical care. However, medical treatment can be lifesaving in an overwhelming infection or immunocompromised host.

The site of the infection is often obvious from the patient's history and presenting manifestations. Identifying the affected organ system allows the range of possible infecting organisms to be narrowed to those known to affect that system. Once the infecting agent has been identified, either positively or by probability, therapy can be specifically tailored to the patient's needs. Viral infections often resolve without treatment other than supportive care, such as providing rest and fluids. Skin infections may respond to a topical agent, avoiding the potential adverse effects of an agent administered systemically.

DIAGNOSIS

To assess the patient's response to infection, identify the infecting organism, and monitor the progress of therapy, the following diagnostic tests may be ordered:

- *WBC count* provides clues about the infecting organism and the body's immune response to it.
- *WBC differential* is also ordered (refer to Table 12–8). Neutrophilia, increased numbers of circulating neutrophils (or PMNs), is a common response with infection or inflammation as the bone marrow responds to an increased need for phagocytes. Along with neutrophilia, more immature neutrophils are present in circulation than normal, indicating an appropriate bone marrow response (Figure 12–10 ■).
- *Procalcitonin (CTpr) and C-reactive protein (CRP)* are diagnostic markers of infection that can be measured in the blood. Blood levels of CTpr and CRP increase dramatically with serious bacterial infection and sepsis, making these markers useful early indicators of systemic infections.
- *Cultures of the wound, blood, or other infected body fluids* are used to identify probable microorganisms by their characteristics, such as shape, growth patterns, and Gram-staining qualities. After the organism is cultured, it is subjected to sensitivity testing using various antibiotics known to be effective against its particular strain to determine which antibiotic is likely to be most effective. Generally 24 to 48 hours are required to grow the organism, potentially delaying the institution of therapy. Because antibiotics can alter the ability to culture an organism, specimens should be obtained before instituting therapy.
- *Serologic testing* provides an indirect means of identifying infecting agents by detecting antibodies to the suspected organism. When the antibody titer against a specific organism rises during the acute phase of an infectious disease and begins to fall during convalescence, the diagnosis is supported. Although it is not as accurate as culture, serology is particularly useful for organisms that cannot easily be cultured, such as hepatitis B or HIV.
- *Direct antigen detection methods* use monoclonal antibodies (purified antibody forms) to detect antigens in specimens from the diseased host. These tests offer rapid and accurate identification of the offending microorganism.
- *Antibiotic peak and trough levels* monitor therapeutic blood levels of the prescribed medication(s). The therapeutic range, that is, the minimum and maximum blood levels at which the drug is effective, is known for a given drug. By measuring blood levels at the predicted peak (1 to 2 hours after oral administration, 1 hour after intramuscular administration, and 30 minutes after intravenous administration) and trough (lowest level, usually a few minutes before the next scheduled dose), healthcare personnel can determine that the patient is maintaining a level within the therapeutic range at all times, ensuring maximal effect from the drug. It is also possible to determine whether the drug is reaching a toxic or harmful level during therapy, increasing the likelihood of adverse effects.
- *Radiologic examination of the chest, abdomen, or urinary system* may be ordered to detect organ abnormalities, indicating an inflammatory response or tissue damage.
- *Lumbar puncture* is performed to obtain cerebrospinal fluid (CSF) for examination and culture if a CNS infection, such as meningitis or encephalitis, is suspected.

Type of WBC	Normal differential	Shift to left
Myelocytes	0%	Present
Banded neutrophils (bands)	3% to 5%	Increased
Segmented neutrophils (segs, polys, PMNs)	50% to 65%	May be stable, increased, or decreased

Figure 12–10 ■ Neutrophils by stage of maturity and normal distribution in the blood.

NURSING CARE OF THE OLDER ADULT

Infections in Older Adults

Because immune function declines with aging, older adults are more susceptible to infections. Infections are among the top five causes for hospitalization and among the leading causes of death among people over 65 years of age (National Center for Health Statistics, 2013; Weir et al., 2011). Physiologic changes that often occur with aging place the older adult at greater risk of acquiring an infection than younger people:

- *Cardiovascular changes:* Decreased tissue perfusion delays the inflammatory response and healing.
- *Respiratory system changes:* Decreased mucociliary clearance, decreased elastic recoil, and diminished cough and laryngeal reflexes decrease the clearance of respiratory secretions and increase the risk for pneumonia. The older adult with pneumonia may not present with cough or sputum production due to decreased immune function. The leading causes of pneumonia in older adults include *S. pneumoniae*, *Haemophilus influenzae*, and *S. aureus*. Influenza A, a viral infection, is a significant risk factor for secondary bacterial pneumonia in older adults (Tabloski, 2014). Both pneumonia and influenza cause high mortality rates in the older person.
- *Genitourinary changes:* Loss of muscle tone, reduced bladder contractility, altered bladder reflexes, and prostatic hypertrophy in men increase the risk for incomplete bladder emptying, urinary incontinence, and urinary tract infection (UTI). UTI is the most common infection and the leading cause of bacteremia and sepsis in older adults, particularly those ages 85 and older.
- *Gastrointestinal system changes:* Impaired swallow reflex, decreased gastric acidity, and delayed gastric emptying increase the risk of aspiration with subsequent pneumonia.
- *Skin and subcutaneous tissue changes:* Thinning of skin, decreased cushioning, decreased sensation, and decreased vasculature increase the risk of injury, ulceration, and infection.
- *Immune changes:* Decreased phagocytosis, reduced inflammatory response, diminished antibody-mediated and cellular immune responses, and slowed or impaired healing processes increase the risk for infection. Immunoglobulin levels remain relatively stable, but primary and secondary antibody responses decline with aging. The thymus gland atrophies and some T-cell populations decrease or decline in function. T-cell activation and the ability to proliferate following activation also decline with advancing age (Grossman & Porth, 2014). Resistance to antigens such as *M. tuberculosis*, influenza and varicella-zoster viruses, malignant cells, and tissue grafts is reduced.

Other factors, such as a lower activity level, poor nutrition and an increased risk for dehydration, a higher prevalence of chronic diseases such as diabetes, use of multiple medications, and altered mentation contribute to the older adult's risk for infection.

Healthcare-associated infections are more common in older adults. The nurse must steadfastly adhere to principles of infection control. Nursing interventions to reduce the risk of HAI include (1) avoiding prolonged bed rest, (2) encouraging patients to take deep breaths, (3) providing adequate fluids, (4) providing regular toileting schedules with good hygiene, and (5) avoiding use of invasive devices such as indwelling catheters unless medically necessary.

The older adult may not exhibit the classic manifestations of inflammation and infection. The manifestations of inflammation—redness, heat, and swelling—tend to be diminished or absent in older adults. The classic manifestations of infection—fever and chills—may be absent altogether because of age-related changes in the immune system, loss of central temperature control mechanisms, decreased muscle mass, and loss of shivering ability. The older adult may have only subtle manifestations of infection or sepsis, including changes in mental status, disorientation, restlessness, and tachypnea.

Prompt identification and treatment of infection improves outcomes in the older adult. In addition to monitoring for changes in the patient's mental status or behavior, the nurse should assess fluid intake and urinary output, activity levels, complaints of fatigue, and respiratory status. Older adults are at increased risk for dehydration due to diminished thirst sensation and impaired water conservation by the kidneys. Carefully evaluate intake and output to determine if input is adequate.

- *Ultrasonic examination* is a noninvasive diagnostic test such as an echocardiogram or renal ultrasonography to identify an infectious site or evaluate the effects of an infection on organ function.

MEDICATIONS

After the infecting organism and affected body system have been identified, specific therapy to cure the infectious disease can be instituted. Antimicrobial preparations are broadly classified as bacteriostatic or bactericidal. *Bacteriostatic agents* inhibit the growth of the microorganism, leaving its destruction to the host's immune system. These agents are generally not indicated for the immunocompromised host. Tetracyclines, erythromycin, and chloramphenicol are bacteriostatic preparations. *Bactericidal agents*, including penicillins, cephalosporins, and aminoglycoside antibiotics, are capable of killing the organism without immune system intervention.

The activity of antimicrobial agents on bacteria, fungi, and viruses falls under five basic mechanisms:

- Impairing cell wall synthesis, leading to lysis and cell destruction
- Inhibiting protein synthesis, causing impaired microbial function
- Altering cell membrane permeability, causing intracellular contents to leak
- Inhibiting the synthesis of nucleic acids
- Inhibiting cell metabolism and growth.

Many microorganisms have the ability to develop resistance to an anti-infective agent; that is, the pathogen continues to live and grow in the presence of the anti-infective. Resistance develops as a result of a chance mutation by the pathogen, allowing a subpopulation of cells to survive. The chance of an organism becoming resistant to an agent is partially related to the dose delivered. Resistance is less likely to occur when a lethal dose is administered; therefore, it is vital that patients understand the need to take all doses of the prescribed drug as ordered. See Moving Evidence Into Action box.

ANTIBIOTICS Medications used to treat bacterial infections are generally known as antibiotics. Most antibiotics are biologic substances, that is, substances produced by other microorganisms. Antibiotics fall into classes of drugs with related chemical structure and activity. Some are effective against only gram-positive bacteria, and others are effective against only gram-negative organisms. Broad-spectrum antibiotics have activity against a wide variety of bacteria, including both gram-positive and gram-negative forms.

No antibiotic is totally safe. Hypersensitivity responses occur; always check for allergies before administering the first dose. Some

Moving Evidence into Action

Teaching to Take Antibiotics Appropriately

Nurses discharging patients from outpatient and acute care settings frequently teach patients to take a complete prescribed dose of oral antibiotics to manage acute infectious illness. Ingesting less than complete doses exposes patients to the risk of resistant infections and less than therapeutic outcomes. There are many potential restraining forces to the completion of antibiotic dosing: cost of purchase; difficulty swallowing the pills; multiple, frequent doses; and the potential for adverse, unpleasant side effects.

Because adherence is so important and nurses are patient educators, Aronson (2005) studied the experience of 11 patients of diverse gender and cultural backgrounds who had just completed a short-term antibiotic regimen to treat a variety of acute infections. A related study by Nicoteri (2010) looked at antibiotic regimen compliance in a group of young adults in a traditional college setting. The patients' descriptions, views, and experiences are the unique aspect of this research on adherence to antibiotic self-administration. In both studies, the central theme that emerged was successful antibiotic self-administration. The patients integrated the dosing into their daily schedules and adapted to any unplanned circumstances. The primary categories involved in self-administration were (1) medication-taking behaviors, (2) factors influencing adherence, and (3) attitudes and beliefs about the medication and the value of completing the prescribed dose. Patients who perceived minimal barriers (such as adverse effects, inconvenience of dosing times, forgetting doses, lack of access or high cost) were found to be more likely to complete the prescribed course of therapy in Nicoteri's study.

Implications for Nursing

Nurses teach patients about short-term antibiotic self-administration in outpatient and inpatient settings. The findings from these studies can be used to guide educational interventions. Based on these findings, encourage patient involvement in the decision to take short-term antibiotic medications to strengthen the relationship with the prescriber. Ask patients to identify the method they will use to remind themselves of each dose; inquire about their knowledge of and plans to manage side effects from the medication.

Moving Knowledge into Action

1. Identify methods that patients can use to remind themselves of dosing schedules.
2. An 86-year-old woman is being discharged to her home following a respiratory infection. Identify the information she will need about short-term antibiotic medication when she is discharged.
3. Make a list of barriers to taking complete doses of antibiotics. How might these barriers differ among traditional college students versus middle or older adults? What do you think is the single most important (to the patient) reason?

Sources: Aronson, B. (2005). Medication management behaviors of adherent short-term antibiotic users. *Clinical Excellence for Nurse Practitioners, 9*(1), 23–30; Nicoteri, J. (2010). Short-term antibiotic adherence in college students. *American Journal for Nurse Practitioners, 14*(1), 20–28.

drugs are toxic to organ systems, exhibiting hepatotoxicity, nephrotoxicity, ototoxicity, or bone marrow suppression. The antibiotics presented in the accompanying Medication Administration box are organized according to their antibacterial action.

ANTIVIRALS Most antibiotics have little effect on viruses because the virus has no cell wall and no cytoplasm, produces no enzymes, and sequesters itself in a host cell to reproduce. Antiviral agents must be very selective in differentiating normal cellular activity from viral activity. In addition, the immune function of the host is a vital component in fighting viral infections; antiviral therapy may be relatively ineffective in the severely immunocompromised host. Timely diagnosis of viral infections can be an additional problem because viruses are less easily identified using laboratory techniques. Antiviral agents in common use are summarized in the Medication Administration box on page 289.

ANTIFUNGALS Antifungal agents are available in both topical and systemic forms. They act by interfering with the cytoplasmic membrane of the fungus. Topical agents include preparations for cutaneous use to treat candidiasis, tineas, and ringworm. Vaginal preparations to treat vulvovaginal candidiasis are also available, as are several nonprescription topical and vaginal antifungal agents.

Amphotericin B (Fungizone) is a systemic antifungal agent for parenteral administration. It is used to treat severe, life-threatening fungal infections including histoplasmosis, blastomycosis, and candidiasis. Another systemic antifungal in current use is flucytosine (Ancobon), which can be administered orally. It is used to treat severe candidiasis infections such as candida septicemia, endocarditis, pulmonary or urinary tract infections, and *Cryptococcus* meningitis.

Fluconazole (Diflucan) has the broadest use as an antifungal agent. It can be administered either orally or parenterally and is used to treat candidiasis infections as well as *Cryptococcus* meningitis. It is generally better tolerated than other systemic antifungal medications.

ANTIPARASITICS Drugs used to treat parasitic infections are as varied as the organisms that cause them. Generally, agents classified as antiparasitic are both expensive and likely to be toxic. Quinine was one of the first antiparasitic drugs developed in the treatment of malaria. Quinine is highly toxic, but newer forms such as chloroquine (Aralen, Chlorcon) and hydroxychloroquine (Plaquenil) are widely used as antimalarial drugs. Metronidazole (e.g., Flagyl) is used to treat infections of protozoan parasites (see the accompanying Medication Administration box).

ISOLATION PRECAUTIONS

Controlling the spread of infectious diseases in the hospital or long-term care setting is particularly important to preventing healthcare-associated infections. Hand hygiene remains the single most important factor in preventing the transmission of infections. Most infectious diseases are transmitted by either direct or indirect contact and their spread is prevented through the use of standard precautions. However, diseases such as chickenpox (varicella) are highly contagious and are spread by the airborne route, requiring special precautions to protect other hospitalized patients.

MEDICATION ADMINISTRATION

Antibiotic Therapy

I. Cell Wall Synthesis Inhibitors

PENICILLINS

Penicillin G
Penicillin V
Amoxicillin (Amoxil)
Nafcillin (Unipen)
Ampicillin (Polycillin)
Dicloxacillin (Dynapen)
Oxacillin (Prostaphlin)
Piperacillin (Pipracil)
Ticarcillin (Ticar)

Combination Agents

Amoxicillin and clavulanate (Augmentin)
Ampicillin and sulbactam (Unasyn)
Ticarcillin and clavulanate (Timentin)
Piperacillin and tazobactam (Zosyn)

Penicillins are bactericidal and interfere with cell wall synthesis and the enzymes involved in cell division and synthesis. They are more effective on gram-positive than gram-negative organisms. Penicillins are considered to be safe, effective, and of low toxicity. Resistance is now more common among *Streptococci* and *Staphylococci*. Penicillins and related antibiotics such as the cephalosporins (see below) contain a molecular structure known as a beta-lactam ring. Some bacteria produce enzymes (beta-lactamases or penicillinases) that cleave (split or divide) this ring, making the antibiotics ineffective. To combat this resistance, beta-lactamase or penicillinase inhibitors such as sulbactam and clavulanate are combined with some antibiotics to create an antibiotic effective against drug-resistant bacterial strains.

Nursing Responsibilities

- Monitor for hypersensitivity responses such as local erythema and itching at the site of injection, skin rashes, urticaria (hives), itching, fever, chills, and anaphylaxis.
- Observe patients receiving parenteral penicillin for at least 30 minutes.
- Discontinue the drug immediately if any hypersensitivity response occurs. Be prepared to administer antihistamines or corticosteroids for a mild reaction. Anaphylaxis is treated with epinephrine subcutaneously or intravenously and with airway support.
- Do not administer penicillin to anyone with a history of a severe allergic reaction to any form of the drug; a cross-reactivity may occur in patients allergic to cephalosporin or carbapenem antibiotics.
- Assess for superinfection (vaginitis, stomatitis, or diarrhea) due to elimination of resident bacteria.

Health Education for the Patient and Family

- Notify the physician if you see white patches on the oral mucosa or if vaginitis develops. An antifungal drug may be prescribed and the antibiotic continued.
- Consuming yogurt or buttermilk may prevent superinfection. Do not take these products within 1 hour of taking the drug.

CEPHALOSPORINS

1st Generation	2nd Generation	3rd Generation	4th Generation
Cephalexin (Keflex)	Cefotetan (Cefotan)	*Cefdinir (Omnicef)*	Cefepime (Maxipime)
Cefazolin (Ancef)	Cefaclor (Ceclor)	Cefditoren (Spectracef)	
Cefadroxil (Duricef)	Cefoxitin (Mefoxin)	Cefixime (Suprax)	
Cephradine (Velosef)	Cefprozil (Cefzil)	Cefotaxime (Claforan)	
	Cefuroxime (Ceftin)	Cefpodoxime (Vantin)	
		Ceftazidime (Fortaz)	
		Ceftibuten (Cedax)	
		Ceftizoxime (Cefizox)	
		Ceftriaxone (Rocephin)	

Cephalosporins are structurally similar to the penicillins and also inhibit cell wall synthesis. They are divided into four groups, or generations. First-generation cephalosporins act primarily against gram-positive organisms. Second- and third-generation drugs are more effective against gram-negative organisms than against gram-positive ones. Fourth-generation cephalosporins act effectively against both gram-positive and gram-negative organisms.

Nursing Responsibilities

- Monitor for previous hypersensitivity response to cephalosporins or penicillins.
- Assess intravenous site for phlebitis; intramuscular injection may cause local pain.
- Monitor laboratory results for adverse response, such as leukopenia and thrombocytopenia, nephrotoxicity (elevated BUN and serum creatinine), or hepatotoxicity (elevated bilirubin, LDH, ALT, AST, and alkaline phosphatase).
- Assess for manifestations of superinfections.

Health Education for the Patient and Family

- Take the medication on an empty stomach, 1 hour before or 2 hours after meals.
- Avoid alcohol while using cefmetazole, cefoperazone, or cefotetan because alcohol intolerance can develop with these antibiotics. These same drugs intensify bleeding tendencies.
- Space doses of the medication relatively evenly throughout the day and evening hours.
- Increase consumption of buttermilk or yogurt to prevent intestinal superinfection.

CARBAPENEMS

Imipenem (Primaxin)
Meropenem (Merrem)
Ertapenem (Invanz)

This newer class of antibiotics includes only three drugs and all must be given parenterally. Imipenem has the broadest antimicrobial spectrum of any drug. This makes it especially useful against mixed organism infections. These antibiotics cross the meninges and achieve therapeutic doses in CSF; they are effective against methicillin-resistant *Staphylococcus aureus* (MRSA). These antibiotics cause bacterial cell wall lysis and subsequent death of the bacteria. Side effects include nausea and vomiting, diarrhea, hypersensitivity reactions, occasional superinfections with bacteria or fungi, and, rarely, seizures.

(*continued*)

MEDICATION ADMINISTRATION (*continued*)

Nursing Responsibilities
- Ertapenem should not be mixed with dextrose or other drugs containing dextrose. IV infusions should be given over at least 30 minutes.
- Check for history of hypersensitivity to cephalosporins and penicillins and monitor for manifestations of reactions.
- Assess for manifestations of superinfection.
- Monitor laboratory indicators of renal function.

Health Education for the Patient and Family
- Report any manifestations of allergy such as skin rash, itching, or hives.

VANCOMYCIN

This antibiotic inhibits cell wall synthesis and is used for serious infections. It is only effective against gram-positive bacteria, especially *S. aureus* and *Staphylococcus epidermidis*, including the strains resistant to methicillin. *C. difficile* is also susceptible to this antibiotic, but infection with *C. difficile* is often treated first with metronidazole to delay emergence of resistance to vancomycin.

Nursing Responsibilities
- Infuse slowly over 60 minutes or more to avoid red man syndrome. The syndrome is characterized by erythematous rash, flushing, tachycardia, and hypotension. Patients may become dizzy and agitated. The occurrence is usually associated with a first dose of vancomycin and is seen within 4 to 6 minutes of the start of a dose or after completion.
- Ototoxicity is a serious adverse effect because hearing loss may be irreversible. Notify the physician immediately if the patient reports a sensation of fullness in the ears, because this indicates ototoxicity.

II. Bacterial Protein Synthesis Inhibitors

TETRACYCLINES

Tetracycline HCl (Sumycin)	Minocycline HCl (Minocin)
Doxycycline (Vibramycin)	Demeclocycline (Declomycin)

Tetracyclines are active against many gram-positive and gram-negative bacteria, such as *Mycoplasma*, *Rickettsia*, and *Chlamydia*. They are bacteriostatic, interfering with microbial protein synthesis. Tetracycline binds readily with metal and solid elements in the bowel, limiting its absorption when administered with food; the other preparations are highly soluble in lipids and can be administered with food.

Nursing Responsibilities
- Schedule doses 1 hour before or 2 hours after meals. Do not give with milk or milk products or antacids.
- Monitor for manifestations of superinfection.
- If the patient is taking an anticoagulant, monitor prothrombin time and for manifestations of bleeding.

Health Education for the Patient and Family
- Avoid excessive sun exposure to reduce the risk of photosensitivity reactions.
- Tetracyclines can stain the enamel of developing teeth when taken during pregnancy; although deciduous (baby) teeth are affected, permanent teeth are not.

MACROLIDES

Azithromycin (Zithromax)	Clarithromycin
Erythromycin (E-Mycin, Erythrocin)	Dirithromycin (Dynabac)
	Troleandomycin (Tao)

Macrolides are bacteriostatic and act effectively against gram-positive and gram-negative organisms. Erythromycin is used to treat streptococcal pharyngitis in patients who are allergic to penicillin, and is the drug of choice for treating pertussis. Clarithromycin and azithromycin produce less nausea than erythromycin, increasing patient adherence.

Nursing Responsibilities
- Administer erythromycin on an empty stomach or immediately before meals.
- Give the drug with a full glass of water. Do not administer with acidic fruit juice.
- Intravenous doses are very irritating to veins; give slowly (20 to 60 minutes per gram).

Health Education for the Patient and Family
- Gastric distress is a common side effect with erythromycin.

AMINOGLYCOSIDES

Amikacin (Amikin)	Gentamicin (Garamycin)
Kanamycin (Kantrex)	Neomycin (Mycifradin)
Paromomycin (Humatin)	Tobramycin (Nebcin)
Streptomycin	

Aminoglycosides are bactericidal, interfering with protein synthesis in the pathogen. They are especially effective against gram-negative organisms. To provide a broader spectrum of activity, they are often combined with other antibiotics, especially penicillins. Aminoglycosides can be administered in multiple or single daily doses. They are ototoxic and nephrotoxic; the risk is highest for older adults, patients with preexisting renal disease, and those receiving other ototoxic or nephrotoxic drugs. Use of paromomycin is limited to its local effects, treating intestinal parasites (amebiasis).

Nursing Responsibilities
- Assess renal function before and during aminoglycoside therapy. Monitor intake and output, daily weight, BUN, and serum creatinine.
- Assess for adverse effects on hearing such as loss of perception of high tones, tinnitus, and vertigo.
- Notify the physician if the patient is receiving other nephrotoxic or ototoxic drugs such as furosemide (Lasix) and ethacrynic acid (Edecrin).
- Administer intravenous preparations separately from other drugs; flush tubing before and after administration.

Health Education for the Patient and Family
- Monitor for a sudden weight gain that may indicate adverse effects on the kidney and report it to the physician.

OXAZOLIDINONES

Linezolid (Zyvox) is the first antibiotic in a class of antibiotics called oxazolidinones. This antibiotic inhibits protein synthesis and is effective against organisms that are resistant to both vancomycin and methicillin. Because of its usefulness against those organisms, its use should be reserved for infections caused by vancomycin-resistant enterococci (VRE) and MRSA.

Nursing Responsibilities
- Monitor for side effects including nausea, diarrhea, hypertension, and headache.
- Monitor platelets if patient is at risk for bleeding; this drug may cause thrombocytopenia.

Health Education for the Patient and Family
- It can be taken with or without food.
- Avoid taking ephedrine, pseudoephedrine, methylphenidate, or cocaine with this drug because high blood pressure may develop.

MEDICATION ADMINISTRATION (*continued*)

III. Bacterial Nucleic Acid Inhibitors

FLUOROQUINOLONES

Ciprofloxacin (Cipro)
Gatifloxacin (Zymar)
Levofloxacin (Levaquin)
Ofloxacin (Floxin)
Lomefloxacin (Maxaquin)
Moxifloxacin (Avelox)
Norfloxacin (Noroxin)
Gemifloxacin (Factive)

Fluoroquinolones are bactericidal and especially active against gram-negative and some gram-positive organisms. They are used to manage infections of the respiratory, gastrointestinal, and genitourinary tracts. Rarely, drugs in this class can cause tendon rupture, with the highest risk in people ages 60 and older and in those taking glucocorticoid medications (Adams et al., 2014).

Nursing Responsibilities

- Increase fluid intake to 2000 to 3000 mL/day unless contraindicated to prevent crystalluria.
- Monitor laboratory results for hepatotoxicity (elevated ALT, AST).

Health Education for the Patient and Family

- If tendon inflammation or pain develops, stop taking the drug and immediately report symptoms to your healthcare provider.
- Drink six to eight glasses of water per day.
- Avoid exposure to sunlight while taking these drugs.

SULFONAMIDES AND TRIMETHOPRIM

Sulfamethoxazole (Gantanol; *in combination with trimethoprim, TMP-SMZ, Bactrim, Septra*)
Sulfisoxazole (Gantrisin)
Sulfadiazine (Coptin)

Sulfonamides are bacteriostatic. Trimethoprim is an antibiotic effective against most gram-positive and many gram-negative organisms. It is often combined with sulfamethoxazole to manage urinary tract infections, *P. jiroveci* pneumonia, and otitis media. Skin rashes and pruritus are the most common hypersensitivity reactions. Severe reactions include exfoliative dermatitis and Stevens-Johnson syndrome.

Nursing Responsibilities

- Assess for history of hypersensitivity to sulfonamides and related medications, such as thiazide diuretics and sulfonylurea preparations.
- Monitor intake and output. Unless contraindicated, maintain a fluid intake of at least 1500 mL/day to prevent crystalluria.
- Assess for evidence of bleeding, easy bruising, or systemic infection, and monitor blood count for possible bone marrow depression.

Health Education for the Patient and Family

- Take medication on an empty stomach with a full glass of water. Maintain a fluid intake of at least 2 quarts per day.
- Protect the skin from excessive sun exposure with clothing and sunscreens to reduce the risk of photosensitivity.

METRONIDAZOLE (FLAGYL)

Metronidazole is effective against anaerobic gram-negative bacteria and protozoan infections caused by amebiasis, giardiasis, and trichomoniasis. It is commonly used to prevent and treat infections following intestinal surgery, and is the drug of first choice with *C. difficile*.

Nursing Responsibilities

- Monitor for CNS effects of dizziness, headache, ataxia, confusion, depression, and peripheral neuropathy.
- Administer with food to minimize gastric distress and metallic taste. Infuse intravenous metronidazole over 60 minutes.
- Discontinue the medication and notify the physician if neurologic reactions occur.
- Increase fluid intake to 2500 mL/day to minimize the risk of nephrotoxicity.

Health Education for the Patient and Family

- This medication may turn urine reddish brown; this is expected and not harmful.
- Stop taking the drug and notify the physician if hypersensitivity reaction or adverse effects occur, such as changes in mentation or coordination, painful or frequent urination, painful or difficult intercourse, impotence.
- Do not drink alcohol while taking this medication; an Antabuse-type reaction (flushing, sweating, headache, vomiting, and abdominal cramps) may occur.
- Maintain a fluid intake of 2.5 to 3 quarts per day.
- When the drug is prescribed for *Trichomonas* infections, treatment of both partners is necessary. Use condoms to prevent cross-contamination during intercourse.

Note: Drugs identified in *italics* are among the 200 most commonly prescribed medications in the U.S.

In determining the need for transmission-based precautions, healthcare personnel consider the usual reservoir or source of the microorganism, the mode of transmission, and the susceptibility of hospital staff and other patients. For example, patients with *P. jiroveci* pneumonia do not require isolation, because immunocompetent individuals are not susceptible to this infection.

The CDC (2007) has published guidelines for isolation precautions to be used in healthcare facilities. These guidelines include both *standard precautions* and *transmission-based* (or *category-specific*) *precautions*.

STANDARD PRECAUTIONS

Standard Precautions, published by the Hospital Infection Control Practices Advisory Committee of the Centers for Disease Control in 1996, provides guidelines for the handling of blood and other body fluids. These guidelines are used with all patients, regardless of whether they have a known infectious disease. The guidelines were developed in light of the realization that many patients with an infectious disease such as HIV or hepatitis B have no apparent manifestations, but can transmit the disease to others. Standard precautions are used by all healthcare workers who have direct or indirect contact with patients or with their body fluids. Activities involving indirect contact include such tasks as emptying trash, changing linens, or cleaning the room.

Standard precautions apply to the following:

- Blood
- All body fluids, secretions, and excretions, regardless of whether they contain visible blood
- Nonintact skin
- Mucous membranes.

Barrier protection is used to prevent exposing skin and mucous membrane surfaces to blood and body fluids. Barrier protection involves using gloves for touching or handling body fluids, and adding other protection such as gowns, masks, and goggles if splashing or spraying is likely. Use of aseptic technique, sterile single-use disposable needles and syringes, and single-use vials for preparing and administering parenteral medications is emphasized. Needles and other

MEDICATION ADMINISTRATION

Antiviral Agents

NEURAMINIDASE INHIBITORS
Oseltamivir (Tamiflu) and zanamivir (Relenza) are used to prevent and treat influenza. They are active against both influenza A and B viruses. When given soon after symptoms develop, the duration and severity of manifestations are reduced. These drugs are generally well tolerated by healthy individuals, although zanamivir (administered as an inhaled powder) is not recommended for people with underlying lung disease.

ADAMANTANES
Amantadine (Symmetrel) and rimantadine (Flumadine) are used to prevent and treat influenza A. Although adamantanes can prevent the disease, viral resistance to these drugs develops rapidly. When administered within 48 hours after symptom onset, common manifestations of influenza are reduced. They are generally well tolerated; CNS side effects such as dizziness, anxiety, insomnia, and difficulty concentrating may occur.

ACYCLOVIR AND GANCICLOVIR
Acyclovir (Zovirax) and ganciclovir (Cytovene) are related compounds used primarily in the treatment of herpes viruses. Acyclovir and related drugs such as valacyclovir (Valtrex) and famciclovir (Famvir) are prescribed mainly to reduce the severity, duration, and frequency of recurrence of genital herpes manifestations. The use of ganciclovir, which profoundly suppresses bone marrow function, is limited primarily to the treatment of cytomegalovirus infection.

RIBAVIRIN
Ribavirin (Virazole) is a broad-spectrum antiviral medication used in combination with peginterferon alfa to treat hepatitis C. Ribavirin is a toxic drug, contraindicated for use during pregnancy. Hemolytic anemia can develop rapidly, necessitating periodic blood counts.

INTERFERONS
Interferons (IFN) are naturally produced cytokines that have antiviral activity. Pegylated interferon (peginterferon or PEG-IFN) is used to treat chronic hepatitis B and hepatitis C, often in combination therapy. Common adverse effects of PEG-IFN include fatigue, flu-like symptoms, muscle and joint pain, and possible depression and insomnia (Adams et al., 2014; Wells et al., 2012).

sharp objects are not recapped or bent, but disposed of in puncture-proof containers to prevent inadvertent percutaneous (needlestick) exposure. Respiratory hygiene/cough etiquette, emphasizing education, cough etiquette, and hand hygiene, is a recent addition to standard precautions (Siegel et al., 2007). Standard precautions are presented in Appendix A.

TRANSMISSION-BASED PRECAUTIONS

In addition to hand hygiene and standard precautions, the nature and spread of some infectious diseases require that special techniques be used to protect uninfected patients and workers. The CDC identifies three types of transmission-based precautions: airborne, droplet, and contact precautions. Transmission-based precautions may be combined for diseases that have multiple routes of transmission. Indications for the use of transmission-based isolation precautions and the specific measures to be taken are outlined in Table 12–9.

●○● NURSING CARE

Nursing management related to infectious disease focuses on health promotion, prevention, and prompt identification and treatment.

Health Promotion

Preventing infection requires education of healthcare personnel and the general public. Education includes understanding the importance of immunizations, the guidelines for using antibiotics to

TABLE 12–9 Transmission-Based Precautions

Category	Infectious Diseases	Purpose	Precautions
Airborne precautions	Pulmonary tuberculosis, chickenpox (with contact precautions), measles	Reduce risk of airborne transmission of infectious agents. Airborne transmission occurs by dissemination of either airborne droplet nuclei or particles containing the infectious agent.	Private room with hand washing and toilet facilities, and special ventilation that does not allow air to circulate to general facility ventilation; mask or special filter respirator for everyone entering room
Droplet precautions	Meningitis, pertussis, influenza	Reduce risk of droplet transmission of infectious agents. Droplet transmission involves contact of mucosal surfaces with respiratory droplets generated during coughing, sneezing, talking, or procedures such as suctioning.	Private room with hand washing and toilet facilities; mask, eye protection, and/or face shields worn by everyone entering room
Contact precautions	Acute diarrhea, chickenpox (with airborne precautions), respiratory syncytial virus (RSV); skin, wound, or urinary tract infection with multidrug-resistant organisms; *S. aureus* infections; scabies infestation	Reduce risk of transmission by direct or indirect contact. Direct contact transmission involves physical transfer of organisms from skin or blood. Indirect contact involves contact with a contaminated object.	Private room with hand washing and toilet facilities; gowns and protective apparel to provide barrier protection; disposable supplies or decontamination of all articles leaving room

prevent the development of drug-resistant microorganisms, and how to prevent the spread of infection. Check immunization records for all family members and encourage them to keep immunizations up to date. Increase public awareness regarding appropriate antibiotic use. Guidelines for preventing the spread of infection to others include the following:

- Avoid crowds and contact with susceptible individuals, especially those who are immunosuppressed (e.g., people who have HIV infection, who are undergoing therapy for cancer, or who have had an organ transplant).
- Use disposable tissues to contain respiratory secretions when coughing or sneezing. Cough into the elbow or upper arm instead of the hand if disposable tissues are not available.
- Use appropriate food-handling precautions for diseases spread via the fecal–oral route, such as hepatitis A.
- Avoid contact with or sharing of body fluids. For example, do not share needles or razors; use a condom during sexual activity, or abstain; have each person clean his or her own blood spills or wounds if possible.

Assessment

The following data are collected through the health history and physical examination. Further focused assessments are described with nursing interventions in the next section.

- ***Health history:*** current manifestations, age, medication use (antipyretics and anti-infectives), nutrition, exposure to infectious individuals, immunizations, invasive procedures and therapies, chronic diseases such as diabetes mellitus, cancer
- ***Physical assessment:*** vital signs, body system(s) where infection is suspected, lymph node enlargement and tenderness.

Priorities of Care

Nursing care priorities related to infection focus on preventing spread of the infection to susceptible individuals, and providing education and support for effective eradication of the pathogen.

Diagnoses, Outcomes, and Interventions

Patients with an infection may be managed in the hospital or at home, depending on the severity of the infection. During the acute phase, nursing care includes administering prescribed antibiotics, implementing and maintaining aseptic technique and infection control measures, and encouraging a balance of rest and activity, good nutritional intake, and other measures to support immunologic function and healing.

Risk for Infection

The spread of infection is a risk in any facility that houses many people. It is a particular risk in hospitals, where many patients have at least some degree of immunosuppression and many drug-resistant strains of pathogens are prevalent. It is vital that nurses use good hand hygiene techniques at all times, employ standard precautions with all patients, and use category-specific isolation techniques as indicated to prevent infectious spread to other patients, themselves, and their families.

Expected Outcome: Infection will be limited to involved patient without evidence of transmission to susceptible individuals.

Evidence for Nursing Care

The Patient with an Infection

Selected resources that nurses may find helpful when planning evidence-based nursing care follow.

- American Medical Directors Association. (2011). *Common infections in the long-term care setting.* Columbia, MD: Author. Retrieved from http://www.guideline.gov
- High, K., Bradley, S., Gravenstein, S., Mehr, D., Quagliarello, V., et al. (2009). Clinical practice guideline for the evaluation of fever and infection in older adult residents of long-term care facilities. *Clinical Infectious Diseases, 48*(2),149–171. Retrieved from http://cid.oxfordjournals.org/content/48/2/149.full.pdf+html
- Shiley, K., Lautenbach, E., & Lee, I. (2010). The use of antimicrobial agents after diagnosis of viral respiratory tract infections in hospitalized adults: Antibiotics or anxiolytics? *Infection Control & Hospital Epidemiology, 31*(11), 1177–1183.

- Admit patients with known or suspected infections to a private room. *This is important to minimize the risk to other patients.*
- Perform hand hygiene using hand sanitizer on entering and leaving the patient's room. If visibly soiled, wash hands using a 10- to 15-second vigorous scrub with soap or antibacterial scrub solution. *A 10- to 15-second scrub removes transient microorganisms from the skin and helps prevent transmission of infection to or from the patient.*
- Use standard precautions and personal protective devices to reduce the risk of transmission. *Gloves, gowns, and masks are to be worn whenever there is a risk of skin or mucous membrane contamination by contact with infectious material, airborne spread of organisms, or droplet nuclei.*
- Explain the reasons for and importance of isolation procedures during hospitalization. *Patients with isolation precautions may feel neglected, dirty, or shunned. Explanation of reasons and procedures can enhance the patient's and family's understanding and acceptance.*
- Place a mask on the patient and/or cover all infectious lesions or wounds completely when transporting the patient for diagnostic or treatment procedures. *These measures help minimize air contamination and the risk to visitors and personnel.*
- Collect a culture and sensitivity (C&S) specimen as ordered or indicated by purulent drainage, pyuria, or other manifestations of infection. *C&S is performed to determine the presence and type of infectious organisms as well as antibiotics most likely to be effective in eradicating it.*

PRACTICE ALERT!

Collect the specimen for C&S before the first dose of antibiotics is administered to ensure adequate organisms for culture.

- Administer prescribed anti-infective agents. *Anti-infectives are used to destroy the invading microorganism.*
- Inform all personnel having contact with the patient of the diagnosis. *This is particularly important for a patient with a disease requiring category-specific isolation so that personnel can take appropriate precautions.*
- Ensure that visitors don appropriate protective wear before they enter the patient's room. *Protective wear reduces their risk of infection.*

- Use appropriate measures for disposing of contaminated tissues, dressings, or other material and for removing soiled linens and equipment from the patient's room. *Check hospital policy or published guidelines for category-specific isolation.*
- Teach the importance of complying with prescribed treatment for the entire course of the regimen. *Because anti-infective agents kill only a portion of the pathogen population with each dose, completion of the entire course of therapy is necessary to reduce the risk of relapse and of creating drug-resistant organisms.*

Anxiety

The patient with an infectious disease may experience anxiety related to his or her manifestations, treatment measures, the prognosis, and expected outcome of the disease. High levels of anxiety interfere with the ability to learn and to comprehend and follow directions.

Expected Outcome: Patient's anxiety level will not interfere with ability to understand and follow directions for treatment.

- Assess level of anxiety. *The level of anxiety influences the patient's response to and interpretation of the situation and degree of threat it poses.*
- Discuss the infection, treatments, prognosis, and expected outcomes. *Discussions help to allay fears and misconceptions.*
- Support and enhance the patient's coping strategies. *An individual uses intrapersonal and interpersonal mechanisms to reduce or relieve anxiety.*
- Include significant others in the plan of care. *Inclusion of the patient and family members provides assurance and confidence, and promotes understanding of the unknown.*
- Explain isolation procedures, and answer any concerns. *Isolation may be necessary to prevent the spread of infection but can cause great anxiety for the patient and family members.*
- Provide referrals as needed for continuing care, for example, to home health agencies for dressing changes or periodic assessment. *Referrals are often necessary to provide ongoing interventions and maintain continuity of care.*

Hyperthermia

Hyperthermia is an expected consequence of the infectious disease process. Fever may produce mild, short-term effects or, when prolonged, may cause serious life-threatening effects.

Expected Outcome: Patient's temperature will remain within defined limits.

- Monitor temperature especially during episodes of chills; note heart rate and rhythm. *Chills indicate a rising temperature. Hyperthermia can cause dysrhythmias.*
- Administer prescribed antipyretic as indicated for elevated temperature. *Although antipyretics lower the temperature and enhance comfort for the patient, this benefit must be weighed against the possible beneficial effect of an elevated temperature in the immune response. Fever increases the motility and activity of WBCs, stimulates the production of interferon, and activates T cells. In addition, temperatures above the normal range inhibit the growth of many microorganisms (Grossman & Porth, 2014).*
- Promote body cooling through lowering the room temperature. *Rapid cooling stimulates the hypothalamus to increase the body's temperature; this increases both shivering and metabolic rate.*

PRACTICE ALERT!

Use ice packs, cool/tepid baths, or a hypothermia blanket with caution to prevent unnecessary shivering.

- Monitor fluid loss; encourage increased fluid and electrolyte intake either orally or intravenously. *Hyperthermia causes fluid loss from evaporation and may result in dehydration and electrolyte imbalance.*
- If diaphoretic, bathe and provide dry clothing and bedding. *These measures increase patient comfort and decrease further water evaporation.*
- Promote rest periods. *Rest increases the energy reserve that is depleted by an increased metabolic, heart, and respiratory rate.*

Delegating Nursing Care Activities

As appropriate and allowed by the designated duties and responsibilities of assistive personnel, the nurse may delegate nursing care activities such as obtaining vital signs and temperature, measuring intake and output, promoting fluid intake, and providing oral and skin care for the patient with an infection. The nurse must verify caregivers' understanding of and ability to follow infection control and transmission precautions prior to delegating nursing care activities.

Continuity of Care

Patient and family teaching is directed toward helping the patient recover from the infection or disease, preventing its spread to others, and preventing life-threatening complications. Instructions should include the following points:

- Use good hand hygiene techniques, particularly after touching infected wounds or lesions, coughing, sneezing, blowing the nose, or using the bathroom. Wash hands thoroughly before performing any procedures, such as dressing changes. Wash hands with soap and water before and after preparing food or eating and before and after using the toilet or handling diapers. Do not share eating utensils.
- Take all prescribed antibiotics as ordered even after manifestations have subsided. Take the prescription at prescribed intervals around the clock.
- Do not share your prescription or save medication in anticipation of future infection.
- Notify your healthcare provider in the following situations:
  - Symptoms do not improve within 24 to 48 hours after antibiotic therapy is instituted, or they worsen.
  - Manifestations of antibiotic allergy (itching, rash, difficulty breathing or swallowing, swelling of the face or tongue) occur. Discontinue medication and contact prescriber.
  - Adverse responses, such as gastrointestinal distress or diarrhea, interfere with completion of the prescription.
  - Manifestations of infection recur after completing prescribed antibiotic.
- Report redness, swelling, or drainage around wounds or persistent high fever.
- Increase fluid intake to at least 2500 mL (2.5 quarts) per day.

- Report any manifestations of opportunistic infections: loose, watery, and foul-smelling diarrhea; vaginal discharge or itching; fuzzy growth or white plaques in mouth or on tongue; blood in urine; chills; fever; or unusual cough.
- In addition, suggest the following resources: county or public health department, Centers for Disease Control and Prevention.

CHAPTER HIGHLIGHTS

- **Innate immunity, a nonspecific response to tissue injury, and the adaptive immune response, which directly targets invading microorganisms and abnormal cells, are critical components of the body's defenses. Supporting these defenses is a key nursing responsibility in promoting patient health.**
- Both natural barriers and the immune system prevent the invasion and replication of pathogens.
- The adaptability and specificity of immune responses is possible because immune cells are genetically encoded to capture pathogens, move them to lymph nodes, and develop specific immune responses to destroy them.
- **The inflammatory response serves to isolate invading antigens. When it occurs in response to acute injury, inflammation produces discomfort but serves a protective role. In contrast, chronic inflammation can damage affected tissue and may serve no protective function.**
- Inflammation is a protective mechanism designed to prevent pathogens from entering the bloodstream and populating functional tissues such as heart, liver, and kidney. Pain acts as a signal that tissue has been damaged and stimulates protective responses such as limiting function while healing progresses. Healing occurs as the inflammatory process isolates the injury and repairs damaged tissue.
- **A fully immunized population is an important infection control strategy and a major factor in maintaining the health of individuals and the population as a whole.**
- **Nurses are instrumental in protecting vulnerable patients from infection, identifying early manifestations of infection, participating with the interprofessional team in treating infection, and educating patients and their families about effective treatment of infection.**
- Localized infections may damage tissue and create pain, but systemic infections can be life threatening. Unfortunately, hospitals are hazardous environments populated with collections of pathogens. Healthcare-associated infections are often introduced into the body by medical procedures.
- Hygiene, protection from harm, and nutrition support the immune defenses. Antimicrobial medications limit the spread of pathogens, but can lose their effectiveness when microbes mutate and develop resistance.

TEST YOURSELF NCLEX-RN® REVIEW

1. A patient receives gamma globulin after being exposed to hepatitis A. Which type of immunity should the nurse expect the patient to develop?
1. natural active
2. natural passive
3. acquired active
4. acquired passive

2. The nurse is caring for a patient with an infection. Which nursing action is a priority when providing the prescribed treatment?
1. Administer prescribed anti-infective.
2. Obtain specimen for culture and sensitivity.
3. Assess for history of hypersensitivities and allergies.
4. Monitor for reaction to prescribed anti-infective.

3. The nurse is providing medications to a patient with an inflammation. Which medication provided by the nurse will inhibit prostaglandin synthesis?
1. aspirin
2. penicillin
3. morphine sulfate
4. warfarin (Coumadin)

4. While reviewing a patient's recent complete blood count, the nurse notes a large percentage of banded neutrophils. What does this finding indicate to the nurse?
1. renal failure
2. acute infection
3. hyperthyroidism
4. autoimmune disorder

5. A patient is admitted with methicillin-resistant *Staphylococcus aureus* cultured from a draining sacral wound. Which type of precaution should the nurse implement for this patient?
1. droplet
2. contact
3. airborne
4. protective

6. A patient with a systemic inflammation is resting in bed, periodically sleeping, and wants additional blankets. Which part of the immune system is responsible for this patient's illness behavior?
1. interferons
2. phagocytes
3. complement system
4. inflammatory cytokines

7. A patient is diagnosed with neutrophilia. What does this finding indicate to the nurse?
   1. a decrease in total white blood cells
   2. a decrease in circulating neutrophils
   3. an increase in circulating neutrophils
   4. an expected average number of white blood cells
8. The nurse is preparing discharge instructions for a patient with an inflammation who is at risk for infection. What should the nurse include when teaching this patient?
   1. Limit daily intake of calories.
   2. Apply heat for 20 minutes at a time.
   3. Resume normal activities of daily living.
   4. Take prescribed antibiotics until fever drops.
9. The nurse is caring for an older patient recovering from an acute illness. Which intervention should the nurse implement to reduce patient's risk of developing a healthcare-associated infection?
   1. Teach the patient to restrict fluids throughout the day.
   2. Coach the patient to deep breathe and cough frequently.
   3. Recommend placement of an indwelling urinary catheter.
   4. Wash hands with soap and water before entering the patient's room.
10. The nurse is instructing unlicensed assistive personnel (UAP) to use standard precautions when providing morning care to assigned patients. What should the nurse teach UAP to specifically do?
    1. Perform hand hygiene, wear masks, and recap needles.
    2. Apply a mask and gown, and spray working surfaces with disinfectant.
    3. Apply gloves, gown, and goggles if coming in contact with body fluids.
    4. Wash hands with alcohol-based hand rub for visibly dirty or blood-contaminated hands.

13 Nursing Care of Patients with Altered Immunity

LEARNING OUTCOMES

1. Review the normal immune system function, including self-recognition.
2. Compare and contrast the four types of hypersensitivity reactions.
3. Explain the pathophysiology of autoimmune disorders and tissue transplant rejection.
4. Discuss the characteristics of immunodeficiencies.
5. Identify laboratory and diagnostic tests used to diagnose and monitor immune response.
6. Describe interprofessional therapies and medications used to treat patients with altered immunity.
7. Correlate the pathophysiologic alterations with the manifestations of HIV/AIDS infection.

CLINICAL COMPETENCIES

1. Assess functional health of patients with altered immunity and monitor, document, and report unexpected manifestations and responses.
2. Function competently within your own scope of practice as a member of the healthcare team caring for patients with altered immune function.
3. Demonstrate sensitivity and respect for expressed values, culture, and preferences when planning and providing individualized and evidence-based care for individuals with altered immune responses.
4. Apply quality measures and best practices in caring for patients with altered immune responses.
5. Demonstrate effective strategies to reduce the risk of harm when caring for patients with altered immune responses.
6. Apply technology and information management tools to support safe care for patients with altered immune responses.

MAJOR CHAPTER CONCEPTS

- Normal immune functioning is essential in protecting the body from internal and external threats. A hyperresponsive immune system, however, which overreacts to antigens or fails to distinguish self proteins from abnormal or nonself proteins, can threaten health and well-being.
- Immune function that targets normal cells and tissues (autoimmunity) or that leads to destruction of transplanted tissue or organs (transplant rejection) threatens the well-being of affected patients. Immunosuppressant therapy is used to prevent tissue and organ damage and maintain the function of transplanted tissue.
- Impaired immune function, whether congenital or acquired, threatens health and physiologic integrity because it prevents the patient from effectively responding to threats such as infection. Nurses play a major role in teaching behaviors to prevent HIV infection, the leading cause of acquired immunodeficiency, and in teaching health and disease management strategies to those affected.

KEY TERMS

acquired immunodeficiency syndrome (AIDS), *315*
allergy, *299*
allograft, *308*
anaphylaxis, *299*
antigenic substances, *298*
autograft, *308*
autoimmune disorder, *306*
histocompatibility, *308*
human immunodeficiency virus (HIV), *315*
hypersensitivity, *299*
immunosuppression, *308*
Kaposi's sarcoma (KS), *319*
seroconversion, *316*

Considering the complexity of the immune system, it is not surprising that abnormal or harmful responses occur. Altered immune system responses include those characterized by hyperresponsiveness of the immune system and those characterized by an impaired immune response. Allergies, autoimmune disorders, and reactions to organ or tissue transplants are all examples of hyperresponsive immune function. AIDS and other immunodeficiency disorders result from impairment of the immune system.

Our understanding of the components of the immune system and specific immune responses and their effects on health is rapidly

increasing. Alterations of the immune system affect the functional health status of individuals in all areas; knowledge of the prevention and care of patients with disorders of the immune system is increasingly important in today's healthcare system.

OVERVIEW OF THE IMMUNE SYSTEM

The immune system protects the body from invasion by foreign antigens, identifies and destroys potentially harmful cells, and removes cellular debris. The lymphoid organs and lymphocytes accomplish these functions through the processes of antibody-mediated immune response and cell-mediated immune response.

The effectiveness of the immune system depends on its ability to differentiate normal host tissue from abnormal or foreign tissue. Body cells, tissues, and fluids have unique antigenic properties recognized by the immune system as "self." **Antigenic substances** stimulate an immune system response, but when identified as "self," the competent immune system does not react. External agents, such as microorganisms, cells and tissues from other humans or animals, and some inorganic substances, have antigenic properties recognized by the immune system as "nonself."

Each body cell displays specific cell surface characteristics, or markers, that are unique to each individual. These are known as *human leukocyte antigens (HLAs)*. An individual's HLA characteristics are coded within a large cluster of genes known as the major histocompatibility complex (MHC) located on chromosome 6. Chromosomes are paired, with each individual inheriting one member of the pair from each parent. A chromosome pair contains multiple genes, each carrying instructions for production of one polypeptide chain. The number of genes in the MHC results in a multitude of HLA combinations. As a result, the possibility of two people having the same HLA type is extremely remote. Identical twins may be the exception, and some siblings have very similar HLA patterns. In tissue grafting and organ transplants, matching the HLA type as closely as possible tends to decrease rejection.

Immunocompetent people have an immune system that identifies antigens and effectively destroys or removes them. When the immune system functions improperly, the result may be an overreaction or a deficiency, resulting in health problems. Overreaction of the immune system leads to hypersensitivity disorders, such as allergies. When the immune system loses the ability to recognize self, autoimmune disorders may ensue. Immunodeficiency diseases or malignancies can develop when the immune system is incompetent or unable to respond effectively, as is the case with acquired immunodeficiency disorder. These alterations in immunity are discussed later in this chapter.

The *antibody-mediated immune response* is accomplished by B lymphocytes (B cells) that are further divided into memory cells and plasma cells. They are activated by contact with an antigen and by T cells. B cells produce antibodies, also known as immunoglobulins, and serve to inactivate an invading antigen. Immunoglobulin M (or IgM) is formed early in nearly every immune response, and is an important component of the immune system complexes seen in autoimmune disorders. The most prevalent immunoglobulin, IgG, is the major antibody protecting against bacterial and viral antigens. Memory cells remember an antigen, and, when exposed to it a second time, immediately initiate the immune response. This action provides the foundation of acquired immunity.

NURSING CARE OF THE OLDER ADULT

Changes in Immune Function in the Older Adult

Immune function tends to decline with aging, a decline known as immunosenescence (Tabloski, 2014). External factors, such as nutritional status and the effects of chemical exposure, ultraviolet radiation, and environmental pollution, affect the older adult's immune status. Internal factors affect it as well, including genetics, the function of the neurologic and endocrine systems, chronic and prior illnesses, and individual anatomic and physiologic variations. These influences make it difficult to predict the effect of aging on the immune system. In some older individuals, the immune system is as effective as that of younger individuals.

Changes associated with immunosenescence include involution of the thymus with less competent T-cell maturation, diminished antibody production and adhesion, and decreased tolerance of self antigens. As a result, the responsiveness, strength, and duration of immune responses decrease. Increased morbidity and mortality associated with infection and increases in cancer and autoimmune disorders are seen.

MEMORY CUE

- B lymphocytes produce antibodies and cytokines in response to extracellular microbes and toxins.
- T lymphocytes produce cellular immunity in response to intracellular viral infections and foreign tissue (tissue transplant).

The T-cell component of the immune system identifies cells containing antigens and signals B cells and other components of the immune system to attack infected cells. T lymphocytes are subdivided into effector cells and regulator cells. The cytotoxic T cell is the primary effector cell. Regulator T cells are divided into two subsets known as helper T cells and suppressor T cells. In addition to destroying cells containing viruses, cytotoxic T lymphocytes also attack malignant cells and are responsible for the rejection of transplanted organs and grafted tissues.

Immune function declines with aging, as described in the Nursing Care of the Older Adult box.

ASSESSING ALTERED IMMUNE SYSTEM FUNCTION

Unlike body systems that are composed of closely related organs, the immune system is diverse and scattered. Optimal immune function depends on intact skin and mucous membrane barriers, adequate blood cell production and differentiation, a functional system of lymphatics and the spleen, and the ability to differentiate foreign tissue and pathogens from normal body tissue and flora. Because of this diversity of organs and functions, assessment of the immune system is often integrated throughout the history and physical examination.

Health History

Before conducting the health history, review the biographic data, including age, gender, race, and ethnic background. Many autoimmune disorders are more prevalent in women than in men. Family history is also important because there is a genetic component in the etiology of many disorders affecting the immune system.

Many interview questions related to the immune system and disorders that affect it are of a sensitive nature. Be sure to provide privacy prior to the interview. If family members are present, request that they leave. Ask the least sensitive questions before moving into those that are more sensitive, such as those related to the use of illicit drugs or sexual activity. Cultural competence is necessary for effective communication.

Physical Assessment

The techniques of inspection and palpation are used to assess a patient's immune system.

- Assess the general appearance; evident fatigue or weakness may indicate acute or chronic illness or immunodeficiency. Note whether the stated and apparent age coincide. Assess height, weight, and body type for apparent weight loss or wasting. Observe ease of movement and note any evident stiffness or difficulty moving. Check vital signs. An elevated temperature may indicate an infection or inflammatory response.
- Inspect the mucous membranes of the nose and mouth for color and condition. Pale, boggy (edematous) nasal mucosa is often associated with chronic allergies. Note petechiae, white patches, or lacy white plaques in the oral mucosa; they may indicate hemolysis or immunodeficiency.
- Assess skin color, temperature, and moisture. Pale or jaundiced skin may indicate a hemolytic reaction. Pallor may also indicate bone marrow suppression with accompanying immunodeficiency. Inspect the skin for evidence of rashes or lesions, such as petechiae; numerous bruises; purple or blue patches or lesions indicative of Kaposi's sarcoma; and wounds that are infected, inflamed, or unhealed. Note the location and distribution of any rashes or lesions.
- Inspect and palpate the cervical, axilla, and groin lymph nodes for evidence of lymphadenopathy (swelling) or tenderness.
- Inspect and palpate the joints for redness, swelling, tenderness, or deformity, which may indicate an autoimmune disorder such as rheumatoid arthritis or systemic lupus erythematosus. Assess joint range of motion, including the spine.

THE PATIENT WITH A HYPERSENSITIVITY REACTION

Hypersensitivity is an altered immune response to an antigen that results in harm to the patient. When the antigen is environmental or exogenous, it is called an **allergy**, and the antigen is referred to as an *allergen*. The tissue response to a hypersensitivity reaction may be bothersome, causing a runny nose or itchy eyes, or it may be life threatening, leading to blood cell hemolysis or laryngospasm, an involuntary tightening of the muscles of the larynx that causes difficulty inhaling.

Hypersensitivity reactions are primarily classified by the type of immune response that occurs on contact with the allergen. They may also be classified as immediate or delayed hypersensitivity responses. Anaphylaxis and transfusion reactions are examples of immediate hypersensitivity reactions; contact dermatitis is a typical delayed response. Allergies are sometimes referred to by the affected organ system (e.g., allergic rhinitis) or the allergen involved, as in hay fever. More than one type of reaction may occur simultaneously.

Pathophysiology

In a hypersensitivity reaction, an antigen–antibody or antigen–lymphocyte interaction causes a response that is damaging to body tissues. Antigen–antibody responses, also known as immediate hypersensitivity responses, are characterized as types I, II, and III. Type IV hypersensitivity is an antigen–lymphocyte reaction, resulting in a delayed hypersensitivity response.

TYPE I IMMEDIATE HYPERSENSITIVITY

Common hypersensitivity reactions, such as allergic asthma, allergic rhinitis (hay fever), allergic conjunctivitis, hives (urticaria), and anaphylactic shock, are typical of type I immediate or IgE-mediated hypersensitivity. This type of hypersensitivity response is triggered when an allergen interacts with IgE bound to mast cells and basophils. The antigen–antibody complex prompts release of histamine and other chemical mediators, complement, acetylcholine, kinins, and chemotactic factors (Figure 13–1 ■).

When a potent allergen such as bee or wasp venom or a drug is injected, resulting in widespread antibody–antigen reaction and response to these chemical mediators, a systemic response such as anaphylaxis, urticaria, or angioedema (localized, rapid swelling beneath the skin) results.

Anaphylaxis is an acute systemic type I response that occurs in highly sensitive individuals following injection of a specific antigen. Substances known to trigger anaphylaxis are summarized in Box 13–1. Anaphylaxis rarely follows oral ingestion although this is possible.

FAST FACTS

- Approximately 3% to 4% of adults have food allergies, whereas 8% of children are affected.
- Food allergies account for 35% to 50% of all cases of anaphylaxis.
- Peanut allergy is the most prevalent food allergy among children.
- Food allergies are estimated to cause 150 to 200 deaths per year.

Source: American Academy of Allergy, Asthma & Immunology (2012).

The reaction begins within minutes of exposure to the allergen and may be almost instantaneous. The release of histamine and other mediators causes vasodilation and increased capillary permeability, smooth muscle contraction, and bronchial constriction. These chemical mediators cause the typical manifestations of anaphylaxis. Initially, a sense of foreboding or uneasiness, light-headedness, and itching palms and scalp may be noted. Hives may develop, along with angioedema of the eyelids, lips, tongue, hands, feet, and genitals. Swelling can also affect

BOX 13–1 Substances Known to Trigger Anaphylaxis in Sensitized People

- Hormones: insulin, vasopressin, parathormone
- Enzymes: trypsin, chymotrypsin, penicillinase
- Pollens: ragweed, grass, trees
- Foods: eggs, seafood, peanuts, tree nuts, grains, beans, cottonseed oil, chocolate
- Vitamins: thiamine, folic acid
- Insect venom: yellow jacket, hornet, paper wasp, honey bee
- Occupational agents: rubber, latex, industrial chemicals
- Antibiotics: penicillins, cephalosporins, amphotericin B, nitrofurantoin
- Local anesthetics: procaine, lidocaine

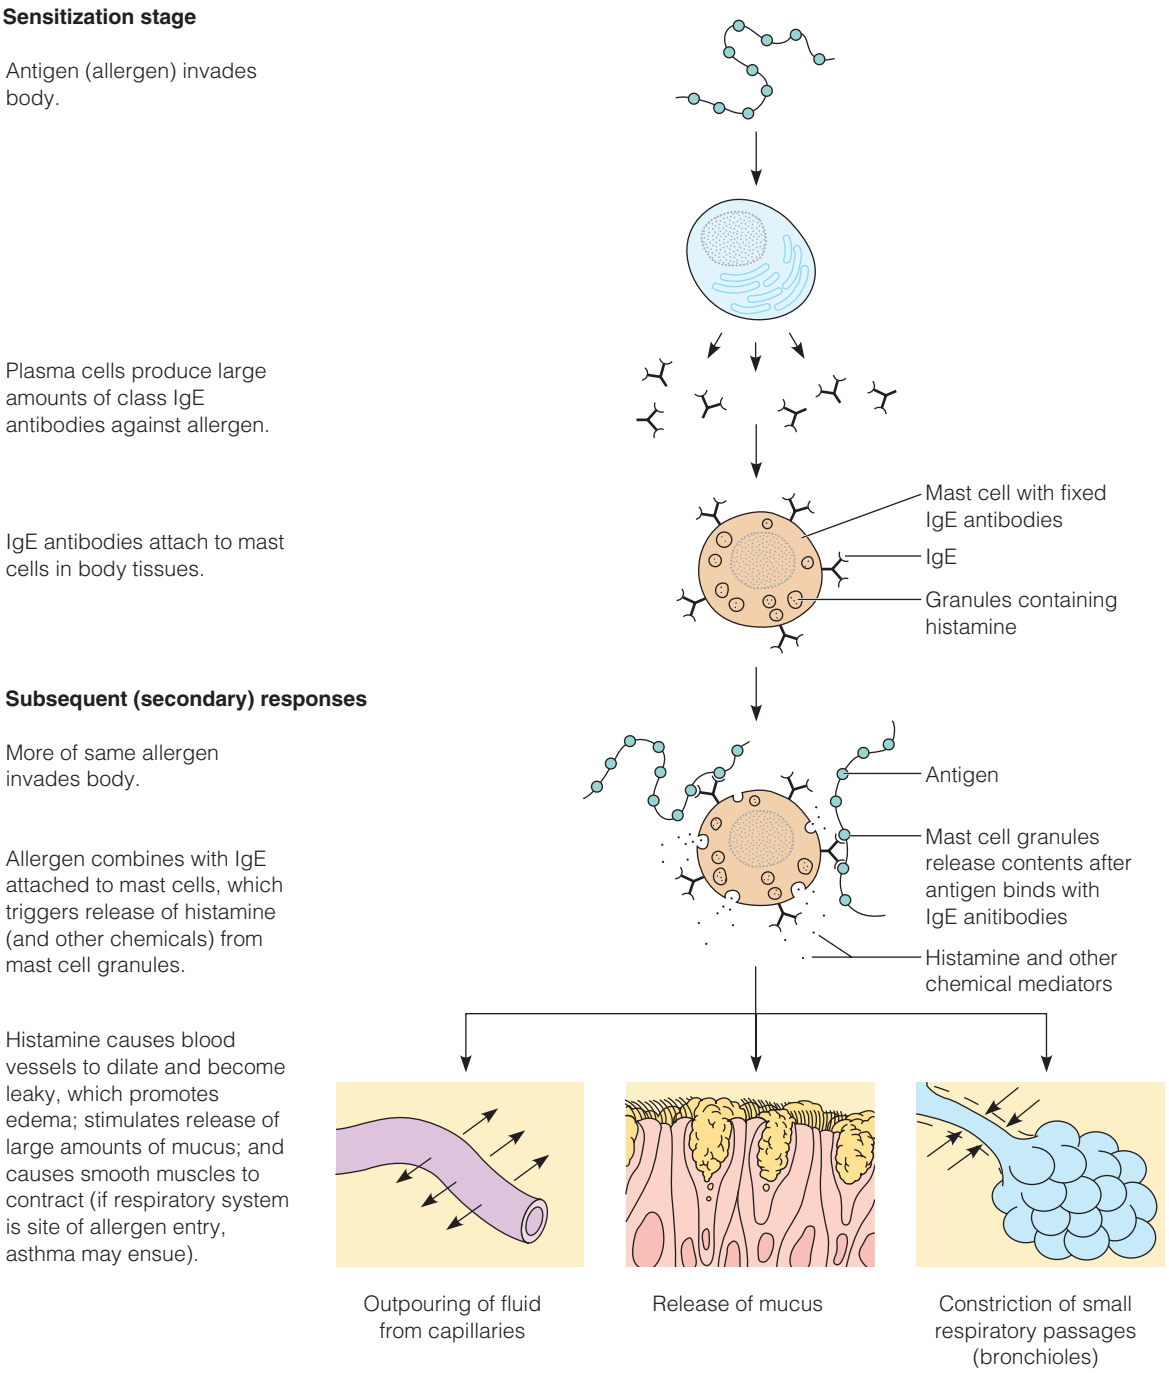

Figure 13–1 ■ Type I IgE-mediated hypersensitivity response.

the uvula and larynx, impairing breathing. This is further complicated by bronchial constriction, manifested by air hunger, stridor and wheezing, and a barking cough. These respiratory effects can be lethal if the reaction is severe and intervention is not provided immediately. Vasodilation and fluid loss from the vascular system can lead to impaired tissue perfusion and hypotension, a condition known as *anaphylactic shock*.

Fortunately, localized responses are the more common manifestations of type I hypersensitivity. Atopic reactions, which have a genetic predisposition, are localized, rather than systemic, IgE-mediated responses to an allergen. They occur when an allergen contacts cell-bound IgE in the bronchial tree, nasal mucosa, and conjunctival tissues. Chemical mediators are released locally, producing symptoms such as asthma, allergic rhinitis (hay fever), conjunctivitis, or atopic dermatitis. Allergens commonly associated with atopic reactions of this type include pollens, fungal spores, house dust mites, animal dander, and feathers (Grossman & Porth, 2014). When an allergic response to food occurs in the digestive system, nausea, vomiting, diarrhea, and cramping may develop. If the gastrointestinal mucosa is altered by a local allergic response, then the allergen may be absorbed, leading to a systemic reaction. Urticaria (hives) is the most common systemic response to food allergies.

TYPE II CYTOTOXIC HYPERSENSITIVITY

Cytotoxic hypersensitivity reactions are characterized by formation of IgG or IgM antibodies against normal or foreign cells or tissues (Grossman & Porth, 2014, Haynes et al., 2012). A hemolytic

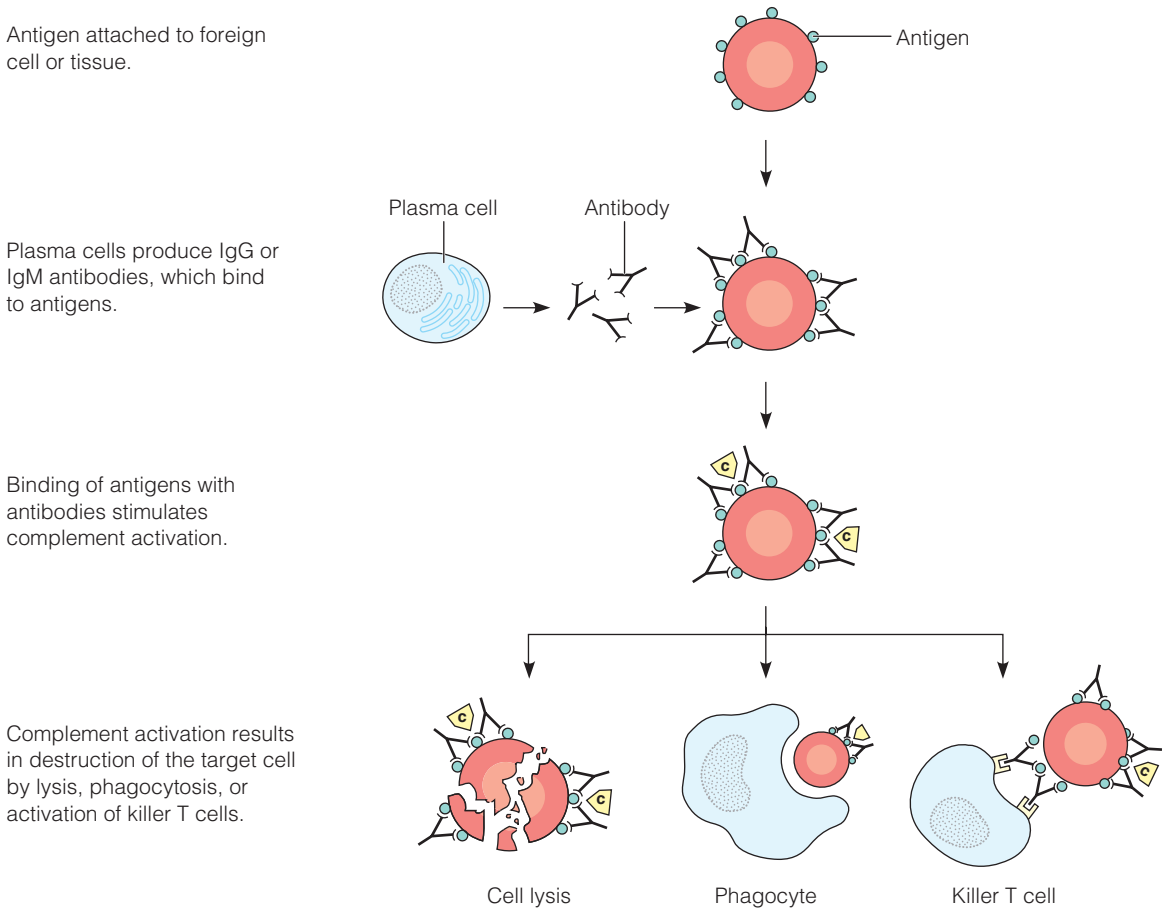

Figure 13–2 ■ Type II cytotoxic hypersensitivity response.

transfusion reaction to blood of an incompatible type is characteristic of a type II or cytotoxic hypersensitivity reaction. IgG- or IgM-type antibodies are formed to a cell-bound antigen such as the ABO or Rh antigen. When these antibodies bind with the antigen, the complement cascade is activated, resulting in destruction of the target cell (Figure 13–2 ■).

Type II reactions may be stimulated by an exogenous antigen, such as foreign tissue or cells, or a drug reaction in which the drug forms an antigenic complex on the surface of a blood cell, stimulating the production of antibodies. The affected cell is then destroyed in the resulting antigen–antibody reaction; for example, hemolytic anemia is sometimes associated with the administration of drugs such as penicillins, cephalosporins, and streptomycin. Withdrawal of the drug stops the reaction and the cell destruction.

Endogenous antigens can also stimulate a type II reaction, resulting in an autoimmune disorder such as Goodpasture's syndrome (pulmonary hemorrhage and glomerulonephritis), in which antigens are formed to specific tissues in the lungs and kidneys. Hashimoto's thyroiditis and autoimmune hemolytic anemia are additional examples of autoimmune type II reactions.

TYPE III IMMUNE COMPLEX–MEDIATED HYPERSENSITIVITY

Type III hypersensitivity reactions result from the formation of IgG or IgM antibody–antigen immune complexes in the circulation. When these complexes are deposited in vessel walls and extravascular tissues, complement is activated and chemical mediators of inflammation such as histamine are released. Chemotactic factors attract neutrophils to the site of inflammation. When neutrophils attempt to phagocytize the immune complexes, lysosomal enzymes are released, increasing tissue damage (Figure 13–3 ■).

Either systemic or local responses may be seen with type III reactions. For example, serum sickness is a systemic response, named because it was first identified after administration of foreign serum (e.g., horse antitetanus toxin). Although foreign serums are no longer administered, serum sickness still occurs in response to some drugs, such as penicillin and sulfonamides. Immune complexes are deposited in the walls of small blood vessels, the kidneys, and joints. Manifestations of serum sickness include fever, urticaria or rash, arthralgias, myalgias, and lymphadenopathy.

Localized responses may occur at a number of different sites. As immune complexes accumulate in the glomerular basement membrane of the kidneys—for example, following a streptococcal infection or with systemic lupus erythematosus—glomerulonephritis develops. An acute alveolar inflammatory response can occur when an antigen (such as dust from moldy hay), is inhaled by agricultural workers.

TYPE IV DELAYED HYPERSENSITIVITY

Type IV reactions differ from other hypersensitivity responses in two ways. First, these reactions are cell mediated rather than antibody mediated, involving T cells of the immune system. Second, type IV reactions are delayed rather than immediate, developing 24 to 48 hours after exposure to the antigen. Type IV hypersensitivity

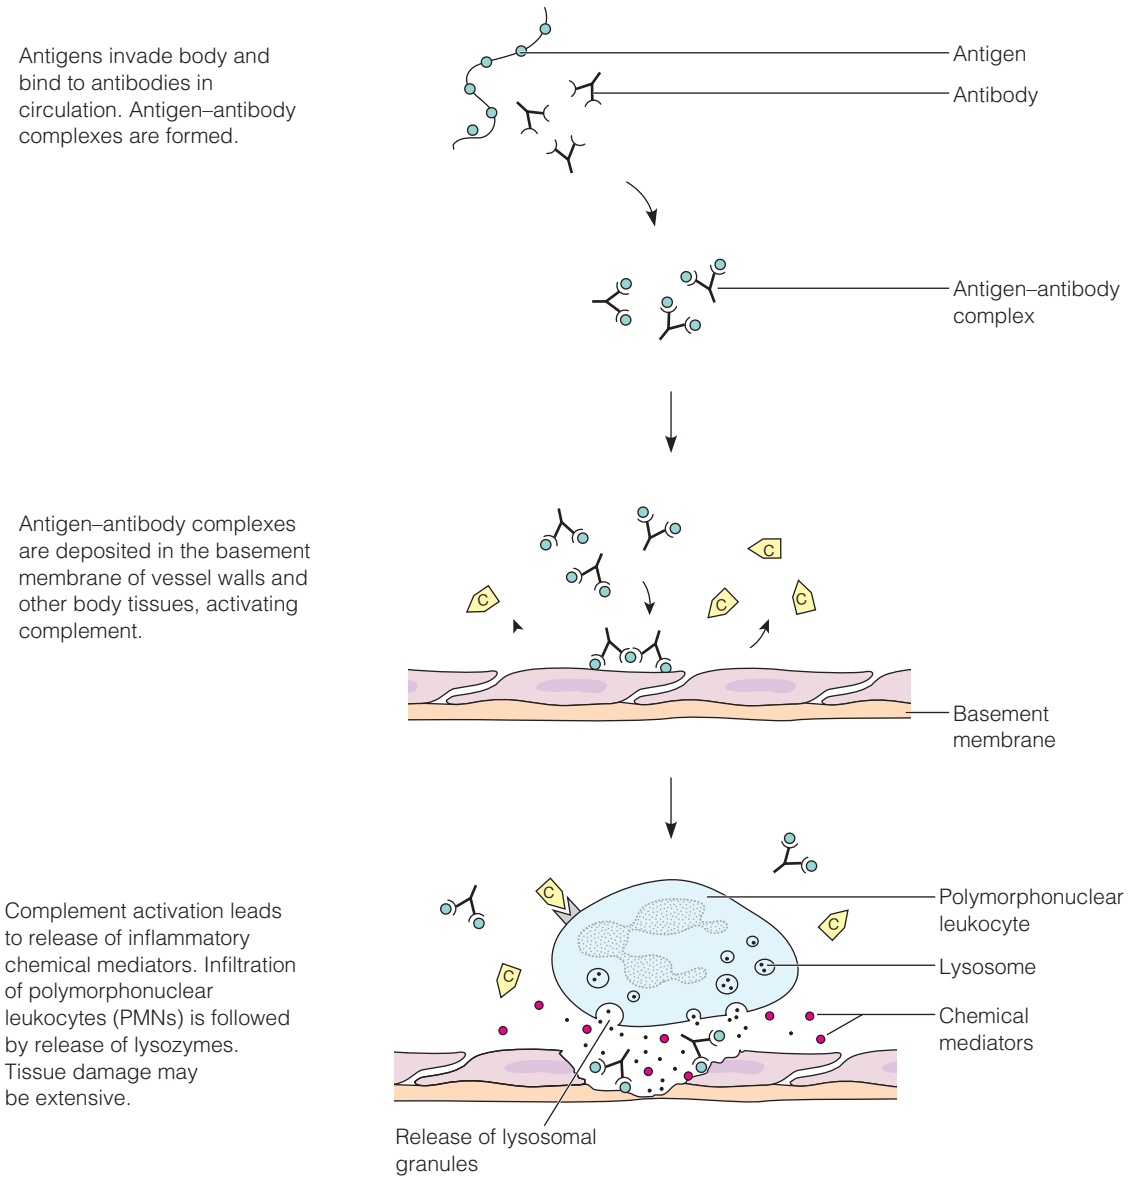

Figure 13–3 ■ Type III immune complex–mediated hypersensitivity response.

responses result from an exaggerated interaction between an antigen and normal cell-mediated mechanisms. This exaggerated interaction results in the release of soluble inflammatory and immune mediators (from the lysozymes within the macrophages) and recruitment of killer T cells, causing local tissue destruction (Figure 13–4 ■).

Contact dermatitis is a classic example of a type IV reaction. Intense redness, itching, blister formation, and thickening affect the skin in the area exposed to the antigen. Many antigens can provoke this response; poison ivy is a prime example. In the healthcare setting, an allergic response to latex can produce contact dermatitis (see next section). Other examples of cell-mediated responses include a positive tuberculin test and graft rejection episodes.

LATEX ALLERGY

Although protective against infection, the repetitive use of latex gloves creates a persistent exposure to latex for healthcare workers. An estimated 5% to 15% of healthcare workers are allergic to latex, whereas less than 1% of the general population has this allergy (American Academy of Allergy, Asthma & Immunology, 2012). When gloves are powdered with cornstarch to facilitate donning and removing gloves, the cornstarch particles aerosolize when the gloves are removed. The cornstarch includes latex particles. This creates a respiratory exposure as well as dermal exposure to latex. In addition, chemicals used in the manufacture of latex products may be irritating. Products such as balloons, condoms, and rubber bands are commonly made of latex.

Sensitivity to latex can present as a simple irritant dermatitis, the most common negative reaction to latex. Type IV hypersensitivity (contact dermatitis) typically presents 24 to 96 hours after contact. Type I systemic allergic reactions, including hives, itching, wheezing, or difficulty breathing, develop within minutes to hours after exposure (National Institute for Occupational Safety and Health [NIOSH], 2012). It is important to protect the patient and the healthcare worker who is allergic to latex. Employers can aid in prevention by selecting products free of latex. Nonlatex gloves are recommended for use where there is no contact with infectious materials or blood.

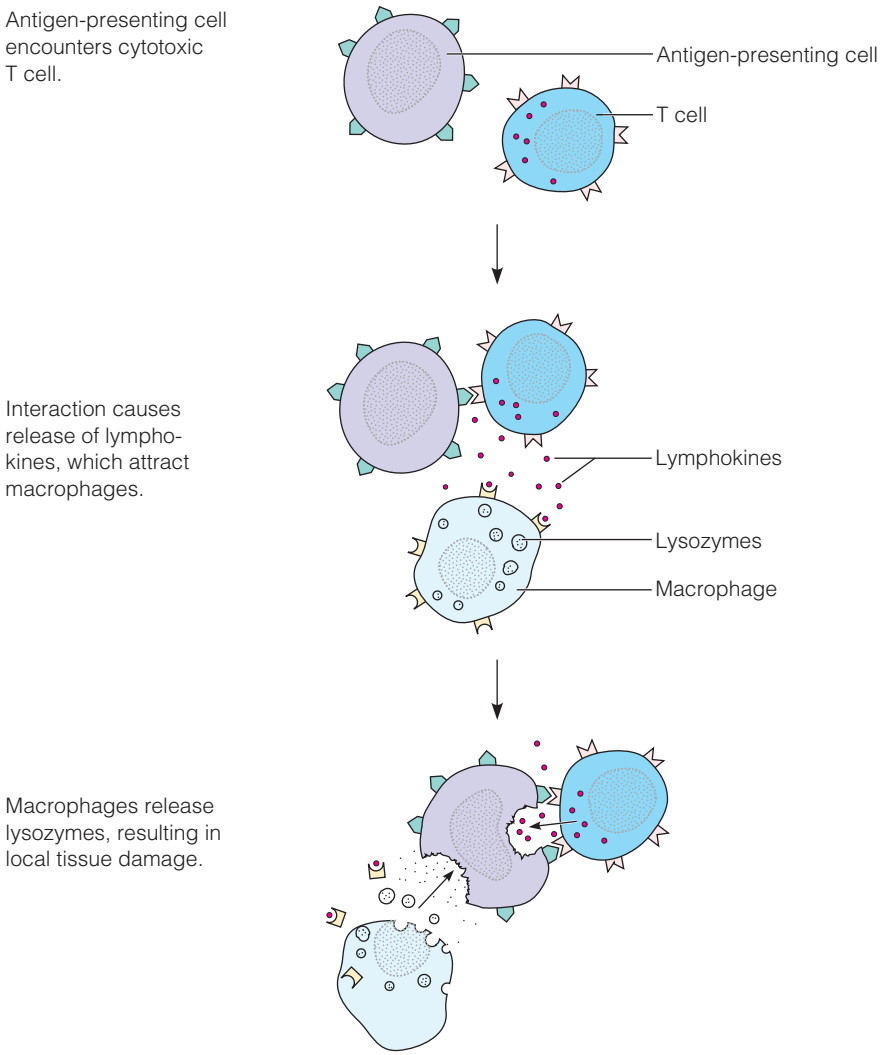

Figure 13–4 ■ Type IV delayed hypersensitivity response.

Powder-free latex gloves reduce latex exposure, as does avoiding use of oil-based creams and lotions when using latex gloves. Hand hygiene after using latex products also limits exposure (NIOSH, 2012).

●○● INTERPROFESSIONAL CARE

The focus of care for patients with allergies is to minimize exposure to the allergen, prevent the hypersensitivity response, and provide prompt, effective interventions for allergic responses. Identifying allergens for the individual to reduce the likelihood of exposure is a key aspect of management. A complete history of the patient's allergies is obtained, including medications, foods, animals, plants, and other materials. The type of hypersensitivity response is documented, along with its onset, manifestations, and usual treatment.

When a documented or suspected hypersensitivity reaction occurs, the allergen (e.g., intravenous medication or transfusion) is withdrawn immediately. With an acute systemic type I hypersensitivity response, managing the patient's airway takes highest priority, followed by maintaining cardiac output. Type II hypersensitivity responses may necessitate aggressive management of bleeding or renal failure. A type III (immune complex) reaction is treated by removing the offending antigen, thereby interrupting the inflammatory response.

With a hypersensitivity response, supportive care is important to relieve discomfort. This often involves the administration of selected antihistamine or anti-inflammatory medications. Other therapies may be prescribed in selected instances, such as plasmapheresis, a procedure that involves continually withdrawing and reinfusing blood from the patient while removing the allergic components from the plasma portion.

DIAGNOSIS

To identify possible allergens or hypersensitivity reactions, the following laboratory tests may be ordered:

- *White blood cell (WBC) count with differential* can detect high levels of circulating eosinophils. Increased numbers of eosinophils are often present in patients with type I hypersensitivities.
- *Radioallergosorbent test (RAST)* is a blood test that measures the amount of IgE directed toward specific allergens. Test results are compared with control values and used to identify hypersensitivities. RAST is preferred to skin testing if a severe allergic response is suspected.
- *Blood type and crossmatch* are ordered prior to any anticipated transfusions. Other blood tests associated with blood transfusions are a *Coombs' direct* (to detect antibodies on red blood cells

[RBCs]) and a *Coombs' indirect* (to check recipient's and donor's blood for antibodies before a blood transfusion).

- *Immune complex assays* may be performed to detect the presence of circulating immune complexes in suspected type III hypersensitivity responses. The normal result is a test negative for circulating immune complexes. A negative test does not, however, rule out an immune complex hypersensitivity response.
- *Complement assay* is also useful in detecting immune complex disorders. In these disorders, complement is, in effect, used up by the development of antigen–antibody complexes. Decreased levels are seen on examination. Both total complement level and amounts of individual components of the complement cascade can be determined.

SKIN TESTS FOR ALLERGIES

Skin tests are also used to determine causes of hypersensitivity reactions. These tests are used to identify specific allergens to which an individual may be sensitive. Allergens for testing are selected according to the patient's history. Test solutions made from extracts of inhaled, ingested, or injected materials, such as pollens, mites, venoms, or some drugs, are used for the prick test and intradermal testing. Epicutaneous testing (prick testing) is generally done first to avoid a systemic reaction; it may be followed by intradermal testing of allergens with a negative response to prick testing.

- ***Prick (epicutaneous or puncture) test:*** A drop of diluted allergenic extract is placed on the skin, and the skin is then pricked or punctured through the drop. With a positive test, a localized pruritic (itchy) wheal and erythema occur. The response is maximal at 15 to 20 minutes.
- ***Intradermal:*** A small amount of allergen extract at a 1:500 or 1:1000 dilution is injected intradermally in the forearm or intrascapular area. If several allergens are being tested, injections are spaced 0.25 to 0.5 inch apart. As control measures, plain diluent (negative control) and histamine (positive control) are injected. If there is no response to a particular allergen at 15 to 20 minutes, the test is negative. The appearance of a wheal and erythema, with a wheal diameter at least 5 mm greater than that produced by the control, indicates a positive response (Figure 13–5 ■).
- ***Patch:*** A 1-inch patch impregnated with the allergen (e.g., perfume, cosmetics, detergents, or clothing fibers) is applied to the skin for 48 hours. Absence of a response indicates a negative test result. Positive responses are graded from mild (erythema in the exposed area) to severe (erythema, papules, vesicles, or ulceration).

Figure 13–5 ■ Positive allergy skin test in a male patient.

FOOD ALLERGY TESTING

Food allergy testing is performed when a food allergy is suspected but the source or implicated food item has not been clearly identified. Food allergy symptoms are typically demonstrated within hours of eating. The patient is asked to keep a diary of foods consumed and allergic responses for a week. An elimination diet, excluding most common food allergens and all suspected foods, is then prescribed for 1 week. If symptoms do not improve, a different variation of the elimination diet is prescribed. If symptoms are relieved, foods are reintroduced to the diet one at a time until symptoms recur, indicating allergy to that food.

MEDICATIONS

When it is impossible to avoid the offending allergen and allergic manifestations are severe or disrupt the patient's activities of daily living (ADLs), medications may be prescribed. *Immunotherapy*, also called hyposensitization or desensitization, consists of injecting an extract of the allergen(s) in gradually increasing doses. Immunotherapy is used primarily for allergic rhinitis or asthma related to inhaled allergens. It has also been shown to be effective in preventing anaphylactic responses to insect venom. With weekly or biweekly subcutaneous injections of the allergen, the patient develops IgG antibodies to the allergen that appear to block effectively the allergic IgE-mediated response. Once a therapy plateau is reached, injections may be discontinued or continued indefinitely either monthly or bimonthly.

Antihistamines are the major class of drugs used in treating the symptoms of hypersensitivity responses, type I in particular. They are also useful to some extent in relieving manifestations (such as urticaria) of some type II and type III reactions. Antihistamines block H_1-histamine receptors, acting as a competitive antagonist to histamine, but they do not affect the production or release of histamine. The prototype antihistamine is diphenhydramine (Benadryl). It and other antihistamines alleviate the systemic effects of histamine such as urticaria and angioedema (localized tissue swelling). They are also useful in relieving allergic rhinitis, drying respiratory secretions through an anticholinergic effect. The preferred route of administration is oral, although diphenhydramine and others can be given parenterally, particularly when immediate action is needed, as in anaphylaxis. Side effects include drowsiness and dry mouth. Antihistamines are not effective in relieving asthmatic responses to allergens and may actually worsen symptoms by their drying effect on respiratory secretions. Antihistamines are often combined with a sympathomimetic agent such as pseudoephedrine to improve their decongestant activity and counteract their sedative effect.

Glucocorticoids (corticosteroids) are used in both systemic and topical forms for many types of hypersensitivity responses. Their anti-inflammatory effects, rather than their immunosuppressive effects, are of most benefit. A short course of corticosteroid therapy is often used for severe asthma, allergic contact dermatitis, and some immune complex disorders. Corticosteroids in topical forms or delivered by inhaler may be used for longer periods of time with few side effects; however, systemic absorption can occur.

OTHER THERAPIES

Other treatments used for hypersensitivity responses are generally dictated by the severity of the response and the organ system affected. Airway management takes highest priority for the patient with an acute anaphylactic reaction. Insertion of an endotracheal tube or emergency tracheostomy may be required to maintain airway patency with severe laryngospasm. Because anaphylaxis places the person at risk for vasomotor collapse and significant hypotension, it is necessary to insert an intravenous line and initiate fluid resuscitation with an isotonic solution such as Ringer's lactate.

Plasmapheresis, removal of harmful components in the plasma (also known as *plasma exchange therapy*), may be used to treat immune complex responses such as glomerulonephritis and Goodpasture's syndrome. Plasma and the glomerular-damaging antibody–antigen complexes are removed by passing the patient's blood through a blood cell separator. The RBCs are then returned to the patient along with an equal amount of albumin or human plasma. This procedure is usually done in a series rather than as a one-time treatment. It is not without risk, and informed consent is required. Potential complications of plasmapheresis include those associated with intravenous catheters, shifts in fluid balance, and alteration of blood clotting.

TREATMENT OF ANAPHYLAXIS

The immediate treatment for anaphylaxis is parenteral epinephrine, an adrenergic agonist (sympathomimetic) drug that has both vasoconstricting and bronchodilating effects. These qualities, combined with its rapid action, make epinephrine ideal for treating an anaphylactic reaction. For mild reactions with wheezing, pruritus, urticaria, and angioedema, an intramuscular or subcutaneous injection of 0.3 to 0.5 mL of 1:1000 epinephrine is generally sufficient (Austen, 2012; Mustafa, 2011). For patients with an injected toxin such as a bee sting, an additional amount equivalent to one-half the above may be injected directly into the site of the sting and a tourniquet applied above it to prevent further systemic absorption. Intravenous epinephrine diluted to a 1:100,000 concentration may be used in the patient with a more severe anaphylactic reaction.

●○● NURSING CARE

Nursing care related to hypersensitivity reactions is primarily directed toward prevention, early identification, and providing prompt, effective treatment.

Health Promotion

Health promotion activities include helping patients identify possible allergens that prompt a hypersensitivity response and discussing strategies to avoid these allergens. Anyone with severe food allergies may need referral to a dietitian to discuss necessary dietary changes and ways to continue meeting nutrient needs. It is important for individuals with hypersensitivities to inform healthcare personnel of all allergens. People who experience anaphylactic reactions should wear a medical alert bracelet or tag at all times to identify the substance(s) that provokes this response. Patients who have experienced an anaphylactic reaction to insect venom or other potentially unavoidable allergens should carry a kit (commonly called a bee sting kit) for immediate treatment of future exposures. This kit typically includes a prefilled syringe of epinephrine and an epinephrine nebulizer, allowing prompt self-treatment.

Assessment

Collect the following data through the health history and physical examination. Further focused assessments are described with nursing interventions in the next section.

- ***Health history:*** risk factors, hypersensitivities (medications, household dust, bee stings, etc.), reaction (rash, hives, difficulty breathing), type of treatment for hypersensitivity reactions; allergy skin testing; asthma, hay fever, or dermatitis
- ***Physical assessment:*** mucous membranes of nose and mouth, skin for lesions or rashes, eyes (tearing and redness), respiratory rate, and adventitious breath sounds.

Priorities of Care

Airway, breathing, and circulation (the ABCs) are of greatest importance for the patient with an acute severe anaphylactic reaction.

Diagnoses, Outcomes, and Interventions

Priority nursing diagnoses will vary according to the type of hypersensitivity reaction experienced by the patient. Because nurses are most likely to become involved with a patient experiencing a type I or type II response, this section focuses on diagnoses for these patients.

Ineffective Airway Clearance

In anaphylactic reactions, the airway may be obstructed due to facial angioedema, bronchospasm, or laryngeal edema. Establishing and maintaining a patent airway is of highest priority.

Expected Outcome: Patient's airway will remain open to allow adequate gas exchange.

- Initiate oxygen per nasal cannula at a rate of 2 to 4 L/min. Apply oxygen emergently and obtain a physician order for oxygen administration, modifying flow rate and method of administration as ordered. *Providing external oxygen increases the alveolar oxygen and its availability to cells of the body.*
- Assess respiratory rate and pattern, level of consciousness and anxiety, nasal flaring, use of accessory muscles of respiration, chest wall movement, audible stridor; and oxygen saturation. Auscultate lung sounds and any adventitious sounds, such as wheezes. *Extreme anxiety or agitation, nasal flaring, stridor, and diminished lung sounds indicate air hunger and possible airway obstruction, necessitating immediate intervention.*
- Position in Fowler's to high Fowler's position *to promote optimal lung expansion and ease of breathing.*
- Insert a nasopharyngeal or oropharyngeal airway, and arrange for immediate intubation as indicated. *Ensuring an adequate airway is vital to preserve life.*
- Administer intramuscular or subcutaneous epinephrine 1:1000, 0.3 to 0.5 mL, as prescribed. This may be repeated in 20 to 30 minutes if necessary. Administer parenteral diphenhydramine (deep intramuscular or intravenous) as prescribed. *Epinephrine is a potent vasoconstrictor and bronchodilator, counteracting the effects of histamine. Effective plasma concentrations of epinephrine are achieved more rapidly when it is administered by IM injection into the vastus lateralis than when injected IM or subcutaneously into the*

arm (Mustafa, 2011). Diphenhydramine is an antihistamine that blocks histamine receptors and their effect. These medications can be effective in rapidly reversing manifestations of anaphylaxis.

- Provide calm reassurance. *Hypoxemia and air hunger are terrifying for the patient. Anxiety can impair the patient's ability to cooperate with treatment and can increase the respiratory rate, making breathing less effective.*

Decreased Cardiac Output

Peripheral vasodilation and increased capillary permeability from the release of histamine can significantly impair cardiac output. When it falls to the degree that tissue perfusion becomes impaired and hypoxia results, a state of anaphylactic shock exists.

Expected Outcome: Patient's blood pressure, circulation, and effective tissue perfusion will be maintained.

- Monitor vital signs frequently, noting fall in blood pressure, decreasing pulse pressure, tachycardia, and tachypnea. *These vital sign changes may indicate shock.*
- Assess skin color, temperature, capillary refill, edema, and other indicators of peripheral perfusion. *As cardiac output falls, peripheral vessels constrict and tissue perfusion is impaired.*
- Monitor level of consciousness. *A change in level of consciousness (lethargy, apprehension, or agitation) is often the first indicator of decreased cardiac output.*
- Insert one or more large-bore (18-gauge or larger) intravenous catheters as prescribed. *Intravenous catheters are inserted as soon as possible to provide sites for rapid fluid replacement.*
- Administer warmed intravenous solutions of lactated Ringer's or normal saline, as prescribed. *These isotonic solutions help maintain intravascular volume. Warmed solutions are used to prevent hypothermia from the rapid administration of large amounts of fluid at room temperature (about 21°C, or 70°F).*
- Insert an indwelling catheter, and monitor urinary output frequently. *As the cardiac output drops, the glomerular filtration rate (GFR) falls. With an output of less than 30 mL/h, the patient is at risk for acute kidney injury from ischemia.*

PRACTICE ALERT!

Aggressive fluid therapy may lead to hypervolemia, resulting in pulmonary edema; assess for shortness of breath and crackles in the lungs.

Delegating Nursing Care Activities

As appropriate and allowed by the designated duties and responsibilities of assistive personnel, the nurse may delegate such nursing care activities as measuring intake and output, monitoring vital signs, and providing hygiene and physical comfort measures for the patient experiencing anaphylaxis.

Continuity of Care

Most hypersensitivity responses are appropriately treated through self-care measures, by the patient or family members. Teaching is a vital component of care. If the patient is at risk for anaphylaxis, involving the family in teaching is essential because the response may occur with such rapidity that the patient will be unable to provide self-care. Include the following points in teaching the patient and family about managing hypersensitivities:

- When and how to use an anaphylaxis kit containing epinephrine and antihistamines in injectable, inhaler, and oral forms
- When to seek medical attention
- Use and adverse reactions of antihistamines and decongestants
- Advantages of autologous blood transfusion if future surgery is scheduled
- Skin care to prevent and care for contact dermatitis
- Helpful resources:
  - ALERT, Inc., Allergy to Latex Education and Resource Team (toll-free: 1-888-97-ALERT)
  - Food Allergy and Anaphylaxis Network.

THE PATIENT WITH AN AUTOIMMUNE DISORDER

Maintaining optimal health and preventing disease depend not only on the immune system's ability to recognize and destroy foreign tissues and other antigens, but also on the immune system's ability to recognize self. When self-recognition (also known as *self-tolerance*) is impaired and immune defenses are directed against normal host tissue, the result is an **autoimmune disorder**.

Autoimmune disorders can affect any tissue in the body. Some are tissue or organ specific, affecting a particular tissue or a particular organ. Hashimoto's thyroiditis is an example of an organ-specific autoimmune disorder. Circulating antibodies are formed to certain thyroid components, ultimately resulting in destruction of the gland. In type 1 diabetes mellitus, cytotoxic T cells attack and destroy beta cells in pancreatic islets (Powers, 2012). Autoimmune disorders may also be systemic, with neither the immune response nor the resulting inflammatory lesions confined to any one organ. Rheumatologic disorders, such as rheumatoid arthritis and systemic lupus erythematosus (SLE), are characteristic of systemic autoimmune disorders.

Pathophysiology

The mechanism that causes the immune system to recognize host tissue as a foreign antigen is not clear. The following factors are under study as possible contributors to the development of autoimmune disorders:

- The release of previously "hidden" antigens into the circulation, such as DNA or other components of the cell nucleus, elicits an immune response.
- Chemical, physical, or biologic changes in host tissue cause self-antigens to stimulate the production of autoantibodies.
- The introduction of an antigen, such as a bacteria or virus, whose antigenic properties closely resemble those of host tissue, resulting in the production of antibodies that target not only the foreign antigen but also normal tissue. This is termed molecular mimicry. Heart damage in rheumatic fever and acute glomerulonephritis following beta-hemolytic streptococcal infections are examples of the development of antibodies against normal tissue (Grossman & Porth, 2014).
- A defect in normal cellular immune function that allows B cells to produce autoantibodies unchecked.

Although the exact mechanism producing autoimmunity is unclear, several characteristics of autoimmune diseases are known.

It is apparent that genetics plays a role because a higher incidence is seen in family members of people with autoimmune disorders. More than one genetic change is likely occurring to cause development of these disorders. Additional factors believed to contribute to the development of autoimmune disorders include age, gender, and environmental factors such as exposure to infectious agents (Diamond & Lipsky, 2012).

The disorders tend to overlap, so that the patient with one autoimmune disorder may develop another or some manifestations of another. The onset of an autoimmune disorder is frequently associated with a physical or psychologic stressor. Autoimmune disorders are frequently characterized by periods of exacerbation and remission.

Specific autoimmune disorders are discussed in the sections of this textbook related to the affected organ systems or functional disruption.

●○● INTERPROFESSIONAL CARE

For the most part, the diagnosis of an autoimmune disorder is based on the patient's manifestations. Although the manifestations of these disorders can often be managed, a cure typically is not possible unless the affected target tissue is removed (e.g., colectomy for the patient with ulcerative colitis).

DIAGNOSIS

Serologic assays are used to identify and measure antibodies directed toward host tissue antigens or normal cellular components. Many detectable autoantibodies are not specific to a single autoimmune disorder and are used to establish the autoimmune process rather than the specific disorder. Although healthy people often have low levels of autoantibodies, levels are much higher in patients affected by an autoimmune disorder. The following serologic assays may be ordered:

- *Antinuclear antibody (ANA)* detects antibodies produced to DNA and other nuclear material. These antibodies can cause tissue damage characteristic of autoimmune disorders such as SLE. The patient's serum is combined with nuclear material and tagged antihuman antibody to detect ANA-antihuman antibody complexes. A negative, or normal, result is a titer of less than 1:20. When complexes are detected at higher levels (greater than 1:20), the test is positive for ANA (Kee, 2014).
- *Lupus erythematosus (LE) cell test* is used to detect SLE and monitor its treatment. Neutrophils that contain large masses of phagocytized DNA from the nuclei of polymorphonuclear leukocytes (PMNs) are called LE cells. Like the ANA, the LE cell test is nonspecific for SLE. A positive result may also be seen in rheumatoid arthritis (RA) or with selected antibiotic and other medications such as phenytoin and oral contraceptives.
- *Rheumatoid factor (RF)* is an immunoglobulin present in the serum of approximately 80% of patients with rheumatoid arthritis. A titer of less than 1:80 (or less than 40 to 60 unit/mL) is considered normal. An RF titer of 1:80 or higher indicates RA. Titers between 1:20 and 1:80 may be present in other autoimmune disorders and diseases such as leukemia, liver cirrhosis, and renal disease.
- *Complement assay* may also be useful in identifying autoimmune disorders. In these disorders, complement may be consumed in the development of antigen–antibody complexes. Decreased levels are seen on examination. Both total complement level and amounts of individual components of the complement cascade can be determined.
- *Anti-CCP antibody test* is a blood test for RA. It measures anti–cyclic citrullinated peptide antibody in blood; the results are specific for RA. These antibodies replace normal protein in the joints of patients with RA.

MEDICATIONS

Newer treatments for autoimmune disorders focus on suppressing autoimmune responses and restoring normal regulatory mechanisms to prevent target organ damage (Diamond & Lipsky, 2012). Therapy may be intermittent, used only during periods of exacerbation, or may be long term to prevent acute flares. Because these drugs suppress the immune system, the patient taking them has an increased risk for infection.

- Immunosuppressive drugs such as azathioprine (Imuran), methotrexate (Rheumatrex, Trexall), abatacept (Orencia), etanercept (Enbrel), anakinra (Kineret), cyclophosphamide (Cytoxan), and cyclosporine (Sandimmune) may be used to inhibit immune responses in autoimmune disorders. These drugs may be cytotoxic, killing proliferating B cells and T cells, or may suppress the production of cytokines critical to the immune response (Adams & Urban, 2013; Lehne, 2013).
- Corticosteroids such as *prednisone* also suppress immune responses and have potent anti-inflammatory effects. Corticosteroids may be prescribed to reduce the inflammatory response and minimize tissue damage. Doses required for immunosuppression are large, increasing the risk for infection and cushingoid effects such as thin, fragile skin and osteoporosis-related fractures (Lehne, 2013).
- Drugs known as *biologicals* are laboratory-produced antibodies that bind tumor necrosis factor alpha (TNF-α) and interleukin-1 (IL-1), both inflammatory elements. These medications decrease the inflammatory process in autoimmune disorders, and include adalimumab (Humira), efalizumab (Raptiva), and infliximab (Remicade) (Adams & Urban, 2013).

●○● NURSING CARE

Nursing interventions for the patient with an autoimmune disorder are individualized and tailored to needs dictated by manifestations of the disorder. Nurses often will be involved with the patient in an outpatient setting, evaluating the patient's response to therapy and self-care management.

Consider the following nursing diagnoses in planning care for the patient with an autoimmune disorder:

- *Activity Intolerance* related to inflammatory effects of autoimmune disorder
- *Ineffective Coping* related to chronic disease process
- *Interrupted Family Processes* related to lack of understanding about autoimmune disorder and its effects
- *Ineffective Protection* related to disordered immune function.

Continuity of Care

Because many autoimmune disorders are chronic, teaching the patient and family about the disorder and its management is a key nursing intervention. The patient may be taking drugs with multiple side

effects or long-term effects, necessitating effective teaching. Patients with autoimmune disorders often do not appear to be ill, making it difficult for friends and families to understand their care needs. The chronicity of these disorders also puts the patient at high risk for unproven remedies and quackery. Provide psychologic support, listening, and teaching. In addition, suggest resources such as local support groups and the American Autoimmune Related Diseases Association.

THE PATIENT WITH A TISSUE TRANSPLANT

Since the first kidney transplant was performed from one identical twin to the other in 1954, organ and tissue transplantation have become increasingly popular, even preferred treatment options. The transplantation of avascular tissues, such as skin, cornea, bone, and heart valves, is considered routine, with little need for tissue matching and **immunosuppression** (the use of drugs to make the immune response less effective). Transplants of organs (e.g., the kidney, heart, heart and lung, liver, pancreas, and bone marrow) are increasingly common. More than 114,000 people are currently on a transplant waiting list (United Network for Organ Sharing, 2012). Commonly performed organ transplants are outlined in Table 13–1; success rates refer to survival of the transplant recipient.

Transplant success is closely tied to obtaining an organ with tissue antigens as close to those of the recipient as possible. Every body cell has cell surface antigens known as human leukocyte antigens (HLAs) that are unique to the individual. Even though identical twins may have the same HLA type, a few of their antigens may be dissimilar enough to cause a transplant between them to be rejected. Matching the HLA type of the donor and recipient as closely as possible decreases the potential for rejection of the transplanted organ or tissue but does not eliminate it.

Pathophysiology

An **autograft**, a transplant of the patient's own tissue, is the most successful type of tissue transplant. Skin grafts are the most common examples of autografts. Increasingly, autologous bone marrow or stem cell transplants and blood transfusions are being used to reduce immunologic responses. When the donor and recipient are identical twins, the term *isograft* is used. Because of the high likelihood of an HLA match, the success of these grafts is good and rejection episodes are mild.

Few people, however, have an identical twin to provide tissue for donation, and when the need is for an organ such as the heart, liver, or lungs, a living-donor transplantation is not possible. Most often, organ and tissue transplants are **allografts**, which are grafts between members of the same species that have different genotypes and HLA. Allografts may come from living donors; examples are bone marrow, stem cells, blood, and a kidney. Most often, organs for transplantation are obtained from a cadaver. Donors are typically people who meet the criteria for brain death; are less than 65 years old; and are free of systemic disease, malignancy, or infection, including HIV, hepatitis B, or hepatitis C. The organ is removed immediately before or after cardiac arrest and preserved until it is transplanted into the waiting recipient. Finally, *xenograft* is a transplant from an animal species to a human. These transplants are the least successful but may be used in selected instances, such as the use of pig skin as a temporary covering for a massive burn.

Histocompatibility, the ability of cells and tissues to survive transplantation without immunologic interference by the recipient, is determined by tissue typing. Tissue typing is performed in an attempt to match the donor and recipient as closely as possible for HLA type and blood type, and to identify preformed antibodies to the donor's HLA.

Both antibody-mediated and cell-mediated immune responses are involved in the complex process of host-versus-graft transplant rejection. Host macrophages process donor antigen, presenting it to T and B lymphocytes. Activated lymphocytes (B and T cells) produce both antibody- and cell-mediated effects. Cytotoxic T cells bind with cells of the transplanted organ, resulting in cell lysis. Helper T cells stimulate the multiplication and differentiation of B cells, and antibodies are produced to graft endothelium. Complement activation or antibody-dependent cell-mediated cytotoxicity leads to transplant cell destruction. Rejection typically begins after the first 24 hours of

TABLE 13–1 Organ Transplant Indications and Success Rate

Organ	Graft Type	Indications for Transplant	Success Rate
Kidney	Allograft; may be isograft	End-stage renal disease	84.8% at 5 years
Heart	Allograft	End-stage cardiac disease refractory to medical management	72.5% at 5 years
Lung	Allograft	Pulmonary hypertension, cystic fibrosis, pulmonary fibrosis, chronic obstructive pulmonary disease	47.5% at 5 years
Liver	Allograft	Severe liver dysfunction due to chronic active hepatitis, primary biliary cirrhosis, sclerosing cholangitis	74.3% at 5 years
Intestine	Allograft	Intestinal failure (inability of intestine to absorb nutrients)	47.3% at 5 years
Bone marrow/ stem cell	Autograft or allograft	Leukemia, aplastic anemia, congenital immunologic defects	30%–70% cure
Skin	Autograft, allograft, or xenograft	Severe burns, plastic surgery	> 95% at 5 years
Cornea	Allograft	Corneal ulceration and opacification	> 95% at 5 years
Pancreas	Allograft	Pancreatic insufficiency, diabetes	82.7% at 5 years
Islet cells	Allograft (multiple donor)	Type 1 diabetes mellitus	100% > 2 years

TABLE 13–2 Transplant Rejection Episodes

Type	Cause	Presentation	Treatment
Hyperacute	Preexisting antibodies to donor ABO or HLA antigens	Occurs within minutes to hours or days of the transplant Rapid deterioration of organ function	The transplant usually cannot be saved; prevent with crossmatch, and use antimetabolites or anti-inflammatory drugs before surgery.
Acute	Primarily a cell-mediated immune response to HLA antigens; antibody-mediated response may also contribute	Occurs within days to months after the transplant Signs of inflammation and impaired organ function	Increase immunosuppression using steroids, cyclosporine, monoclonal antibodies, or antilymphocyte globulins.
Chronic	Probably antibody-mediated response; may also involve inflammatory damage to vessel endothelium	Occurs 4 months to years after the transplant Gradual deterioration of organ function	None; loss of graft will occur, requiring retransplant.

the transplant, although it may present immediately. Rejection episodes are characterized as hyperacute, acute, or chronic, as summarized in Table 13–2.

Hyperacute tissue rejection occurs immediately or up to 2 to 3 days after the transplant of new tissue. Hyperacute rejection is due to preformed antibodies and sensitized T cells to antigens in the donor organ. It is most likely to occur in patients who have had a previous organ or tissue transplant, such as a blood transfusion, and may be evident even before the transplant procedure is completed. The grafted organ initially appears pink and healthy, but soon becomes soft and cyanotic as blood flow is impaired. Organ function deteriorates rapidly, and manifestations of organ failure develop.

Acute tissue rejection is the most common and treatable type of rejection episode. It occurs between 4 days and 3 months after the transplant. Acute rejection is mediated primarily by the cellular immune response, resulting in transplant cell destruction. The patient experiencing acute rejection demonstrates manifestations of inflammation, with fever, redness, swelling, and tenderness over the graft site. Signs of impaired function of the transplanted organ may be noted (e.g., elevated blood urea nitrogen [BUN] and creatinine, liver enzyme and bilirubin elevations, or elevated cardiac enzymes and signs of heart failure).

Chronic tissue rejection occurs from 4 months to years after transplant of new tissue. Chronic rejection is most likely the result of antibody-mediated immune responses. Antibodies and complement are deposited in transplant vessel walls, causing narrowing and decreased function of the organ due to ischemia. The gradual deterioration of transplanted organ function is seen with chronic tissue rejection.

Graft-versus-host disease (GVHD) is a potentially fatal complication of stem cell transplantation to immunocompromised patients (Grossman & Porth, 2014). In GVHD, immunocompetent cells in the grafted tissue recognize host tissue as foreign and mount a cell-mediated immune response. If the host is immunocompromised, as is often the case when a stem cell transplant is performed, host cells are unable to destroy the graft and instead become the targets of destruction. Three important strategies for preventing or decreasing the severity of GVHD include (1) deleting donor T cells in the tissue or organ prior to infusion into the patient (however, this may increase the risk of graft failure and infection), (2) using umbilical cord stem cells in adult patients, and (3) using closer HLA matching between donor and recipient. Acute GVHD occurs within the first 100 days following a transplant and primarily affects the skin, liver, and gastrointestinal tract. The patient develops a maculopapular pruritic rash beginning on the palms of the hands and soles of the feet. The rash may spread to involve the entire body and lead to desquamation. Gastrointestinal manifestations include abdominal pain, nausea, and bloody diarrhea. GVHD that begins after or lasts longer than 100 days is said to be chronic. If it is limited to the skin and liver, the prognosis is good. If multiple organs are involved, the prognosis is poor (Grossman & Porth, 2014).

●○● INTERPROFESSIONAL CARE

Care before and after tissue transplant is directed toward reducing the risk that transplanted tissue will be rejected or result in GVHD. Diagnostic studies are directed first at identifying the potential recipient's blood type and HLA profile. Potential donors are identified through diagnostic studies, and the recipient's immune response to the transplant is monitored. Immunosuppressive therapy with medications is a vital part of post-transplant care. The development of effective immunosuppressive drugs as well as improved methods of tissue typing are responsible for the success of organ transplants using allografts.

DIAGNOSIS

Laboratories specializing in transplant procedures are equipped to make the following diagnostic tests prior to organ or tissue transplantation:

- *Blood type* of both the donor and recipient are determined and they must match.
- *Crossmatching* of the patient's serum against the donor's lymphocytes is performed to identify any preformed antibodies against antigens on donor tissues. If present, these antibodies would likely result in an immediate or hyperacute graft rejection with probable loss of the transplant.
- *HLA testing* of recipients and potential donors is performed. A close match of HLA antigens is most important to prevent bone marrow and kidney transplant rejection, but is less critical for heart, lung, and liver transplants. HLA tests are performed for six antigens important to transplant survival: two each of HLA-A, HLA-B, and HLA-DR.
- *Mixed lymphocyte culture (MLC) assay tests* also are used to determine histocompatibility between the donor and the recipient.

This test identifies whether lymphocytes of the recipient will react against the potential donor's HLA. When a pretransplant test reveals a high potential for reaction, potent immunosuppression may prevent rejection. If the intended recipient is severely immunocompromised, the results may be falsely negative.

- *Panel reactive antibodies* are assessed to determine the patient's level of sensitization to donor antigens. High PRA levels indicate a greater risk for transplant rejection, and increase the difficulty of finding a compatible donor organ.
- *Ultrasonography* or *magnetic resonance imaging (MRI)* of the transplanted organ may be performed to evaluate its size, perfusion, and function.
- *Tissue biopsies* of the transplanted organ are performed routinely to assess for evidence of tissue rejection.

MEDICATIONS

The mainstays of drug therapy for patients following a tissue or organ transplant are immunosuppressive agents. See Figure 13–6 ■ for an illustration of where various immunosuppressive drugs exert their effect on immune function. Varying regimens of these drugs are used, depending on the transplanted tissue and the medical center; however, a combination of corticosteroids and cyclosporine or tacrolimus is common for maintenance therapy. Antilymphocyte therapy and the use of monoclonal antibodies are increasingly common in the immediate post-transplant period and for treating steroid-resistant rejection episodes.

Corticosteroids, primarily prednisone (Deltasone, others) and methylprednisolone (Solu-Medrol, others), are important agents. Corticosteroids suppress production of IL-1 and IL-2, decrease monocyte migration, and suppress proliferative and cytotoxic T-cell activity. Although they are very effective, large doses of corticosteroids used post-transplant are associated with significant adverse effects. Wound healing is impaired, and the metabolism of fats, proteins, and carbohydrates is altered. Blood glucose increases with steroid use, impairing glucose control. Fat distribution changes, producing a cushingoid appearance with a moon face, increased truncal

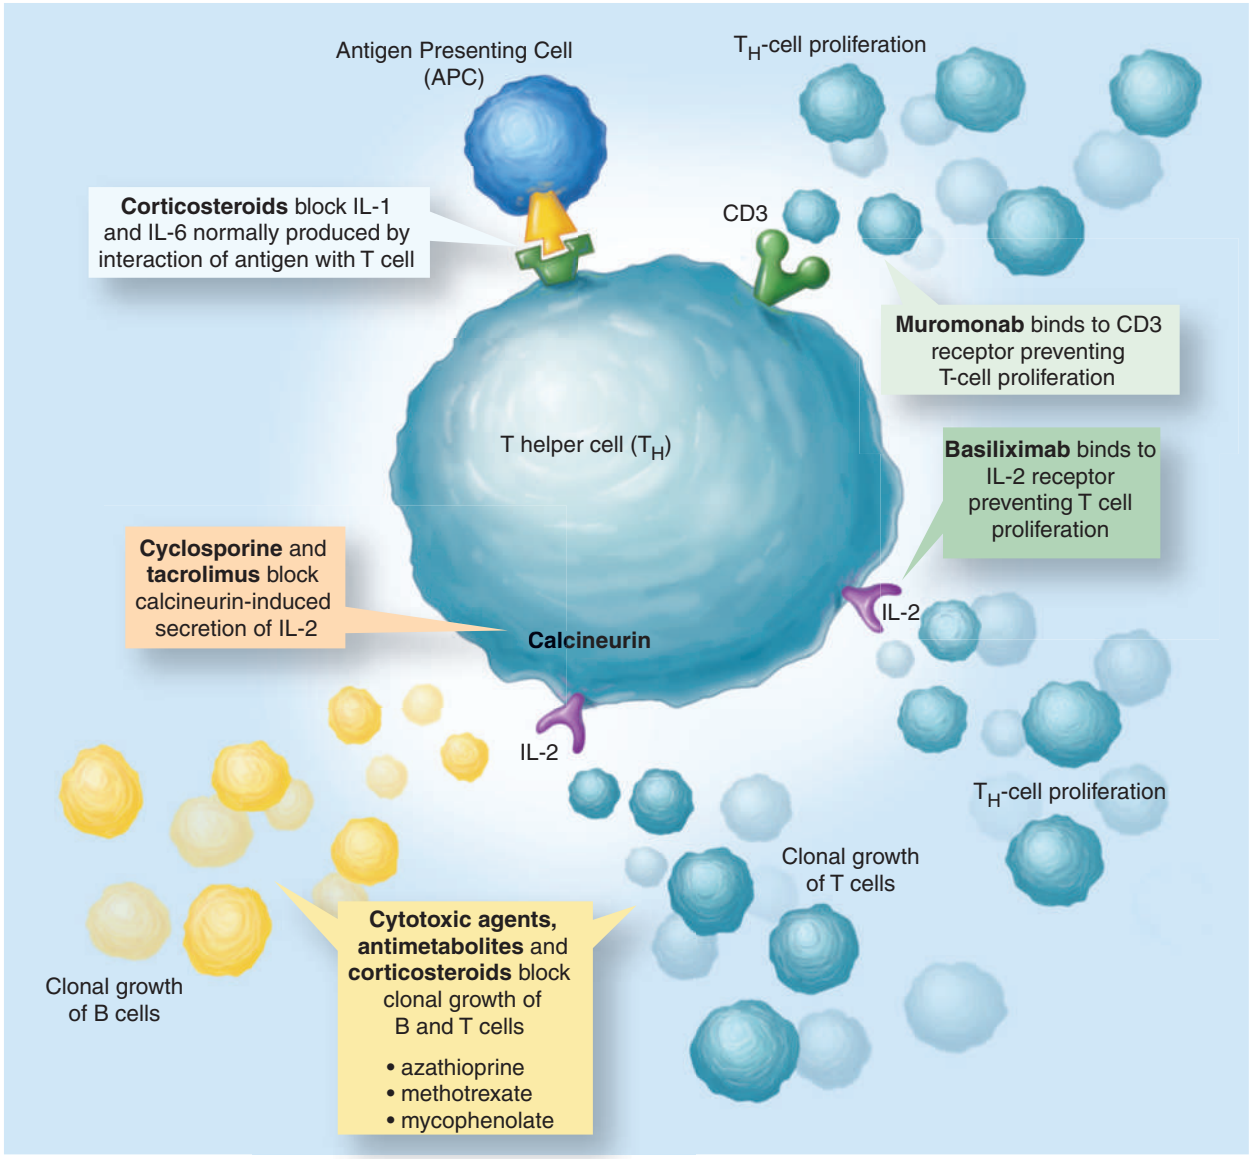

Figure 13–6 ■ Mechanism of action of immunosuppressive agents.

fat, and wasting of extremities. Fluid retention and hypertension are potential problems, as are osteoporosis, gastrointestinal bleeding, and emotional disturbances.

Cyclosporine and tacrolimus (Prograf) inhibit calcineurin, an enzyme necessary for the production of IL-2. As a result, B-cell and cytotoxic T-cell proliferation and the immune response are suppressed. The incidence of cyclosporine and tacrolimus toxicity and side effects is related to blood levels, so blood levels are monitored closely. These drugs are nephrotoxic, especially at high doses. Observable toxic effects include hypertension and central nervous system (CNS) symptoms such as headache, tremor, and insomnia. An increased risk for malignancy is associated with long-term use. Hepatotoxicity can develop with high doses of cyclosporine, particularly when administered intramuscularly.

Azathioprine (Imuran) inhibits DNA synthesis and proliferation of T cells and B cells, thus suppressing both cell-mediated and antibody-mediated immunity. Because azathioprine is rapidly metabolized by the liver, it can be given to patients with impaired renal function, but may not be effective in patients with impaired hepatic function. Bone marrow suppression is the most common adverse effect of this drug, necessitating frequent evaluation of the complete blood count (CBC). Hepatotoxicity and increased risk of neoplasm are also associated with azathioprine administration. Nursing responsibilities related to azathioprine are listed in the accompanying Medication Administration box. Patients who cannot tolerate azathioprine may receive a newer immunosuppressant, mycophenolate mofetil (CellCept).

Muromonab-CD3, also known as OKT3 or Orthoclone, is the first monoclonal antibody produced for therapeutic use in humans. As a monoclonal antibody, OKT3 is specific to T cells, blocking their generation and function. It binds with a surface antigen on T cells, inactivating and removing them from circulation. It also blocks cytotoxic T cells attached to the graft. Because of significant side effects, the use of OKT3 is limited primarily to treatment of steroid-resistant rejection. Newer monoclonal antibodies such as basiliximab (Simulect) and daclizumab (Zenapax) cause fewer side effects and are more widely used.

Polyclonal antilymphocyte antibodies are also used as adjunctive immunosuppressant therapy. Lymphocyte immune globulin (Atgam) is usually used in combination with corticosteroids and a cytotoxic drug such as azathioprine to prevent rejection of a kidney transplant.

●○● NURSING CARE

The patient who has an organ or tissue transplant has both immediate and long-term nursing care needs. Both the patient and the family must be considered in providing nursing care.

Health Promotion

Part of the health promotion activities focus on preventing the need for a tissue transplant. It is important to increase public awareness regarding unhealthy lifestyle behaviors, such as obesity and excessive alcohol consumption, and their relationship to chronic disease and organ failure. Patients with diabetes mellitus and hypertension must understand the importance of effectively managing these disorders to prevent end-stage renal disease. Other risk factors may simply relate to an individual's heredity; understanding how heredity could affect future health might influence the patient's lifestyle choices.

Assessment

Assessment data collected following a tissue transplant focus on identifying potential rejection episodes. Further focused assessments are described with nursing interventions in the Diagnoses, Outcomes, and Interventions section.

Priorities of Care

Because of the continuing risk of transplant rejection and the need for immunosuppression, *Ineffective Protection* and *Risk for Transplant Rejection* are priority nursing diagnoses.

Diagnoses, Outcomes, and Interventions

Nursing care for the patient undergoing a tissue transplant must address the patient's underlying disease process as well as the transplant surgery. The continuing need for immunosuppressive drug therapy also has emotional and psychologic consequences.

Ineffective Protection

Ineffective protection is a problem for the transplant patient at all stages. Before the transplant occurs, failure of the affected organ may put the patient at risk for infection and other multisystemic problems. Incisions and invasive perioperative procedures impair skin and mucous membrane protection from infectious organisms and other antigens. Immunosuppressive drugs given postoperatively to prevent graft rejection disarm the immune response to a certain extent, increasing the risk of infections and malignant growths.

Expected Outcome: Patient will remain free of infection.

SAFETY ALERT

Use strict aseptic technique when changing dressings and caring for invasive catheters such as intravenous lines and indwelling urinary catheters to protect against external and resident host microorganisms.

- Wash hands and use hand sanitizer on entering room and before providing direct care. *Hand hygiene removes transient organisms from the skin, reducing the risk of transmission to the patient.*
- Assess frequently for manifestations of infection. Monitor vital signs, including temperature, every 4 hours. Assess for evidence of inflammation, abnormal wound drainage, changes in urine or other body secretions, complaints of pain, or behavior changes that may indicate infection. Culture abnormal wound drainage. *The patient on immunosuppressive therapy is more susceptible to infection, and usual manifestations may not be evident. Both the body temperature and inflammatory response can be suppressed by therapy. Prompt identification and intervention for infection is important in the immunosuppressed patient.*
- Monitor laboratory values, including CBC and tests of organ function; report changes to the physician. *An elevation in the WBC count with increased numbers of immature cells (bands) or a decline in function of the transplanted organ (e.g., a rising BUN and creatinine in the patient with a kidney transplant) may be early indications of infection or transplant failure.*

MEDICATION ADMINISTRATION

Immunosuppressive Agents

CALCINEURIN INHIBITORS AND RELATED DRUGS

cyclosporine (Neoral, Sandimmune)

tacrolimus (Prograf)

sirolimus (Rapamune)

temsirolimus (Torisel)

These drugs inhibit IL-2 production and B-cell and T-cell development and activation. They are given concurrently with a glucocorticoid and in combination with other immunosuppressants and inhibit immune system activity and organ rejection.

Nursing Responsibilities

- Monitor BUN and creatinine for evidence of nephrotoxicity.
- Teach the signs and symptoms of infection unique to immunesuppressed individuals. A temperature of 38.1°C (100.6°F) is significant evidence of infection. A sore throat may be a manifestation. Other signs and symptoms of inflammation and infection may be absent.
- Teach hygiene measures to avoid infection with special emphasis on proper hand hygiene and avoidance of infected individuals.
- Monitor blood pressure and availability and use of antihypertensive medications.
- Teach to avoid grapefruit juice, which inhibits metabolism of these immunosuppressive drugs and increases the risk of toxicity. Lipid-lowering drugs may be necessary to prevent hyperlipidemias associated with these drugs.

CYTOTOXIC AGENTS

azathioprine (Imuran)

cyclophosphamide (Cytoxan)

mycophenolate (CellCept)

Cytotoxic agents act by decreasing the proliferation of cells within the immune system and are widely used to prevent rejection following a tissue or organ transplant. They are usually administered concurrently with corticosteroid therapy, allowing lower doses of both preparations and resulting in fewer side effects.

Nursing Responsibilities

- Monitor blood count, with particular attention to the WBC and platelet counts. Notify the physician if WBCs fall below 4000 or platelets below 75,000.
- Monitor renal and liver function studies, including creatinine, BUN, eGFR, creatinine clearance, and liver enzymes. Report abnormal levels to the physician.
- Administer the drug as ordered. Administer oral preparations with food to minimize gastrointestinal effects. Antacids may be ordered.
- Monitor intake and output.
- Monitor for signs of abnormal bleeding, bleeding gums, bruising, petechiae, joint pain, hematuria, and black or tarry stools.
- Use meticulous hand hygiene and other appropriate measures to protect the patient from infection. Assess for signs of infection.
- Pulmonary fibrosis is a rare (<1%) potential adverse effect of cyclophosphamides. Therefore, monitor respiratory function and for clinical signs of dyspnea or cough.

Health Education for the Patient and Family

- Increase fluids to maintain good hydration and urinary output; void frequently, and avoid taking the drug in the evening, which allows the drug to dwell in the bladder overnight.
- Avoid large crowds and situations where exposure to infection is probable.
- Report signs of infection, such as chills, fever, sore throat, fatigue, or malaise, to the physician.
- Use contraceptive measures to prevent pregnancy during treatment; these drugs are teratogenic.
- Avoid the use of aspirin or ibuprofen while taking these drugs. Report any signs of bleeding to the physician. Check labels: Many over-the-counter products contain aspirin.
- With cyclophosphamide, amenorrhea may occur.
- If taking cyclophosphamide, report difficulty breathing or cough to the physician.

MONOCLONAL ANTIBODIES

muromonab-CD3 (Orthoclone OKT3)

basiliximab (Simulect)

daclizumab (Zenapax)

alemtuzumab (Campath)

rituximab (Rituxan, MabThera)

belatacept (Nulojix, LEA 29Y)

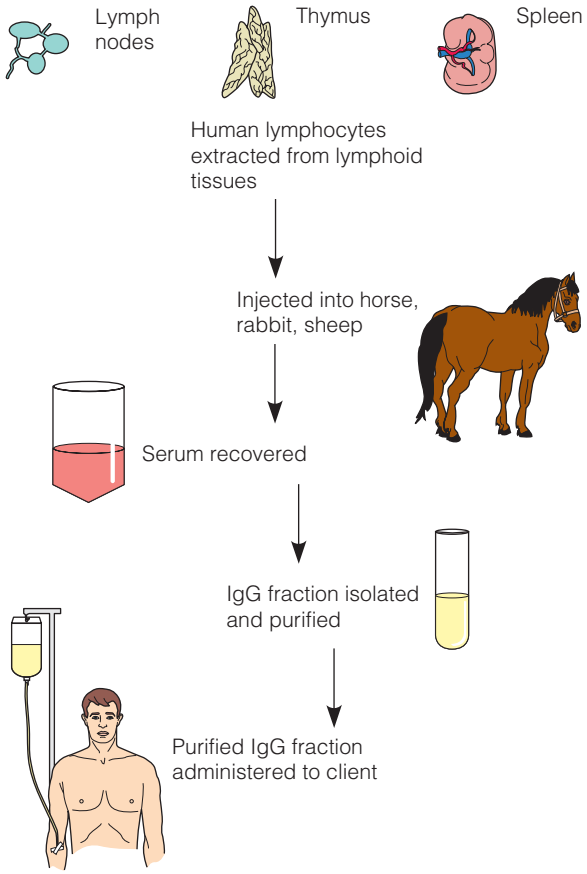
Monoclonal antibodies are formed in mice, and when injected into humans, bind with a surface antigen on T cells, and, in some cases, B cells and NK cells, preventing their activation and immune functions. Infusion reactions, acute hypersensitivity, and anaphylaxis may occur with these drugs: The patient should be closely observed for 2 hours following each dose. As with other immunosuppressive drugs, the risk for infection is increased.

Nursing Responsibilities

- Premedicate as ordered with hydrocortisone, acetaminophen, and diphenhydramine to reduce potential adverse effects.
- Observe for signs of infusion reaction, including chills, fever, rash, and hypotension. Acute hypersensitivity responses also may occur; observe for evidence of urticaria, angioedema, laryngeal edema, wheezing, or other signs of anaphylactic reaction.
- Ensure that emergency medications for resuscitation are in the patient's room or in proximity to it.
- Observe closely for potential adverse effects, including chills and fever; tachycardia; headache and tremor; hypertension or hypotension; nausea, vomiting, and diarrhea; chest pain, dyspnea, and wheezing.
- Monitor CBC for evidence of leukopenia or pancytopenia. Monitor kidney function (fluid balance, eGFR, BUN, creatinine) and liver function tests (alkaline phosphatase, ALT, AST, bilirubin). Monitor for signs of abnormal bleeding (easy bruising, bleeding gums, hematuria).
- Assess for infection.

Health Education for the Patient and Family

- Teach about the drug and its purpose.
- Discuss potential adverse and side effects, and emphasize the need to report symptoms promptly.
- Inform the patient that adverse effects are most likely to occur following initial doses, necessitating close observation at that time. Reassure the patient that this is standard protocol for this medication.



ANTILYMPHOCYTE GLOBULIN

lymphocyte immune globulin (Atgam, ATG)

Lymphocyte immune globulin contains antilymphocyte antibodies produced by immunizing horses with human lymphocytes to stimulate antibody production (see the illustration). Serum from the animal is then recovered, and the active IgG fraction is isolated, purified, and administered parenterally to the patient. It binds with peripheral lymphocytes and mononuclear cells, removing them from circulation. Lymphocyte immune globulin is used to prevent immediate transplant rejection and to treat steroid-resistant rejection episodes.

MEDICATION ADMINISTRATION (*continued*)

As with monoclonal antibodies, multiple side effects and a risk for anaphylaxis are associated with ATG.

A horse is inocultated with washed human lymphocytes, stimulating the production of immunoglobulin with poly anti-lymphocyte antibodies. These are then extracted from horse serum, purified, and administered intravenously to the patient

Nursing Responsibilities

- Premedicate as ordered with acetaminophen and diphenhydramine prior to each dose. Steroids may also be administered before the initial dose. Have epinephrine and hydrocortisone injections available at the bedside in case of anaphylactic reaction.
- Administer by intravenous infusion into a central line over 4 to 6 hours.
- Monitor vital signs hourly while medication is infusing.
- Assess for adverse effects, including chills and fever, erythema, and pruritus. Notify the physician; these may be treated symptomatically.
- Monitor CBC daily, notify the physician if WBC falls to less than 3000/mm^3 or platelet count to less than 100,000/mm^3. The medication may be stopped or reduced.
- Assess renal function studies to monitor for serum sickness. Report complaints of joint pain.
- Monitor for signs of infection, and report any signs promptly.

CORTICOSTEROIDS

prednisone

methylprednisolone (Medrol, Solu-Medrol)

Corticosteroids suppress lymphocyte activity and proliferation. They are immunosuppressants when given in large doses, but have dangerous adverse effects when used for a prolonged time. These include increased risk for infection, thinning of the skin, and osteoporosis and pathologic fractures. Other adverse reactions include hypertension, hyperglycemia, and psychosis. A few months after transplantation, patients may be weaned off corticosteroids without increasing the frequency of rejection episodes.

Health Education for the Patient and Family

- Explain the need for special precautions and close monitoring while this drug is being administered.
- Instruct the patient to report any adverse effects, including malaise or joint pain, promptly.
- Ask the patient to report any evidence of easy bruising, bleeding gums, or black stools.
- Teach family members about the importance of not exposing the patient to individuals with infectious diseases.

Note: Medications identified in *italics* are among the 200 most frequently prescribed drugs in the US.

- Initiate reverse or protective isolation procedures as indicated by the patient's immune status. *These procedures further protect the severely immunocompromised patient from infection.*
- Instruct ill family members and visitors to avoid contact with the patient. *A minor upper respiratory infection can be a significant illness in the immunocompromised host.*
- Help ensure adequate nutrient intake, offering supplementary feedings as indicated or maintaining enteral or parenteral nutrition if necessary. *Adequate nutrition is important for healing and immune system function.*
- Change intravenous bags and tubing at least every 24 hours, and change peripheral intravenous sites every 72 to 96 hours, unless contraindicated. Remove invasive catheters and lines as soon as they are no longer necessary. *Changing lines and sites is important to reduce bacterial contamination. Fewer invasive lines provide fewer sites for bacterial invasion of the body.*
- Emphasize the importance of meticulous hand hygiene after using the bathroom and before eating. *This reduces the risk of infection with endogenous organisms.*
- Provide good mouth care. *Good mouth care reduces the population of oral microorganisms and helps maintain an intact mucous membrane lining.*
- Monitor for potential adverse effects of medications:
  - Thrombocytopenia and possible bleeding
  - Fluid retention with edema and possible hypertension
  - Renal or hepatic toxicity
  - Cardiac effects, particularly in the presence of fluid retention and hypervolemia.

  Medications used to maintain immunosuppression and preserve the allograft have many potential adverse effects that can alter normal protective and homeostatic mechanisms.

Risk for Transplant Rejection

The risk for transplant rejection is highest in the initial postoperative period, but it is never completely eliminated for the patient who has had an allograft. The patient who has had a stem cell (or bone marrow) transplant has the additional risk of developing GVHD, which can affect the integrity of skin, mucous membranes, and other organs.

Expected Outcome: Patient's episodes of rejection will be detected early and effectively managed to preserve the integrity of the transplant.

- Administer immunosuppressive therapy as prescribed. *Suppression of the immune response is necessary to reduce the risk of graft destruction by normal immune responses and to preserve the graft's function.*
- Assess for evidence of graft rejection, including tenderness, erythema, and swelling over the site; sudden weight gain, edema, and hypertension; chills and fever; malaise; and an increased WBC count and sedimentation rate. Report any changes immediately. *Early identification of rejection allows adjustment of medication regimens and, possibly, preservation of the graft.*
- Monitor results of laboratory studies for function of the transplanted organ. *With a functional graft, results (e.g., renal or liver function studies) will improve; a functional decline may be an early indicator of rejection.*
- Assess for and report signs of GVHD immediately, including maculopapular rash, erythema of the skin and possible desquamation, hair loss, abdominal cramping and diarrhea, or jaundice with elevated bilirubin and liver enzymes (AST, ALT). *GVHD is a potentially lethal complication in the immunosuppressed patient and necessitates immediate intervention.*
- Stress the importance of maintaining immunosuppressive therapy and reporting signs of graft rejection promptly to the physician. *Continued immunosuppression and prompt treatment of rejection are vital to preserving graft function.*

Anxiety

The patient who undergoes an organ or tissue transplant often faces the unwelcome choices of death from organ failure or receiving an organ that his body will likely attempt to reject. In most cases, the patient understands that to receive this transplant, someone else must die and be willing to give up an organ. When the transplant comes from a living donor (bone marrow or kidney), the patient may worry not only about himself, but also about the condition of the donor. Fear of rejection and guilt may be even greater in this instance.

Expected Outcome: Patient will appropriately communicate needs, fears, and concerns.

- Assess level of anxiety by noting such cues as expressions of apprehension, fear, or inadequacy; facial expression, tension, or shakiness; difficulty focusing; helplessness; poor eye contact; and restlessness. *Patients may have difficulty identifying or verbalizing feelings of fear and anxiety. Nonverbal cues are often useful in recognizing states of anxiety.*
- Provide opportunities to express feelings. Use opening statements such as "Facing an organ transplant must be very stressful" or "What concerns you most about this transplant?" Listen attentively. *Encouragement and active listening allow the patient to express feelings of anxiety or fear.*
- Arrange tasks to allow as much time with the patient as possible. When leaving, tell the patient when you will return. *Time spent with the patient facilitates the development of trust.*
- Provide clear, concise directions. *Highly anxious patients have difficulty focusing and retaining information.*
- Encourage involvement in care but do not request unnecessary decisions. *The patient needs to feel a sense of control, but may become irritated if asked to make decisions unrelated to the situation.*
- Encourage family members to remain with the patient as much as possible. *This can help reduce the patient's anxiety.*
- Encourage the use of coping behaviors that have been effective for the patient in the past. *Coping mechanisms and behaviors help lower anxiety to a more acceptable level.*
- Reduce or eliminate environmental stressors to the extent possible. *This gives the patient a better sense of control.*
- Assist with stress reduction and relaxation techniques, such as guided imagery, meditation, and muscle relaxation. *These techniques help the patient gain control over physical responses to anxiety.*
- Refer to a counselor, mental health specialist, or spiritual adviser as appropriate. *Counseling can help the patient identify and deal with his or her concerns and fears.*

Delegating Nursing Care Activities

As appropriate and allowed by the designated duties and responsibilities of assistive personnel, the nurse may delegate nursing care activities such as measuring intake and output, obtaining daily weights, and assisting with ADLs for the patient undergoing organ or tissue transplant.

Continuity of Care

Teaching the patient and family about an organ or tissue transplant begins before the transplant and continues throughout hospitalization and follow-up treatment. Transplant coordinators are nurses specializing in the transplant process and are excellent resources for patients, families, and nursing staff.

Initial teaching focuses on the options, risks, and potential benefits of the transplant itself. Include the procedure by which the organ is selected and obtained, as well as the procedure by which it is transplanted into the patient. If a living related donor is an option, discuss the risks and benefits for both the patient and the donor. Outline the post-transplant treatment regimen, including any lifestyle changes that may be necessary. Being on a transplant registry is a tedious process; the patient must be ready to present for transplant when an organ is available. The transplant process is complex, expensive, and anxiety provoking.

Following the transplant, provide verbal and written instructions, including the following:

- Manifestations of transplant rejection and the importance of notifying the physician
- Immunosuppressive drug regimen and side effects
- Wound care
- Avoiding exposure to infectious diseases, particularly respiratory infections, and wearing a mask when going outside
- Meticulous personal hygiene, hand hygiene technique, and frequent mouth care
- Wearing a medical alert bracelet or tag
- Follow-up visits to the physician or clinic
- Helpful resources:
  - American Council on Transplantation
  - Local and state support groups related to specific organ transplant, such as the National Kidney Foundation.

Impaired Immune Responses

Disorders of impaired immune responses may be either congenital or acquired. The function of either T or B cells may be impaired, reducing the body's ability to defend against foreign antigens or abnormal host tissue.

No matter what the cause, patients with immunodeficiency disorders demonstrate an unusual susceptibility to infection. When the antibody-mediated response is primarily affected, the patient is at particular risk for severe and chronic bacterial infections. These patients do not develop long-lasting immunity to such diseases as chickenpox and may experience recurrent episodes. Patients with a defect of cell-mediated immunity tend to develop disseminated viral infections such as herpes simplex and cytomegalovirus (CMV). Candidiasis (yeast) and other fungal infections are also common. Because T cells are involved with activating antibody-mediated immune responses as well, overwhelming bacterial infections may occur. Immunodeficiency in its most severe form occurs when both antibody-mediated and cell-mediated responses are impaired. Patients with combined immunodeficiency are susceptible to all varieties of infectious organisms, including those not normally considered to be pathogens.

Most immunodeficiency diseases are genetically determined and rare. They affect children more than adults. The noted exception is AIDS, an infectious disease caused by a virus.

THE PATIENT WITH HIV INFECTION

In 1981, five cases of *Pneumocystis* pneumonia (PcP) and 26 cases of a rare cancer, Kaposi's sarcoma, were diagnosed in young, previously healthy homosexual males in Los Angeles and New York City. The term **acquired immunodeficiency syndrome (AIDS)** was used to describe the immune system deficits associated with these opportunistic disorders. Prior to this time, both PcP and Kaposi's had been seen only in older adults or debilitated or severely immunodeficient people. Other groups at risk for AIDS were soon identified: injection drug users, individuals with hemophilia, recipients of blood transfusions, and immigrants from Haiti. Research to identify the cause of this apparently new disease progressed feverishly, and in 1983, a common antibody was identified in patients with AIDS. The **human immunodeficiency virus (HIV)** was isolated in 1984. It then became apparent that AIDS was the final, fatal stage of HIV infection. HIV is a retrovirus transmitted by direct contact with infected blood and body fluids. Significant concentrations of the virus are present in blood, semen, vaginal and cervical secretions, and cerebrospinal fluid (CSF) of infected individuals. It is also found in breast milk and saliva.

It began, like so many epidemics, with a few isolated cases, and has become a worldwide plague. (See the Focus on Cultural Diversity box on page 316.) Progression of HIV disease to AIDS has slowed because of the effectiveness of antiretroviral therapy (ART; also referred to as combination antiretroviral therapy [cART] or highly active antiretroviral therapy [HAART]). Without treatment, chronic HIV infection progresses to clinical disease (AIDS) in about 10 years; with the advent of ART, a young HIV-infected person in the United States can potentially expect to live another 50 years (Fauci & Lane, 2012).

Although the incidence of HIV has leveled and mortality due to AIDS has declined, the epidemic is far from over. In the United States it continues to disproportionately affect African Americans, men who have sex with men (MSM), people who engage in high-risk heterosexual behavior (sex with individuals known to be infected with HIV or at high risk for having HIV), and injection drug users. AIDS data no longer accurately reflect trends in HIV infections; the progression to AIDS is now determined by the access, adherence, and response to ART. Because of this, AIDS data are useful in determining needs for care and treatment resources (Centers for Disease Control and Prevention [CDC], 2012a).

Incidence and Prevalence

Through 2010, the CDC (2012a) estimated that 1.2 million people in the United States were living with HIV/AIDS, with 20% undiagnosed and unaware of their HIV infection. There were 33,015 new cases of AIDS in 2010 in the United States. Deaths among people with AIDS had decreased from 50,610 in 1995 to 17,774 in 2009, more than likely the result of improved treatments rather than a decline in spread of the disease. A continued decline in deaths is dependent on access to quality care and treatment and continued development of alternatives for those experiencing treatment failure.

The risk factors for HIV infection are behavioral. Among adults in the United States, 61% of reported new HIV infections are MSM, including homosexuals, bisexuals, and such groups as prison populations. Unprotected anal intercourse is the major route of transmission in this group. Heterosexual intercourse also is a risk, accounting for an estimated 27% of new HIV infections in 2009 (CDC, 2012a). Injection drug use is another leading risk factor, accounting for approximately 17% of cases, with sharing of needles and other drug paraphernalia the primary route of transmission. Heterosexual intercourse with an infected drug user and exchanging sex for drugs are major risk factors for women. In the United States, HIV disproportionately affects African Americans and Hispanics/Latinos. See the accompanying Moving Evidence into Action box.

FAST FACTS

HIV/AIDS in the United States

- Whereas African Americans represent 14% of the population, they accounted for an estimated 44% of new HIV infections in 2009.
- HIV/AIDS is the ninth leading cause of death for African Americans (National Center for Health Statistics, 2011).
- The rate of new HIV infections among Black men is an estimated 6 1/2 times that of White men; among Black women, the new infection rate is 15 times that of White women.
- Hispanics/Latinos represent 16% of the population but accounted for 20% of new HIV infections in 2009.
- Among Hispanic/Latino men, the rate of new infections is more than twice that of White men; Hispanic/Latina women have a new infection rate that is 4 1/2 times that of White women (CDC, 2012b).

Moving Evidence into Action

Sexual Assertiveness as a Risk Factor for HIV Infection

African American women are disproportionately affected by HIV infection; the rate of new HIV infection among African American women is 15 times that of Caucasian women (CDC, 2012a). It is estimated with nearly two-thirds of women affected by HIV/AIDS are African Americans. In most cases, the infection is transmitted through unprotected sexual contact with an infected male. In a sexual encounter, women must assert themselves to negotiate condom use. Kennedy and Jenkins (2011) provide an analytical review of published research on sexual assertiveness among African American women and its relationship to disparities in HIV infection. Three main themes emerged in the literature review: (1) Sexual assertiveness, the most significant predictor of condom use, is related to the risk for HIV infection in African American women; (2) communicating preferences and negotiating condom use in the heterosexual relationship requires sexual assertiveness; and (3) women who are sexually unassertive are at risk for HIV infection because their partners are less likely to use condoms.

Implications for Nursing

The prevalence of HIV infection among African American women demands that nurses and other healthcare professionals address health promotion and disease prevention strategies with women at risk. Risk factors such as substance abuse, depression, victimization, and posttraumatic stress disorder need to be assessed on entry into care. HIV/AIDS prevention strategies and programs addressing communication, sexual negotiation, behavioral strategies, and empowerment should be culturally appropriate and gender tailored.

Moving Knowledge into Action

1. Identify specific ways in which an HIV/AIDS prevention program focusing on sexual assertiveness and negotiation and condom use might be tailored to African American women.
2. How might the program differ if the audience were primarily Hispanic women?
3. What additional areas for research might further knowledge and guide strategies for HIV prevention in women in high-risk groups?

FOCUS ON CULTURAL DIVERSITY

HIV/AIDS

- An estimated 34 million people are infected with AIDS worldwide, with virtually every country in the world reporting cases (World Health Organization [WHO], 2011). The highest incidence is found in sub-Saharan Africa, South and Southeast Asia, the United States, western Europe, South America, and Canada.
- Over 60% of all people infected with HIV or who have AIDS live in sub-Saharan Africa, and another 15% live in South and Southeast Asia, largely in Thailand and India.
- The most common mode of transmission is heterosexual intercourse. The cofactors that increase the risk of HIV transmission include the presence of ulcerative or inflammatory sexually transmitted infections, trauma, menses, and lack of male circumcision (Zolopa & Katz, 2012).

Although HIV/AIDS is often thought of as a disease affecting young adults, adults over age 50 account for approximately 30% of individuals living with AIDS in the United States (CDC, 2011b). Survival of individuals infected earlier in their life accounts for a significant portion of these adults. Older adults, while continuing to be sexually active, may not see themselves as being at risk for HIV/AIDS and fail to use condoms or practice safer sex. In 2011, however, 17% of new HIV/AIDS diagnoses were in people ages 50 and older (CDC, 2011b) Manifestations may be overlooked by healthcare professionals, leading to a delayed diagnosis and increased severity of the disease.

It is clear that HIV is not transmitted by casual contact, nor is there any evidence of its transmission by vectors such as mosquitoes. Blood donation poses no risk of contracting HIV to the donor, because only new sterile equipment is used. A small but real occupational risk exists for healthcare workers. Percutaneous exposure to infected blood or body fluids through a needlestick injury or nonintact skin is the primary route of transmission. Documented evidence indicates that parenteral exposure poses a 1:300 risk of becoming HIV positive (Fauci & Lane, 2012). Mucosal exposures, such as splashing in the eyes or mouth, pose a much smaller risk.

Pathophysiology and Manifestations

HIV is a retrovirus, meaning it carries its genetic information in RNA. On entry into the body, the virus infects cells that have the CD4 antigen (T lymphocytes). Once inside the cell, the virus sheds its protein coat and uses an enzyme called *reverse transcriptase* to convert the RNA to DNA (Figure 13–7 ■). This viral DNA is then integrated into host cell DNA and duplicated during normal processes of cell division. Within the cell, the virus may remain latent or become activated to produce new RNA and to form *virions*. The virus then buds from the cell surface, disrupting its cell membrane and leading to destruction of the host cell.

Although the virus may remain inactive in infected cells for years, antibodies are produced to its proteins, a process known as **seroconversion**. These antibodies are usually detectable 6 weeks to 6 months after the initial infection. Helper T or CD4 cells are the primary cells infected by HIV, but it also infects macrophages, dendrites, and certain cells of the CNS. Helper T cells play a vital role in normal immune system function, recognizing foreign antigens and infected cells and activating antibody-producing B cells. They also direct cell-mediated immune activity and influence the phagocytic activity of monocytes and macrophages. The loss of these helper T cells leads to the immunodeficiencies seen with HIV infection. Figure 13–8 ■ illustrates the typical course of untreated HIV infection.

The manifestations of HIV infection range from no symptoms to severe immunodeficiency with multiple opportunistic infections and cancers (see the Pathophysiology Linkage box on page 318). Most patients develop an acute mononucleosis-type illness within days to weeks after contracting the virus. Typical manifestations include fever, sore throat, arthralgias and myalgias, headache, rash, and lymphadenopathy. Pathologic changes are also noted in the CNS of many infected individuals although the mechanism of neurologic dysfunction is unclear. The patient may also experience nausea, vomiting, and abdominal cramping. The patient often attributes this

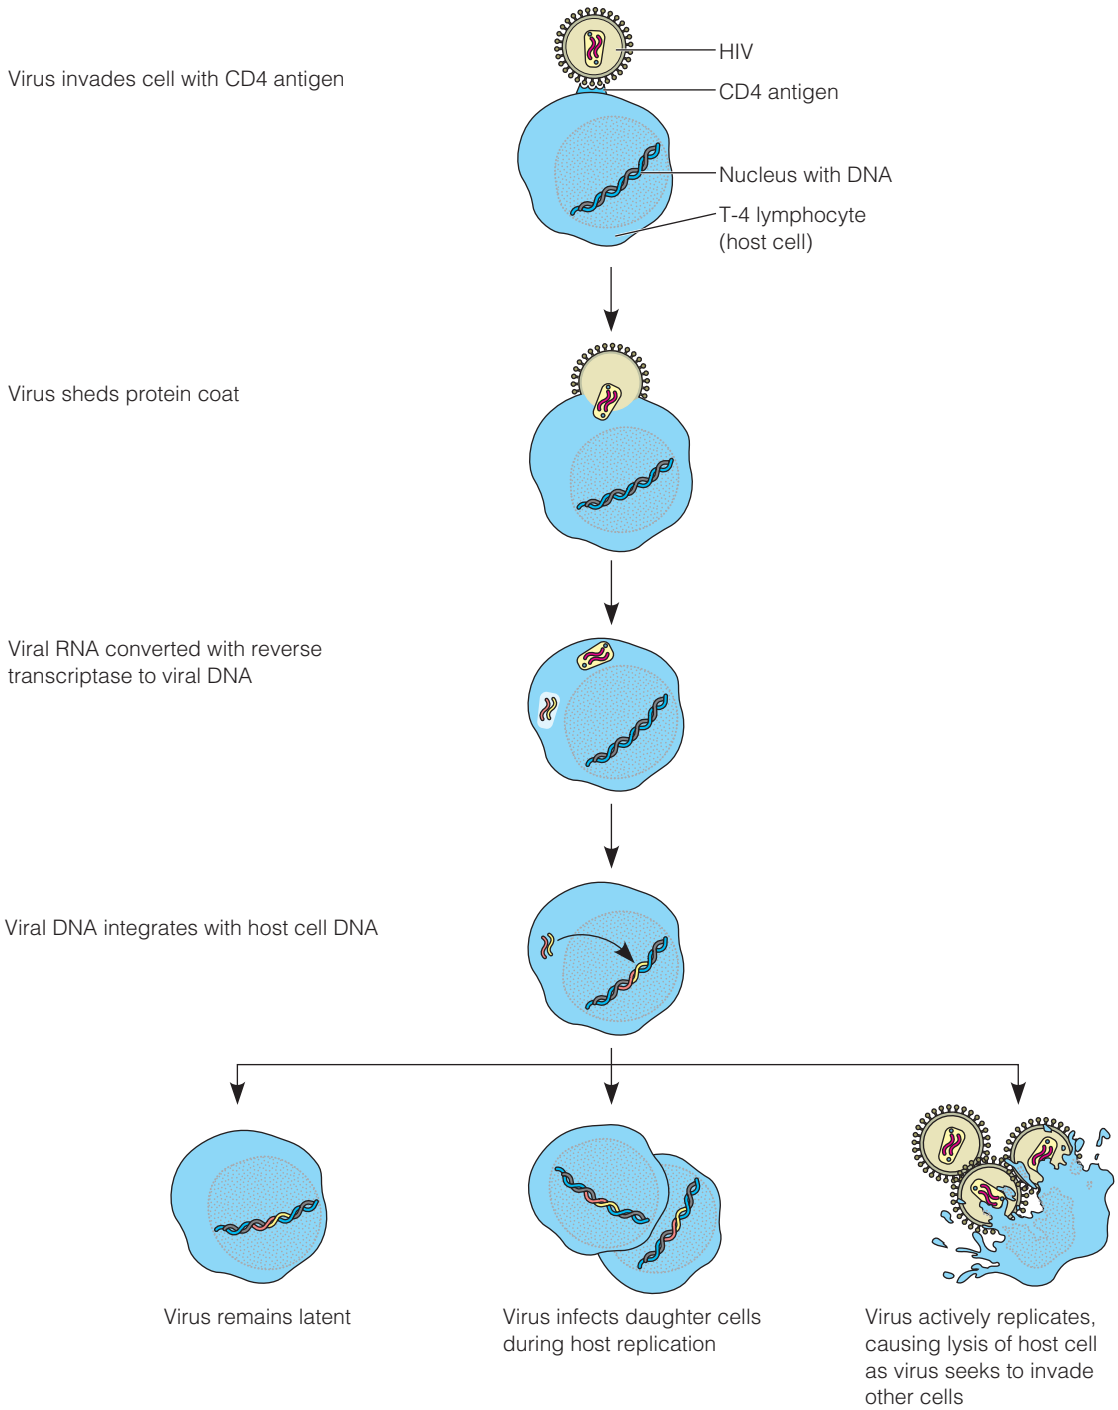


Figure 13–7 ■ How HIV infects and destroys CD4 cells.

initial manifestation of HIV infection to a common viral illness such as influenza, upper respiratory infection, or stomach virus.

Following this acute illness, patients who are treated enter a prolonged asymptomatic period. Although the virus is present and can be transmitted to others, the infected host has few or no symptoms. Most HIV-infected individuals are in this stage of the disease. The length of the asymptomatic period varies widely, but its mean length is estimated to be 8 to 10 years in untreated individuals and significantly longer in those undergoing ART.

Some patients with few other symptoms develop persistent generalized lymphadenopathy. This is defined as enlargement of two or more lymph nodes outside the inguinal chain with no other illness or condition to account for the lymphadenopathy.

The move from asymptomatic disease or persistent lymphadenopathy to AIDS is defined by a CD4 T-cell count of less than 200/mcL, with or without the presence of opportunistic disease (Fauci & Lane, 2012). The patient may complain of general malaise, fever, fatigue, night sweats, and involuntary weight loss (Figure 13–9 ■). Persistent skin dryness and rash may be a problem. Diarrhea is common, as are oral lesions such as hairy leukoplakia, candidiasis, and gingival inflammation and ulceration. With the development of significant constitutional disease, neurologic manifestations, or opportunistic

PATHOPHYSIOLOGY LINKAGE

HIV Infection/AIDS

Manifestations	Related Pathophysiology
Acute retroviral syndrome (ARS) or primary HIV infection: fever, sore throat, arthralgias and myalgias, headache, rash, nausea, vomiting, and abdominal cramping Difficult to diagnose; similar to infectious mononucleosis	This is the first phase in the natural history of HIV disease beginning about 14 days after infection. Virus disseminates to lymphoid tissue (nodes, spleen, GALT) where target CD4 T cells are concentrated. These cells are infected with a high load of rapidly replicating HIV RNA during ARS. Persistent generalized lymphadenopathy develops and the lining of the intestine is damaged. Antibodies cannot be detected for 6 weeks to 6 months but the infected patient is highly contagious.
Asymptomatic infection (latency): from 3 years to more than 15 years, depending on availability and adherence to treatment with antiretroviral medications	A strong cell-mediated and humoral anti-HIV immune defense decreases viral load in the blood. However the virus harbors and continues to replicate in lymphoid and neurologic tissues. In untreated patients, the number of CD4 T cells declines during this period; this decline may be abrupt or gradual.
AIDS: systemic manifestations (general malaise, fatigue, low-grade fever, night sweats, involuntary weight loss, skin dryness, or rashes); opportunistic infections and neoplasms	As the T4 cells fall below 200/mm^3, virus titers rise rapidly and immune activity drops precipitously. It is the loss of immune competence that enables normally benign opportunistic parasites such as viruses, fungi, or protozoa to cause infections. Malignancies develop as immune surveillance fails.

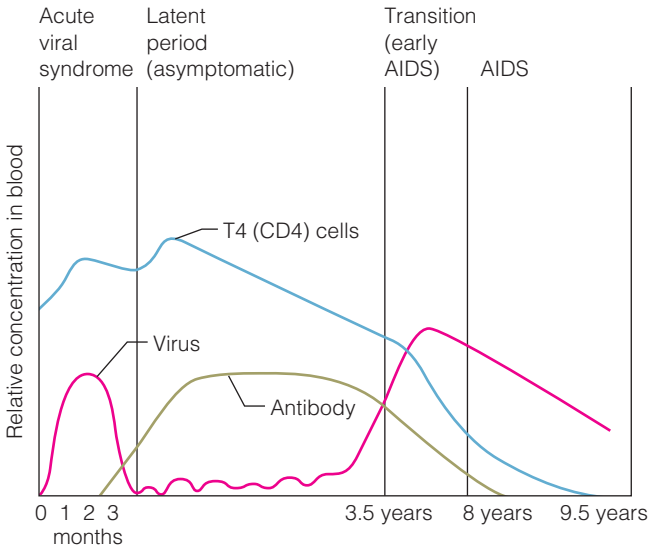

Figure 13–8 ■ The progression of untreated HIV infection. Acute illness develops shortly after the virus is contracted, corresponding with a rapid rise in viral levels. Antibodies are formed and remain present throughout the course of infection. Late in the disease, viral activation results in a marked increase in virus, while CD4 cells diminish as they are destroyed with viral replication. Antibody levels gradually decrease as immune function is impaired.

infections or cancers, the patient has manifestations that are characteristic of AIDS and a very poor prognosis. When manifestations develop, the outcome varies. Antiretroviral therapy is credited with prolonging the asymptomatic period of HIV disease, decreasing the incidence of opportunistic infections, and improving survival (Zolopa & Katz, 2012).

NEUROLOGIC EFFECTS

Neurologic problems attributable to HIV include inflammatory, demyelinating, and degenerative changes (Fauci & Lane, 2012). They result from both the direct effects of the virus on the nervous system and opportunistic infections.

Figure 13–9 ■ Generalized wasting in a patient with AIDS.

HIV-associated neurocognitive disorders (HAND) are a complex of neurologic manifestations of the HIV infection itself. These include disruptions of motor function as well as cognitive, behavioral, and psychosocial symptoms (Grossman & Porth, 2014). HIV-associated dementia (HAD; formerly called *AIDS dementia complex*), usually a late complication of HIV disease, is characterized by fluctuating memory loss, confusion, difficulty concentrating, lethargy, and diminished motor speed. Patients become apathetic, losing interest in work and social and recreational activities. As the complex progresses, the patient develops severe dementia with significant intellectual impairment and motor disturbances, ultimately entering a nearly vegetative state (Fauci & Lane, 2012; Grossman & Porth, 2014).

Infections and lesions common with AIDS may also affect the CNS. Toxoplasmosis and non-Hodgkin's lymphoma are space-occupying lesions that may cause headache, altered mental status, and neurologic deficits. Cryptococcal meningitis and CMV infection also are common in people with AIDS. CNS complications have declined with the use of ART (Zolopa & Katz, 2012).

OPPORTUNISTIC INFECTIONS

Opportunistic infections are the most common manifestation of AIDS, often occurring simultaneously. The risk of opportunistic

infections is predictable by the CD4 T-cell count. The normal CD4 T-cell count is greater than 1000/mcL. When the CD4 count falls to less than 500/mcL, manifestations of immunodeficiency are seen. With a count of less than 200/mcL, opportunistic infections and cancers are likely.

PNEUMOCYSTIS PNEUMONIA *Pneumocystis* pneumonia (PcP) is the most common pneumonia affecting patients with AIDS. PcP is an opportunistic infection; it rarely develops when the CD4 count is above 250/mcL (Zolopa & Katz, 2012). PcP is caused by *P. jiroveci*, a common environmental organism that is not pathogenic in patients with intact immune systems. Unlike many pneumonias, the manifestations of PcP are nonspecific and may progress insidiously. Patients often present with fever, cough, dyspnea, tachypnea, and tachycardia. Complaints of mild chest pain and sputum may also be present. Breath sounds may initially be normal. With severe disease, the patient may present with cyanosis and significant respiratory distress. The most common cause of pulmonary disease in individuals with HIV infection who have been treated with ART is community-acquired bacterial or viral pneumonia rather than PcP (Zolopa & Katz, 2012).

TUBERCULOSIS An estimated 4% of patients with AIDS develop tuberculosis (TB), contributing significantly to the rise in incidence of this disease in the United States (Zolopa & Katz, 2012). In some patients, active TB results from reactivation of a prior infection. In other patients, it is a new, primary disease facilitated by impaired immune function. Worldwide, TB is the leading cause of death among those with HIV infections (CDC, 2011a). Rapid progression, diffuse pulmonary infiltrates, and disseminated disease occur more commonly in patients with AIDS. Multiple-drug-resistant strains of tuberculosis present a significant problem.

Patients with pulmonary TB present with a cough productive of purulent sputum, fever, fatigue, weight loss, and lymphadenopathy. Disseminated disease affects the bone marrow, bone, joints, liver, spleen, CSF, skin, kidneys, gastrointestinal tract, lymph nodes, brain, and other sites.

OTHER INFECTIONS Herpes virus infections are common in patients with AIDS and may be severe. CMV can affect the retina, gastrointestinal tract, or lungs. Disseminated herpes simplex or herpes zoster may occur, although severe mucocutaneous manifestations are more common.

Even for patients receiving ART, sinusitis is common and often frustrating. It manifests as headache, fever, and sinus congestion and discharge. Treatment includes antibiotics and guaifenesin to reduce sinus congestion.

Parasitic infections with *Toxoplasma gondii* and *Cryptococcus neoformans* commonly affect the CNS. Toxoplasmosis occurs as encephalitis or an intracerebral mass lesion. Changes in mental status, focal neurologic signs, and seizures may result. *Cryptococcus* infection may present as either meningitis or disseminated disease, primarily affecting the lungs. *Cryptosporidium*, a protozoon affecting the gastrointestinal tract, is an important cause of prolonged diarrhea in patients with AIDS. Bacterial salmonella infections are also a relatively common cause of diarrhea.

Candida albicans infection is a common opportunistic infection in patients with AIDS. It is usually manifested as oral thrush or esophagitis. Oral thrush presents as white, friable plaques on the buccal mucosa or tongue and, in the patient with HIV infection, is often an early indication of progression to AIDS. Patients with esophagitis have difficulty swallowing and substernal pain or burning that increases with swallowing. Vaginal candidiasis is more common and more severe in women with HIV and is treated with topical or systemic medication.

Women with AIDS have a high incidence of pelvic inflammatory disease (PID). Although the pathogens appear to be the same as those in PID affecting non–HIV-infected women, the disease is more severe. Inpatient treatment with intravenous antibiotics is often necessary.

SECONDARY CANCERS

As cell-mediated immune function declines, the risk of malignancy increases. The CDC classification of AIDS currently includes three cancers: Kaposi's sarcoma, non-Hodgkin's lymphoma, and invasive cervical carcinoma. Hodgkin's lymphoma is also common (Fauci & Lane, 2012; Zolopa & Katz, 2012).

KAPOSI'S SARCOMA Early in the epidemic, **Kaposi's sarcoma (KS)** was often the presenting symptom of AIDS. With the advent of ART, it is seen in fewer than 1% of patients with HIV. Kaposi's sarcoma is caused by a herpes virus transmitted primarily through sexual contact; men who have sex with men are more likely to be infected with the virus responsible for KS. KS also may develop in people whose immune system is suppressed due to immunosuppressive medications.

A tumor of the endothelial cells lining small blood vessels, KS presents as vascular macules, papules, or violet lesions affecting the skin and viscera (Figure 13–10 ■). The palate, toe webs, the face (especially the tip of the nose and pinnae of the ears), and visceral organs including the gastrointestinal tract, lungs, and lymphatic system are common sites for KS lesions.

The lesions of KS are initially painless, but may become painful as the disease progresses. Internally, the tumors may obstruct organ function or cause bleeding. When the lungs are involved, gas exchange may be severely impaired, resulting in pulmonary hemorrhage. Rapidly progressing KS is treated with chemotherapy; milder forms may improve with the initiation of ART (Zolopa & Katz, 2012).

LYMPHOMAS Lymphomas are malignancies of the lymphoid tissue, including lymphocytes, lymph nodes, and the lymphoid organs such

Figure 13–10 ■ Kaposi's sarcoma lesions.
Source: BSIP/UIG/Getty Images

as the spleen and bone marrow. Lymphomas are a late manifestation of HIV disease; the risk of lymphoma development increases with the duration of the disease, even with effective ART. The CNS is a common site for these lymphomas, although they may be found in the bone marrow, gastrointestinal tract, liver, skin, and mucous membranes. They are aggressive tumors, growing and spreading rapidly. Headache and changes in mental status are common early symptoms of lymphomas affecting the CNS. Hodgkin's lymphoma also occurs five times more frequently in patients with HIV infection than in those without (Zolopa & Katz, 2012).

CERVICAL CANCER Cervical cancer develops frequently in women with HIV infection and tends to be aggressive. Women with concurrent HIV infection and cervical cancer usually die of the cervical cancer, not AIDS. Because of this, it is recommended that women with HIV infection have Papanicolaou (Pap) smears every 6 months and aggressive treatment of cervical dysplasia with colposcopic examination and cone biopsy.

OTHER HIV/AIDS-ASSOCIATED DISEASES

With the advances in ART, AIDS has become a chronic disease and patients face increased risk for developing cardiovascular and other diseases.

CARDIOVASCULAR COMPLICATIONS Coronary heart disease (CHD), the leading cause of death in the United States, affects a significant percentage of patients with HIV infection. Dyslipidemia (high cholesterol, high triglycerides, low levels of high-density lipoproteins, high levels of low-density lipoproteins) and smoking, both major risk factors for CHD, are more common in patients with HIV infection than in those unaffected by HIV. CD4 counts lower than 500/mcL appear to be an independent risk factor for CHD, possibly due to the positive effect of viral replication on coagulation (Fauci & Lane, 2012).

HEPATIC COMPLICATIONS An estimated one-third of deaths in patients with HIV infection can be attributed to liver disease. As many as 90% of U.S. patients with HIV infection also are or have been infected with the hepatitis B virus; infection with HCV and other hepatitis viruses is common. Antiretroviral therapy also can have negative effects on the liver, resulting in injury (Fauci & Lane, 2012).

HIV-ASSOCIATED NEPHROPATHY Nephropathy is a kidney disorder. HIV-associated nephropathy (HIVAN) is a complication of HIV infection that disproportionately affects African Americans and Hispanics/Latinos. It manifests as excessive protein in the urine, excessive nitrogen in the blood (azotemia), normal-to-large kidneys on ultrasound images, normal blood pressure, and glomerular lesions revealed by renal biopsy. Before ART, nephropathy rapidly progressed to renal failure and end-stage renal disease (ESRD), leading to the need for dialysis. HIVAN remains the leading cause of ESRD in patients with HIV infection (Fauci & Lane, 2012).

●○● INTERPROFESSIONAL CARE

Although multiple research studies to identify a cure for HIV infection and AIDS are under way, no cure is currently available. This makes prevention a vital strategy in HIV care. Search for a vaccine has not been successful to date. The FDA recently moved to approve daily use of an antiretroviral drug combination (Truvada, a combination of emtricitabine [Emtriva] and tenofovir disoproxil fumarate [Viread]) to prevent HIV infection in people at high risk, including gay and heterosexual partners of an individual with HIV infection. The drug is not a "magic bullet"; however, when used in combination with condoms and counseling, it significantly reduced the risk of infection in healthy gay and bisexual men, and in heterosexual couples in which one partner was infected (Perrone, 2012).

The goals of care for the patient with HIV disease are as follows:

- Early identification of the infection and determination of appropriate treatment
- Promotion of health maintenance activities to prolong the asymptomatic period as long as possible
- Prevention of opportunistic infections
- Treatment of disease complications, such as cancers
- Provision of emotional and psychosocial support.

DIAGNOSIS

Diagnostic testing is used to screen for and identify the infection, as well as to monitor the patient's disease and immune status. When a preliminary, positive rapid test is explained to patients, phrases like "a possibility of being infected" or "false-positive results do occur" can be used to indicate the likelihood of HIV infection based on the HIV prevalence in the setting and the patient's individual risk. Confirmation of positive results is required with an ELISA or Western blot antibody test. See Box 13–2 for current recommendations for HIV testing based on CDC and WHO guidelines.

BOX 13–2 Current Recommendations for HIV Testing of Adults and Adolescents

1. All HIV testing should be voluntary; verbal informed consent is sufficient. Testing is confidential, and accompanied by appropriate pretest information and post-test counseling. Mechanisms should be in place to ensure correct, high-quality test results. Referral to appropriate prevention, care, and treatment services should be provided as indicated.
2. All individuals entering a healthcare setting, including primary and antenatal care, outpatient facilities, family planning, and sexually transmitted infection (STI) clinics, should receive routine, voluntary screening for HIV, regardless of risk.
3. All patients seeking treatment for STIs and all patients beginning treatment for TB should be screened for HIV.
4. Healthcare providers should encourage patients and their prospective sex partners to be tested before initiating a new sexual relationship or after a separation. Partners and family members of patients with HIV should be tested as soon as possible after the diagnosis.
5. Repeat HIV screening should be performed for patients with known risk at least annually. Individuals likely to be at high risk include injection drug users and their sex partners, individuals who exchange sex for money or drugs, sex partners of individuals with HIV infection, men who have sex with men (MSM), transgender people, and heterosexual individuals who themselves or whose sex partners have had more than one sex partner since their most recent HIV test.

Source: Centers for Disease Control and Prevention. (2006). *Revised recommendations for HIV testing of adults, adolescents, and pregnant women in health-care settings.* Retrieved from http://www.cdc.gov/mmwr/preview/mmwrhtml; World Health Organization. (2013). *HIV testing and counseling: Consolidated ARV guidelines, June 2013.* Retrieved from http://www.who.int/hiv/pub/guidelines/arv2013/clinical/testingintro/en/index8.html.

- *HIV rapid antibody test*. The rapid tests consist of test strips with embedded HIV antigen. If antibodies to HIV are found in the patient's blood, the strip turns a color indicating the test is positive. The results are interpreted visually and are widely used because results can be given immediately. Personnel without formal laboratory training (point-of-care testing) can perform rapid antibody tests. Although positive results must be confirmed with further testing, learning results immediately gives the patient important information to make wise choices about his or her behaviors and self-care.
- *Enzyme-linked immunosorbent assay (ELISA)* is the most widely used screening test for HIV infection. ELISA tests for HIV antibodies; it does not detect the virus. Therefore, a patient may have a negative ELISA test early in the course of infection, before detectable antibodies have developed. The test has a 99.5% or higher sensitivity when performed at least 13 weeks after infection (Fauci & Lane, 2012; Kee, 2014). This means that more than 99.5% of tests performed on blood containing HIV antibodies will show a positive result. False positives can occur; therefore, an initial positive result is always retested and confirmed using a different method of antibody detection, usually the Western blot.
- *Western blot antibody testing* is more reliable but more time consuming and more expensive than ELISA. When combined with ELISA, however, a specificity of greater than 99.9% is achieved. Specificity is a measure of the probability that a negative test result indicates that no antibodies are present. In this test, the patient's serum is mixed with HIV proteins to detect reaction. If antibodies to HIV are present, a detectable antigen–antibody response will occur.
- *HIV viral load tests* measure the amount of actively replicating HIV. Levels correlate with disease progression and response to antiretroviral medications. Several tests are available; the most commonly used are the RT-PCR assay and the bDNA assay to identify the number of HIV RNA copies in plasma or blood (Fauci & Lane, 2012).
- *CBC* is performed to detect anemia, leukopenia, and thrombocytopenia, which are often present in HIV infection. Lymphopenia (or low levels of lymphocytes) is especially common in this disease.
- Absolute *CD4 lymphocyte count* is the most widely used test to monitor the progress of the disease and guide therapy. The CD4 cell count correlates very closely with the immunodeficiency disorders seen in AIDS. AIDS is now defined not only by the presence of opportunistic infections and other diseases indicative of immunodeficiency, but also by HIV-seropositive status and a CD4 count of less than 200/mm^3 or a percentage of CD4 lymphocytes of less than 14%. CD4 counts are recommended every 3 to 6 months for all people with HIV disease.
- *HIV drug-resistance testing* is recommended when patients with HIV infection enter into care, regardless of when ART will be initiated (Panel on Antiretroviral Guidelines for Adults and Adolescents, 2012). HIV readily mutates to become resistant to antiretroviral drugs; the use of assays to determine antiretroviral drugs to which the virus is likely to be sensitive or resistant has become the standard of care helping guide ART.

Other diagnostic tests are used primarily to detect secondary cancers and opportunistic infections in the patient with HIV. Tests ordered are both general and specific to the patient's manifestations and may include the following:

- *Tuberculin skin testing* to detect possible tuberculosis infection
- *MRI* of the brain to identify lymphomas
- *Specific cultures and serology examinations for opportunistic infections* such as PcP, toxoplasmosis, and others
- *Pap smears* every 6 months for early detection of cervical cancer in women with cervical dysplasia.

MEDICATIONS

Pharmacologic management of the patient with HIV disease has four primary goals: (1) to suppress the infection itself, decreasing symptoms and prolonging life; (2) to provide prophylaxis of opportunistic infections; (3) to stimulate hematopoietic response; and (4) to treat opportunistic infections and malignancies. Today the drugs have been combined and dosing schedules simplified, which helps patients adhere to medication administration schedules (Hodder et al., 2010; Juday et al., 2011).

The Panel on Antiretroviral Guidelines for Adults and Adolescents (2012) and the International AIDS Society—USA Panel (Thompson et al., 2010) strongly recommend initiation of treatment when the CD4 count falls to 500/mm^3 or lower. Treatment should be initiated regardless of CD4 count in patients who are symptomatic (e.g., have an AIDS-defining disease), are co-infected with hepatitis B, have HIV-associated neuropathy, and in women who are pregnant. Effectiveness of treatment is monitored by viral load and CD4 cell counts; positive results are indicated by a reduction in viral load along with preserving the CD4 count above 350/mm^3. Starting treatment before immune failure, when the CD4 count is above 500 or 1000, may protect the immune system.

The action of antiretroviral drugs can be broadly classified as agents that inhibit replication of the virus, and agents that block entry of the virus into cells. Nucleoside/nucleotide reverse transcriptase inhibitors (NRTIs), nonnucleoside reverse transcriptase inhibitors (NNRTIs), protease inhibitors (PIs), and integrase inhibitors (INSTIs) inhibit enzymes required for viral replication. Fusion inhibitors and CCR5 antagonists, in contrast, interfere with viral entry into cells. The current standard of treatment is a combination of three or more antiretroviral drugs from at least two different classes (Zolopa & Katz, 2012). Combination therapies increase the likelihood of decreasing viral load, and adherence to administration schedules has been eased by making various combinations available in one pill (Hodder et al., 2010; Juday et al., 2011). Patients beginning the ART protocol must understand the benefits, risks, costs, and effects on daily life. ART does not eradicate HIV infection.

ART medications are expensive; the newer triple combinations such as Trizivir (one pill twice a day) and Atripla (one pill once a day) have a wholesale price of between $1670 and $2080 for a 30-day supply (Panel on Antiretroviral Guidelines for Adults and Adolescents, 2012). This cost does not include medications to prevent or treat opportunistic infections or cancer. In most cases, available fixed-dose combinations of ART drugs allow daily or twice-a-day dosing, simplifying treatment regimens. However, all ART medications cause significant adverse reactions leading to less than perfect adherence, as with most chronic diseases; in the case of HIV, however, the outcome could be fatal.

Each patient must be able to adhere to the treatment regimen. It may be preferable to delay initiating therapy until the patient is able

NURSING CARE OF THE OLDER ADULT

HIV Infection

The number of older adults with HIV infection is increasing. Two factors contributing to this increase are that people with HIV infection are healthier and living longer, and older adults are less likely to use condoms, perceiving less risk of pregnancy and STIs. Consequently, the Panel on Antiretroviral Guidelines for Adults and Adolescents (2012) has recently provided guidelines for ART in older patients who have an HIV infection. These guidelines include the following recommendations:

- Use ART for patients over 50 years old, regardless of CD4 cell count, because older adults may have a less effective immunologic response to HIV.
- Closely monitor bone, kidney, metabolic, cardiovascular, and liver function in older adults on ART due to an increased risk for adverse effects of therapy.
- Regularly assess drug–drug interactions between antiretroviral drugs and other medications taken by the older adult.
- Collaborate with HIV specialists and primary care providers to optimize care for the older adult with complex comorbidities.
- Provide counseling to prevent secondary transmission of HIV.

to agree to adhere so irregular dosing does not lead to viral resistance. Some providers gauge patient ability to follow the ART regimen by the patient's success with prophylaxis for an opportunistic infection. Discontinuation or interruption of ART is considered dangerous; because of the burden of adverse reactions, patients may desire brief holidays from taking the medications. When treatment must be interrupted (for example, for surgery or due to drug toxicities), staggered discontinuation of the drugs is recommended (Thompson et al., 2010).

Ingersoll and Heckman (2005) found that the most effective provider–patient relationship for fostering adherence is a balance of appropriate challenge and support. Providers who were never confrontational seem to be perceived by patients as giving permission to be less adherent. Although depression, substance use, and financial considerations undoubtedly influence adherence to ART, and need to be addressed, provider–patient relationships have a significant influence on adherence behavior (Mohammadpour et al., 2010). See the accompanying box addressing ART considerations in the older adult with HIV infection.

NUCLEOSIDE REVERSE TRANSCRIPTASE INHIBITORS The NRTIs (also called nucleoside analogs) are mainstays of ART. This class of drugs inhibits the action of viral reverse transcriptase, a retroviral enzyme that catalyzes the substrates for conversion and copying of viral RNA to DNA sequences. This enzyme is necessary for viral integration into cellular DNA and replication. The nucleoside analogs act as a chemical decoy for building blocks of the formation of the DNA copy, preventing the RNA from being copied into DNA. Each drug substitutes for a particular nucleoside base at different points on the chain. See the accompanying Medication Administration box for this group of drugs.

Zidovudine (Retrovir, AZT), the first antiretroviral agent approved for use with HIV infection, now is generally reserved for second- or third-line regimens because it causes anemia and neutropenia. Zidovudine is often given in combination with lamivudine (Combivir) or in combination with lamivudine and abacavir (Trizivir). Zidovudine may also be used prophylactically following a documented parenteral exposure to HIV.

Abacavir causes hypersensitivities in genetically predisposed individuals. Before prescribing this medication, HLA B*5701 testing should be done; if the test is positive, the patient will have a hypersensitivity reaction and should not take the medication.

PROTEASE INHIBITORS Protease is a viral enzyme necessary for the formation of specific viral protein needed for viral assembly and maturation. PIs bond chemically with protease to block the function of the enzyme and result in the production of immature, noninfectious viral particles. When combined with other antiviral drugs, these chemicals increase the chance of eliminating the virus by interfering with different stages of its life cycle. However, viral resistance occurs rather quickly. PIs inhibit and induce metabolism of other drugs, so their use with other medications and the dose of those medications must be carefully planned. Some drugs will circulate longer because their metabolism is inhibited; others will be speedily metabolized and eliminated.

Protease inhibitors and nucleoside analogs are associated with serious metabolic derangements. These include elevated cholesterol and triglycerides, insulin resistance and diabetes mellitus, and changes in body fat composition, which are particularly distressing to the patients. These body fat changes are primarily abdominal obesity and skeletal wasting. This set of symptoms is referred to as lipodystrophy. Elevated cholesterol should be treated with pravastatin or atorvastatin. Lovastatin and simvastatin react with PIs, so they need to be avoided. Reduction of dietary sources of cholesterol should be made. Unlike most PIs, atazanavir (Reyataz) has a beneficial effect on lipids, is effective in reducing viral load, and is usually well tolerated by patients (Kirtin, 2008).

NONNUCLEOSIDE REVERSE TRANSCRIPTASE INHIBITORS Etravirine (Intelence), delavirdine (Rescriptor), efavirenz (Sustiva), and nevirapine (Viramune) are NNRTIs that may be used in combination with nucleoside analogs and protease inhibitors. However, one limitation to NNRTIs is the high incidence of cross-resistance to NRTIs. Some studies have shown that nevirapine and efavirenz may significantly reduce serum levels of the protease inhibitors. Only one NNRTI should be used at a time. Nevirapine has a reported risk for liver toxicity and severe rash, particularly when used in women with higher CD4 counts (Fauci & Lane, 2012).

ENTRY INHIBITORS These newer antiviral drugs act by binding to the virus or the host cells and preventing viral entry into the host cells. Enfuvirtide (Fuzeon) blocks the HIV virus from entering human cells. Unfortunately, it must be administered by injection twice a day and it is very expensive. Patients who develop resistance to ART regimens are candidates for this regimen. Side effects include injection site pain, itching, and hardening of the tissue; allergic reactions; peripheral neuropathy; insomnia; depression; dyspnea; anorexia; and arthralgia.

Maraviroc (Selzentry) is the first antiretroviral drug that targets the host cells rather than targeting the virus directly. CCR5 antagonists block certain HIV viruses from entry to host immune cells. Certain forms of HIV viruses (R5 tropic viruses) require a CCR5 receptor as a "co-receptor" to gain entry to the cell; with this entry inhibitor, the R5 tropic virus cannot interact with the receptor and

therefore is blocked from entering human cells. Before prescribing, a blood test is made to identify the type of viruses the patient carries; if the R5 form of the virus is found, the patient may be a candidate for taking this drug. Preexisting cardiac and liver conditions are associated with adverse reactions.

HIV INTEGRASE STRAND TRANSFER INHIBITOR Raltegravir (Isentress) targets integrase, an HIV enzyme that integrates the viral genetic material into human DNA. Raltegravir is also called a *strand transfer inhibitor*, referring to the process of DNA strand transfer from the virus to the host. It is taken orally twice daily and side effects include nausea, diarrhea, and headache. It is approved only for individuals who have developed resistance to ART combinations, and it is not considered effective if used alone.

OTHER DRUGS The use of interferon-α, active immunotherapy with inactivated HIV, and other strategies such as bone marrow transplant and transfer of genetically modified lymphocytes are currently under investigation (Fauci & Lane, 2012). Patients who are co-infected with hepatitis B or C require drugs such as peginterferon-α or adefovir (Hepsera). As more drugs become available, the burden to choose the best regimen increases for the healthcare provider. Referral to a physician who specializes in care of patients with HIV/AIDS is recommended.

The most important limiting factor when choosing a regimen is patient adherence. Second to that is selecting an effective combination of drugs without overlapping toxicities or toxicities so debilitating that adherence will be further impaired. Interruption of ART is associated with rapid increases in viral load, a drop in CD4 cell counts, and an increased risk for disease progression (Fauci & Lane, 2012).

Body composition changes and metabolic abnormalities associated with ART include: increased fat deposition to the midsection, breasts, and neck with atrophy in the face, buttocks, and extremities (Figure 13–11 ■); increased low-density lipoprotein cholesterol and triglycerides; and insulin resistance. The combination of changes is consistent with metabolic syndrome, which increases the risk of cardiovascular disease and diabetes. These conditions are commonly treated with medications. A number of pharmacologic agents are used to prevent and treat opportunistic infections and malignancies in the patient with HIV.

Figure 13–11 ■ Fat redistribution associated with protease inhibitors.
Source: Medical-On-Line/Alamy

It is recommended that all patients with HIV infection receive pneumococcal, influenza, hepatitis A, hepatitis B, and *Haemophilus influenzae b* vaccines. Individuals with a positive PPD and negative chest x-ray are given prophylactic isoniazid. When the patient's CD4 cell count falls to less than 200/mm^3, prophylactic treatment for PcP is begun, usually with trimethoprim-sulfamethoxazole. As CD4 cell counts fall, prophylaxis against other opportunistic infections such as *Mycobacterium avium* complex (MAC) infection, toxoplasmosis, CMV infection, and endemic fungal diseases may be initiated (Zolopa & Katz, 2012).

●○● NURSING CARE

The patient with HIV and AIDS has many nursing care needs, including both physical and psychosocial support needs. Because there is as yet no cure for HIV disease, many of these needs fall within the realm of nursing to promote knowledge and understanding, self-care, comfort, and quality of life. Adherence to ART and the course of HIV infection may well be affected by the patient's social support systems, control, perceived self-efficacy in management, and coping mechanisms.

As the epidemic continues, nurses are providing care for increasing numbers of patients with HIV infection at various stages of disease including those who are undiagnosed. These patients are not only in special care settings, but also on general units, maternal–child units, hospice, and home settings. As patients with HIV disease live longer, nurses will increasingly encounter patients in whom HIV disease is a secondary diagnosis with another primary diagnosis, for example, seizures, heart disease, diabetes mellitus, or an operative procedure.

Health Promotion

To stop the spread of HIV, it is important to identify those who are infected but undiagnosed (approximately 21% of patients who are HIV positive). The CDC (2006) and WHO (2013) recommend HIV testing for patients in all healthcare settings. The WHO also recommends that testing also be made available in community-based settings, particularly in HIV epidemic areas or settings. Informed consent is necessary for testing, although specific written consent is not required. In opt-out testing, consent for screening is part of the general consent for care, unless specifically declined by the patient. Current guidelines further recommend linking HIV testing and counseling with prevention, care, and treatment services (WHO, 2013).

In the absence of an effective immunization to prevent HIV infection, education, counseling, and behavior modification are the primary tools for HIV/AIDS prevention. Nurses play a vital role in providing education about this epidemic and infection prevention for individuals and communities.

All sexually active individuals need to know how HIV is spread. Following are the only totally safe sex practices:

- No sex
- Long-term mutually monogamous sexual relations between two uninfected people
- Mutual masturbation without direct contact.

Patients who do engage in sexual activity need to know and practice safer sex. Reducing the number of sexual partners—for

MEDICATION ADMINISTRATION

Antiretroviral Drugs

NUCLEOSIDE REVERSE TRANSCRIPTASE INHIBITORS (NRTIS)

zidovudine (AZT, Retrovir)
emtricitabine (Emtriva)
lamivudine (Epivir)
didanosine (Videx)
tenofovir disoproxil fumarate (Viread)
stavudine (Zerit)
abacavir sulfate (Ziagen)

COMBINATIONS OF NRTIS

lamivudine and zidovudine (Combivir)
abacavir and zidovudine (Epzicom)
abacavir, zidovudine, and lamivudine (Trizivir)
tenofovir and emtricitabine (Truvada)

Nursing Responsibilities

- Assess for possible contraindications to therapy including allergic response, previous episodes of pancreatitis, and impaired renal or liver function.
- Abacavir sulfate causes allergic reactions in some patients. Prior to administering, HLA B*5701 testing is performed; if the test is positive, the patient should not take abacavir. Monitor for an allergic response: sudden fever, skin rash, severe tiredness or achiness, diarrhea, nausea, vomiting, stomach pain, sore throat, shortness of breath, cough, or general ill feeling. Stop the medication and inform the physician immediately.
- Administer with caution to patients taking vincristine (cancer drug), rifampin (Tb), pentamidine (PcP), ethambutol (Tb), or metronidazole (bacterial and protozoal infections). Concurrent use may increase the risk of acute and fatal pancreatitis.
- Assess for adverse effects. Nausea and headache are common. They may be self-limiting, decreasing with time, or significant and continuing, necessitating a change of therapy. Peripheral neuropathies may develop; these manifest as a sharp burning pain sensation in the hands and/or legs. Anemia and neutropenia are treated with erythropoietin (epoetin alpha) and G-CSF (filgrastim).
- Assess CBC with differential and serum chemistries for evidence of liver or pancreas changes. Lactic acidosis, an indication of liver disease may develop; monitor lactate levels and pH. Notify the physician of significant changes.
- Didanosine interferes with the absorption of ketoconazole and dapsone (given for opportunistic infection prophylaxis or treatment). Doses of these drugs should be scheduled at least 2 hours apart from didanosine doses. Do not use alcohol while taking didanosine; alcohol may increase the risk of pancreatitis.

Health Education for the Patient and Family

- Antiretroviral medications will not cure HIV infection but rather slow its progress and reduce significant symptoms.
- Follow individual drug guidelines for administration with or without food, swallowing whole, and dissolving a powder or chewing a tablet.
- You are still infective and can pass the infection to others. Use safer sex practices and other measures to prevent transmission to partners. Do not donate blood or breast-feed.
- Notify the physician if signs of an infection or adverse response develop: sore throat, swollen lymph glands, fever; unusual fatigue or weakness; easy bruising, bleeding gums, or an injury that will not heal; persistent or intractable nausea; muscle pain or wasting.
- Continue all scheduled follow-up visits and laboratory studies to monitor for drug toxicity.
- Check with the physician before taking any prescription or over-the-counter drug.

PROTEASE INHIBITORS (PIS)

amprenavir (Agenerase)
tipranavir (Aptivus)
indinavir (Crixivan)
saquinavir mesylate (Invirase)
fosamprenavir calcium (Lexiva)
ritonavir (Norvir)
darunavir (Prezista)
atazanavir sulfate (Reyataz)
nelfinavir mesylate (Viracept)
lopinavir/ritonavir (Kaletra)

Nursing Responsibilities

- Assess for evidence of cardiovascular or liver disease and diabetes mellitus. Most PIs are associated with lipodystrophy (enlarged abdomen, loss of tissue from the face, arms, and legs) and diabetes mellitus (elevated blood glucose).
- The protease inhibitors are known to precipitate kidney stones. Monitor creatinine clearance and patient reports of colicky flank pain.
- Ritonavir is combined with other PIs—an approach called *PI boosting.* The benefit of taking ritonavir in combination with other PIs is the added strength and effectiveness of some drugs and decreased food interactions. However, ritonavir interacts with many drugs, both prescription and over the counter.
- Administer by mouth. Follow individual drug guidelines for administration with or without food, swallowing whole, and dissolving a powder or chewing a tablet.
- Assess for adverse effects. Nausea and intestinal distress are common. Headache and peripheral neuropathies also are common. Skin reactions may be severe in about 1% of patients. Side effects may be self-limiting, decreasing with time, or significant and necessitating a change of therapy.

NONNUCLEOSIDE REVERSE TRANSCRIPTASE INHIBITORS (NNRTIS)

etravirine (Intelence)
delavirdine (Rescriptor)
efavirenz (Sustiva)
nevirapine (Viramune)

Nursing Responsibilities

- Assess for history of liver disease before administering these drugs.
- Administer by mouth. Follow individual drug guidelines for administering with or without food, swallowing whole, dissolving a powder, or chewing a tablet.
- Assess for evidence of severe skin rash accompanied by blisters, fever, joint or muscle pain, redness and swelling of the eyes, sores in the mouth, and swelling; serious kidney problems; anemia; and liver and muscle problems. Individuals should tell their primary care provider if they have any of these side effects.
- Efavirenz side effects may include abnormal thinking, confusion, depression, hallucinations, memory loss, paranoid thinking, and thoughts of suicide.

MEDICATION ADMINISTRATION (*continued*)

MULTICLASS COMBINATION AGENTS

ATRIPLA: efavirenz (NNRTI), emtricitabine (NRTI), and tenofovir disoproxil fumarate (NRTI)

TRIZIVIR: abacavir (NRTI), lamivudine (NRTI), and zidovudine (NRTI)

Nursing Responsibilities

- Trizivir contains abacavir sulfate, which causes allergic reactions in some patients. Prior to administering, HLA B*5701 testing should be made and if the test is positive, the patient should not take abacavir. Monitor for an allergic response: sudden fever, skin rash, severe tiredness or achiness, diarrhea, nausea, vomiting, stomach pain, sore throat, shortness of breath, cough, or general ill feeling. Stop the medication and inform the physician immediately.
- NRTIs can cause a sometimes fatal lactic acidosis and liver disease as well as blood problems or muscle weakness. Notify the physician if an individual taking this medication experiences digestive system problems, joint or muscle pain and weakness, pain or tingling of hands or feet, headache, dizziness, and unusual tiredness.
- Administer by mouth.
- Assess for evidence of severe skin rash accompanied by blisters, fever, joint or muscle pain, redness and swelling of the eyes, sores in the mouth, and swelling; serious kidney problems; anemia; and liver and muscle problems.

ENTRY INHIBITORS

enfuvirtide (Fuzeon)

maraviroc (Selzentry)

Nursing Responsibilities

- Enfuvirtide is injected; maraviroc is administered orally.
- Both enfuvirtide and maraviroc must be given in combination with other antiviral drugs.
- Enfuvirtide is supplied as a powder and must be dissolved in water for injection. Roll but do not shake the mixture because excessive foam may form. Inject when completely dissolved or refrigerate up to 24 hours. Do not inject solution until it warms to room temperature. Rotate sites.
- Side effects may include cough, fever, upper respiratory tract infections, abdominal pain, dizziness, and rash. These may indicate allergy. Musculoskeletal aches, stiffness, or weakness may indicate bone necrosis caused by the drugs. Instruct patient to report these to the physician immediately.
- Monitor liver function (cirrhosis and hepatitis decrease liver function) tests including bilirubin, amylase, lipase, AST, and ALT.
- Monitor kidney function (serum creatinine and BUN).

INTEGRASE INHIBITORS

raltegravir (Isentress)

Nursing Responsibilities

- Administer orally with or without food.
- Assess for side effects: headache, dizziness, diarrhea, and nausea.

example, by entering into and remaining in a long-term mutually monogamous relationship with an uninfected partner—reduces the risk. Patients should not engage in unprotected sex, especially if the HIV status of the partner is unknown. Latex condoms have been shown to reduce the risk of transmitting HIV. Their effectiveness is improved when nonoxynol-9, a spermicide, is used for lubrication; however, it may cause genital ulcers, which can facilitate HIV transmission. To be effective, condoms must be used with every sexual encounter involving vaginal, oral, or anal intercourse and they need to be applied and removed properly. A female condom is also available for use.

Healthy gay and bisexual men and heterosexual individuals whose partner has HIV infection may be able to further reduce the risk of contracting the infection by taking the combination antiretroviral medication Truvada (emtricitabine and tenofovir disoproxil fumarate) daily. Recent studies found the combination of condom use, counseling, and daily Truvada cut the risk of infection by 42% in gay and bisexual men and by 75% in heterosexual couples (Perrone, 2012).

Healthcare workers exposed to HIV infection or adults who experience a high-risk exposure to HIV may choose postexposure prophylaxis. Risk of exposure for healthcare workers may occur via needlesticks or cuts with a sharp object or via mucous membrane or nonintact skin contact with semen, vaginal secretions, fluids contaminated with visible blood, and possibly CSF, synovial fluid, and pleural, peritoneal, pericardial, or amniotic fluids. CDC (2005) and National Public Health Service guidelines recommend treatment with combination ART, which includes three or more NRTIs for all occupational exposures (Kuhar et al., 2013). A 4-week course of treatment is recommended and should be started within 72 hours, preferably within 2 to 3 hours of exposure (Fauci & Lane, 2012).

The most difficult group of high-risk people to reach and educate has been injection drug users. People in this group should never share needles, syringes, or other drug paraphernalia. Many cities have initiated needle exchange programs, providing a sterile needle and syringe in exchange for a used one. Undiluted household bleach is effective to clean paraphernalia when sterile supplies are not available. It is important to also teach people in this population about safer sex practices, because most heterosexual HIV transmission occurs between injection drug users and their partners.

Screening of voluntary blood donors and donated blood supplies has reduced the risk of transmission by transfusion to 1 in 100,000. Because current blood-screening methods use antibody testing, receiving donated blood continues to carry a small risk. Patients in the *window period* between contraction of the virus and the development of detectable antibodies are able to transmit the virus to others, even though they do not yet test positive for HIV. This window period usually lasts from 6 weeks to 6 months; rarely, it lasts up to 1 year. When possible, encourage patients to use autologous transfusion, donating their own blood prior to an anticipated surgery.

Encourage patients who are HIV positive to abstain from donating blood, organs, or sperm. They should understand tactics to avoid exchange of body fluids by not sharing needles or other drug paraphernalia, not sharing razors, and not obtaining a tattoo. Stress the importance of informing all medical personnel providing direct care (especially anyone performing a dental, surgical, or obstetric procedure) about the diagnosis.

Healthcare workers can prevent most exposures to HIV by using standard precautions (see Figure 13–12 ■ and Appendix A). Testing to determine HIV status remains voluntary and relies on the use of antibody-screening methods. It is therefore impossible to identify every patient who is HIV positive. With standard precautions, all patients are treated alike, eliminating the need to know the patient's HIV status. All high-risk body fluids are treated as if they are infectious, and barrier precautions are used to prevent skin, mucous membrane, or percutaneous exposure to them. Counseling, testing and postexposure prophylaxis are provided to healthcare workers with a documented needlestick exposure to the blood of an individual with HIV infection.

Assessment

Collect the following data through health history and physical examination. Further focused assessments are described with nursing interventions.

- ***Health history:*** risk factors (transfusion, unprotected sex, needle exposure), infections (STIs, hepatitis, tuberculosis), medications, recreational drug use
- ***Physical assessment:*** height, weight, nutrition, skin and mucous membranes, vision, lymph nodes, breath sounds, abdominal tenderness, motor strength, coordination, cranial nerves, gait, deep tendon reflexes, genitourinary examination, mental status.

Figure 13–12 ■ This nurse is disposing of a needle and syringe in a special container, a necessary practice to avoid the transmission of HIV through needlesticks with contaminated needles.
Source: Science Photo Library/Alamy

Priorities of Care

Nursing care priorities for the patient with HIV infection change over the course of the disease. Health maintenance activities, education, and support of coping mechanisms are important in the early stages of the disease. As the disease progresses and the patient experiences more physical symptoms, direct care needs become more important while the need for psychosocial support continues.

Diagnoses, Outcomes, and Interventions

Teaching and counseling for health maintenance and prevention of the spread of HIV are important nursing roles for patients, people at high risk, and the general public. Counseling the patient with a new diagnosis of HIV infection is vital. HIV infection and AIDS continue to carry a social stigma that may interfere with the patient's usual support systems and coping mechanisms. Typically the patient maintains self-care in the community, although acute opportunistic infections may necessitate hospitalization. See the accompanying Case Study & Nursing Care Plan.

Readiness for Enhanced Individual Coping

On receiving the test results indicating HIV seropositive status, the person with HIV infection is faced with multiple issues rarely affecting other patients. HIV is a chronic infection for which there currently is no known cure. Once the decision to initiate ART has been made, the patient faces a lifelong commitment to therapy that is expensive and associated with multiple adverse effects. Social support systems, family relationships, and the ability to obtain and retain useful work and health insurance may be disrupted by the disease. The patient may experience guilt about his or her lifestyle and how the disease was contracted. As the disease progresses, social isolation, fatigue, body image changes, medication side effects, and multiple other issues affect the patient's ability to cope.

Expected Outcome: Patient demonstrates acceptance of change in health status as evidenced by taking active role in healthcare decisions.

- Assess social support network and usual methods of coping. *This will help both the nurse and the patient identify people and mechanisms that can help the patient cope more effectively with the disease.*

Evidence for Nursing Care

The Patient with HIV Infection

Selected resources that nurses may find helpful when planning evidence-based nursing care for the patient with HIV infection follow.

CASE STUDY & NURSING CARE PLAN A Patient with HIV Infection

Jeff Lu is a 36-year-old elementary school teacher who lives with two housemates. Mr. Lu sees his primary care physician, complaining of fatigue, persistent sore throat, intermittent bouts of diarrhea, and mild shortness of breath for about a month. He expresses fear that he has contracted HIV, and says he has avoided testing in the past because of the impact positive test results would have on his career, lifestyle, and family. Mr. Lu has been open about his homosexuality since his teens, and is a vocal activist for gay, lesbian, and bisexual issues. He is not currently in a committed relationship and admits to using condoms "less than 100% of the time." The physician orders a mononucleosis test, ELISA, Western blot analysis, CD4 T-cell count, a p24 antigen test, and an erythrocyte sedimentation rate (ESR). Mr. Lu has a return appointment in 1 week for follow-up.

ASSESSMENT

On Mr. Lu's follow-up visit, Carole Kee, RN, obtains a nursing history. Mr. Lu continues to have flu-like symptoms and states that he just has not been as active as usual and is worried about his health. His appetite has decreased because of soreness in his mouth, and he has noted some whitish patches on his tongue and cheeks.

A chest x-ray film reveals no abnormality. The results of laboratory tests are as follows:

- ELISA: positive for antibodies against HIV
- Western blot analysis: positive for antibodies against HIV
- p24 antigen test: positive for circulating HIV antigens
- ESR: increased to 25 mm/h (normal for men is 10 to 15 mm/h)
- CD4 T-cell count: 599/mm^3 (normal range is 600 to 1200 mm^3).

Mr. Lu's physical examination reveals that he has enlarged lymph nodes in his neck and white patches on the oral mucosa. His skin is warm to the touch. Vital signs are as follows: T 37.7°C (99.9°F), P 84 bpm, R 20/min, and BP 120/78 mmHg.

Mr. Lu is given the results of the laboratory tests and the medical diagnosis of HIV infection. He is obviously distressed but says that now that he has to face what he has avoided for so long, he needs to know "everything there is to know" about ART and how to live with HIV infection.

DIAGNOSES

- *Anxiety* related to diagnosis and fear
- *Readiness for Enhanced Knowledge* about the HIV disease process and self-care
- *Imbalanced Nutrition: Less Than Body Requirements* related to soreness in mouth
- *Risk for Infection* related to altered immune protection

EXPECTED OUTCOMES

- Patient will verbalize anxiety and use appropriate coping mechanisms.
- Patient will verbalize and demonstrate knowledge of HIV infection and its management.
- Patient will verbalize measures to prevent HIV transmission to others, including safer sex practices.
- Patient will maintain adequate nutrition for optimal body and cellular function.
- Patient will remain free of infections and their complications.

PLANNING AND IMPLEMENTATION

- Provide opportunities for Mr. Lu to verbalize his feelings.
- Avoid false reassurances.
- Provide appropriate and adequate information about HIV infection and ART.
- Coordinate referral to a healthcare provider who specializes in HIV infection management.
- Review safer sex practices and other measures to prevent HIV transmission.
- Teach anxiety-controlling techniques, such as deep breathing and meditation.
- Monitor weight and serum albumin levels at each visit until stabilized.
- Provide dietary consultation referral.
- Encourage oral care before and after meals.
- Assess bowel sounds and monitor elimination pattern.
- Teach Mr. Lu to avoid exposure to infection and people with known illnesses until his CD4 cell count returns to normal levels.
- Monitor response to prescribed medications.
- Encourage regular physical exercise.

EVALUATION

Mr. Lu receives a prescription for an antifungal medication and referral to a physician whose practice is limited to patients with HIV infection. When he meets with this physician, the decision is made to start ART based on his CD4 cell count and symptoms of HIV disease. Mr. Lu initially is started on combination ART with daily efavirenz, tenofovir, and emtricitabine (Atripla).

Critical Thinking in the Nursing Process

1. How does age affect the body's response to fighting HIV infection? What other factors affect the risk of HIV infection and its progression?
2. Which classes of antiretroviral drugs are found in the combination formula Atripla? What is the rationale for prescribing drugs from more than one class? What teaching regarding timing, interactions, and possible adverse reactions to the drug does Mr. Lu need?
3. Although Mr. Lu has health insurance through his employer, he is concerned about the cost of the prescribed ART. How should the nurse respond? What resources are available to help with the cost burden of ART?
4. Mr. Lu tells the nurse that although he isn't ready to call it a committed relationship, he has been seeing one person exclusively for the past 3 months. He asks what his partner can do to minimize his risk of contracting HIV. How should the nurse respond?

See Evaluating Your Response in Appendix B.

- Support the patient's social network. *Nontraditional families may offer more support than the traditional family. This in turn may necessitate a liberal interpretation of the term* family *in some healthcare settings.*
- Employ an interactive helping process focusing on the patient's and significant others' needs, problems, and feelings to enhance or support coping, problem solving, and interpersonal relationships (Wilkinson, 2014). *This is a critical component of patient-centered care for the individual with HIV infection and his or her family.*
- Use short-term counseling to help the patient cope with the crisis presented by the diagnosis of HIV infection or by an AIDS-defining illness. *Short-term counseling can help the patient cope with the immediate crisis and return to a normal state of functioning.*
- Promote interaction between the patient, significant others, and family. *The diagnosis of HIV infection and manifestations of HIV*

disease may bring about isolation from others and decrease the patient's ability to cope.

- Provide information, support, and, as appropriate, guidance for the patient in making decisions regarding care and treatment. *This gives the patient a greater sense of self-worth and control over the situation, increasing coping abilities.*
- Provide reassurance, acceptance, and encouragement during crisis episodes. *Providing consistent acceptance and support for the patient with HIV infection enhances coping during times of crisis.*
- Assist to accept responsibility for actions without blaming others. *Effective coping cannot occur without accepting responsibility for one's actions.*
- Support positive coping behaviors, decisions, actions, and achievements. *As self-esteem is enhanced, coping improves* (Côté & Pepler, 2005).

Risk-Prone Health Behavior

The risk for contracting HIV infection is related to lifestyle and behaviors. Changing these unsafe behaviors, for example, engaging in unprotected sexual intercourse or sharing supplies for injection drug use, is critical to reducing an individual's risk. Once diagnosed with HIV, behavior modifications are important to prevent spread of the infection to others.

Expected Outcome: Patient will verbalize acceptance of health status changes and begin to make lifestyle and behavior changes to prevent disease spread to others (Wilkinson, 2014).

- Assist to accept responsibility for actions without blaming others. *Effective coping cannot occur without accepting responsibility for one's actions.*
- Provide positive reinforcement of self-directed lifestyle and behavior changes initiated by the patient. *Reinforcement of positive behaviors helps strengthen the patient's ability to maintain new ways of acting and develop behavioral habits to support a healthy lifestyle.*
- Assist the patient to clarify her or his own values and beliefs. *Identifying personal values and beliefs facilitates effective decision making.*
- Reinforce personal strengths that are identified. *Focusing on personal strengths enables movement away from negative thoughts.*
- Assist in setting realistic goals. *Establishing and meeting realistic short-term goals is helpful in increasing self-confidence and decreasing negative self-talk.*
- Refer to clergy, social worker, clinical specialist, and/or counselor as appropriate. *Individuals with expertise in counseling may be necessary to enable coping with current situation.*

Impaired Skin Integrity

Dryness, malnutrition, immobility from fatigue, and skin lesions on pressure sites contribute to impaired integrity of the skin for the patient with HIV disease. Maintaining skin integrity is important as the first line of defense against infection in an immunosuppressed patient.

Expected Outcome: Patient's skin will remain intact without evidence of underlying tissue breakdown.

- Assess the skin frequently for lesions and areas of breakdown. *Early identification of impaired skin integrity allows prompt intervention.*
- Monitor lesions for signs of infection or impaired healing. *Infection or poor tissue perfusion not only impairs healing but may lead to further skin breakdown.*
- Turn at least every 2 hours if unable to turn self, more frequently if necessary. Prevent skin shearing by using a turnsheet and adequate personnel when repositioning. *Turning decreases unrelieved pressure on bony prominences and improves circulation to the tissues. Shearing causes tissue trauma that can lead to decubitus ulcers.*
- Keep skin clean and dry using mild, nondrying soaps or oils for cleansing. *Night sweats and diarrhea, if present, can cause breakdown and damage to the skin. Frequent cleansing with nondrying products discourages bacterial growth, thus reducing the risk of infection.*

PRACTICE ALERT!

Applying protective creams to reddened areas in the rectal area protects skin from the caustic effects of diarrhea.

- If blisters are noted, leave intact, and dress with a hydrocolloid (e.g., DuoDERM) dressing. *Blisters provide natural sterile coverings for damaged tissue, improving healing and preventing bacterial invasion.*
- Caution against scratching. If confused, trim fingernails and use mitts or soft restraints to prevent scratching. Check circulation of hands and fingers frequently if mitts or restraints are used. *Scratching and skin damage allow bacteria to be introduced into lesions, increasing the risk of infection. Tight or restrictive restraints or mitts may compromise circulation.*
- Encourage ambulation if possible; if the patient is confined to bed, encourage active or passive range-of-motion exercises. *Activity increases circulation, decreases pressure and skin breakdown, and helps maintain muscle tone.*
- Monitor nutritional intake and albumin levels. *Maintenance of optimal nutrition decreases the risk of tissue breakdown and improves resistance to infection.*

Imbalanced Nutrition: Less Than Body Requirements

Many factors associated with HIV disease, including manifestations of the disease itself, put the patient at risk for altered nutrition and weight loss. Nausea and anorexia may be manifestations of the disease or the result of antiretroviral therapy. Chronic diarrhea is a common manifestation of HIV disease. Wasting syndrome is also common, manifested by involuntary weight loss of greater than 10% to 15% of baseline weight, severe diarrhea, fever, and chronic fatigue and weakness. The exact cause of wasting syndrome is unclear, but the diarrhea and fatigue contribute, as does the increased metabolic rate associated with fever. Oral and esophageal candidiasis and KS of the gastrointestinal tract may cause painful swallowing, making eating difficult and thereby contributing to anorexia. Poor nutritional status in the patient with HIV can ultimately result in altered comfort, a change in body image, muscle wasting, increased risk of infection, and higher mortality and morbidity.

Expected Outcome: Patient will maintain body weight appropriate for height and body mass index (BMI) and serum albumin within accepted ranges.

- Assess nutritional status, including weight; BMI; caloric intake; and laboratory studies, such as total protein and albumin levels, hemoglobin, and hematocrit. *These factors provide a baseline to determine the effectiveness of interventions.*
- Identify possible causes of altered nutrition. *Identification of contributing factors provides direction for planned interventions.*
- Administer prescribed medications for candidiasis and other manifestations as prescribed. *Eliminating this opportunistic infection improves comfort and facilitates food intake. Topical viscous anesthetic can help reduce pain and improve oral intake.*
- Administer antidiarrheal medications after stools and antiemetics prior to meals. Provide antipyretics as needed to control fever. *Reducing diarrhea will improve nutrient absorption; preprandial medication with an antiemetic reduces nausea and improves food intake. Reduction of fever lowers the body's metabolic demands.*

PRACTICE ALERT!

High-fiber foods can increase intestinal motility and the incidence of diarrhea.

- Provide a diet high in protein and kilocalories. *A high-protein, high-kilocalorie diet provides the necessary nutrients to meet metabolic and tissue healing needs.*
- Offer soft foods and serve small portions. *Soft foods are easily digested. Small portions are more appealing to the anorectic or nauseated patient.*
- Involve in meal planning and encourage significant others to bring favorite foods from home. *The patient is more likely to consume adequate amounts of preferred foods. Allowing food choices enhances the patient's sense of control.*
- Assist with eating as needed. *Fatigue and weakness can prevent the patient from eating an adequate amount of food.*
- Provide supplementary vitamins and enteral feedings, such as Ensure. *This improves nutritional status and caloric intake.*
- Provide or assist with frequent oral hygiene. *Oral hygiene improves comfort and appetite, and reduces the risk of mucosal lesions.*
- Administer appetite stimulants, such as megestrol (Megace) and dronabinol (Marinol), as ordered. *Both drugs may increase appetite and promote weight gain.*

Risk for Sexual Dysfunction

The diagnosis of HIV infection can significantly alter the patient's expressions of sexuality. Guilt over the diagnosis may interfere with libido. The patient may be angry with a significant other or partner if that person was the probable source of infection. The patient may fear spreading the disease to others via sexual relations. As the disease progresses, its manifestations can affect body image and self-esteem, impairing sexuality. Other symptoms, such as nausea, fatigue, and weakness, may also interfere with libido and sexual satisfaction. If nurses are not comfortable discussing sexuality, referral to a counselor is appropriate.

Expected Outcome: Patient and partner will demonstrate willingness to discuss impact of HIV infection on sexuality and sexual function.

- Examine own feelings about sexuality, role in dealing with a patient's sexuality, the patient's lifestyle, and sexual preferences. *To deal effectively with the patient's concerns, the nurse must be comfortable with his or her own feelings of sexuality and be able to accept the patient's lifestyle. Referring the patient to another nurse or counselor may be necessary.*
- Establish a trusting, therapeutic relationship through the use of time, active listening, caring, and self-disclosure. Maintain a nonthreatening, nonjudgmental attitude toward the patient. *Sexuality is a private issue that will be uncomfortable or impossible for the nurse and patient to discuss without a mutually trusting relationship.*
- Provide factual information about HIV infection and its effects. *This helps the patient separate fears and myths from reality.*
- Discuss safer sex practices, including hugging, cuddling, nonsexual contact, the use of latex condoms and spermicidal lubricant, and mutual masturbation. *Alternative forms of sexual activity and expressing affection can allow the patient and significant other to remain close throughout the course of the disease.*
- Encourage discussion of fears and concerns with significant other. *Open communication helps the patient deal with issues related to sexuality.*
- For the patient without a significant other, stress the need to continue to meet people and develop social relationships while practicing safer sex. *The risk of isolation is high in the patient with HIV infection, and relationships with others help the patient to cope with the disease.*
- Refer the patient and significant other to local support groups for people and partners of people with HIV. *Support groups provide a social and support network of people facing the same issues.*

Delegating Nursing Care Activities

As appropriate and allowed by the designated duties and responsibilities of assistive personnel, the nurse may delegate nursing care activities such as measuring intake and output, obtaining daily weights, and assisting with activities and hygiene for the patient with HIV infection.

Continuity of Care

Teaching needs for both the patient and significant other are extensive. The primary need is for information about the disease, its spread, and its expected course. The patient and family need current factual information to plan realistically and to combat myths, misperceptions, and prejudices. At the same time, it is important to include information about current research and progress in treating the disease to maintain a sense of hopefulness.

The following topics should be discussed with the patient and family to prepare for home care:

- Guidelines for safer sex practices
- Nutrition, rest and exercise, stress reduction, lifestyle changes, and maintaining a positive outlook
- Infection prevention and transmission including hand hygiene and wearing gloves when handling patient's secretions or excretions
- Importance of regular medical follow-up and monitoring of immune status
- Signs and symptoms of opportunistic infections and malignancies, as well as other symptoms that should be reported

- Medications and adverse effects; the importance of adherence to prescribed ART once initiated
- Cessation of smoking, alcohol, and recreational or illicit drug use
- Home health, hospice, and respite care services as appropriate
- Community resources, such as support groups, social agencies, and counselors
- Helpful resources:
  - CDC National AIDS Hotline
  - Gay Men's Health Crisis Network
  - National Association of People with AIDS
  - National Organization on HIV over Fifty.

CHAPTER HIGHLIGHTS

- **Normal immune functioning is essential in protecting the body from internal and external threats. A hyperresponsive immune system, however, which overreacts to antigens or fails to distinguish self proteins from abnormal or nonself proteins, can threaten health and well-being.**
- The immune system is a complex combination of cellular and humoral components that protect against disease. Immunity develops when the body recognizes foreign proteins as "nonself" and develops nonspecific inflammatory responses and specific cellular responses to each foreign antigen.
- With aging, there is a general decline in the sensitivity and regulation of the immune system, which may result in autoimmune disease.
- Hypersensitivities are excessive responses to antigens that result in harm to the patient. These range from benign to life threatening. Damage to host tissue is caused by chemicals of the immune response, destruction of cells, or creation of large antigen–antibody complexes that accumulate in the kidney glomerular capillaries.
- Allergic reactions are treated pharmacologically to prevent or moderate allergic responses. Desensitization, a weekly process of introducing increasing amounts of known allergens subdermally, also may be used to prevent or moderate allergic responses.
- Latex allergy, a potential problem for healthcare professionals, can present as a simple irritant dermatitis (type IV hypersensitivity) or as an acute type I systemic allergic reaction, including hives, itching, wheezing, or difficulty breathing.
- Anaphylaxis is an acute systemic type I response that can potentially lead to respiratory arrest and cardiac failure. Early recognition of its signs and symptoms and immediate emergency care are necessary to preserve life.
- **Immune function that targets normal cells and tissues (autoimmunity) or that leads to destruction of transplanted tissue or organs (transplant rejection) threatens the well-being of affected patients. Immunosuppressant therapy is used to prevent tissue and organ damage and maintain the function of transplanted tissue.**
- Autoimmune disorders are diverse, ranging from damage limited to specific cells within an individual organ to systemic disorders with widespread effects, and characterized by an abnormal immune response to normal cells and tissues.
- Intentional immunosuppression is necessary to prevent initial rejection of a transplanted organ or tissue, to maintain the transplant, and to halt any rejection process that may develop. Most immunosuppressing drugs are nephrotoxic; immunosuppression places patients at greater risk for infection and cancers.
- **Impaired immune function, whether congenital or acquired, threatens health and physiologic integrity because the patient cannot effectively respond to threats such as infection. Nurses play a major role in teaching behaviors to prevent HIV infection, the leading cause of acquired immunodeficiency, and in teaching health and disease management strategies to those affected.**
- HIV infection continues to spread and many patients are unaware they have the virus. AIDS, the end stage of HIV infection, is profound immunosuppression that results from viral destruction of cellular components of host immunity.
- Although HIV infection cannot be cured, it can be treated with antiretroviral therapy (ART), a combination of drugs that limits viral replication and host susceptibility to opportunistic infections and cancer. Consistent adherence to the treatment regimen is critical to inhibiting viral replication. ART is, however, expensive and associated with significant adverse effects.
- Education, counseling, and psychosocial support are key components of care for the person with HIV infection and his or her significant others.

TEST YOURSELF NCLEX-RN® REVIEW

1. The nurse is caring for a patient experiencing a type I immediate hypersensitivity reaction. For which health problem is the nurse providing care to the patient?
1. anaphylaxis
2. graft rejection
3. hemolytic anemia
4. systemic lupus erythematosus

2. A patient received a liver transplant 1 day ago. If the patient were to develop an acute transplant rejection episode, when should the nurse expect to see the manifestations?
1. within the first 8 hours
2. within the first 24 hours
3. approximately 2 days later
4. approximately 4 days to 3 months later

3. The nurse notes a cough, shortness of breath, and tachypnea in a patient with AIDS. Which opportunistic infection is probably causing these manifestations?
   1. cytomegalovirus
   2. *Toxoplasma gondii*
   3. *Pneumocystis jiroveci*
   4. *Cryptococcus neoformans*
4. Which explanation should the nurse provide to a patient who has tested positive for HIV?
   1. "You have been diagnosed with AIDS."
   2. "At this point, AIDS is not active in your blood."
   3. "Antibodies to the AIDS virus are present in the blood."
   4. "This means that you will not develop AIDS in the future."
5. A patient is taking the nucleoside reverse transcriptase inhibitor zidovudine (Retrovir) for HIV. What should the nurse identify as an adverse reaction to this medication?
   1. neutropenia
   2. polycythemia
   3. cardiotoxicity
   4. nephrotoxicity
6. A patient is being scheduled for allergy testing. Which method should a nurse expect to be used first?
   1. prick test
   2. inhalation
   3. intradermal injection
   4. subcutaneous injection
7. The nurse suspects a patient receiving a blood transfusion is experiencing a hypersensitivity reaction. What action should the nurse perform first?
   1. Discard the product immediately.
   2. Replace all tubing and attach a new line with normal saline.
   3. Flush the line and run normal saline attached at the Y connection.
   4. Remove the intravenous catheter and establish access distal to the site.
8. A patient diagnosed as being HIV positive is prescribed a protease inhibitor and nucleoside analog. For which metabolic abnormality should the nurse monitor in the patient?
   1. diabetes mellitus
   2. lactose intolerance
   3. Hashimoto's thyroiditis
   4. systemic lupus erythematosus
9. What should be the priority when initiating or changing the drug regimen in a patient who is HIV positive?
   1. cost of therapy
   2. access to dental care
   3. toxicities associated with each drug
   4. patient willingness to adhere to the drug regimen
10. A patient recovering from a kidney transplant is prescribed immunosuppressant therapy. Which agent should the nurse administer to induce immunosuppression immediately following the transplant?
    1. azathioprine
    2. corticosteroids
    3. muromonab-cd3
    4. lymphocyte immune globulin

14 Nursing Care of Patients with Cancer

LEARNING OUTCOMES

1. Explain known carcinogens, carcinogenesis, and identify risk factors for cancer.
2. Compare the mechanisms and characteristics of normal cells with malignant cells.
3. Describe the physical and psychologic effects of cancer.
4. Describe and compare laboratory and diagnostic tests for cancer.
5. Discuss the role of chemotherapy in cancer treatment and classify chemotherapeutic agents.
6. Compare and contrast the role of surgery, radiation therapy, and biotherapy in the treatment of cancer.
7. Explain causes and discuss the nursing interventions for common oncologic emergencies.
8. Design an appropriate care plan for patients with cancer and their families regarding cancer diagnosis, treatment, and coping strategies.

CLINICAL COMPETENCIES

1. Perform focused and comprehensive assessments of the patient with cancer, including functional status, physical and psychologic needs, and expressed values and preferences.
2. Use assessed data to determine priority nursing diagnoses, select individualized nursing interventions, evaluate patient responses, and revise the plan of care as needed to promote, maintain, or restore functional health, and to alleviate suffering.
3. Provide effective care for patients with cancer, integrating planned nursing care with the interprofessional plan of care.
4. Use current evidence and patient preferences to plan and implement optimal nursing care for patients with cancer.
5. Plan and provide appropriate teaching for self-care of cancer-related and treatment-related symptoms, such as pain, nausea and vomiting, mucositis, fatigue, or anemia.
6. Use quality measures, processes, and tools to improve outcomes for patients with cancer.
7. Include cultural variation and diverse values in designing and implementing individualized plans of care for patients with cancer.
8. Demonstrate effective use of technology, current evidence, and care standards to reduce the risk of harm for patients with cancer.
9. Use technology to obtain high-quality healthcare information and plan, document, communicate, and coordinate care for patients with cancer.

MAJOR CHAPTER CONCEPTS

- Cancer is a life-threatening and complicated disease characterized by uncontrolled growth and spread of abnormal cells. Cancer can affect people of any age, gender, ethnicity, or geographic region. An estimated 5% to 10% of cancers have a hereditary component, therefore it is important to identify patients who have a genetic predisposition.
- The diagnosis and treatment of cancer is a pivotal, life-changing event that requires immediate and ongoing adjustment to enhance patients' ability to cope and improve survival and quality of life.
- The goals of cancer treatment are aimed at cure and control of cancer as well as management of cancer-related and treatment-related symptoms.
- Nurses play a pivotal role in cancer prevention, providing quality patient-centered individualized care for patients with cancer. Major nursing responsibilities when caring for patients with cancer include managing cancer-related or treatment-related symptoms, such as pain, nausea and vomiting, mucositis, or fatigue, and identifying and managing oncologic emergencies. Tumor lysis syndrome (TLS) is a life-threatening oncologic emergency for patients with cancer.

Cancer is a group of complex diseases characterized by uncontrolled growth and spread of abnormal cells (American Cancer Society [ACS], 2013a). Cancer can manifest in different ways depending on which body system is affected and the type of tumor cells involved. Cancer can affect people of any age, gender, ethnicity, or geographic region. Although the incidence and mortality rates of cancer have continued to decline since 1990, it remains one of the most feared diseases (ACS, 2013a). The fear engendered by even the suggestion of a cancer diagnosis often evokes feelings of hopelessness and helplessness (Galway et al., 2012).

This chapter focuses on the general pathogenesis, pathophysiology, and etiology of cancer; identifies current diagnostic and treatment modalities; and discusses nursing care appropriate for patients with cancer. Discussions of cancers that affect specific body systems can be found in corresponding disorders chapters in the text.

Cancer occurs when normal cells mutate into abnormal cells with uncontrolled growth and spread in the body. Cancer can affect any body tissue. The nurse recognizes that cancer is a disruptive and life-threatening process affecting not only the person who is diagnosed with cancer, but also his or her significant others and family members. Nursing interventions are based on the understanding that cancer is a chronic disease with acute episodes, and that the patient is often treated with a combination of treatment modalities. Equally important, the nurse recognizes that caring for the patient with cancer involves prevention, early detection, risk reduction, treatment, long-term follow-up and rehabilitation, comprehensive symptom management, palliation, and patient education and counseling (Kuijpers et al., 2013).

Oncology is the study of cancer. The term is derived from the Greek word *oncoma*, meaning "bulk." Oncologists specialize in caring for patients with cancer; they may be medical physicians, surgeons, radiologists, immunologists, or researchers. The oncology nurse is an important and significant member of the oncology team. Oncology nurses have received specialized training in cancer care and treatment. They have special skills in assisting the patient and family with physical and psychosocial issues associated with cancer, treatment, and palliation (ONS, 2013e). Collaboration among healthcare professionals (e.g., surgeons, oncologists, nurses, physical therapists, and social workers) ensures the most effective care and treatment for the patient with cancer.

INCIDENCE AND MORTALITY

In the United States, cancer is the second most common cause of death. About, 665,540 new cancer cases were expected to be diagnosed in 2014 (ACS, 2014). One in every four deaths in the United States is caused by cancer and more than 1600 people die of cancer each day (ACS, 2014). Mortality rates for different cancers vary. Lung cancer remains the leading cause of all cancer deaths in both men and women, accounting for approximately 27% of all cancer deaths (ACS, 2014).

Due to advances in cancer prevention, early detection, and treatment, the 5-year survival rate for individuals with cancers continues to improve in the United States. However, minority ethnic groups such as African American and Asian American populations have a disproportionate burden of cancer. African Americans have the highest mortality rate for all cancers and major cancers among all ethnic groups (ACS, 2013a). For example, breast cancer occurs more commonly in Caucasian women than in African American women, yet the survival rate is 90% for Caucasian women compared to only 78% for African Americans; breast cancer death rates are 40% higher in African American women than in Caucasian women (ACS, 2013a). Similar disparities are seen in survival rates for colorectal, prostate, and endometrial cancers in these ethnic groups. Although much of the disparity remains unexplained, research has shown that lack of health insurance, lower incomes, unequal access to healthcare, knowledge deficit, differences in tumor characteristics, and cultural beliefs and attitudes are influential factors contributing to cancer disparity among African Americans (Wallace et al., 2011). For information about diversity, cancer risk, and incidence, see the accompanying Focus on Cultural Diversity box.

FAST FACTS

Cancer in the United States

- Breast cancer is the most frequently diagnosed cancer in women, with an estimated incidence of 232,670 new cases in 2014.
- Prostate cancer is the most frequently occurring cancer in men, with an estimated incidence of 233,000 new cases during 2014. The incidence rates of prostate cancer are significantly higher in African American men than in Caucasian men.
- Melanoma occurs mainly among Caucasians; the incidence rates are more than 10 times higher than those of African Americans.
- The incidence of bladder cancer is about four times higher in men than in women, and almost two times higher in Caucasians than in African Americans.

Risk Factors

Risk factors are factors that make an individual or a population vulnerable to a specific disease or other unhealthy outcome. Risk factors can be divided into those that are controllable and those that are not controllable. Knowledge and assessment of risk factors are especially important in counseling patients and families about measures to prevent cancer. Figure 14–1 ■ summarizes the interaction of factors that promote cancer.

GENETICS AND HEREDITY

Genetics is the study of genes. Genes encode for the growth and development of the body's cells. *Human genome* refers to the totality of human genes. *Genomics* is the study of all the genes in the human genome together, including the genes' interactions with each other, the environment, and the influence of other psychosocial and cultural factors (Jorde et al., 2010). See Box 14–1 for one way in which genomics can be used to help guide treatment decisions by patients and the interprofessional team.

Heredity is how genes are passed from generation to generation. In cancer, an estimated 5% to 10% of cancers have a hereditary component (ACS, 2013a). Even though the majority of patients will not have an inherited form of cancer, it is important to determine which patients have a genetic predisposition. With the availability of cancer gene testing, such as for the breast cancer genes *BRCA-1* and *BRCA-2*, nurses need to understand the limitations of genetic testing. For example, when genetic testing is unable to identify a causative mutation, such as *BRCA-1*

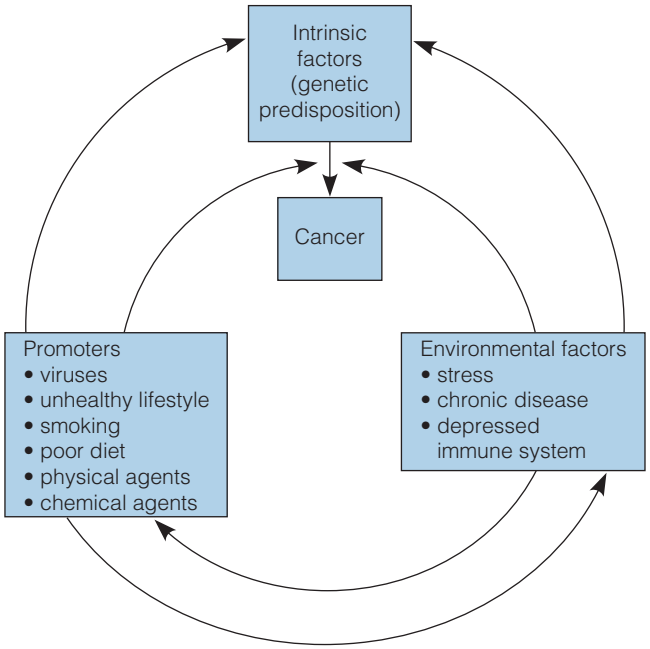

Figure 14–1 ■ Interaction of factors that promote cancer. Most people have immune systems that are competent enough to resist the establishment of cancer from an initiated cell. Cancer can take hold, however, when a number of promotional factors occur together and over enough time to weaken immune resistance. Like factors are grouped together for ease of presentation but may occur in any combination.

and *BRCA-2*, the testing result does not eliminate a risk for cancer in the patient or his or her family members (Jorde et al., 2010).

Recurring patterns of cancer within a family are a risk factor for a hereditary component, but do not necessarily indicate that a specific gene or mutation is the cause. An increased rate of cancer between relatives can be due to genetics, as well as shared environmental exposures, lifestyle, and other nongenetic risk factors. Therefore, it is critical to elucidate other nongenetic risk factors. For example, consider a 65-year-old patient who never smoked and had no family history of lung cancer. For this patient it is important to assess exposure to secondhand smoke, occupational exposures, and other potential inhaled toxins. Familial cancers generally occur during old age, whereas hereditary cancers usually happen at a younger age (Jorde et al., 2010). For most cancers, research has yet to distinguish true genetic transfer from environmental causes. Although further research is needed to identify cancers that are due to the inheritance of defective genes, familial predisposition to malignancies should be counted among risk factors so that people at risk can reduce behaviors that promote cancer. For example, a patient with a family history of lung cancer should be counseled to avoid smoking, to avoid areas where smoking is allowed, and to avoid working in an occupation that may expose the patient to inhaled carcinogens.

AGE

Cancer is a disease associated with aging—more than 75% of cancer diagnoses occur after age 55 (ACS, 2013a). A number of factors are associated with this increased risk in older adults. One possible factor is that at least five cycles of genetic mutations seem necessary to cause permanent damage to the afflicted cells. In addition,

BOX 14–1 Genomics and Breast Cancer

ONCOTYPE DX: BREAST CANCER ASSAY

Advances in genomics in diagnosing and treating cancer make it imperative for nurses to incorporate genomic competencies and skills into clinical practice. The Oncotype DX test for breast cancer is one example of how genomics can be used to help patients make informed and individualized treatment decisions. The Oncotype DX test analyzes the activity of a group of 21 genes that can affect how a cancer is likely to behave and respond to treatment.

Nurses can use the knowledge of the Oncotype DX:

- To help patients diagnosed with early-stage breast cancer to estimate the risk of cancer recurrence and to make decisions about the risks and potential benefits of chemotherapy.
- To help patients diagnosed with ductal carcinoma in situ (DCIS) estimate the risk of cancer recurrence and to make decisions about the risks and potential benefits of radiation therapy.

Oncotype DX test results assign a recurrence score of 0 to 100:

- Recurrence score lower than 18: The cancer or DCIS has a low risk of recurrence. The benefit of chemotherapy for early-stage breast cancer or radiation therapy for DCIS is likely to be small and will not outweigh the risks of side effects.
- Recurrence score between 18 and 31: The cancer or DCIS has an intermediate risk of recurrence. It is unclear whether the benefits of chemotherapy for early-stage breast cancer or radiation therapy for DCIS outweigh the risks of side effects.
- Recurrence score greater than 31: The cancer or DCIS has a high risk of recurrence, and the benefits of chemotherapy for early-stage breast cancer or radiation therapy for DCIS are likely to be greater than the risks of side effects.

Nurses can help patients by providing information regarding insurance coverage and financial assistance:

- The Medicare program and several other major insurance companies cover the Oncotype DX test.
- Genomic Health has the Genomic Access Program to assist the patient in verifying insurance coverage and obtaining reimbursement and to provide testing for the patient facing financial hardships or those who are uninsured or underinsured. The Oncotype DX test costs about $4,000. For insurance- and payment-related questions, call 1-866-ONCOTYPE (1-888-662-6897).

Moving Knowledge into Action

As an oncology nurse at a breast center, you are planning care for a patient with newly diagnosed stage 1 breast cancer. The patient asks for your opinion regarding whether she should have chemotherapy based on her Oncotype DX test scores. In your assessment, you note that the patient has an Oncotype score of 13.

1. Identify resources of information to use when planning care for this patient.
2. What nursing interventions to manage this patient's knowledge deficit would be most appropriate to include in the care plan?
3. What additional assessment data should you collect?

FOCUS ON CULTURAL DIVERSITY

Risk and Incidence of Cancer

- Hispanics have higher rates of cancers associated with infectious agents, such as uterine, cervix, liver, and stomach cancer.
- Hispanic women residing in the United States have about a 60% higher cervical cancer incidence than non-Hispanic White women.
- The incidence of liver cancer is almost twice as high in Hispanics compared to non-Hispanic Whites.
- African Americans are more likely to develop cancer than any other ethnic or racial group in the United States.
- African Americans have the highest death rate and shortest survival of any racial and ethnic group in the United States for most cancers.
- African Americans have the highest incidence and mortality for colorectal and lung cancers.
- Breast cancer occurrence is about 10% lower in African American women than in Caucasian women, but the mortality rate is approximately 40% higher.
- African American men are at least 59% more likely to develop prostate cancer than men of any other ethnic or racial group.
- Cancer incidence and mortality are lower in Native American men and women than in any other ethnic or racial group.

long-term exposure to high doses of promotional agents is usually necessary to allow the cancer to take hold. In addition, poor overall immune response accompanies aging as a result of a progressive and overall diminution of immune functions that affect all cells and organs of the innate and adaptive immune system (Fulop et al., 2011). Another problem is that free radicals (molecules resulting from the body's metabolic and oxidative processes) tend to accumulate in the cells over time. With aging, the immune cells show an increase in oxidant and inflammatory compounds and a decrease in antioxidant defenses, causing cellular damage and mutation (Fulop et al., 2011; Hasselbalch, 2013).

Hormonal changes that occur with aging can be associated with cancer. Postmenopausal women receiving exogenous estrogen have an increased risk for breast and uterine cancers. Older men are at risk for prostate cancer, possibly due to breakdown of testosterone into carcinogenic forms. See the Nursing Care of the Older Adult box on page 337 for a discussion about older adults and cancer.

Stress resulting from severe and/or cumulative losses is implicated in promoting cancer (Gregorio et al., 2012; Hasselbalch, 2013). These losses, which are common to older adults, include the death of a spouse or friends, cancer diagnosis of family members, loss of position and status in society, and a decline in physical abilities. These repeated stressors are related to changes in the immune system that may lead to the development of cancer.

GENDER

Gender is a risk factor for certain types of cancer. Breast cancer is the most frequently diagnosed cancer in women; prostate cancer in men. The incidence of bladder cancer is about four times higher in men than in women (ACS, 2013a). Thyroid cancer occurs more commonly among females, whereas bladder cancer is seen more often among males (ACS, 2013a). See Chapters 48 and 49 for more information on gender-specific cancers.

POVERTY

The poor are at higher risk for cancer than the population in general. Lack of health insurance and inadequate access to healthcare, especially preventive screening and counseling, may be major factors (ACS, 2013a). Although other factors that may be involved, such as diet and stress, usually come under the category of controllable risks, these risks are frequently uncontrollable in this population.

STRESS

Continuous unmanaged stress that keeps hormones such as epinephrine and cortisol at high levels can result in systematic fatigue and impaired immunologic surveillance. When the body attempts to adapt to physiologic and psychologic stressors, it goes through a series of stages called the general adaptation syndrome (Gregorio et al., 2012; Hasselbalch, 2013). First, the "alarm reaction" occurs, in which adrenal hormones increase, allowing the body to cope with the stressor. Eventually, the body reaches the "stage of resistance," in which the stress hormones are significantly reduced, indicating that adaptation has occurred. If the physiologic adaptation is supported by appropriate coping strategies, the stressor is considered managed and body systems return to prealarm functioning. However, if adaptation continues and the stress hormones remain elevated, the "stage of exhaustion" sets in. This stage will maintain life, but at great expense to body systems, resulting in general wear-and-tear and depression of the immune system (Antoni et al., 2012).

DIET

Dietary factors appear to be one of the most important factors for cancer risk. A diet that is high in red meat and saturated fat appears to increase risk. Vegetables, fruits, fiber, folate, and calcium may be protective (ACS, 2013a). Some foods are considered genotoxic, such as the nitrosamines and nitrous indoles (a crystalline alkaloid compound) found in preserved meats and pickled, salted foods. Other foods, such as high-fat, low-fiber foods—the mainstay of many American diets—promote colon, breast, and sex hormone–dependent tumors. When fish and meat are excessively fried or broiled, potent carcinogenic compounds can form that may cause tumors in the mammary glands, colon, liver, pancreas, and bladder. Repeatedly using fat to fry foods at high temperatures produces high levels of polycyclic hydrocarbons, which increase cancer risk considerably. Other food-related substances believed to increase cancer risk include sodium saccharine, red food dyes, and both regular and decaffeinated coffee.

OCCUPATION

Occupational risk might be considered to be either controllable or uncontrollable. For many people, both education and ability limit their choice of occupation; during times of high unemployment, moreover, changing one's occupation because it poses risk factors may not be a viable option. Federal standards are designed to protect workers from hazardous substances, but many believe that these standards are not strict enough and that inspections are not frequent enough to prevent violations.

Specific risks vary according to the occupation. For example, outdoor workers such as farmers and construction workers are exposed to solar radiation, healthcare workers such as x-ray technicians and biomedical researchers are exposed to ionizing radiation

NURSING CARE OF THE OLDER ADULT

Older Adults with Cancer

Nurses need to be aware of how cancer and cancer treatments affect older adults. Cancer is the second leading cause of death in people over age 65 (ACS, 2013a). The incidence of cancer increases with advancing age, probably as a result of the accumulated exposure to carcinogens and to age-related declines in the action of the immune system (Antoni et al., 2012; Fulop et al., 2011; Gregorio et al., 2012; Hasselbalch, 2013). The most commonly seen cancers in older women are colorectal, breast, lung, pancreatic, and ovarian. In older men, lung, colorectal, prostate, pancreatic, and gastric cancers occur most frequently.

The importance of screening and early detection of cancer does not diminish with age. Unfortunately, older adults may be less likely to undergo cancer screening or seek treatment for cancer due to fear, depression, cognitive impairments, poor access to healthcare, or financial constraints (Hoffe & Balducci, 2012; Sarfaty et al., 2011). Some older adults (and healthcare providers) mistake cancer symptoms for normal age-related changes. Believing that little can be done, they do not seek healthcare for their symptoms. When they do seek treatment, chronic conditions frequently seen in older adults may make the diagnosis of cancer more difficult by masking or confounding the usual symptoms associated with cancer.

Older adults are at greater risk for side effects associated with cancer treatment because of age-related physiologic changes and chronic conditions associated with aging (Goto et al., 2012). This is particularly true for the side effects of chemotherapeutic agents and radiation therapy. The incidence of toxic effects on the heart and central nervous system is increased (Goto et al., 2012). The side effects of chemotherapy can contribute to fatigue and cause problems related to immobility and functional decline (Goto et al., 2012). The problems associated with chemotherapy do not rule out its use in older adults with cancer, but the nurse must be aware of potential problems and monitor the patient closely for the development of side effects. The nurse needs to consider the effects of aging on responses to the disease and its treatment. Alterations in the function of the immune system are more frequent in older adults, increasing their risk for developing infection (Antoni et al., 2012; Fulop et al., 2011; Gregorio et al., 2012; Hasselbalch, 2013).

HEALTH EDUCATION FOR THE PATIENT AND FAMILY

- Discuss the warning signs of cancer.
- Stress the importance of seeking healthcare if any of the warning signs develop.
- Get an annual physical examination.
- For women, learn how to perform a monthly breast self-exam (BSE) and emphasize the importance of continuing BSE and regular mammography after menopause.
- Teach men the early signs of prostate cancer, and encourage them to discuss the potential benefits, risks, and uncertainties associated with prostate cancer screening to allow them to make an informed decision about prostate cancer screening (ACS, 2014).

and carcinogenic substances, and exposure to asbestos is a problem for people who work in old buildings with asbestos insulation in the walls. Table 14–1 correlates known carcinogens and occupations.

INFECTION

A number of viruses have been linked to some cancers, such as hepatitis B virus and hepatitis C virus for liver and pancreatic cancer, and the human papillomavirus (HPV) for cervical and anal cancers (ACS, 2013a). Avoiding those specific infections will decrease risk. Although some infections may be unavoidable (Epstein-Barr, for example), others such as genital herpes and HPV-induced genital warts can often be avoided by following safer sex practices (e.g., the use of condoms) or obtaining an HPV vaccine.

TOBACCO USE

Smoking-related diseases remain the world's most preventable cause of death (ACS, 2013a). Lung cancer is considered highly preventable because of its relationship to smoking. The genotoxic carcinogenic substances in tobacco are considered weak; therefore, stopping smoking can reverse the damage it causes. However, many other substances in tobacco are highly promotional, so that the larger the dose and longer the use, the higher the risk for developing cancer. Research has shown a significantly lower lung cancer death risk for former smokers compared to current smokers.

Tobacco is related to other forms of cancer. Smokers face an increased risk for oropharyngeal, esophageal, laryngeal, gastric, pancreatic, and bladder cancers (ACS, 2013a). Pipe and cigar smokers

TABLE 14–1 Chemical Carcinogens and Relationship to Occupation

Chemical Agent	Action	Occupation Affected
Polycyclic hydrocarbons (smoke, soot, tobacco, and smoked foods) and benzopyrene	Genotoxic	Miners, coal/gas workers, chimney sweeps, migrant workers, workers in offices where smoking is allowed in closed areas
Arsenic	Genotoxic	Pesticide manufacturers, miners
Vinyl chloride polymers	Promotional	Plastics workers, artists
Methylaminobenzine	Genotoxic	Fabric workers, rubber and glue workers
Asbestos	Promotional	Construction workers, workers in old, run-down buildings with asbestos insulation, insulation makers
Wood and leather dust	Promotional	Woodworkers, carpenters, leather toolers
Chemotherapy drugs	Genotoxic	Drug manufacturers, pharmacists, nurses

are especially susceptible to oropharyngeal and laryngeal cancers. Oral and esophageal cancers are more common among those who chew tobacco or use snuff. Smokers who have a genetic decrease in alpha$_1$-antitrypsin (an enzyme that protects lung tissue) that results in emphysema face an even higher cancer risk than smokers without this defect.

Secondhand smoke (SHS), or environmental tobacco smoke, contains 7000 chemicals, at least 69 of which are human carcinogens for which there is no safe level of exposure (U.S. Department of Health and Human Services, 2010). Each year about 3400 nonsmoking adults die of lung cancer as a result of breathing SHS (ACS, 2013a). In the United States efforts have been made to prevent SHS including legislation; for example, currently 3501 municipalities have passed smoke-free legislation.

ALCOHOL USE

Alcohol promotes cancer by enhancing the contact between carcinogens such as those in tobacco and the stem cells that line the oral cavity, larynx, and esophagus (ACS, 2013a). People who both smoke and drink a considerable amount of alcohol daily have an increased risk for oral, esophageal, and laryngeal cancers.

RECREATIONAL DRUG USE

Recreational drug use often promotes an unhealthy lifestyle that increases general cancer risk; for example, drug users often do not maintain adequate nutrition. Furthermore, recreational drugs are implicated as promoters because of their suppressive effect on the immune system. Although it has not been directly implicated in cancer development, marijuana has been demonstrated to cause chromosomal damage that may over time result in cancer-causing deoxyribonucleic acid (DNA) damage and genetic mutations. Marijuana smoke is more injurious to lung tissue than tobacco smoke.

OBESITY

Overweight and obesity contribute to 14% to 20% of all cancer-related mortality in the United States (ACS, 2013a). Excessive body fat has been linked to an increased risk of hormone-dependent cancers. Because sex hormones are synthesized from fat, obese people often have excessive amounts of the hormones that feed hormone-dependent malignancies of the breast, bowel, ovary, endometrium, and prostate. Overweight and obesity are clearly associated with increased risk for developing many cancers, including cancers of the breast (in postmenopausal women), colon, endometrium, kidney, and adenocarcinoma of the esophagus (ACS, 2013a).

SUN EXPOSURE

As the protective ozone layer thins, more of the sun's damaging ultraviolet radiation reaches the earth. As a consequence, the rate of skin cancers has increased. Sun-related skin cancers are now considered to be a problem for all people, regardless of skin color, but people of northern European extraction with very fair skin, blue or green eyes, and light-colored hair are most vulnerable. Older adults with decreased pigment are more at risk, even those with darker skin.

PATHOPHYSIOLOGY

Cancer is a complex disease with hundreds of agents that can contribute to its pathogenesis. Advances in research have greatly increased the understanding of how cancer develops. We now know that the development of cancer is a process in which normal cells are changed and acquire malignant properties. Before a discussion of the various theories of the causes of cancer, a review of how normal cells divide and adapt to changing conditions will be useful.

BOX 14–2 Functions of DNA

- Determines protein production.
- Instructs cells to produce specific chemicals.
- Instructs cells to develop specific structures.
- Determines individual traits and characteristics.
- Controls other DNA by telling a cell to "switch on."

Normal Cell Growth

Mature normal cells are uniform in size and have nuclei that are characteristic of the tissue to which the cells belong. Within the nucleus of normal cells, chromosomes containing DNA molecules carry the genetic information that controls the synthesis of polypeptides (proteins). Genes are subunits of chromosomes and consist of portions of DNA that specify the production of particular sets of proteins. Thus, genes control the development of specific traits. The genetic code in the DNA of every gene is translated into protein structures that determine the type, maturity, and function of a cell. Any change or disruption in a gene can result in an inaccurate "blueprint" that can produce an aberrant cell, which may then become cancerous. Box 14–2 lists some of the functions of DNA.

The Cell Cycle

Two coordinated events are responsible for cellular reproduction. Reproduction occurs as the result of replication of cellular DNA and mitosis, when the cell divides into two daughter cells with identical DNA.

The **cell cycle** consists of four phases. In the gap 1 or G_1 phase, the cell enlarges and synthesizes proteins to prepare for DNA replication. During this phase the cell prepares to replicate and enter into the synthesis phase. During the synthesis (S) phase, DNA is replicated and the chromosomes in the cell are duplicated. During the gap 2 or G_2 phase, the cell prepares itself for mitosis. Finally, with all preparation complete, the cell begins mitosis in the M phase. This phase culminates in the division of the parent cell into two exact copies called daughter cells, each having identical genetic material. The cells then immediately enter G_1 where they begin the cell cycle again, or divert into a resting phase called G_0. The cell cycle is controlled by cyclins, which combine with and activate enzymes called cyclin-dependent kinases. Some cyclins cause a "braking" action and prevent the cycle from proceeding. Checkpoints in the cell cycle ensure that it proceeds in the correct order.

A malfunction of any of these regulators of cell growth and division can result in the rapid proliferation of immature cells. In some cases, these cells are considered cancerous (malignant). Knowledge of cell cycle events is used in the development of chemotherapeutic drugs, which are designed to disrupt the cancer cells during different stages of their cell cycle. These drugs and their use are discussed later in the chapter.

Differentiation

Differentiation is a normal process occurring over many cell cycles that allows cells to specialize in certain tasks. For example, some

epithelial cells lining the lungs develop into tall columnar cells with cilia. These columnar cells sweep potentially dangerous debris out of the lungs. When adverse conditions occur in body tissues during differentiation, protective adaptations can produce alterations in cells. Some of these alterations are helpful, but in other cases the cells mutate beyond usefulness and become liabilities. Potentially unproductive cellular alterations that occur during cell differentiation include the following:

- **Hyperplasia** is an increase in the number or density of normal cells. Hyperplasia occurs in response to stress, increased metabolic demands, or elevated levels of hormones. Examples include the hyperplasia of myocardial cells in response to a prolonged increase in the body's demand for oxygen, and hyperplasia of uterine cells in response to rising levels of estrogen during pregnancy. Hyperplastic cells are under normal DNA control.
- **Metaplasia** is a change in the normal pattern of differentiation such that dividing cells differentiate into cell types not normally found in that location in the body. The metaplastic cell is normal for its particular type, but it is not in its normal location. Some metaplastic cells are less functional than the cells they replace. Metaplasia is a protective response to adverse conditions. Metaplastic cells are under normal DNA control and are reversible when the stressor or other disruptive condition ceases.
- **Dysplasia** represents a loss of DNA control over differentiation occurring in response to adverse conditions. Dysplastic cells show abnormal variation in size, shape, and appearance and a disturbance in their usual arrangement. Examples of dysplasia include changes in the cervix in response to continued irritation, such as from HPV, or leukoplakia on oral mucous membranes in response to chronic irritation from smoking.
- **Anaplasia** is the regression of a cell to an immature or undifferentiated cell type. Anaplastic cell division is no longer under DNA control. Anaplasia usually occurs when a damaging or transforming event takes place inside the dividing, still undifferentiated cell, leading to loss of useful function. Anaplasia may occur in response to overwhelmingly destructive conditions inside the cell or in surrounding tissue.

Although hyperplasia, metaplasia, and dysplasia often reverse after the irritating factor is eliminated, they can lead to malignancy under certain conditions. This is especially true of dysplasia, which represents a loss of DNA control. Anaplasia is not reversible, but the degree of anaplasia determines the potential risk for cancer.

Theories of Carcinogenesis

Factors that cause cancer are both external (chemicals, radiation, and viruses) and internal (hormones, immune conditions, and inherited mutations). Causal factors may act together or in sequence to initiate or promote **carcinogenesis**, a process by which normal cells are transformed into cancer cells. Often, more than 10 years pass between exposures or mutations and detectable cancer.

Central to these theories are two important concepts about the etiology of cancer. First, damaged DNA, whether inherited or from external sources, sets up the necessary initial step for cancer to occur. Second, impairment of the human immune system, from whatever cause, lessens its ability to destroy abnormal cells.

CELLULAR MUTATION

The theory of cellular mutation suggests that certain agents cause mutations in cellular DNA and transform cells into cancer cells. Such agents are called **carcinogens**. It is believed that the carcinogenic process has three stages: initiation, promotion, and progression. The initiation stage involves permanent damage to the cellular DNA as a result of exposure to a carcinogen (e.g., radiation, chemicals) that was not repaired or had a defective repair. Promotion may last for years and includes conditions, such as smoking or alcohol use, that act repeatedly on the already affected cells. In the progression stage further inherited changes acquired during cell replication develop into a cancer.

ONCOGENES

Proto-oncogenes are normal genes that promote cell growth and repair. **Oncogenes** are abnormal genes that promote cell proliferation and are capable of triggering cancerous characteristics. Oncogenes can be classified according to their overall function. One classic example of an oncogene is BCR-ABL fusion protein, which results from a translocation between chromosomes 9 and 22, known as the Philadelphia chromosome. The increased expression of this protein allows for unregulated cell proliferation and is found in patients with chronic myelogenous leukemia (CML) and other leukemias (Riley et al., 2012).

A decrease in the body's immune surveillance may allow the expression of oncogenes; this can occur during times of stress or in response to certain carcinogens. For example, patients with AIDS, who have a decreased number of T-helper lymphocytes, have a much higher than normal incidence of certain cancers, including non-Hodgkin's lymphoma and Kaposi's sarcoma (Petoumenos et al., 2013).

TUMOR SUPPRESSOR GENES

Tumor suppressor genes normally block cell growth by suppressing oncogenes. They can become inactive by deletion or mutation. For example, inherited mutations in the *p53* gene are associated with sarcomas, breast cancer, leukemia, and renal tumors.

Known Carcinogens

A number of agents are known to cause cancer, or at least are strongly linked to certain kinds of cancers. These known carcinogens include viruses, drugs, hormones, and chemical and physical agents. The National Toxicology Program (NTP) and the International Agency for Research on Cancer (IARC) play an important role in the identification and evaluation of carcinogens. See their respective websites for a list of substances known or reasonably anticipated to be human carcinogens.

Carcinogens can be categorized into two groups: Genotoxic carcinogens directly alter DNA and cause mutations, and promoter substances cause other adverse biologic effects, such as cytotoxicity, hormonal imbalances, altered immunity, or chronic tissue damage. Promoter substances do not cause cancer in the absence of previous cell damage (initiation) and often require high-level and long-term contact with the altered cells (refer to Table 14–1). Although everyone comes in contact with a vast number of substances considered carcinogenic, not everyone develops cancer. Other factors, such as genetic predisposition, impairment of the immune response, and repeated exposure to the carcinogen, are necessary for a cancer to develop.

BOX 14–3 Cancers Associated with Different Viruses

HERPES SIMPLEX VIRUS TYPES 1 AND 2 (HSV-1 AND HSV-2)
- Carcinoma of the lip
- Cervical carcinoma
- Kaposi's sarcoma

HUMAN CYTOMEGALOVIRUS (HCMV)
- Kaposi's sarcoma
- Prostate cancer

EPSTEIN-BARR VIRUS (EBV)
- Burkitt's lymphoma

HUMAN HERPESVIRUS 6 (HHV-6)
- Lymphoma

HEPATITIS B VIRUS (HBV)
- Primary hepatocellular cancer

PAPILLOMAVIRUS
- Malignant melanoma
- Cervical, penile, and laryngeal cancers

HUMAN T-LYMPHOTROPIC VIRUSES (HTLVS)
- Adult T-cell leukemia and lymphoma
- T-cell variant of hairy-cell leukemia
- Kaposi's sarcoma

VIRUSES

Several viruses have been associated with the development of cancer. They damage cells and induce hyperplastic cell growth. Viral infection may play a role in cell mutation that can progress to malignant cells. Most people are able to suppress this progression. Box 14–3 identifies these viruses and the cancers with which they are associated. In addition, viruses play a significant role in weakening immunologic defenses against neoplasms. For example, human immunodeficiency virus (HIV), which infects T-helper lymphocytes and monocytes, impairs an individual's protection against certain cancers such as lymphoma and Kaposi's sarcoma (Petoumenos et al., 2013).

Other viruses have been associated with human malignancies. Hepatitis B virus integrates its DNA with liver cell DNA and is believed to cause primary hepatocellular carcinoma. Papillomaviruses cause plantar, common, and flat warts, which are benign and usually regress spontaneously; however, they also cause genital warts and laryngeal papillomas, which are associated with malignant melanoma and cervical, penile, and laryngeal cancers. Vaccines to prevent virus-induced cancers are being investigated in various cancers, such as melanoma, lung cancer, and osteosarcoma (Berinstein et al., 2012). More research is needed to investigate the effectiveness of immunotherapy, such as vaccines.

DRUGS AND HORMONES

Certain drugs can be either genotoxic or promotional. For example, chemotherapeutic drugs used to disrupt the cell cycle of malignant cells can be genotoxic for normal cells. They can also be promotional: By drastically reducing the number of leukocytes, they impair immune function. Examples of these chemotherapeutic drugs include busulfan, chlorambucil, and cyclophosphamide. Some recreational drugs are implicated as carcinogens. These include the genotoxic betel nut chewed by many Pacific Islanders and the immunosuppressant promoters heroin and cocaine.

Hormones are also potential genotoxic carcinogens or promoters. Gonadotropic hormones often mediate cancers of the reproductive organs. Estrogen, both natural and synthetic, and diethylstilbestrol (DES) have been linked to cervical, endometrial, and breast cancers. Estrogen-containing contraceptive pills have been implicated in breast cancer, but they also have been shown to decrease the risk of ovarian cancer. Investigators have not reached a final conclusion about the cancer risk posed by contraceptives. Newer research suggests that alterations in the molecular structure of testosterone in older men may promote the development of prostate cancer. Glucocorticosteroids (cortisone) and anabolic steroids may act as promoters by altering the immune response or endocrine balance.

CHEMICAL AGENTS

Many chemicals are both genotoxic and promotional. Because many of these substances are encountered in the workplace, they constitute occupational hazards. Examples of industrial and environmental carcinogens include polycyclic hydrocarbons, found in soot; benzopyrene, found in cigarette smoke; and arsenic, found in pesticides. These chemicals have some genotoxic action; some alter DNA replication. Other industrial and environmental chemicals are considered promotional agents, including wood and leather dust, polymer esters (used in plastics and paints), carbon tetrachloride, asbestos, and phenol (NTP, 2005). Polycyclic aromatic hydrocarbons, nitrosamines, phenols, and other chemicals in tobacco act as either carcinogens or promoters of cancer (refer to Table 14–1).

Natural substances in the body may also be carcinogenic or promotional. For example, end products of metabolism that are produced in excess amounts or are ineffectively eliminated, such as bile acids from a high-fat diet, may promote cancer.

Some foods contain carcinogens added during preparation or preservation. Examples include the sugar substitute sodium saccharine and nitrosamines and nitrous indoles, which are found in pickled, salted foods. In some cases, food contaminants produce carcinogenic chemicals. The *Aspergillus* fungi produce aflatoxin, a highly potent carcinogen. These organisms grow on improperly stored vegetable products, such as grains and peanuts.

PHYSICAL AGENTS

It has been well documented that excessive exposure to radiation causes increased rates of cancer by damaging the DNA in cells, by activating other oncogenetic factors, or by suppressing antitumor activity (protein inhibitors). Both solar radiation from ultraviolet rays and ionizing radiation from industrial or medical sources are carcinogenic. This fact has implications for workers exposed to these agents and for the population in general. Radon, a naturally formed radioactive gas found in the basements of many homes, is a known carcinogen. People who have lived in areas where nuclear weapons have been tested or whose groundwater has been polluted by nuclear wastes are at risk for developing cancers. The effects of high-dose radiation exposure and subsequent cancer development have been demonstrated in the survivors of the atomic bombs at Nagasaki and Hiroshima and in workers exposed to radiation during the cleanup of nuclear disasters such as Chernobyl.

Types of Neoplasms

A **neoplasm** is a mass of new tissue (a collection of cells) that grows independently of its surrounding structures and has no physiologic purpose. The term *neoplasm* is often used interchangeably with

tumor, from the Latin word meaning "swelling." Neoplasms are said to be autonomous because they grow at a rate uncoordinated with body needs, they share some of the properties of the parent cells but with altered size and shape, and they do not benefit the host and in some cases are harmful.

Neoplasms are not completely autonomous because they require a blood supply with nutrients and oxygen to sustain their growth. Neoplasms typically are classified as benign or malignant on the basis of their potential to damage the body and on their growth characteristics.

BENIGN NEOPLASMS

Benign neoplasms are localized growths. They form a solid mass, have well-defined borders, and frequently are encapsulated. Benign neoplasms tend to respond to the body's homeostatic controls. Thus, they often stop growing when they reach the boundaries of another tissue (a process called *contact inhibition*). They grow slowly and often remain stable in size. Because they are usually encapsulated, benign neoplasms often are easily removed and tend not to recur.

Although typically harmless, benign neoplasms nevertheless can be destructive if they crowd surrounding tissue and obstruct the function of organs. For example, a benign meningioma of the brain or spinal cord can cause increased intracranial pressure (IICP), which progressively impairs an individual's cerebral function. Unless the meningioma can be successfully removed, the steadily rising IICP will eventually lead to coma and death.

MALIGNANT NEOPLASMS

In contrast to benign neoplasms, malignant neoplasms grow aggressively and do not respond to the body's homeostatic controls. Malignant neoplasms are not cohesive, and present with an irregular shape. Instead of slowly crowding other tissues aside, malignant neoplasms cut through surrounding tissues, causing bleeding, inflammation, and necrosis (tissue death) as they grow. This invasive quality of malignant neoplasms is reflected in the word origin of *cancer*, from the Greek *karkinos*, meaning "crab."

Malignant cells from the primary tumor may travel through the blood or lymph to invade other tissues and organs of the body and form a secondary tumor called a **metastasis**. This term also refers to the process by which such spreading of malignant neoplasms—perhaps their most destructive trait—occurs. Malignant neoplasms can recur after surgical removal of the primary and secondary tumors and after other treatments. Table 14–2 compares benign and malignant neoplasms.

TABLE 14–2 Comparison of Benign and Malignant Neoplasms

Benign	Malignant
Local	Invasive
Cohesive	Noncohesive
Well-defined borders	Does not stop at tissue border
Pushes other tissues out of the way	Invades and destroys surrounding tissues
Slow growth	Rapid growth
Encapsulated	Metastasizes to distant sites
Easily removed	Not always easy to remove
Does not recur	Can recur

Malignant neoplasms vary in their degree of differentiation from the parent tissue. Highly differentiated cancer cells try to mimic the specialized function of the parent tissue, but undifferentiated cancers, consisting of immature cells, have almost no resemblance to the parent tissue and so perform no useful function. Undifferentiated cancers rob the body of its energy and nutrition as they grow. Undifferentiated anaplastic cells have little structural or functional relationship to the parent cells and are the basis of many malignant neoplasms. The degree of differentiation of anaplastic cells is a consideration in the classification and staging of neoplasms, discussed later in this chapter.

Characteristics of Malignant Cells

Malignant neoplasms may be identified by the following predictable cellular characteristics:

- ***Loss of regulation of the rate of mitosis*** This leads to rapid cell division and growth of the neoplasm.
- ***Loss of specialization and differentiation*** Malignant cells do not perform typical cellular functions. Many produce hormones and enzymes similar to those of the parent tissue, but usually in excessive amounts, possibly revealing their presence.
- ***Loss of contact inhibition*** Malignant cells do not respect other cellular boundaries. They easily invade and destroy other tissues.
- ***Progressive acquisition of a cancerous phenotype*** Cellular mutation seems to be a sequential process involving successive generations of cells, each generation becoming more deviant than the previous one. Additionally, malignant cells seem to be immortal; that is, they do not stop growing and die, as do normal cells, which have a genetically determined life span.
- ***Irreversibility*** The transformation into a malignant cell is irreversible. Rarely does a malignant neoplasm revert to a benign state.
- ***Altered cell structure*** Cytologic examination of malignant cells reveals distinct differences in the cell nucleus and cytoplasm as well as an overall cell shape that differs from that of normal cells of the particular tissue type.
- ***Simplified metabolic activities*** The work of malignant cells is simpler than that of normal cells; they show an increased synthesis of substances needed for cell division, and they have no need to create proteins for the specialized functions of the tissues they invade.
- ***Transplantability*** Malignant cells often break away from the primary tissue site and travel to other locations in the body, where they establish new growths.
- ***Ability to promote their own survival*** Malignant cells may create ectopic sites to produce the hormones they need for their growth. By their very presence and their ability to initiate vascular permeability, malignant cells promote the development of nonneoplastic stroma, a connective tissue framework consisting of collagen and other components, which then supports the neoplasm. They may create their own blood supply. Through a process called angiogenesis, tumor cells secrete a polypeptide angiogenic growth factor that stimulates blood vessels from surrounding normal tissue to grow into the tumor. Finally, malignant cells divert nutrition from the host to meet their own needs, by diffusion when the tumor is less than 1 mm and thereafter by means of the newly formed blood vessels. If unchecked, malignant cells eventually destroy their host.

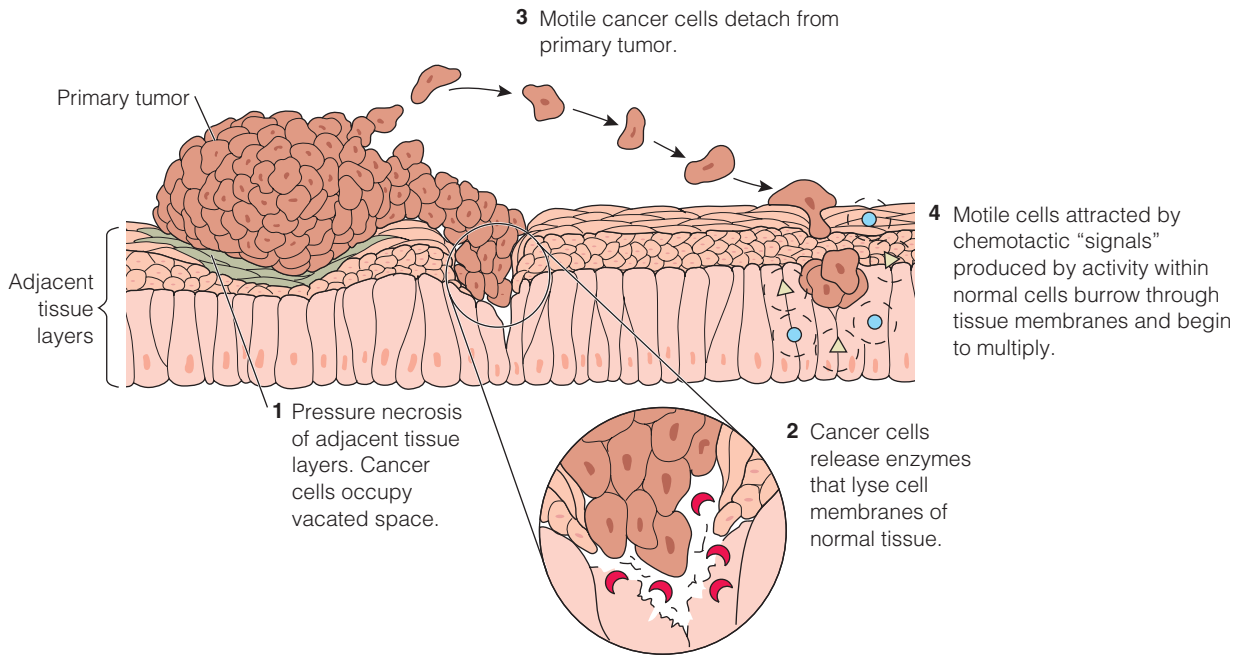

Figure 14–2 ■ How cancer cells invade normal tissue.

Tumor Invasion and Metastasis

Metastasis, the ability of cancer cells to invade adjacent tissues and travel to distant organs, is considered cancer cells' most ominous characteristic. This quality makes treatment a considerable challenge.

INVASION

Aggressive tumors possess several qualities that facilitate invasion (Figure 14–2 ■):

- ***Ability to cause pressure atrophy*** The pressure of a growing tumor can cause atrophy and necrosis of adjacent tissues. The malignancy then moves into the vacated space.
- ***Ability to disrupt the basement membrane of normal cells*** Many cancer cells can bind to elements of the basement membrane and secrete enzymes that degrade that physical barrier, thus facilitating their movement into normal tissues, lymph, and blood circulation.
- ***Motility*** Because malignant cells are less tightly bound to each other than normal cells (reduced adhesiveness), they easily separate from the neoplasm and move into surrounding body fluids and tissues.
- ***Response to chemical signals from adjacent tissues*** Chemotaxis (the movement of cells in response to a chemical stimulus) calls the tumor cells into the normal tissues, possibly as a result of the degrading of the basement membranes of the normal cells. This breakdown of normal cellular membranes releases the chemical stimulus physiologically designed to draw normal phagocytic cells to clean up the debris. (Refer to Chapter 12 on the inflammatory response for more information on chemotaxis.) Malignant cells are known to respond chemotactically to the end product of cellular metabolism. Some cancer cells even produce a substance called autocrine motility factor, which calls other malignant cells to a normal tissue. The first invading cells produce this substance, which then actively draws other malignant cells from the primary tumor into the invaded normal tissue.

METASTASIS

The factors that favor invasion also contribute to the process of metastasis. Metastasis can occur by means of one or more mechanisms including embolism in the blood or lymph, or spread by way of body cavities.

A blood- or lymph-borne metastasis allows a new tumor to be established in a distant organ. Figure 14–3 ■ shows metastasis

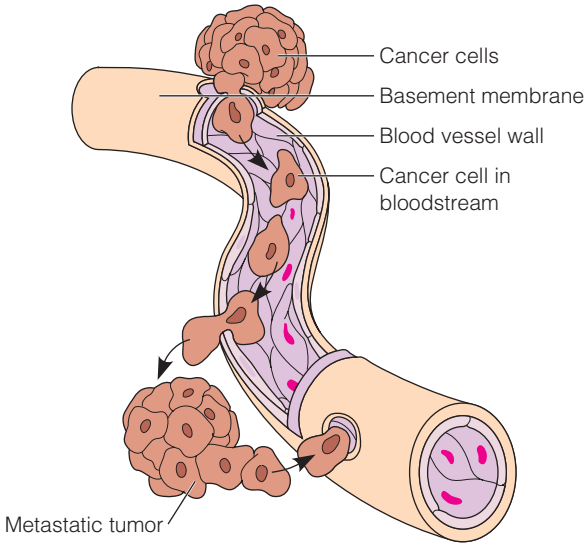

Figure 14–3 ■ Metastasis through the bloodstream. Cancer cells secrete enzymes and a motility factor that disrupt the basement membrane in the blood vessel. In this way, the cancer cells gain access to the circulation. Once in the blood, only about 1 cell in 1000 escapes immune detection, but that can be enough. Undetected cells move out of the blood, again secreting enzymes and cutting through the vessel wall into new tissue. The tissue selected for establishing a new tumor may be downstream from the original tumor, or a chemical attraction may cause the malignant cells to target a specific site. Once in the new site, the malignant cells multiply and establish a metastatic tumor.

through the bloodstream. A tumor's ability to metastasize in this manner requires the following steps:

1. Intravasation of malignant cells through blood or lymphatic vessel walls and into the circulation
2. Survival of the malignant cells in the blood (To survive, the cells must escape the notice of the body's immune surveillance; only about 1 in 1000 cells does so.)
3. Extravasation from the circulation and implantation in a new tissue.

The tumor cells tend to clump together, forming an embolus, and continue growing until their size prevents further travel in the vessel or lymph channel. The growing neoplastic mass then uses its invasive abilities (secreting enzymes and motility factor) to move into the nearest organ.

About 60% of metastatic lesions tend to occur in a pattern that reflects blood or lymph circulation. However, it has been demonstrated that some malignant cells defy a bloodborne pattern and actually target specific organs to which they prefer to metastasize. For example, lung cancer frequently metastasizes to the adrenal glands, and breast cancer frequently metastasizes to bone. Malignant cells that gain access to lymph channels may travel to a preferred organ and then move into it the same way they move through blood vessels. Alternatively, the malignant cells may become trapped in the lymph node and continue to grow. Eventually, the malignant cells replace the node's tissues. At this point, emboli from the cancerous node disseminate to other nodes, creating a cascade reaction. The malignant cascade causes widespread transfer of the tumor to uncharacteristic sites.

A malignant tumor may break through the walls of the organ in which it is primarily housed, shedding cells into the nearby body cavity. The cells then are free to establish new tumors in a distant area of that cavity. For example, malignant cells from a colon cancer may be seeded into the peritoneal cavity, establishing a new tumor in the mesenteric epithelium.

Metastatic lesions are differentiated from primary neoplasms by cell morphology: Metastatic cells do not resemble the tissue in which they reside. The most common sites of metastasis are the lymph nodes, liver, lungs, bones, and brain. Table 14–3 lists different cancers and common sites of metastasis.

For metastasis to occur, the cancerous cells must avoid detection by the immune system. Thus, impairment of the immune system is a major factor in the establishment of metastatic lesions. Cells may escape detection in several different ways:

TABLE 14–3 Various Cancers and Sites of Metastases

Primary Tumor	Common Metastatic Sites
Bronchogenic (lung)	Spinal cord, brain, liver, bone
Breast	Regional lymph nodes, vertebrae, brain, liver, lung, bone
Colon	Liver, lung, brain, ovary, bone
Prostate	Bladder, bone (especially vertebrae), liver
Malignant melanoma	Lung, liver, spleen, regional lymph nodes, brain

BOX 14–4 Factors That May Weaken or Alter the Immune Response

- Accumulated stress
- Depression
- Increased age
- Pregnancy
- Chronic disease
- Chemotherapy treatment for the primary cancer

- Aggressive cancer cells may compile a large mass (greater than 1 cm) so rapidly that the immune system is unable to overcome the tumor before it takes hold in a new tissue.
- For tumor cells to be recognized as foreign by the immune system, they must display on their surface a special antigen called tumor-associated antigen (TAA). TAA marks tumor cells for destruction by the lymphocytes. Some oncogenic viruses depress the expression of TAA on infected cells. Some tumors in advanced stages of growth no longer display TAA. Thus, such tumor cells escape detection as they travel through the blood or lymph.
- If an individual's immune response is weakened or altered, then a metastatic tumor may take hold with little opposition. Factors that may weaken or alter the immune response are listed in Box 14–4.

An estimated 50% to 60% of all cancers have already metastasized by the time the primary tumor is identified. This may account for the current 50% death rate and certainly supports the need for patient education to facilitate early diagnosis. The time it takes for metastasis to occur is extremely variable and often difficult to predict. Some cancers, such as basal cell carcinomas, do not metastasize. The aggressiveness and location of the tumor, and the state of the person's immune system, determine whether and how rapidly metastasis takes place.

PHYSIOLOGIC AND PSYCHOLOGIC EFFECTS OF CANCER

Much of the nursing care for patients with cancer is related to the effects of cancer disease and the side effects of cancer treatment. Although the pathophysiologic effects of cancer vary with the type and location of the cancer, the accompanying Pathophysiology Linkages lists common manifestations of cancer with the related pathophysiology.

PATHOPHYSIOLOGY LINKAGE

Cancer

Manifestation	Related Pathophysiology
Ascites	Obstruction to the portal vein in liver, which can cause portal hypertension, resulting in backup of fluid
Malaise or fatigue	Effect of inflammatory mediators such as interleukins and tumor necrosis factor-α (TNF-α) on the central nervous system
Anorexia, nausea, vomiting	Effect of inflammatory mediators and endotoxins on the vomiting center in the medulla
Pain	Stretching and compression of body tissues by the tumor; activation of nociceptors by chemicals released by ischemic tissues or tumor metabolites and toxins

Disruption of Function

Physiologic functioning can be upset by obstruction or pressure. For example, a large tumor in the bowel can stop intestinal motility, resulting in a bowel obstruction. Prostatic tumors can obstruct the bladder neck or urethra, resulting in urine retention. Intracranial pressure can be dangerously increased by a glioma. Obstruction or pressure can cause anoxia and necrosis of surrounding tissues, which in turn cause a loss of function of the involved organ or tissue. For example, a kidney tumor may progress to renal failure. Pressure against the superior vena cava from an adjacent lung tumor or tumor-infiltrated lymph nodes can interrupt the blood flow to the heart.

In the liver, either a primary hepatocellular cancer or metastatic lesion can have several significant effects. In liver parenchymal tissue, it impairs the multiple life-sustaining functions of the liver, such as carbohydrate metabolism, synthesis of plasma proteins, detoxification, and immunologic functions. These functional impairments result in severe nutritional, hormonal, hematologic, and immunologic problems. (See Chapter 25 for a more complete discussion of liver functions and effects of disruption.) Because more than 1 L of blood per minute passes through the liver via the portal vein, obstruction to this flow by a tumor can cause portal hypertension. This results in backup of fluid and increased pressure in the splanchnic circulation. The end result is ascites (third-spaced fluid in the peritoneal cavity) and varices (friable, overdistended blood vessels) of the esophageal, gastric, mesenteric, and hemorrhoidal vessels.

Hematologic Alterations

Hematologic alterations can impair the normal function of blood cells. For example, in leukemia, a malignant proliferative disease of the hematopoietic (blood cell–producing) system, the immature leukocytes cannot perform the normal protective phagocytic functions, so immunity is compromised. The excessive numbers of immature leukocytes in the bone marrow diminish erythrocyte and thrombocyte (platelet) production, resulting in secondary anemia, neutropenia, and thrombocytopenia. In addition, gastrointestinal tumors disrupt the absorption of vitamin B_{12} and iron; growing tumors accumulate and store purines, depriving the bone marrow of substances needed for erythropoiesis (red blood cell production); and renal cell carcinoma produces its own erythropoietin hormone, resulting in production of an excessively large number of red blood cells and viscous blood, which impairs circulation, plugs small capillaries, and promotes thrombus formation (polycythemia).

Infection

If the tumor invades and connects two incompatible organs, such as the bowel and bladder, creating a fistula, infection becomes a serious problem. As they destroy viable tissue and thus their source of nutrition, tumors may become necrotic and septicemia may result. Some tumors are less efficient in creating capillaries; as a consequence, the center of the tumor may become necrotic and infected. When a tumor grows near the surface of the body, it may erode through to the surface, breaking down the natural defenses of intact skin and mucous membranes and providing a site for the entry of microorganisms. Any malignant involvement of the organs or tissues of immunity—such as the liver, bone marrow, Peyer's patches in the small intestine, spleen, or lymph nodes—can seriously impair the immune response, allowing infections to develop in vulnerable tissues.

Hemorrhage

Tumor erosion through blood vessels can cause extensive bleeding, giving rise to severe anemia. Hemorrhage can be serious enough to cause life-threatening hypovolemic shock.

Anorexia-Cachexia Syndrome

A characteristic feature of cancer is the wasted appearance of its victims, called **cachexia**. In many cases, unexplained rapid weight loss is the first manifestation that brings the patient to a healthcare provider. This can be due to a variety of problems associated with cancer, such as pain, infection, depression, or the side effects of chemotherapy and radiation. Usually the emaciation, malnutrition, and loss of energy are attributed to the anorexia-cachexia syndrome.

This syndrome is specific to cancer because of the effect of cancer cells on the host's metabolism. The neoplastic cells divert nutrition to their own use while causing changes that reduce the patient's appetite. Early in the disease, altered glucose metabolism leads to an increase in serum glucose levels, which creates negative feedback resulting in *anorexia* (loss of appetite). In addition, the tumor secretes substances that decrease appetite by altering taste and smell and producing early satiety. Pain, infection, and depression can contribute to anorexia. Some types of cancers cause specific food aversions, such as to red meat, coffee, or chocolate.

Avaricious cancer cells support their growth through widespread catabolism of the body's tissue and muscle proteins. This catabolism, coupled with inadequate nutrient intake, results in the typical cachexia. Normally, a starvation state reduces the body's basal metabolic rate. However, in many people with cancer, the metabolic rate is increased, probably because of the hyperactive metabolic and reproductive activities of the malignant cells. One theory suggests that cytokinins the body produces in response to the tumor are responsible for both early satiety and cachexia. One specific cytokine, called tumor necrosis factor alpha or cachectin, is believed to enhance the increased metabolic consumption of nutrients. Cancers of the gastrointestinal system further promote anorexia-cachexia by decreasing absorption and use of nutrients; the side effects of some treatment modalities enhance this effect. Figure 14–4 ■ shows the characteristic appearance of a cachectic person.

Figure 14–4 ■ Cachectic person. Cancer robs its host of nutrients and increases body catabolism of fat and muscle to meet its metabolic needs.

Paraneoplastic Syndromes

Paraneoplastic syndromes are indirect effects of cancer. They may be early warning signs of cancer or indicate complications or return of a malignancy. The most frequently occurring paraneoplastic syndromes are endocrine, occurring when cancers set up ectopic sites of hormone production, and neurologic, occurring when cancer damages the nervous system (Grossman & Porth, 2014). Table 14–4 lists laboratory indicators of ectopic functioning. These ectopic sites produce excessive amounts of the hormone, which harm the host. Consider the following examples:

- Breast, ovarian, and renal cancers may set up ectopic parathyroid hormone sites, causing severe hypercalcemia.
- Oat cell and other lung cancers may produce ectopic secretions of insulin (causing hypoglycemia), parathyroid hormone (PTH), antidiuretic hormone (ADH, which causes excessive fluid retention, hypertension, and peripheral edema), and adrenocorticotropic hormone (ACTH). See Chapter 19 for a description of the multiple problems caused by excessive secretions of cortisone.

Other paraneoplastic syndromes include hematologic abnormalities such as anemia, thrombocytopenia, and coagulation abnormalities; nephrotic syndrome; cutaneous syndromes; and neurologic syndromes, such as distant tumors that produce IICP.

Pain

Pain is a major healthcare problem for patients with cancer. Despite extensive progress in the scientific understanding of pain, more than 60% of patients with cancer experience moderate to severe pain at some time during their illness (Ogboli-Nwasor et al., 2013). Despite recommendations of the World Health Organization and even if effective treatments are available for 70% to 90% of cases, undertreatment is well documented and can involve up to 50% of patients (Ogboli-Nwasor et al., 2013). Undertreatment is usually attributed to an inappropriate use of opioids and barriers related to lack of knowledge and training for healthcare providers, patients, family, institutions, and society (Ogboli-Nwasor et al., 2013). Communication and knowledge deficit are the major barriers to effective pain management. Because pain management for people with cancer has a reputation for being ineffective, the anticipation of pain may engender fear in even the most stoic people.

TABLE 14–4 Laboratory Indicators of Ectopic Functioning

Hormone	Specific Laboratory Test
Antidiuretic hormone (ADH)	Serum and urine osmolality
Adrenocorticotropic hormone (ACTH)	Plasma ACTH ACTH suppression test ACTH stimulation test Urine catecholamines
Calcitonin	Serum calcitonin
Insulin	Serum glucose Glucose tolerance test
Parathyroid hormone (PTH)	Serum PTH Serum calcium
Thyroxine	Serum thyroid-stimulating hormone (TSH), T_3, T_4

TYPES OF CANCER PAIN

Cancer pain can be divided into two main categories, acute and chronic, with subgroupings. These classifications serve to indicate appropriate therapeutic approaches. Acute pain has a well-defined pattern of onset, exhibits common signs and symptoms, and is often identified with hyperactivity of the autonomic system. Chronic pain, which lasts more than 6 months, frequently lacks the objective manifestations of acute pain, primarily because the autonomic nervous system adapts to this chronic stress. Chronic pain often results in personality changes, alterations in functional abilities, and lifestyle disruptions that can seriously affect compliance with treatment and the quality of life.

Most cancer patients who cite acute pain as the primary symptom that led to the diagnosis tend to associate pain with the introduction to their disease. If these patients experience pain during the illness or after treatment, they often perceive the pain as introducing another cancer, a recurrence of the original cancer, or a component of cancer treatments (Rosedale & Fu, 2010).

Chronic pain may be related to treatment or may indicate progression of the disease. Identifying the pain as treatment related rather than tumor related is extremely important because it has a definite effect on the patient's psychologic outlook. For the patient whose pain is due to the advancement of the disease, psychologic factors play an even more important role. Hopelessness and fear of impending death intensify physiologic pain and contribute to overall suffering (which goes well beyond just physical pain).

Three other categories used to classify patients with cancer pain include patients with preexisting pain, those with a history of drug abuse, and dying patients with cancer-related pain. The first two groups may have altered perceptions of pain and may not have the anticipated response to pain medication. For the dying patient, pain is strongly associated with both the patient's and family's confrontation of issues of hopelessness and death. Confronting these issues can intensify the perception of pain.

CAUSES OF CANCER PAIN

Direct tumor involvement is the primary cause of the pain experienced by people with cancer. This includes metastatic bone disease, nerve compression, and involvement of visceral organs. The pain from tumor involvement is believed to be mechanical, resulting from stretching of tissues and compression. Chemicals from ischemia or tumor metabolites and toxins that activate and sensitize nociceptors and mechanoreceptors are also responsible for tumor pain. Refer to Chapter 9 for a more complete discussion of the mechanics of pain.

Side effects or toxic effects of cancer therapies (e.g., surgery, radiation, and chemotherapy) may cause cancer pain. These are usually the result of traumatized tissue; one example of this is the oropharyngeal ulcerations that occur with some types of chemotherapy. However, these therapies may also be used to manage pain, such as radiation to decrease pain associated with bone metastasis.

Physical Stress

When the immune system discovers a neoplasm, it tries to destroy it using the resources of the body. The body mounts an all-out assault on the foreign invader, calling on many resources, including chemical mediators, hormones and enzymes, blood cells, antibodies, proteins, and inflammatory and immune responses. These protective responses mobilize fluid, electrolyte, and nutritional systems.

This massive effort requires tremendous energy. If the neoplasm is small enough (i.e., microscopic), the immune system can destroy it, and a tumor will never manifest. A neoplasm of 1 cm is large enough to overwhelm most immune systems; however, the body will continue to try to fight it until it reaches the stage of exhaustion and is no longer capable (Selye, 1984). Thus, many patients with cancer present with fatigue, weight loss, anemia, dehydration, and altered blood chemistries (e.g., decreases in electrolytes).

Psychologic Stress

People confronted with the diagnosis of cancer exhibit a variety of psychologic and emotional responses. Some people see cancer as a death sentence and experience overwhelming grief, often giving up. Others may feel guilt, considering the cancer a punishment for past behaviors, such as smoking, unhealthy eating habits, or for delaying diagnosis or treatment. They may experience anger, especially if they believe that they had been practicing a healthful lifestyle; beneath that anger may reside feelings of powerlessness. Fear is common: fear of the outcome of the illness, fear of the effects of treatment, fear of pain, fear of death. Some people feel isolated because of the stigma of cancer and old beliefs of contagion. Body image concerns and sexual dysfunction may be present but often are unexpressed, especially if the cancer is of the breast or sexual organs, or causes visible body changes.

●○● INTERPROFESSIONAL CARE

Interprofessional care for the patient with cancer begins with a variety of specialized laboratory and diagnostic tests.

DIAGNOSIS

Several procedures are used to diagnose cancer. X-ray imaging, computed tomography (CT), ultrasonography, and magnetic resonance imaging (MRI) can locate abnormal tissues or tumors. However, only microscopic histologic examination of the tissue reveals the type of cell and its structural difference from the parent tissue. Tissue samples are acquired through biopsy, shed cells (e.g., Papanicolaou smear), or collections of secretions (e.g., sputum). Lymph nodes are biopsied to determine whether metastasis has begun. Simple screening procedures can be used to identify substances secreted by the tumor, such as the prostatic-specific antigen (PSA) blood test used to identify early prostatic cancers. Increases in enzymes or hormones released by normal tissues when they are damaged can contribute to the diagnosis. Increased alkaline phosphatase noted in bone metastases and osteosarcoma is one example of an enzyme increase associated with cancer. Tumor markers are used for early diagnosis, for tracking responses to therapy, and for devising immunologic treatments.

CLASSIFICATION To help standardize diagnosis and treatment protocols, an elaborate identification system has been developed. This consists of naming the tumor (classification) and describing its aggressiveness (grading) and spread within or beyond the tissue of origin (staging).

Tumors are classified and named by the tissue or cell of origin. Tumor nomenclature often incorporates the Latin stem identifying the tissue from which the tumor arises. For example, a carcinoma arises from epithelial tissue; adjectives are added to further specify the location. A glandular malignancy arising from epithelial tissue is classified as an adenocarcinoma. A tumor arising from supportive tissues is called a sarcoma; the specific type of tissue is added as a prefix. For example, a cancer of fibrous connective tissue is called fibrosarcoma, and a smooth muscle cancer is a leiomyosarcoma. A tumor from seminal or germ tissue is called a seminoma. Table 14–5 compares the nomenclature of benign and malignant neoplasms.

Other names for tumors incorporate the name of the discoverer of that particular cancer, such as Burkitt's lymphoma or Hodgkin's lymphoma. Hematopoietic malignancies (known as *liquid tumors*) are usually named by the type of immature blood cell that dominates. An example is myelocytic leukemia, named for the immature form of the granulocyte that is predominant in this malignancy.

GRADING AND STAGING Grading evaluates the amount of differentiation (level of functional maturity) of the cell and estimates the rate of growth based on the mitotic rate. Cells that are the most differentiated—that is, most like the parent tissue and therefore the least malignant—are classified as grade 1 and are associated with a better prognosis. Grade 4 is reserved for the least differentiated and most aggressively malignant cells. Because of the differences inherent in tumor appearance and biologic behavior, grading criteria may vary with different locations and types of tumors.

Staging is used to classify solid tumors and refers to the relative size of the tumor and extent of the disease. The TNM classification system is an internationally recognized staging system: The T stands for the relative tumor size, depth of invasion, and surface spread; N indicates the presence and extent of lymph node involvement; and M denotes the presence or absence of distant metastases. Table 14–6 shows the basic outline of the TNM system; however, other systems are also used to differentiate types and locations of tumors (e.g., melanomas, cervical cancer, Hodgkin's lymphoma).

CYTOLOGIC EXAMINATION For the malignant tissues to be identified by name, grade, and stage, they must first be subjected to histologic and cytologic examination by light or electron microscope. Specimens are collected by three basic methods:

1. ***Exfoliation from an epithelial surface*** Examples include scraping cells from the cervix (Pap smear) or bronchial washings.
2. ***Aspiration of fluid from body cavities or blood*** Examples include white blood cells for evaluation of hematopoietic cancers, pleural fluid, and cerebrospinal fluid.
3. ***Needle aspiration of solid tumors*** This could include the breast, lung, or prostate.

Cytologic examination is also carried out on specimens from biopsied tissues or tumors and on collected body secretions, such as sputum or urine.

After collection, specimens are spread on a glass slide, fixed, and stained if necessary. The morphologic features of the cells are examined, with special attention to the nucleus and cytoplasm. Other special pathologic procedures can be carried out on the specimen, but they must be ordered ahead of time if special preparations of the specimen are necessary. Several special diagnostic cytologic procedures, such as cytogenetics, are proving useful in diagnosing and monitoring patient response to treatment.

TUMOR MARKERS A **tumor marker** is a protein molecule detectable in serum or other body fluids. This marker is used as a biochemical indicator of the presence of a malignancy. Small amounts

TABLE 14–5 Nomenclature for Benign and Malignant Neoplasms

	Tissue of Origin	Benign	Malignant
Ectoderm/endoderm	Epithelium	Papilloma	Carcinoma
	Gland	Adenoma	Adenocarcinoma
	Liver cells	Hepatocellular adenoma	Hepatocellular carcinoma
	Neuroglia	Glioma	Glioma
	Melanocytes	Melanoma	Malignant melanoma
	Basal cells		Basal cell carcinoma
	Germ cells	Tetroma	Seminoma
Mesoderm	Connective tissue		
	Adipose tissue	Lipoma	Liposarcoma
	Fibrous tissue	Fibroma	Fibrosarcoma
	Bone tissue	Osteoma	Osteosarcoma
	Cartilage	Chondroma	Chondrosarcoma
	Muscle		
	Smooth muscle	Leiomyoma	Leiomyosarcoma
	Striated muscle	Rhabdomyoma	Rhabdomyosarcoma
	Neural tissue		
	Nerve cells	Ganglioneuroma	Neuroblastoma
	Endothelial tissues		
	Blood vessels	Hemangioma	Angiosarcoma
			Kaposi's sarcoma
	Meninges	Meningioma	Malignant meningioma
Hematopoietic tissues	Granulocytes	Granulocytosis	Leukemia
	Plasma cells		Multiple myeloma
	Lymphocytes		Lymphomas

of tumor marker proteins are found in normal body tissues or benign tumors and are not specific for malignancy. However, high levels are suspicious and mandate follow-up diagnostic studies. Tumor marker tests are most useful for monitoring the patient's response to therapy and for detecting residual disease. However, one marker, PSA, is a detector of prostate cancer.

TABLE 14–6 TNM Staging Classification System

	Stage	Manifestations
Tumor	T_0	No evidence of primary tumor
	T_{IS}	Tumor *in situ*
	T_1, T_2, T_3, T_4	Ascending degrees of tumor size and involvement
Nodes	N_0	No abnormal regional nodes
	N_{1a}, N_{2a}	Regional nodes—no metastasis
	N_{1b}, N_{2b}, N_{3b}	Regional lymph nodes—metastasis suspected
	N_x	Regional nodes cannot be assessed clinically
Metastasis	M_0	No evidence of distant metastasis
	M_1, M_2, M_3	Ascending degrees of metastatic involvement of the host, including distant nodes

Tumor markers fall into two general categories: those derived from the tumor itself and those associated with host (immune) response to the tumor. Examples of tumor markers include the following:

- ***Antigens*** These are present in fetal tissue but normally are suppressed after birth. Thus, their presence in large amounts may reflect an anaplastic process in tumor cells. Alpha-fetoprotein (AFP) and carcinoembryonic antigen (CEA) are oncofetal antigens.
- ***Hormones*** Hormones are present in considerable amounts in human blood and tissues, but very high levels not related to other conditions may signify the presence of a hormone-secreting malignancy. Some common hormones seen as tumor markers include human chorionic gonadotropin (HCG), antidiuretic hormone (ADH), parathyroid hormone (PTH), calcitonin, and catecholamines.
- ***Proteins*** These narrow down the type of tissue that may be malignant, although they can also be increased in hyperplastic disorders. Examples of tissue-specific proteins include serum immunoglobulin and beta$_2$ microglobulin.
- ***Enzymes*** Rapid, excessive growth of a tissue may cause some of the enzymes and isoenzymes normally present in that particular tissue to spill into the bloodstream. Elevated levels can point to either hyperplasia of the tissue or cancer. Prostatic acid phosphatase (PAP) and neuron-specific enolase (NSE) are examples. Table 14–7 compares selected tumor-derived markers with their presence in neoplasms and other conditions.

TABLE 14–7 Tumor-Derived Markers Associated with Specific Neoplasms

	Tumor Marker	Associated Neoplasm
Oncofetal antigens	Carcinoembryonic antigen (CEA)	Adenocarcinomas of colon, lung, breast, ovary, stomach, pancreas
	Alpha-fetoprotein (AFP)	Hepatocellular carcinoma, gonadal germ cell tumors (seminoma)
Hormones	Human chorionic gonadotropin (HCG)	Gonadal germ cell tumors
	Calcitonin	Medullary cancer of thyroid
	Catecholamines/metabolites	Pheochromocytoma
Isoenzymes	Prostatic acid phosphatase (PAP)	Adenocarcinoma of prostate
	Neuron-specific enolase (NSE)	Small-cell lung carcinoma, neuroblastoma
	Lactic dehydrogenase	Lymphoma, Ewing's sarcoma
Specific proteins	Prostate-specific antigen (PSA)	Adenocarcinoma of prostate
	Immunoglobin	Multiple myeloma
	CA 125	Epithelial ovarian cancer
	CA 19-9	Adenocarcinoma of pancreas, colon
	CA 15-3	Breast cancer

ONCOLOGIC IMAGING Because physical assessment usually cannot detect cancer until the tumor has reached a size that poses a major risk for metastasis, radiologic examination is extremely important in early diagnosis. This diagnostic process may involve routine x-ray imaging (usually for screening only), CT, MRI, ultrasonography, nuclear imaging, angiography, and positron emission tomography. These diagnostic tests, including preparation and nursing implications, are discussed in the assessment chapters as well as with specific body system cancers throughout the book.

X-RAY IMAGING Standard x-ray imaging is the method of choice for screening such body areas as the breast (mammography), lung, and bone to identify changes in tissue density that may indicate malignancies. X-ray imaging is still the method of choice for lung cancer, but does not usually reveal tumors until late in their development when they have reached about 1 cm in size.

COMPUTED TOMOGRAPHY CT allows the visualization of cross sections of the anatomy. Because CT scans reveal subtle differences in tissue densities, they provide much greater accuracy in tumor diagnosis than standard x-rays. This procedure is useful in screening for renal cell and most gastrointestinal tumors. CT scans are especially useful for evaluating possible lymph node involvement.

MAGNETIC RESONANCE IMAGING During an MRI, the patient is placed within a strong magnetic field, pulsed radio waves are directed at him or her, then a computer analyzes the tissue characteristics based on the transmitted signals. Related diagnostic imaging procedures—positron emission tomography (PET) and single photon emission computed tomography (SPECT)—create visible images by measuring electrical impulses from different body structures. MRI is the diagnostic tool of choice for both screening and follow-up of cranial and head and neck tumors.

ULTRASONOGRAPHY Ultrasonography measures sound waves as they bounce off various body structures, revealing abnormalities that indicate tumors. For example, transrectal ultrasonography has provided excellent imaging of early prostate cancers and is used to guide needle biopsy. Ultrasound imaging is more useful for detecting masses in the denser breast tissue of young women.

NUCLEAR IMAGING Nuclear imaging involves the use of a special scanner in conjunction with the ingestion or injection of specific radioactive isotopes. This is an invasive but usually safe diagnostic method for identifying tumors in various body tissues. The procedure is often used to check for possible bone or other organ metastases.

ANGIOGRAPHY Angiography is performed when the precise location of the tumor cannot be identified or there is a need to visualize the tumor's extent prior to surgery. The procedure involves injecting a radiopaque dye into a major blood vessel proximal to the organ or tissue to be examined. The movement of the dye through the vasculature of the organ or tissue is traced by means of fluoroscopy or serial x-ray films. Blockage to the flow of the dye indicates the tumor's location. Dye may be used to identify blood vessels supplying a tumor, allowing the surgeon to know where to safely ligate vessels.

DIRECT VISUALIZATION Direct visualization procedures are invasive but do not require the use of radiography. Examples include sigmoidoscopy (viewing the sigmoid colon with a fiberoptic flexible sigmoidoscope), cystoscopy (viewing the urethra and bladder), endoscopy (viewing the upper gastrointestinal tract), and bronchoscopy (inspecting the tracheobronchial tree). These methods allow the visual identification of the organs within the limits of the scope and usually permit biopsy of suspicious lesions or masses. Flexible fiberoptic scopes may be more useful because they allow deeper penetration than do traditional scopes. These procedures all require some patient preparation, cause moderate to considerable discomfort, and may require sedation or anesthesia, as in the case of bronchoscopy. Some procedures, such as sigmoidoscopy and cystoscopy, may be performed in the physician's office and therefore cost less, making them more accessible screening procedures.

When the tumor is exposed, a sample of tissue (biopsy) is sent to the pathology laboratory for a frozen-section histologic examination. This can be done rapidly while the patient remains on the operating table under anesthesia. If the initial report is negative, the benign mass is usually removed to prevent further symptoms. If the report is positive for cancer, the tumor, and often adjacent lymph nodes are dissected, along with any other suspicious tissue. The tumor, nodes, and any other specimens are sent to the pathology laboratory for

more in-depth analysis. The patient then receives the usual postoperative care.

LABORATORY TESTS Most laboratory tests of blood, urine, and other body fluids are used to rule out nutritional disorders and other noncancerous conditions that may be causing the patient's symptoms. In conjunction with other diagnostic studies, some laboratory tests can be quite useful either in screening for other pathologic conditions or for validating the cancer diagnosis. Table 14–8 identifies some useful laboratory tests, their normal values, and their possible indications.

PSYCHOLOGIC SUPPORT DURING DIAGNOSIS Preparing for and awaiting the results of diagnostic tests can create extreme anxiety. Many patients compare the experience to that of a prisoner awaiting trial and sentencing: After they know what the "sentence" is, then they can prepare for the future. In addition to coping with the possibility of a life-threatening disease, or at least a life-altering one, patients often face the prospect of uncomfortable, even painful, diagnostic procedures. They have important decisions to make that depend on the outcome of those tests. Many unspoken questions may exist, including the following:

- Do I have cancer?
- If so, what kind, and how serious?
- Has it spread?
- Will I survive?
- What kind of treatment is needed?
- How will this affect my lifestyle?
- How will this affect family members and friends?

Denial or intellectualization can help some patients to cope with cancer, but others display signs of anxiety and stress as they attempt to cope. The nurse can provide valuable support during this

TABLE 14–8 Laboratory Tests Used for Cancer Diagnosis*

Test	Reference Value	Abnormality Indicated
Acid phosphatase (ACP)	0.0–0.8 unit/L	Elevated in prostate, breast, and bone cancer and in multiple myeloma
Adrenocorticotropic hormone (ACTH)	8–80 pg/mL	Decreased in adrenal cancer Elevated in pituitary cancer or with tumor that secretes ACTH (bronchiogenic cancer)
Alanine aminotransferase (ALT)	10–35 unit/mL (Frankel)	Moderate elevation in liver cancer
Albumin	3.5–5.0 g/dL	Decreased in malnutrition, metastatic liver cancer
Alkaline phosphatase (ALP)	42–136 unit/L	Elevated in cancer of liver, bone, breast, and prostate; in leukemia; and in multiple myeloma
Alpha-fetoprotein (AFP)	Male and nonpregnant female: <15 ng/mL	Elevated in germ cell tumors (e.g., seminoma), testicular cancer
Aspartate aminotransferase (AST)	5–40 unit/mL (Frankel)	Elevated in liver cancer
Bilirubin	Total: 0.1–1.2 mg/dL Direct: 0.1–0.3 mg/dL	Elevated in liver and gallbladder cancer
Bleeding time	Ivy method: 3–7 min	Prolonged in leukemia and metastatic liver cancer
Blood urea nitrogen (BUN)	5–25 mg/dL	Decreased in malnutrition; increased in renal cancer
Calcitonin	Male: <40 pg/mL Female: <25 pg/mL	Elevated to >500 pg/mL in thyroid medullary cancer, breast cancer, and lung cancer
Calcium (Ca)	4.5–5.5 mEq/L 9.0–11.0 mg/dL	Elevated in bone cancer and ectopic parathyroid hormone production (paraplastic syndrome)
Carcinoembryonic antigen (CEA)	<2.5 ng/mL in nonsmokers <5 ng/mL in smokers >12 ng/mL neoplasms	Elevated with GI cancers, lung, breast, bladder, kidney, cervical, leukemias Used to evaluate effectiveness of cancer treatment
Chloride (Cl)	95–105 mEq/L	Decreased in vomiting, diarrhea, syndrome of inappropriate antidiuretic hormone (SIADH)
C-reactive protein	>1:2 titer is positive	Elevated in metastatic cancer and Burkitt's lymphoma
Creatinine	0.5–1.5 mg/dL	Decreased in malnutrition; elevated in most cancers
Dexamethasone suppression test	>50% reduction in plasma cortisol	Nonsuppression in adrenal cancer and ACTH-producing tumors, severe stress
Estradiol-serum	Female: 20–300 pg/mL Menopausal female: <30 pg/mL Male: 15–50 pg/mL	Elevated in estrogen-producing tumors and testicular tumors
Fibrinogen	200–400 mg/dL	Decreased in leukemia and as a side effect of chemotherapy

(*continued*)

TABLE 14–8 Laboratory Tests Used for Cancer Diagnosis* (*continued*)

Test	Reference Value	Abnormality Indicated
Gamma glutamyltransferase (GGT)	Male: 4–23 International Unit/L Female: 3–13 International Unit/L	Elevated in cancer of liver, pancreas, prostate, breast, kidney, lung, and brain
Fasting blood sugar	70–110 mg/dL	Decreased in malnutrition, cancer of stomach, liver, and lung
Haptoglobin	20–270 mg/dL	Elevated in Hodgkin's lymphoma and cancer of lung, large intestine, stomach, breast, and liver
Hematocrit (Hct)	Male: 40%–54% Female: 36%–46%	Decreased in anemia, leukemia, Hodgkin's lymphoma, lymphosarcoma, multiple myeloma, and malnutrition and as a side effect of chemotherapy
Hemoglobin (Hgb)	Male: 13.5–18 g/dL Female: 12–15 g/dL 1:3 ratio of Hgb:Hct	Decreased in anemia, many cancers, Hodgkin's lymphoma, leukemia, and malnutrition and as a side effect of chemotherapy
Human chorionic gonadotropin (HCG)	Nonpregnant female <0.01 International Unit/L	Elevated in choriocarcinoma
Insulin	5–25 microunit/mL	Elevated in insulinoma (islet cell tumor) and insulin-secreting cancers (e.g., lung cancer)
Lactic dehydrogenase (LDH)	100–190 International Unit/L	Elevated in liver, brain, kidney, muscle cancers, acute leukemia, anemia
Occult blood	Negative	Positive in gastric and colon cancers
Serum osmolality	280–300 mOsm/kg H_2O	Decreased in SIADH
Urine osmolality	50–1200 mOsm/kg H_2O	Increased in SIADH
Parathyroid hormone (PTH-C)	50–330 pg/mL	Increased in PTH-secreting tumors
Platelet (thrombocyte) count	150,000–400,000/mm^3	Decreased in bone, gastric, and brain cancer, in leukemia, and as a side effect of chemotherapy
Potassium (K)	3.5–5.3 mEq/L	Decreased in vomiting and diarrhea and in malnutrition
Prostate-specific antigen (PSA)	0–4 ng/mL	Elevated from 10 to 120+ in prostate cancer
Protein, total	6.0–8.0 g/dL	Decreased in malnutrition, gastrointestinal cancer, Hodgkin's lymphoma; elevated in vomiting, diarrhea, multiple myeloma
Red blood cells (RBCs)	Male: 4.6–6.0 million/mm^3 Female: 4.0–5.0 million/mm^3	Decreased in anemia, leukemia, infection, multiple myeloma
Sodium (Na)	135–145 mEq/L	Decreased in SIADH, vomiting; elevated in dehydration
Uric acid	Male: 3.5–8.0 mg/dL Female: 2.8–6.8 mg/dL	Increased in leukemia, metastatic cancer, multiple myeloma, Burkitt's lymphoma, after vigorous chemotherapy
White blood cells (WBC)		
Total leukocytes	4,500–10,000/mm^3	Elevated in acute infection, leukemias, tissue necrosis; decreased as a side effect of chemotherapy
Neutrophils	50%–70%	Elevated in bacterial infection and Hodgkin's lymphoma; decreased in leukemia and malnutrition and as a side effect of chemotherapy
Eosinophils	1%–3%	Elevated in cancer of bone, ovary, testes, and brain
Basophils	0.4%–1.0%	Elevated in leukemia and healing stage of infection
Monocytes	4%–6%	Elevated in infection, monocytic leukemia, and cancer; decreased in lymphocytic leukemia and as a side effect of chemotherapy
Lymphocytes	25%–35%	Elevated in lymphocytic leukemia, Hodgkin's lymphoma, multiple myeloma, viral infections, and chronic infections; decreased in malnutrition, cancer, and other leukemias and as a side effect of chemotherapy

Note: *All values refer to serum values unless otherwise indicated. Values are approximate; check the reference standards specified by your own agency's laboratory.

very difficult stage by helping patients become actively involved in managing their life and disease. Talk with patients as soon as they enter the healthcare system, asking what they know already about what is going to happen and soliciting questions from them. Taking this approach and encouraging patients to share what knowledge and experience they have allows them to maintain control. From there, the nurse can provide the information needed.

As patients begin to feel more comfortable with the nurse, they may express concerns, fears, and other emotions. The nurse should actively listen and be supportive, but avoid giving advice and false reassurance, providing appropriate information when needed. For patients who are not ready to discuss concerns or for those who appear angry, being nonjudgmental and providing nonverbal support may facilitate more open communication. An atmosphere of calmness, warmth, caring, and respect can ease the tension and often unspoken terror of this initial period.

Support of and communication with the patient's significant others is extremely important. Often they try to be strong for the patient but have many fears and emotional concerns that they do not feel comfortable expressing. The nurse needs to be available to the family while the patient is undergoing diagnostic procedures. Allowing them to talk without the need to edit for the patient's benefit can help them manage their own difficulties in coping with their loved one's potential cancer diagnosis.

CANCER TREATMENT

The goals of cancer treatment are aimed at cure, control, or palliation of symptoms. These goals may overlap. Cancer may be treated through surgery, chemotherapy, radiation therapy, biotherapy, photodynamic therapy, bone marrow and stem cell transplants, hormonal therapy, and complementary therapies. Once cancer is diagnosed, the initial focus is on surgical and medical treatment. The goals of treatment are as follows:

- Eliminate the tumor or malignant cells.
- Prevent metastasis.
- Reduce cellular growth and the tumor burden.
- Promote functional abilities and provide pain relief to those whose disease has not responded to treatment.

SURGERY Surgery remains an important approach in cancer care. Surgical resection is used for diagnosis and staging of more than 90% of all cancers and for primary treatment of more than 60% of cancers. The goals of surgery have expanded to include prophylaxis, diagnosis, treatment, reconstruction, and palliation.

Prophylactic surgery aims to remove tissues or organs that are likely to develop cancer. Advances in identification of genetic markers make prophylactic surgery an option for individuals with a strong family history and genetic predisposition for the development of cancer. For example, a woman with a strong history of breast cancer, positive findings of *BRCA-1* or *BRCA-2*, and an abnormal finding on mammography may consider prophylactic mastectomy as one of the selective options. Other examples of prophylactic operations include colectomy and oophorectomy. With limited research on the long-term physiologic and psychologic effects on individuals undergoing prophylactic surgery for cancer, it is vitally important for nurses and other healthcare professionals to discuss thoroughly with the patient and family potential risks and postoperative outcomes of the prophylactic surgery prior to the surgery. Nurses should respect the patient's decision whether or not to pursue the prophylactic surgery. For those patients who choose prophylactic surgery as a preventive measure for cancer, comprehensive preoperative teaching and counseling should be provided and long-term postoperative follow-up should be ensured to monitor the patient's physiologic and psychologic adjustment to the surgery.

Diagnostic surgery aims to ensure histologic diagnosis and staging of cancer through biopsy, endoscopy, laparoscopy, and open surgical exploration. Table 14–9 provides information about common surgical diagnostic procedures.

As a primary treatment for cancer, the goal of surgery is to remove the entire tumor and involved surrounding tissue and lymph nodes as much as possible and feasible. This sometimes necessitates mutilation of the body and the creation of new structures to assume function of the lost structures. For example, removal of the distal sigmoid colon and rectum requires a new means of bowel elimination, so the remaining healthy segment of the bowel is brought out through a created opening (stoma) in the abdominal wall, resulting in a permanent colostomy (see Chapter 24). In like manner, when the bladder is removed, the ureters are transplanted into a created pouch just under the abdominal wall. This serves as a continent ileostomy, a substitute reservoir for urine (see Chapter 27). Surgery can destroy sensitive nerve plexuses, resulting in alteration or loss of normal functioning; for example, prostate surgery may result in incontinence and impotence. Surgical removal of involved regional lymph nodes can lead to long-term lymphedema (swelling in the affected area) that greatly impacts cancer survivors' quality of life, for instance, lymphedema following surgery for breast cancer and melanoma (Norman et al., 2009).

Not all surgery results in such radical changes in functioning. The following surgeries can eliminate cancer successfully with less distressing results:

- Removing a nonessential portion of the organ or tissue containing the tumor, such as *in situ* small-bowel tumors
- Removing an organ whose function can be replaced chemically, such as the thyroid
- Resecting one of a pair of organs when the unaffected organ can take over the function of the missing one, such as a lung.

TABLE 14–9 Surgical Diagnostic Procedures

Procedure	Explanation
Fine-needle biopsy	Use of a very thin needle to aspirate a small amount of tissue from the tumors
Needle core biopsy	Use of a slightly larger needle than that used for a fine-needle biopsy to extract a small amount of tissue from tumors that cannot be aspirated by fine-needle aspiration
Incisional biopsy	Removal of part of a larger tumor by cutting through the skin
Excisional biopsy	Removal of an entire tumor through operation
Endoscopy	Use of a small viewing lens or video camera through natural body openings to view tumors such as cancer of the esophagus, stomach, or colon
Laparoscopy	Use of a small viewing lens or video camera through a small incision in the abdominal wall

Although the removal of any major body part has physiologic and psychologic consequences, the alternative—terminal disease—is usually less desirable.

When the tumor is in a nonresectable location or deeply invaded with metastases, surgery may be done to achieve palliation to allow the involved organs to function as long as possible, to relieve pain, to provide comfort, or to bypass an obstruction. Surgery may be done to reduce the bulk of the tumor in advanced disease, both at primary and metastatic sites. Decreasing the tumor size enhances the ability to control the remaining disease through other modalities. Surgery is often used in conjunction with other treatments to affect a cure. In cases when extensive removal of tissue is contraindicated (e.g., in surgical removal of a brain tumor), radiation may be used prior to surgery in an attempt to shrink the tumor before it is removed.

Surgical intervention may be used for reconstruction and rehabilitation to achieve more desirable functional and cosmetic effect after curative or radical surgery. One example is the construction of transabdominal myocutaneous (TRAM) flaps in conjunction with or following modified radical mastectomy (see Chapter 49). For surgical interventions for cancers affecting specific body systems, see later chapters.

Surgical oncologists are working with researchers to identify premalignant disease earlier in high-risk populations and to conduct studies on ways to reverse oncogenic cell activity. Surgeons work with molecular biologists using sophisticated techniques to develop monoclonal antibodies. Laser technology is being explored for use in different types of cancer surgery because it minimizes blood loss, reduces deformity, increases the accuracy of tissue resection, and enhances healing. Lasers are currently being used as an alternative to radical prostatectomy in order to preserve urinary continence and sexual functioning.

Another collaborative strategy is intraoperative radiation therapy, in which radiosensitive, nondiseased organs that may be damaged by radiation therapy are moved away from the radiation field and shielded. Radiation is administered while the patient is on the operating table. This technique allows more penetrating radiation to be directed to the malignant tumor with less trauma to normal, vulnerable tissues or organs.

Nursing responsibilities focus on preparing the patient physically and psychologically for surgery, as well as teaching routine postoperative care in which the patient is expected to participate (refer to Chapter 4). Before surgery, the nurse should give the patient the opportunity to ask questions and to discuss concerns and fears. In some cases, the patient may want to discuss alternative treatment options. In the latter case, the nurse should contact the oncologist and the surgeon and set up a conference for the patient before surgery.

CHEMOTHERAPY **Chemotherapy** involves the use of cytotoxic medications to cure liquid and solid cancers, such as leukemias, lymphomas, and breast and prostate cancer; to decrease tumor size, adjunctive to surgery or radiation therapy; or to prevent or treat suspected metastases. Chemotherapy may be used in conjunction with biotherapy. All chemotherapy has side effects or toxic effects. The type and severity depend on the drugs used.

Chemotherapy disrupts the cell cycle in various phases by interrupting cell metabolism and replication. It also works by interfering with the ability of the malignant cell to synthesize vital enzymes and chemicals. Phase-specific drugs work during only some phases of the cell cycle; non-phase-specific drugs work through the entire cell cycle. Figure 14–5 ■ lists some of the drugs useful in each phase of the cell cycle.

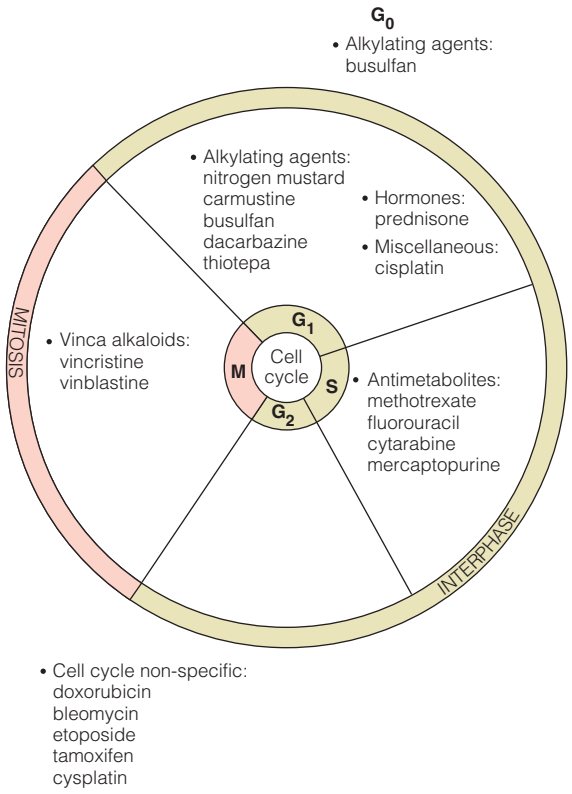

Figure 14–5 ■ Chemotherapeutic drugs useful in each phase of the cell cycle. Based on their chemical makeup and biologic activity, different drugs used for cancer treatment act in specific phases and subphases of the cell cycle. Some drugs, called non-phase-specific drugs, are generalized and act throughout the cycle. Chemotherapy often involves combinations of drugs designed to attack the cancer cells at many different times in the cycle to enhance effectiveness.

Most chemotherapy involves combinations of drugs administered over varying periods of time according to different protocols. One protocol for adult acute lymphocytic leukemia (ALL) uses the acronym DVPA: daunorubicin given on days 1 through 3; vincristine given on days 1, 8, 15, and 22; prednisone given on days 1 through 28, and asparaginase given on days 17 through 28. The treatment regimen is administered in cycles with rest periods, especially if toxic effects such as liver dysfunction or severe neutropenia (abnormally low amounts of neutrophils, a type of white blood cell) occur. The treatment is continued until remission of the cancer is achieved. If the cancer progresses the particular protocol is abandoned and a new protocol may be tried.

Several courses of chemotherapy are necessary based on the hypothesis of cell killing. A 1-cm tumor contains about 10^9 (10 billion) total cells, most of which are viable. During each cell cycle, the chemotherapy kills a fixed percentage of cells, always leaving some behind. With each reduction, the tumor burden of cells decreases until the number of viable, clonogenic cells (i.e., those that are able to clone daughter cells) becomes small enough to allow the body's immune system to finish the job. For this reason, oncologists usually give the

maximum amount of chemotherapy tolerated by the patient. High-dose chemotherapy remains controversial.

CLASSES OF CHEMOTHERAPY DRUGS Chemotherapeutic agents can be classified either by the effects of the agent on the cell or by the pharmacologic properties of the agent. According to the effects of the agent on the cell, chemotherapeutic agents can be divided into cell cycle–specific and cell cycle–nonspecific agents. Cell cycle–specific agents are effective at a specific phase (for example, S and M phases) in the cell cycle to prevent cell replication by damaging cellular DNA and blocking production of protein necessary for DNA and RNA synthesis. Cell cycle–nonspecific agents are effective throughout all the phases of the cell cycle, including the resting phase. Both cell cycle–specific and cell cycle–nonspecific agents are effective in rapidly dividing cells to prohibit the growth of fast-growing tumors.

The most common way of classifying chemotherapeutic agents is based on pharmacologic properties of the agent. The classifications include alkylating agents, antimetabolites, antitumor antibiotics, mitotic inhibitors, hormones and hormone antagonists, and miscellaneous agents.

ALKYLATING AGENTS Alkylating agents are not phase specific and basically act on preformed nucleic acids by creating defects in tumor DNA. They cause crosslinking of DNA strands, which can permanently interfere with replication and transcription.

Alkylating agents work with both proliferating and nonproliferating cells (those in G_0 phase). Their toxicity relates to their ability to kill slowly cycling stem cells and manifests in delayed, prolonged, or permanent bone marrow failure. Toxicity can cause a mutagenic effect on bone marrow stem cells, culminating in a treatment-resistant form of acute myelogenous leukemia. Because of the alkylating agents' effect on stem cells, they cause irreversible infertility. Other common adverse effects include nephrotoxicity (kidney damage) and hemorrhagic cystitis (bladder damage).

The several subclasses of alkylating agents include nitrogen mustard (mechlorethamine), nitrosoureas (carmustine), alkyl sulfonates (busulfan), triazines (dacarbazine), ethyleneamines (thiotepa), and cisplatin. Cisplatin is an alkylating agent containing platinum and chlorine atoms. It is most active in the G_1 subphase, but it is not phase specific. Cisplatin binds to DNA and acts much like alkylating agents by forming intrastrand DNA crosslinks (gluing strands of DNA together so that they cannot separate). Its major toxic effect is reversible renal tubular necrosis. Cisplatin may be used alone or in combination with other chemotherapeutic drugs for testicular and ovarian cancers.

ANTIMETABOLITES The different types of antimetabolites include folic acid analogues (methotrexate), pyrimidine analogues (5-fluorouracil), cytosine arabinoside (ARA-C), and purine analogues (6-mercaptopurine). Antimetabolites are phase specific, working best in the S phase and having little effect in G_0. They interfere with nucleic acid synthesis by either displacing normal metabolites at the regulatory site of a key enzyme or by substituting for a metabolite that is incorporated into DNA or RNA molecules. Toxic effects usually do not occur until very high levels of the drug are administered. Toxicity is more likely when the drugs accumulate in third-spaced fluid, such as pleural fluid (a characteristic that makes them useful in treating malignant pleural effusions). Because the drug diffuses slowly from the third-spaced fluid, exposure of the tissue to the drug is prolonged. Most toxic effects relate to rapidly proliferating cells, such as cells in the gastrointestinal tract, hair, and skin and WBCs. Manifestations include nausea and vomiting, stomatitis, diarrhea, alopecia, and leukopenia. Some of the drugs can cause liver and lung toxicity.

ANTITUMOR ANTIBIOTICS Antitumor antibiotics are derived from natural sources that are generally too toxic to be used as antibacterial agents. They are not phase specific and act in several ways: They disrupt DNA replication and RNA transcription; create free radicals, which generate breaks in DNA and other forms of damage; and interfere with DNA repair. In addition, these drugs bind to cells and kill them, probably by damaging the cell membrane. Their main toxic effect is damage to the cardiac muscle. This limits the amount and duration of treatment. Examples of these antibiotics include actinomycin D, doxorubicin, bleomycin, mitomycin-C, and mithramycin.

MITOTIC INHIBITORS Mitotic inhibitors are drugs that act to prevent cell division during the M phase. Mitotic inhibitors include the plant alkaloids and taxoids. Plant alkaloids consist of medications extracted from plant sources: Vinca alkaloids (e.g., vincristine and vinblastine) and etoposide (called VP-16). The Vinca alkaloids are phase specific, acting during mitosis. They bind to a specific protein in tumor cells that promotes chromosome migration during mitosis and serves as a conduit for neurotransmitter transport along axons. The toxicity of these drugs is characterized by depression of deep tendon reflexes, paresthesias (pain and altered sensation), motor weakness, cranial nerve disruptions, and paralytic ileus. Etoposide acts in all phases of the cell cycle, causing breaks in DNA and metaphase arrest. Although etoposide may cause bone marrow suppression and nausea and vomiting, the most common toxic effect is hypotension resulting from too rapid intravenous administration. The taxoids act during the G_2 phase to inhibit cell division. Paclitaxel is used for the treatment of Kaposi's sarcoma and metastatic breast and ovarian cancer. Taxotere is used for breast cancer. Toxicities associated with these drugs include alopecia, bone marrow depression, and severe hypersensitivity reactions (e.g., hypotension, dyspnea, and urticaria).

HORMONES AND HORMONE ANTAGONISTS The main hormones used in cancer therapy are the corticosteroids (e.g., prednisone), which are phase specific (G_1). These act by binding to specific intracellular receptors, repressing transcription of mRNA, and thereby altering cellular function and growth. Corticosteroids have multiple side effects such as impaired healing, hyperglycemia, hypertension, osteoporosis, and hirsutism.

Hormone antagonists work with hormone-binding tumors, usually those of the breast, prostate, and endometrium. They block the hormone's receptor site on the tumor and prevent it from receiving normal hormonal growth stimulation. These drugs do not cure, but cause regression of the tumor in about 40% of breast and endometrial tumors and 80% of prostate tumors. Tamoxifen competes with estradiol receptors in breast tumors. Raloxifene blocks estrogen in the breast. Diethylstilbestrol competes with hormone receptors in endometrial and prostate tumors. Aromatase inhibitors (Arimidex, Femara, and Aromasin) reduce the amount of estrogen produced in postmenopausal women. Antiandrogen (flutamide) and luteinizing hormone–releasing hormone block testosterone synthesis in prostate cancers. The main side effects of these drugs are alterations of the secondary sexual characteristics.

MISCELLANEOUS AGENTS Several miscellaneous agents act at different phases in the cell cycle. L-Asparaginase and hydroxyurea are examples of miscellaneous agents.

EFFECTS OF CHEMOTHERAPEUTIC DRUGS The side effects and toxic effects of chemotherapy vary with the drug used and the length of treatment. Because most of these drugs act on fast-growing cells, the side effects are manifestations of damage to normal rapidly dividing somatic cells. The side effects of hormones express the action of the hormone used or suppression of the normal hormone, such as the masculinizing effects of male hormones administered for ovarian cancers.

Tissues usually affected by cytotoxic drugs include the following:

- Mucous membranes of the mouth, tongue, esophagus, stomach, intestine, and rectum. This may result in anorexia, loss of taste, aversion to food, erythema and painful ulcerations in any portion of the gastrointestinal tract, nausea, vomiting, and diarrhea.
- Hair cells, resulting in alopecia.
- Bone marrow depression affecting most blood cells (e.g., granulocytes, lymphocytes, thrombocytes, and erythrocytes). This results in an impaired ability to respond to infection, a diminished ability to clot blood, and severe anemia.
- Organs, such as heart, lungs, bladder, kidneys. This kind of damage is related to specific agents, such as cardiac toxicity with doxorubicin or pneumonitis with bleomycin.
- Reproductive organs, resulting in impaired reproductive ability or altered fetal development.

Table 14–10 gives the classifications of chemotherapeutic drugs, common examples, target malignancies, adverse effects and side effects, and nursing implications. Consult current pharmacology

TABLE 14–10 Classifications of Chemotherapeutic Drugs

Drug Classification	Common Drugs	Target Malignancies	Adverse Effects or Side Effects	Nursing Implications
