Pathogens usually enter the urinary tract by ascending from the mucous membranes of the perineal area into the lower urinary tract. Bacteria that have colonized the urethra, vagina, or perineal tissues are the usual source of infection (Grossman & Porth, 2014). From the bladder, bacteria may continue to ascend the urinary tract, eventually infecting the parenchyma (functional tissue) of the kidneys. Hematogenous spread of infection to the urinary tract is rare. Infections introduced in this manner are usually associated with previous damage or scarring of the urinary tract. Bacteria introduced into the urinary tract may cause asymptomatic bacteriuria or an inflammatory response with manifestations of UTI. Asymptomatic bacteriuria is commonly found in pregnant women, older adults, and patients with diabetes mellitus or who have an indwelling urinary catheter. Up to 50% of older men and women may have asymptomatic bacteriuria (Gupta & Trautner, 2012).

UTIs can be categorized in several ways. Anatomically, they may affect the lower or the upper urinary tract. Lower urinary tract infections include *urethritis*, inflammation of the urethra; *prostatitis*, inflammation of the prostate gland; and **cystitis**, inflammation of the urinary bladder. The most common upper urinary tract infection is **pyelonephritis**, inflammation of the kidney and renal pelvis. The infection may involve superficial tissues such as the bladder mucosa, or may invade other tissues such as prostate or renal tissues. Epidemiologically, UTIs are identified as community acquired or catheter associated.

CYSTITIS

Cystitis, inflammation of the urinary bladder, is the most common UTI. It usually results from colonization of the bladder by bacteria normally found in the lower gastrointestinal tract. The infection tends to remain superficial, involving the bladder mucosa. The mucosa becomes hyperemic (red) and may hemorrhage, and the inflammatory response causes pus to form (Figure 27–2 ■). This process causes the classic manifestations associated with cystitis, including **dysuria** (painful or difficult urination), urinary frequency and **urgency** (a sudden, compelling need to urinate), and **nocturia** (voiding two or more times at night). In addition, the urine may have a foul odor and appear cloudy (*pyuria*) or bloody (**hematuria**) because of mucus, excess white cells in the urine, and bleeding of the inflamed bladder wall. Suprapubic pain and tenderness also may be present. See the following box for manifestations of cystitis.

Older patients may not experience the classic symptoms of cystitis. Instead, they often present with nonspecific manifestations such as nocturia, incontinence, confusion, behavior change, lethargy, anorexia, or just "not as usual" (Tingström et al., 2010). Fever may be present; however, hypothermia also may develop in an older adult.

Although the bacteriostatic effect of prostatic fluid and a longer urethra provide an effective barrier to bladder infection for adult males, in older men an enlarged prostate can impede urine flow, leading to incomplete bladder emptying and urinary stasis. Bacteria are not completely flushed with voiding, allowing colonization of the bladder.

MANIFESTATIONS OF CYSTITIS

- Dysuria
- Pyuria
- Frequency
- Hematuria
- Urgency
- Suprapubic discomfort
- Nocturia

Cystitis is usually uncomplicated and readily responds to treatment. When left untreated, the infection can ascend to involve the kidneys. Severe or prolonged infection may lead to sloughing of bladder mucosa and ulcer formation. Chronic cystitis can lead to bladder stones (discussed later in this chapter).

CATHETER-ASSOCIATED UTI

UTIs are the most commonly reported healthcare-associated infection; about 80% of hospital-acquired UTIs are associated with a urinary catheter (Dailly, 2012). The longer the catheter remains in place, the greater the risk for infection. Bacteria, including *E. coli*, *Proteus*, *Pseudomonas*, and *Klebsiella*, reach the bladder by either migrating through the column of urine within the catheter or by moving up the mucous sheath of the urethra outside the catheter. Biofilm, a living layer of pathogens, forms on the catheter itself. These pathogens are relatively resistant to antibiotics, making catheter removal necessary to remove the source of the infection (Gupta & Trautner, 2012). Causative organisms associated with catheter-associated UTI are more likely to demonstrate antibiotic resistance than those found in community-acquired UTI.

Catheter-associated UTIs, including pyelonephritis, often are asymptomatic. Gram-negative bacteremia is the most significant complication associated with these UTIs. Most catheter-associated UTIs resolve when the catheter is removed and a 7- to 14-day course of antibiotic is administered. Intermittent catheterization carries a lower risk of infection than does an indwelling catheter, and is preferred for patients who are unable to empty their bladder by voiding (for example, patients with spinal cord injury).

PYELONEPHRITIS

Pyelonephritis is inflammation of the renal pelvis and parenchyma, the functional kidney tissue. *Acute pyelonephritis* is a bacterial infection of the kidney; *chronic pyelonephritis* is associated with nonbacterial infections and inflammatory processes that may be metabolic, chemical, or immunologic in origin.

ACUTE PYELONEPHRITIS Acute pyelonephritis usually results from an infection that ascends to the kidney from the lower urinary tract. Asymptomatic bacteriuria or cystitis can lead to acute pyelonephritis. Risk factors include pregnancy (because of slowed ureteral peristalsis), urinary tract obstruction, and congenital malformation. Urinary tract trauma, scarring, calculi (stones), kidney disorders such as polycystic or hypertensive kidney disease, and chronic diseases such as diabetes may also contribute to pyelonephritis. *Vesicoureteral reflux*, a condition in which urine moves from the bladder back toward the kidney, is a common risk factor in children who develop pyelonephritis and is also seen in adults when bladder outflow is obstructed.

The infection spreads from the renal pelvis to the renal cortex. The pelvis, calyces, and medulla of the kidney are primarily affected, with white blood cell (WBC) infiltration and inflammation. The kidney becomes grossly edematous. Localized abscesses may develop on the cortical surface of the kidney. As with cystitis, *E. coli* is the organism responsible for 85% of the cases of acute pyelonephritis. Other organisms commonly found include *Proteus* and *Klebsiella*, bacteria that normally inhabit the intestinal tract.

The onset of acute pyelonephritis is typically rapid, with chills and fever, malaise, vomiting, flank pain, costovertebral tenderness, urinary frequency, and dysuria (see the Pathophysiology Linkage feature).

PATHOPHYSIOLOGY LINKAGE

Acute Pyelonephritis

Manifestation	Related Pathophysiology
Dysuria, urinary frequency	Inflammation of the urethra and urinary bladder stimulate local nerve endings causing pain and detrusor muscle spasms.
Pyuria	WBCs infiltrate infected tissue of the kidney and lower urinary tract to remove invading bacteria.
Hematuria	Vasodilation and increased vascular permeability of inflamed tissue lead to exudate formation and allow RBCs to escape into urine.
Flank pain, costovertebral tenderness	Inflammation with swelling and edema of the kidney pelvis, calyces, and medulla stretches the capsule surrounding and supporting the kidney, simulating pain receptors.
Malaise	Inflammatory mediators such as interleukins and tumor necrosis factor-α (TNF-α) affect the central nervous system, causing subjective feelings of weakness, fatigue, and discomfort.
Acute fever, shaking chills	Pyrogens (fever-producing substances) released by infecting bacteria (endotoxins) and inflamed tissue (cytokines and prostaglandins) reset the thermostatic center in the hypothalamus (Grossman & Porth, 2014).
Anorexia, nausea, vomiting	Inflammatory mediators and endotoxins directly stimulate the vomiting center in the medulla.

Symptoms of cystitis also may be present. The older adult may present with a change in behavior, acute confusion, incontinence, or a general deterioration in condition.

CHRONIC PYELONEPHRITIS Chronic pyelonephritis involves chronic inflammation and scarring of the tubules and interstitial tissues of the kidney. It is a common cause of chronic kidney disease. It may develop as a result of UTIs or other conditions that damage the kidneys, such as hypertension or vascular conditions, severe vesicoureteral reflux, or obstruction of the urinary tract.

The patient with chronic pyelonephritis may be asymptomatic or have mild manifestations such as urinary frequency, dysuria, and flank pain. Hypertension can develop as kidney tissue is destroyed.

●○● INTERPROFESSIONAL CARE

Treatment of UTI focuses on eliminating the causative organism, preventing relapse or reinfection, and identifying and correcting any contributing factors. Drug treatment with antibiotics and urinary anti-infectives is commonly used. In some cases, surgery may be indicated to correct contributing factors.

DIAGNOSIS

Laboratory testing for UTI includes the following:

- *Urinalysis* to assess for pyuria, bacteria, and blood cells in the urine. A bacteria count greater than 100,000 (10^5) per milliliter is

indicative of infection. Rapid tests for bacteria in the urine include using a *nitrite dipstick* (which turns pink in the presence of bacteria) and the *leukocyte esterase test*, an indirect method of detecting bacteria by identifying lysed or intact WBCs in the urine.

Urine should be collected via suprapubic aspiration or by midstream clean-catch specimen; if necessary, straight catheterization or "mini-cath," with strict aseptic technique, may be used. Catheterization is avoided if possible to reduce the risk of further infection.

- *Gram stain of the urine* may be done to identify the infecting organism by shape and characteristic (gram-positive or gram-negative).
- *Urine culture and sensitivity* tests may be ordered to identify the infecting organism and the most effective antibiotic. Culture requires 24 to 72 hours, so treatment to eliminate the most common organisms often is initiated without culture.
- *WBC with differential* may be done to detect typical changes associated with infection, such as *leukocytosis* (elevated WBC) and increased numbers of neutrophils.

SAFETY ALERT

Obtain urine specimens from a patient with an indwelling urinary catheter by briefly (15 minutes or less) clamping the proximal drainage tubing, then withdrawing urine directly from the port using sterile technique. Sterile technique is necessary to reduce the risk of catheter-associated UTI.

In men and in adult women with recurrent infections or persistent bacteriuria, additional diagnostic testing may be ordered to evaluate for structural abnormalities and other contributing factors:

- Imaging studies such as *intravenous pyelography (IVP)* or *CT scan* are used to evaluate for structural or functional abnormalities, such as vesicoureteral reflux, of the kidneys, ureters, and bladder.
- *Voiding cystourethrography* may be ordered to detect structural or functional abnormalities of the bladder and urethral strictures.
- *Cystoscopy* may be used to diagnose conditions such as prostatic hypertrophy, urethral strictures, bladder calculi, tumors, polyps or diverticula, and congenital abnormalities. A tissue biopsy may be obtained during the procedure, and other interventions performed (e.g., stone removal or stricture dilation).
- *Manual pelvic* or *prostate examinations* are done to assess for structural changes of the genitourinary tract, such as prostatic enlargement, cystocele, or rectocele.

MEDICATIONS

Most acute uncomplicated infections of the lower urinary tract in women can be treated with a short course of antibiotic therapy. In contrast, upper UTIs and those occurring in men usually require longer treatment to eradicate the infecting organism and prevent recurrence.

Short-course therapy (a 3-day course of treatment) reduces treatment cost, increases compliance, and has a lower rate of side effects. Oral *trimethoprim-sulfamethoxazole* (TMP-SMX), SMX, TMP, or a quinolone antibiotic such as *ciprofloxacin* (Cipro), ofloxacin (Floxin), or levofloxacin (Levaquin, Quixin) may be ordered. Rates of bacterial resistance to TMP-SMX and ciprofloxacin are increasing in some regions; a 5- to 7-day course of nitrofurantoin (Furadantin, Macrobid, Macrodantin) is an effective alternative. Sulfonamides and quinolone antibiotics are avoided during pregnancy. Ampicillin and cephalosporin antibiotics have been shown to be safe and are the drugs of choice for treating UTI during pregnancy (Gupta & Trautner, 2012).

Men and women with pyelonephritis, urinary tract abnormalities or stones, or a history of previous infections with antibiotic-resistant infections require a 7- to 10-day antibiotic course. The patient with severe illness may need hospitalization and intravenous antibiotic therapy. An antibiotic combination such as IV ampicillin and gentamicin or ceftriaxone (Rocephin) may be prescribed for severe illness or sepsis associated with UTI. The nursing implications for antibiotic therapy can be found in Chapter 12.

PRACTICE ALERT!

Follow-up urine culture is scheduled 10 days to 2 weeks following completion of antibiotic therapy for UTI to ensure that bacteria have been eradicated from the urinary tract.

The outcome of treatment for UTI is determined by follow-up urinalysis and culture. *Cure*, as evidenced by no pathogens present in the urine, is the desired outcome. Treatment *failure* occurs when therapy fails to eradicate bacteria in the urine. *Recurrent infection* occurs when a persistent source of infection causes repeated infection after initial cure. *Reinfection* is the development of a new infection with a different pathogen following successful UTI treatment.

Patients who experience frequent symptomatic UTIs may be treated prophylactically with a drug such as TMP-SMZ, TMP, nitrofurantoin, or methenamine (Hiprex, Urex). TMP and nitrofurantoin do not achieve effective plasma concentrations at recommended doses, but do reach effective concentrations in the urine. Nursing implications for these urinary anti-infectives and for phenazopyridine (Pyridium), a urinary analgesic, are outlined in the accompanying Medication Administration box.

Antibiotics and urinary anti-infectives are not generally recommended to treat asymptomatic bacteriuria except in pregnant women. The preferred treatment for catheter-associated UTI is removal of the indwelling catheter followed by a 10- to 14-day course of antibiotic therapy to eliminate the infection.

SURGERY

Surgery may be indicated for recurrent UTI if diagnostic testing indicates calculi, structural anomalies, or strictures that contribute to the risk of infection.

Stones, or *calculi*, in the renal pelvis or in the bladder are an irritant and provide a matrix for bacterial colonization. Treatment may include surgical removal of a large calculus from the renal pelvis or cystoscopic removal of bladder calculi. *Percutaneous ultrasonic pyelolithotomy* or *extracorporeal shock wave lithotripsy* (described later in this chapter) may be used instead of surgery to crush and remove stones. **Ureteroplasty**, surgical repair of a ureter, may be indicated for structural abnormality or stricture of a ureter. This may be combined with a ureteral reimplantation if vesicoureteral reflux is present. The patient returns from these surgeries with an indwelling urinary catheter (Foley or suprapubic) and a **ureteral stent** (a thin catheter inserted into the ureter to provide for urine flow and ureteral support), which remains in place for 3 to 5 days. Care of the patient with a ureteral stent is outlined in the box on page 752.

MEDICATION ADMINISTRATION

Urinary Anti-Infectives and Analgesics

URINARY ANTI-INFECTIVES

methenamine (Hiprex, Urex)

nitrofurantoin (Furadantin, Macrobid, Macrodantin)

trimethoprim (Proloprim, Trimpex)

Urinary anti-infectives are usually used prophylactically to prevent recurrence of UTI in patients with frequent symptomatic infections. Nitrofurantoin also may be used to treat UTI.

Nursing Responsibilities

- These drugs are contraindicated for patients with impaired renal function; methenamine and trimethoprim are also contraindicated for patients with impaired liver function. Report abnormal laboratory values such as elevated creatinine or BUN, bilirubin, alanine aminotransferase (ALT), aspartate aminotransferase (AST), and lactic dehydrogenase (LDH).
- Use with caution in older or chronically ill patients. Monitor closely for adverse effects.
- Do not administer trimethoprim to pregnant women because of possible adverse effects on the fetus.
- Monitor the patient taking nitrofurantoin for manifestations of pulmonary sensitivity or peripheral neuropathy. Discontinue the drug and notify the physician.
- Monitor for signs of phenytoin toxicity (sedation, ataxia, and increased blood levels) if trimethoprim is given concurrently. Phenytoin doses may need to be reduced.

Health Education for the Patient and Family

- These drugs are used along with hygiene practices to prevent recurrent UTI. Take as directed, even when no symptoms are present.
- Drink six to eight glasses of water or fluid per day while taking these drugs.
- Take the drug with meals or food to reduce gastric effects; however, avoid milk products because they may interfere with absorption.
- Trimethoprim should not be taken during pregnancy. Contact your physician before attempting to become pregnant.
- Contact your doctor if you develop any of the following: chest pain, difficulty breathing, cough, chills, and fever; numbness and tingling or weakness of the extremities; rash or pruritus (itching).
- Nitrofurantoin turns the urine brown. This is not harmful and subsides when the drug is discontinued.

URINARY ANALGESIC

phenazopyridine (Pyridium)

Phenazopyridine is a urinary tract analgesic that may be used for symptomatic relief of the pain, burning, frequency, and urgency associated with UTI during the first 24 to 48 hours of therapy. Its use is somewhat controversial because it does not treat the infection and may delay effective treatment in the patient with recurrent UTI who saves a dose or two "for the next time."

Nursing Responsibilities

- Monitor renal function (urine output, weight, serum creatinine, and BUN) during treatment; report changes.

Health Education for the Patient and Family

- Take with meals to minimize gastric upset.
- Consume 2 to 3 quarts of fluid daily while taking this drug.
- If you have diabetes, check your blood sugars regularly while taking this drug.
- This drug turns urine orange or red. Protect your clothing from staining.
- Contact lenses may become stained if worn while taking this drug.
- Promptly contact your doctor if symptoms of UTI recur; do not take phenazopyridine before you seek medical treatment.
- If you develop itching or notice a yellow tinge to your skin or eyes, stop taking the drug and notify the physician.

Note: Drugs identified in *italics* are among the 200 most commonly prescribed medications in the U.S.

COMPLEMENTARY THERAPIES

Complementary therapies such as homeopathy, aromatherapy, or herbal preparations may be used in conjunction with antibiotics to treat UTI. Research supports the use of cranberry products to prevent UTI in women with recurrent symptomatic infections (Jepson & Craig, 2008). Blueberry juice also is commonly used to prevent and treat UTI. Adding bergamot, sandalwood, lavender, or juniper oil to bath water helps relieve the discomfort of UTI. Herbal supplements such as saw palmetto have a urinary antiseptic effect, and may be beneficial in treating or preventing UTI. Consult a qualified herbologist for recommended doses and appropriate use.

●○● NURSING CARE

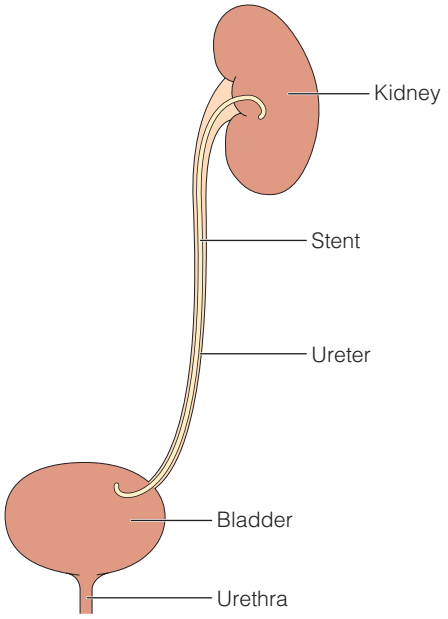
Health Promotion

Teach measures to prevent UTI to all patients, particularly to young, sexually active women. Encourage patients to maintain a generous fluid intake of 2.0 to 2.5 quarts per day, increasing intake during hot weather or strenuous activity. Discuss the need to avoid voluntary urinary retention, emptying the bladder every 3 to 4 hours. Instruct women to cleanse the perineal area from front to back after voiding and defecating. Teach to void before and after sexual intercourse to flush out bacteria introduced into the urethra and bladder. Teach measures to maintain the integrity of perineal tissues: Avoid bubble baths, feminine hygiene sprays, and vaginal douches; wear cotton briefs, avoid synthetic materials; if postmenopausal, use hormone replacement therapy or estrogen cream. Unless contraindicated, suggest measures to maintain acid urine: Drink two glasses of low-sugar cranberry juice daily; take ascorbic acid (vitamin C); and avoid excess intake of milk and milk products, other fruit juices, and sodium bicarbonate (baking soda).

Assessment

Focused assessment data for the patient with a UTI includes the following:

- *Health history:* current symptoms, including frequency, urgency, burning on urination, voidings per night; color, clarity, and odor of urine; other manifestations such as lower abdominal, back, or flank pain; nausea or vomiting; fever; duration of symptoms and any treatment attempted; history of previous UTIs and their frequency; possibility of pregnancy and type of birth control used; chronic diseases such as diabetes; current medications and any known allergies
- *Physical assessment:* general health; vital signs including temperature; abdominal shape, contour, tenderness to palpation (especially suprapubic); percuss for costovertebral tenderness (see Box 26–1); observe color, clarity, and odor of urine.



NURSING CARE OF THE PATIENT

With a Ureteral Stent

Ureteral stents are used to maintain patency and promote healing of the ureters (see the accompanying figure). A stent may be temporary, used during and after a surgical procedure, or it may be used for longer periods in patients with ureteral obstruction due to tumors, strictures, or other causes.

Stents made of a nontoxic material such as silicone or polyurethane may be positioned during surgery or cystoscopy. They are radiopaque with side drainage holes placed along the length of the stent. One or both ends of the stent may be pigtail or J shaped to prevent migration.

- Label all drainage tubes including stents for easy identification. Attach each catheter and stent to a separate closed drainage system. *Careful labeling allows close monitoring of output from all sources and reservoirs. The use of separate drainage systems minimizes the risk of infection.*
- If the stent has been brought to the surface, secure it and maintain its position. *The stent is usually placed in the renal pelvis. It is important to secure it well to prevent trauma to the kidney, inadvertent removal of the stent, and ureter obstruction.*
- Monitor urine output, including color, consistency, and odor. Monitor for signs of infection or bleeding: fever, tachycardia, pain, hematuria, and cloudy or malodorous urine. *The stent facilitates urine flow but may become obstructed because of bleeding, calculi, or sediment. Obstruction may result in hydronephrosis and kidney damage. The stent itself is a foreign body in the urinary tract and can increase the risk of UTI.*
- Maintain fluid intake, encouraging fluids that acidify urine, such as low-sugar apple, cranberry, and blueberry juice. *The stent can precipitate calculus formation as well as UTI. Increasing fluid intake and acidifying the urine help prevent these complications.*
- For an indwelling stent, stress the need for regular follow-up to monitor for and prevent complications such as UTI and calculi. *The patient with an indwelling stent may tend to forget that the stent is in place and become lax in compliance with follow-up and preventive measures.*

Note that the older adult with a UTI may not complain of dysuria. Be alert for other manifestations of UTI such as incontinence or cloudy or malodorous urine. Inflammatory and immune responses tend to diminish with aging, reducing the irritative symptoms of UTI. See the accompanying Nursing Care of the Older Adult box.

Priorities of Care

Collaborating with the interprofessional team to ensure adequate treatment and eradication of the infection is the priority for nursing care. Teaching the patient and, as appropriate, caregivers strategies to prevent future UTIs also should be considered priority nursing actions. The nurse also focuses on promoting comfort and maintaining urinary elimination.

Diagnoses, Outcomes, and Interventions

The patient's general health, abilities for self-care, and risk factors that may contribute to UTI are considered when planning and implementing nursing care for the patient with a UTI. See the Case Study & Nursing Care Plan for the patient with cystitis on page 755.

Acute Pain

Pain is a common manifestation of both lower and upper UTI. Urinary tract pain is caused primarily by distention and increased pressure within the tract. The severity of the pain is related to the rate at which inflammation and distention develop, not their degree.

In cystitis, inflammation causes a sensation of fullness; dull, constant suprapubic pain; and possibly low back pain. The inflamed bladder wall and urethra cause dysuria, pain, and burning on urination. Bladder spasms may develop, causing periodic severe, stabbing discomfort. Pain associated with pyelonephritis is often steady and dull, localized to the outer abdomen or flank region. Urologic disorders rarely cause central abdominal pain.

NURSING CARE OF THE OLDER ADULT

Minimizing the Risk for UTI

Aging affects normal protective mechanisms that help prevent UTI. The pH of urine increases with aging, allowing bacteria to grow and multiply more readily. Glucosuria, more common in older adults due to the higher incidence of diabetes, facilitates bacterial growth. Incomplete bladder emptying and urinary retention are more common due to problems such as prostatic hypertrophy in men, bladder prolapse in women, and neurogenic bladder in both sexes. Changes in vaginal pH in women and decreased prostatic secretions in men may also contribute to an increased incidence of UTI.

While many UTIs in older adults are asymptomatic and self-limited, infections can lead to bacteremia, sepsis, and shock. Manifestations of UTI in older adults include dysuria, urgency, frequency, incontinence, occasional hematuria, and confusion. Symptoms such as fever, chills, and flank pain and tenderness may be absent. Dementia may make diagnosis more difficult.

Teach the older adult to maintain a generous fluid intake to promote flushing of the urinary bladder and urethra. Instruct to maintain good hygiene, but to not bathe more often than necessary; frequent bathing and feminine hygiene sprays or douches may dry perineal tissues, increasing the risk of UTI. Emphasize the importance of reporting a change in urine color, odor, clarity, or symptoms such as burning, frequency, or urgency to the primary care provider.

Evidence for Nursing Care

The Patient with Urinary Tract Infection

Selected resources that nurses may find helpful when planning evidence-based nursing care follow.

- Hooton, T. M., Bradley, S. F., Cardenas, D. D., Colgan, R., Geerlings, S. E., Rice, J. C, . . . Infectious Diseases Society of America. (2010). Diagnosis, prevention, and treatment of catheter-associated urinary tract infection in adults: 2009 International Clinical Practice Guidelines from the Infectious Diseases Society of America. *Clinical Infectious Diseases, 50*(5), 625–663.
- National Guideline Clearinghouse (NGC). (2012). *Guideline synthesis: Diagnosis and management of lower urinary tract infection.* Rockville, MD: Agency for Healthcare Research and Quality.
- Pratt, R., & Pellowe, C. (2010). Good practice in management of patients with urethral catheters. *Nursing Older People*, *22*(8), 25–29.

Expected Outcome: Patient will express improved comfort and rate pain at an acceptable level.

- Assess pain: timing, quality, intensity, location, duration, and aggravating and alleviating factors. *A change in the nature, location, or intensity of the pain could indicate an extension of the infection or a related but separate problem.*
- Teach or provide comfort measures such as warm sitz baths, warm packs or heating pads, and balanced rest and activity. Systemic analgesics, urinary analgesics, or antispasmodic medication may be used as ordered. *Warmth relaxes muscles, relieves spasms, and increases local blood supply. Because pain can stimulate a stress response and delay healing, it should be relieved when possible.*
- Increase fluid intake unless contraindicated. *Increased fluid dilutes urine, reducing irritation of the inflamed bladder and urethral mucosa.*
- Instruct to notify primary care provider if pain and discomfort continue or intensify after therapy is initiated. *Pain and discomfort in voiding typically are relieved within 24 hours of the initiation of antibiotic therapy. Continued discomfort may indicate a complicated UTI or other urinary tract disorder.*

Impaired Urinary Elimination

Inflammation of the bladder and urethral mucosa affects the normal process and patterns of voiding, causing frequency, urgency, and burning on urination, as well as nocturia. Urine may be blood tinged, cloudy, and malodorous. The patient with short- or long-term urinary retention requires additional measures to assess for and prevent UTI.

Expected Outcome: The patient's usual patterns of urinary elimination will be restored.

- Monitor (or instruct the patient to monitor) color, clarity, and odor of urine. *Urine should return to clear yellow within 48 hours, unless drug therapy causes a change in the color of urine. If clarity does not return, further investigation may be necessary.*

SAFETY ALERT

Provide for easy access to toileting. Make sure that lighting is adequate and that pathways are free of obstacles. Frequency, urgency, and nocturia increase the risk of urinary incontinence and of injury due to falls, particularly in a patient who is older or debilitated.

- Instruct to avoid caffeinated drinks, including coffee, tea, and cola; citrus juices; drinks containing artificial sweeteners; and alcoholic beverages. *Caffeine, citrus juices, and artificial sweeteners irritate bladder mucosa and the detrusor muscle, and can increase urgency and bladder spasms.*
- Use strict aseptic technique and a closed urinary drainage system when inserting a straight or indwelling urinary catheter. Unless contraindicated, instill anesthetic lubricating gel into the urethra (10 mL for a male and 6 mL for a female) prior to catheter insertion. Insert indwelling catheters to the full recommended length (4 or more inches in women and to the bifurcation in men) before inflating the balloon. *Bacteria colonizing the perineal tissues or on the nurse's hands can be introduced into the bladder during catheterization. Aseptic technique reduces this risk. Anesthetic gel promotes comfort, protects fragile urethral tissues from trauma, and reduces the risk for catheter-associated UTI (Bardsley, 2005). Inflation of the balloon while in the urethra damages urethral tissues and can cause significant discomfort for the patient.*
- When possible, use intermittent straight catheterization to relieve urinary retention. Remove indwelling urinary catheters as soon as possible. *Using intermittent straight catheterization allows the bladder to fill and completely empty in a more normal manner, maintaining physiologic function and reducing the risk of infection (Gupta & Trautner, 2012). See the accompanying Moving Evidence into Action box for evidence-based practice aimed at reducing the risk of catheter-associated UTI.*
- Maintain the closed urinary drainage system, and use aseptic technique when emptying the catheter drainage bag. Maintain gravity flow, preventing reflux of urine into the bladder from the drainage system. *Bacteria can enter the drainage system when its integrity is interrupted (e.g., disconnecting the catheter from the drainage system) or during emptying of the drainage bag. These bacteria can ascend the column of urine to the bladder, causing UTI.*
- Provide perineal care on a regular basis and following defecation. Use antiseptic preparations only as ordered. *Regular cleansing of perineal tissues reduces the risk of colonization by bowel or other bacteria. While antiseptic solutions may be ordered for catheter care, they can dry perineal tissues and reduce normal flora, increasing the risk of colonization by pathogens, and should not routinely be used.*

Readiness for Enhanced Self-Health Management

The patient with a urinary tract infection is at an increased risk for future UTI and needs to understand risk factors and measures to prevent recurrent infection. In addition, once the manifestations of UTI are relieved, motivation to continue the treatment plan declines. Failure to complete the full course of therapy and recommended follow-up can lead to continued bacteriuria, recurrent infections, and the development of antibiotic-resistant bacteria.

Expected Outcome: Patient will verbalize understanding of the infectious process and its treatment, and ways to reduce risk for future UTIs.

- Teach how to obtain a midstream clean-catch urine specimen. *Cleansing of the urinary meatus and perineal area reduces contamination of the specimen by external cells and bacteria. Ninety percent of urethral bacteria are cleared in the first 10 mL of voided urine; a midstream specimen is representative of urine in the bladder.*
- Assess knowledge about the disease process, risk factors, and preventive measures. *The patient may have little understanding of UTI, its causes, and contributing factors.*

Moving Evidence into Action

Reducing Catheter-Associated Complications

Insertion of an indwelling (retention) catheter is a commonly performed procedure in hospitals, with up to 25% of patients having an indwelling catheter at some time during hospitalization. Catheters often remain in place when there is no clear indication for their continued use (Dailly, 2012). Indwelling catheters are not only associated with an increased risk for UTI, but also often affect the patient's comfort and mobility as well. Nurses on an older adult acute care unit determined that more than half of the patients with indwelling catheters had no clear indication for catheterization (Gotelli et al., 2008). Using a nurse-driven protocol, the need for catheterization was assessed using specific criteria, and the catheter removed when criteria were no longer met. As a result, the prevalence of catheterization on this unit dropped from 24% at any given time to just over 16%. Implementation of evidence-based care is not uniform, however. An audit of urinary catheter care demonstrated the need for and effectiveness of a urinary catheter assessment and monitoring tool to promote best practice (Dailly, 2012).

Implications for Nursing

Although a physician's order is required for inserting an indwelling catheter, nurses often are in the best position to evaluate the need for continued catheterization as the patient progresses. These studies demonstrate the effectiveness of (1) providing nurses with clear criteria for assessing the need for catheterization, (2) use of a tool to monitor ongoing need, and (3) empowering nurses to remove an indwelling catheter and implement a bladder retraining program when criteria are no longer met. These nursing actions can have a positive impact on patient outcomes, reducing the risk for catheter-associated infection and other complications.

Moving Knowledge into Action

1. Aggressive diuretic or fluid therapy, accurate intake and output measurement, and incontinence in the presence of stage III pressure ulcers are some of the criteria used to determine the continued need for an indwelling urinary catheter in one of these studies. What other criteria would you consider in determining the appropriateness of continued catheterization? Provide justification for the criteria you identify.
2. An indwelling urinary catheter has been called a "one-point restraint." Identify why this is the case, and discuss potential noninfectious complications of urinary catheterization.
3. Patients who have had a urinary catheter in place for an extended period may require a bladder retraining program. Develop such a program for an older adult in an acute care or post–acute care setting.

- Discuss the prescribed treatment plan and the importance of taking all prescribed antibiotics. *Symptoms are largely relieved within 24 to 48 hours of starting antibiotic therapy; however, bacteria may remain in the urinary tract. Completing the prescribed regime is important to prevent recurrent infections and resistant bacteria.*
- Help the patient develop a plan for taking medications. *Missed doses of antibiotic can result in subtherapeutic blood levels and reduced effectiveness. Taking medication in association with a regular daily activity such as meals helps patients remember doses.*
- Instruct to keep appointments for follow-up and urine culture. *Follow-up urine culture, often scheduled 7 to 14 days after completion of antibiotic therapy, is vital to ensure complete eradication of bacteria and prevent relapse or recurrence.*
- Teach measures to prevent future UTI (see the preceding Health Promotion section). *A history of UTI is an independent risk factor for future infections (Gupta & Trautner, 2012). Teaching measures to manage other risk factors can reduce the patient's risk for future UTIs.*

Delegating Nursing Care Activities

As appropriate and allowed within the designated duties and responsibilities of assistive personnel, the nurse may delegate nursing care activities such as obtaining a clean-catch urine specimen, assisting with toileting and hygiene, and providing urinary catheter care for the patient with UTI.

Continuity of Care

Because both upper and lower urinary tract infections are usually managed in the community, teaching is the most important nursing intervention. Provide instruction on the following topics:

- Risk factors for UTI and how to minimize or eliminate these factors through increased fluid intake, regular elimination, and personal hygiene measures
- Early manifestations of UTI and the importance of seeking medical intervention promptly
- Maintaining optimal immune system function by attending to physical and psychosocial stressors, such as inadequate rest, poor nutrition, and high levels of emotional stress
- The importance of completing the prescribed treatment and keeping follow-up appointments.

Residents of long-term care facilities, people with impaired cognition, and those who require an indwelling urinary catheter or intermittent catheterization have a significant risk of reinfection. Teach caregivers to recognize subtle signs of infection such as increased urinary incontinence, a change in behavior, or increasing frailty. In addition, include the following topics:

- Use alternatives to an indwelling catheter when possible. For urinary incontinence, try scheduled toileting, incontinence pads or diapers, and external catheters if possible. For urinary retention, teach the patient or caregiver to perform straight catheterization every 3 to 4 hours using clean technique.
- When an indwelling catheter is necessary, teach measures such as perineal care, managing and emptying the collection chamber, maintaining a closed system, and bladder irrigation or flushing if ordered.

THE PATIENT WITH URINARY CALCULI

Obstruction of urine flow impairs renal function and is a common cause of acute and chronic kidney disease (Seifter, 2012). See Table 27–1 for common causes of urinary tract obstruction. **Urinary calculi**, stones in the urinary tract, are the most common cause of upper urinary tract obstruction. The term **lithiasis** means *stone formation*. When the stones form in the kidney, it is known as *nephrolithiasis*; when they form elsewhere in the urinary tract (for example, the bladder), it is called *urolithiasis*. Stones may form and obstruct the urinary tract at any point (Figure 27–3 ■); however, in the United States and other industrialized countries, renal or kidney stones are the most common.

CASE STUDY & NURSING CARE PLAN A Patient with Cystitis

Miija Waisanen is a 25-year-old second-year nursing student who recently got married. Mrs. Waisanen has never been pregnant, and she is using a diaphragm for birth control. She presents at the local urgent care clinic complaining of low back pain, frequency, urgency, and burning on urination that began the day before.

ASSESSMENT

Patrice Ramiros, RN, admits Mrs. Waisanen to the clinic. Mrs. Waisanen denies having had similar symptoms in the past or ever having been diagnosed with a UTI. She describes her pain as a constant, dull ache that does not change with movement. She feels the need to urinate almost constantly, but experiences difficulty in starting her stream, and burning pain and cramping when voiding. She reports getting up four times the night before to urinate. She denies painful intercourse and states that her last menstrual period began only 2 weeks ago. Physical examination reveals BP 112/68 mmHg; P 90 bpm and regular, afebrile. Suprapubic tenderness noted but no flank or costovertebral angle tenderness. Clean-catch urine specimen shows hematuria, multiple WBCs, and a bacteria count greater than 10^5 per milliliter.

The nurse practitioner prescribes trimethoprim-sulfamethoxazole (TMP-SMZ) 160 mg/800 mg PO bid for 3 days, and aspirin or acetaminophen 650 mg PO every 4 hours as needed for pain. Mrs. Waisanen is instructed to return to the clinic in 7 days for a follow-up urine culture, or sooner if her symptoms do not improve.

Clinical Reasoning in Patient Care

1. What additional information should you obtain from Mrs. Waisanen prior to her discharge from the clinic?

DIAGNOSES

- *Acute Pain* related to infection and inflammatory process in the urinary tract
- *Impaired Urinary Elimination* related to inflammation as evidenced by frequency, urgency, nocturia, and dysuria
- *Readiness for Enhanced Self-Health Management* related to risk factors for and treatment of UTI

EXPECTED OUTCOMES

- Patient will report relief of low back pain and burning on urination.
- Patient will regain a normal voiding pattern without frequency, urgency, nocturia, and abnormal urine characteristics.
- Patient will verbalize understanding of the disease process, related risk factors, follow-up instructions, and symptoms of recurrence indicating the need for medical attention.

PLANNING AND IMPLEMENTATION

- Teach comfort measures: warm sitz baths, a heating pad on low heat applied to her lower back or abdomen, rest, increased fluid intake, avoiding caffeinated beverages, and taking aspirin or acetaminophen as ordered.
- Advise to refrain from sexual intercourse until infection and inflammation have cleared to avoid further irritation of inflamed tissues.
- Discuss the possible relationship between using a diaphragm for birth control and UTI in women.
- Discuss dietary and hygiene practices to prevent UTI, symptoms indicating the need for further intervention, and the risks of undertreatment.

EVALUATION

Six months later, Mrs. Waisanen rotates through the urgent care clinic for her community-based nursing experience. Ms. Ramiros asks how she is doing. Mrs. Waisanen reports that her symptoms and urine cleared within about a day after starting the antibiotic and she has had no further problems. She has seen her women's healthcare nurse practitioner to change her birth control to oral contraceptives, increased her intake of fluid and vitamin C, and no longer puts off urinating until she "has time to go!"

Clinical Reasoning in Patient Care

2. Identify important teaching related to Mrs. Waisanen's prescribed antibiotic therapy and recommended follow-up care.
3. What physiologic and psychosocial factors put Mrs. Waisanen at risk for developing a UTI?
4. Compare and contrast the benefits and drawbacks to short-course therapy versus conventional therapy for UTI.
5. Develop a care plan for Mrs. Waisanen for the nursing diagnosis *Ineffective Self-Health Management.*

See Evaluating Your Response in Appendix B.

TABLE 27–1 Major Causes of Urinary Tract Obstruction by Location

Location	Obstructive Process
Kidney pelvis	Calculi (stones)
	Polycystic kidney disease
	Infection and scarring
Ureters	Calculi
	Scarring and stricture
	Congenital defects or strictures
	External processes such as pregnancy, tumors, lymph node enlargement
Bladder	Neurogenic bladder
	Tumors
	Calculi and other foreign bodies
Urethra	Benign prostatic hypertrophy
	Tumors
	Scarring and stricture
	Trauma

Incidence and Risk Factors

Urolithiasis is common; about 13% of males and 7% of females will develop urinary stones at some point during their lifetime (Asplin et al., 2012). In the United States, the incidence varies by region, with the highest frequency in southern and midwestern states. Calculi are more common among Whites than Blacks. Most people affected are in young or middle adulthood.

Although the majority of stones are idiopathic (having no demonstrable cause), a number of risk factors have been identified. The greatest risk factor for stone formation is a prior personal or family history of urinary calculi. A genetic predisposition toward the accumulation of certain mineral substances in the urine or a congenital lack of protective factors may explain the familial link. Other identified risk factors include dehydration with resultant increased urine concentration, immobility, and excess dietary intake of calcium, oxalate, or proteins. Gout, hyperparathyroidism, and urinary stasis or repeated infections also contribute to calculus formation.

Physiology Review

Normally, a balance exists in the kidneys between the need to conserve water and the need to eliminate poorly soluble materials such as

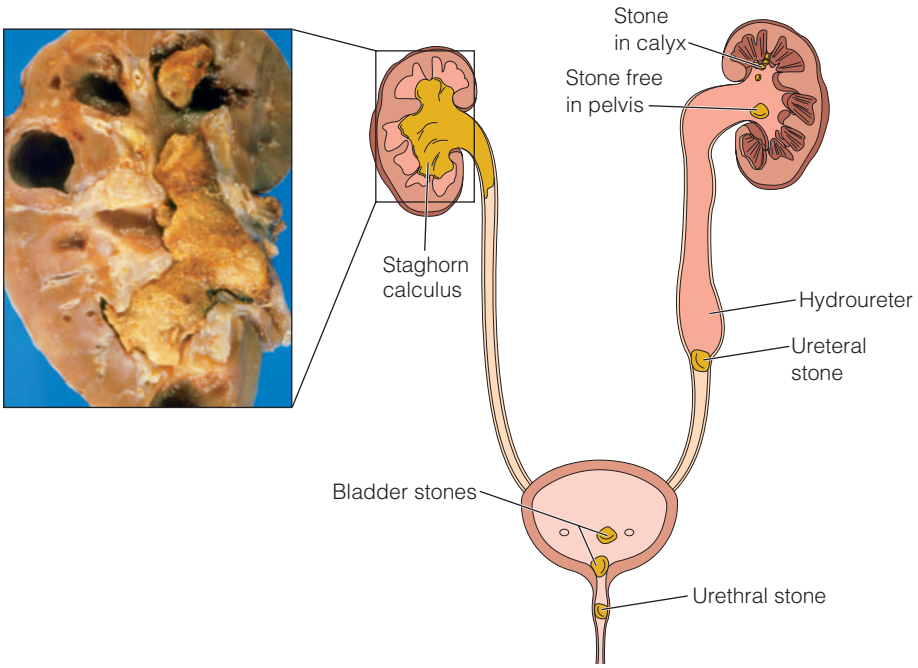


Figure 27–3 ■ Development and location of calculi within the urinary tract.
Source: Dr. E. Walker/Photo Researchers, Inc.

calcium salts. This balance is affected by factors such as diet, environmental temperature, and activity. Protective inorganic and organic substances in the urine, such as pyrophosphate, citrate, and glycoproteins, normally inhibit stone formation.

Pathophysiology

Three factors contribute to urolithiasis: supersaturation, nucleation, and lack of inhibitory substances in the urine.

When the concentration of an insoluble salt in the urine is very high, that is, when the urine is supersaturated, crystals may form. Usually, these crystals disperse and are eliminated because the bonds holding them together are weak. However, a nucleus of crystals may develop stable bonds to form a stone. More often, crystals form around an organic matrix or mucoprotein nucleus to become a stone. The stimulus required to initiate crystallization in supersaturated urine may be minimal. Ingesting a meal high in insoluble salt, or decreased fluid intake as occurs during sleep, allows the concentration to increase to the point where precipitation occurs and stones are formed and grow. When fluid intake is adequate, no stone growth occurs. The acidity or alkalinity of the urine and the presence or absence of calculus-inhibiting compounds also affect lithiasis.

Most (75% to 85%) kidney stones are *calcium stones*, composed of calcium oxalate and/or calcium phosphate. These stones are generally associated with high concentrations of calcium in the blood or urine. *Uric acid stones* develop when the urine concentration of uric acid is high. They are more common in men, and may be associated with gout. Genetic factors contribute to the development of uric acid stones and calcium stones. *Struvite* (magnesium-ammonium phosphate) *stones* are associated with UTI caused by urease-producing bacteria such as *Proteus*. These stones can grow to become very large, filling the renal pelvis and calyces. They often are called *staghorn stones* because of their shape (refer to Figure 27–3). *Cystine stones* are rare, and are associated with a genetic defect. The types of renal calculi, contributing factors, and recommended dietary modifications are listed in Table 27–2.

MEMORY CUE

- Most urinary stones form in the renal pelvis and are composed primarily of calcium salts.
- Men are affected by urinary stones more frequently than women.
- Loss of calcium from the bones (e.g., due to immobility) and dehydration are major risk factors for urinary stones.

Manifestations

The symptoms caused by urinary calculi vary with their size and location (see the Manifestations box). Manifestations develop as a result of obstructed urine flow with resulting distention, and tissue trauma caused by passage of the rough-edged, crystalline stone.

Calculi affecting the kidney calyces and pelvis may cause few symptoms. If the stone has gradually or partially obstructed urinary flow, dull, aching flank pain may be present, but renal calculi often are silent, without symptoms. Bladder calculi may cause few symptoms other than dull suprapubic pain with exercise or after voiding.

Renal colic, acute, severe flank pain on the affected side, develops when a stone obstructs the ureter, causing ureteral spasm. The pain of renal colic may radiate to the suprapubic region, groin, and external genitals (the scrotum or labia). The severity of the pain often causes a sympathetic response with associated nausea, vomiting, pallor, and cool, clammy skin.

Manifestations of UTI, including chills and fever, frequency, urgency, and dysuria, may accompany urinary calculi at any level. Trauma to the urinary tract by the calculi may cause gross or microscopic hematuria. Gross hematuria is often the only sign of bladder stones.

Complications

Urinary stones may obstruct urine flow, leading to complications such as hydronephrosis and urinary stasis with subsequent infection.

TABLE 27–2 Risk Factors and Interventions for Renal Calculi

Stone Type and Incidence	Risk Factors	Management
Calcium phosphate and/or oxalate 75%–85%	Hypercalciuria and hypercalcemia: hyperparathyroidism, immobility, bone disease, vitamin D intoxication, multiple myeloma, renal tubular acidosis, prolonged steroid intake Alkaline urine Dehydration Inflammatory bowel disease	Pharmacology: Thiazide diuretics, phosphates. Dietary: Limit foods high in sodium and protein, maintain calcium intake, increase foods that acidify urine. Other: Increase hydration, exercise.
Uric acid 5%–10%	Gout, increased purine intake, acid urine	Pharmacology: Potassium citrate (to alkalinize urine), allopurinol. Dietary: Avoid foods that are high in purines. Other: Increase hydration.
Struvite 5%	UTIs, especially *Proteus* infections	Pharmacology: Antibiotic therapy for UTI. Other: Surgical intervention or a lithotripsy is performed to remove stone.
Cystine 1%	Genetic defect, acid urine	Pharmacology: Penicillamine, sodium bicarbonate Dietary: Restrict sodium. Other: Increase hydration.

OBSTRUCTION

Stones can obstruct the urinary tract at any point from the calyces of the kidney to the distal urethra, impeding the outflow of urine. If the obstruction develops slowly, there may be few or no symptoms, whereas sudden obstruction (e.g., blockage of a ureter by a passing stone) may cause severe manifestations. Urinary tract obstruction can ultimately lead to renal failure. The degree of obstruction, its location, and the duration of impaired urine flow determine the effect on renal function.

HYDRONEPHROSIS The kidneys continue to produce urine, causing increased pressure and distention of the urinary tract behind the obstruction. **Hydronephrosis**, distention of the renal pelvis and calyces, and *hydroureter*, distention of the ureter, are possible results. If the pressure is unrelieved, the collecting tubules, proximal tubules, and glomeruli of the kidney are damaged, causing a gradual loss of renal function.

Acute hydronephrosis typically causes colicky pain on the affected side. The pain may radiate into the groin. Chronic hydronephrosis develops slowly, and may have few manifestations other than dull, aching back or flank pain. When hydronephrosis is significant, a palpable mass may be felt in the flank region. Hematuria and signs of UTI such as pyuria, fever, and discomfort may occur. Gastrointestinal symptoms such as nausea, vomiting, and abdominal pain may accompany hydronephrosis (see the Manifestations box on page 758).

INFECTION Urinary stasis associated with partial or complete obstruction increases the risk of urinary tract infection. Either upper or lower UTI may develop.

●○● INTERPROFESSIONAL CARE

Management of urinary calculi focuses on relieving acute symptoms, destroying or removing stones, and preventing further stone formation. Asymptomatic stones (those not causing pain, infection, or obstruction) are treated conservatively.

MANIFESTATIONS OF URINARY CALCULI

KIDNEY STONES
- Often asymptomatic
- Dull, aching flank pain
- Microscopic hematuria
- Manifestations of UTI

URETERAL STONES
- Renal colic
  - Acute, severe flank pain on affected side
  - Often radiates to suprapubic region, groin, and external genitals
- Nausea, vomiting, pallor, and cool, clammy skin

BLADDER STONES
- May be asymptomatic
- Dull suprapubic pain, possibly associated with exercise or voiding
- Gross or microscopic hematuria
- Manifestations of UTI

DIAGNOSIS

Laboratory and diagnostic tests that may be ordered when urinary calculi are suspected include the following:

- *Urinalysis* to assess for hematuria and the presence of WBCs and crystal fragments. The urine pH is helpful in identifying the type of stone.
- *Chemical analysis* of any stones passed in the urine determines the type of stone and suggests measures to prevent further stone formation. Retrieving stones or teaching the patient to do so is a nursing responsibility. All urine is strained and may be saved. Any visible stones or sediment is sent for analysis.
- *Urine calcium, uric acid*, and *oxalate* levels measure the amount of these substances excreted over a 24-hour period, and may be assessed to help identify possible causes of lithiasis. Elevated calcium levels occur in hyperparathyroidism, Cushing's syndrome, and osteoporosis, all of which may contribute to lithiasis. Uric acid levels may be elevated in patients with gout and those at risk

MANIFESTATIONS OF ACUTE AND CHRONIC HYDRONEPHROSIS

ACUTE
- Acute, colicky pain; may radiate into groin
- Hematuria, pyuria
- Fever
- Nausea, vomiting, abdominal pain

CHRONIC
- Dull, aching flank pain
- Hematuria, pyuria
- Fever
- Palpable flank mass

for forming uric acid calculi. Urine oxalate excretion may help to differentiate calcium oxalate from calcium phosphate stones.

- *Serum calcium*, *phosphorus*, and *uric acid* levels may be obtained to help identify factors contributing to calculus formation.
- *KUB* (kidneys, ureters, and bladder) x-ray of the lower abdomen may show calculi as opacities in the kidneys, ureters, and bladder.
- *Renal ultrasonography* uses reflected sound waves to detect stones and evaluate the kidneys for possible hydronephrosis.
- *Spiral computed tomography (CT) scan* of the kidney, with or without contrast medium, shows calculi, ureteral obstruction, and other renal disorders.
- *Cystoscopy* is used to visualize and possibly remove calculi from the urinary bladder and distal ureters.

MEDICATIONS

An acute episode of renal colic is treated with analgesia, medications to promote stone passage, and hydration. A narcotic analgesic such as morphine sulfate is given, often intravenously, to relieve pain and reduce ureteral spasm. Indomethacin, a nonsteroidal anti-inflammatory drug (NSAID) given as a suppository, may reduce the amount of narcotic analgesia required for acute renal colic. An oral alpha-adrenergic blocker such as tamsulosin (Flomax) is prescribed to relax ureteral muscle and promote passage of the stone. Oral or intravenous fluids reduce the risk of further stone formation and promote urine output.

After analysis of the calculus, various medications may be ordered to inhibit or prevent further lithiasis. A thiazide diuretic, frequently prescribed for calcium calculi, acts to reduce urinary calcium excretion and is very effective in preventing further stones. Potassium citrate alkalinizes urine (raises the pH) and is often prescribed to prevent stones that tend to form in acidic urine (uric acid, cystine, and some forms of calcium stones). Refer to Table 27–2 for other preparations related to types of stones. Nursing responsibilities focus on teaching the patient about the prescribed medication, its importance in preventing further stone formation, and potential adverse effects.

NUTRITION AND FLUID MANAGEMENT

Diet modifications may be prescribed to address factors found to contribute to lithiasis.

Increased fluid intake of 2.5 to 3.0 L/day is recommended, regardless of stone composition. A fluid intake to ensure the production of approximately 2.0 to 2.5 L of urine a day prevents the stone-forming salts from becoming concentrated enough to precipitate. Fluid intake should be spaced throughout the day and evening. Some authorities recommend that patients drink one to two glasses of water at night to prevent concentration of urine during sleep.

TABLE 27–3 Teaching Patients with Urolithiasis: Possible Dietary Modifications

Foods high in oxalate	Asparagus, beer and colas, beets, cabbage, celery, spinach, chocolate and cocoa, fruits, green beans, nuts, tea, tomatoes
Purine-rich foods	Goose, organ meats, sardines and herring, venison; moderate in beef, chicken, crab, pork, salmon, veal

Recommended dietary changes may include reduced intake of the primary substance forming the calculi. For calcium stones, however, restricting dietary calcium may actually increase the risk of stone formation while promoting bone loss. A low-sodium restricted-protein diet has been shown to be more effective in preventing the recurrence of calcium stones. Dietary sodium also is restricted in patients who form cystine stones (Asplin et al., 2012). Oxalate, found in foods such as spinach, nuts, and chocolate, may be limited in patients found to have calcium oxalate stones and high levels of oxalate in their urine.

The patient with uric acid stones requires a diet low in purines. Organ meats, sardines, and other high-purine foods are eliminated from the diet. Foods with moderate levels of purines, such as red and white meats and some seafood, may be limited. Table 27–3 lists foods high in oxalate and purines.

TREATMENT

Treatment of existing calculi depends on the location of the stone, the extent of obstruction, renal function, the presence or absence of UTI, and the patient's general state of health. In general, the stone is removed if it is causing obstruction, infection, unrelieved pain, or serious bleeding.

Lithotripsy, using sound or shock waves to crush a stone, is the preferred treatment for urinary calculi. Several techniques are available. *Extracorporeal shock wave lithotripsy (ESWL)* is a noninvasive technique for fragmenting kidney stones using shock waves generated outside the body. Acoustic shock waves are aimed under fluoroscopic guidance at the stone (Figure 27–4 ■). These shock waves travel through soft tissue without causing damage, but shatter the stone as its greater density stops their progress. Repeated shock waves

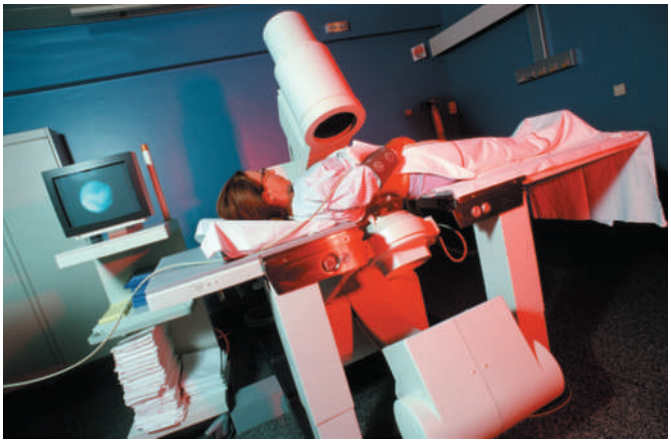

Figure 27–4 ■ Extracorporeal shock wave lithotripsy. Acoustic shock waves generated by the shock wave generator travel through soft tissue to shatter the urinary stone into fragments, which are then eliminated in the urine.
Source: Visuals Unlimited.

pulverize the stone into fragments small enough to be eliminated in the urine. The procedure may require 30 minutes to 2 hours to complete. Intravenous sedation generally is adequate to maintain comfort during the procedure. Pregnancy is an absolute contraindication for lithotripsy procedures, and, because its effects on the ovary are unknown, it is relatively contraindicated for women of childbearing age (Grasso, 2012; Meng et al., 2012). See the box below for nursing care of the patient undergoing a lithotripsy procedure.

Lithotripsy also may be performed using a percutaneous ultrasonic or laser technique. *Percutaneous nephrolithotomy* uses a nephroscope inserted into the kidney pelvis through a small flank incision (Figure 27–5 ■). The stone is fragmented using a small ultrasonic transducer or laser, and the fragments are removed through the nephroscope. In a *ureteroscopy* procedure, laser beams are used to disintegrate the stone, without damaging soft tissue. A ureteroscope (passed up the ureter from the bladder during cystoscopy) is used to guide the laser probe into direct contact with the stone.

A double-J stent may be inserted into the affected ureter to maintain its patency following ESWL or other lithotripsy procedures. (See the box on page 752 for nursing care of the patient with a ureteral stent.)

Bladder stones may be removed using an instrument passed through a cystoscope to crush the stones. The remaining stone fragments are then irrigated out of the bladder using an acid solution to counteract the alkalinity that precipitated stone formation.

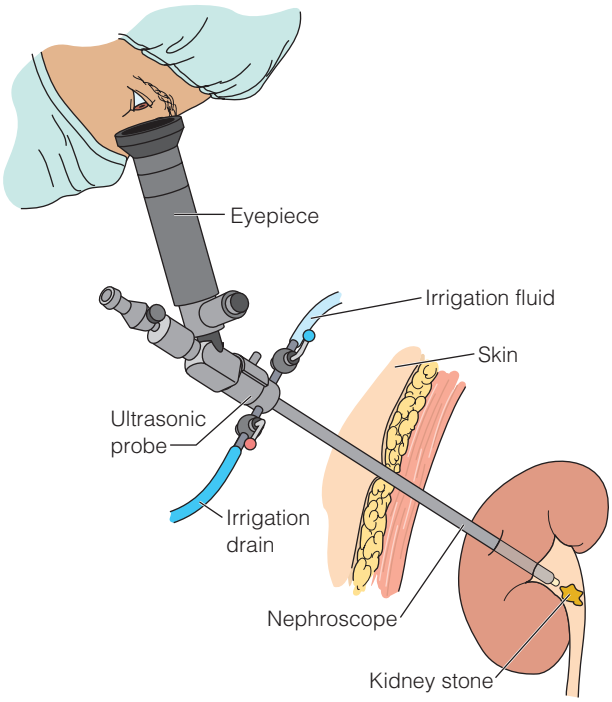

Figure 27–5 ■ Percutaneous ultrasonic lithotripsy. A nephroscope is inserted into the renal pelvis, and ultrasonic waves are used to fragment the stone. The fragments then are removed through the nephroscope.

●○● NURSING CARE

Health Promotion

Discuss the importance of maintaining an adequate fluid intake with all patients. Stress the need to increase fluid intake during warm weather and strenuous exercise or physical labor. Discuss the relationship between weight-bearing activity and retention of calcium in the bones. Encourage all patients to remain as physically active as possible to prevent bone resorption (loss) and possible hypercalciuria.

Instruct patients with known gout to maintain a generous fluid intake so as to produce at least 2 L of urine every day. Discuss the risk of lithiasis with patients who have frequent UTIs, and teach measures to reduce the incidence of UTI and the risk for lithiasis.

Assessment

Obtain subjective and objective assessment data specific to urolithiasis:

- *Health history:* complaints of flank, back, or abdominal pain, radiation, characteristics and timing, aggravating or relieving factors; nausea and vomiting; possible contributing factors such as

NURSING CARE OF THE PATIENT

Having Lithotripsy

PREOPERATIVE CARE

- Assess knowledge and understanding of the procedure, providing information as needed. *Anxiety is reduced, and recovery is enhanced and hastened when the patient is fully prepared for surgery.*
- Follow directions from the radiology department, physician, or anesthetist for withholding food and fluids and for bowel preparation prior to surgery. *Conscious sedation, general anesthesia, or spinal anesthesia may be required, depending on the procedure. Fecal material in the bowel may impede fluoroscopic visualization of the kidney and stone.*

POSTOPERATIVE CARE

- In the initial period, monitor vital signs frequently. *The kidney is highly vascular; therefore, hemorrhage and resulting shock are potential complications of lithotripsy. Bleeding may be internal or retroperitoneal and difficult to detect.*
- Monitor amount, color, and clarity of urine output. *Urine is often bright red initially, but bleeding should diminish within 48 to 72 hours. Cloudy urine may indicate the presence of an infection.*
- Maintain placement and patency of urinary catheters, if present. Anchor ureteral catheters or nephrostomy tubes securely. Irrigate gently if ordered. *A kinked or plugged catheter may result in hydroureter, hydronephrosis, and kidney damage. Decreased urinary output and flank pain are possible symptoms of obstructed urine flow. Excessive force in irrigation may cause trauma and bleeding.*
- Prepare for discharge by teaching care of the indwelling catheter, urine-collection device, and incision site (if present). Teach signs and symptoms to report: urine leakage from incision for more than 4 days, symptoms of infection, pain, and bright hematuria. *Many patients are discharged with dressings and catheters in place. The patient and family need necessary information to provide self-care.*
- Teach measures to reduce the risk of further lithiasis. *Many patients have repeated episodes of lithiasis and renal colic. Prevention of stone formation is important to preserve renal function.*

dehydration; previous or family history of kidney stones; current or previous treatment measures
- *Physical assessment:* general appearance including position, vital signs; skin color, temperature, moisture, turgor; abdominal, flank, or costovertebral tenderness; amount, color, and characteristics of urine (presence of hematuria, bacteria, pyuria, pH).

Priorities of Care

Maintaining unobstructed urine flow from the kidneys through the urinary meatus is the interprofessional care priority. The nurse assesses urinary output and monitors for complications such as hydronephrosis or acute kidney injury. Promoting comfort also is a nursing care priority, particularly in the patient with renal colic.

Diagnoses, Planning, and Interventions

Acute Pain

Pain is the primary outward manifestation of urolithiasis, particularly when a stone lodges within a ureter, causing acute obstruction and distention. Invasive and noninvasive procedures to remove or crush stones also may be painful.

Expected Outcome: Patient will report pain at a level of 2 or lower on a scale of 0 to 10.

- Assess pain using a standard pain scale and its characteristics. Administer analgesia as ordered and monitor its effectiveness. *The intensity, type of pain, and its responsiveness to analgesia provide valuable clues as to its cause. Regular administration of prescribed analgesics controls pain more effectively than waiting until pain becomes intolerable. Administering an ordered NSAID on a routine schedule may significantly reduce the need for narcotic analgesia in patients with renal colic.*
- Unless contraindicated, encourage fluid intake and ambulation in the patient with renal colic. *Increased fluids and ambulation increase urinary output, facilitating movement of the calculus through the ureter and decreasing pain.*
- Use nonpharmacologic measures such as positioning, moist heat, relaxation techniques, guided imagery, and diversion as adjunctive therapy for pain relief. *Adjunctive pain relief measures can enhance the effectiveness of analgesics and other prescribed treatment.*

SAFETY ALERT

The intensity of renal colic pain can cause a vasovagal response with resulting hypotension and syncope. Always provide for the patient's safety.

Impaired Urinary Elimination

Obstruction of the urinary tract is the primary complication associated with urolithiasis. Obstruction can ultimately lead to stasis, infection, or irreversible renal damage.

Expected Outcome: Patient's urinary output and renal function studies will remain within expected parameters.

- Monitor amount and character of urine output. If catheterized, measure output hourly. Document any hematuria, dysuria, frequency, urgency, and pyuria. Strain all urine for stones, saving any recovered stones for laboratory analysis. *The amount of urine output helps determine urinary tract patency and adequacy of hydration. Hematuria, gross or microscopic, is often associated with calculi and with procedures used to remove stones, such as cystoscopy or lithotripsy. A change in the amount of hematuria may indicate stone passage or a complication. Dysuria, frequency, urgency, and cloudy urine are symptoms of UTI, often associated with urolithiasis. Antibiotic therapy may be required. Analysis of stones recovered from the urine can direct measures to prevent further lithiasis.*
- Maintain patency and integrity of all catheter systems. Secure catheters well, label as indicated, and use sterile technique for all ordered irrigations or other procedures. *A kinked or plugged catheter, particularly a ureteral catheter or nephrostomy tube, may damage the urinary system. Labeling catheters can prevent mistakes, such as inappropriate irrigation or clamping. Any catheter increases the risk of infection; use of aseptic technique in all procedures reduces this risk.*

Evidence for Nursing Care

The Patient with Urinary Calculi

A selected resource that nurses may find helpful when planning evidence-based nursing care follows.

- Non-traumatic acute flank pain. (2010, April). In P. Bader, D. Echtle, V. Fonteyne, K. Livadas, G. De Meerleer, et al., *Guidelines on pain management* (pp. 82–90). Arnhem, The Netherlands: European Association of Urology. Retrieved from http://www.guideline.gov/content.aspx?id=23898&search=urolithiasis.

PRACTICE ALERT!

A stone that completely obstructs the ureter can lead to hydronephrosis and acute kidney injury on the affected side. Report symptoms such as dull flank pain or aching and changes in renal function studies (BUN, serum creatinine, and eGFR). Because the other kidney continues to function, urine output may not fall significantly with obstruction of one ureter. A drop in eGFR or rising BUN and serum creatinine levels may be early signs of renal failure.

Readiness for Enhanced Knowledge

The patient with urolithiasis needs information about the disease and its possible consequences, any diagnostic or therapeutic procedures performed, and strategies to prevent future lithiasis.

Expected Outcome: Patient will verbalize an understanding of the disease, factors contributing to its development, recommended treatment, and self-care strategies to prevent future episodes of stone development.

- Assess understanding and previous learning. *Relating information to previously learned material enhances retention and understanding.*
- Present all material in a manner appropriate to knowledge base, developmental and educational level, and current needs. *Learning is an active process that requires the patient's participation. Tailoring teaching to the individual increases involvement.*
- Teach about all diagnostic and treatment procedures. *Knowing what to expect reduces anxiety, enhances compliance, and hastens recovery.*
- If the patient will be managed in the community, teach to:
  - Collect and strain all urine, saving any stones.
  - Report stone passage to the physician and bring the stone in for analysis.
  - Report any changes in the amount or character of urine output to physician.

When pain can be managed with oral analgesics, urinary stones are managed in the community. The patient needs to know how and why to collect the calculus and indicators of complications, such as reduced urine output and cloudy or bloody urine.

- Teach measures to prevent further urolithiasis:
  - Increase fluid intake to 2500 to 3500 mL/day.
  - Follow recommended dietary guidelines.
  - Maintain activity level to prevent urinary stasis and bone resorption.
- Take medications as prescribed.
  The risk of recurrent lithiasis is approximately 50%; however, this risk can be reduced by following measures to prevent conditions favoring stone formation.
- Teach about the relationship between urinary calculi and UTI, emphasizing preventive measures and the importance of prompt treatment. *Urinary tract infection promotes urolithiasis and thus requires prompt treatment to reduce this risk.*

Delegating Nursing Care Activities

As appropriate and allowed within the designated duties and responsibilities of assistive personnel, the nurse may delegate nursing care activities such as measuring intake and output, straining all urine, and assisting with ADLs for the patient with urinary calculi.

Continuity of Care

The patient with urinary calculi needs to know how to manage existing stones and what to do to reduce the risk of future stone formation. Discuss the following topics to prepare the patient and family for home care:

- Importance of maintaining a fluid intake adequate to produce 2.0 to 2.5 quarts of urine per day
- Prescribed medications, their management, and potential adverse effects
- Dietary recommendations
- Prevention, recognition, and management of UTI
- Any further diagnostic or treatment measures planned.

When the patient is to be discharged with dressings, a nephrostomy tube, or a catheter, teach the patient and family about the following:

- How to change dressings, maintaining aseptic technique
- Assessment of the wound and skin for healing and possible complications such as infection or skin breakdown
- How to manage drainage systems and maintain their patency
- Emptying drainage bags and assessing urine output
- When to contact the physician and recommendations for follow-up care.

THE PATIENT WITH A URINARY TRACT TUMOR

A malignancy can develop in any part of the urinary tract from the kidney pelvis to the urinary meatus; however, 90% develop in the bladder, about 8% develop in the renal pelvis, and only 2% develop in the ureter or urethra (Scher & Motzer, 2012). When diagnosed early, the 5-year survival rate for bladder cancer is 93% (American Cancer Society [ACS], 2012).

Incidence and Risk Factors

An estimated 73,410 new cases of bladder cancer were diagnosed in the United States in 2012, and 14,880 people died as a result of the disease. The incidence of bladder cancer is nearly four times higher in men than it is in women, and about twice as high in White men as it is in Black men (ACS, 2012). Most people who develop bladder cancer are over age 60.

Two major factors are implicated in the development of bladder cancer: the presence of carcinogens in the urine and chronic inflammation or infection of bladder mucosa. Cigarette smoking is the primary risk factor for bladder cancer. The risk in smokers is twice that of nonsmokers (ACS, 2012). The chemicals and dyes used in the plastics, rubber, and cable industries; substances in the work environment of textile workers, leather finishers, spray painters, and petroleum workers; and high levels of arsenic in drinking water also are associated with a higher risk of bladder cancer. Additional risk factors for bladder cancer include residence in an urban area, chronic UTIs, and bladder calculi. The risk for bladder cancer appears to be reduced by increasing the intake of fluids and vegetables.

FAST FACTS

- The incidence of bladder cancer has remained relatively stable in recent years.
- In men, bladder cancer is the fourth most frequently occurring cancer, and the eighth leading cause of cancer deaths.
- Men develop bladder cancer at a rate four times that of women.
- The incidence of bladder cancer among Caucasian men is nearly twice that of African American men (ACS, 2012).

Pathophysiology

Most urinary tract malignancies arise from epithelial tissue. Transitional epithelium lines the entire tract from the renal pelvis through the urethra. Carcinogenic breakdown products of certain chemicals and from cigarette smoke are excreted in the urine and stored in the bladder, possibly causing a local influence on abnormal cell development. Squamous cell carcinoma of the urinary tract occurs less frequently than transitional epithelial cell tumors.

Urinary tract tumors begin as nonspecific cellular alterations that develop into either flat or papillary lesions. These lesions may be either superficial or invasive. Most bladder tumors are papillary lesions (*papillomas*), a polyp-like structure attached by a stalk to the bladder mucosa (Figure 27–6 ■). Papillomas are generally superficial, noninvasive tumors that bleed easily and frequently recur (Scher & Motzer, 2012). They rarely progress to become invasive, and the prognosis for recovery is good.

Carcinoma *in situ* (CIS), which occurs less frequently, is a poorly differentiated flat tumor that invades directly and is associated with a poorer prognosis. These tumors often initially present as superficial lesions, later progressing to become invasive (Figure 27–7 ■). Grade I tumors are highly differentiated and rarely progress to become invasive, whereas grade III tumors are poorly differentiated and usually progress (Scher & Motzer, 2012). The tumor, node, metastasis (TNM) system, outlined in Table 27–4, is used to stage bladder tumors. When metastasis occurs, the pelvic lymph nodes, lungs, bones, and liver are most commonly involved. More information about tumor grading and staging can be found in Chapter 14,

Figure 27–6 ■ Papillary transitional cell carcinoma of the urinary bladder.
Source: Custom Medical Stock Photo, Inc.

which discusses cancer physiology, treatment, and nursing care of the patient with cancer.

Manifestations

Painless hematuria is the presenting sign in 75% of urinary tract tumors. Hematuria may be gross or microscopic and is often intermittent, causing delay in seeking treatment. Inflammation surrounding the tumor occasionally causes manifestations of a UTI, including frequency, urgency, and dysuria. Ureteral tumors may cause colicky pain from obstruction. Tumors of the urinary tract typically cause few outward signs and may not be discovered until obstructed urine flow causes flank pain or renal failure.

PRACTICE ALERT!

Intermittent painless hematuria is the most common presenting symptom of bladder cancer. Instruct all patients with painless hematuria to contact their physician for follow-up testing.

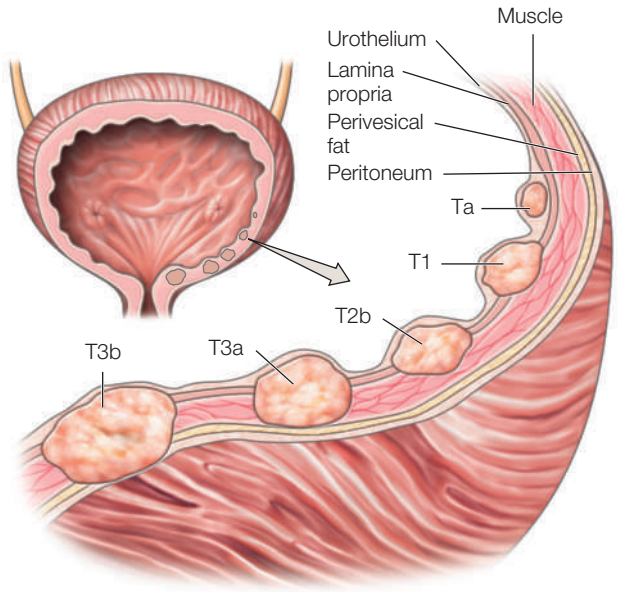

Figure 27–7 ■ Stages of bladder tumor development and invasiveness, beginning at the 3 o'clock position of the bladder and continuing in a clockwise manner.

●○● INTERPROFESSIONAL CARE

Treatment of the patient with a tumor of the urinary tract focuses on removing or destroying the cancerous tissue, preventing further invasion or metastasis, and maintaining renal and urinary function.

DIAGNOSIS

When a urinary tract tumor is suspected, the following diagnostic tests may be ordered:

- *Urinalysis* is done to evaluate for hematuria. Gross or microscopic hematuria is often the first indicator of a neoplasm in the urinary tract.
- *Urine cytology*, microscopic examination of cells in the urine, is performed to identify abnormal cells (tumor or pretumor cells). Periodic urine cytology is recommended for patients at high risk for bladder cancer or its recurrence due to carcinogen exposure.
- *Ultrasound of the bladder* is a noninvasive test to detect bladder tumors. *Intravenous pyelography* may reveal a rigid deformity of the bladder wall, obstruction of urine flow at the point of the tumor, or bladder filling or emptying defects.

TABLE 27–4 Bladder Tumor Staging

Depth of Involvement	Stage	TNM (Tumor, Node, Metastasis) Stage	Tumor Involvement
Superficial	C_{IS}	T_a	Limited to the bladder mucosa
	I	T_1	Involvement of the bladder mucosa and submucosal layers
Invasive	II	T_2	Invasion of superficial muscle of bladder wall
		T_{3a}	Deep muscle invasion
	III	T_{3b}	Involvement of perivesicular fat
	IV	$T_{3-4}N_+$	Regional (pelvic) lymph node involvement
		$T_{3-4}M_1$	Metastasis to distant lymph nodes or organs

- *Cystoscopy* and *ureteroscopy* allow direct visualization, assessment, and biopsy of lesions of the urethra, bladder, or ureters to provide definitive diagnosis of urinary tract tumors.
- *CT scan* or *MRI* is primarily used to evaluate tumor invasion or metastasis.

MEDICATIONS

Immunologic or chemotherapeutic agents administered by intravesical instillation (into the bladder) may be used either as the primary treatment for bladder cancer when multiple early lesions are present or to prevent recurrence following endoscopic tumor removal. Bacille Calmette-Guérin (BCG; BCG Live, TheraCys) is a suspension of attenuated *Mycobacterium bovis* used to treat CIS and recurrent bladder tumors. Instillation into the bladder causes a local inflammatory reaction that eliminates or reduces superficial tumors. Systemic mycobacterial infection is a rare complication of intravesical BCG therapy that may require antituberculin treatment. Other chemotherapeutic agents may be administered intravesically, including thiotepa, mitomycin C, and interferon. Bladder irritation, frequency, dysuria, and contact dermatitis are possible adverse reactions to intravesical chemotherapy. Suppression of bone marrow function can occur as a result of intravesical treatment.

RADIATION THERAPY

Radiation therapy primarily is used as a palliative treatment for inoperable tumors and patients who cannot tolerate surgery. Radiation therapy may be used in combination with systemic chemotherapy to improve local and distant relapse rates.

SURGERY

A number of surgical procedures, ranging from simple resection of noninvasive tumors to removal of the bladder and surrounding structures, are used to treat urinary tract tumors. Indications for each procedure and specific nursing implications are outlined in Table 27–5.

Transurethral tumor resection may be performed by excision, *fulguration* (destruction of tissue using electric sparks generated by high-frequency current), or *laser photocoagulation* (use of light energy to destroy abnormal tissue). Laser surgery carries the lowest risk of bleeding and perforation of the bladder wall. Following cystoscopic tumor resection, patients are followed at 3-month intervals for tumor recurrence. Recurrences may develop anywhere in the urinary tract, including the renal pelvis, ureter, or urethra.

Cystectomy, surgical removal of the bladder, is necessary to treat invasive cancers. Partial cystectomy may be done to remove a solitary lesion; however, radical cystectomy is the standard treatment for invasive tumors. The bladder and adjacent muscles and tissues are removed. In men, the prostate and seminal vessels are also removed, resulting in impotence. In women, a total hysterectomy and bilateral salpingo-oophorectomy (removal of the uterus, fallopian tubes, and ovaries) accompanies the procedure, causing sterility. At the time of surgery, a **urinary diversion** is created to provide for urine collection and drainage. An ileal conduit (Figure 27–8A ■), bilateral cutaneous urostomy (Figure 27–8B), or a continent urinary diversion (Figure 27–8C) is created to collect and drain urine. Table 27–6 describes the most frequently used urinary diversion techniques.

Surgical procedures to remove tumors involving other portions of the urinary tract vary according to the site and stage of the tumor. When the distal ureter is involved, the tumor may be resected and the ureter implanted into the opposite ureter to provide for drainage. A proximal ureteral tumor necessitates removal of the ureter and kidney on the affected side.

See the box on page 765 for nursing care of the patient undergoing tumor resection and a urinary diversion.

●○● NURSING CARE

The patient who undergoes treatment for a tumor of the urinary tract has many nursing care needs because of alterations in the elimination, health perception–health management, cognitive-perceptual, self-perception–self-concept, role-relationships, and coping–stress tolerance health patterns.

Health Promotion

Encourage all patients not to smoke. Provide referral to smoking cessation programs or clinics for patients who wish to quit smoking. Encourage patients at high risk for developing bladder cancer to have periodic examinations, including urinalysis and possible urine cytology.

Assessment

Nursing assessment related to urinary tract cancer includes both subjective and objective information:

- *Health history:* risk factors; history of hematuria or manifestations of UTI (dysuria, frequency, urgency, pyuria); lower abdominal discomfort or flank pain
- *Physical assessment:* general health; abdominal tenderness; urine for analysis.

TABLE 27–5 Surgical Procedures to Treat Bladder Tumors

Procedure	Indications	Nursing Implications
Transurethral resection of bladder tumor	Diagnose and resect superficial bladder tumors; control bleeding	Maintain continuous bladder irrigation postoperatively; monitor for excessive bleeding; ensure catheter patency. Increase fluids to 2500–3000 mL/day. Give stool softeners to prevent straining.
Partial cystectomy	Resect solitary, isolated tumor at stage T_2 or T_3 not involving trigone	Maintain patency of urethral and/or suprapubic catheter to make sure suture lines are free of pressure; monitor for excess bleeding.
Complete or radical cystectomy	Remove large, invasive tumors; involvement of trigone	Permanent urinary diversion is required. Maintain patency and position of stents; urethral catheter may be in place to drain pelvic cavity.

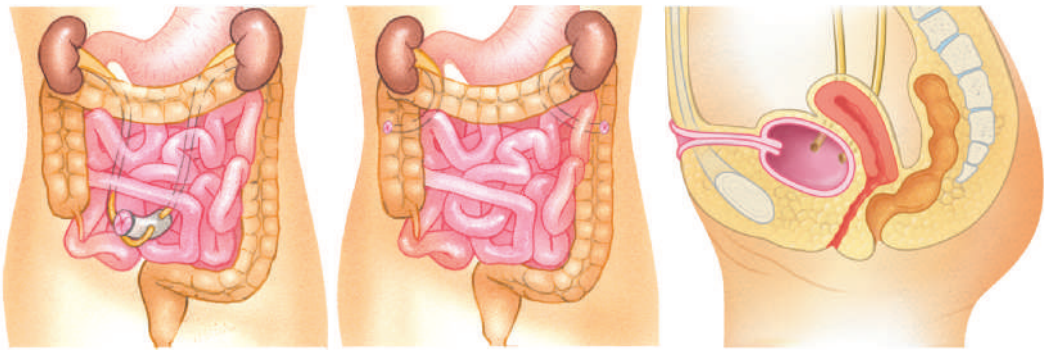

Figure 27–8 ■ Common urinary diversion procedures. A, Ileal conduit. A segment of ileum is separated from the small intestine and formed into a tubular pouch with the open end brought to the skin surface to form a stoma. The ureters are connected to the pouch. B, Bilateral cutaneous urostomy. The ureters are brought to the surface of the abdomen to form individual stomas. C, Continent urinary diversion. A segment of ileum is separated from the small intestine and formed into a pouch. Nipple valves are formed at each end of the pouch by intussuscepting tissue backward into the reservoir to prevent leakage.

Priorities of Care

Maintaining urinary output is the priority nursing care focus for the patient with a bladder tumor. Priority needs for the patient who has undergone a urinary diversion procedure also include maintaining skin integrity, preventing infection, and helping restore a healthy body image.

Diagnoses, Outcomes, and Interventions

For additional potential nursing diagnoses and interventions for the patient with a bladder tumor, see the Case Study & Nursing Care Plan on page 767.

Impaired Urinary Elimination

Whether the patient has undergone transurethral resection of a bladder tumor or radical cystectomy with urinary diversion, urinary elimination is altered at least temporarily.

Expected Outcome: Patient's urine output will remain within expected parameters for amount, color, clarity, and odor.

- Monitor urine output from all catheters, stents, and tubes for amount, color, and clarity hourly for the first 24 hours postoperatively, then every 4 to 8 hours. *Decreased urine output may indicate impaired catheter or drainage system patency. Prompt intervention is necessary to prevent hydronephrosis. A change in color or clarity may indicate a complication such as hemorrhage or infection.*

PRACTICE ALERT!

Promptly report urine output of less than 30 mL/hr, which may indicate low vascular volume or renal insufficiency. Prompt intervention is vital to restore cardiac output and prevent acute kidney injury.

- Label all catheters, stents, and their drainage containers. Maintain separate closed gravity drainage systems for each. *Clear identification of each tube can prevent errors in irrigating and calculating outputs. Separate closed systems minimize the risk and extent of potential bacterial contamination and resultant infection.*
- Secure ureteral catheters and stents with tape; prevent kinking or occlusion; and maintain gravity flow by keeping drainage bag below level of kidneys. *Impaired urine flow can lead to urinary retention and distention of the bladder, a newly created reservoir, or the renal pelvis (hydronephrosis).*
- Encourage fluid intake of 3000 mL/day. *Increased fluid intake maintains a high urinary output, reducing the risk of infection. Dilute urine is less irritating to the skin surrounding the stoma site. Electrolyte reabsorption from reservoirs may increase risk of calculi; high fluid intake and urine output reduce this risk.*

TABLE 27–6 Urinary Diversion Procedures

Procedure	Description	Nursing Considerations
Ileal conduit	Portion of ileum is isolated from small intestine, leaving vascular, lymphatic, and neural connections intact; ileum is formed into pouch with the open end brought to surface to form a stoma; ureters are inserted into pouch.	Most common urinary diversion. Continuous urine drainage necessitates appliance. Postoperative edema may interfere with urine output. Risk of infection is less than for cutaneous ureterostomy, but potential for reflux is high. Good skin care is vital because of constant contact with urine.
Cutaneous ureterostomy	Each ureter is brought to the surface of the abdomen to form a stoma.	Continuous urine drainage requires dual appliances. Risk of infection is high due to direct route from the skin to the kidneys. Good skin care is vital because of constant contact with urine.
Continent urinary reservoir	A portion of the stomach, colon, or small intestine is used to form a reservoir to which the ureters are attached. Nipple valves are formed to prevent reflux. A nipple valve and stoma may be formed or the pouch may be attached to the urethral stump, avoiding creation of a stoma.	Drainage collection device not necessary. Patient must be able and motivated to manage self-catheterization. Reservoir may absorb urea and electrolytes, resulting in imbalances. Significant portion of bowel is required to form pouch and stoma.

NURSING CARE OF THE PATIENT

Having a Cystectomy and Urinary Diversion

PREOPERATIVE CARE

- Provide routine preoperative care.
- Assess knowledge of the proposed surgery and its long-term implications, clarifying misunderstandings and discussing concerns. *Patients having surgery for cancer of the urinary tract are trying to cope with the diagnosis of cancer and may not fully understand the surgery and its potential effects. Open discussion can facilitate postoperative recovery and adjustment.*
- Begin teaching about postoperative tubes and drains, self-care of stoma, and control of drainage and odor. *Postoperative physiologic and psychologic stressors may interfere with learning. A basic understanding of what to expect in the way of tubes, drains, and procedures reduces stress in the immediate postoperative period. Preoperative teaching can enhance recall and postoperative learning.*
- Assist in identifying stoma site, avoiding folds of skin, bones, scar tissue, and the waistline or belt area. Be sure to consider the patient's occupation and style of clothing. The site should be visible to the patient and accessible for manipulation. *Stoma placement is a vital component of adjustment and self-care. Care is taken to place the stoma away from areas of constant irritation by clothing or movement. It should be located so that the patient can cover and disguise the collecting device, maintain the seal to prevent leakage, and effectively cleanse and maintain the site.*
- Perform bowel-preparation activities as ordered. *Bowel preparation is done to prevent fecal contamination of the peritoneal cavity and to decompress the bowel during surgery.*

POSTOPERATIVE CARE

- Provide routine postoperative care.
- Monitor intake and output carefully, assessing urine output every hour for the first 24 hours, then every 4 hours or as ordered. Call the physician if urine output is less than 30 mL/hr. *Tissue edema and bleeding may interfere with urinary output from stoma, catheters, or drains. Maintenance of urine outflow is vital to prevent hydronephrosis and possible renal damage. A urine output of at least 30 mL/hr is necessary for effective renal function.*
- Assess color and consistency of urine. Expect pink or bright red urine fading to pink and then clearing by the third postoperative day. Urine may be cloudy due to mucus production by bowel mucosa. *Bright red blood in the urine from a urinary diversion may indicate hemorrhage, necessitating further surgery. Excessive cloudiness or malodorous urine may indicate infection.*
- Assess size, color, and condition of the stoma and surrounding skin every 2 hours for the first 24 hours, then every 4 hours for 48 to 72 hours. Expect the stoma to appear bright red and slightly edematous initially. Slight bleeding during cleansing is normal. *Compromised circulation causes the stoma to appear pale, gray, or cyanotic or blanch when touched. Other complications, such as infection or impaired healing, may be evidenced by a change in the appearance of the stoma or incision.*
- Irrigate the ileal diversion catheter with 30 to 60 mL of normal saline every 4 hours or as ordered. *Mucus produced by the bowel wall may accumulate in the newly devised reservoir or obstruct catheters.*
- Monitor serum electrolyte values, acid–base balance, and renal function tests such as BUN and serum creatinine. *Reabsorption of electrolytes from reservoirs created by portions of bowel may result in electrolyte imbalance and metabolic acidosis. Optimal renal function is necessary to maintain a normal state of homeostasis.*
- Teach the patient and family about stoma and urinary diversion care, including odor management, skin care, increased fluid intake, pouch application and leakage prevention (refer to Box 27–2), self-catheterization for patients with continent reservoirs, and signs of infection and other complications. *The ability to provide self-care is a significant factor in the adjustment to a changed body image. Teaching family members facilitates acceptance and adjustment. The family also needs this knowledge in case illness or disability interferes with the self-care capacity.*

- Monitor urine output closely for first 24 hours after stents or ureteral catheters are removed. *Edema or stricture of ureters may impede output, leading to hydronephrosis and kidney damage.*
- Encourage activity to tolerance. *Ambulation promotes drainage of urine from reservoirs and helps prevent calcium loss from bones, which could precipitate calculus formation.*

SAFETY ALERT

Use aseptic techniques and strictly follow guidelines for irrigating catheters. Catheters placed in the kidney pelvis are irrigated using gentle pressure and small amounts of fluid (10 to 15 mL) to avoid damaging renal tissues.

Risk for Impaired Skin Integrity

The skin surrounding the stoma site of an ileal conduit is at risk for irritation and breakdown. Because urine is acidic and contains high concentrations of electrolytes, it has a corrosive effect on skin. In addition, adhesives and sealants used to prevent pouch leakage may irritate the skin.

Expected Outcome: Patient's peristomal skin will remain intact without evidence of irritation or impending breakdown.

- Assess peristomal skin for redness, excoriation, or signs of breakdown. Assess for urine leakage from catheters, stents, or drains. Keep the skin clean and dry. Change wet dressings. *Intact skin is the first line of defense against infection. Impaired skin integrity may lead to local or systemic infection and impaired healing.*
- Ensure gravity drainage of urine collection device or empty bag every 2 hours. *Overfilling of the collection bag may damage the seal, allowing leakage and contact of urine with skin.*
- Change urine collection appliance as needed, removing any mucus from stoma. *Meticulous care and protection of skin surrounding stoma can maintain integrity and prevent breakdown.*

Disturbed Body Image

A radical cystectomy and urinary diversion affect the patient's body image. In most cases, an abdominal stoma is created, requiring either a drainage appliance or regular catheterization of the stoma to drain urine. Removal of the prostate and seminal vesicles or the uterus and ovaries leaves the patient sterile. If radiation or chemotherapy is planned as adjunctive therapy, the patient may experience hair loss, stomatitis, nausea and vomiting, or other disturbing side effects of therapy.

BOX 27–2 Teaching for Self-Care: Urinary Stoma Care

- Assess knowledge, learning needs, and ability and willingness to assist with procedure. Explain the procedure and respond to questions as needed.
- Instruct to gather all supplies prior to starting procedure: a clean, disposable pouch; liquid skin barrier or barrier ring; 4 × 4 gauze squares; stoma guide; adhesive solvent; clean gloves; and a clean washcloth.

Provide the following instructions:

- Wash hands prior to starting procedure; gloves may be worn if desired.
- Remove old pouch, pulling gently away from skin. Warm water or adhesive solvent may be used to loosen the seal if necessary.
- Assess stoma. Normally the stoma is bright red and appears moist. Report a dark purple, black, or very pale stoma to the physician. Slight bleeding with cleansing is normal, especially in the immediate postoperative period.
- Prevent urine flow during cleaning by placing a rolled gauze square or tampon over the stoma opening.
- Cleanse skin around the stoma with soap and water, rinse, and pat or air dry.
- Use the stoma guide to determine correct size for the bag opening and/or protective ring seal. Trim the bag or seal as needed.
- Apply skin barrier; allow to dry.
- Apply the bag with an opening no more than 1 to 2 mm wider than outside of stoma. Allow no wrinkles or creases where the bag contacts the skin.
- Connect bag to the urine-collection device. Dispose of old pouch, used supplies, and gloves appropriately. Wash hands.

Document teaching, ability to follow directions and perform the procedure, and response of the patient.

Expected Outcome: Patient will acknowledge impact of bladder cancer treatment or surgery on personal roles and relationships,

- Use therapeutic communication techniques, actively listening and responding to the patient's and family's concerns. *Patients must know their feelings and concerns are respected and valued. Denial, anger, guilt, bargaining, or depression are common during grieving and normal for a patient undergoing a significant change in body image.*
- Recognize and accept behaviors that indicate use of coping mechanisms, encouraging adaptive mechanisms. *The patient may initially use defensive coping mechanisms such as denial, minimization, and dissociation from the immediate situation to reduce anxiety and maintain psychologic integrity. Adaptive mechanisms include learning as much as possible about the surgery and its effects, practicing procedures, setting realistic goals, and rehearsing various alternative outcomes.*
- Encourage looking at, touching, and caring for the stoma and appliance as soon as possible. Allow the patient to proceed gradually, providing support and encouragement. *Accepting the stoma as part of the self is vital to adapting to the changed body image and is indicated by a willingness to provide self-care.*
- Discuss concerns about returning to usual activities, perceived relationship changes, and resumption of sexual relations. Provide referral to support group or provide for contact with someone who has successfully adjusted to a urinary diversion. *Patients and families may be reluctant to discuss topics of concern. An atmosphere of openness and acceptance facilitates expression of concerns and anxieties related to the changed body image.*

Risk for Infection

Diagnostic instrumentation procedures, surgical manipulation, and disruption of normal urinary tract defense mechanisms increase the risk of ascending urinary tract infection. When an ileal conduit or artificial bladder is created using bowel tissue, the normal bacteriostatic activity of bladder mucosa is lost. In addition, the peristaltic action of the ureters may be disrupted, and the vesicoureteral junction no longer prevents urine reflux. Adjunctive chemotherapy or radiation treatments may impair normal immune function and further increase the risk of infection.

Expected Outcome: Patient will remain free of urinary tract infection.

- Maintain separate closed drainage systems, keeping drainage bags lower than the kidney, and prevent loops or kinks in drainage tubing, which impede urine flow. *Although urine is sterile when it leaves the kidney, bacteria grow rapidly in urine. Prevention of urine reflux is essential to preventing UTI.*
- Monitor for signs of infection: elevated temperature, cloudy or foul-smelling urine, hematuria, general malaise, back or abdominal pain, and nausea and vomiting. *Infection undermines the healing process. Early detection and treatment help prevent long-term consequences such as chronic pyelonephritis.*
- Teach signs and symptoms of infection and self-care measures to prevent UTI. *The patient with a cystectomy and ileal diversion, urostomy, or continent reservoir is at risk of UTI for life because of impaired urinary defense mechanisms. Using clean or aseptic technique in providing care, increasing fluid intake, and using measures to acidify urine minimize this risk to a certain degree but do not eliminate it.*

PRACTICE ALERT!

Impaired immune function (due to aging or the effects of chemotherapy) and urine cloudiness (related to the effects of urine on ileal mucosa) can mask usual signs of UTI such as fever and altered urine clarity. Be alert for more generalized manifestations such as increased fatigue and malaise.

Delegating Nursing Care Activities

As appropriate and allowed by the designated duties and responsibilities of unlicensed assistive personnel, the nurse may delegate nursing care activities such as recording intake and output and assisting with ambulation and hygiene for the patient with a urinary tract tumor.

Continuity of Care

The need for individual and family teaching for the patient who has had surgery to treat a urinary tract tumor is significant. For many patients, surgery means a lifelong change in urinary elimination. Even the patient who has undergone transurethral excision of bladder tumors requires follow-up cystoscopy on a regular basis and needs to be alert for signs of tumor recurrence.

CASE STUDY & NURSING CARE PLAN A Patient with a Bladder Tumor

Ben Hussain is a 61-year-old married man with five adult children. One week ago, Mr. Hussain became alarmed when his urine became bright red. Even though he had no other symptoms, he called his physician. The physician ordered a urinalysis and urine cytology, revealing gross hematuria and poorly differentiated abnormal cells. Cystoscopy and tissue biopsy confirm a stage C tumor involving the bladder trigone. Mr. Hussain is admitted for a radical cystectomy and continent urinary diversion.

ASSESSMENT

Mr. Hussain's admission history, obtained by Tara Mills, RN, indicates that he has lost 4.5 to 7 kg (10 to 15 lb) during the past few months. He smoked two to three packs of cigarettes per day for 40 years, but cut back to a pack a day about a year ago. He says he could not quit smoking entirely. He drinks five to six cups of coffee daily and consumes an average of three to four alcoholic drinks a day. Mr. Hussain says that he is "a little nervous about surgery and what they're going to find." Ms. Mills notes that he fidgets and talks rapidly throughout their interview. He expresses concern about how he will handle the pain after surgery, because he had never been hospitalized before his cystoscopy. Physical assessment findings include T 36.7°C (98.2°F) PO, P 84 bpm, R 18/min, and BP 154/86 mmHg. Examinations of the skin, neuromuscular, and cardiac systems are within normal limits. Scattered expiratory crackles are noted on auscultation of lung fields. Bowel sounds are very active; Mr. Hussain explains that he began taking his bowel-preparation laxative the day before admission. Slight tenderness is noted in the suprapubic region. Mr. Hussain's urine is clear and bright pink. CBC and chemistry screening results are within normal limits. Surgery is planned for 9:00 a.m. the following day.

DIAGNOSES

- *Anxiety* related to undetermined extent of disease and fear of pain
- *Readiness for Enhanced Knowledge* related to care and management of continent urinary diversion
- *Impaired Urinary Elimination* related to cystectomy and urinary diversion
- *Risk for Impaired Gas Exchange* related to smoking history and effects of anesthesia

Clinical Reasoning in Patient Care

1. Review Mr. Hussain's assessment (above). Do you think any additional priority nursing diagnoses should be included in his plan of care? If so, identify them.

EXPECTED OUTCOMES

- Patient will verbalize decreased feelings of anxiety.
- Patient will demonstrate appropriate postoperative pain relief through subjective reports of pain severity and objective findings.
- Patient will be able to care for urinary diversion and surrounding skin prior to discharge.
- Patient will demonstrate self-catheterization of stoma using appropriate technique prior to discharge.
- Patient will maintain normal urine output with acceptable color and clarity and no signs of infection.
- Patient will maintain adequate gas exchange as evidenced by good skin color, O_2 saturation greater than 95%, and clear lung sounds on auscultation.

PLANNING AND IMPLEMENTATION

- Orient Mr. Hussain and his family to care unit preoperatively, answering questions fully and encouraging expression of fears.
- Provide written and verbal explanations when feasible.
- Administer analgesia around the clock for the first 48 to 72 hours. Monitor for signs of unrelieved pain.
- Explain all procedures related to stoma and diversion care as they are being performed.
- Encourage Mr. Hussain to look at stoma and touch it when ready.
- Teach stoma and skin care, as well as self-catheterization, emphasizing measures to prevent skin irritation and urinary tract infection.
- Monitor urine output, color, clarity, and consistency every hour for first 24 hours, then every 4 hours for 24 hours, then every 8 hours. Report output of less than 30 mL/hr, bright bleeding, or excessively cloudy or malodorous urine.
- Assist with use of incentive spirometer every hour while awake. Ambulate as soon as possible. Assess lung sounds every 4 hours, reporting increased crackles or diminished breath sounds.
- Refer Mr. and Mrs. Hussain to local stoma group on discharge.

EVALUATION

On discharge, Mr. Hussain has performed self-catheterization and stoma and skin care several times. His wife is able to catheterize the stoma and demonstrate skin care. His urine is pale yellow and slightly cloudy. Mr. Hussain is ambulating independently and using hydrocodone with acetaminophen (Vicodin) twice a day for pain relief. His lungs are clear, and he is very proud of having "survived" 7 days without a cigarette. He says, "Now I'm going to shoot for 7 weeks, then 7 months, then 7 years without a smoke!" A home health referral is made to continue teaching Mr. Hussain to care for his diversion and appliance.

Clinical Reasoning in Patient Care

2. How does cigarette smoking contribute to the increased risk of urinary tract tumors?
3. Mr. Hussain expresses fear of becoming addicted to hydrocodone and says he does not intend to take the prescription once he gets home. How should you respond?
4. Suppose Mr. Hussain had become confused, disoriented, and tremorous and had begun to experience visual hallucinations 2 to 3 days postoperatively. What would you suspect the cause to be? What would be the appropriate response?
5. Develop a care plan for Mr. Hussain for the nursing diagnosis *Risk for Sexual Dysfunction.*

See Evaluating Your Response in Appendix B.

The patient who has had a urinary diversion needs teaching about care of the stoma and surrounding skin, prevention of urine reflux and infection, signs and symptoms of UTI and renal calculi, and, in some cases, self-catheterization using clean technique.

THE PATIENT WITH URINARY RETENTION

Urinary retention, incomplete emptying of the bladder, can lead to overdistention of the bladder, poor detrusor muscle contractility, and inability to urinate. If the problem persists, hydroureter and hydronephrosis can result.

Physiology Review

Normally, bladder emptying is controlled by the interaction of muscle tone and the autonomic nervous system. The sympathetic nervous system (SNS) relaxes the detrusor muscle, allowing the bladder to fill with urine. The internal sphincter, a continuation of the detrusor muscle, remains closed during filling. Pressures within the bladder remain low during filling, in contrast to high sphincter and urethral pressures. Voluntary muscles of the external sphincter and pelvic floor help maintain these high pressures. When the bladder contains 150 to 300 mL of urine, signals from stretch receptors in the bladder wall are transmitted to the spinal cord and cerebral

cortex. Reflexive bladder emptying can be consciously inhibited. During *micturition* (bladder emptying), parasympathetic stimulation causes the detrusor muscle of the bladder fundus to contract, opening the internal sphincter. The external sphincter then relaxes, allowing urine to flow out.

Pathophysiology

Either mechanical obstruction of the bladder outlet or a functional problem can cause urinary retention. *Benign prostatic hypertrophy (BPH)* is a common cause; difficulty initiating and maintaining urine flow is often the presenting complaint in men with BPH. Fecal impaction may be a contributing factor in urinary retention, particularly in older adults or immobile patients. Acute inflammation associated with infection or trauma of the bladder, urethra, or perineal tissues may also interfere with micturition. Scarring due to repeated UTI can lead to urethral stricture and a mechanical obstruction. Bladder calculi may also obstruct the urethral opening from the bladder.

Surgery may disrupt detrusor muscle function, leading to urine retention. Abdominal or pelvic surgery, use of spinal anesthesia, and surgeries of long duration carry the highest risk for disrupting bladder function (Johansson & Christensson, 2010). Long-standing diabetes and drugs also may interfere with its function. Anticholinergic medications such as atropine, glycopyrrolate (Robinul), propantheline bromide (Pro-Banthine), scopolamine hydrochloride (Transderm-Scop), and others can lead to acute urinary retention and bladder distention. Many other drug groups have anticholinergic side effects and may cause urinary retention. Among these are antianxiety agents such as diazepam (Valium), antidepressant and tricyclic drugs such as imipramine (Tofranil), antiparkinsonian drugs, antipsychotic agents, and some sedative/hypnotic drugs. In addition, antihistamines common in over-the-counter (OTC) cough, cold, allergy, and sleep-promoting drugs have anticholinergic effects and may interfere with bladder emptying. Diphenhydramine (Benadryl) is an example of a nonprescription antihistamine.

Voluntary urinary retention (particularly common among nurses) may lead to overfilling of the bladder and a loss of detrusor muscle tone.

Manifestations

The patient with urinary retention is unable to empty the bladder completely. Overflow voiding or incontinence may occur, with 25 to 50 mL of urine eliminated at frequent intervals. Assessment reveals a firm, distended bladder that may be displaced to one side of midline. Percussion of the lower abdomen reveals a dull tone, reflective of fluid in the bladder.

Severe urinary retention with resulting bladder distention impairs the ability of the vesicoureteral junction to prevent backflow of urine into the ureters (refer to Figure 27–1 on page 748). Reflux of urine from the distended bladder distends the ureters (hydroureter) and kidneys (hydronephrosis). Hydronephrosis impairs renal function, and acute kidney injury can result.

●○● INTERPROFESSIONAL CARE

Urinary retention is confirmed using a bladder scan or by inserting a urinary catheter (if possible) and measuring the urine output. Use of a bladder scan is preferred to reduce the risk of UTI.

An indwelling urinary catheter or intermittent straight catheterization can prevent urinary retention and overdistention of the bladder. In acute situations, patients treated with intermittent catheterization may regain normal voiding patterns sooner than those in whom an indwelling urinary catheter is used (Johansson & Christensson, 2010). Cholinergic medications such as bethanechol chloride (Urecholine), which promote detrusor muscle contraction and bladder emptying, may be used. A medication with no anticholinergic side effects may be substituted when urinary retention is related to drug therapy.

Mechanical obstructions are treated by removing or repairing the obstruction, when possible. Resection of the prostate gland may be done for urinary retention related to BPH. Bladder calculi are removed, and measures to prevent their formation are instituted.

●○● NURSING CARE

Health promotion measures to prevent urinary retention include monitoring urine output and performing repeated bladder scans in at-risk patients and evaluating drug regimens for medications known to interfere with detrusor muscle function. Pay particular attention to elimination when these drugs are ordered for (or used by) a patient with BPH or other mechanical obstruction of urine flow.

Impaired Urinary Elimination

Nursing measures to promote urination include placing the patient in normal voiding position and providing for privacy. Additional measures include running water, placing the patient's hands in warm water, pouring warm water over the perineum, or taking a warm sitz bath.

In acute urinary retention, catheterization may be necessary to relieve bladder distention and prevent hydronephrosis. Use a relatively small catheter (16 Fr. for a man, 14 Fr. for a woman). A coudé-tipped catheter is passed more easily in the older man with an enlarged prostate. Use of 2% lidocaine gel (10 mL injected into the male urethra or 6 mL injected into the female urethra) reduces discomfort during catheterization and the risk of catheter-associated infection and promotes pelvic muscle relaxation (Bardsley, 2005). Carefully observe the patient as the distended bladder drains.

Continuing care for the patient with urinary retention varies, depending on the cause. Some patients may be taught intermittent self-catheterization. Instruct all patients who have experienced urinary retention to avoid OTC drugs that affect micturition, especially those with an anticholinergic effect (allergy and cold medications, many nonprescription sleep aids). Other measures include double-voiding (urinate, remain on the toilet for 2 to 5 minutes, then urinate again), scheduled voiding, or, when other measures fail, an indwelling catheter. When an indwelling catheter is necessary, teach the patient and family to use clean technique when changing from overnight bag to leg bag, and to promptly report signs of UTI to the primary care provider.

PRACTICE ALERT!

Some patients may experience a vasovagal response, becoming pale, sweaty, and hypotensive, if the bladder is rapidly drained. Draining urine in 500-mL increments and clamping the catheter for 5 to 10 minutes between increments may prevent this response. Hematuria also may occur with rapid bladder decompression. Promptly notify the physician if hematuria develops.

THE PATIENT WITH NEUROGENIC BLADDER

The neurologic connections influencing bladder filling, the perception of fullness and the need to void, and bladder emptying are complex. Disruption of the central or peripheral nervous systems may interfere with normal mechanisms, causing **neurogenic bladder**.

Pathophysiology

As noted in the physiology section on urinary retention, bladder filling and emptying are controlled by the central nervous system (CNS). This neurologic control can be disrupted at any level: the cerebral cortex (voluntary impulses), the micturition center of the midbrain, the spinal cord tracts, or the peripheral nerves of the bladder itself.

SPASTIC BLADDER DYSFUNCTION

A simple reflex arc exists between the bladder and the spinal cord at levels S_2 through S_4. The stimulus of more than 400 mL of urine in the bladder causes reflex contraction of the detrusor muscle and bladder emptying unless voluntary control (cerebral input) is used to suppress it. Disruption of CNS transmission above the sacral spinal cord segment typically leads to *spastic neurogenic bladder*. Both sensory and voluntary control of urination are interrupted partially or totally, while the sacral reflex arc remains intact. The stimuli generated by bladder filling cause frequent spontaneous detrusor muscle contraction and involuntary bladder emptying. Spinal cord injury above the sacral segment is the most common cause of a spastic bladder. Other causes include stroke, multiple sclerosis, and other CNS lesions.

FLACCID BLADDER DYSFUNCTION

Damage to the sacral spinal cord at the level of the reflex arc, the cauda equina, or the sacral nerve roots causes loss of detrusor muscle tone and a *flaccid neurogenic bladder*. The perception of bladder fullness is lost, and the bladder becomes overdistended, with weak and ineffective detrusor muscle contractions. Flaccid neurogenic bladder is seen with myelomeningocele and during the spinal shock phase of a spinal cord injury above the sacral region. During the spinal shock phase, all reflex activity below the level of spinal cord injury is suppressed.

Peripheral neuropathies may cause bladder atony and overfilling. Either sensory or motor pathways (or both) may be disrupted, leading to incomplete bladder emptying and large residual volumes after voiding. Diabetes mellitus is the most common cause of peripheral bladder neuropathy. Other causes include multiple sclerosis, chronic alcoholism, and prolonged overdistention of the bladder.

●○● INTERPROFESSIONAL CARE

Management of neurogenic bladder focuses on maintaining continence and avoiding complications associated with overfilling or incomplete emptying of the bladder. Because self-care is the goal, teaching is a primary intervention for the healthcare team.

DIAGNOSIS

The following diagnostic tests may be ordered for the patient with a neurogenic bladder:

- *Urine culture* to detect possible UTI related to impaired bladder function.
- *Urinalysis* and *eGFR, serum creatinine* and *BUN* to evaluate renal function. Ascending infection or hydronephrosis resulting from bladder overfilling and vesicoureteral reflux can damage the kidneys. Impaired renal function may lead to blood cells or protein in the urine, and elevated BUN and creatinine levels.
- *Postvoid bladder scan* to measure residual urine. Amounts greater than 50 mL may indicate ineffective detrusor muscle contractions, common in neurogenic bladder.
- *Cystometrography* to evaluate bladder filling and the detrusor muscle tone and function.

MEDICATIONS

Medications may be prescribed to increase or decrease the contractility of the detrusor muscle, to increase or decrease the tone of the internal sphincter, or to relax the external urethral sphincter.

Bethanechol, a cholinergic drug, stimulates detrusor muscle contraction in flaccid neurogenic bladder. It is generally used to manage short-term urinary retention (e.g., following surgery or childbirth). It may be used in combination with bladder-training techniques to promote complete emptying of a neurogenic bladder. Anticholinesterase drugs such as neostigmine (Prostigmin) and pyridostigmine (Mestinon) also may be used to increase detrusor muscle tone.

Anticholinergic drugs (parasympathetic blockers) relax the detrusor muscle and contract the internal sphincter, increasing bladder capacity in patients with spastic bladder dysfunction. *Oxybutynin (Ditropan)*, tolterodine (Detrol), darifenacin (Enablex), solifenacin succinate (VESIcare), and trospium (Sanctura) inhibit the muscarinic effects of acetylcholine on smooth muscle, reducing detrusor muscle spasticity and promoting bladder filling. Other anticholinergic drugs also may be used, including propantheline (Pro-Banthine) or flavoxate (Urispas). Dry mouth, blurred vision, and constipation are potential adverse effects of anticholinergic medications. See the Medication Administration box for drugs used to modify detrusor muscle activity.

NUTRITION

Dietary measures to reduce the risk for UTI and urinary calculi may be suggested for the patient with neurogenic bladder. A moderate to high fluid intake and a diet that acidifies the urine are helpful. Cranberry juice is recommended to maintain urine acidity. Refer to Table 27–3 for foods the patient may be advised to avoid in the diet to help prevent urolithiasis. The timing of fluid intake may be regulated to promote continence.

BLADDER RETRAINING

Patients with spastic neurogenic bladder may use measures to stimulate reflex voiding, allowing scheduled toileting. Techniques include using trigger points, for example, stroking or pinching the abdomen, inner thigh, or glans penis. Pulling pubic hairs, tapping the suprapubic region, or inserting a gloved finger into the rectum and gently stretching the anal sphincter can also stimulate urination.

The *Credé's method* (applying pressure to the suprapubic region with the fingers of one or both hands), manual pressure on the abdomen, and the Valsalva maneuver (bearing down while holding one's breath) promote bladder emptying for the patient with a spastic or flaccid bladder.

PRACTICE ALERT!

Increasing lower abdominal and bladder pressure with the Credé's method can stimulate autonomic dysreflexia in some patients with spinal cord injuries. Autonomic dysreflexia is a medical emergency in which the blood pressure rises rapidly due to SNS stimulation.

MEDICATION ADMINISTRATION

The Patient with Neurogenic Bladder

ANTICHOLINERGIC DRUGS TO TREAT SPASTIC BLADDER

oxybutynin (Ditropan, Ditropan XL)

darifenacin (Enablex)

solifenacin succinate (VESIcare)

trospium (Sanctura)

tolterodine (Detrol, Detrol LA)

propantheline bromide (Pro-Banthine)

flavoxate hydrochloride (Urispas)

Anticholinergic drugs inhibit the response to acetylcholine, relaxing the detrusor muscle and increasing internal sphincter tone. The combination of detrusor relaxation and internal sphincter contraction increases the bladder capacity of patients with spastic or hyperreflexive neurogenic bladder. Of these medications, darifenacin, solifenacin succinate, and tolterodine have the most specific effects on the detrusor muscle with fewer anticholinergic side effects.

Nursing Responsibilities

- Assess for contraindications, such as glaucoma, gastrointestinal or urinary tract obstruction, severe ulcerative colitis or toxic megacolon, unstable cardiovascular status, or myasthenia gravis.
- Observe for the desired effect of increased bladder capacity with decreased incontinence and spasm.
- Monitor for possible interaction with other drugs such as narcotic analgesics, antidysrhythmic medications, antihistamines, antidepressants, or psychoactive drugs.
- Monitor heart rate and blood pressure, especially when given to patients with known cardiovascular disease.
- Assess for adverse effects such as urinary hesitancy or retention, dysrhythmias, mental status changes, and gastrointestinal disturbances.

Health Education for the Patient and Family

- Take the drug as ordered. Some of these drugs (e.g., trospium) need to be taken on an empty stomach for optimal absorption; others may be taken irrespective of food intake.
- Promptly report eye pain, rapid heartbeat, difficulty breathing, rash or hives, or changes in mental function to your primary care provider.
- These drugs may cause drowsiness or blurred vision. Use caution when driving, operating machinery, or performing other tasks requiring mental acuity.
- Hard candies help relieve dry mouth associated with these drugs.
- Do not use alcohol or nonprescription antihistamines while taking these drugs.

CHOLINERGIC DRUGS TO STIMULATE MICTURITION

bethanechol chloride (Urecholine)

Bethanechol stimulates the parasympathetic nervous system, increasing detrusor muscle tone and producing a contraction strong enough to initiate micturition. It is used primarily to treat acute postoperative and postpartum urinary retention.

Nursing Responsibilities

- Assess for contraindications, including hypersensitivity, hyperthyroidism, peptic ulcer disease, asthma, significant bradycardia or hypotension, coronary heart disease, epilepsy, and parkinsonism.
- Do not give to patients who have had recent gastrointestinal or bladder surgery or those with possible gastrointestinal or urinary tract obstruction.
- Give oral forms on an empty stomach to reduce the risk of nausea and vomiting.
- Administer parenteral bethanechol subcutaneously. Keep atropine, the antidote for bethanechol overdose or toxicity, available.
- Observe for desired effect within 30 to 60 minutes after oral administration, 5 to 15 minutes after injection.
- Assess for adverse effects such as malaise, headache, abdominal cramping, nausea, hypotension with reflex tachycardia, wheezing, and dyspnea.

Health Education for the Patient and Family

- Take the medication 1 hour before or 2 hours after meals.
- Use caution when rising from a recumbent or sitting position; you may feel dizzy or light-headed.

Note: Drugs identified in *italics* are among the 200 most commonly prescribed medications in the U.S.

The patient with a flaccid bladder may require catheterization to completely empty the bladder. An indwelling catheter may be used initially, but intermittent catheterization is preferred (Panicker et al., 2010). Clean intermittent self-catheterization is performed every 3 to 4 hours to prevent overdistention of the bladder.

SURGERY

Surgery may be required when urination cannot be effectively managed using more conservative measures. Injection of botulinum toxin A into the detrusor muscle via cystoscopy has been shown to improve bladder capacity and quality of life for up to 12 months in many patients (Chen et al., 2011; Panicker et al., 2010). *Rhizotomy*, or destruction of the nerve supply to the detrusor muscle or the external sphincter, may be used for patients with hyperreflexia or spasticity. Urinary diversion is another surgical technique used when conservative management fails. Implantation of an artificial sphincter may be useful for some patients with neurogenic bladder. Refer to Table 27–6 for urinary diversion techniques and page 765 for nursing care of the patient undergoing a urinary diversion.

●○● NURSING CARE

Nursing care of the patient with a neurogenic bladder is directed toward promoting urinary drainage and continence, preventing complications, and teaching the patient and family self-care techniques.

Assessment

Nursing assessment for neurogenic bladder includes obtaining a complete nursing history, focusing on information related to CNS or spinal cord injury or disease, as well as disorders that affect the peripheral nervous system (e.g., diabetes). Ask about measures used to stimulate or control urination. Inspect and palpate the lower abdomen and suprapubic region for tenderness or bladder distention. If available, evaluate the volume of urine in the bladder using a portable bladder scanner. Alternately, percuss the suprapubic region for a dull percussion tone indicative of a full bladder. Dullness up to the level of the umbilicus indicates at least 500 mL of urine in the bladder. Assess urine for color, clarity, and odor. Collect a specimen for analysis as indicated.

Diagnoses, Planning, and Interventions

Although each patient has individual nursing care needs, examples of nursing diagnoses appropriate for the patient with a neurogenic bladder include the following:

- *Impaired Urinary Elimination* related to impaired bladder innervation
- *Toileting Self-Care Deficit* related to neurologic injury
- *Risk for Impaired Skin Integrity* related to urinary incontinence
- *Risk for Infection* related to impaired urination reflex

Continuity of Care

Include the following in teaching for the patient with neurogenic bladder and family members:

- Measures to stimulate reflex voiding and promote bladder emptying
- Use of prescribed medications, including desired and adverse effects, and interactions with other drugs
- Manifestations of UTI or urolithiasis, and measures to reduce the risk of these complications.

THE PATIENT WITH URINARY INCONTINENCE

The most common manifestation of impaired bladder control is **urinary incontinence (UI)**, or involuntary urination. UI can have a significant impact on patients, leading to physical problems such as skin breakdown, infection, and rashes. Psychosocial consequences include embarrassment, isolation and withdrawal, feelings of worthlessness and helplessness, and depression.

Incidence and Prevalence

An estimated 25 million people in the United States have some degree of urinary incontinence. The estimated cost of managing UI is $14.2 billion yearly. UI is especially common among older patients (see accompanying box). UI often leads to institutionalization; in long-term care, foster care, and homebound populations, the incidence is more than 50% (National Association for Continence, 2013; NKUDIC, 2012). The actual prevalence of urinary incontinence is nearly impossible to determine. Embarrassment and the availability of products to protect clothing and prevent detection contribute to patients' not seeking evaluation of and treatment for incontinence.

FAST FACTS

- UI is especially common among older patients. Although the prevalence of urinary incontinence increases in older adults, it is *not* a normal consequence of aging and it *can* be treated.
- An estimated 38% or more of women ages 60 and older experience UI.
- Among men ages 60 and older, the prevalence is about 17%.
- Annual healthcare costs associated with UI exceed $463 million; when the amount spent on commercial products to manage UI is included, spending likely exceeds $14 billion annually.

Pathophysiology

Urinary continence requires input from the CNS, a bladder able to expand and contract, and sphincters that can maintain a urethral pressure higher than that in the bladder. Intact cognition, mobility, motivation, and manual dexterity also are necessary to maintain continence. Mechanically, incontinence results when the pressure within

NURSING CARE OF THE OLDER ADULT

Reducing the Risk for UI

Urinary incontinence, the involuntary loss of urine, is a common problem in older adults. Although UI should never be considered a normal consequence of aging, age-related changes contribute to its development. Bladder capacity tends to decline with age and involuntary bladder muscle contractions are more common. Fluid ingested during the day tends to be excreted later in the day and into the night. In women, decreased estrogen levels and pelvic muscle relaxation decrease bladder outlet and urethral resistance pressures. Decreased estrogen also causes atrophic vaginitis and urethritis, with manifestations of dysuria and urgency. In men, the prostate enlarges with aging. Other risk factors for UI in older adults include impaired mobility and chronic degenerative diseases, impaired cognition, medications, low fluid intake, diabetes, and stroke.

Assessment for UI in the older adult focuses on risk factors, the extent and manifestations of the disorder, and contributing factors. Using clear language, ask about problems with urine loss, its frequency, and any contributing factors. Inquire about frequency, urgency, and burning on urination. Identify current medications and the time of day each is taken. Assess patterns of fluid intake and output. Assess the abdomen for evidence of bladder distention or tenderness. Perform a mental status examination if indicated.

Assess the home environment (whether in the community or a residential living facility) for possible barriers to urinary elimination:

- Inadequate lighting, particularly at night
- Narrow doorways that may interfere with access to the toilet
- Inadequate toilet facilities
- The need for mobility aids such as safety bars, a raised toilet seat, or a bedside commode.

Discuss the following points to help prevent UI in the older adult:

- Maintain a generous fluid intake. Reduce or eliminate fluid intake after the evening meal to reduce nocturia.
- Wear comfortable clothing that is easy to remove for toileting.
- Maintain good hygiene, but do not bathe more often than necessary; frequent bathing and feminine hygiene sprays or douches may dry perineal tissues, increasing the risk of UI.
- Perform pelvic muscle exercises (Kegel exercises) several times a day to increase perineal muscle tone.
- Reduce consumption of caffeine-containing beverages (coffee, tea, colas), citrus juices, and artificially sweetened beverages containing NutraSweet.
- Use behavioral techniques such as scheduled toileting, habit training, and bladder training to reduce the frequency of incontinence. *Scheduled toileting* is toileting at regular intervals (e.g., every 2 to 4 hours). *Habit training* is toileting the patient on a schedule that corresponds with the normal pattern. *Bladder training* gradually increases the bladder capacity by increasing the intervals between voidings and resisting the urge to void.
- See your primary care provider regularly for a pelvic or prostate exam.
- For women, discuss possible benefits and risks of hormone replacement therapy, physical therapy, or surgery to treat incontinence.
- Report a change in urine color, odor, or clarity, or symptoms such as burning, frequency, or urgency to your primary care provider.

TABLE 27–7 Types of Urinary Incontinence

	Description	Pathophysiology	Contributing Factors
Stress	Loss of urine associated with increased intra-abdominal pressure during sneezing, coughing, lifting. Quantity of urine lost is usually small.	Relaxation of pelvic musculature and weakness of urethra and surrounding muscles and tissues lead to decreased urethral resistance.	• Multiple pregnancies • Decreased estrogen levels • Short urethra, change in angle between bladder and urethra • Abdominal wall weakness • Prostate surgery • Increased intra-abdominal pressure due to tumor, ascites, obesity
Urge	Involuntary loss of urine associated with a strong urge to void	Hypertonic or overactive detrusor muscle leads to increased pressure within bladder and inability to inhibit voiding.	• Neurologic disorders such as stroke, Parkinson's disease, multiple sclerosis; peripheral nervous system disorders • Detrusor muscle overactivity associated with bladder outlet obstruction, aging, or disorders such as diabetes
Overflow	Inability to empty bladder, resulting in overdistention and frequent loss of small amounts of urine	Outlet obstruction or lack of normal detrusor activity leads to overfilling of bladder and increased pressure.	• Spinal cord injuries below S_2 • Diabetic neuropathy • Prostatic hypertrophy • Fecal impaction • Drugs, especially those with anticholinergic effect
Functional	Incontinence resulting from physical, environmental, or psychosocial causes	Ability to respond to the need to urinate is impaired.	• Confusion or dementia • Physical disability or impaired mobility • Therapy or sedation • Depression • Regression

the urinary bladder exceeds urethral resistance, allowing urine to escape. Any condition causing higher than normal bladder pressures or reduced urethral resistance can potentially result in incontinence. Relaxation of the pelvic musculature, disruption of cerebral and nervous system control, and disturbances of the bladder and its musculature are common contributing factors.

Incontinence may be an acute, self-limited disorder, or it may be chronic. The causes may be congenital or acquired, reversible or irreversible. Congenital disorders associated with incontinence include epispadias (absence of the upper wall of the urethra) and meningomyelocele (a neural tube defect in which a portion of the spinal cord and its surrounding meninges protrude through the vertebral column). CNS or spinal cord trauma, stroke, and chronic neurologic disorders such as multiple sclerosis and Parkinson's disease are examples of acquired, irreversible causes of incontinence. Reversible causes include acute confusion, medications such as diuretics or sedatives, prostatic enlargement, vaginal and urethral atrophy, UTI, and fecal impaction.

Incontinence is commonly categorized as stress incontinence, urge incontinence (also known as overactive bladder), overflow incontinence, and functional incontinence. Table 27–7 summarizes each type of incontinence and its physiologic cause and associated factors. *Mixed incontinence*, with elements of both stress and urge incontinence, is common. *Total incontinence* is loss of all voluntary control over urination, with urine loss occurring without stimulus and in all positions.

Incontinence is associated with an increased risk for falls, fractures, pressure ulcers, urinary tract infection, and depression. It contributes to the stress of caregivers, and often is a factor in institutionalizing a patient.

●○● INTERPROFESSIONAL CARE

UI management is directed at identifying and correcting the cause if possible. If the underlying disorder cannot be corrected, techniques to manage urine output can often be taught. For stress, urge, or mixed UI, evidence-based treatment guidelines support use of conservative measures (pelvic floor muscle training [Kegel exercises] and bladder training) for a minimum of 3 months in women before considering use of medications or surgery (American Medical Directors Association, 2010; National Institute for Health and Care Excellence, 2013).

Evaluation for incontinence begins with a complete history, including specific questions about lower urinary tract symptoms and the duration, frequency, volume, and associated circumstances of urine loss. A voiding diary (Figure 27–9 ■) is often used to collect detailed information. The history also includes information about chronic or acute illnesses, previous surgeries, and current medication use, both prescription and OTC.

Physical assessment includes abdominal, rectal, and pelvic assessment as well as evaluation of mental and neurologic status, mobility, and dexterity. Findings often associated with incontinence in women include weak abdominal and pelvic muscle tone, cystocele or urethrocele, and atrophic vaginitis. In men, an enlarged prostate gland is the physical finding most commonly associated with incontinence.

See the Moving Evidence into Action feature on page 773 for evidence-based practice for diagnosing lower urinary tract symptoms in women.

DIAGNOSIS

With an appropriate history and physical examination, diagnostic testing rarely is required. Certain tests may, however, be done to rule out UTI or to guide treatment:

- *Urinalysis* and *urine culture* using a clean-catch specimen are done to rule out infection and other acute causes of incontinence.
- *Postvoiding residual (PVR) volume* may be measured to determine how completely the bladder empties with voiding. Less than 50 mL PVR is expected; when 100 mL or more is obtained, further testing is indicated.

Your Daily Voiding Diary **Date** _____

This diary will help you and your healthcare team identify factors causing bladder control problems. Choose a 24-hour period when you can record your fluid intake (type and amount), urine output and episodes of urine leakage, any strong urge to void just prior to leaking, and your activity when leak episodes occur. The line below illustrates how to use your diary.

Time	Fluid Intake		Urine Output	Leaks	Urge	Activity
	Amount	Type			Yes No	
7 am	2 cups	coffee	sm (med) lg	(sm) med lg	Yes	walking
			sm med lg	sm med lg		
			sm med lg	sm med lg		
			sm med lg	sm med lg

Moving Evidence into Action

Lower Urinary Tract Symptoms in Women

The underdiagnosis and inadequate treatment of UI is a commonly recognized problem; less well recognized is the extent to which women experience lower urinary tract symptoms (LUTS) with or without accompanying UI. LUTS include storage symptoms (e.g., frequency, urgency, and nocturia), voiding symptoms (slow stream, hesitancy, straining, and terminal dribble), and postmicturition symptoms (incomplete bladder emptying, postvoiding dribble). Various studies have indicated that up to 67% of women over age 18 years experience LUTS; the prevalence increases with aging. Many women are reluctant to seek treatment for LUTS; when they do, primary care providers often do not offer appropriate treatment information (Bradway et al., 2008).

Implications for Nursing

Asking specific questions about LUTS can facilitate identification of symptoms affecting the patient's qualify of life (Bradway & Cacchione, 2010). Accurate assessment and diagnosis are vital to planning and implementing appropriate care and achieving the desired outcomes of continence and quality of life. Successful treatment promotes self-esteem and provides positive reinforcement for continuing planned strategies.

Moving Evidence into Action

1. Identify at least five questions you should ask a patient to determine the presence of LUTS. How will you follow up to identify the potential effect of LUTS on the patient's quality of life (consider activities of daily living [ADLs], employment, social interactions, intimate relationships)?
2. Identify patient teaching for a woman who experiences frequency, urgency, nocturia, and postvoid dribbling but who only occasionally loses urine.
3. What nursing care measures and patient teaching will you provide for the patient with stress incontinence that may not be appropriate or necessary for the patient with urge incontinence? For the patient with urge incontinence but not stress incontinence?
4. Develop a nursing care and teaching plan using the nursing diagnosis *Readiness for Enhanced Urinary Elimination.*

- *Bladder stress testing* may be performed. In this test, a measured amount of fluid is instilled into the bladder and the patient observed for urine leakage during coughing in both the supine and standing positions.

If conservative treatment measures have failed to correct UI, the following diagnostic tests may be considered:

- *Cystometrography* is used to assess neuromuscular function of the bladder by evaluating detrusor muscle function, pressure within the bladder, and the filling pattern of the bladder.
- *Uroflowmetry* is a noninvasive test used to evaluate voiding patterns.
- *Cystoscopy* or *ultrasonography* may be ordered to identify structural disorders contributing to incontinence, such as an enlarged prostate or a tumor.

MEDICATIONS

Both stress and urge incontinence may improve with drug treatment.

Drugs that contract the smooth muscles of the bladder neck may reduce episodes of mild stress incontinence. Duloxetine (Cymbalta), a drug that inhibits the uptake of both norepinephrine and serotonin, is the drug of choice for treating stress UI that is not fully controlled with nonpharmacologic treatment (e.g., teaching, pelvic muscle exercise). In clinical trials, this drug reduced the frequency of UI and the number of voidings per day, particularly when combined with pelvic floor muscle training. Adverse effects such as nausea, headache, insomnia, and constipation are common with duloxetine; for most patients, however, these effects diminish over time (Wells et al., 2012).

When incontinence is associated with postmenopausal atrophic vaginitis, estrogen therapy may be effective. Both systemic estrogens and local creams are used. Results are improved with the addition of an α-adrenergic receptor agonist such as pseudoephedrine or phenylephrine unless contraindicated by a preexisting condition such as hypertension (Wells et al., 2012).

Patients with urge incontinence may be treated with preparations that increase bladder capacity. Anticholinergic drugs inhibit muscarinic receptors of the parasympathetic nervous system, reducing detrusor muscle contractions. A number of drugs have been approved to treat urge UI, including *oxybutynin* (Ditropan and the extended-release form, Ditropan XL), tolterodine (Detrol and its longer-acting form, Detrol LA), trospium (Sanctura), darifenacin (Enablex), and solifenacin (VESIcare). These drugs can be taken once or twice a day, and have fewer side effects than less specific anticholinergic drugs. These drugs are contraindicated for the patient with acute glaucoma. Urinary retention is a potential side effect that must be considered when these drugs are used (see the Medication Administration box on page 770). Studies about the use and effectiveness of botulinum toxin A to control detrusor muscle overactivity are currently underway in the United States and Europe. Botulinum toxin A is injected directly into the muscle; its effects last for a period of 3 to 9 months, necessitating repeated injections.

SURGERY

Surgery may be used to treat stress incontinence associated with cystocele or urethrocele and overflow incontinence associated with an enlarged prostate gland.

Suspension of the bladder neck, a technique that brings the angle between the bladder and urethra closer to normal, is effective in treating stress incontinence associated with urethrocele in 80% to 95% of patients. A laparoscopic, vaginal, or abdominal approach may be used to perform this surgery. Care of the patient with a bladder neck suspension is outlined in the accompanying box.

Prostatectomy, using either the transurethral or suprapubic approach, is indicated for the patient who is experiencing overflow incontinence as a result of an enlarged prostate gland and urethral obstruction. Other surgical procedures of potential benefit in the treatment of incontinence include implantation of an artificial sphincter, formation of a urethral sling to elevate and compress the urethra, and augmentation of the bladder with bowel segments to increase bladder capacity.

COMPLEMENTARY THERAPIES

Biofeedback and relaxation techniques may help reduce episodes of UI. Biofeedback uses electronic monitors to teach conscious control over physiologic responses of which the individual is not normally aware. Developing awareness of perceptible information allows the patient to gain voluntary control over urination. Biofeedback is widely used to manage urinary incontinence.

NURSING CARE OF THE PATIENT

Having a Bladder Neck Suspension

PREOPERATIVE CARE

- Provide routine preoperative care and teaching.
- Discuss the need to avoid straining and the Valsalva maneuver postoperatively. Suggest measures such as increasing fluid and fiber intake and using a stool softener to prevent postoperative constipation. *Straining and increased abdominal pressure during the Valsalva maneuver may place excessive stress on suture lines and interfere with healing.*

POSTOPERATIVE CARE

- Provide routine postoperative care.
- Monitor urine output, including quantity, color, and clarity. Expect urine to be pink initially, gradually clearing. *Bright red urine, excessive vaginal drainage, or incisional bleeding may indicate hemorrhage. Instrumentation of the urinary tract increases the potential for UTI; cloudy urine may be an early sign.*
- Maintain stability and patency of suprapubic and/or urethral catheters. Secure catheters in position. *Maintaining bladder decompression eliminates pressure on suture lines. Preventing movement or pulling on catheters reduces the risk for resultant pressure on surgical incisions.*
- Carefully monitor urine output after catheter removal. *Difficulty voiding is common following catheter removal. Early intervention to prevent bladder distention is important to prevent pressure on suture lines.*
- If the urethral or suprapubic catheter will remain in place on discharge, teach proper care to the patient and family members as needed. *Appropriate self-care and early recognition of problems reduce the risk for significant complications.*

●○● NURSING CARE

Health Promotion

Although UI rarely causes serious physical effects, it frequently has significant psychosocial effects, and can lead to lowered self-esteem, social isolation, and even institutionalization. Get the word out—inform all patients that UI is not a normal consequence of aging and that treatments are available. To reduce the incidence of UI, teach all women to perform pelvic floor muscle (Kegel) exercises (Box 27–3) to improve perineal muscle tone. Advise women to seek advice from their women's healthcare or primary care practitioner about using topical hormone therapy during menopause to maintain perineal tissue integrity. Advise older men to have routine prostate examinations to prevent urethral obstruction and overflow incontinence. Pelvic floor muscle exercises also may benefit men who experience UI following prostatectomy, but evidence supporting this is limited.

Assessment

Nursing assessment for the patient with UI includes both subjective and objective data:

- *Health history:* voiding diary; frequency of incontinent episodes, amount of urine loss and activities associated with incontinence; methods used to deal with incontinence; use of Kegel exercises or medications; any chronic diseases, related surgeries, and so on; effects of incontinence on usual activities, including social activities
- *Physical assessment:* physical and mental status, including any physical limitations or impaired cognition; inspect, palpate, and percuss abdomen for bladder distention; inspect perineal tissues for redness, irritation, or tissue breakdown; observe for bulging of bladder into vagina when bearing down; assess pelvic muscle tone as indicated.

Priorities of Care

Although the priority of specific interventions depends on the patient's mental and physical status, teaching to manage symptoms and prevent complications associated with urinary incontinence is always a priority. Teaching is directed toward the patient whenever possible, and toward caregivers (personal or institutional) when the patient must depend on others for toileting assistance.

BOX 27–3 Pelvic Floor Muscle (Kegel) Exercises

- Identify the pelvic muscles with these techniques:
  - Stop the flow of urine during voiding and hold for a few seconds.
  - Tighten the muscles at the vaginal entrance around a gloved finger or tampon.
  - Tighten the muscles around the anus as though resisting defecation.
- Perform exercises by tightening pelvic muscles, holding for 10 seconds, and relaxing for 10 seconds. Continue the sequence (tighten, hold, relax) for 25 repetitions.
- Keep abdominal muscles and breathing relaxed while performing exercises.
- Exercises of 25 repetitions should be performed twice per day.
- Encourage exercising at a specific time each day or in conjunction with another daily activity (such as bathing or watching the news). Establish a routine because these exercises should be continued for life.
- Assistive devices, such as vaginal cones and biofeedback, may be useful for patients who have difficulty identifying appropriate muscle groups.

Diagnoses, Planning, and Interventions

In planning nursing care, consider the patient's mental status, mobility, and motivation. Behavioral techniques can be effective, but require long-term commitment and the physical and mental capability to use them.

Nursing care and modification of routines can restore continence fully or partially even in a patient who is institutionalized. Scheduled toileting, bladder training, and prompted voiding combined with positive reinforcement such as praise can reduce the need for diapers, incontinence pads, and indwelling catheters.

Readiness for Enhanced Urinary Elimination

Dietary modifications, exercises to strengthen pelvic floor muscles, and bladder training programs often are effective to restore and maintain continence.

Expected Outcome: Patient will demonstrate a normal pattern of urinary elimination without episodes of urinary incontinence.

- Instruct to keep a voiding diary, recording the time and amount of all fluid intake and urinary output, status at the time of voiding (dry or wet) and on arising from sleep, and activities. *Voiding diaries provide valuable information for identifying the type of incontinence and possible measures to reduce or eliminate incontinent episodes.*
- Teach pelvic floor muscle exercises (refer to Box 27–3). Instruct to consciously tighten pelvic muscles when the need to void is perceived and to relax the abdomen while walking to the bathroom. *Improved pelvic muscle strength helps retain urine and prevent stress incontinence by increasing urethral pressure. Exercises also decrease abnormal detrusor muscle contractions, decreasing pressure within the bladder.*
- Using the patient's voiding diary, suggest dietary and fluid intake modifications to reduce stress and urge incontinence. Include the potential benefits of limiting caffeine, alcohol, citrus juice, and artificial sweetener consumption; limiting fluid intake to no less than 1.5 to 2.0 L/day; and limiting evening fluid intake. *Caffeine, alcohol, and citrus juices are bladder irritants and may promote detrusor instability, increasing the risk of urge incontinence. Artificial sweeteners may also irritate the bladder. Fluid intake of 1.5 to 2.0 L/day is adequate to maintain health for most patients; excess fluid may increase stress incontinence if bathroom facilities are not readily available.*

PRACTICE ALERT!

Limiting total fluid intake to less than 1.5 to 2.0 L/day is not recommended for patients with UI. Inadequate fluid increases urine concentration, leading to bladder wall irritation and possibly increasing problems of urge incontinence (Pellatt, 2012).

Toileting Self-Care Deficit

Functional incontinence may be the predominant problem in an older adult who is institutionalized. Limited mobility, impaired vision, dementia, lack of access to facilities and privacy, and tight

Evidence for Nursing Care

The Patient with Urinary Incontinence

Selected resources that nurses may find helpful when planning evidence-based nursing care follow.

- American Medical Directors Association. (2010). *Urinary incontinence*. Columbia, MD: Author.
- Dowling-Castronovo, A., & Bradway, C. (2012). *Nursing standard of practice protocol: Urinary incontinence (UI) in older adults admitted to acute care*. New York, NY: Hartford Institute for Geriatric Nursing, New York University College of Nursing.
- National Institute for Health and Clinical Excellence (NICE). (2013). *Urinary incontinence: The management of urinary incontinence in women.* London, UK: National Institute for Health and Clinical Excellence.

staffing patterns increase the risk for incontinence in previously continent residents. The primary problem in functional incontinence is an outside factor that interferes with the ability to respond normally to the urge to void. An immobilized patient may wet the bed if a call light is not within reach; a patient with Alzheimer's disease may perceive the urge to void but be unable to interpret its meaning or respond by seeking a bathroom. For these patients, self-care deficit in toileting is a primary problem.

Expected Outcome: Patient will recognize and respond to urge to urinate, or will recognize and acknowledge need for help with toileting.

- Assess physical and mental abilities and limitations, usual voiding pattern, and ability to assist with toileting. *A thorough assessment allows planned interventions to address specific needs and promote independence.*
- Provide assistive devices as needed to facilitate independence, such as raised toilet seats, grab bars, a bedside commode, or nightlights. *Fostering independence in toileting bolsters self-concept and maintains a positive body image.*
- Plan a toileting schedule based on the patient's normal elimination patterns to achieve approximately 300 mL of urine output with each voiding. *Allowing the bladder to fill to a point at which the urge to void is experienced and then emptying it completely helps maintain normal bladder capacity and bacteriostatic functions.*
- Position for ease of voiding—sitting for females, standing for males—and provide privacy. *Normal positioning, usual toileting facilities, and privacy enhance the ability to void on schedule and empty the bladder completely.*
- Adjust fluid intake so that the majority of fluids are consumed during times of the day when the patient is most able to remain continent. Unless fluids are restricted, maintain a fluid intake of at least 1.5 to 2.0 L/day. *An adequate fluid intake is vital to promote hydration and urinary function. Overly concentrated urine can irritate the bladder, increasing incontinence.*
- Assist with clothing that is easily removed (e.g., elastic-waist pants or loose dresses). Velcro and zipper fasteners may be easier to use than snaps and buttons. *Clothing that is difficult to remove can increase the risk of incontinence in the patient with mobility problems or impaired dexterity.*

Impaired Social Interaction

Urinary incontinence increases the risk for social isolation due to embarrassment, fear of not having ready access to a bathroom, body odor, or other factors. Social isolation, in turn, can increase problems of incontinence, because normal cues and relationships are lost, and the need to remain dry is less strongly felt.

Expected Outcome: Patient will resume previous pattern of social interactions.

- Assess reasons for and extent of social isolation. Verify the degree of social isolation with the patient or significant other. *Do not assume that social isolation is only related to urinary incontinence. Other problems frequently associated with aging (such as a hearing deficit) may be primary or contributing factors.*
- Refer patient for urologic examination and incontinence evaluation. *Patients who assume that urinary incontinence is a normal part of the aging process may not be aware of treatment options.*
- Explore alternative coping strategies with patient, significant other, staff, and other healthcare team members. *Protective pads or shields, good perineal hygiene, scheduled voiding, and clothing that does not interfere with toileting can enhance continence.*

Delegating Nursing Care Activities

As appropriate and allowed by the designated duties and responsibilities of unlicensed assistive personnel, the nurse may delegate nursing care activities such as assisting to obtain a clean-catch urine specimen, maintaining a voiding diary for the patient who is unable to do so, and using a bladder scanner to determine postvoid residual urine. Many nursing care activities to reduce incontinent episodes are appropriate for delegation to unlicensed caregivers, particularly for residents of long-term care facilities. These activities include scheduled toileting, positioning the patient for ease of voiding, adjusting the schedule of fluid intake, and encouraging clothing that is easy to remove for toileting.

Continuity of Care

Because UI is a contributing factor in the institutionalization of many older people, patient and family teaching can have a significant impact on maintaining independence and residence in the community. Address possible causes of incontinence and appropriate treatment measures. Refer for urologic examination if not already completed. Discuss fluid intake management, perineal care, and products for clothing protection.

CHAPTER HIGHLIGHTS

- **Urinary tract infections (UTIs) are common among adult women and patients in hospitals and long-term care facilities. In the untreated or immunocompromised patient, UTI can lead to sepsis or chronic kidney disease. Preventing UTI through patient and caregiver teaching and use of evidence-based guidelines is a major nursing responsibility.**
- Short-course antibiotic therapy is appropriate for uncomplicated infections of the lower urinary tract that are not associated with the presence of an indwelling urinary catheter.
- Teach patients about perineal hygiene and the importance of maintaining adequate fluid intake as measures to help prevent UTI.
- **The urinary tract can be affected by obstructive processes such as stones and tumors. Early recognition of obstructive processes and maintaining unobstructed urinary output are critical to maintain kidney function.**
- Urinary stones (most commonly kidney stones in the United States) can obstruct the urinary tract at any level, and cause significant pain as they move from the kidney through the ureter. Instruct patients who have had a kidney stone to maintain a generous fluid intake, particularly during exercise and warm weather, to reduce the risk of further stone formation.
- **Bladder cancer is the most commonly occurring malignancy of the urinary tract. When identified and treated early, bladder function can be preserved and the prognosis is good. Invasive bladder cancer may necessitate removal of the bladder and urinary diversion, altering patterns of urinary elimination and body image.**
- The risk for bladder cancer is greater among men than women, and cigarette smoking is the most significant risk factor for bladder cancer. Most tumors can be resected transurethrally if diagnosed early, before spreading to deeper layers of the bladder wall, the lymph nodes, and adjacent tissue.
- When resection of the urinary bladder is necessary, a urinary diversion is created to collect urine. A collection appliance must be worn constantly on an ileal conduit; when a continent urinary diversion is created, the pouch is emptied by intermittent catheterization of the stoma.
- **Changes in muscle tone can affect the ability to effectively empty the urinary bladder and/or maintain urinary continence. Urinary incontinence, while treatable and rarely life threatening, can lead to embarrassment, social isolation, and institutionalization.**
- Urinary retention may occur as a result of some medications, neurologic damage or disease, or obstruction (e.g., an enlarged prostate gland). If the underlying condition cannot be treated, medications or intermittent catheterization are used to promote bladder emptying.
- Older adults in particular are at risk for urinary incontinence, a treatable condition. A health history, voiding diary, and diagnostic testing are used to establish the type of urinary incontinence and direct treatments such as surgery, pelvic floor muscle exercises, medications, and scheduled toileting.

TEST YOURSELF NCLEX-RN® REVIEW

1. A female patient who was treated 3 months ago for a urinary tract infection is experiencing the same symptoms now. What should the nurse ask the patient during the health assessment?
   1. "How much fluid do you drink each day?"
   2. "What form of birth control are you using?"
   3. "Does your partner have similar symptoms?"
   4. "Did you complete the antibiotic prescribed for the first infection?"
2. A perimenopausal patient is experiencing frequency, urgency, nocturia, dysuria, and cloudy, rust-colored urine for the third time in the past 2 years. What should the nurse include when teaching this patient? (Select all that apply.)
   1. preprocedure instruction for an IVP
   2. recommendations for perineal cleansing
   3. recommendations for screening cystoscopy
   4. potential benefits of estrogen vaginal cream
   5. return to the office in 10 days for follow-up culture
3. The nurse identifies that a patient with immobility is at risk for the development of urolithiasis. What should the nurse include when planning this patient's care?
   1. Monitor urine pH.
   2. Administer calcium supplements.
   3. Maintain an indwelling urinary catheter.
   4. Increase fluid intake to 3000 mL/day.
4. A patient admitted with possible kidney stones suddenly experiences acute crampy pain on the left side that radiates into the groin. The patient is nauseated, vomits clear fluid, and voids pink urine. What should the nurse do first?
   1. Strain all urine.
   2. Notify the physician.
   3. Administer the prescribed narcotic analgesic.
   4. Obtain a bladder scan to assess for residual urine.
5. The nurse is teaching a group of community members about measures to reduce the risk for bladder cancer. What should the nurse include when providing these instructions? (Select all that apply.)
   1. Empty the bladder every 2 hours.
   2. Do not start smoking; if you smoke, stop.
   3. Increase the intake of fluids and vegetables.
   4. Avoid using hair dyes and pesticides in the home.
   5. Limit the intake of coffee and other caffeinated beverages.
6. At a local health fair, a male participant remarks to the nurse about urine occasionally being pink and wonders if this should be a concern. How should the nurse respond?
   1. Advise to make an appointment to see a physician.
   2. Teach to increase fluid intake to 2.5 to 3 quarts per day.
   3. Instruct to track the relationship between urine color and activities.
   4. Instruct to notify the physician if pain or difficulty voiding develops.

7. The nurse evaluates teaching provided to a patient with a newly created ileal diversion with a continent reservoir. Which patient behavior indicates teaching has been effective?
   1. Demonstrates care for the collection device.
   2. Demonstrates self-catheterization of the stoma.
   3. Identifies factors contributing to the risk for bladder cancer.
   4. States the importance of promptly reporting cloudy urine to the physician.
8. The nurse is identifying goals of care for a patient with stress incontinence. Which goal would be a priority for this patient?
   1. States chronic and benign nature of the disorder.
   2. Identifies products for protecting clothing and furniture.
   3. Limits intake of beverages containing artificial sweeteners.
   4. Performs pelvic floor muscle exercises as taught at least twice a day.
9. A patient has difficulty getting to the bathroom in time to prevent urine leaks once the need to void occurs. What should the nurse teach this patient?
   1. Wear clothing that is easily removed for toileting.
   2. Establish a voiding schedule that includes emptying the bladder at least every 2 hours.
   3. Limit intake of caffeine-containing beverages, particularly in the evening.
   4. Discuss potential benefits of bladder suspension surgery with a physician.
10. The nurse is caring for a patient in the spinal shock phase following spinal cord injury. Which action is the most appropriate to maintain this patient's bladder functioning?
    1. Stimulate voiding using the Credé's method.
    2. Assess for urinary retention following each voiding.
    3. Catheterize with straight catheter every 3 to 4 hours.
    4. Insert an indwelling urinary catheter to accurately measure output.

See Test Yourself answers in Appendix B.

28 Nursing Care of Patients with Kidney Disorders

LEARNING OUTCOMES

1. Describe the pathophysiology of common kidney disorders, relating pathophysiology to normal functions and manifestations of the disorder.
2. Discuss risk factors for kidney disorders and nursing measures to reduce these risks.
3. Explain diagnostic studies used to identify disorders of the kidneys and their effects.
4. Discuss the effects of and nursing implications for medications and treatments used for patients with kidney disorders.
5. Compare and contrast renal replacement therapies, including dialysis and kidney transplant, to manage acute kidney injury and chronic kidney disease.

CLINICAL COMPETENCIES

1. Assess and monitor the health status of patients with kidney disorders, recognizing and reporting unexpected manifestations or status changes.
2. Provide safe and effective nursing care for patients undergoing renal replacement therapies, surgery involving the kidneys, or renal transplant, respecting the patient's expressed needs, values, and preferences.
3. Using assessed data and current standards of practice, plan and implement evidence-based nursing care for patients with renal disorders using research and best practices.
4. Collaborate and coordinate with the patient and other members of the interprofessional team to prioritize and implement care.
5. Provide teaching appropriate to the individual and situation for patients with kidney disorders.
6. Evaluate patient responses to care, revising the plan of care as needed to promote, maintain, or restore functional health status for patients with renal disorders.
7. Participate in studies and projects to improve outcomes for patients with acute or chronic kidney disorders.
8. Apply technology and information management tools to support safe processes of care for patients with kidney disorders.

MAJOR CHAPTER CONCEPTS

- Congenital and acquired disorders of the kidneys can profoundly affect urinary elimination and ultimately all body systems.
- Glomerular disorders affect urine formation and waste elimination. Although their causes are diverse, glomerular disorders cause loss of proteins and blood cells in the urine, a decrease in the glomerular filtration rate, and severe edema. These disorders are a leading cause of chronic kidney disease and end-stage renal failure.
- The renal and cardiovascular systems are closely interrelated. Vascular disorders such as hypertension and atherosclerosis can have a serious impact on renal function.
- Acute kidney injury is a frequent complication of hospitalization and critical illness that increases mortality, length of stay, costs, and the risk for subsequent chronic kidney disease. Nurses play a key role in preventing and recognizing acute kidney injury, thus minimizing its negative consequences.
- Diabetes mellitus and hypertension, two prevalent chronic conditions in the United States, are the leading causes of chronic kidney disease and, ultimately, kidney failure. Aggressive glycemic control and blood pressure management reduce the risk of kidney disease; likewise, early identification and effective management of chronic kidney disease can delay the onset of kidney failure.

KEY TERMS

acute kidney injury (AKI), *795*
acute tubular necrosis (ATN), *796*
azotemia, *782*
chronic kidney disease (CKD), *807*
dialysis, *801*
glomerular filtration rate (GFR), *780*
glomerulonephritis, *782*
hematuria, *781*
hemodialysis, *801*
kidney failure, *795*
nephrectomy, *791*
nephrotic syndrome, *784*
oliguria, *782*
peritoneal dialysis, *801*
proteinuria, *781*
ultrafiltration, *802*
uremia, *808*

The internal environment of the body normally remains in a relatively constant or *homeostatic* state. The kidneys help maintain homeostasis by regulating the composition and volume of extracellular fluid. They excrete excess water and solutes and can conserve water and solutes when deficits occur. In addition, the kidneys help regulate acid–base balance and they excrete metabolic wastes. Regulation of blood pressure is another key function of the kidneys. Both primary kidney disorders (such as glomerulonephritis) and systemic diseases (such as diabetes mellitus) can affect renal function. In the United States, more than 20 million people (about 10% of adults) have chronic kidney disease (National Kidney and Urologic Diseases Information Clearinghouse [NKUDIC], 2012). Every year, approximately 1 in every 1000 people in the United States develops end-stage renal disease (ESRD), the final phase of chronic kidney disease in which little or no kidney function remains. Chronic kidney disease accounted for more than 90,000 deaths in 2009, and is a major cause of lost work time and wages (NKUDIC, 2012). Ironically, the increased prevalence of chronic kidney disease in recent years is partially related to the success of dialysis and transplantation.

FAST FACTS

- At the end of 2009, more than 871,000 people in the United States were receiving treatment for kidney failure.
- The incidence of chronic kidney disease is growing most rapidly among people ages 65 and older, while it remains stable in younger adults.
- Minority populations are affected to a greater extent than Caucasians; the rate of kidney failure is highest in African Americans, followed by American Indians, Hispanics, Asian Americans, and, finally, Caucasian Americans.
- Diabetes is the leading cause of ESRD in the United States; hypertension is the second leading cause. (National Kidney Foundation, 2013; NKUDIC, 2012).

AGE-RELATED CHANGES IN KIDNEY FUNCTION

Glomeruli in the renal cortex are lost with aging, reducing kidney mass. Because of the large functional reserve of the kidneys, however, renal function remains adequate unless additional stressors affect the renal system. The **glomerular filtration rate (GFR)**, the amount of filtrate made by the kidneys per minute, declines due to age-related factors affecting the renovascular system (such as arteriosclerosis, decreased renal vascularity, and decreased cardiac output). By age 80, the GFR may be less than half of what it was at age 30.

Age-related changes in renal function have significant implications. The kidneys are less able to concentrate urine and compensate for increased or decreased salt intake. When combined with diminished effectiveness of antidiuretic hormone (ADH) and a reduced thirst response, both common in aging, this decreased ability to concentrate urine increases the risk for dehydration. Potassium excretion may be decreased because of lower aldosterone levels. As a result, fluid and electrolyte imbalances are more common and potentially critical in the older patient.

Decreased GFR in the older adult also reduces the clearance of drugs excreted through the kidneys. This reduced clearance prolongs the half-life of drugs and may necessitate lower drug doses and longer dosing intervals. Common medications affected by decreased GFR include the following:

- Cardiac drugs: digoxin, procainamide
- Antibiotics: aminoglycosides, tetracyclines, cephalosporins
- Histamine H_2 antagonists: cimetidine
- Antidiabetic agents: chlorpropamide.

When caring for older adults, it is especially important to monitor drugs that are toxic to the renal tubules. Radiologic dyes and aminoglycoside, tetracycline, and the cephalosporin antibiotics are part of this group.

Age-related changes in renal function and related nursing implications are summarized in Table 28–1.

Kidney Disorders

THE PATIENT WITH POLYCYSTIC KIDNEY DISEASE

Polycystic kidney disease, a hereditary disease characterized by formation of fluid-filled cysts and massive kidney enlargement, affects both children and adults. This disease has two forms: The autosomal dominant form primarily affects adults; the autosomal recessive form is present at birth (Grossman & Porth, 2014). Autosomal recessive polycystic kidney disease is rare. It usually is diagnosed prenatally or in infancy. Renal failure generally develops during childhood, necessitating kidney transplant or dialysis. Autosomal dominant polycystic kidney disease (ADPKD) is relatively common, affecting 1 in every 400 to 1000 people and accounting for approximately 4% of patients with ESRD in the United States (NKUDIC, 2010; Salant & Gordon, 2012). See the Genetic Considerations box. This section focuses on autosomal dominant polycystic kidney disease, the more common form of the disorder.

Pathophysiology

Renal cysts are fluid-filled sacs affecting the nephron, the functional unit of the kidneys. The cysts, which arise from tubular epithelial cells, may range in size from microscopic to several centimeters in diameter and affect the renal cortex and medulla of both kidneys. Cysts may detach from the tubule, continuing to enlarge by active fluid secretion. As the cysts enlarge and multiply, the kidneys also enlarge. Although only a small percentage of nephrons are involved, the cysts compress adjacent renal parenchyma. Renal blood vessels and nephrons are compressed and obstructed, leading to tissue ischemia. This activates the renin–angiotensin system within the kidney. Functional tissue is destroyed, with compression, ischemia, and accumulation of inflammatory mediators likely playing a role (Figure 28–1 ■).

People affected by polycystic kidney disease often develop cysts elsewhere in the body, including the liver, spleen, pancreas, lungs, and reproductive organs. Up to 83% of people with ADPKD develop liver cysts, which may bleed or become infected. Diverticular disease of the colon is common, and may lead to perforation of the bowel. About 25% of people with polycystic kidney disease have cardiac valve abnormalities, including mitral valve prolapse ("floppy" mitral valves) and aortic valve insufficiency. The risk of subarachnoid or cerebral hemorrhage from a ruptured cerebral aneurysm is significantly increased in patients with ADPKD.

TABLE 28–1 Nursing Implications of Age-Related Changes in Kidney Function

Functional Change	Effect	Implications
Decreased GFR	Decreased clearance of drugs excreted primarily through the kidneys increases drug half-life and blood levels, and risk of drug toxicity.	Monitor carefully for signs of toxicity, especially when administering digoxin, aminoglycoside antibiotics, tetracycline, vancomycin, chlorpropamide, procainamide, cimetidine, and cephalosporin antibiotics.
Decreased number of functional nephrons; lower levels of aldosterone; increased resistance to ADH	Ability to conserve water and sodium is decreased; potassium excretion is impaired; and hydrogen ion excretion is decreased, resulting in reduced ability to compensate for acidosis.	Monitor for dehydration and hyponatremia. Maintain fluid intake of 1500–2500 mL/day unless contraindicated. Monitor for hyperkalemia, especially if taking a potassium-sparing diuretic, heparin, angiotensin-converting enzyme (ACE) inhibitor, angiotensin receptor blocker (ARB), beta-blocker, or NSAID; increased risk for acidosis.
Reduced numbers of functional nephrons	Renal reserve is decreased, leading to increased risk of failure.	Avoid giving nephrotoxic drugs if possible. Monitor urine output and blood chemistries for early signs of renal failure.

Figure 28–1 ■ A polycystic kidney. The functional tissue of the kidneys is gradually destroyed and replaced with fluid-filled cysts.
Source: A. Glauberman/Photo Researchers, Inc.

Manifestations

Polycystic kidney disease is slowly progressive. Symptoms usually develop by age 40 to 50. Common manifestations include flank pain, microscopic or gross **hematuria** (blood in the urine), **proteinuria** (proteins in the urine), and *polyuria* and *nocturia*, as the concentrating ability of the kidney is impaired. Urinary tract infection and renal calculi are common, as cysts interfere with normal urine drainage. Most patients develop hypertension from disruption of renal vessels. The kidneys become palpable, enlarged, and knobby. Symptoms of renal insufficiency and chronic renal failure typically develop by age 60 to 70. The progression to ESRD tends to occur more rapidly in Blacks and in men.

GENETIC CONSIDERATIONS

Adult Polycystic Kidney Disease

- Approximately 90% of cases are inherited as an autosomal dominant trait; the remaining 10% are due to spontaneous mutations.
- ADPKD type 1, due to mutation of a gene on chromosome 16, accounts for approximately 85% of cases. It tends to have an earlier onset of symptoms and renal failure.
- ADPKD type 2, due to gene mutation on chromosome 4, is responsible for most remaining cases. The onset of manifestations and renal failure is later with ADPKD-2 polycystic kidney disease.
- In both types of ADPKD, the genetic mutation affects production of *polycystin* membrane proteins and tubular epithelial cell growth and differentiation (Salant & Gordon, 2012).

●○● INTERPROFESSIONAL CARE

Diagnostic tests used to determine the extent of polycystic kidney disease include the following:

- *Renal ultrasonography* is the diagnostic procedure of choice for polycystic kidney disease.
- *Computed tomography (CT) scan* or *MRI* of the kidney may be used to detect cystic disease at an earlier stage when there is a positive family history.
- *Genetic testing* for ADPKD type 1 and type 2 is available, and is particularly important when a family member is being considered as a potential kidney donor.

Management of adult polycystic kidney disease is largely supportive. Care is taken to avoid further renal damage by nephrotoxic substances, UTI, obstruction, or hypertension. A fluid intake of 2000 to 2500 mL/day is encouraged to help prevent UTI and lithiasis. Hypertension associated with polycystic disease is generally controlled using a multidrug regimen to achieve a target blood pressure of 130/80 mmHg. Angiotensin-converting enzyme (ACE) inhibitors and angiotensin receptor blockers (ARBs) may slow the expansion of renal cysts and help preserve GFR. Ultimately, dialysis or renal transplantation is required. Patients with polycystic kidney disease are typically good candidates for transplantation because of the absence of associated systemic disease, but may still experience effects of the extrarenal elements of the disease.

●○● NURSING CARE

For those with adult polycystic kidney disease, an autosomal dominant disorder, discuss genetic counseling and screening of family members for evidence of the disease. Consider the following nursing

diagnoses when planning care for the patient with polycystic kidney disease:

- *Excess Fluid Volume* related to impaired renal function
- *Grieving* related to potential loss of kidney function
- *Readiness for Enhanced Knowledge* regarding measures to help preserve kidney function
- *Risk for Ineffective Coping* related to potential genetic transmission of the disorder to offspring.

Teach the patient with polycystic kidney disease about the disease, its genetic nature, and its usual course. Discuss measures to maintain optimal renal function. Instruct to maintain a fluid intake of at least 2500 mL/day. Include additional information about preventing UTI (such as hygiene measures) and early manifestations of UTI. Stress the importance of seeking treatment to prevent further kidney damage. Advise to avoid drugs that are potentially toxic to the kidneys and to check with the primary care provider before taking any new drug. Discuss the potential benefits of genetic counseling with the patient and family.

THE PATIENT WITH A GLOMERULAR DISORDER

Disorders and diseases involving the glomerulus are the leading cause of chronic kidney disease in the United States. They are the underlying disease process for more than half of those people needing dialysis and result in a significant number of deaths per year.

Glomerular disorders may be either primary, involving mainly the kidney, or secondary to a multisystem disease or hereditary condition. Primary glomerular disease is often immunologic or idiopathic in origin. Diabetes mellitus, undiagnosed or inadequately treated hypertension, and systemic lupus erythematosus (SLE) are frequently implicated in secondary glomerular disorders.

FAST FACTS

- Glomerular disorders and diseases are the leading cause of chronic kidney disease in the United States.
- Hematuria, proteinuria, and hypertension often are early manifestations of glomerular disorders.
- Acute poststreptococcal glomerulonephritis (also called acute proliferative glomerulonephritis) is the most common primary glomerular disorder.
- Diabetes mellitus, hypertension, and SLE are common causes of secondary glomerulonephritis.

Physiology Review

The glomerulus is a tuft of capillaries surrounded by a thin, double-walled capsule (Bowman's capsule). About 20% of the resting cardiac output flows through the glomeruli of the kidneys, forming approximately 180 L of plasma filtrate. More than 99% of this filtrate is reabsorbed in the renal tubules. The rate of glomerular filtration is controlled by opposing forces: The pressure and amount of blood flowing through the glomeruli promote filtration, whereas the pressure in Bowman's capsule and the colloid osmotic (*oncotic*) pressure of the blood oppose it. The total surface area of glomerular capillaries also affects the GFR. The glomerular capillary membrane has three layers: the capillary endothelial layer, the basement membrane, and the capsule epithelial layer. Water and the smallest solutes (such as electrolytes) pass freely across this membrane, whereas larger molecules (such as plasma proteins) are retained in the blood.

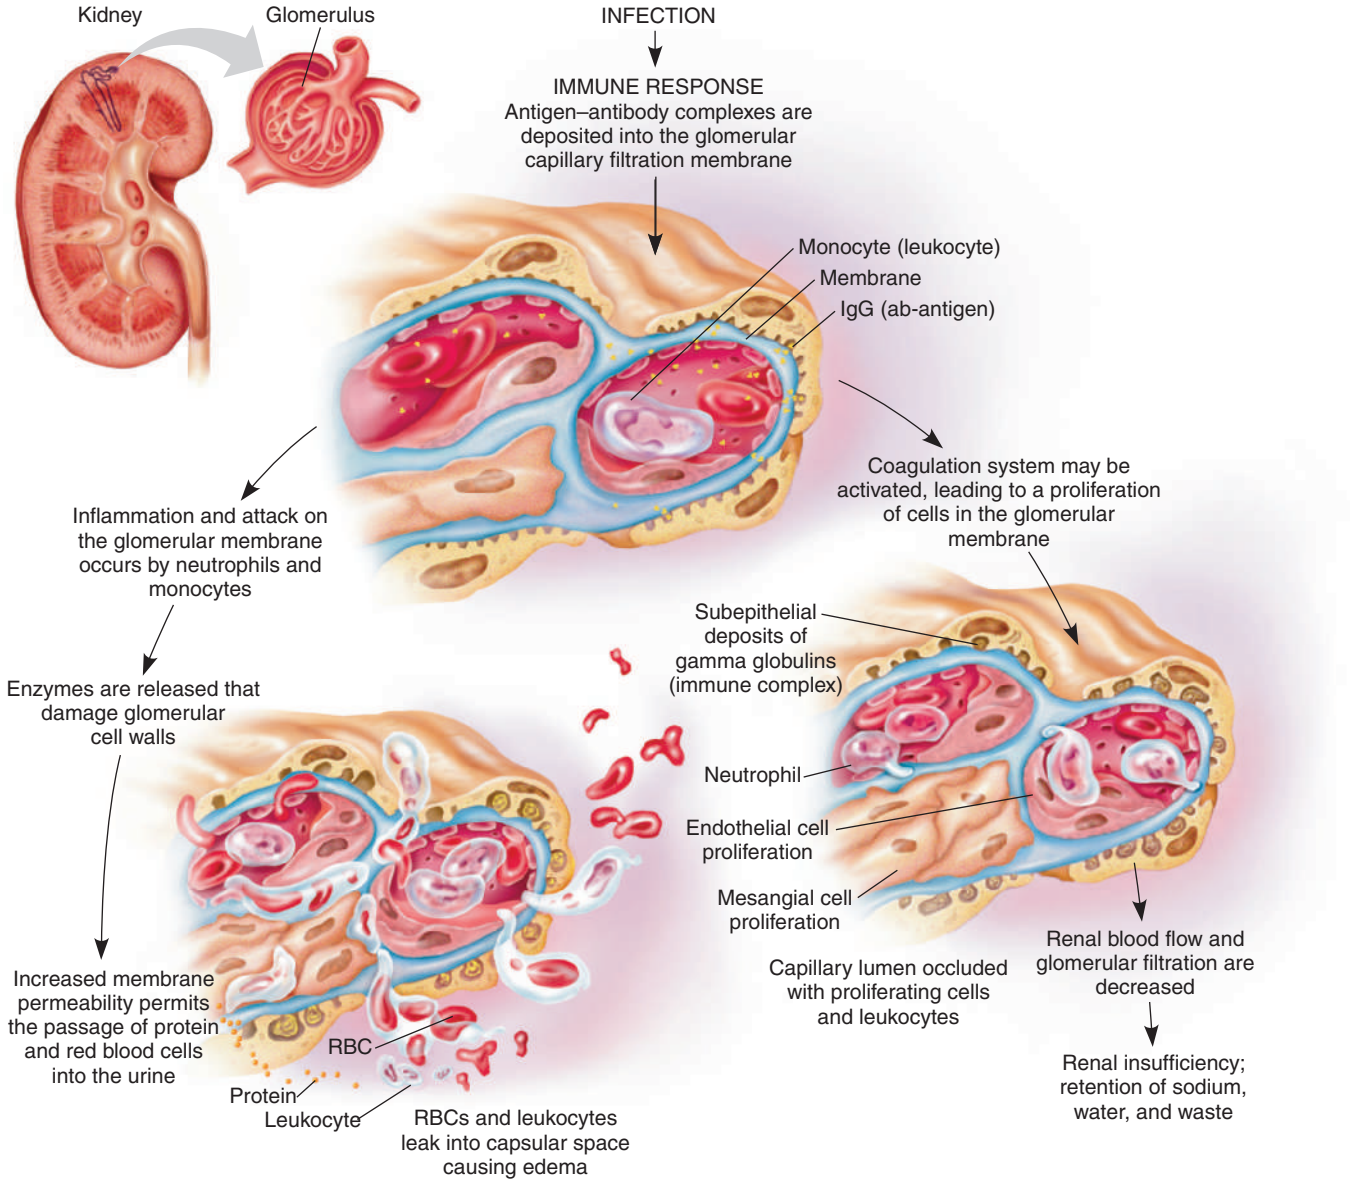
Pathophysiology

Glomerular disease affects both the structure and function of the glomerulus, disrupting glomerular filtration. The capillary membrane becomes more permeable to plasma proteins and blood cells. This increased permeability in the glomerulus causes the manifestations common to glomerular disorders: hematuria, proteinuria, and edema. The GFR falls, leading to **azotemia** (increased blood levels of nitrogenous waste products) and hypertension. Glomerular involvement may be diffuse (involving all glomeruli) or focal (involving some glomeruli while others remain essentially normal).

Both hematuria and proteinuria are caused by glomerular capillary membrane damage, which allows blood cells and proteins to escape from the blood into the glomerular filtrate. Hematuria may be either gross or microscopic. Proteinuria is considered to be the most important indicator of glomerular injury, because it increases progressively with increased glomerular damage. Loss of plasma proteins leads to *hypoalbuminemia* (low serum albumin levels), which in turn reduces the plasma oncotic pressure (osmotic pressure created by plasma proteins), leading to edema.

As plasma proteins are lost, the forces opposing filtration diminish, and the amount of filtrate increases. The increased flow of filtrate stimulates the renin–angiotensin–aldosterone mechanism, producing vasoconstriction and a resulting fall in GFR. Increased aldosterone production causes salt and water retention, which further contribute to edema. As the GFR falls, filtration and elimination of nitrogenous wastes, including urea, decrease, causing azotemia. **Oliguria**, urine output of less than 400 mL in 24 hours, may result from the decreased GFR. Hypertension results from fluid retention and disruption of the renin–angiotensin system, a key regulator of blood pressure.

The major primary glomerular disorders include acute glomerulonephritis, rapidly progressive glomerulonephritis, nephrotic syndrome, and chronic glomerulonephritis. Diabetic nephropathy and lupus nephritis are the most common secondary forms of glomerular disease.



ACUTE POSTINFECTIOUS GLOMERULONEPHRITIS

Glomerulonephritis is inflammation of the glomerular capillary membrane. Acute glomerulonephritis can result from systemic diseases or primary glomerular diseases, but acute postinfectious glomerulonephritis (also known as *acute poststreptococcal glomerulonephritis*) is the most common form. The usual initiating event for this disorder is infection of the pharynx or skin with group A beta-hemolytic streptococci. Staphylococcal or viral infections, such as hepatitis B, mumps, or varicella (chickenpox), can lead to a similar postinfectious acute glomerulonephritis. Acute postinfectious glomerulonephritis is primarily a disease of childhood that also can affect adults.

In acute postinfectious glomerulonephritis, circulating antigen–antibody immune complexes formed during the primary infection become trapped in the glomerular membrane, leading to an inflammatory response. The complement system is activated, and vasoactive substances and inflammatory mediators are released. Endothelial cells proliferate, and the glomerular membrane swells and becomes

PATHOPHYSIOLOGY ILLUSTRATED
Acute Postinfectious Glomerulonephritis

Infection from group A beta-hemolytic streptococci causes an immune response that results in inflammation and damage to the glomeruli. Protein and red blood cells are allowed to pass through the glomeruli. Blood flow to the glomeruli is reduced due to obstruction with damaged cells and renal insufficiency results, leading to the retention of sodium, water, and waste.

permeable to plasma proteins and blood cells. Renal involvement is diffuse, spread throughout the kidneys. See the Pathophysiology Illustrated: Acute Postinfectious Glomerulonephritis feature.

MANIFESTATIONS AND COMPLICATIONS Acute postinfectious glomerulonephritis is characterized by an abrupt onset of hematuria, proteinuria, salt and water retention, and evidence of azotemia occurring 10 to 14 days after the initial infection. The urine often appears brown or cola colored. Salt and water retention increase extracellular fluid volume, leading to hypertension and edema. The edema is primarily noted in the face, particularly around the eyes (*periorbital* edema). Dependent edema, affecting the hands and upper extremities in particular, may be noted. Other manifestations may include fatigue, anorexia, nausea and vomiting, and headache (see the Pathophysiology Linkage table on page 784).

The older adult may have less apparent symptoms. Nausea, malaise, arthralgias, and proteinuria are common manifestations; hypertension and edema are seen less often. Pulmonary infiltrates

PATHOPHYSIOLOGY LINKAGE

Acute Glomerulonephritis

Manifestation	Related Pathophysiology
Hematuria, cola-colored urine	Disruption of the glomerular capillary membrane allows red blood cells to escape from the vascular system into Bowman's capsule, ultimately being excreted in the urine.
Proteinuria	Plasma proteins cross the damaged glomerular capillary membrane, becoming part of the filtrate and excreted urine.
Salt and water retention	Loss of plasma proteins reduces plasma oncotic pressure, reducing this oppositional force to filtration. The amount of filtrate increases, stimulating the renin–angiotensin–aldosterone system and prompting salt and water retention.
Edema, periorbital and facial, dependent	Increased vascular volume due to salt and water retention coupled with decreased plasma oncotic pressure forces more fluid out of capillaries into interstitial tissues.
Hypertension	Activation of the renin–angiotensin–aldosterone system leads to vasoconstriction and increased peripheral vascular resistance, as well as increased vascular volume due to salt and water retention.
Azotemia	Vasoconstriction reduces renal blood flow, reducing filtration and excretion of metabolic waste products.
Fatigue, anorexia, nausea, and vomiting	Retained metabolic waste products and fluid and electrolyte and acid–base imbalances affect energy production and vomiting centers in the CNS.
Headache	Increased intravascular volume and fluid and electrolyte and acid–base imbalances lead to intra-cranial vasodilation.

may occur early in the disorder, often due to worsening of a preexisting condition such as heart failure.

The prognosis for adults with acute glomerulonephritis is less favorable than it is for children. The symptoms may resolve spontaneously within 10 to 14 days. Full recovery is usual in children, whereas only 60% or more of affected adults recover completely. The remaining patients have persistent symptoms, and some have permanent kidney damage.

ANTIGLOMERULAR BASEMENT MEMBRANE GLOMERULONEPHRITIS

Antiglomerular basement membrane (anti-GBM) glomerulonephritis is characterized by autoantibodies to antigens in the glomerular basement membrane and manifestations of severe glomerular injury. Anti-GBM glomerulonephritis often progresses to renal failure within months. When lung hemorrhage accompanies the disorder, it is called *Goodpasture's syndrome*. Although people of all ages can be affected, Goodpasture's syndrome primarily is seen in young men under the age of 30 and in older adults in their 60s and 70s (Lewis & Nelson, 2012; Watnick & Dirkx, 2012).

In anti-GBM glomerulonephritis, glomerular cells proliferate and, together with macrophages, form crescent-shaped lesions that obliterate Bowman's space. Glomerular damage is diffuse, leading to a rapid, progressive decline in renal function. In Goodpasture's syndrome, antibodies also may bind to alveolar basement membranes, damaging alveoli and causing pulmonary hemorrhage.

Patients with anti-GBM glomerulonephritis often present with complaints of weakness, nausea and vomiting, and possible abdominal or flank pain. Some may relate a history of an upper respiratory tract infection preceding the onset of the glomerulonephritis. Renal manifestations include hematuria, proteinuria, and edema. Moderate hypertension may develop. On urinalysis, hematuria and massive proteinuria are noted. Presentation with oliguria is an ominous sign; rapid progression to renal failure may occur. Alveolar membrane damage can lead to mild or life-threatening pulmonary hemorrhage. Cough, shortness of breath, and hemoptysis (bloody sputum) are early respiratory manifestations.

NEPHROTIC SYNDROME

Nephrotic syndrome is a group of clinical findings as opposed to a specific disorder. It is characterized by massive proteinuria, hypoalbuminemia, hyperlipidemia, and edema. A number of disorders can affect the glomerular capillary membrane, changing its porosity and allowing plasma proteins to escape into the urine.

Minimal change disease (MCD) is the most common cause of nephrotic syndrome in children but accounts for only 10% to 15% of adults with nephrotic syndrome. In MCD, the size and form of glomeruli appear normal by light microscopy. Relapse, common in children, occurs less frequently in adults. When it occurs, however, relapse can be resistant to effective treatment.

In White, non-Hispanic adults, *membranous glomerulonephropathy* is the most common cause of nephrotic syndrome. The glomerular basement membrane thickens, although no inflammation is present. This form of nephrotic syndrome develops secondarily to malignancy, infection, or an autoimmune disorder in up to 30% of cases. The cause often cannot be identified (idiopathic). *Focal sclerosis*, in which scarring (sclerosis) of glomeruli occurs, and *membranoproliferative glomerulonephritis*, caused by thickening and proliferation of glomerular basement membrane cells, are additional forms of nephrotic syndrome.

With plasma protein loss in the urine and resulting hypoalbuminemia, the oncotic pressure of the plasma falls. Fluid shifts from the vascular compartment to interstitial spaces, causing the edema characteristic of nephrotic syndrome. Salt and water retention, possibly due to activation of the renin–angiotensin system, contribute to the edema. Edema may be severe, affecting the face and periorbital area as well as dependent tissues (Figure 28–2 ■).

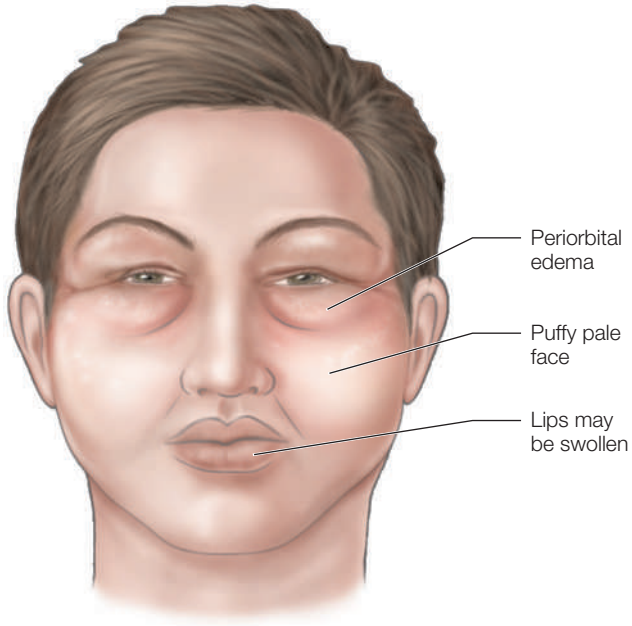


Figure 28–2 ■ Severe edema characteristic of nephrotic syndrome.

Loss of plasma proteins stimulates the liver to increase albumin production and lipoprotein synthesis. As a result, serum triglyceride and low-density lipoprotein (LDL) levels increase, as do urine lipids (*lipiduria*). Hyperlipidemia increases the risk for atherosclerosis in patients with nephrotic syndrome.

Thromboemboli (mobilized blood clots) are a relatively common complication of nephrotic syndrome. Loss of clotting and anticlotting factors along with plasma proteins is thought to disrupt the coagulation system, increasing the risk for renal venous thrombosis, deep venous thrombosis, and pulmonary embolism. Renal venous thrombosis can cause flank or groin pain on one or both sides, gross hematuria, and a reduced GFR.

Nephrotic syndrome usually resolves without long-term effects in children. The prognosis for adults is less optimistic because the syndrome often occurs secondarily to another disorder. Many adults do not recover completely, experiencing persistent proteinuria and, potentially, progressive renal impairment.

CHRONIC GLOMERULONEPHRITIS

Chronic glomerulonephritis is typically the result of progressive glomerular disorders such as anti-GBM glomerulonephritis, lupus nephritis, or diabetic nephropathy. In many cases, however, no previous glomerular disease has been identified.

Slow, progressive destruction of the glomeruli and a gradual decline in renal function are characteristic of chronic glomerulonephritis. The kidneys decrease in size symmetrically, and their surfaces become granular or roughened. Eventually, entire nephrons are lost.

Symptoms develop insidiously, and the disease is often not recognized until signs of renal failure develop. Chronic glomerulonephritis may be diagnosed when hypertension and impaired renal function are found coincidentally during a routine physical examination or treatment for an unrelated disorder. Viral or bacterial infectious diseases can exacerbate the disorder, prompting its diagnosis.

The course of chronic glomerulonephritis varies, with years to decades between the diagnosis and the development of end-stage renal failure.

DIABETIC NEPHROPATHY

Diabetic nephropathy, kidney disease common in the later stages of diabetes mellitus (DM), is the leading cause of chronic kidney disease in North America. About 40% of patients with diabetes develop nephropathy; because type 2 diabetes is more prevalent, it accounts for a higher portion of patients with chronic kidney disease. Diabetes-associated kidney lesions are more common in Blacks, Native Americans, and Hispanics (Powers, 2012).

Initial evidence of microproteinuria indicating renal damage is typically seen within 5 to 10 years after the onset of diabetes. Overt proteinuria and nephropathy generally develop within another 5 to 10 years of the onset of microproteinuria.

The characteristic lesion of diabetic nephropathy is glomerulosclerosis and thickening of the glomerular basement membrane. As the disease progresses, the glomerular capillary lumen narrows, reducing the surface area for glomerular filtration. Arteriosclerosis, a common feature of long-term diabetes and hypertension, contributes to the disease, as do nephritis and tubular lesions. Pyelonephritis, inflammation of the kidney, is also implicated in the development of diabetic nephropathy. More about diabetic nephropathy is found in Chapter 20.

LUPUS NEPHRITIS

Systemic lupus erythematosus (SLE) is an inflammatory autoimmune disorder affecting the connective tissue of the body. Most patients with SLE develop kidney abnormalities related to their disease; many develop manifestations of nephritis. Circulating immune complexes deposited in the glomerulus as well as those that form within the glomerular capillary wall trigger an inflammatory response leading to glomerular injury in SLE. Manifestations of lupus nephritis range from microscopic hematuria to massive proteinuria. Its progression may be slow and chronic or *fulminant*, with a sudden onset and the rapid development of renal failure. End-stage kidney disease eventually develops in about 20% of patients with lupus nephritis. Improved management of the underlying disease, immunotherapy, dialysis, and renal transplantation have significantly improved the prognosis in recent years.

●○● INTERPROFESSIONAL CARE

Management of all types of glomerulonephritis—acute and chronic, primary and secondary—focuses on identifying the underlying disease process and preserving kidney function. In most glomerular disorders, there is no specific treatment to achieve a cure. Treatment goals are to maintain renal function, prevent complications, and support the healing process.

DIAGNOSIS

Laboratory and diagnostic testing are valuable to evaluate kidney function and identify the cause of glomerulonephritis.

The following studies are used to evaluate kidney function:

- *Urinalysis* often shows red blood cells (RBCs) and proteins in the urine of patients with a glomerular disorder and may be the first indication of the disease. These substances, normally too large to

enter glomerular filtrate, escape due to increased porosity of glomerular capillaries in glomerular disorders.

- *Blood urea nitrogen (BUN)* is measured. Urea is eliminated from the body by filtration in the glomerulus; minimal amounts are reabsorbed in the renal tubules. Glomerular diseases interfere with filtration and elimination of urea nitrogen, causing blood levels to rise. Normal BUN values are listed in Table 28–2. Levels up to 50 mg/dL or 17.7 mmol/L indicate mild azotemia, and levels higher than 100 mg/dL or 35.7 mmol/L indicate severe renal impairment.
- *Serum creatinine* is a good indicator of kidney function. Levels greater than 4 mg/dL indicate serious renal impairment.
- *Urine creatinine* levels decrease when renal function is impaired because creatinine is not effectively eliminated from the body.
- *Estimated GFR (eGFR)* is a calculated value used to evaluate renal function. Four variables are used to calculate the eGFR: serum creatinine, age in years, gender, and race (African American or other). Values of 60mL/min/1.73 m^2 body surface area (BSA) are within the normal range for adults (20 years old and above), and may simply be reported as >60 mL/min/1.73 m^2.
- *Creatinine clearance* may be used to evaluate the GFR. The *clearance*, or amount of blood cleared of creatinine in 1 minute, depends on the amount and pressure of blood being filtered and the filtering ability of the glomeruli. Disorders such as glomerulonephritis affect glomerular filtration, decreasing the creatinine clearance.
- *Serum electrolytes* are evaluated because impaired kidney function alters their excretion.

The following studies may be ordered to help identify the underlying cause or etiology:

- *Antistreptolysin O (ASO) titer* and other tests detect antigenic proteins or antibodies (such as anti-dsDNA, anti-DNA, and others) to help determine the underlying cause of glomerular dysfunction.
- *Renal ultrasound* may show enlarged kidneys in acute glomerulonephritis, whereas bilateral small kidneys are typical of late chronic glomerulonephritis.
- *Kidney scan* demonstrates delayed uptake and excretion of the radioactive material in glomerular diseases.
- *Biopsy* is the most reliable diagnostic procedure for glomerular disorders. Biopsy helps determine the type of glomerulonephritis, the prognosis, and appropriate treatment.

MEDICATIONS

Although no drugs are available to cure glomerular disorders, medications are used to treat underlying disorders, reduce inflammation, and manage the symptoms.

Antibiotics are prescribed for the patient with poststreptococcal glomerulonephritis to eradicate any remaining bacteria, removing the stimulus for antibody production. Nephrotoxic antibiotics, such as the aminoglycoside antibiotics, streptomycin, and some cephalosporins, are avoided.

Aggressive immunosuppressive therapy is used to treat acute inflammatory processes such as anti-GBM glomerulonephritis, Goodpasture's syndrome, and exacerbations of SLE. When begun early, immunosuppressive therapy significantly reduces the risk of ESRD and renal failure. Prednisone, a glucocorticoid, is prescribed

TABLE 28–2 Changes in Laboratory Values Associated with Kidney Disease

Test	Normal Value	Value in Renal Disease
Blood urea nitrogen (BUN)	5–25 mg/dL Slightly higher in older adults	25–50 mg/dL or higher
BUN:creatinine ratio	10:1 to 20:1	Decreased ratio in acute tubular necrosis; increased in glomerular disease, azotemia
Creatinine, serum	0.5–1.2 mg/dL; 45–106 mmol/L (SI units) Slightly lower in females, older adults	Elevated; levels > 4 mg/dL indicate severe impairment of renal function
Creatinine clearance	85–135 mL/min Slightly lower in females Values decline in older adults	Reduced renal reserve: 32.5–85.0 mL/min Renal insufficiency: 6.5–32.5 mL/min Renal failure: < 6.5 mL/min
eGFR	≥ 60 mL/min/1.73 m^2	Decreased in renal impairment
Serum albumin	3.5–5 g/dL; 52%–68% of total protein; lower in older adults	Decreased in nephrotic syndrome
Serum electrolytes	Potassium: 3.5–5.3 mEq/L; 3.5–5.3 mmol/L Sodium: 135–145 mEq/L; 135–145 mmol/L Calcium: 4.5–5.5 mEq/L; 9–11 mg/dL; 2.3–2.8 mmol/L Phosphorus: 1.7–2.6 mEq/L; 2.5–4.5 mg/dL; 0.78–1.52 mmol/L	Increased in renal insufficiency Decreased in nephrotic syndrome Decreased in renal failure Increased in renal failure
Red blood cell count	Female: 4.0–5.0 million/mm^3 Male: 4.6–6.0 million/mm^3	Decreased in chronic kidney disease
Urine creatinine	1–2 g/24 h	Decreased in disorders of impaired renal function
Urine protein	25–150 mg/24 h	Increased in disorders of impaired renal function
Urine red blood cells	< 2/HPF; no RBC casts	Present in glomerular disorders

in relatively large doses of 1 mg per kilogram of body weight per day; for example, a 73-kg (160-lb) man would receive 70 to 75 mg per day. Other immunosuppressive agents such as cyclophosphamide (Cytoxan), azathioprine (Imuran), or cyclosporine (Sandimmune, Restasis, others) are prescribed in conjunction with corticosteroids. Corticosteroid use in poststreptococcal glomerulonephritis may actually worsen the condition, so it is avoided.

Oral glucocorticoids such as prednisone also are used in high doses to induce remission of nephrotic syndrome. When glucocorticoids alone are ineffective, other immunosuppressive agents such as cyclophosphamide or chlorambucil (Leukeran) may be used to induce or maintain remission.

ACE inhibitors or ARBs may be ordered to reduce protein loss associated with nephrotic syndrome and slow the progression of renal failure. They have a protective effect on the kidney in patients with diabetic nephropathy and other glomerular disorders.

Antihypertensives are prescribed to maintain the blood pressure within normal levels. Blood pressure management is important because systemic and renal hypertension are associated with a poorer prognosis in patients with glomerular disorders.

TREATMENTS

Restricted activity may be recommended during the acute phase of poststreptococcal glomerulonephritis. When the edema of nephrotic syndrome is significant or the patient is hypertensive, sodium intake may be restricted to 1 to 2 g/day. Dietary protein may be restricted if azotemia is present. When proteins are restricted, those included in the diet should be complete or high-value proteins. Complete proteins supply the essential amino acids required for growth and tissue maintenance. Complete and incomplete (low-quality) proteins are compared in Table 28–3.

Plasma exchange therapy (also called *plasmapheresis*), a procedure to remove damaging antibodies from the plasma, is used in conjunction with immunosuppressive therapy to treat anti-GBM glomerulonephritis and Goodpasture's syndrome. Plasma and glomerular-damaging antibodies are removed using a blood cell separator. The RBCs are then returned to the patient along with albumin or human plasma to replace the plasma removed. This procedure is usually done in a series of treatments. It is not without risk, and informed consent is required. Potential complications of plasma exchange therapy include those associated with intravenous catheters, fluid volume shifts, and altered coagulation.

Renal failure resulting from a glomerular disorder may necessitate dialysis to restore fluid and electrolyte balance and remove waste products from the body. Dialysis procedures and related nursing care are explained in the acute kidney injury section later in this chapter.

TABLE 28–3 Complete and Incomplete Protein Sources

	Complete Proteins	Incomplete Proteins
Definition	Provide all essential amino acids needed for growth and tissue maintenance	Lack one or more essential amino acids or contain inadequate proportions
Examples	Milk, eggs, cheese, meats, poultry, fish, and soy	Vegetables, breads, cereals and grains, legumes, seeds, and nuts

●○● NURSING CARE

Health Promotion

Discuss the importance of effectively treating streptococcal infections in all age groups to help reduce the risk for acute glomerulonephritis. Stress the importance of completing the full course of antibiotic therapy to eradicate the infecting bacteria. Teach patients with diabetes mellitus and SLE about potential renal effects of their disease. Discuss measures to reduce the risk of associated nephritis, such as effectively managing the disease, treating hypertension, and avoiding drugs and substances that are potentially toxic to the kidneys.

Assessment

Focused assessment data related to glomerular disorders include the following:

- *Health history:* complaints of facial or peripheral edema or weight gain, fatigue, nausea and vomiting, headache, general malaise, abdominal or flank pain; cough or shortness of breath; changes in amount, color, or character of urine (e.g., frothy urine); history of skin or pharyngeal streptococcal infection, diabetes, SLE, or kidney disease; current medications
- *Physical assessment:* general appearance; vital signs; weight; presence of periorbital, facial, or peripheral edema; inspect skin for lesions, infection; inspect throat, obtain culture as indicated; obtain urine specimen for color, character, odor.

Priorities of Care

Monitoring renal function and fluid volume status are key components of care, as is protecting the patient from infection.

Diagnoses, Outcomes, and Interventions

Nursing care for the patient with a glomerular disorder is supportive and educational. Both manifestations of glomerular disorders and their treatment can interfere with a patient's ability to maintain usual roles and responsibilities. For additional potential nursing diagnoses and interventions, see the Case Study & Nursing Care Plan on page 789.

Excess Fluid Volume

Excess fluid volume and resulting edema are common manifestations of glomerular disorders. When proteins are lost in the urine, the oncotic pressure of plasma falls, and fluid shifts into the interstitial spaces. The body responds to this fluid shift by retaining sodium and water to maintain intravascular volume, leading to excess fluid volume.

Expected Outcome: Patient's fluid balance will be restored (weight within expected range for individual, no evidence of central or peripheral edema).

- Monitor vital signs, including blood pressure, apical pulse, respirations, and breath sounds, at least every 4 hours. Report significant changes and unexpected results. *Excess fluid increases the cardiac workload and the blood pressure. Tachycardia may result. Associated electrolyte imbalances can cause dysrhythmias. Increased pulmonary*

Evidence for Nursing Care

The Patient with Glomerulonephritis

Selected resources that nurses may find helpful when planning evidence-based nursing care follow.

- Fink, H. A., Ishani, A., Taylor, B. C., Greer, N. L., MacDonald, R., Rossini, D., . . . Wilt, T. J. (2012). Screening for, monitoring, and treatment of chronic kidney disease stages 1 to 3: A systematic review for the U.S. Preventive Services Task Force and for an American College of Physicians Clinical Practice Guideline. *Annals of Internal Medicine, 156*(8), 570–581, W195–W202.

vascular pressure can lead to pulmonary edema, tachypnea, dyspnea, and crackles (rales) in the lungs.

- Record intake and output every 4 to 8 hours, or more frequently as indicated. *Accurate intake and output records help determine fluid volume status.*
- Weigh daily, using consistent technique (time of day, scale, and clothing). *Accurate daily weights are the best indicator of approximate fluid balance.*
- Monitor serum electrolytes, hemoglobin and hematocrit, BUN, creatinine, and eGFR. *Glomerular disorders affect fluid balance and may alter electrolyte balance as well, potentially leading to complications such as cardiac dysrhythmias. Increased intravascular volume can result in low hemoglobin and hematocrit values. BUN, creatinine, and eGFR provide information about renal function.*
- Maintain fluid restriction as ordered. Offer ice chips (in limited and measured amounts) and frequent mouth care to relieve thirst. With the patient, develop a fluid intake schedule. *Fluids may be restricted to reduce fluid overload, edema, and hypertension. Ice chips and frequent mouth care moisten mucous membranes and help relieve thirst while maintaining oral tissue integrity. Including the patient in planning fluid intake promotes a sense of control and understanding of the treatment regimen.*

SAFETY ALERT

Carefully monitor and regulate intravenous infusions; include fluid used to dilute IV medications as intake. Significant "hidden" fluid intake can occur with intravenous medication administration.

- Arrange dietary consultation regarding sodium- or protein-restricted diets. *Including the patient and dietitian in planning allows individualization of the diet to patient preferences. The glomerular disorder may reduce appetite; considering food preferences can help maintain adequate nutrition.*
- Monitor for desired and adverse effects of prescribed medications. *Diuretic therapy helps reduce excess fluid volume; however, glomerular disorders can affect the patient's response to treatment. In addition, diuretics can exacerbate the electrolyte imbalances and muscle weakness often associated with glomerular disorders.*
- Provide frequent position changes and good skin care. *Perfusion may be altered by tissue edema, increasing the risk of breakdown.*

Fatigue

Fatigue is a common manifestation of glomerular disorders. Anemia, loss of plasma proteins, headache, anorexia, and nausea compound this fatigue. The ability to maintain usual physical and mental activities may be impaired.

Expected Outcome: Patient will use energy conservation techniques to allow effective ADL maintenance and role performance.

- Document energy level. *As glomerular function improves, fatigue begins to resolve, and energy increases.*
- Schedule activities and procedures to provide adequate rest and energy conservation. Prevent unnecessary fatigue. *Adequate rest and energy conservation reduce fatigue and improve the patient's ability to tolerate and cope with required treatments and activities.*
- Assist with ADLs as needed. *The goal is to conserve limited energy reserves.*
- Discuss the relationship between fatigue and the disease process with patient and family. *Understanding the nature of the disease and associated fatigue helps the patient and family cope with reduced energy and comply with prescribed rest.*
- Reduce energy demands with frequent, small meals and short periods of activity. Limit the number of visitors and visit length. *Small, frequent meals reduce the energy needed for eating and digestion. Limiting visitors and visit length helps conserve energy. In addition, nurses can assist the fatigued patient who may be reluctant to ask visitors to leave.*

Risk for Infection

The effects of both the glomerular disorder and treatment with anti-inflammatory and cytotoxic drugs can depress the immune system, increasing the risk for infection. The anti-inflammatory effect of corticosteroids may mask early manifestations of infection.

Expected Outcome: Patient will remain free of infection.

- Monitor vital signs, temperature, and mental status every 4 hours. *An elevated temperature may indicate infection; anti-inflammatory drugs may moderate this response, however. Tachycardia, increasing lethargy, or confusion may be the initial signs of infection.*
- Assess frequently for signs of infection such as purulent wound drainage, productive cough, adventitious breath sounds, and red or inflamed lesions. Monitor for manifestations of UTI, such as dysuria, frequency and urgency, and cloudy, foul-smelling urine. *Early identification and treatment of infection is important to prevent systemic complications in the susceptible patient.*
- Monitor CBC, focusing on the WBC and differential. *An elevated WBC and increased numbers of immature WBCs in the blood (left shift) may be early indicators of infection.*
- Perform effective hand hygiene. Protect from cross-infection by providing a private room and restricting ill visitors. *Patients with decreased resistance to infection need increased protection.*
- Avoid or minimize invasive procedures. *Maintaining the protective skin barrier is especially important for the patient with altered immune status.*
- If catheterization is required, use sterile intermittent straight catheterization or maintain a closed drainage system for an indwelling catheter. Prevent urine reflux from the drainage system to the bladder or the bladder to the kidneys by ensuring a patent, gravity flow system. *The urinary tract is a frequent entry point for infection, particularly in the hospitalized or institutionalized patient. Maintaining strict asepsis during catheterization is vital.*

CASE STUDY & NURSING CARE PLAN A Patient with Acute Glomerulonephritis

Jung-Lin Chang is a 23-year-old graduate student who presents at the university health center with brown and foamy urine. The physician admits him to the infirmary and orders a throat culture, ASO titer, CBC, BUN, serum creatinine, eGFR, and urinalysis.

ASSESSMENT

Connie King, the nurse admitting Mr. Chang, notes that his history is essentially negative for past kidney or urinary problems. He relates having had a "pretty bad" sore throat a couple of weeks before admission, which he self-treated with a few leftover antibiotics. The sore throat resolved, and he felt well until noticing the change in his urine. He has eaten little the past 2 days, but was not alarmed because his food intake is irregular most of the time.

Physical assessment findings include T 37.1°C (98.8°F) PO, P 98 bpm, R 18/min, and BP 136/90 mmHg. Weight 75 kg (165 lb), up from his normal of 72.5 kg (160 lb). Moderate periorbital edema and edema of hands and fingers noted.

Throat culture is negative, but the ASO titer is high. CBC essentially normal. BUN 42 mg/dL, serum creatinine 2.1 mg/dL. Urinalysis reveals the presence of protein, red blood cells, and RBC casts. A subsequent 24-hour urine protein analysis shows 1025 mg of protein (normal 30 to 150 mg/24 h).

The physician diagnoses acute poststreptococcal glomerulonephritis and places Mr. Chang on limited activities, a fluid restriction (1200 mL/day), and a restricted sodium and protein diet.

Clinical Reasoning in Patient Care

1. How did Mr. Chang's self-treatment with antibiotics from a previous infection potentially contribute to his current situation?
2. In addition to acute glomerulonephritis, what other abnormal immune responses may develop as a consequence of group A beta-hemolytic streptococcal infection?
3. What teaching should the nurse provide to reduce Mr. Chang's risk of future infection-related problems?

DIAGNOSES

- *Excess Fluid Volume* related to plasma protein deficit and sodium and water retention
- *Risk for Imbalanced Nutrition: Less Than Body Requirements* related to anorexia
- *Readiness for Enhanced Self-Health Management* related to glomerulonephritis and treatment

EXPECTED OUTCOMES

- Patient will maintain blood pressure within normal limits.
- Patient will return to usual weight with no evidence of edema.
- Patient will consume adequate calories following prescribed dietary limitations.
- Patient will demonstrate an understanding of acute glomerulonephritis and prescribed treatment regimen.

PLANNING AND IMPLEMENTATION

- Take vital signs every 4 hours; notify physician of significant changes.
- Weigh daily; intake and output every 8 hours.
- Assist to develop a plan for consuming allowed fluids throughout the day.
- Arrange dietary consultation to plan a diet that includes preferred foods as allowed.
- Provide small meals with high-carbohydrate between-meal snacks.
- Teach Mr. Chang and his family about acute glomerulonephritis and prescribed treatment.
- Instruct in appropriate antibiotic use.

EVALUATION

Mr. Chang decides to return to his parents' home for the 6 to 12 weeks of convalescence prescribed by his physician. His renal function gradually returns to normal with no further azotemia and minimal proteinuria after 4 months. He verbalizes understanding of the relationship between the strep throat, his inappropriate use of antibiotics, and the glomerulonephritis. He says, "I may not always remember to take every pill on time in the future, but I sure won't save them for the next time again!"

Clinical Reasoning in Patient Care

4. What additional diagnostic studies would you anticipate should Mr. Chang's symptoms, BUN, serum creatinine, and urinalysis fail to resolve?
5. Identify important nursing responsibilities and patient teaching related to these studies.
6. The initial manifestations of acute poststreptococcal glomerulonephritis and anti-GBM glomerulonephritis are very similar. What diagnostic test would the physician use to make the differential diagnosis? Develop a plan of care for a patient undergoing this examination.

See Evaluating Your Response in Appendix B.

Intermittent catheterization is associated with a lower risk of UTI than an indwelling catheter.

- Provide a nutritionally sound diet with complete proteins. *A well-balanced, nutritionally sound diet is important to maintain nutritional status and support immune function.*
- Teach measures to prevent infection. *Care often is provided in the home, requiring the patient and family to use appropriate infection control measures.*

Ineffective Role Performance

The manifestations and treatment of glomerular disorders can affect the ability to maintain usual roles and activities. Fatigue and muscle weakness may limit physical and social activities. Activity limitations may be ordered to minimize the degree of proteinuria. If azotemia is present, malaise, nausea, and mental status changes can interfere with role function. Facial and periorbital edema affect the patient's self-esteem and may lead to isolation.

Expected Outcome: Patient will acknowledge impact of the disorder and its manifestations on ability to maintain current roles and identify strategies to meet or modify responsibilities.

- Encourage self-care and active participation in decision making. *Increased autonomy helps restore self-confidence and reduce powerlessness.*
- Provide time for verbalization of thoughts and feelings; listen actively, acknowledging and accepting fears and concerns. *Adequate time and active listening encourage expression of concerns and the effect of the disease or treatments on daily life. This helps the patient deal with the illness, its treatment, and associated losses.*
- Support coping skills, helping the patient identify personal strengths. *This support helps the patient gain confidence.*
- When possible, enlist the support of family, other patients, and friends. *These people can provide physical, psychologic, emotional, and social support.*

- Discuss the effect of the disease and treatments on roles and relationships, helping identify potential changes in roles, relationships, and lifestyle. Help the patient and family develop a plan for alternative behaviors and relationships, encouraging the patient to maintain usual roles to the extent possible. *Developing a plan helps reduce the strain of role changes and maintain a sense of dignity and control.*
- Evaluate the need for additional support and social services for the patient and family. Provide referrals as indicated. *Depending on patient and family strengths, the severity of the disorder, and its treatment and prognosis, ongoing social support services may be necessary to facilitate coping and adaptation.*

Delegating Nursing Care Activities

As appropriate and allowed by the designated duties and responsibilities of unlicensed assistive personnel, the nurse may delegate nursing care activities such as measuring intake and output, obtaining daily weights, assisting with ADLs, and providing for distraction and socialization for the patient with a glomerular disorder.

Continuity of Care

Glomerular disorders may be self-limited or progressive. In either case, the course is lengthy, ranging from months to years. Self-management is essential. Provide instructions for the patient and family, including the following topics:

- Information about the disease and the prognosis
- Prescribed treatment, including activity and diet restrictions; the use and potential effects, both beneficial and adverse, of all medications
- Risks, manifestations, prevention, and management of complications such as edema and infection
- Signs, symptoms, and implications of improving or declining renal function
- Measures to prevent further kidney damage, such as nephrotoxic drugs to avoid
- Community resources, such as home care providers and support groups.

THE PATIENT WITH A VASCULAR KIDNEY DISORDER

Renal function is dependent on an adequate supply of blood. Blood supports renal cell metabolism and is vital to kidney function, the nephron in particular. The kidney can regulate fluid, electrolyte, and acid–base balance and serve as a major organ of excretion only when its blood supply is sufficient.

Hypertension

Hypertension, sustained elevation of the systemic blood pressure, can result from or cause kidney disease.

Prolonged hypertension damages the walls of arterioles and accelerates the process of atherosclerosis. This damage primarily affects the heart, brain, kidneys, eyes, and major blood vessels. In the kidney, arteriosclerotic lesions develop in the *afferent* (leading into) and *efferent* (going out of) arterioles and the glomerular capillaries. The glomerular filtration rate declines and tubular function is affected, resulting in proteinuria and microscopic hematuria. In the United States, an estimated 20% of adults with hypertension have chronic kidney disease, and uncontrolled or poorly controlled hypertension is the second leading cause of chronic kidney disease (National Center for Chronic Disease Prevention and Health Promotion, 2014).

Malignant hypertension is a rapidly progressive form of hypertension that can develop in patients with untreated primary hypertension or in people with no prior history of hypertension. The diastolic pressure is in excess of 120 mmHg and may be as high as 150 to 170 mmHg. Malignant hypertension affects less than 1% of hypertensive patients; it is more common in African Americans than in people of European ancestry. Untreated, malignant hypertension causes a rapid decline in renal function due to vessel changes, renal ischemia, and infarction.

Approximately 5% to 10% of hypertensive patients have *secondary hypertension*, which is actually a manifestation of an underlying disease. Renal vascular disease and diseases of the renal parenchyma, such as diabetic nephropathy, are commonly associated with secondary hypertension.

Management of hypertension to maintain the blood pressure within an optimal range is vital to prevent kidney damage. When hypertension is secondary to kidney disease, adequate blood pressure control can slow the decline in renal function. See Chapter 32 for more information about hypertension and its management.

Renal Artery Stenosis

Renal artery stenosis (RAS), which causes about 5% of all cases of hypertension, can affect one or both kidneys. It is most often caused by atherosclerosis, particularly in older adults. The lumen of the renal artery is gradually occluded by plaque, affecting blood flow to the kidney. Atherosclerotic renovascular disease is more commonly found in people with evidence of coronary heart disease or peripheral vascular disease. In younger women, RAS is usually due to fibromuscular dysplasia, structural abnormalities of the arterial wall.

Renal artery stenosis stimulates the renin–angiotensin system as well as the sympathetic nervous system. Hypertension develops, along with flushing and significant blood pressure variations. Most patients have evidence of chronic kidney disease and significant cardiovascular risk by the time RAS is diagnosed. An epigastric bruit (murmur) and other manifestations of vascular insufficiency may also be present.

Doppler ultrasonography is used to screen for RAS. The affected kidney appears small and atrophied on renal ultrasound. Magnetic resonance angiography (MRA) and computed tomography (CT) angiography with contrast allow visualization of renal blood vessels and are used to diagnose RAS.

Conservative therapy is used for most patients with RAS. ACE inhibitors or ARBs are used along with other antihypertensive drugs to control blood pressure. Statins may be prescribed to slow atherosclerotic plaque deposition, and low-dose aspirin is used to prevent clotting within partially occluded vessels. In some cases, percutaneous transluminal angioplasty is performed to dilate the affected vessel and position a stent to maintain patency. In this procedure, a balloon-tipped catheter is inserted via the femoral artery and aorta to dilate the renal artery. While this procedure is often effective, particularly in fibromuscular dysplasia, it is not without risk, including loss of renal function.

Nursing care of the patient with RAS focuses on collaborating with the interprofessional team to achieve target blood pressures, monitoring renal function, implementing measures to preserve remaining renal function (e.g., ensuring adequate hydration, preventing urinary tract infection, and avoiding nephrotoxic medications), and teaching the patient and family about the prescribed treatment.

Renal Artery Occlusion

Renal arteries can be occluded by either a primary process affecting the renal vessels or by emboli, clots, or other foreign material. Risk factors for acute renal artery thrombosis (formation of a blood clot in the renal artery) include severe abdominal trauma, vessel trauma from surgery or angiography, aortic or renal artery aneurysms, and severe aortic or renal artery atherosclerosis. Emboli from the left side of the heart can travel via the aorta to occlude the renal artery. Emboli may form as a result of atrial fibrillation (irregular and uncoordinated electrical activity of the atria), following myocardial infarction, as vegetative growths on heart valves associated with bacterial endocarditis, or from fatty plaque in the aorta.

Renal arterial occlusion may be asymptomatic when the occlusion develops slowly and the affected vessels are small. Acute occlusion leading to ischemia and infarction typically causes sudden, severe localized flank pain, nausea and vomiting, fever, and hypertension. Hematuria and oliguria may occur. In the older patient, the new onset of hypertension or worsening of previously controlled hypertension may signal renal artery thrombosis.

Laboratory studies reveal leukocytosis (elevated WBC), and elevated renal enzyme levels, including aspartate transaminase (AST) and lactic dehydrogenase (LDH). These enzymes, normally present in renal cells, are released into the circulation when cells necrose and die. With bilateral arterial occlusion and infarction, renal function deteriorates rapidly, leading to acute kidney injury.

Surgery to restore blood flow to the affected kidney may be indicated for acute occlusion. Management usually is more conservative, using anticoagulant therapy, intrarenal fibrinolysis, hypertension control, and supportive treatment.

Renal Vein Occlusion

A thrombus (clot) formed in a renal vein can occlude the vessel. The cause of the thrombus often is unclear. In adults, renal venous thrombosis usually occurs with nephrotic syndrome. Other predisposing factors include pregnancy, oral contraceptive use, and certain malignancies.

Gradual or acute deterioration of renal function may be the only manifestation of renal vein occlusion. If the thrombus breaks loose, it can become a pulmonary embolism. The definitive diagnosis is made by visualizing the thrombus through renal venography.

Fibrinolytic drugs such as streptokinase or tissue plasminogen activator (tPA) may be given to dissolve or break up the thrombus. Anticoagulant therapy is used to prevent further clotting and pulmonary emboli. Renal function often improves with treatment.

THE PATIENT WITH KIDNEY TRAUMA

The kidneys are relatively well protected by the rib cage, back muscles, and abdominal contents, but trauma due to blunt force or penetrating injury may inflict damage. Many renal injuries heal uneventfully, but prompt diagnosis and immediate treatment can be lifesaving in the event of major damage.

Pathophysiology and Manifestations

Blunt force is the most common cause of kidney injury. Falls, motor vehicle crashes, and sports injuries can damage the kidney. Damage may occur from a direct blow, as a result of rapid acceleration/deceleration injury, or a combination. The injury may be minor, causing a contusion or small hematoma, or more serious, resulting in laceration or other damage. The kidney may fragment or "shatter," causing significant blood loss and urine extravasation. Tearing of the renal artery or vein may cause rapid hemorrhage, with shock and possible death.

Gunshot wounds, knife wounds, impalement injuries, and fractured ribs can penetrate the kidney. Minor penetrating injuries may lacerate the capsule or renal cortex. Major injuries include laceration or destruction of renal parenchyma or the vascular supply. Renal artery, renal vein, and renal pelvis lacerations are critical injuries.

The primary manifestations of kidney trauma are hematuria (gross or microscopic), flank or abdominal pain, and oliguria or anuria. There may be localized swelling, tenderness, or ecchymoses in the flank region. Retroperitoneal bleeding from the kidney may cause Turner's sign, a bluish discoloration of the flank. Signs of shock may be present, including hypotension, tachycardia, tachypnea, cool and pale skin, and an altered level of consciousness.

●○● INTERPROFESSIONAL CARE

Hemoglobin and hematocrit levels fall in significant renal injury with hemorrhage. Hematuria is typically noted on urinalysis. AST levels rise within 12 hours of significant renal trauma. Renal ultrasonography is used to diagnose bleeding and kidney damage. A CT scan with contrast may be performed to visualize renal structures and establish a definitive diagnosis.

Treatment of minor kidney injuries is generally conservative, including bed rest and observation. In these injuries, bleeding is typically minor and self-limiting. With major or critical trauma, immediate treatment focuses on controlling hemorrhage and treating or preventing shock. Surgery may be required to stop the bleeding. Major lacerations may require surgical repair, partial nephrectomy, or total **nephrectomy** (removal) of the damaged kidney.

●○● NURSING CARE

Nursing care for the patient who has experienced renal trauma focuses on timely and accurate assessment, close observation, and appropriate intervention to preserve life and prevent complications (Blair, 2011). Obtain a urine specimen for analysis when kidney trauma is suspected. Monitor level of consciousness, vital signs, skin color and temperature, and urine output for possible signs of shock.

THE PATIENT WITH A RENAL TUMOR

Renal tumors may be benign or malignant, primary or metastatic. Benign renal tumors are infrequent and are often found only on autopsy. Primary renal malignancies account for about 4% of adult cancers and approximately 13,570 deaths per year (American Cancer Society [ACS], 2012). Most primary renal tumors arise from renal

MANIFESTATIONS OF RENAL TUMORS

- Microscopic or gross hematuria
- Flank pain
- Palpable abdominal mass
- Fever
- Fatigue
- Weight loss
- Anemia or polycythemia

cells; a primary tumor may develop in the renal pelvis, although less frequently. Wilms tumor is kidney cancer of childhood, accounting for about 5% of childhood cancers (ACS, 2012). Metastatic lesions to the kidney are associated with lung and breast cancer, melanoma, and malignant lymphoma.

Males are affected by renal cancer more than females by a 2:1 ratio. The highest incidence is seen in people over the age of 55 years. Smoking and obesity are risk factors, as are hypertension and occupational exposure to certain chemicals. Some renal cancers are associated with genetic factors. Patients with ESRD may also develop renal cancer.

Pathophysiology and Manifestations

Most (92%) primary renal tumors are renal cell carcinomas (ACS, 2012). These tumors arise from tubular epithelium and can occur anywhere in the kidney. The tumor, which can range in size up to several centimeters, has clearly defined margins and contains areas of ischemia, necrosis, and hemorrhage. Renal tumors tend to invade the renal vein, and often have metastasized when first identified. Metastases tend to occur in the lungs, bone, lymph nodes, liver, and brain.

Renal tumors are often silent, with few manifestations. The classic triad of symptoms, gross hematuria, flank pain, and a palpable abdominal mass, is seen in only about 10% of people with renal cell carcinoma. Hematuria, often microscopic, is the most consistent symptom. Systemic manifestations include fever without infection, fatigue, and weight loss. See the accompanying Manifestations box.

The tumor may produce hormones or hormone-like substances, including parathyroid hormone, prostaglandins, prolactin, renin, gonadotropins, and glucocorticoids. These substances produce *paraneoplastic syndromes*, with additional manifestations such as hypercalcemia, hypertension, and hyperglycemia. The progression of renal cell carcinomas varies from prolonged periods of stable disease to very aggressive. Table 28–4 outlines the staging and prognosis for renal cell cancers.

TABLE 28–4 Renal Cell Cancer Staging

Stage	Extent of Tumor
I	Confined to the kidney capsule
II	Invasion through the capsule but confined to local fascia
III	Regional lymph node, ipsilateral renal vein, or inferior vena cava involvement
IV	Locally invasive or distant metastases

Source: Adapted from Longo, D., et al. (Eds.). (2012). *Harrison's principles of internal medicine* (18th ed.). New York, NY: McGraw-Hill Medical.

●○● INTERPROFESSIONAL CARE

Hematuria is often the only initial manifestation of renal cancer; its presence indicates a need for further diagnostic studies, including the following:

- *Renal ultrasonography* to detect renal masses and differentiate cystic kidney disease from renal carcinoma.
- *CT scan* of the abdomen and pelvis to determine tumor density, local extension of the tumor, and regional lymph node or vascular involvement (Figure 28–3 ■).
- *Chest x-ray*, *bone scan*, *MRI*, and *liver function studies* to identify potential metastases.

Radical nephrectomy is the treatment of choice for stage I or II kidney tumors. In a radical nephrectomy, the adrenal gland, upper ureter, fat and fascia surrounding the kidney, and the entire kidney are removed. Regional lymph nodes may also be resected. Although nephrectomy can be done using a laparoscopic approach, laparotomy primarily is used for radical nephrectomy. See the Nursing Care box on page 793 for care of the patient having a nephrectomy.

No chemotherapy drug consistently causes tumor regression in patients with advanced renal carcinoma. Sunitinib (Sutent), sorafenib (Nexavar), and pazopanib (Votrient) are orally administered antiangiogenesis agents (drugs that inhibit new blood vessel formation) used as first-line treatment for advanced renal cancer. Interferon-α and interleukin-2 have led to prolonged remission in a small proportion of patients, and may be used. Targeted therapy with monoclonal antibodies may be used, but is associated with significant adverse effects (Scher & Motzer, 2012; Wells et al., 2012).

●○● NURSING CARE

Diagnoses, Outcomes, and Interventions

Nursing care for the patient with renal cancer focuses on needs related to the cancer diagnosis and to the surgical intervention.

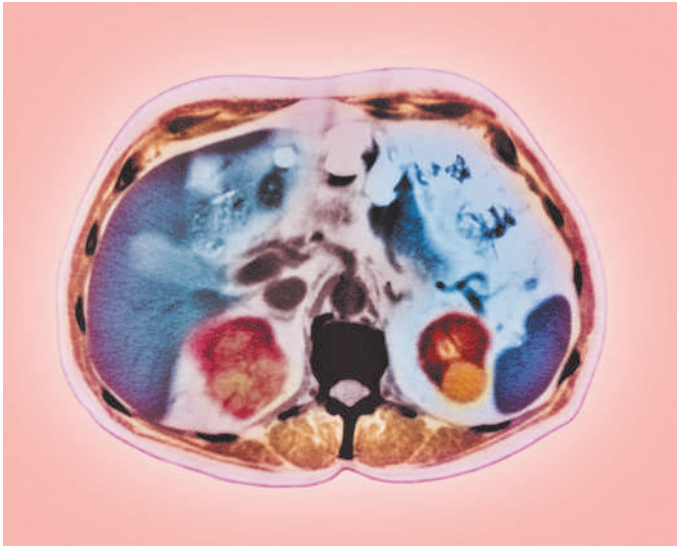

Figure 28–3 ■ A tumor of the right kidney is seen in the lower left of this color CT scan of the abdomen. The front of the body is at top in this view; the two kidneys (dark red) are seen either side of the spine (black, lower center). The tumor distorts the shape of the right kidney. The well-defined orange mass in the left kidney is a cyst.

NURSING CARE OF THE PATIENT

Having a Nephrectomy

PREOPERATIVE CARE

- Provide routine preoperative care.
- Report abnormal laboratory values to the surgeon. *Bacteriuria, blood coagulation abnormalities, or other significant abnormal values may affect surgery and postoperative care.*
- Discuss operative and postoperative expectations as indicated, including the location of the incision (refer to Figure 28–4) and anticipated tubes, stents, and drains. *Preoperative teaching about postoperative expectations reduces anxiety for the patient and family during the early postoperative period.*

POSTOPERATIVE CARE

- Provide routine postoperative care.
- Frequently assess urine color, amount, and character, noting any hematuria, pyuria, or sediment. Promptly report oliguria or anuria, as well as changes in urine color or clarity. *Preserving function of the remaining kidney is critical; frequent assessment allows early intervention for potential problems.*
- Note the placement, status, and drainage from ureteral catheters, stents, nephrostomy tubes, or drains. Label each clearly. Maintain gravity drainage; irrigate only as ordered. *Maintaining drainage tube patency is vital to prevent potential hydronephrosis. Bright bleeding or unexpected drainage may indicate a surgical complication.*
- Support the grieving process and adjustment to the loss of a kidney. *Loss of a major organ leads to a body image change and grief response. When renal cancer is the underlying diagnosis, the patient may also grieve the loss of health and potential loss of life.*
- Provide the following home care instructions for the patient and family:
  a. The importance of protecting the remaining kidney by preventing UTI, renal calculi, and trauma. See Chapter 27 for measures to prevent UTI and calculi. *Damage to the remaining kidney by UTI, renal calculi, or trauma can lead to renal failure.*
  b. Maintain a fluid intake of 2000 to 2500 mL/day. *This important measure helps prevent dehydration and maintain good urine flow.*
  c. Gradually increase exercise to tolerance, avoiding heavy lifting for a year after surgery. Participation in contact sports is not recommended to reduce the risk of injury to the remaining kidney. *Lifting is avoided to allow full tissue healing. Trauma to the remaining kidney could seriously jeopardize renal function.*
  d. Care of the incision and any remaining drainage tubes, catheters, or stents. *This routine postoperative instruction is vital to prepare the patient for self-care and prevent complications.*
  e. Report unexpected signs and symptoms to the physician, including manifestations of UTI (dysuria, frequency, urgency, nocturia, or cloudy, malodorous urine) or systemic infection (fever, general malaise, or fatigue), redness, swelling, pain, or drainage from the incision or any catheter or drain tube site. *Prompt treatment of postoperative infection is vital to allow continued healing and prevent compromise of the remaining kidney.*

Postoperative pain may be significant and the risk for respiratory complications is high. The remaining kidney must be protected from damage to preserve renal function. Psychologically, the patient may grieve the loss of a major organ and the diagnosis of cancer.

Acute Pain

The size and location of the incision used for a radical nephrectomy (Figure 28–4 ■) make pain management a challenge. Intercostal blocks, patient-controlled analgesia (PCA), or routine analgesic administration can effectively relieve the discomfort. Nursing care

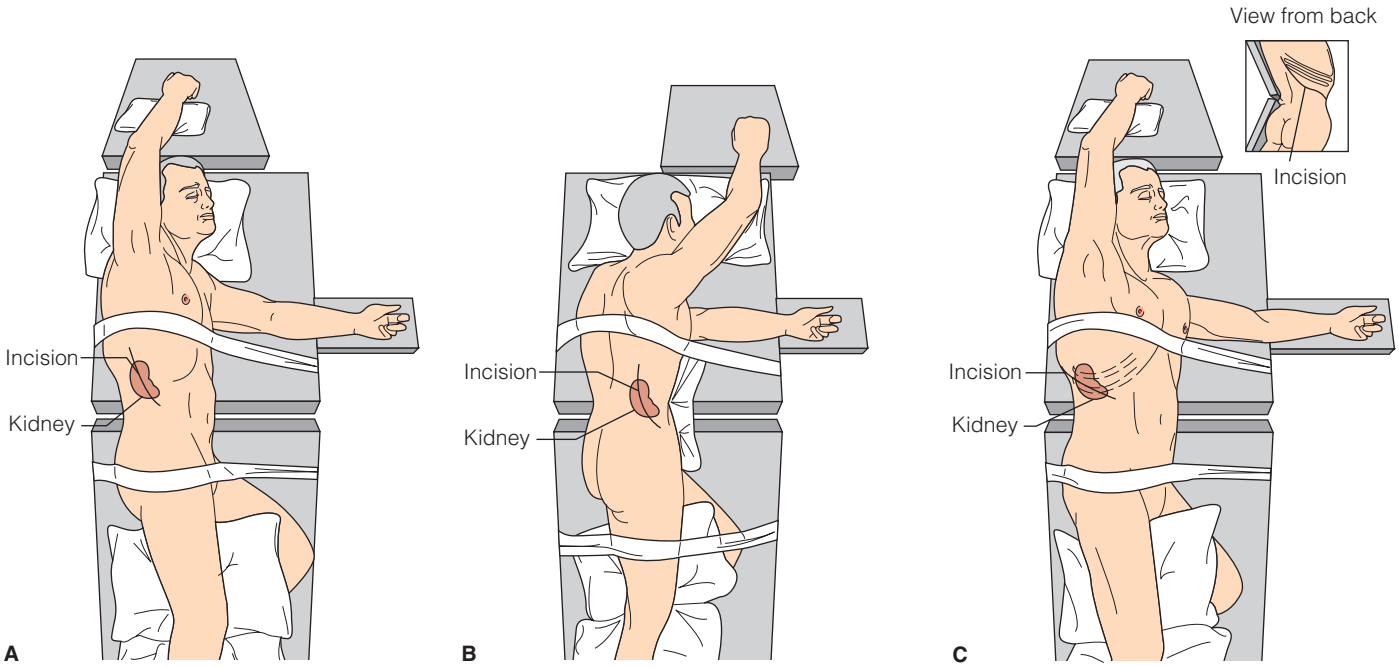

Figure 28–4 ■ Incisions used for kidney surgery: A, flank; B, lumbar; and C, thoracoabdominal.

focuses on assessing pain relief, providing supportive measures to enhance analgesia, and ensuring that pain or the fear of pain does not lead to respiratory complications.

Expected Outcome: Patient will report and manage pain within an acceptable range.

- Assess frequently for adequate pain relief. Use a standard pain scale and nonverbal signs such as grimacing, tense body position, apparent dozing, elevated pulse, change of blood pressure, or rapid, shallow respirations. Notify the physician of inadequate pain relief. *The patient may assume that pain is to be expected or may fear becoming addicted to analgesics. Careful questioning and assessment allow effective pain management. Responses to analgesics are individual, and the prescribed dose may need to be adjusted.*
- Assess the incision for inflammation or swelling and drainage catheters and tubes for patency. *An obstructed catheter can lead to hydronephrosis, hematoma, or abscess, increasing incisional pain.*
- Assess for abdominal distention, tenderness, and bowel sounds. *Intra-abdominal bleeding, peritonitis, or paralytic ileus can cause pain that may be confused with incisional pain.*
- Use adjunctive pain relief measures such as positioning, diversional activities, management of environmental stimuli, guided imagery, and relaxation techniques. *These can enhance the effects of analgesia.*

Ineffective Breathing Pattern

The location of the incision combined with the respiratory depressant effects of narcotic analgesics increases the risk for respiratory complications in the patient who has had a nephrectomy.

Expected Outcome: Patient will maintain open airways and effective ventilation.

- Position to promote respiratory excursion, using semi-Fowler's position and side-lying positions as allowed and tolerated. *Lung expansion is improved in semi-Fowler's and Fowler's positions.*

PRACTICE ALERT!

Pneumothorax on the operative side is common. Assess respiratory status frequently, including rate and depth, cough, breath sounds, oxygen saturation, and temperature. Early identification and intervention can prevent major respiratory complications.

- Change position frequently; ambulate as soon as possible. *These measures promote lung expansion and the movement of mucus out of airways.*
- Encourage frequent (every 1 to 2 hours) deep breathing, spirometer use, and coughing. Assist to splint the incision. *These measures promote alveolar ventilation, gas exchange, and airway clearance.*

Risk for Impaired Urinary Elimination

Surgery involving the urinary tract increases the risk for altered renal function and urine elimination. In addition, removal of one kidney dictates extra caution to maintain renal circulation, a sterile urinary tract, and free urine flow.

Expected Outcome: Patient's urinary output and fluid balance will remain within normal ranges without evidence of infection or compromised renal function.

- Monitor vital signs, central venous pressure (CVP), and urine output every 1 to 2 hours initially, then every 4 hours. *Hypovolemia due to hemorrhage, diuresis, or fluid sequestering (third spacing) reduces blood flow to the kidney and increases the risk of renal ischemia with possible acute tubular necrosis and acute kidney injury.*
- Frequently assess the amount and nature of drainage on surgical dressings and from drainage tubes, stents, and catheters. Measure and record output from each drain or catheter separately. *Frequent and accurate assessment of drainage helps to identify excess bleeding, abnormal fluid loss, infection, or other potential surgical complications.*

SAFETY ALERT

Prevent kinking, twisting, or tension on drains and tubes. Do not clamp. Irrigate carefully and only with a physician's order. Notify the physician immediately if any tube becomes dislodged. It is vital to maintain the patency of drains, particularly any affecting the remaining kidney, to prevent the excess pressure of hydronephrosis.

- Maintain fluid intake with intravenous fluids until oral intake is resumed. Encourage an intake of 2000 to 2500 mL/day as soon as the patient tolerates oral liquids. *A liberal fluid intake prevents dehydration, helps to dilute any nephrotoxic substances, and promotes good urinary output.*
- Use strict aseptic technique in caring for all urinary catheters, tubes, stents, drains, and incisions. *Asepsis is vital to prevent infection and possible compromise of the remaining kidney.*
- Following catheter removal, assess frequently for urinary retention. Notify the physician if the patient is unable to void within 4 to 6 hours or if manifestations of retention (distended bladder, discomfort, urinary dribbling) develop. *Maintenance of urine output is vital to prevent stasis and possible complications such as infection and hydronephrosis.*
- Monitor laboratory results, including urinalysis, BUN, serum creatinine, and serum electrolytes. Report abnormal findings to the physician. *Abnormal values may indicate early acute renal failure; prompt intervention is necessary to preserve renal function.*

Grieving

The patient having a radical nephrectomy for renal cancer not only loses a major organ but also has to adjust to the diagnosis of cancer. Although the prognosis for recovery may be good, many people perceive cancer as always fatal. Providing support for the patient and family during the initial stages of grieving can improve physical recovery, psychologic coping, and eventual adaptation.

Expected Outcome: Patient will verbalize thoughts, feelings, fears and concerns about loss.

- Work to develop a trusting relationship with the patient and family members. *Trust increases the nurse's effectiveness in helping them work through the process of grieving.*
- Listen actively, encouraging the patient and family to express fears and concerns. *As they begin to express their concerns, patient and family members can begin to deal more effectively with them.*
- Assist the patient and family members to identify strengths, past experiences, and support systems. *These resources can be employed when working through the grieving process.*

- Demonstrate respect for cultural, spiritual, and religious values and beliefs; encourage use of these resources to cope with losses. *Value and belief systems can provide a structure and form for dealing with the grieving process.*
- Encourage discussion of the potential impact of loss on the patient and the family structure and function. Assist family members to share concerns with one another. *Sharing of fears and concerns among family members promotes involvement and support of the entire family unit so that the individual is not left to cope alone.*
- Refer to cancer support groups, social services, or counseling as appropriate. *Support groups and counseling services provide additional resources for coping.*

Delegating Nursing Care Activities

As appropriate and allowed by the designated duties and responsibilities of unlicensed assistive personnel, the nurse may delegate nursing care activities such as measuring intake and output, obtaining vital signs, encouraging use of an incentive spirometer, and assisting with ambulation and ADLs for the patient with renal cancer.

Continuity of Care

If renal cancer was detected at an early stage and cure is anticipated, teaching for home care focuses on protecting the remaining kidney. Include the following measures to prevent infection, renal calculi, hydronephrosis, and trauma:

- Maintain a fluid intake of 2000 to 2500 mL/day, increasing the amount during hot weather or strenuous exercise.
- Urinate when the urge is perceived, and before and after sexual intercourse.
- Properly clean the perineal area.
- Watch for manifestations of UTI and understand the importance of early and appropriate evaluation and intervention.
- If the patient is an older adult male, he should watch for manifestations of prostatic hypertrophy, a major cause of urinary tract obstruction. Stress the importance of routine screening examinations.
- Avoid contact sports such as football or hockey; use measures to prevent motor vehicle crashes and falls, which could damage the remaining kidney.

Kidney Failure

Kidney failure is a condition in which the kidneys are unable to effectively remove accumulated metabolites from the blood, leading to altered fluid, electrolyte, and acid–base balance. The cause may be a primary kidney disorder, or it may occur secondary to a systemic disease or other urologic defects. The onset of kidney failure may be either acute or chronic. Acute kidney injury has an abrupt onset, and with prompt intervention is often reversible. Chronic kidney disease (CKD), which may culminate in kidney failure, develops slowly and insidiously, often producing few symptoms until the kidneys are severely damaged and unable to meet the excretory needs of the body. Acute kidney injury and the final stages of chronic kidney disease are characterized by azotemia, increased levels of nitrogenous wastes in the blood.

FAST FACTS

- Acute kidney injury is characterized by an abrupt decline in kidney function that impairs the ability to maintain fluid, electrolyte, and acid–base balance.
- Up to 7% of patients admitted to the hospital develop acute kidney injury; in critical care units, this jumps to nearly 30%.
- Kidney failure may represent the end stage of chronic kidney disease. It is irreversible; renal replacement therapies (transplant or dialysis) are necessary to sustain life.
- An estimated 10% of adults (more than 20 million) in the United States have chronic kidney disease that may ultimately lead to renal failure (NKUDIC, 2012).
- Kidney failure is characterized by azotemia, accumulation of nitrogenous (protein) waste products in the blood.

Kidney failure is common and costly. In 2009, more than 398,800 patients with ESRD were being treated with dialysis and approximately 172,500 had a functioning kidney transplant. The annual cost of ESRD treatment (in 2009 dollars) is over $40 billion. The cost is also measured in lives and lifestyle. The 5-year survival rate for patients undergoing dialysis is 35.8%. Although many patients report satisfaction with their quality of life, often patients on dialysis are unable to work, and the family structure may disintegrate under the strain of treatment. Kidney transplant improves both survival (85.5% at 5 years) and quality of life (NKUDIC, 2012).

THE PATIENT WITH ACUTE KIDNEY INJURY

Acute kidney injury (AKI), also known as *acute renal failure* (*ARF*), is a rapid decline in renal function with azotemia and fluid and electrolyte imbalances. Serum creatinine and/or BUN values significantly increase over hours to days in AKI, and the urine output often falls (Lewington & Kanagasundaram, 2011; Waikar & Benventre, 2012). The most common causes of acute kidney injury are ischemia, sepsis, and nephrotoxins. The kidney is particularly vulnerable because of the amount of blood that passes through it. A fall in blood pressure or volume can cause ischemia of kidney tissues. Sepsis also produces hemodynamic effects with generalized vasodilation and a fall in GFR. Nephrotoxins in the blood damage renal tissue directly.

Incidence and Risk Factors

Approximately 5% to 7% of all hospitalized patients develop acute kidney injury; the incidence jumps to as much as 30% in critical and special care units (Waikar & Bonventre, 2012). The mortality rate for AKI in seriously ill patients is 40% to 90% (Dirkes, 2011). This high death rate is probably more related to the populations affected by AKI—older patients and the critically ill—than to the disorder itself (Grossman & Porth, 2014).

Major trauma or surgery, infection and sepsis, hemorrhage, severe heart failure, severe liver disease, and urinary tract obstruction are risk factors for AKI. Drugs and radiologic contrast media that are

toxic to the kidney (*nephrotoxic*) also increase the risk for AKI. Older adults develop AKI more frequently due to their higher incidence of serious illness, major surgeries, and treatment with nephrotoxic drugs. The older adult also may have some degree of preexisting renal insufficiency associated with aging.

Physiology Review

The functional unit of the kidneys, the nephron, produces urine through three processes: glomerular filtration, tubular reabsorption, and tubular secretion. In the glomerulus, a filtrate of water and small solutes is formed. The solute concentration of this filtrate is equal to that of plasma, with the exception of large molecules such as plasma proteins and blood cells. The GFR, the amount of filtrate formed per minute, is affected by blood volume and pressure, the autonomic nervous system, and other factors. From the glomerulus, the filtrate flows into the tubules, where the processes of tubular reabsorption and tubular secretion change its composition. Most water and many filtered solutes such as electrolytes and glucose are reabsorbed. Metabolic waste products such as urea, hydrogen ion, ammonia, and some creatinine are secreted into the tubule for elimination. By the time urine exits the collecting duct into the renal pelvis, 99% of the filtrate has been reabsorbed.

Pathophysiology

The causes and pathophysiology of acute kidney injury are commonly categorized as prerenal, intrinsic kidney injury, and postrenal obstruction. Prerenal AKI is the most common, accounting for about 55% of the total. In *prerenal AKI*, hypoperfusion and ischemia lead to an acute increase in serum creatinine or BUN without directly affecting the integrity of kidney tissues. *Intrinsic AKI*, due to direct damage to functional kidney tissue, is responsible for another 40%. Urinary tract obstruction with resulting kidney damage is the precipitating factor for *postrenal AKI*, the least common form (~5%). Table 28–5 summarizes the causes of acute kidney injury. See Pathophysiology Illustrated: Acute Kidney Injury on page 797.

PRERENAL AKI

Prerenal AKI results from conditions that affect renal blood flow and perfusion. Any disorder that significantly decreases vascular volume, cardiac output, or systemic vascular resistance can affect renal blood flow. The kidneys normally receive 20% to 25% of the cardiac output to maintain the GFR. A drop in renal blood flow to less than 20% of normal causes the GFR to fall. As the filtration of substances by the glomeruli is reduced, less reabsorption of substances in the tubule is required. As a result, kidney cells require less energy and oxygen, and their metabolism slows. Prerenal AKI is rapidly reversed when blood flow is restored, and the renal parenchyma remains undamaged. Continued ischemia can lead to tubular cell necrosis and significant nephron damage. Intrinsic AKI due to ischemic injury may result.

MEMORY CUE

- Prerenal AKI is common, particularly in trauma, surgical, and critically ill patients.
- Restoration of blood pressure and blood flow to the kidneys rapidly reverses prerenal AKI.
- If not promptly identified and treated, prerenal AKI leads to ischemic acute tubular necrosis and intrinsic AKI.

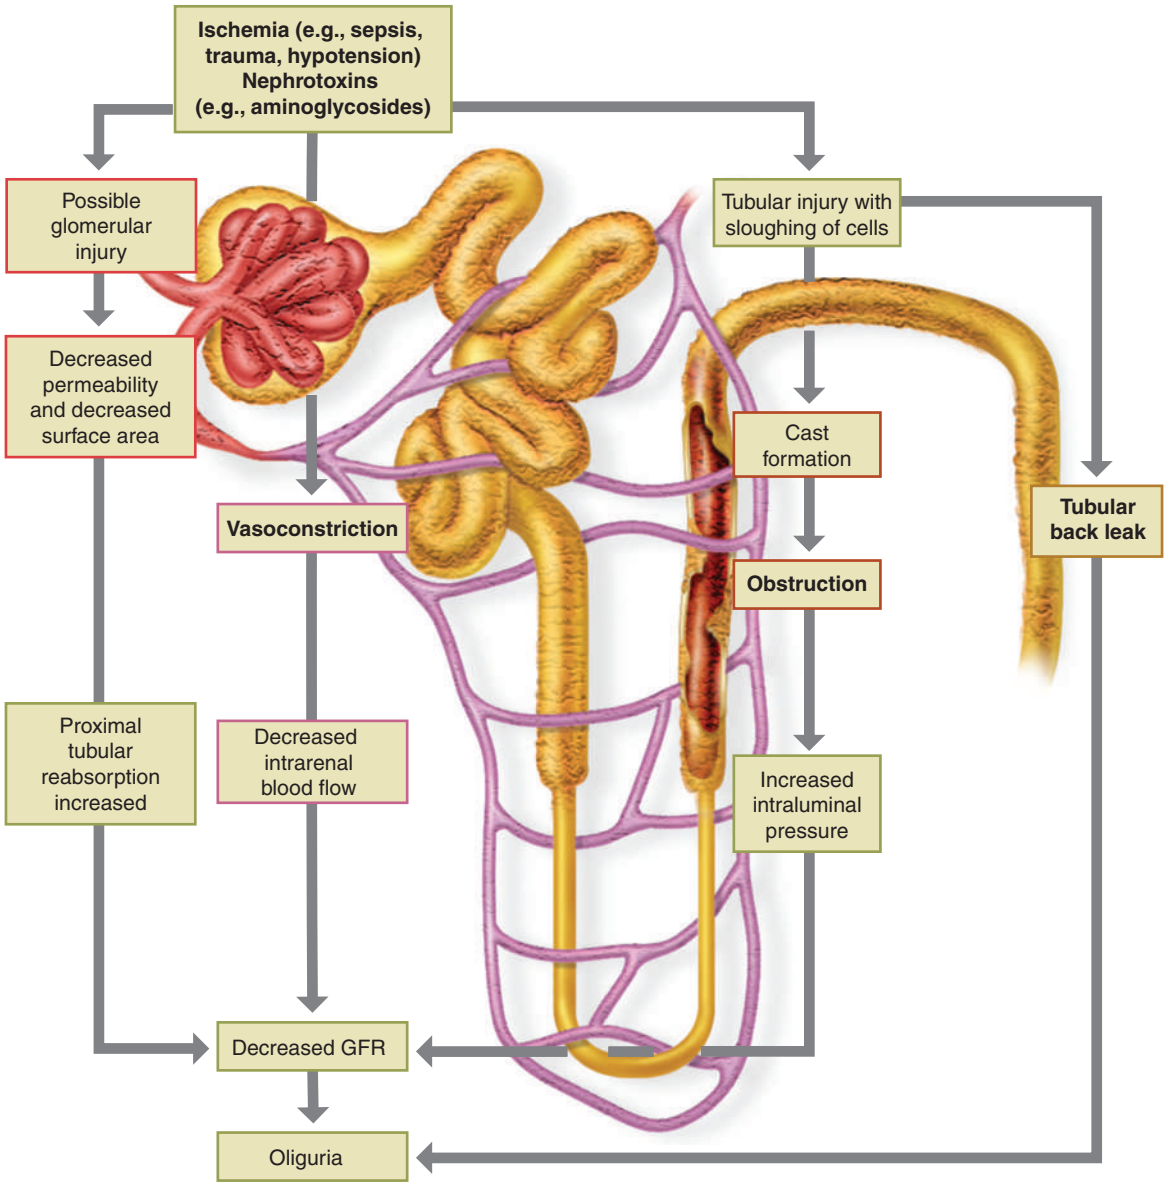
POSTRENAL AKI

Obstructive causes of acute renal failure are classified as postrenal. Any condition that prevents urine excretion can lead to postrenal AKI. Benign prostatic hypertrophy is the most common precipitating factor. Others include renal or urinary tract calculi and tumors. See Chapter 27 for more information about kidney stones.

INTRINSIC AKI

Intrinsic acute kidney injury is characterized by acute damage to the renal parenchyma and nephrons. Sepsis, ischemia, and nephrotoxins are the most common causes of intrinsic AKI. Less commonly, infectious diseases or immunologic disorders can cause intrinsic AKI. In acute glomerulonephritis, glomerular inflammation can reduce renal blood flow and cause AKI.

ACUTE TUBULAR NECROSIS Nephrons are especially susceptible to injury from ischemia or exposure to nephrotoxins. **Acute tubular necrosis (ATN)**, destruction of tubular epithelial cells, causes an abrupt and progressive decline of renal function. Prolonged ischemia is the primary cause of ATN. When ischemia and nephrotoxin exposure occur concurrently, the risk for ATN and tubular dysfunction is especially high. Risk factors for ischemic ATN include major surgery, severe hypovolemia, sepsis, trauma, and burns. The impact of ischemia resulting from vasodilation and fluid loss in sepsis, trauma, and burns often is compounded by toxins released by bacteria or from damaged tissue.



Ischemia lasting more than 2 hours causes severe and irreversible damage to kidney tubules with patchy cellular necrosis and

TABLE 28–5 Causes of Acute Kidney Injury

	Cause	Examples
Prerenal	Hypovolemia	Hemorrhage, dehydration, excess fluid loss from GI tract, burns, wounds
	Low cardiac output	Heart failure, cardiogenic shock
	Altered vascular resistance	Sepsis, anaphylaxis, vasoactive drugs
Intrarenal	Glomerular/microvascular injury	Glomerulonephritis, disseminated intravascular coagulation (DIC), vasculitis, hypertension, toxemia of pregnancy, hemolytic uremic syndrome
	Acute tubular necrosis	Ischemia due to conditions associated with prerenal AKI; toxins such as drugs, heavy metals; hemolysis, rhabdomyolysis (muscle cell breakdown)
	Interstitial nephritis	Nephrotoxic drugs, infectious diseases, immunologic disorders, idiopathic
Postrenal	Ureteral obstruction	Calculi, cancer, external compression
	Urethral obstruction	Prostatic enlargement, calculi, cancer, stricture, blood clot

PATHOPHYSIOLOGY ILLUSTRATED

Acute Kidney Injury

sloughing. The GFR is significantly reduced as a result of (1) ischemia, (2) activation of the renin–angiotensin system, and (3) tubular obstruction by cellular debris, which raises the pressure in the glomerular capsule.

Sepsis affects blood flow and perfusion of the kidneys. Furthermore, sepsis may cause interstitial edema and inflammatory damage to renal tubular cells.

Common nephrotoxins associated with ATN include radiologic contrast agents, the aminoglycoside antibiotics, and amphotericin B. Many other drugs (e.g., NSAIDs and some chemotherapy drugs), heavy metals such as mercury and gold, and some common chemicals such as ethylene glycol (antifreeze) are potentially toxic to the renal tubule. The risk for ATN is higher when nephrotoxic drugs are given to older patients or patients with preexisting renal insufficiency, and when used in combination with other nephrotoxins. Dehydration increases the risk by increasing the toxin concentration in nephrons.

Nephrotoxins destroy tubular cells by both direct and indirect effects. As tubular cells are damaged and lost through necrosis and sloughing, the tubule becomes more permeable. This increased permeability results in filtrate reabsorption, further reducing the ability of the nephron to eliminate wastes.

Rhabdomyolysis caused by release of excess myoglobin from injured skeletal muscles can cause ATN. Myoglobin is a protein that acts as the oxygen reservoir for muscle fibers, much as hemoglobin does for the blood. Muscle trauma, strenuous exercise, hyperthermia or hypothermia, drug overdose, infection, and other factors can precipitate rhabdomyolysis. The myoglobin clogs renal tubules causing ischemic injury, and contains an iron pigment that directly damages the tubules. *Hemolysis*, red blood cell destruction, releases hemoglobin

into the circulation with much the same effect as rhabdomyolysis. In tumor lysis syndrome, uric acid released from tumor cells destroyed by chemotherapy precipitates in the renal tubules, causing AKI.

Course and Manifestations

The course of acute kidney injury due to ATN typically includes three phases: initiation, maintenance, and recovery.

INITIATION PHASE

The initiation phase may last hours to days, and may be seen as a continuum from prerenal azotemia to intrinsic AKI (Lerma, 2011a). It begins with the initiating event (e.g., hemorrhage) and ends when tubular injury occurs. If AKI is recognized and the initiating event is effectively treated during this phase, the prognosis is good. The initiation phase of AKI has few symptoms; in fact, it is often identified only when manifestations of the maintenance phase develop.

MAINTENANCE PHASE

The maintenance phase of AKI is characterized by a significant fall in GFR and tubular necrosis. Oliguria may develop, and the kidney cannot efficiently eliminate metabolic wastes, water, electrolytes, and acids from the body during this phase. Azotemia, fluid retention, electrolyte imbalances, and metabolic acidosis develop. These abnormalities are more severe in the oliguric patient than in the nonoliguric one, leading to a poorer prognosis with oliguria.

During the maintenance phase, salt and water retention cause edema, increasing the risk for heart failure and pulmonary edema. Retained fluid can result in lower serum creatinine levels, delaying recognition of worsening AKI (Bagshaw & Wald, 2011). Impaired potassium excretion leads to hyperkalemia. When the serum potassium level is greater than 6.0 to 6.5 mEq/L, manifestations of its effect on neuromuscular function develop. These include muscle weakness, nausea and diarrhea, electrocardiographic changes, and possible cardiac arrest. Other electrolyte imbalances include hyperphosphatemia and hypocalcemia. Metabolic acidosis results from impaired hydrogen ion elimination by the kidneys.

Erythropoietin secretion by the kidneys is suppressed in AKI, causing anemia to develop after several days. Immune function may be impaired, increasing the risk for infection. Other manifestations of the maintenance phase include the following:

- Edema and hypertension due to salt and water retention
- Confusion, disorientation, agitation or lethargy, hyperreflexia, and possible seizures or coma due to azotemia and electrolyte and acid–base imbalances
- Anorexia, nausea, vomiting, and decreased or absent bowel sounds
- Uremic syndrome if AKI is prolonged (see the section on chronic kidney disease later in this chapter).

RECOVERY PHASE

The recovery phase of ATN is characterized by a process of tubule cell repair and regeneration and gradual return of the GFR to normal or pre-AKI levels. Diuresis may occur as the nephrons and GFR recover, and retained salt, water, and solutes are excreted. Serum creatinine, BUN, potassium, and phosphate levels remain high and may continue to rise in spite of increasing urine output. Renal function improves rapidly during the first 5 to 25 days of the recovery phase, and continues to improve for up to 1 year.

Complications

Although mild AKI may be asymptomatic, AKI can have significant effects on the kidneys' excretory and regulatory functions. Uremia, accumulation of toxic waste products in the body, affects multiple organs and body functions, including mental status. Uremia is discussed in depth in a later section on chronic kidney disease. Fluid, electrolyte, and acid–base balance are disrupted, with initial hypervolemia, hyperkalemia, and metabolic acidosis. Hypovolemia may develop during the diuretic phase of AKI. Other potential complications include infections, bleeding, cardiac complications (such as dysrhythmias and pericarditis), and malnutrition (Waikar & Bonventre, 2012).

●○● INTERPROFESSIONAL CARE

Preventing acute kidney injury is a goal in caring for all patients, especially those in high-risk groups. Maintaining an adequate vascular volume, cardiac output, and blood pressure is vital to preserve kidney perfusion. Nephrotoxic drugs are avoided whenever possible. When a nephrotoxic drug or substance must be used, the risk of AKI can be reduced by using the minimum effective dose, maintaining hydration, and eliminating other known nephrotoxins from the medication regimen.

Treatment goals for acute kidney injury are to (1) identify and correct the underlying cause, (2) prevent additional kidney damage, (3) restore the urine output and kidney function, and (4) compensate for renal impairment until kidney function is restored.

STAGING

Staging is used to guide treatment decisions for patients with AKI. Two systems are currently in use for staging AKI: the RIFLE and AKIN criteria (Kidney Disease: Improving Global Outcomes [KDIGO] Acute Kidney Injury Work Group, 2012; Lerma, 2011b)). Both systems use serum creatinine and urine output to determine the severity of AKI; the GFR may be used to determine the RIFLE class (Table 28–6).

DIAGNOSIS

Diagnostic tests are used to identify the cause of acute kidney injury and monitor its effects on homeostasis:

- *Urinalysis* often shows the following abnormal findings in acute kidney injury:
  a. A fixed specific gravity of 1.010 (equal to the specific gravity of plasma) because the tubules are unable to concentrate the filtrate
  b. Proteinuria, which may be significant if glomerular damage is the cause of AKI
  c. The presence of RBCs (due to glomerular dysfunction), WBCs (related to inflammation), and renal tubular epithelial cells (indicating ATN)
  d. Cell casts, which are protein and cellular debris molded in the shape of the tubular lumen. In AKI, red and white blood cells and renal tubular epithelial casts may be present. Brownish pigmented casts and positive tests for occult blood indicate hemoglobinuria or myoglobinuria.
- *Serum creatinine*, *BUN*, *BUN/creatinine ratio*, and *eGFR* are used to evaluate renal function. In AKI, serum creatinine levels increase rapidly, within 24 to 48 hours of the onset. The BUN/creatinine ratio is reduced, and the eGFR falls in AKI. Creatinine levels generally peak within 5 to 10 days. Creatinine and BUN levels tend to

TABLE 28–6 Acute Kidney Injury Staging Criteria

AKIN Stage	RIFLE Class	Serum Creatinine	Urine Output
Stage 1	Risk	Increased 1.5× (150%) from baseline	Less than 0.5 mL/kg/h for more than 6 h
Stage 2	Injury	Increased 2× (200%) from baseline	Less than 0.5 mL/kg/h for more than 12 h
Stage 3	Failure	Increased 3× (300%) from baseline	Less than 0.3 mL/kg/h for 24 h or anuria for 12 h
	Loss		Persistent acute renal failure: complete loss of kidney function for more than 4 weeks
	End-stage kidney disease		Complete loss of kidney function for more than 3 months

Source: Adapted from Kidney Disease: Improving Global Outcomes (KDIGO) Acute Kidney Injury Work Group. (2012). KDIGO Clinical Practice Guideline for Acute Kidney Injury. *Kidney International, 2*(Suppl. 2012), 1–138; and Lerma, E. (2011b). RIFLE classification system for acute kidney injury. *Medscape Reference: Drugs, Diseases & Procedures*. Retrieved from http://emedicine.medscape.com/article/1925597-overview.

increase more slowly when urine output is maintained. The onset of recovery is marked by a halt in the rise of the serum creatinine and BUN.

- *Serum electrolytes* are monitored to evaluate the fluid and electrolyte status. The serum potassium rises at a moderate rate and is often used to indicate the need for dialysis. Hyponatremia is common, due to the water excess associated with AKI.
- *Arterial blood gases* often show a metabolic acidosis due to the kidneys' inability to adequately eliminate metabolic wastes and hydrogen ions.
- *CBC* shows reduced RBCs, moderate anemia, and a low hematocrit. AKI affects erythropoietin secretion and RBC production. Iron and folate absorption may also be impaired, further contributing to anemia.

Laboratory findings associated with kidney disease are summarized in Table 28–2 earlier in this chapter.

- *Renal ultrasonography* is used to identify obstructive causes of renal failure, and to differentiate acute kidney injury from end-stage chronic kidney disease. In AKI, the kidneys may be enlarged, whereas they typically appear small and shrunken in chronic kidney disease.
- *CT scan* or *MRI* may be done to evaluate kidney size and identify possible obstructions.
- *Kidney biopsy* may be necessary to differentiate between AKI and chronic renal failure.

MEDICATIONS

The primary focus in drug management for acute kidney injury is to restore and maintain renal perfusion and to eliminate drugs that are nephrotoxic from the treatment regimen.

Intravenous fluids and blood volume expanders are given as needed to restore renal perfusion. Dopamine (Intropin) may be administered in low doses by intravenous infusion, to increase renal blood flow. Alternately, norepinephrine (Levarterenol, Noradrenaline), a vasopressor and cardiac inotrope, may be used. Fenoldopam (Corlopam), a rapid-acting vasodilator that increases renal blood flow, may be used to prevent AKI in critically ill patients (Wells et al., 2012). Atrial natriuretic peptide (ANP) in low doses has been shown to reduce the need for dialysis and shorten the length of hospitalization in patients with AKI (Nigwekar et al., 2009).

If restoration of renal blood flow does not improve urinary output, a loop diuretic such as furosemide (Lasix) or an osmotic diuretic such as mannitol may be given with intravenous fluids to help manage fluid overload. A combination of a loop diuretic and a thiazide diuretic may be used in patients who fail to respond to a loop or osmotic diuretic.

Aggressive hypertension management limits renal injury when AKI is associated with disorders such as toxemia and pregnancy-induced hypertension. ACE inhibitors, ARBs, or other antihypertensive medications are used to control arterial pressures.

All drugs that are either directly nephrotoxic or that may interfere with renal perfusion (such as potent vasoconstrictors) are discontinued. NSAIDs, nephrotoxic antibiotics such as the aminoglycosides, and other potentially harmful drugs (e.g., contrast media) are avoided throughout the course of acute kidney injury.

The patient with AKI has an increased risk of gastrointestinal bleeding, probably related to the stress response and impaired platelet function. Regular doses of antacids, histamine H_2-receptor antagonists (e.g., famotidine or ranitidine), or a proton-pump inhibitor such as omeprazole (Prilosec) are often ordered to prevent GI hemorrhage.

Hyperkalemia may require active intervention as well as restricted potassium intake. Serum levels greater than 6.5 mEq/L are treated to prevent cardiac effects of hyperkalemia. With significant hyperkalemia, calcium chloride, bicarbonate, and insulin and glucose may be given intravenously to reduce serum potassium levels by moving potassium into the cells. Nebulized albuterol, a β_2-agonist, may be used in combination with insulin and glucose to reduce serum potassium levels. A potassium-binding exchange resin such as sodium polystyrene sulfonate (Kayexalate, SPS Suspension) may be given orally or by enema. This agent removes potassium from the body by exchanging sodium for potassium, primarily in the large intestine. Aluminum hydroxide (AlternaGEL, Amphojel, Nephrox), an antacid, is used to control hyperphosphatemia in renal failure. It binds with phosphates in the GI tract, which are then excreted in the feces.

Because many drugs are eliminated from the body by the kidney, drug dosages may need to be adjusted. Doses within the usual range can lead to potentially toxic blood levels, because their elimination is slowed and half-life prolonged. Nursing implications for medications commonly prescribed for the patient with AKI are summarized in the Medication Administration box on page 800.

FLUID MANAGEMENT

Once vascular volume and renal perfusion are restored, fluid intake is usually restricted. The allowed daily fluid intake is calculated by allowing 500 to 800 mL for insensible losses (respiration, perspiration,

MEDICATION ADMINISTRATION

The Patient with Acute Kidney Injury

LOOP DIURETICS

bumetanide (Bumex)

ethacrynic acid (Edecrin)

furosemide (Lasix)

torsemide (Demadex)

The loop diuretics, named for their primary site of action in the loop of Henle, are highly effective diuretics used to manage hypervolemia in AKI. Loop diuretics may be given with intravenous dopamine to promote renal blood flow. In ATN due to a nephrotoxin, loop diuretics are used to clear the toxin from the nephrons more rapidly. Loop diuretics cause potassium wasting, which is generally not a concern in AKI because renal failure impairs normal potassium elimination.

Nursing Responsibilities

- Monitor intake and output, daily weight (or more frequently as ordered), vital signs, skin turgor, and other indicators of fluid volume status frequently.
- Assess for orthostatic hypotension because these potent diuretics can lead to hypovolemia.
- Monitor laboratory results, especially serum electrolyte, glucose, BUN, and creatinine levels.
- Administer by mouth or, if ordered, by intravenous injection or infusion.
- Assess response. Urine output typically increases within 10 minutes after intravenous administration.
- Monitor hearing and for complaints such as tinnitus. High doses of loop diuretics increase the risk of ototoxicity, especially with ethacrynic acid. These effects may be reversible if detected early and the drug is discontinued.
- Avoid administering concurrently with other ototoxic agents, such as aminoglycoside antibiotics and cisplatin.

Health Education for the Patient and Family

- Maintain fluid intake or restriction as ordered.
- Rise slowly from lying or sitting positions, because a fall in blood pressure may cause light-headedness.
- Take in the morning and, if ordered twice a day, late afternoon to avoid sleep disturbance.
- Take with food or milk to prevent gastric distress.
- NSAIDs interfere with the effectiveness of loop diuretics and should be avoided.

OSMOTIC DIURETICS

mannitol (Osmitrol, Isotol)

Osmotic diuretics act by increasing the osmotic draw in the blood and urine. In the blood, the effect is to pull extracellular water into the vascular system, increasing the GFR. These substances are then freely filtered in the glomerulus and increase the osmotic draw of the urine, inhibiting water reabsorption. The effect is to increase urine volume and flow. In addition, osmotic diuretics dilute waste products in the urine, decreasing the risk of renal damage due to excess concentrations.

Nursing Responsibilities

- Assess urine output. Osmotic diuretics are contraindicated in anuria. A test dose may be administered; urine output of 30 mL/h following the test dose shows an adequate response.
- Do not give these diuretics to patients who have heart failure or who are severely dehydrated. They increase vascular volume and may worsen heart failure. These drugs are not effective unless extracellular volume is adequate.
- Administer mannitol intravenously as ordered, using a 5-micron in-line filter.
- Monitor vital signs, breath sounds, and urinary output.
- Discontinue the drug if signs of heart failure or pulmonary edema develop or if renal function continues to decline.

Health Education for the Patient and Family

- Report shortness of breath, headache, chest pain, or dizziness immediately.

ELECTROLYTES AND ELECTROLYTE MODIFIERS

calcium chloride

calcium gluconate

sodium bicarbonate

sodium polystyrene sulfonate (Kayexalate)

Calcium chloride or gluconate is administered intravenously in the initial management of hyperkalemia. Calcium is administered to correct hypocalcemia and reduce hyperphosphatemia. (Calcium and phosphate have a reciprocal relationship in the body: as the level of one rises, the level of the other falls.) Sodium bicarbonate helps correct acidosis and move potassium back into the intracellular space. Sodium polystyrene sulfonate is not used to replace an electrolyte, but to remove excess potassium from the body by exchanging sodium for potassium in the large intestine.

Nursing Responsibilities

- Assess serum electrolyte levels prior to and during therapy. Report rapid shifts or adverse responses to the physician.
- Administer as appropriate and prescribed:
  a. Intravenous calcium chloride or calcium gluconate into a large vein through a small-bore needle; avoid infiltration because extravasation of intravenous solution will cause tissue necrosis.
  b. Intravenous sodium bicarbonate per infusion or as oral tablets.
  c. Sodium polystyrene sulfonate as an oral solution or as a retention enema.
- Monitor for adverse reactions, such as dysrhythmias, electrolyte imbalances, and metabolic alkalosis.

Health Education for the Patient and Family

- Intravenous calcium may make you light-headed; remain in bed for at least 30 minutes after administration.
- Chew sodium bicarbonate tablets and follow with 8 ounces of water. Do not take with milk.
- Retain the sodium polystyrene sulfonate enema as long as possible.

Note: Drugs identified in *italics* are among the 200 most commonly prescribed medications in the U.S.

bowel losses) and adding the amount excreted as urine (or lost in vomitus) during the previous 24 hours. For example, if a patient with AKI excretes 325 mL of urine in 24 hours, the patient is allowed a fluid intake (including oral and intravenous fluids) of 825 to 1125 mL for the next 24 hours. Fluid balance is carefully monitored, using accurate weight measurements and the serum sodium as the primary indicators. Hemodynamic monitoring may be initiated to aid in fluid management of the critically ill patient.

NUTRITION

Renal insufficiency and the underlying disease process increase the rate of *catabolism* (the breakdown of body proteins) and decrease the rate of *anabolism* (body tissue repair). The patient with AKI needs adequate nutrients and calories (between 25 and 45 calories/kg/day) to prevent catabolism. Proteins may be limited to minimize the degree of azotemia; however, current evidence supports protein intake adequate to prevent protein malnutrition (1 or more grams per

kilogram per day). Dietary proteins should be of high biologic value (rich in essential amino acids). Carbohydrates and fats are increased to maintain adequate calorie intake and provide a protein-sparing effect. Oral or enteral nutrition is provided whenever possible to support gastrointestinal integrity (KDIGO, 2012). Parenteral nutrition may be instituted if enteral nutrition fails to meet the patient's needs or results in additional problems. The disadvantages of parenteral nutrition in the patient with AKI are the high volume of fluid required and the risk for infection through the venous line.

RENAL REPLACEMENT THERAPY

Manifestations of *uremia*, organ dysfunction due to accumulated metabolic wastes, severe fluid overload, hyperkalemia, or metabolic acidosis in a patient with renal failure, indicate a need to replace renal function. **Dialysis** is the diffusion of solute molecules across a semipermeable membrane from an area of higher solute concentration to one of lower concentration. It is used to remove excess fluid and metabolic waste products in acute kidney injury and renal failure. Early use of dialysis can reduce the rate of complications. Dialysis may be used to rapidly remove nephrotoxins in acute tubular necrosis. While dialysis compensates for lost renal elimination functions, it does not replace lost erythropoietin production. Anemia is a continuing problem for the patient receiving dialysis.

In dialysis, blood is separated from a dialysis solution (*dialysate*) by a semipermeable membrane. Either **hemodialysis**, a procedure in which blood passes through a semipermeable membrane filter outside the body, or **peritoneal dialysis**, which uses the peritoneum surrounding the abdominal cavity as the dialyzing membrane, may be used. Intermittent hemodialysis is most commonly used for the patient with AKI in the United States (Waikar & Bonventre, 2012).

INTERMITTENT HEMODIALYSIS Hemodialysis uses the principles of diffusion and ultrafiltration to remove electrolytes, waste products, and excess water from the body. Blood is taken from the patient via a vascular access and pumped to the dialyzer (Figure 28–5 ■). The porous membranes of the dialyzer unit allow small molecules such as water, glucose, and electrolytes to pass through, but block larger molecules such as serum proteins and blood cells. The dialysate, a solution of approximately the same composition and temperature as normal extracellular fluid, passes along the other side of the membrane. Small solute molecules move freely across the membrane by diffusion. The direction of movement for any substance is determined by the concentrations of that substance in the blood and the dialysate. Electrolytes and waste products such as urea and creatinine diffuse from the blood into the dialysate. If it is necessary to add something to the blood, such as calcium to replace depleted stores, it can be added to the dialysate to diffuse into the blood. Excess water is removed by creating a higher hydrostatic pressure of the blood moving through the dialyzer than of the dialysate, which flows in the opposite direction.

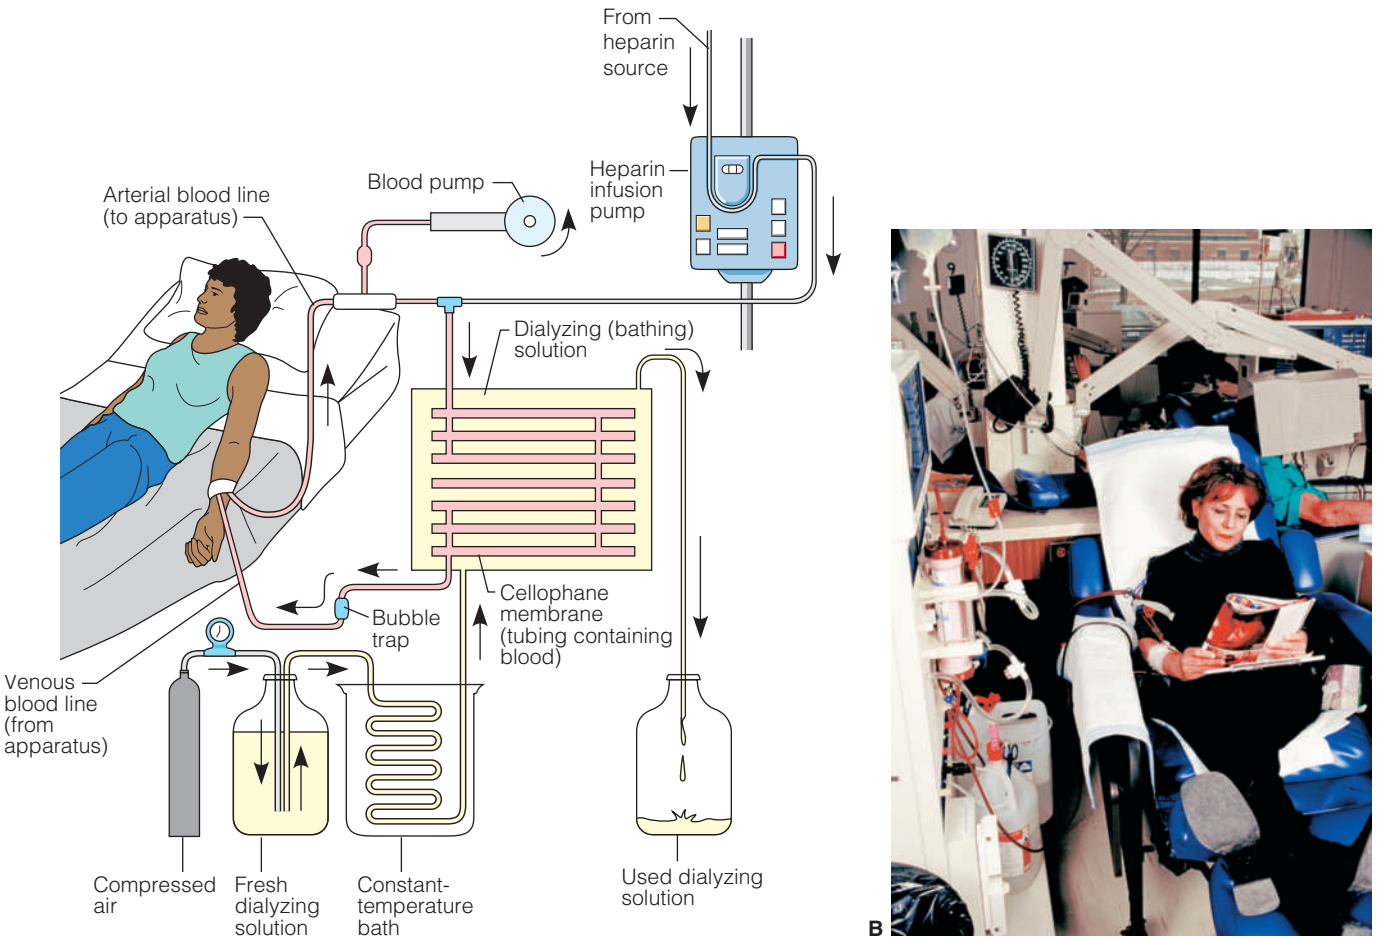


Figure 28–5 ■ A, The components of a hemodialysis system. B, A woman receiving kidney dialysis.

This process is known as **ultrafiltration**. Solute is carried in solution across the membrane in a process known as *convection*.

Initially, patients with AKI typically undergo hemodialysis for 3 to 4 hours per day for three to four times per week as indicated. Hemodialysis is not used if the patient is hemodynamically unstable (e.g., with hypotension or low cardiac output). The following complications are associated with hemodialysis:

- Hypotension, the most frequent complication during hemodialysis, due to changes in serum osmolality, rapid removal of fluid from the vascular compartment, vasodilation, and other factors
- Bleeding related to altered platelet function associated with uremia and the use of heparin during dialysis
- Infection (local or systemic) related to WBC damage and immune system suppression. *Staphylococcus aureus* septicemia is commonly associated with contamination of the vascular access site. Patients on chronic hemodialysis have higher rates of hepatitis B, hepatitis C, cytomegalovirus, and HIV infection than the general population.

See the Nursing Care box on page 804 for care of the patient undergoing hemodialysis.

CONTINUOUS RENAL REPLACEMENT THERAPY Patients with acute kidney injury may be unable to tolerate hemodialysis and rapid fluid removal if their cardiovascular status is unstable (e.g., due to trauma, major surgery, heart failure). *Continuous renal replacement therapy (CRRT)* is a procedure that allows more gradual fluid and solute removal. In CRRT, blood is continuously circulated through a highly porous hemofilter for a period of 8 to 12 or more hours (Figure 28–6 ■). Excess water and solutes such as electrolytes, urea, creatinine, uric acid, and glucose drain into a collection device. Fluid is replaced with normal saline or a balanced electrolyte solution as needed during CRRT. This slower process helps maintain hemodynamic stability and avoid complications associated with rapid changes in ECF composition. The most common CRRT techniques are outlined in Table 28–7.

CRRT is typically performed in an intensive care unit or specialized nephrology unit. A double-lumen venous catheter is used for most types of CRRT. Strict aseptic technique is vital in caring for vascular access sites to reduce the risk of infection.

SAFETY ALERT

When longer-term dialysis is anticipated, arteriovenous fistula (AVF) is preferred for vascular access. Complications related to vascular access, such as infection and clotting, occur at a significantly lower rate with AVF than with catheters.

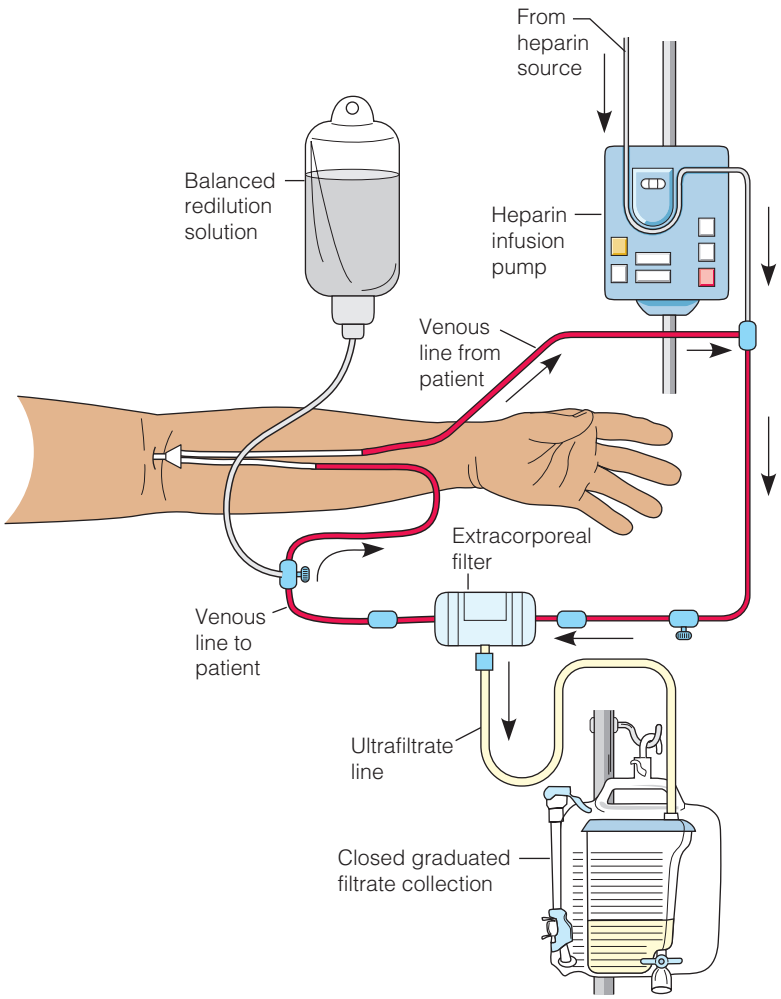

Figure 28–6 ■ Continuous renal replacement therapy (CRRT).

TABLE 28–7 Continuous Renal Replacement Therapies

Type	Indications	Description
Continuous venovenous hemofiltration (CVVH)	Remove fluid and some solutes.	Convective dialysis: Venous blood circulates through a hemofilter, where fluid and small-to-midsized solutes are removed by ultrafiltration and convection; crystalloid replacement fluid is required.
Continuous venovenous hemodialysis (CVVHD)	Remove fluid and waste products.	Diffusive dialysis: Venous blood circulates through a hemofilter surrounded by dialysate where mostly small molecules are removed by diffusion; blood and dialysate flow rates are slower than for hemodialysis; replacement fluid is not required.
Continuous venovenous hemodiafiltration (CVVHDF)	Remove fluid and waste products.	Convective and diffusive clearance: Venous blood circulates through a hemofilter surrounded by dialysate, replacement fluid is added; effective in clearing small and midsize molecules and urea.

VASCULAR ACCESS Acute or temporary vascular access for hemodialysis or CRRT usually is gained by inserting a double-lumen catheter into the subclavian, jugular, or femoral vein. The double-lumen catheter has a central partition separating the blood withdrawal side of the catheter from the return side. Blood is drawn into the catheter through small openings in the proximal portion of the catheter, and returned to the circulation through an opening in the distal end of the catheter to avoid withdrawing the blood that has just been dialyzed.

For longer-term vascular access, an *arteriovenous fistula* (*AVF*) (Figure 28–7 ■) is created. In preparation for fistula formation, the nondominant arm is not used for venipuncture or blood pressure measurement during renal failure. The fistula is created by surgical anastomosis of an artery and vein, usually the radial artery and cephalic vein. It takes about a month for the fistula to mature so that it can be used for taking and replacing blood during dialysis. A functional AVF has a palpable pulsation and a bruit on auscultation. Venipunctures and blood pressures are avoided on the arm with the fistula.

An *arteriovenous graft* also may be used for vascular access. The graft, a tube made of Gore-Tex, is surgically implanted and connects the artery and the vein. Blood flows through the graft from the artery to the vein. The rate of complications and mortality associated with catheter access is higher than with AV fistulas or grafts. Ideally, an AV fistula is created as soon as the potential need for long-term renal replacement therapies is identified. Localized AV fistula or graft problems can occur, however. Infection and clotting or thrombosis are the most common shunt problems. Aneurysms may also develop. Both infection and thrombosis can lead to systemic complications such as septicemia and embolization. These local complications may cause the fistula or graft to fail, necessitating development of a new site. The psychologic impact of AV fistula or graft failure is significant, often causing depression and low self-esteem.

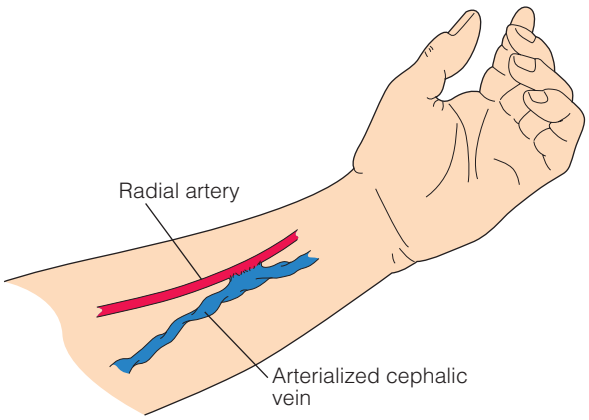

Figure 28–7 ■ An arteriovenous fistula.

PERITONEAL DIALYSIS In peritoneal dialysis, the highly vascular peritoneal membrane serves as the dialyzing surface (Figure 28–8 ■). Warmed sterile dialysate is instilled (either manually or using an automated peritoneal dialysis cycler) into the peritoneal cavity through a catheter inserted into the peritoneal cavity. Metabolic waste products and excess electrolytes diffuse into the dialysate while it remains in the abdomen. Water movement is controlled using dextrose as an osmotic agent to draw it into the dialysate. The fluid is then drained by gravity out of the peritoneal cavity into a sterile bag. This process of dialysate infusion, dwell time of the solution in the abdomen, and drainage is repeated at prescribed intervals.

Because excess fluid and solutes are removed more gradually in peritoneal dialysis, it poses less risk for the unstable patient; however, this slower rate of metabolite removal can be a disadvantage in AKI. Peritoneal dialysis increases the risk for developing peritonitis. It is contraindicated for patients who have had recent abdominal surgery, significant lung disease, or peritonitis. See the Nursing Care box on page 805 for care of the patient having peritoneal dialysis.

●○● NURSING CARE

Health Promotion

Acute kidney injury often can be prevented by measures that maintain fluid volume and cardiac output and reduce the risk of exposure to nephrotoxins. Carefully monitor critically ill, postoperative, and other at-risk patients for early signs of hypovolemia (low urine output; altered mental status; changes in vital signs, skin color, or temperature) or infection. Promptly report a fall in urine output to less than 30 mL/h and other evidence of decreased cardiac output. Maintain intravenous fluids as ordered. Alert the physician if the patient is receiving more than one nephrotoxic drug or if a nephrotoxic drug is ordered for a dehydrated patient. Closely observe patients receiving blood or blood cells for early signs of transfusion reaction and intervene appropriately.

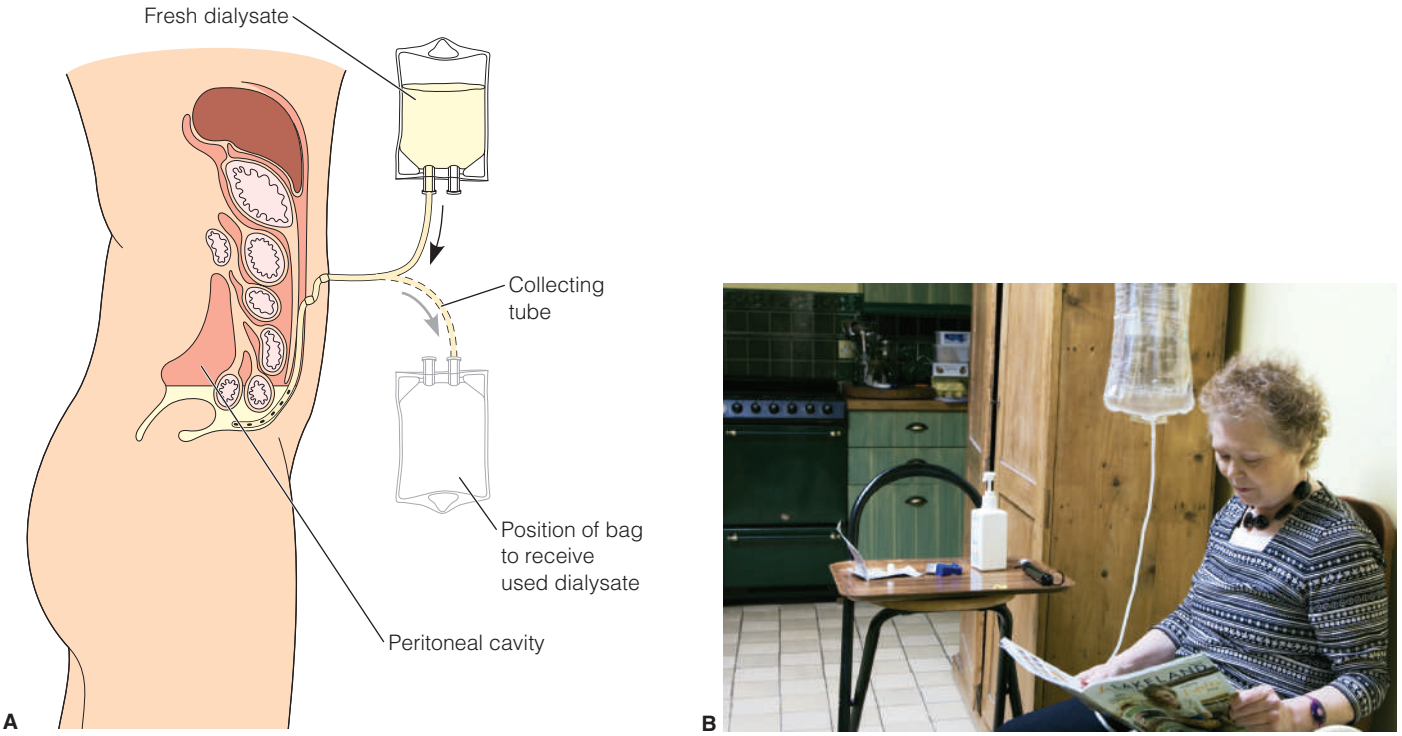

Figure 28–8 ■ A, The components of peritoneal dialysis. B, A woman receiving peritoneal dialysis at home.

NURSING CARE OF THE PATIENT

Undergoing Hemodialysis

PREDIALYSIS CARE

- Assess vital signs, including orthostatic blood pressures (lying, sitting, and standing), apical pulse, respirations, and lung sounds. *These data provide baseline information to help evaluate the effects of hemodialysis. The patient who is hypotensive may not tolerate rapid fluid volume changes during dialysis.*
- Record weight. *Weight changes are an effective indicator of fluid volume*.
- Assess vascular access site for a palpable pulsation or vibration and an audible bruit and for inflammation. *Infection and thrombus formation are the most common problems affecting the access site in patients undergoing hemodialysis*.
- Use strict aseptic technique when accessing the AV fistula or graft and during the dialysis procedure. *Preventing infection, a major complication of hemodialysis and vascular access, is a critical nursing responsibility.*
- Alert all personnel to avoid using the extremity with the vascular access site (or the nondominant arm, if long-term access has not been established) for blood pressures or venipuncture. *These procedures may damage vessels and lead to failure of the arteriovenous fistula*.

POSTDIALYSIS CARE

- Assess and document vital signs, weight, and vascular access site condition. *Rapid fluid and solute removal during dialysis may lead to hypotension, the most acute complication of hemodialysis.*
- Monitor BUN, serum creatinine, serum electrolyte, and hematocrit levels between dialysis treatments. *These values help determine the effectiveness of the treatment, and the timing of future dialysis sessions. Significant anemia may necessitate iron and folate supplements or periodic blood transfusions*.
- Assess for dialysis disequilibrium syndrome, with headache, nausea and vomiting, altered level of consciousness, and hypertension. *Rapid changes in BUN, pH, and electrolyte levels during dialysis may lead to cerebral edema and increased intracranial pressure*.
- Assess for other adverse responses to dialysis, such as dehydration, muscle cramps, or seizure activity. Treat as ordered. *Excess fluid removal and rapid changes in electrolyte balance can cause fluid deficit, muscle cramps, and seizure activity*.
- Assess for bleeding at the access site or elsewhere. Use standard precautions at all times. *Renal failure and heparinization during dialysis increase the risk for bleeding. Frequent exposure to blood and blood products increases the risk for hepatitis B or C or other bloodborne diseases*.
- If a transfusion is given during dialysis, monitor for possible transfusion reaction (e.g., chills and fever; dyspnea; chest, back, or arm pain; and urticaria or itching). *Patients in renal failure may receive multiple transfusions, increasing the risk of transfusion reaction. Close monitoring during and after the transfusion is important to identify early signs of a reaction*.
- Provide psychologic support and listen actively. Address concerns and accept responses such as anger, depression, and noncompliance. Reinforce patient and family strengths in coping with renal failure and hemodialysis. *Grieving is a normal response to loss of organ function. The patient may feel hopeless or helpless and resent dependence on a machine. The nurse can help the patient and family work through these responses and focus on positive aspects of living*.
- Refer to social services and counseling as indicated. *Patients with renal failure may need additional support services to help them adapt to and live with their disease*.

NURSING CARE OF THE PATIENT

Undergoing Peritoneal Dialysis

PREDIALYSIS CARE

- Document vital signs including temperature, orthostatic blood pressures (lying, sitting, and standing), apical pulse, respirations, and lung sounds. *These baseline data help assess fluid volume status and tolerance of the dialysis procedure. Poor respiratory function may affect the ability to tolerate peritoneal dialysis. Temperature measurement is vital, because infection is the most common complication of peritoneal dialysis*.
- Weigh daily or between dialysis runs as indicated. *Weight is an accurate indicator of fluid volume status*.
- Note BUN, serum electrolyte, creatinine, pH, and hematocrit levels prior to peritoneal dialysis and periodically during the procedure. *These values are used to assess the efficacy of treatment*.
- Measure and record abdominal girth. *Increasing abdominal girth may indicate retained dialysate, excess fluid volume, or early peritonitis*.
- Maintain fluid and dietary restrictions as ordered. *Fluid and diet restrictions help reduce hypervolemia and control azotemia*.
- Have the patient empty the bladder prior to catheter insertion. *Emptying the bladder reduces the risk of inadvertent puncture*.
- Warm the prescribed dialysate solution to body temperature (37°C [98.6°F]) if the procedure is being performed manually. *Dialysate is warmed to prevent hypothermia; an automated cycler will warm the dialysate prior to instillation*.
- Explain all procedures and expected sensations. *Knowledge helps reduce anxiety and elicit cooperation*.

INTRADIALYSIS CARE

- Use strict aseptic technique during the dialysis procedure and when caring for the peritoneal catheter. *Peritonitis is a common complication of peritoneal dialysis; sterile technique reduces the risk*.
- Add prescribed medications to the appropriate dialysate; prime the tubing with solution and connect it to the peritoneal catheter, securing connections and avoiding kinks. *This allows dialysate to flow freely into the abdominal cavity and prevents leaking or contamination*.
- Instill dialysate into the abdominal cavity over a period of approximately 10 minutes. Clamp tubing and allow the dialysate to remain in the abdomen for the prescribed dwell time. Keep drainage tubing clamped at all times during instillation and dwell time. *Dialysate should flow freely into the abdomen if the peritoneal catheter is patent. Dialysis, the exchange of solutes and water between the blood and dialysate, occurs across the peritoneal membrane during the dwell time*.
- During instillation and dwell time, observe closely for signs of respiratory distress, such as dyspnea, tachypnea, or crackles. Place in Fowler's or semi-Fowler's position and slow the rate of instillation slightly to relieve respiratory distress if it develops. *Respiratory compromise may result from rapid dialysate instillation or overfilling of the abdomen or from a diaphragmatic defect that allows fluid to enter the thoracic cavity*.
- After prescribed dwell time, open drainage tubing clamps and allow dialysate to drain by gravity into a sterile container. Note the clarity, color, and odor of returned dialysate. *Blood or feces in the dialysate may indicate organ or bowel perforation; cloudy or malodorous dialysate may indicate an infection*.
- Accurately record amount and type of dialysate instilled (including any added medications), dwell time, and the amount and character of the drainage. *When more dialysate drains than has been instilled, excess fluid has been lost (output). If less dialysate is returned than has been instilled, a fluid gain has occurred (intake)*.
- Monitor BUN, serum electrolyte, and creatinine levels. *These values are used to assess the effectiveness of dialysis*.
- Troubleshoot for possible problems during dialysis:
  a. Slow dialysate instillation. Increase the height of the container and reposition the patient. Check tubing and catheter for kinks. Check abdominal dressing for wetness, indicating leakage around the catheter. *Slow dialysate flow may be related to a partially obstructed tube or catheter*.
  b. Excess dwell time. *Prolonged dwell time may lead to water depletion or hyperglycemia*.
  c. Poor dialysate drainage. Lower the drainage container, reposition, check for tubing kinks. Check abdominal dressing. *Tubing or catheter obstruction can interfere with dialysate drainage*.

POSTDIALYSIS CARE

- Assess vital signs, including temperature. *Comparison of pre- and postdialysis vital signs helps identify beneficial and adverse effects of the procedure*.
- Time meals to correspond with dialysis outflow. *Scheduling meals while the abdomen is empty of dialysate enhances intake and reduces nausea*.
- Teach the patient and family about the procedure. *The patient may elect to use peritoneal dialysis at home to manage end-stage renal disease and prevent uremia*.

Assessment

Both subjective and objective data are useful when assessing the patient with acute kidney injury:

- *Health history:* complaints of anorexia, nausea, weight gain, or edema; recent exposure to a nephrotoxin such as an aminoglycoside antibiotic or radiologic procedure using an injected contrast medium; previous transfusion reaction; chronic diseases such as diabetes, heart failure, or kidney disease
- *Physical assessment:* vital signs including temperature; urine output (amount, color, clarity, specific gravity, presence of blood cells or protein); weight; skin color, peripheral pulses; presence of edema (periorbital or dependent); lung sounds, heart sounds, and bowel tones.

Priorities of Care

Priority nursing care needs for the patient with AKI relate to addressing alterations in fluid and electrolyte balance, supporting nutritional status, and teaching/learning.

Diagnoses, Outcomes, and Interventions

The patient with acute kidney injury has numerous nursing care needs related not only to the renal failure but also to the underlying condition that precipitated it.

Altered Fluid and Electrolyte Balance

In acute kidney injury, the kidneys often cannot excrete adequate urine to maintain a normal extracellular fluid balance. Metabolic waste products are retained, and electrolyte homeostasis is disrupted.

Expected Outcome: Patient's fluid and electrolyte balance will be restored, and patient will experience no adverse effects of altered homeostasis.

- Maintain hourly intake and output records. *Accurate intake and output records help guide therapy, especially fluid restrictions.*
- Weigh daily or more frequently, as ordered. Use standard technique (same scale, clothing, or coverings) to ensure accuracy. *Rapid weight changes are an accurate indicator of fluid volume status, particularly in the patient with oliguria.*
- Assess vital signs at least every 4 hours. *Hypertension, tachycardia, and tachypnea may indicate excess fluid volume.*
- If not contraindicated, place in semi-Fowler's position *to enhance cardiac and respiratory function.*
- Report abnormal serum electrolyte values and manifestations of electrolyte imbalance. The patient with AKI is at particular risk for the following electrolyte imbalances:
  a. *Hyperkalemia* due to impaired potassium excretion. Manifestations include irritability, nausea, diarrhea, abdominal cramping, cardiac dysrhythmias, and ECG changes.
  b. *Hyponatremia* due to water retention. Manifestations include nausea, vomiting, and headache, with possible central nervous system (CNS) manifestations of lethargy, confusion, seizures, and coma.
  c. *Hyperphosphatemia* due to decreased phosphate excretion. Manifestations include hyperreflexia, paresthesias, and possible tetany.

  AKI impairs electrolyte and water excretion, causing multiple electrolyte imbalances.

PRACTICE ALERT!

Frequently assess breath and heart sounds, neck veins for distention, and back and extremities for edema. Report abnormal findings. Adventitious breath sounds (crackles), abnormal heart sounds such as an S_3 or S_4 gallop, distended neck veins, and peripheral edema may indicate hypervolemia, heart failure, or pulmonary edema.

- Restrict fluids as ordered. Provide frequent mouth care and encourage using hard candies to decrease thirst. If ice chips are allowed, include the water content (approximately one-half of the total volume) as intake. *Fluids are restricted to minimize fluid retention and complications of fluid volume excess.*
- Administer medications with meals. *Giving oral medications with meals minimizes ingestion of excess fluids.*
- Turn frequently and provide good skin care. *Edema decreases tissue perfusion and increases the risk of skin breakdown, especially in the older or debilitated patient.*

Imbalanced Nutrition: Less Than Body Requirements

Anorexia and nausea associated with renal failure often interfere with food intake and nutrition. In addition, patients experiencing AKI are at risk for protein-energy malnutrition related to their disease process (KDIGO, 2012).

Expected Outcome: Patient will maintain adequate nutritional status as evidenced by stable weight and serum albumin levels within expected parameters.

Evidence for Nursing Care

The Patient with Acute Kidney Injury

Selected resources that nurses may find helpful when planning evidence-based nursing care follow.

- Kidney Disease: Improving Global Outcomes (KDIGO) Acute Kidney Injury Work Group. (2012). KDIGO clinical practice guideline for acute kidney injury. *Kidney International*, *2* (Suppl. 2012), 1–138.
- Lewington, A., & Kanagasundaram, S. (2011). *Clinical practice guidelines: Acute kidney injury* (5th ed.). Hampshire, United Kingdom: UK Renal Association. Retrieved from http://www.renal.org/guidelines.

- Monitor and record food intake, including the amount and type of food consumed. *A detailed intake record helps guide decisions about nutritional status and necessary supplements.*
- Weigh daily. *Weight changes over time (days to weeks) reflect nutritional status, while rapid weight changes are more reflective of fluid volume status. In AKI, weight may remain stable or increase due to fluid retention even though tissue mass is being lost.*
- Arrange for dietary consultation to plan meals within prescribed limitations that consider the patient's food preferences. *Diets restricted in protein, salt, and potassium can be unpalatable; intake and appetite improve when preferred foods are included as allowed.*
- Engage the patient in planning daily menus. *Participation in meal planning increases the patient's sense of control and autonomy.*
- Allow family members to prepare meals within dietary restrictions. Encourage family members to eat with the patient. *Familiar foods and social interaction encourage eating and increase enjoyment of meals.*
- Provide frequent, small meals or between-meal snacks. *These measures promote food intake in patients who are fatigued or anorectic.*
- Administer antiemetics as ordered and provide mouth care prior to meals. *Nausea and a metallic taste in the mouth, common manifestations of uremia, can decrease food intake.*
- Administer parenteral nutrition as ordered if the patient is unable to eat or tolerate enteral nutrition. *Preventing or slowing tissue catabolism is important for the patient with AKI.*

SAFETY ALERT

Intravenous lines and parenteral nutrition solutions can increase the risk for infection. Monitor sites carefully for signs of infection or inflammation.

Readiness for Enhanced Knowledge

The patient with AKI has multiple learning needs. These include information about AKI, diagnostic and laboratory studies, management strategies, and implications for the recovery period.

Expected Outcome: Patient will express an understanding of condition and its management.

- Assess anxiety level and ability to comprehend instruction. Tailor information and presentation to developmental level and physical, mental, and emotional status. *The patient with AKI may be critically ill or have uremic effects that hinder learning. During the initial stages of AKI, it may be necessary to limit information to immediate concerns.*

- Assess knowledge and understanding. *To enhance understanding and retention, relate information presented to previous learning.*
- Teach about diagnostic tests and therapeutic procedures. *Teaching reduces anxiety and improves understanding and cooperation.*
- Discuss dietary and fluid restrictions. *These measures may be continued after discharge.*
- If the patient is discharged prior to the recovery phase of AKI, teach the signs and symptoms of complications, such as fluid volume excess or deficit, heart failure, and electrolyte imbalances. *As kidney function returns, urine output increases, but the concentrating ability of the nephrons and electrolyte excretion remain impaired. This impaired function increases the risk of excess fluid loss, possible dehydration, orthostatic hypotension, and electrolyte imbalance.*
- Teach how to monitor weight, blood pressure, and pulse. *These are important means of assessing fluid status.*
- Instruct to avoid nephrotoxic drugs and chemicals for up to 1 year following an episode of AKI. *During recovery, nephrons are vulnerable to damage by nephrotoxins such as NSAIDs, some antibiotics, radiologic contrast media, and heavy metals. Because alcohol can increase the nephrotoxicity of some materials, discourage alcohol ingestion.*

Delegating Nursing Care Activities

As appropriate and allowed by the designated duties and responsibilities of unlicensed assistive personnel (UAP), the nurse may delegate nursing care activities such as measuring vital signs and intake and output, obtaining daily weights, and assisting with hygiene and activities for the patient with AKI. When delegating care, ensure UAP have a clear understanding of fluid restrictions, the necessity of accuracy when measuring fluid intake and output, and restrictions on use of the designated extremity for measuring blood pressure.

Continuity of Care

Often the patient is critically ill when AKI develops. Critical illness and the resulting state of the patient and family crisis can impair learning and retention of information. Include family members in teaching during the initial stages to promote understanding of what is happening and the reasons for specific treatment measures. Inclusion of the family reduces their anxiety, and provides a valuable resource for reinforcing patient teaching about care after discharge.

Patient teaching needs for home care include the following:

- Avoiding exposure to nephrotoxins, particularly those in over-the-counter products
- Preventing infection and other major stressors that can slow healing
- Monitoring weight, blood pressure, and pulse
- Manifestations of relapse
- Continuing dietary restrictions
- Knowing when to contact the physician.

THE PATIENT WITH CHRONIC KIDNEY DISEASE

Although the kidneys often recover from acute injury, many chronic conditions can lead to progressive destruction of kidney tissue and loss of function. Nephron units are lost and kidney mass decreases, with progressive deterioration of glomerular filtration, tubular secretion, and reabsorption. This process may progress slowly for many years without being recognized. **Chronic kidney disease (CKD)** is defined as kidney damage with resulting dysfunction (GFR less than 60 mL/min) that persists for three or more months (Fink et al., 2012). Eventually, the kidneys are unable to excrete metabolic wastes and regulate fluid and electrolyte balance adequately, a condition known as kidney failure or end-stage renal disease (ESRD), the final stage of CKD.

Incidence and Risk Factors

The incidence of CKD and ESRD is increasing, particularly in older adults. The incidence of recognized CKD among people ages 65 and older more than doubled from 2000 to 2008 (NKUDIC, 2012). See the Nursing Care box on page 809 for care of the older adult with CKD.

Moving Knowledge into Action

You are assigned to care for Judy Devak, 22 years old, admitted with a fractured right femur and multiple contusions following a motor vehicle crash. She was hypotensive when paramedics arrived, with vital signs of BP 90/60 mmHg, P 120 bpm, and R 24/min. Ms. Devak is in skeletal traction; surgical fixation of her fractured femur is planned for later today. Physical assessment findings include T 36.3°C (97.4°F) PO, P 100 bpm, R 18/min, and BP 124/68 mmHg. Skin pale, cool, and dry, with multiple scrapes, minor abrasions, and bruises on face and extremities. A linear bruise is noted on her chest and abdomen from the seat belt. One unit of whole blood was infused prior to admission; a second unit is currently infusing. An indwelling urinary catheter is in place.

1. What additional assessment data (subjective and objective) should you collect at this time and why? Is there data in Ms. Devak's current medical record that you should review?
2. What do you consider Ms. Devak's highest priority nursing care needs to be at this time?
3. Identify collaborative care activities you anticipate prior to Ms. Devak's planned surgery later today. Which members of the interprofessional team should be involved in her care?
4. What information can you provide to Ms. Devak's family about her condition?

You note that Ms. Devak's hourly output has dropped from 55 mL to 45 to 28 mL of clear yellow urine. The physician orders a 500-mL intravenous fluid challenge, STAT urinalysis, BUN, and serum creatinine.

1. Outline the procedure for and nursing responsibilities related to administering a fluid challenge.
2. Lab results show: BUN 28 mg/dL; serum creatinine 1.7 mg/dL; urine specific gravity 1.010 with WBCs, red and white cell casts, and tubular epithelial cells in the sediment. How will you respond?

The physician diagnoses probable acute kidney injury and orders a nephrology consultation.

1. Identify Ms. Devak's risk factors for and the probable cause of her acute kidney injury.
2. How does this additional diagnosis affect your nursing assessment, care planning, and priorities of care?
3. Are there additional members of the interprofessional team you think should become involved in Ms. Devak's care at this time? If so, which disciplines do you think should be represented?

FAST FACTS

- The incidence of CKD and ESRD is significantly higher in people ages 65 and older.
- African Americans have the highest incidence of ESRD, followed by Native Americans, Asian/Pacific Islanders, and European Americans.
- People of Hispanic origin have a higher incidence of CKD and ESRD than non-Hispanics.
- Diabetes mellitus is the leading cause of CKD, followed by hypertension, glomerulonephritis, and cystic kidney disease (U.S. Renal Data System [USRDS], 2011).

Conditions causing CKD typically involve diffuse, bilateral disease of the kidneys with progressive destruction and scarring of the entire nephron. Acute kidney injury significantly increases the risk for CKD. Other known risk factors include autoimmune disease, proteinuria, or a family history of kidney disease (Bargman & Skorecki, 2012).

Pathophysiology

The pathophysiology of CKD varies, depending on the underlying disease process. Table 28–8 outlines the pathologic processes leading to nephron destruction, CKD, and kidney failure for the most common causes. Regardless of the initiating cause, glomerulosclerosis and interstitial inflammation and fibrosis are characteristic of CKD and contribute to declining renal function (Copstead & Banasik, 2013). Entire nephron units are gradually destroyed. In the early stages, as nephrons are lost, remaining functional nephrons hypertrophy. Glomerular capillary flow and pressure increase in these nephrons, and more solute particles are filtered to compensate for lost renal mass. This increased demand predisposes the remaining nephrons to glomerulosclerosis (scarring), resulting in their eventual destruction. Proteinuria resulting from glomerular damage is thought to contribute to tubular injury. This process of continued loss of nephron function may continue even after the initial disease process has resolved (Bargman & Skorecki, 2012).

The course of CKD is variable, progressing over a period of months to many years. In the early stages, unaffected nephrons compensate for the lost nephrons. The GFR is normal or slightly decreased, and the patient is asymptomatic with normal BUN and serum creatinine levels. As the disease progresses and the GFR falls further, hypertension and some manifestations of renal insufficiency such as fatigue, anemia, and fluid and electrolyte imbalances may be seen. Any further insult to the kidneys at this stage (such as infection, dehydration, exposure to nephrotoxins, or urinary tract obstruction) can further reduce function and precipitate the onset of renal failure and uremic syndrome. The serum creatinine and BUN levels rise sharply, the patient becomes oliguric, and manifestations of uremia are seen. In ESRD, the final stage of CKD, the GFR is less than 15 mL/min and renal replacement therapy is necessary to sustain life. Table 28–9 summarizes the stages of chronic kidney disease.

Manifestations and Complications

Chronic kidney disease may not be identified until its final, uremic stage is reached. **Uremia** (or *uremic syndrome*), which means "urine in the blood," refers to the syndrome or group of symptoms associated with ESRD. In uremia, fluid and electrolyte balance is altered, the regulatory and endocrine functions of the kidney are impaired, and accumulated metabolic waste products affect essentially every other organ system. Declining renal function is associated with progressive systemic inflammation and elevated levels of C-reactive protein and other inflammatory substances. This inflammatory response contributes to accelerated cardiovascular disease and the negative nutritional impact of CKD (Bargman & Skorecki, 2012).

Early manifestations of uremia include nausea, apathy, weakness, and fatigue, symptoms that often are dismissed as a viral infection or influenza. As the condition progresses, frequent vomiting, increasing weakness, lethargy, and confusion develop. See the Multisystem Effects of Uremia feature on page 810.

FLUID AND ELECTROLYTE EFFECTS

Loss of functional kidney tissue impairs its ability to regulate fluid, electrolyte, and acid–base balance. In the early stages of CKD, impaired filtration and reabsorption lead to proteinuria, hematuria, and decreased urine-concentrating ability. Salt and water are poorly conserved, and risk for dehydration increases. Polyuria, nocturia, and a fixed specific gravity of 1.008 to 1.012 are common. As the GFR decreases and renal function deteriorates further, sodium and water retention are common, necessitating salt and water restrictions.

Hyperkalemia develops as renal failure progresses. Manifestations of hyperkalemia, such as muscle weakness, paresthesias, and

TABLE 28–8 Pathophysiology of Chronic Kidney Disease

Cause	Pathophysiology
Diabetic nephropathy	Initial increases in glomerular flow rate lead to hyperfiltration with eventual glomerular damage, and thickening and sclerosis of the glomerular basement membrane and the glomerulus. Gradual destruction of nephrons leads to a fall in the GFR.
Hypertensive nephrosclerosis	Long-standing hypertension leads to sclerosis and narrowing of renal arterioles and small arteries with subsequent reduction of blood flow leading to ischemia, glomerular destruction, and tubular atrophy.
Chronic glomerulonephritis	Chronic interstitial inflammation of renal parenchyma leads to obstruction and damage to the tubules and capillaries that surround them, affecting glomerular filtration and tubular secretion and reabsorption, with gradual loss of entire nephrons.
Polycystic kidney disease	Multiple bilateral cysts compress renal tissue, impairing renal perfusion and leading to ischemia, renal vascular remodeling, and release of inflammatory mediators, which damage and destroy normal kidney tissue.

TABLE 28–9 Stages of Chronic Kidney Disease

Stage	Glomerular Filtration Rate	Description and Manifestations
Stage 1	> 90 mL/min/1.73 m^2	Kidney damage with normal or increased GFR Asymptomatic; normal BUN and creatinine
Stage 2	60–89 mL/min/1.73 m^2	Mildly decreased GFR Asymptomatic, possible hypertension; blood work generally within normal limits
Stage 3	30–59 mL/min/1.73 m^2	Moderate GFR decrease Hypertension; possible anemia and fatigue, anorexia, possible malnutrition, bone pain; slight elevation of BUN and serum creatinine
Stage 4	15–29 mL/min/1.73 m^2	Severely decreased GFR Hypertension, anemia, malnutrition, altered bone metabolism; edema, metabolic acidosis, hypercalcemia; possible uremia; azotemia with increasing BUN and serum creatinine levels
Stage 5	< 15 mL/min/1.73 m^2	End-stage renal disease Kidney failure with azotemia and overt uremia

Source: Adapted from National Kidney Foundation. (2002). KDOQI clinical practice guidelines for chronic kidney disease: Evaluation, classification and stratification. *American Journal of Kidney Disease, 39*(Suppl. 1), S1–S266. Retrieved from http://www.kdoqi.org.

ECG changes, are not usually seen until the GFR is less than 5 mL/min. Phosphate excretion is impaired, leading to hyperphosphatemia and hypocalcemia. Reduced calcium absorption due to impaired vitamin D activation also contributes to hypocalcemia. Hypermagnesemia develops with advancing renal failure; magnesium-containing antacids are avoided for this reason.

As renal failure advances, hydrogen ion excretion and buffer production are impaired, leading to metabolic acidosis. Respiratory rate and depth increase (Kussmaul's respirations) to compensate for metabolic acidosis. Although metabolic acidosis is often asymptomatic, other possible manifestations include general malaise, weakness, headache, nausea and vomiting, and abdominal pain.

CARDIOVASCULAR EFFECTS

Cardiovascular disease is the leading cause of death in patients with CKD. It results from accelerated atherosclerosis. Hypertension, hyperlipidemia, and inflammation all contribute to the process. Cerebral and peripheral vascular manifestations of atherosclerosis are also seen.

Systemic hypertension is a common manifestation of CKD. Hypertension results from excess fluid volume, increased renin–angiotensin activity, increased peripheral vascular resistance, and decreased prostaglandins. Increased extracellular fluid volume can lead to edema and heart failure. Pulmonary edema may result from heart failure and increased permeability of the alveolar capillary membrane.

NURSING CARE OF THE OLDER ADULT

Chronic Kidney Disease

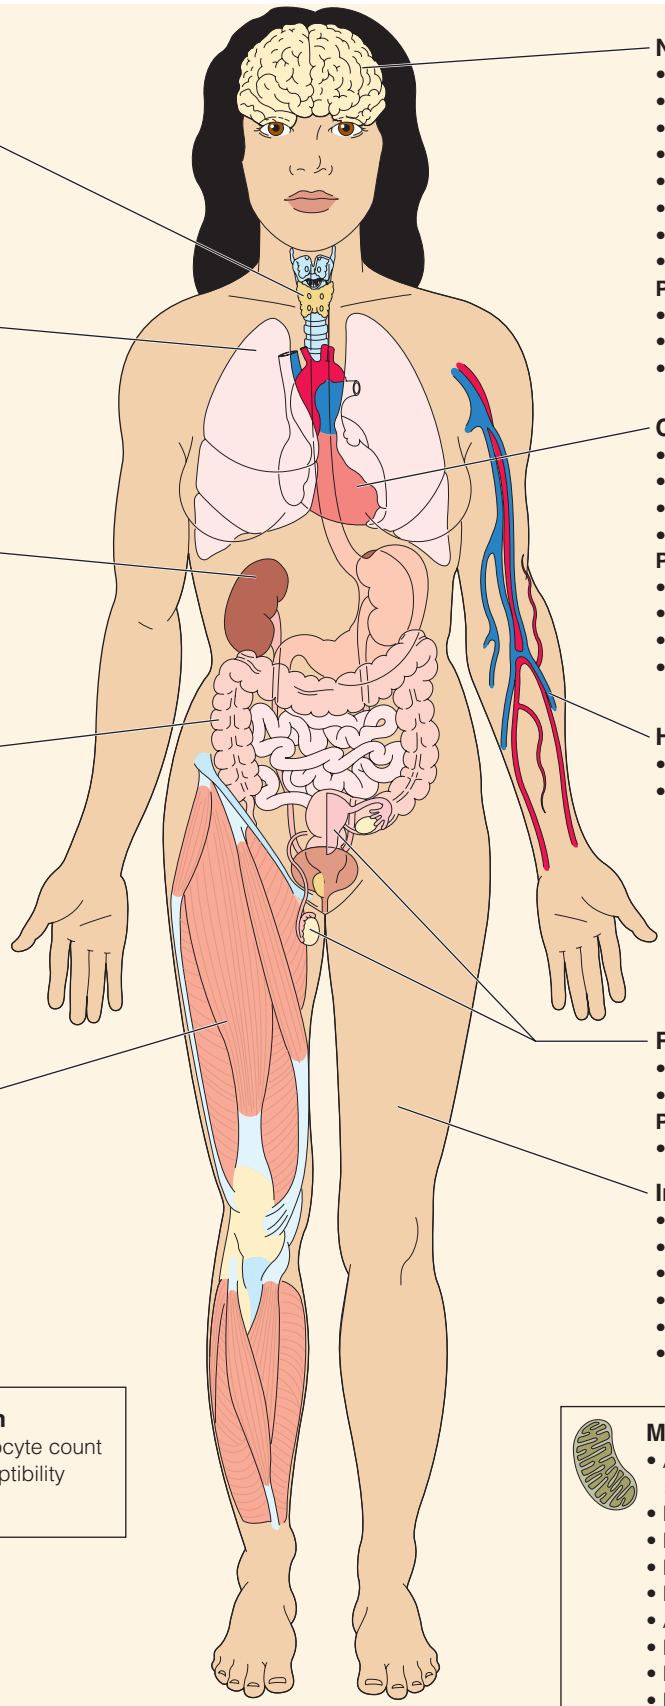
Structural and functional changes occur in the aging kidney. Structurally, the number of nephrons decreases. The GFR declines, resulting in decreased renal clearance of drugs. Urine-concentrating ability decreases, and the kidney is less able to conserve sodium. Renal compensation for acid–base imbalances takes longer. Despite these changes, the kidney retains its ability to regulate fluid and electrolyte homeostasis remarkably well unless additional stresses are added. Any additional stressors such as hypotension, exposure to nephrotoxic drugs, or an inflammatory process such as glomerulonephritis may precipitate renal failure in the older adult.

The manifestations of chronic kidney disease often are missed in aging patients (e.g., edema may be attributed to heart failure or high blood pressure to preexisting hypertension). Serum creatinine levels may rise slowly. Because older adults have less muscle mass, they produce less creatinine, a by-product of muscle cell metabolism. Likewise, the BUN may remain within normal limits.

The same measures are used to treat ESRD in older adults as in younger people. Hemodialysis, peritoneal dialysis, and renal transplantation are appropriate if necessary. Treatment options (including conservative treatment or no treatment) and their potential benefits and ramifications should be clearly explained.

ASSESSING FOR HOME CARE

A number of factors should be considered in assessing the older adult's ability to manage treatment such as dialysis at home:



- Does the patient have reasonable access to a dialysis center or outpatient unit? Is transportation available?
- Would home hemodialysis be appropriate? Is a caregiver available to be trained to manage dialysis? Does the patient's home have appropriate electrical and plumbing fixtures?
- Would continuous ambulatory peritoneal dialysis be appropriate? Does the patient have the manual dexterity, will, and cognitive ability to manage dialysis infusions? If not, would intermittent peritoneal dialysis using a dialyzing machine be more appropriate?
- Are family members or other support persons available to provide assistance to the patient as needed?

RESOURCES FOR HOME CARE

The following resources may be useful for patients with kidney disease:

- American Association of Kidney Patients
  800-749-2257
- American Kidney Fund
  800-638-8289
  866-300-2900 (Spanish help line)
- National Kidney Foundation
  800-622-9010

MULTISYSTEM EFFECTS OF Uremia

Endocrine
- Hyperparathyroidism
- Glucose intolerance

Respiratory
- Pulmonary edema
- Pleuritis
- Kussmaul's respirations

Urinary
- Proteinuria
- Hematuria
- Fixed specific gravity
- Nocturia
- Oliguria, anuria

Gastrointestinal
- Anorexia
- Nausea and vomiting
- Gastroenteritis
- Hiccups
- Abdominal pain
- Uremic fetor

Potential Complications
- Peptic ulcer
- GI bleeding

Musculoskeletal
- Osteodystrophy
- Bone pain
- Spontaneous fractures

Neurologic
- Apathy
- Lethargy
- Headache
- Impaired cognition
- Insomnia
- Restless leg syndrome
- Gait disturbances
- Paresthesias

Potential Complications
- Seizures
- Decreased LOC
- Coma

Cardiovascular
- Hypertension
- Edema
- Coronary heart disease
- Dysrhythmias

Potential Complications
- Pericarditis
- Pericardial effusion
- Cerebrovascular disease
- Heart failure

Hematologic
- Anemias
- Impaired clotting

Reproductive
- Amenorrhea (female)
- Impotence (male)

Potential Complication
- Spontaneous abortion

Integumentary
- Pallor
- Uremic skin color (yellow-green)
- Dry skin, poor turgor
- Pruritis
- Ecchymoses
- Uremic "frost"

Immune System
- Diminished leukocyte count
- Increased susceptibility to infection

Metabolic Processes
- Azotemia (↑ BUN and serum creatinine)
- Hyperkalemia
- Hyperphosphatemia
- Hypocalcemia
- Hypermagnesia
- Acidosis
- Hyperlipidemia
- Hyperuricemia
- Malnutrition

Retained metabolic toxins can irritate the pericardial sac, causing an inflammatory response and signs of pericarditis. *Cardiac tamponade*, a potential complication of pericarditis, occurs when inflammatory fluid in the pericardial sac interferes with ventricular filling and cardiac output. Once a common complication of uremia, pericarditis is less common when dialysis is initiated early.

HEMATOLOGIC EFFECTS

Anemia is common in CKD, caused by multiple factors. The kidneys produce erythropoietin, a hormone that controls RBC production. In renal failure, erythropoietin production declines. Retained metabolic toxins further suppress RBC production and contribute to a shortened RBC life span. Nutritional deficiencies (iron and folate) and inflammation with impaired iron utilization also contribute to anemia.

Anemia contributes to manifestations such as fatigue, weakness, depression, and impaired cognition. It affects cardiovascular function, and may be a major contributing factor to coronary heart disease and heart failure associated with ESRD.

Renal failure impairs platelet function, increasing the risk of bleeding disorders such as epistaxis and GI bleeding. The mechanism of impaired platelet function associated with renal failure is poorly understood.

IMMUNE SYSTEM EFFECTS

Uremia increases the risk for infection. High levels of urea and retained metabolic wastes impair all aspects of inflammation and immune function. The WBC declines, humoral and cell-mediated immunity are impaired, and phagocyte function is defective. Both the acute inflammatory response and delayed hypersensitivity responses are affected (Grossman & Porth, 2014). Fever is suppressed, often delaying the diagnosis of infection.

GASTROINTESTINAL EFFECTS

Anorexia, nausea, and vomiting are the most common early symptoms of uremia. Hiccups also are commonly experienced. Gastroenteritis is frequent. Ulcerations may affect any level of the GI tract and contribute to an increased risk of GI bleeding. Peptic ulcer disease is particularly common in patients with uremia. *Uremic fetor*, a urine-like breath odor often associated with a metallic taste in the mouth, may develop. Uremic fetor can further contribute to anorexia.

NEUROLOGIC EFFECTS

Uremia alters both central and peripheral nervous system function. CNS manifestations occur early and include changes in mentation, difficulty concentrating, fatigue, and insomnia. Psychotic symptoms, seizures, and coma are associated with advanced uremic encephalopathy.

Peripheral neuropathy is common in advanced uremia. Both the sensory and motor tracts are involved. The lower limbs are initially affected. *Restless leg syndrome*, sensations of crawling or creeping, prickling, or itching of the lower legs with frequent leg movement, increases during rest. Paresthesias and sensory loss typically occur in a "stocking-glove" pattern. As uremia progresses, motor function is impaired, causing muscle weakness, decreased deep tendon reflexes, and gait disturbances.

MUSCULOSKELETAL EFFECTS

Hyperphosphatemia and hypocalcemia associated with uremia stimulate parathyroid hormone secretion. Parathyroid hormone causes increased calcium resorption from bone. In addition, osteoblast (bone-forming) and osteoclast (bone-dissolving) cell activities are affected. This bone resorption and remodeling, combined with decreased vitamin D synthesis and decreased calcium absorption from the GI tract, lead to *renal osteodystrophy*, also known as renal rickets. Osteodystrophy is characterized by osteomalacia, softening of the bones, and osteoporosis, decreased bone mass. Bone cysts may develop. Manifestations of osteodystrophy include bone tenderness, pain, and muscle weakness. The patient is at increased risk for spontaneous fractures.

ENDOCRINE AND METABOLIC EFFECTS

Accumulated waste products of protein metabolism are a primary factor involved in the effects and manifestations of uremia. Serum creatinine and BUN levels are significantly elevated. Uric acid levels are increased, contributing to an increased risk of gout.

Tissues become resistant to the effects of insulin in uremia, leading to glucose intolerance. High blood triglyceride levels and lower than normal high-density lipoprotein (HDL) levels contribute to the accelerated atherosclerotic process.

Reproductive function is affected. Pregnancies are rarely carried to term, and menstrual irregularities are common. Reduced testosterone levels, low sperm counts, and impotence affect the male patient with ESRD.

DERMATOLOGIC EFFECTS

Anemia and retained pigmented metabolites cause pallor and a yellowish hue to the skin in uremia. Dry skin with poor turgor, a result of dehydration and sweat gland atrophy, is common. Bruising and excoriations are frequently seen. Metabolic wastes not eliminated by the kidneys may be deposited in the skin, contributing to itching or pruritus. In advanced uremia, high levels of urea in the sweat may result in *uremic frost*, crystallized deposits of urea on the skin.

●○● INTERPROFESSIONAL CARE

Early management of CKD focuses on eliminating or controlling factors that may cause additional kidney damage and further decrease renal function. Included are measures to slow the progression of the disease to ESRD. Additional treatment goals include the following:

- Maintain nutritional status while minimizing the accumulation of toxic waste products and manifestations of uremia.
- Prevent and treat cardiovascular disease.
- Identify and treat complications of CKD.
- Prepare for renal replacement therapies such as dialysis or renal transplant.

DIAGNOSIS

Diagnostic testing is used both to identify CKD and to monitor kidney function. A number of tests may be performed to determine the underlying renal disorder. Once the diagnosis is established, renal function is monitored primarily through blood levels of metabolic wastes and electrolytes.

- *Urinalysis* is done to detect abnormal urine components. In CKD, the specific gravity may be fixed at approximately 1.010 due to impaired tubular secretion, reabsorption, and urine concentrating ability. Abnormal proteins, blood cells, and cellular casts may be noted in the urine.
- *Urine culture* is ordered to identify any urinary tract infection that may hasten the progress of CKD.
- *BUN* and *serum creatinine* are obtained to evaluate kidney function and assess the progress of renal failure. A BUN of 20 to 50 mg/dL signals mild azotemia; levels greater than 100 mg/dL indicate severe renal impairment. Uremic symptoms are seen when the BUN is around 200 mg/dL or higher. Serum creatinine levels of greater than 4 mg/dL indicate serious renal impairment.
- *eGFR* is used to evaluate the GFR and stage of chronic kidney disease. The eGFR is a calculated value determined using a formula that includes the serum creatinine, patient's age, gender, and race (African American or non–African American).
- *Serum electrolytes* are monitored throughout the course of CKD. The serum sodium may be within normal limits or low because of water retention or impaired sodium conservation. Potassium levels are elevated but usually remain below 6.5 mEq/L. Serum phosphate is elevated, and the calcium level is decreased. Metabolic acidosis is identified by a low pH, low CO_2, and low bicarbonate levels.
- *CBC* reveals moderately severe anemia with a hematocrit of 20% to 30% and a low hemoglobin. The number of RBCs and platelets is reduced.
- *Renal ultrasonography* is done to evaluate kidney size. In long-standing CRF, kidney size decreases as nephrons are destroyed and kidney mass is reduced.
- *Kidney biopsy* may be done to identify the underlying disease process if this is unclear. It is also used to identify an acute process from chronic failure. Kidney biopsy may be performed in surgery or done percutaneously using needle biopsy.

MEDICATIONS

Chronic kidney disease affects both the pharmacokinetic and pharmacodynamic effects of drug therapy. Most medications are excreted primarily by the kidney. The half-life and plasma levels of many drugs increase in chronic kidney disease. Drug absorption may be decreased when phosphate-binding agents are administered concurrently. Proteinuria can significantly reduce plasma protein levels, leading to manifestations of toxicity when highly protein-bound drugs are given. In addition, any potentially nephrotoxic agent is avoided or used with extreme caution. Drugs such as meperidine, metformin (Glucophage), and other oral hypoglycemic agents eliminated by the kidney are avoided entirely. NSAIDs, which may cause a further decline in kidney function, are avoided (Bargman & Skorecki, 2012). Because the kidneys are the primary route of magnesium excretion, magnesium-containing antacids and laxatives are avoided in CKD (Watnick & Dirkx, 2012).

ACE inhibitors and ARBs have been shown to reduce proteinuria and slow the progression of CKD (Fink et al., 2012) and often are used for this purpose. Diuretics such as furosemide or other loop diuretics may be prescribed to reduce extracellular fluid volume and edema. Diuretic therapy can reduce hypertension and cause potassium wasting, lowering serum potassium levels. Other antihypertensive agents, particularly the calcium channel blockers diltiazem (Cardizem, others) and verapamil (Calan, Isoptin, others), are used to maintain the blood pressure within normal levels, slow the progress of renal failure, and prevent complications of coronary heart disease and cerebrovascular disease.

Patients with CKD have a significantly increased risk for cardiovascular disease and premature death. Numerous randomized controlled trials have demonstrated the benefit of statin drugs in reducing cardiovascular mortality in patients with CKD (Fink et al., 2012).

Other drugs may be used to manage electrolyte imbalances and acidosis. Sodium bicarbonate or calcium carbonate may be used to correct mild acidosis. Oral phosphorus binding agents such as calcium carbonate or calcium acetate are given to lower serum phosphate levels and normalize serum calcium levels. Phosphate binders such as lanthanum (Fosrenol) or sevelamer (Renagel) may be used as alternates to calcium-containing products. Drugs that can promote potassium retention (such as potassium-sparing diuretics, NSAIDs, ACE inhibitors, and ARBs) are eliminated if measures such as dietary potassium restriction fail to prevent hyperkalemia (Watnick & Dirkx, 2012). If the serum potassium rises to dangerously high levels, a combination of bicarbonate, insulin, and glucose may be given intravenously to promote potassium movement into the cells. Sodium polystyrene sulfonate (Kayexalate), a potassium-ion exchange resin, can be given either orally or rectally (as an enema).

Folic acid and iron supplements are given to combat anemia associated with chronic renal failure. A multiple vitamin preparation is often prescribed, because anorexia, nausea, and dietary restrictions may limit nutrient intake. Epoetin alfa (Epogen, Procrit, human recombinant erythropoietin) or darbepoetin (Aranesp) is used to stimulate red blood cell production in patients with CKD who are severely anemic. These drugs are not without risk: Hypertension is a common adverse effect, and adverse cardiovascular events such as stroke and thromboembolism have occurred (Bargman & Skorecki, 2012).

NUTRITION AND FLUID MANAGEMENT

Maintaining adequate nutrition and preventing protein-calorie malnutrition are the focus of nutritional management during early stages of CKD. As renal function declines, the elimination of water, solutes, and metabolic wastes is impaired. Accumulation of these wastes in the body leads to uremic symptoms. Dietary modifications can slow the progress of nephron destruction, reduce uremic symptoms, and help prevent complications.

Unlike carbohydrates and fats, the body is unable to store excess proteins. Unused dietary proteins are degraded into urea and other nitrogenous wastes, which are then eliminated by the kidneys. Protein-rich foods contain inorganic ions such as hydrogen ion, phosphate, and sulfites that are eliminated by the kidneys. A daily protein intake of 0.6 to 0.75 g/kg of body weight, or approximately 40 to 50 g/day for an average male patient, provides the amino acids necessary for tissue repair. The majority of proteins should be of high biologic value, rich in the essential amino acids. Carbohydrate and fat intake is increased to maintain energy requirements and provide approximately 35 kcal/kg per day.

Sodium intake is regulated to help manage hypertension and maintain the extracellular fluid volume at normal levels. Sodium is

restricted to 3 g/day initially (mild restriction) or to 2 g/day if necessary to control hypertension and prevent heart failure (Watnick & Dirkx, 2012). More stringent sodium restriction may be necessary as renal failure progresses. Unless hyponatremia is present, the patient is instructed to drink adequate water to prevent thirst. The patient is instructed to monitor weight daily and report any weight gain in excess of 2.3 kg (5 lb) over a 2-day period.

In stages 4 and 5, intake of potassium and phosphorus is restricted. Potassium intake is limited to less than 2 g/day (normal intake is about 3 g/day). The patient is cautioned to avoid using salt substitutes, which typically contain high levels of potassium chloride. Intake of phosphorus is limited to 800 to 1000 mg/day (the usual daily intake is 1000 to 1200 mg/day). Foods high in phosphorus include eggs, dairy products, and meat.

RENAL REPLACEMENT THERAPIES

When pharmacologic and dietary management strategies are no longer effective to maintain fluid and electrolyte balance and prevent uremia, dialysis or kidney transplantation is considered.

A number of considerations affect the choice of long-term treatment. Hemodialysis and peritoneal dialysis each have advantages and disadvantages. Establishing vascular access for hemodialysis may take several months. Planning ahead to develop the access before dialysis is necessary can ease the transition to dialysis. Established access is not a consideration for peritoneal dialysis. The peritoneal catheter can be placed and treatment initiated as soon as it is indicated. When dialysis treatments will be performed at home, initiating instruction before it is required can result in more effective learning. If a family member will serve as a dialysis helper, training begins prior to the onset of uremia.

If transplantation is considered, tissue typing and identification of potential living related donors can be done prior to the onset of ESRD. To make an informed decision, both the patient and the potential donor need to understand the risks, benefits, and options available. If the decision for transplant is made early, dialysis can potentially be avoided. The patient's age, concurrent health problems, donor availability, and personal preference influence the choice of renal replacement therapy.

DIALYSIS Approximately 70% of all people being treated for ESRD in the United States are receiving dialysis at an average maintenance cost of about $82,000 per year for hemodialysis patients and $61,600 for patients using peritoneal dialysis (USRDS, 2011). For the patient who is not a candidate for renal transplantation or who has had a transplant failure, dialysis is life sustaining.

The most common therapies for ESRD in the United States are hemodialysis performed in a dialysis center, followed by kidney transplant and peritoneal dialysis (USRDS, 2011). Both hemodialysis and peritoneal dialysis can be done in the home, but few patients use home hemodialysis. Of the two, peritoneal dialysis is typically the choice for at-home treatment. Because the morbidity and mortality for each are comparable, factors such as the desire and ability to manage home care, employment, and availability of a dialysis center become the primary factors influencing the choice of hemodialysis or peritoneal dialysis.

Patients on long-term dialysis have a higher risk for complications and death than the general population. Many have other chronic diseases along with ESRD. Infection and cardiovascular disease are common causes of illness and death. The 1-year survival rate for patients receiving dialysis is nearly 80%; long-term survival, however, falls to 35.8% at 5 years (NKUDIC, 2012).

The decision to initiate dialysis is not easy. Like insulin therapy for people with diabetes, dialysis manages the symptoms of ESRD but does not cure it. Dialysis is a constant factor of life, requiring thinking and planning ahead at all times. Patients on dialysis may not be able to maintain a job. Families often fall apart with the day-to-day stress. Even with dialysis, the patient may have constant flu-like symptoms, never feeling truly well. Patients on hemodialysis may feel powerless because of their dependence on others for treatment. On the other hand, home peritoneal dialysis places a continuing burden on the patient to maintain treatment. In the end, the patient may choose to discontinue treatment, preferring death over continued dialysis.

Hemodialysis for ESRD typically is done three times a week for a total of 9 to 12 hours per week. The amount of dialysis needed (or *dialysis dose*) is individually determined by factors such as body size and residual renal function, dietary intake, and concurrent illness. Hypotension and muscle cramps are common complications during hemodialysis treatments. Infection and vascular access problems are common long-term complications of hemodialysis. Cardiovascular disease is the leading cause of death for patients receiving hemodialysis. The death rate from cardiovascular disease is higher in patients on hemodialysis than those on peritoneal dialysis or who have had a kidney transplant for reasons that are unclear (Liu & Chertow, 2012). See the previous section on AKI and the box on page 804 for more information about hemodialysis and related nursing care.

Peritoneal dialysis is currently used by approximately 5% of people who require long-term dialysis in the United States. In Canada and Europe, 35% to 45% of patients with ESRD are treated with peritoneal dialysis. In underdeveloped countries, peritoneal dialysis is used to treat the majority of patients with ESRD.

Continuous ambulatory peritoneal dialysis (CAPD) is the most common form of peritoneal dialysis used. Dialysate (2 L) is instilled into the peritoneal cavity, and the catheter is sealed. The patient can then continue normal daily activities, emptying the peritoneal cavity and replacing the dialysate three to five times per day. No special equipment is needed. A variation of CAPD is *continuous cyclic peritoneal dialysis (CCPD)*, which uses a delivery device during nighttime hours and a continuous dwell (dialysate retained in the peritoneal cavity) during the day. CAPD can be performed anywhere, and CCPD allows for home treatment at night, leaving the patient free during the day.

Peritoneal dialysis has several advantages over hemodialysis. Heparinization and vascular complications associated with an AV fistula are avoided. The clearance of metabolic wastes is slower but more continuous, avoiding rapid fluctuations in extracellular fluid composition and associated symptoms. More liberal intake of fluids and nutrients is often allowed for the patient on CAPD. While glucose absorbed from dialysate can increase blood glucose levels in an individual with diabetes, regular insulin can be added to the infusion to manage hyperglycemia. The patient on peritoneal dialysis is better able to self-manage the treatment regimen, reducing feelings of helplessness.

The major disadvantages of peritoneal dialysis include less effective metabolite elimination and risk of infection (peritonitis).

Peritoneal dialysis may not be effective for large patients with no residual kidney function. Metabolic complications of peritoneal dialysis are common, including weight gain, hyperglycemia, and hypoproteinemia. Absorption of dextrose from the dialysate can add several hundred calories daily, while albumin and other proteins are lost across the peritoneal membrane (Liu & Chertow, 2012). Finally, the presence of an indwelling peritoneal catheter may cause a body image disturbance. See the Nursing Care box on page 805 for more information about dialysis and nursing care for the patient undergoing peritoneal dialysis.

KIDNEY TRANSPLANT Kidney transplant has become the treatment of choice for many patients with ESRD. Kidneys are the solid organs most commonly transplanted, and to date kidney transplantation is the most successful of transplantation procedures. The first kidney transplant was performed in 1954; the donor and recipient were identical twins. Kidney transplant as a treatment for ESRD is limited primarily by availability of organs. In 2011, nearly 17,000 people received a kidney transplant; however, based on Organ Procurement and Transportation Network (OPTN) data as of August 2012, more than 92,000 people are currently awaiting a transplant.

Kidney transplant improves both survival and quality of life for the patient with ESRD. The patient on dialysis has an 80% probability of surviving after a year of dialysis; the transplant recipient has a greater than 91.7% probability of survival after a year. At 5 years, the difference is even greater: 35.8% for dialysis compared with more than 85.5% for transplant (NKUDIC, 2012). The transplant patient is no longer tethered to a dialysis catheter, machine, or center. Dietary and fluid restrictions are reduced, and the body image is more whole.

Most transplanted kidneys are obtained from deceased donors; however, transplants from living donors are increasing. In 2011, of transplanted kidneys, 34% came from living donors, most of whom were related to the recipient (OPTN, 2012a). With both deceased and living donor transplants, a close match between blood and tissue type is desired. In general, a match of ABO blood group is necessary; that is, the donor and recipient must share the same blood group (A, B, or O). Human leukocyte antigens (HLAs) are compared between the donor and recipient; six antigens in common are considered to be a "perfect" match. The success of well-matched living-donor transplants is better than for deceased donor organ transplants, with a 1-year graft survival of 95.1% compared to 89% for deceased donor transplants (OPTN, 2012b). Close tissue matching probably accounts for the better outcome with living donors. People with normal kidneys who are in good physical health may donate a kidney. Predonation counseling is vital: Although a laparoscopic approach may be used to remove the donor's kidney, there is a risk that trauma or disease may damage the remaining kidney in the future. If the transplant fails, the psychologic impact on the donor can be significant. Nursing care of the patient having a nephrectomy is summarized in the box on page 815.

Ideally, deceased donor kidneys are obtained from people who meet the criteria for brain death, are less than 60 years old, and are free of systemic disease, malignancy, or infection, including HIV and hepatitis B or C. Expanded deceased donor criteria may allow donation of a kidney from a deceased donor who is older than 60 years or who has cardiovascular disease (hypertension or stroke) or an elevated serum creatinine (OPTN, 2012a). Kidneys are removed after brain death has been determined, and are preserved by hypothermia or a technique called continuous hypothermic pulsatile perfusion. A kidney preserved by hypothermia is transplanted within 24 to 48 hours. Continuous pulsatile perfusion allows up to 3 days before transplantation. The system used to allocate deceased donor kidneys for transplantation is outlined in Box 28–1.

BOX 28–1 How Deceased Donor Kidneys Are Allocated for Transplant

The scarcity of organs for transplant raises questions about how deceased donor kidneys are allocated—who receives a kidney and who does not. Past inequities in the allocation process (e.g., more men than women, more Caucasians than people of other ethnicities, more rich than poor, and more young than old) led to the development of the United Network for Organ Sharing (UNOS) in 1986. UNOS has policies for organ distribution, including kidneys, hearts, livers, and other transplanted organs.

UNOS maintains national, regional, and local lists of patients awaiting transplants. When an organ becomes available, donor information is entered into the UNOS computer. The computer then runs a match program, generating a list of patients ranked by criteria such as blood and tissue type, organ size, and medical urgency of the patient. Factors such as time on the waiting list and distance between the donor and the transplant center also are considered. A candidate with a perfect match (six HLAs in common) and compatible blood type gets priority for the kidney, regardless of region or geographic area. Otherwise, the list of patients in the local area is checked first, then the regional list of patients awaiting transplant. If no match is found in the region, the organ becomes available to patients nationwide.

The UNOS allocation system, standardized fees, and Medicare coverage for transplantation have done much to ensure equitable access to available kidneys. Still, controversy exists. Patients with resources for travel may register in several different regions for an organ. Up to 10% of patients receiving a transplant in any center may be foreign nationals competing with U.S. citizens for scarce organ resources. A transplant center can accept or reject a candidate for transplant who has lost a kidney because of noncompliance.

As long as the demand for kidneys exceeds the supply of donor organs, it is likely that controversy will exist regarding their allocation. Nurses can help by identifying potential donors and contacting the transplant coordinator. In addition, nurses can inform the public about organ donation and the allocation system, and encourage donation.

The donor kidney is placed in the lower abdominal cavity of the recipient, and the renal artery, vein, and ureter are anastomosed (Figure 28–9 ■). The renal artery of the donor kidney is connected to the hypogastric artery, and the renal vein to the iliac vein. The ureter is connected to one of the recipient's ureters or directly to the bladder, using a tunnel technique to prevent reflux. Nursing care for the patient having a kidney transplant is outlined in the box on page 815.

Unless the donor and recipient are identical twins, the grafted organ stimulates an immune response to reject the transplanted organ. Immunosuppressive drugs minimize this response. Azathioprine or mycophenolate mofetil are commonly used, often in combination with prednisone, a corticosteroid. Cyclosporine, a potent immunosuppressive, also may be used. These drugs suppress a portion of the immune system and the inflammatory response, increasing the risk for infections and cancers with long-term therapy. Glucocorticoids such as prednisone and methylprednisolone are used for both

NURSING CARE OF THE PATIENT

Having a Kidney Transplant

PREOPERATIVE CARE

- Provide routine preoperative care.
- Assess knowledge and feelings about the procedure, answering questions and clarifying information as needed. Listen and address concerns about surgery, the source of the donor organ, and possible complications. *Addressing concerns and reducing preoperative anxiety improve postoperative recovery*.
- Continue dialysis as ordered. *Continued renal replacement therapy is necessary to manage fluid and electrolyte balance and prevent uremia prior to surgery*.
- Administer immunosuppressive drugs as ordered before surgery. *Immunosuppression is initiated before transplantation to prevent immediate graft rejection*.
- Report abnormal or unexpected laboratory values to the surgical team. *Significant hyperkalemia increases the risk for intraoperative cardiac dysrhythmias* (*Chandraker et al., 2012*).

POSTOPERATIVE CARE

- Provide routine postoperative care.
- Maintain urinary catheter patency and a closed system. *Catheter patency is vital to keep the bladder decompressed and prevent pressure on suture lines. A closed drainage system minimizes the risk for urinary tract infection*.
- Measure urine output every 30 to 60 minutes initially. *Careful assessment of urine output helps determine fluid balance and transplant function. Acute tubular necrosis is a common early complication, usually due to tissue ischemia during the period between removal of the kidney from the donor and transplantation. Oliguria is an early sign*.
- Monitor vital signs and hemodynamic pressures closely. *Diuresis may occur immediately, resulting in hypovolemia, low cardiac output, and impaired perfusion of the transplanted kidney*.
- Maintain fluid replacement, generally calculated to replace urine output over the previous 30 or 60 minutes, milliliter for milliliter. *Fluid replacement is vital to maintain vascular volume and tissue perfusion*.
- Administer diuretics as ordered. *Loop and/or osmotic diuretics such as furosemide or mannitol may be used to promote postoperative diuresis*.
- Remove the catheter within 2 to 3 days or as ordered. Encourage to void every 1 to 2 hours and assess frequently for signs of urinary retention following catheter removal. *The bladder may have atrophied prior to surgery, reducing its capacity. Urinary retention places stress on suture lines and increases the risk of infection*.
- Monitor serum electrolytes and renal function tests. *These tests are used to monitor graft function and fluid and electrolyte status. Electrolyte imbalances may develop as the transplanted kidney begins to function and diuresis occurs. Elevated serum creatinine and BUN levels may be early signs of rejection or graft failure*.
- Monitor for possible complications:
  a. *Hemorrhage* from an arterial or venous anastomosis can be either acute or insidious. Indicators include swelling at the operative site, increased abdominal girth, and signs of shock, including changes in vital signs and level of consciousness. *Hemorrhage is a surgical emergency, requiring prompt recognition and treatment to preserve the graft*.
  b. *Ureteral anastomosis failure* causes urine leakage into the peritoneal cavity. It may be marked by decreased urine output with abdominal swelling and tenderness. *Failure of the ureteral anastomosis requires surgical intervention*.
  c. *Renal artery thrombosis* is characterized by an abrupt onset of hypertension and reduced GFR. *Renal artery thrombosis can result in transplant failure*.
  d. *Infection* due to immunosuppression is an immediate and continuing risk. The inflammatory response is blunted, and infection may not significantly elevate the temperature. Monitor for signs such as change in level of consciousness, cloudy or malodorous urine, or purulent drainage from the incision. *Prevention and prompt treatment of infections are particularly important in the immunosuppressed patient*.
- Include the following in predischarge teaching for the patient and family:
  a. The use and effects of prescribed medications, including antihypertensive medications, immunosuppressive agents, prophylactic antibiotics, and others as ordered.
  b. Monitoring of vital signs (including temperature) and weight.
  c. Manifestations of organ rejection, such as swelling and tenderness over the graft site, fever, joint aching, weight gain, and decreased urinary output. Stress the importance of promptly reporting signs and symptoms to the physician.
  d. Ordered or recommended dietary restrictions such as restricted carbohydrate and sodium intake, and increased protein intake.
  e. Measures to prevent infection, such as avoiding crowds and obviously ill individuals.

  The patient and family will manage care after discharge, and therefore need a good understanding of what to expect, how to monitor graft status, and measures to reduce the adverse effects of medications.
- Provide psychologic support, address concerns, and provide information as needed. *The patient knows that transplant success is not guaranteed. In addition, the patient has often been managing a chronic disease independently and is used to having a degree of control. Providing information and allowing the patient to retain control relieves anxiety and improves recovery*.

maintenance of immunosuppression and to treat acute rejection episodes. Side effects of long-term corticosteroid use include impaired wound healing, emotional disturbances, osteoporosis, and cushingoid effects on glucose, protein, and fat metabolism.

Azathioprine inhibits both cellular and humoral immunity. Because the liver rapidly metabolizes this drug, the dose may not need to be altered in the presence of renal failure. Bone marrow suppression, abnormalities of liver function, and alopecia are the primary significant adverse effects for azathioprine. The action of mycophenolate mofetil is similar to that of azathioprine. Its advantages are minimal bone marrow suppression and increased potency in preventing or reversing rejection of the transplanted organ (Chandraker et al., 2012).

Cyclosporine primarily affects cellular immunity, the helper T cells in particular. Among its many adverse effects, which include hepatotoxicity and hirsutism, nephrotoxicity is a primary concern for the patient undergoing a kidney transplant.

Even with immunosuppressive therapy, the transplanted kidney can be rejected at any time. Either acute or chronic rejection may develop. *Acute rejection* develops within months of the transplant. It is caused by a cellular immune response with T-lymphocyte proliferation (Grossman & Porth, 2014). Few manifestations may be apparent

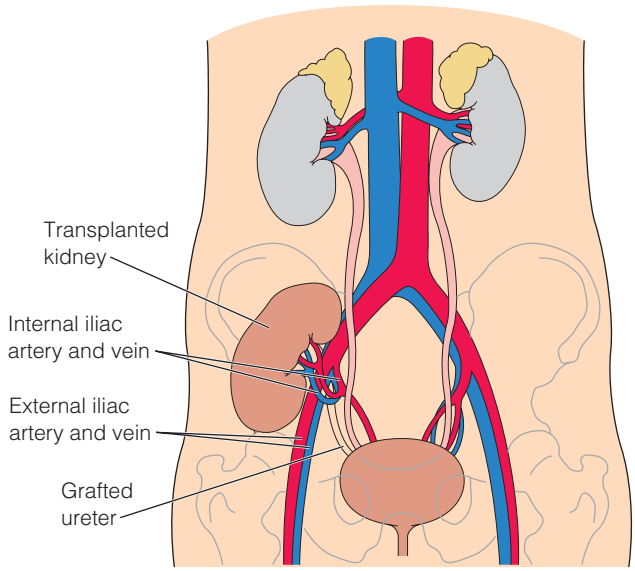


Figure 28–9 ■ Placement of a transplanted kidney in the iliac fossa with anastomosis to the hypogastric artery, iliac vein, and bladder.

other than a rise in serum creatinine and possible oliguria. Methylprednisolone, a glucocorticoid, and OKT3 monoclonal antibody are used to manage acute rejection episodes. OKT3 can cause severe systemic reactions, including chills, fever, hypotension, headache, and possible pulmonary edema. *Chronic rejection*, which may develop months to years following the transplant, is a major cause of graft loss. Both humoral and cellular immune responses are involved in chronic rejection. It does not respond to increased immunosuppression. The presenting manifestations of chronic rejection—progressive azotemia, proteinuria, and hypertension—are those of progressive renal failure.

Hypertension is a possible complication of kidney transplant, resulting from graft rejection, renal artery stenosis, or renal vasoconstriction. Patients may develop glomerular lesions and manifestations of nephrosis. Hypertension and altered blood lipids (increased LDLs and decreased HDLs) increase the risk of death from myocardial infarction and stroke following transplant.

Long-term immunosuppression has adverse effects as well. Infection is a continuing threat. Bacterial and viral infections may develop, as well as fungal infections of the blood, lungs, and CNS. Tumors are common, with carcinoma in situ of the cervix, lymphomas, and skin cancers most prevalent. The risk of congenital anomalies is increased in infants whose mothers have undergone immunosuppressive therapy. Corticosteroid use may lead to bone problems, gastrointestinal disorders such as peptic ulcer disease, and cataract formation.

●○● NURSING CARE

Health Promotion

Measures to reduce the risk of CKD focus on preventing kidney disease and appropriately managing diabetes and hypertension. Promote early and effective treatment of all infections, particularly skin and pharyngeal infections caused by streptococcal bacteria. Discuss measures to reduce the risk for urinary tract infections, and stress the importance of prompt treatment to eradicate the infecting organism. Discuss the relationship among diabetes, hypertension, and kidney disease. Emphasize that maintaining blood glucose levels and the blood pressure within the recommended ranges reduces the risk of adverse effects on the kidneys. Ensure that all patients with less than optimal renal function are well hydrated, particularly when a nephrotoxic drug is prescribed or anticipated. Finally, encourage the patient with CKD to investigate options for early transplantation to avoid long-term dialysis.

Assessment

Both subjective and objective data are used to assess the patient with CKD:

- *Health history:* complaints of anorexia, nausea, weight gain, or edema; current treatment (if any), including type and frequency of dialysis or previous kidney transplant; chronic diseases such as diabetes, heart failure, or kidney disease
- *Physical assessment:* mental status; vital signs including temperature, heart and lung sounds, and peripheral pulses; urine output (if any); weight; skin color, moisture, condition; presence of edema (periorbital or dependent); bowel tones; presence and location of an AV fistula, shunt, graft, or peritoneal catheter.

See the box on page 809 for assessment of the older adult with CKD.

Priorities of Care

Nursing care priorities for the patient with chronic kidney disease change over time. During stages 1 through 3, measures to support kidney function and prevent further damage are of highest priority. Maintaining fluid balance, preventing urinary tract infection, effectively managing diabetes and hypertension, and avoiding exposure to nephrotoxins are important nursing care priorities. With the onset of ESRD, the nurse collaborates with the interprofessional team in managing renal replacement therapies and patient responses to declining kidney function.

Diagnoses, Outcomes, and Interventions

Whether the patient with CKD and ESRD is facing long-term dialysis or renal transplantation, a number of nursing care needs can be identified. This section focuses on nursing care related to impaired renal

function, nutritional deficits due to dietary restrictions and nausea, increased risk for infection, and changes in body image. See the Case Study & Nursing Care Plan on page 818 for additional potential nursing diagnoses and interventions for the patient with chronic kidney disease.

Impaired Kidney Function

Chronic diseases such as diabetes mellitus and hypertension are the leading causes of CKD. As kidney and nephron function declines, the kidney is less able to maintain fluid and electrolyte balance and eliminate waste products from the body.

Expected Outcome: Patient will not experience adverse effects of declining kidney function.

- Monitor intake and output, vital signs including orthostatic blood pressures, and weight. *These provide important data to identify changes in fluid volume. Weight changes are a more accurate indicator of fluid volume status in the oliguric or anuric patient than intake and output measurements.*
- Monitor respiratory status, including lung sounds, every 4 to 8 hours. *Fluid volume overload may lead to heart failure and possible pulmonary edema.*
- Monitor BUN, serum creatinine, eGFR, pH, electrolytes, and CBC. Report significant changes. *As renal function declines, the GFR falls and progressive azotemia with increasing BUN and serum creatinine is seen. Metabolic acidosis develops as the kidney is unable to eliminate hydrogen ions and conserve bicarbonate. Hyponatremia, hyperkalemia, hyperphosphatemia, and hypocalcemia are associated with renal failure. The RBC count, hemoglobin, and hematocrit decline due to deficient erythropoietin to stimulate cell production in the bone marrow. An acute fall in hemoglobin and hematocrit may indicate GI bleeding, a risk in patients with ESRD.*
- Report manifestations of electrolyte imbalances, such as cardiac dysrhythmias and other ECG changes, muscle tremors and possible tetany, and Kussmaul's respirations. *Manifestations of electrolyte imbalance may indicate the need for intervention.*
- Administer medications to treat electrolyte imbalances as ordered. *Medications may be prescribed to help maintain electrolyte and acid–base balance and prevent adverse effects of imbalances.*
- Collaborate with the patient who has diabetes to maintain the blood glucose within a range of 90 to 130 mg/dL. As appropriate, discuss the selection and use of oral hypoglycemic medications with the interprofessional team. *Evidence supports preventing hyperglycemia as a strategy to slow the progression of CKD (Bargman & Skorecki, 2012). Selected oral hypoglycemic drugs may increase the risk for complications such as hypoglycemia, fluid and electrolyte imbalances, and metabolic acidosis.*
- Administer antihypertensive medications as ordered. *Hypertension management is an important factor in slowing the progression of CKD.*
- Time activities and procedures to allow rest periods. *The anemia associated with CKD may cause significant fatigue and activity intolerance.*

SAFETY ALERT

Monitor carefully for desired and adverse effects of all medications. Impaired renal function affects drug elimination and increases the risk for toxic effects.

Imbalanced Nutrition: Less Than Body Requirements

Anorexia, nausea, and vomiting are common manifestations of ESRD and uremia. The patient often has a metallic taste and bad breath, which also diminish appetite. A diet restricted in protein and sodium will compound these problems. Food intake may be insufficient to meet metabolic needs. Catabolism, the breakdown of body proteins to meet energy needs, exacerbates azotemia and uremia.

Expected Outcome: Patient will maintain adequate nutritional status as evidenced by stable weight, body mass index (BMI), and laboratory values.

- Monitor food and nutrient intake as well as episodes of vomiting. *Careful monitoring helps determine the adequacy of intake.*
- Weigh daily before breakfast. *This provides the most accurate measurement. Remember that a gain of 1 kg (2.2 lb) or more over a 24-hour period is more likely to reflect fluid retention than a gain in body mass.*
- Administer antiemetic agents 30 to 60 minutes before eating. *Antiemetics reduce nausea and the risk of vomiting with food intake.*
- Assist with mouth care prior to meals and at bedtime. *Mouth care improves taste, stimulates the appetite, and maintains the integrity of oral mucous membranes.*
- Serve small meals and provide between-meal snacks. *Small meals are less likely to prompt nausea and help improve food intake.*
- Arrange for a dietary consultation. Provide preferred foods to the extent possible, and involve the patient in planning daily menus. Encourage family members to bring food as dietary restrictions allow. *Providing preferred foods within restrictions promotes intake.*
- Monitor nutritional status by tracking weight, laboratory values such as serum albumin and BUN, and anthropometric measurements. *Indicators of impaired nutrition develop gradually and may be subtle. Careful assessment is important.*
- Administer enteral or parenteral nutrition as prescribed. Routinely monitor blood glucose levels, and use strict aseptic technique when handling parenteral nutrition solutions and the venous access site. *When the patient is unable to consume adequate nutrients, enteral nutritional support is preferred. Parenteral nutrition may be necessary to prevent catabolism and increasing azotemia. Hyperglycemia and infection are risks associated with parenteral nutrition. Immune system suppression associated with renal failure further increases the risk for infection.*

Risk for Infection

Chronic kidney disease affects the immune system and leukocyte function, increasing susceptibility to infection. Invasive devices required for hemodialysis or peritoneal dialysis add to this risk. The patient who has had a kidney transplant remains on immunosuppressive therapy for life, further depressing the immune system and increasing the risk for infection.

Expected Outcome: Patient will remain free of infection or sepsis.

- Use standard precautions and good hand hygiene technique at all times. *Hand hygiene is a primary means of preventing the transfer of organisms. Patients who are on hemodialysis or who have had blood transfusions to treat anemia have an increased risk for hepatitis B, hepatitis C, and HIV infection.*

CASE STUDY & NURSING CARE PLAN A Patient with End-Stage Renal Disease

Walter Cohen, 45 years old, has had type 1 diabetes since the age of 20. He was diagnosed with diabetic nephropathy 10 years ago. Despite ACE inhibitor therapy, blood pressure control with antihypertensive medications, and frequent blood glucose monitoring with insulin coverage, he developed overt proteinuria 5 years ago and has now progressed to end-stage renal disease. He enters the nephrology unit for temporary hemodialysis and to prepare for home peritoneal dialysis.

ASSESSMENT

Mr. Cohen states that his diabetes has always been difficult to control. He has had numerous hypoglycemic episodes and has been hospitalized "several times" for ketoacidosis. Recently he has developed symptoms of peripheral neuropathy and increasing retinopathy. He attributed his lack of appetite, nausea, vomiting, and fatigue during the past month to "a touch of the flu." His weight remained stable, so he did not worry about not eating much.

Physical assessment findings include T 36.5°C (97.8°F) PO, P 96 bpm, R 20/min, and BP 178/100 mmHg. Skin cool and dry. Breath odor fetid. Scattered fine rales noted in bilateral lung bases. Soft S_3 gallop noted at cardiac apex. Bilateral pitting edema of lower extremities to just below the knees; fingers and hands edematous. Abdominal assessment essentially normal, with hypoactive bowel sounds. Urinalysis shows a specific gravity of 1.011, gross proteinuria, and multiple cell casts. CBC results: RBC 2.9 million/mm^3; hemoglobin 9.4 g/dL; hematocrit 28%. Blood chemistry abnormalities include BUN 198 mg/dL; creatinine 18.5 mg/dL; sodium 125 mEq/L; potassium 5.7 mEq/L; calcium 7.1 mg/dL; phosphate 6.8 mg/dL. A temporary jugular venous catheter will be placed for hemodialysis the next day, followed by peritoneal catheter insertion later in the week.

Clinical Reasoning in Patient Care

1. Compare Mr. Cohen's CBC and chemistry values with normal ranges for these tests. Explain the pathologic processes contributing to changes from the normal. What nursing processes should you initiate to help ensure Mr. Cohen's safety and abilities to carry out his ADLs?
2. What are the safety implications of Mr. Cohen's peripheral neuropathy and increasing retinopathy? Identify nursing care measures to reduce his risk for injury.

DIAGNOSES

- *Excess Fluid Volume* related to failure of kidneys to eliminate excess body fluid
- *Imbalanced Nutrition: Less Than Body Requirements* related to effects of uremia
- *Risk for Infection* related to invasive catheters and impaired immune function

EXPECTED OUTCOMES

- Patient will adhere to the prescribed fluid restriction of 900 mL/day.
- Patient will demonstrate reduced extracellular fluid volume by weight loss, decreased peripheral edema, clear lung sounds, and normal heart sounds.
- Patient will consume and retain 100% of prescribed diet, including snacks.
- Patient will remain free of infection.
- Patient will demonstrate appropriate peritoneal catheter care and CAPD.

PLANNING AND IMPLEMENTATION

- Collaborate with Mr. Cohen to distribute allowed fluids throughout the day.
- Provide mouth care at least every 4 hours and before every meal.
- Keep sugarless hard candy and ice chips at the bedside; include ice consumed as fluid intake.
- Weigh daily before breakfast; monitor vital signs, and heart and lung sounds, every 4 hours.
- Document intake and output every 4 hours.
- Arrange dietary consultation for menu planning.
- Administer prescribed antiemetic 1 hour before meals.
- Monitor food intake, noting percentage and types of food consumed.
- Teach CAPD procedure and peritoneal catheter care.
- Assist to identify strengths and needs in health regimen management.

EVALUATION

Mr. Cohen was hospitalized for 2 weeks, undergoing four hemodialysis sessions to reduce uremic symptoms. An arteriovenous fistula has been created in his left arm in case he should need hemodialysis in the future. He begins peritoneal dialysis the second week, and by discharge he is able to manage the catheter care and dialysis runs with the help of his wife. His heart and lung sounds are normal, and he has minimal peripheral edema on discharge. His temperature is normal, and no evidence of infection is noted. Mr. Cohen remains anorectic and slightly nauseated, but is eating most of his prescribed diet and snacks. He has lost 4.5 kg (10 lb) with excess fluid removal by dialysis, but his weight remains stable during the second week. Mr. Cohen and his wife have been introduced to another patient who has been on CAPD for several years and promises to help them with problem solving.

Clinical Reasoning in Patient Care

3. How does diabetes mellitus damage the kidneys and lead to CKD? Why is this more significant for a patient with type 1 diabetes than for someone with type 2 diabetes?
4. Why do high levels of urea in the blood often cause changes in cognition and mental status? What manifestations of encephalopathy would you expect to see?
5. How might Mr. Cohen's insulin dosage and diet need to be changed with the institution of peritoneal dialysis? Why?

See Evaluating Your Response in Appendix B.

SAFETY ALERT

Use strict aseptic technique when managing ports, catheters, and incisions, to reduce the risk of introducing infectious organisms when immune responses are impaired.

- Monitor temperature and vital signs at least every 4 hours. *A low-grade fever or increased pulse rate may indicate an infection in the immunosuppressed patient.*
- Monitor WBC count and differential. *Increased WBCs may indicate a bacterial infection; decreased WBCs may indicate viral infection. A shift in the differential showing more immature WBCs (bands) in circulation is another indicator of infection.*
- Culture urine, peritoneal dialysis fluid, and other drainage as indicated. *Culture is done to verify the presence of pathogens.*
- Monitor clarity of dialysate return. *Dialysate should return clear in the patient undergoing peritoneal dialysis. Cloudy dialysate may indicate peritonitis, the most common complication of peritoneal dialysis, and should be reported and cultured.*
- Provide good respiratory hygiene including position changes, coughing, and deep breathing. *These measures improve clearance of respiratory secretions, reducing the risk for infection.*

Moving Evidence into Action

Physical Activity in Patients with ESRD

In this study, Painter, Ward, and Nelson (2011) surveyed patients with ESRD about activity levels. Although 52% of respondents reported having some physical activity, only 13.2% reported activity at levels recommended for older adults to achieve health. Study participants, whose average age was 62.4 years, were undergoing some form of renal replacement therapy, with the majority (83%) on hemodialysis. Consistent with prevalent causes of CKD, half of the participants had diabetes, a third reported cardiovascular disease, and an additional 22% had both diabetes and cardiovascular disease. Using a standard for recommended physical activity of at least 30 minutes of moderate intensity exercise on three or more days per week, only 13.2% of respondents reported achieving the standard. Men were more likely than women to engage in some or recommended levels of activity. Participants with diabetes and/or diabetes and cardiovascular disease had the lowest activity levels. Those who had undergone kidney transplant were more likely to participate in physical activity than those undergoing dialysis.

Implications for Nursing

Patients with diabetes mellitus and hypertension, the leading causes of chronic kidney disease, benefit from a program of regular physical activity. Furthermore, physical activity is known to have a positive impact on cardiovascular disease, the leading cause of death among people with CKD. Muscle weakness and lack of energy are common manifestations of ESRD and often cited as reasons for not engaging in physical activity. However, those participants who were active reported improved energy, muscle strength, sleep, and mood as benefits of exercise or physical activity.

Nurses who care for patients with ESRD (on nephrology units, in dialysis centers, etc.) have regular opportunities to educate patients about the benefits of regular physical activity. Working with the interprofessional care team, nurses are in a position to recommend and encourage a program of physical activity for patients with ESRD.

Moving Knowledge into Action

1. This study found that patients who had undergone a kidney transplant were more likely to participate in some or recommended levels of activity than those undergoing dialysis. Taking the holistic nature of CKD into consideration, identify possible reasons for this difference.
2. Identify assessment tools and data you could use to evaluate the current level of participation in physical activity of a patient with ESRD.
3. Which other members of the interprofessional care team should be involved in developing a plan to increase activity level for a patient with ESRD? Do team members differ for patients with diabetes versus those with known cardiovascular disease?
4. What interventions can you, as the nurse, implement to promote activity in patients undergoing renal replacement therapy? How might these interventions differ for young, middle, and older adults?

- Restrict visits from obviously ill people. Teach the patient and family about the risk for infection and measures to reduce the spread of infection. *The patient's resistance to infection is impaired, necessitating extra caution in preventing unnecessary exposures.*

Disturbed Body Image

Chronic disease and impaired kidney function can affect a patient's body image. Hemodialysis requires an arteriovenous fistula or shunt; a permanent peritoneal catheter is required for peritoneal dialysis. Although kidney transplant can restore an image of wholeness, a visible scar remains and the organ may be perceived as "foreign."

Expected Outcome: Patient will acknowledge impact of CKD and treatment on roles, relationships, and lifestyle, and express willingness to use available resources in developing an adaptive response to changes.

- Involve the patient in care, including meal planning, dialysis, and catheter, port, or incision care to the extent possible. *Involvement improves acceptance and stimulates discussion about the effect of the disease and treatment measures on the patient's life.*
- Encourage expression of feelings and concerns, accepting perceptions and feelings without criticism. *Self-expression enhances the patient's self-worth and acceptance.*
- Include the patient in decision making and encourage self-care. *Increased autonomy enhances the patient's sense of control, independence, and self-worth.*
- Support positive gains, but do not support denial. *The patient may have difficulty accepting the renal failure, but adaptation to the loss is important.*
- Help the patient develop and achieve realistic goals. *Realistic goals allow the patient to see progress.*
- Provide positive reinforcement and feedback. *These measures support growth and adaptation.*
- Reinforce effective coping strategies. *Reinforcement helps the patient develop positive versus negative strategies for coping.*
- Facilitate contact with a support group or other community members affected by renal failure. *The patient benefits by providing and receiving support in a group of people going through similar circumstances.*
- Refer for mental health counseling as indicated or desired. *Counseling can help the patient develop effective coping and adaptation strategies.*

Delegating Nursing Care Activities

As appropriate and allowed by the designated duties and responsibilities of unlicensed assistive personnel, the nurse may delegate nursing care activities such as obtaining vital signs and daily weights, and assisting with ambulation and ADLs for a patient with chronic kidney disease.

Continuity of Care

Chronic kidney disease and ESRD are long-term processes that require patient management. No matter what treatment option is chosen (hemodialysis, peritoneal dialysis, or renal transplantation), day-to-day management falls to the patient and family. Teaching for home care includes the following topics:

- Nature of chronic kidney disease and renal failure, including expected progression and effects
- Monitoring of weight, vital signs, and temperature
- Prescribed medications, including purpose, intended effect, and potential adverse effects and their management
- Prescribed dietary restrictions (Involve the patient, a dietitian, and the family member usually responsible for cooking. Include strategies to manage nausea and prevent thirst within allowed limits.)

- How to assess and protect a fistula or shunt for hemodialysis (or the extremity to be used if one is anticipated)
- Peritoneal catheter care and the procedure for peritoneal dialysis as indicated (Include a family member or significant other, in case the patient is unable to perform the procedure independently at some time.)
- Following kidney transplant, prescribed medications, adverse effects and their management, infection prevention, graft protection, and manifestations of organ rejection
- The benefits of and strategies for incorporating physical activity into daily life and the treatment plan. See the accompanying Moving Evidence into Action box.

Refer to a dietitian for diet planning and counseling. If home hemodialysis is planned, refer the designated dialysis helper for formal training. Both the National Kidney Foundation and the American Association of Kidney Patients may be able to provide support and educational materials for the patient with ESRD. Local and state chapters of these organizations can provide additional support.

CHAPTER HIGHLIGHTS

- **Congenital and acquired disorders of the kidneys can profoundly affect urinary elimination and ultimately all body systems.**
- **Glomerulonephritis, inflammation of the glomerulus of the kidney, leads to loss of proteins and blood cells in the urine, a decrease in the glomerular filtration rate, and severe edema.**
- **The renal and cardiovascular systems are closely interrelated. Vascular disorders, such as hypertension, renal artery stenosis, or obstruction of the renal artery or vein, can have serious consequences in terms of renal function.**
- Renal cell malignancies, while uncommon, often are not evident until the cancer is advanced and has metastasized to other sites.
- **Acute kidney injury is a frequent complication of hospitalization and critical illness that increases mortality, length of stay, costs, and the risk for subsequent chronic kidney disease. Nurses play a key role in preventing and recognizing acute kidney injury, thus minimizing its negative consequences.**
- Ischemic and nephrotoxic damage to the kidney are the most common precipitating factors for AKI.
- **Diabetes mellitus and hypertension are the leading causes of chronic kidney disease and kidney failure. Aggressive glycemic control and blood pressure management reduce the risk of kidney disease; likewise, early identification and effective management of chronic kidney disease can delay the onset of kidney failure.**
- When the kidneys fail, renal replacement therapies are necessary to eliminate metabolic waste products and sustain life. Dialysis and kidney transplant are the primary renal replacement therapies used.

TEST YOURSELF NCLEX-RN® REVIEW

1. An older patient with heart failure is prescribed digoxin (Lanoxin) 0.125 mg by mouth three times a week. What action should the nurse take regarding this prescribed medication?
   1. Assess the latest GFR before administering the medication.
   2. Provide the medication as prescribed with a large amount of water.
   3. Administer the drug as prescribed while monitoring for manifestations of toxicity.
   4. Discuss the need for a larger dose with the healthcare provider because of the patient's age.

2. After being diagnosed with polycystic kidney disease, an adult patient asks if current children are at risk for developing the disorder. How should the nurse respond?
   1. The adult form of this disorder is rare and should not affect grown children.
   2. The children should undergo genetic testing and screening for evidence of the disease.
   3. Because the condition was just diagnosed, there is no risk of passing the condition on to any children.
   4. The children would have developed symptoms of the disorder in utero or shortly after birth if they had inherited the defective gene.

3. The nurse is completing a health history with a young adult patient diagnosed with acute postinfectious glomerulonephritis. When focusing on recent health problems, about which disease process should the nurse ask the patient?
   1. strep throat
   2. urinary tract infection
   3. gastrointestinal disorder
   4. fractures or other musculoskeletal trauma

4. The nurse is evaluating teaching provided to a patient with acute glomerulonephritis. Which patient action indicates that additional teaching is not necessary?
   1. Limits fluid intake to less than 1500 mL/day.
   2. Demonstrates care of the vascular access device for dialysis.
   3. Selects soy or animal proteins for allowed grams of protein in diet.
   4. States the need to remain on bed rest until urine returns to clear yellow.

5. A patient recovering from a partial nephrectomy is in the post-anesthesia care unit. Which interventions would be a priority for this patient? (Select all that apply.)
   1. Irrigate all catheters with sterile normal saline.
   2. Label and secure all catheters, tubes, and drains.
   3. Administer cough suppressant medication as needed.
   4. Report the onset of bright red bleeding to the surgeon.
   5. Connect all catheters and drains to a single collection device.
6. The nurse is planning care to reduce the risk of a patient in the intensive care unit from developing acute kidney injury. Which intervention should the nurse implement for this patient?
   1. Administer antihypertensive drugs.
   2. Avoid all potentially nephrotoxic drugs.
   3. Maintain fluid volume and cardiac output.
   4. Assess for a history of diabetes or hypertension.
7. During a home visit the nurse evaluates discharge teaching provided to a patient recovering from an acute kidney injury. Which patient statement indicates that teaching has been effective?
   1. "I will eat only vegetable proteins."
   2. "I will avoid taking drugs that may harm my kidneys."
   3. "I will limit my fluid intake to 1500 mL or less per day."
   4. "I will catheterize myself for residual urine at least once a week."
8. The nurse is planning care for a patient beginning hemodialysis. What should be included in this patient's plan of care? (Select all that apply.)
   1. Restrict fluid and protein intake.
   2. Obtain weight and orthostatic vital signs.
   3. Determine urine specific gravity and pH.
   4. Monitor serum creatinine, BUN, and hematocrit levels.
   5. Assess blood pressure of extremity where fistula has been created.
9. The nurse is discussing the goals of treatment with a patient experiencing end-stage renal disease. Which goal should the nurse identify as being appropriate for this patient?
   1. Identify a live-in caregiver.
   2. Demonstrate the ability to independently perform hemodialysis in the home.
   3. State the advantages and disadvantages of types of renal replacement therapies.
   4. Relate the hospice philosophy and identify indicators of the need for hospice care.
10. Following a kidney transplant, the nurse notes that a patient's urine is cloudy. What should the nurse do about this finding?
    1. Record the finding.
    2. Notify the physician.
    3. Irrigate the urinary catheter.
    4. Increase the intravenous flow rate.

UNIT

7 Building Clinical Competencies

Responses to Altered Urinary Elimination

CLINICAL SCENARIO

Directions: *Read the following clinical scenario and answer the questions that follow. To complete this exercise successfully you will not only use knowledge of the content in this unit, but also principles related to setting priorities and maintaining patient safety.*

You have been assigned to work with the following four patients for the 0700 shift on a renal medical-surgical unit. Significant data obtained during report is as follows:

- Phillip Jones is a 45-year-old who was admitted 2 days ago after a fall from a deer hunting stand. He experienced a bruised right kidney and numerous ecchymotic areas to the right side from the fall. His vital signs are temperature 37.2°C (99°F), pulse 98 bpm, respirations 28/min, and blood pressure 110/68 mmHg. He is complaining of abdominal pain and difficulty urinating.
- Agnes Smith is an 84-year-old who was admitted 2 hours ago with urinary incontinence, anorexia, confusion, and lethargy. Her vital signs on admission were temperature 36.1°C (97°F), pulse 120 bpm, respirations 26/min, and blood pressure 96/50 mmHg. The healthcare provider ordered intravenous levofloxacin (Levaquin) to be started as soon as possible after collection of urine and blood cultures.
- Joseph Rouse is a 45-year-old who is to undergo surgery for removal of uric acid stones after having a failed lithotripsy. His vital signs are temperature 37.6°C (99.6°F), pulse 94 bpm, respirations 24/min, blood pressure 112/68 mmHg. His skin is pale, cool, and clammy. He is complaining of nausea, severe left-sided flank pain with spasms, and light-headedness.
- Angela Baldwin is a 34-year-old who has a medical history of systemic lupus erythematosus. She was admitted with complaints of left flank pain and generalized edema. Urinalysis results indicate hematuria and proteinuria. Vital signs are temperature 37.8°C (100°F), pulse 88 bpm, respirations 26/min, and blood pressure 144/90 mmHg. She is admitted for aggressive immunosuppressive therapy.

CLINICAL REASONING

1. Based on Mrs. Smith's suspected diagnosis of sepsis due to urinary tract infection, what additional measures are needed upon review of the patient's vital signs?

Priority Setting

2. Which priority nursing actions should be instituted for Mr. Jones following kidney trauma?
   A. Monitor level of consciousness and urine output.
   B. Monitor vital signs for hypotension and bradycardia.
   C. Observe for hypertension and check urine for hematuria.
   D. Observe urine for oliguria and proteinuria.

Health Promotion

3. To prevent reoccurrence of a urinary tract infection, what should Mrs. Smith be taught?
4. To prevent further kidney stones, what should Mr. Rouse be taught about his diet?
5. To prevent further kidney damage, what should Ms. Baldwin be taught about her diet?

Nursing Process

6. Mr. Jones is complaining of inability to void. A bladder scan indicates that he has 800 mL of urine in his bladder. Which interventions does the nurse perform?
   A. Insert a urinary catheter and completely drain the bladder at once.
   B. Insert a urinary catheter and drain urine in 500-mL increments.
   C. Ambulate Mr. Jones to the bathroom to try to void and run water in the sink.
   D. Give Mr. Jones a glass of water to drink to encourage voiding.

Communication

7. If Ms. Baldwin asks, "Are these urinary problems I am having an indication that the lupus is getting worse?" how will you respond?

Delegation

8. What data collection tasks and interventions can be delegated to unlicensed assistive personnel (UAP) for each patient?

A. _____
B. _____
C. _____
D. _____

Interprofessional Care

9. Mr. Rouse has returned from surgery. For which of the following urinary outputs should the nurse collaborate with the healthcare provider?

A. 20 mL per hour
B. 40 mL per hour
C. 300 mL per 8 hours
D. 400 mL per 8 hours

Continuity of Care

10. Upon discharge, Mr. Rouse is prescribed to follow a low-purine diet to prevent reoccurrence of uric acid stones. The nurse determines that the patient understood dietary instructions if he suggests which of the following as an appropriate meal combination?

A. liver with onions and potatoes
B. chicken sandwich with French fries
C. spaghetti with ground beef meat sauce
D. macaroni and cheese with stewed tomatoes

Safety

11. Mrs. Smith has a Foley catheter inserted due to ongoing incontinence and development of a stage II pressure ulcer. The nurse notes a physician's order for another urine culture and sensitivity specimen. Which of the following activities related to specimen collection are focused at patient safety and safe specimen collection?

A. Obtain the specimen from the urine collection bag.
B. Clamp the proximal drainage tube for 1 hour prior to specimen collection.
C. Aspirate the urine specimen via the tubing port after thorough disinfection and using a sterile syringe.
D. Disconnect the Foley catheter from the drainage bag and allow urine to flow directly from the catheter to the sterile container.

Quality Improvement

12. The nurse manager of a medical-surgical unit notes an increase in the number of catheter-related urinary tract infections (CAUTIs). Describe a quality improvement project that could be implemented on the nursing unit to reduce CAUTIs.

Informatics

13. When caring for Mrs. Smith, her admitting medical diagnoses include "possible urinary tract infection." You have collected and sent a urine culture and sensitivity (C&S) to the laboratory. In what part of the laboratory documentation system would you expect to find the results of the C&S?

A. nurses' progress note
B. microbiology results
C. general chemistry results
D. hematology results

Responses to Altered Cardiovascular Function

29 Assessing the Cardiovascular and Lymphatic Systems 825

30 Nursing Care of Patients with Coronary Heart Disease 861

31 Nursing Care of Patients with Cardiac Disorders 919

32 Nursing Care of Patients with Vascular and Lymphatic Disorders 966

33 Nursing Care of Patients with Hematologic Disorders 1014

Activity–Exercise Pattern

Physiologic energy is necessary for exercise and to carry out daily living activities; the heart, blood, and vascular system deliver the fuel for energy production to the cells.

29 Assessing the Cardiovascular and Lymphatic Systems

LEARNING OUTCOMES

1. Describe the anatomy, physiology, and functions of the cardiovascular and lymphatic systems.
2. Describe normal variations in cardiovascular assessment findings for the older adult.
3. Give examples of genetic disorders of the cardiovascular system.
4. Identify specific topics for consideration during a health history assessment interview of the patient with cardiovascular or lymphatic disorders.
5. Explain techniques used to assess cardiovascular and lymphatic structure and function.
6. Identify manifestations of impaired cardiovascular structure and functions.

CLINICAL COMPETENCIES

1. Complete a health history for patients having alterations in the structure and functions of the cardiovascular or lymphatic systems.
2. Conduct and document a physical assessment of cardiovascular and lymphatic status.
3. Assess an ECG strip and identify normal rhythm and cardiac events and abnormal cardiac rhythm.
4. Monitor the results of diagnostic tests and communicate abnormal findings within the interprofessional team.

MAJOR CHAPTER CONCEPTS

- Correct structure and function of the cardiovascular and lymphatic systems are vital to the transport of oxygen and carbon dioxide throughout the body and for the return of excess tissue fluids back to the bloodstream.
- Manifestations of dysfunction, injury, and disorders affecting the cardiovascular and lymphatic systems may be detected during a general health assessment as well as during focused cardiovascular and lymphatic system assessments.

EQUIPMENT NEEDED

- Stethoscope with a diaphragm and a bell
- Blood pressure cuff
- Good light source
- Watch with a second hand
- Centimeter ruler
- Tape measure
- Doppler ultrasound device (if needed) and transducer gel

The cardiovascular system is comprised of the heart (the system's pump), the peripheral vascular system (a network of arteries, veins, and capillaries), and the hematologic system (blood and blood components). The lymphatic system (the lymph, lymph nodes, and spleen) is a special vascular system that helps maintain sufficient blood volume in the cardiovascular system by picking up excess tissue fluid and returning it to the bloodstream.

The heart beats an average of 80 times per minute, or once every 0.86 second, every minute of an individual's life. As the heart ejects blood with each beat, a closed system of blood vessels transports oxygenated blood to all body organs and tissues and then returns deoxygenated blood to the heart for reoxygenation in the lungs. Deficits in the structure or function of the cardiovascular and lymphatic system may adversely affect all body tissues and may affect self-care, mobility, comfort, self-concept, sexuality, and role performance.

Anatomy, Physiology, and Functions of the Heart

THE HEART

The heart is a hollow, cone-shaped organ approximately the size of an adult man's fist. Beating from 60 to 100 beats each minute for a lifetime, it moves more than 1800 gallons of blood each day (Huether & McCance, 2011). Located in the mediastinum of the thoracic cavity, between the vertebral column and the sternum, the heart is flanked laterally by the lungs. The heart weighs less than 0.5 kg (1 lb) in a normal healthy adult. Two-thirds of the heart mass lies to the left of the sternum; the upper base lies beneath the second rib, and the pointed apex is approximate with the fifth intercostal space, midpoint to the clavicle (Figure 29–1 ■).

The heart is covered by the pericardium, a double layer of fibroserous membrane (Figure 29–2 ■). The pericardium encases the heart and anchors it to surrounding structures, forming the pericardial sac. The snug fit of the pericardium prevents the heart from overfilling with blood. The outermost layer is the parietal pericardium; the visceral pericardium (or epicardium) adheres to the heart surface. The small space between the visceral and parietal layers of the pericardium is called the pericardial cavity. Ten to 30 mL of a serous lubricating fluid produced in this space cushions the heart as it beats.

The heart wall consists of three layers of tissue: the epicardium, the myocardium, and the endocardium (refer to Figure 29–2). The epicardium covers the entire heart and great vessels, and then folds over to form the parietal layer that lines the pericardium and adheres to the heart surface. The myocardium, the middle layer of the heart wall, consists of specialized cardiac muscle cells (myofibrils) that provide the bulk of contractile heart muscle. The endocardium is a thin three-layer membrane that lines the inside of the heart's chambers and great vessels.

Chambers and Valves of the Heart

The heart has two upper atria and two lower ventricles. They are separated longitudinally by the interventricular septum (Figure 29–3 ■). The right atrium receives deoxygenated blood from the veins of the body: The superior vena cava returns blood from the body area above the diaphragm, the inferior vena cava returns blood from the body below the diaphragm, and the coronary sinus drains blood from the heart. The left atrium receives freshly oxygenated blood from the lungs through the pulmonary veins. The right ventricle receives deoxygenated blood from the right atrium and pumps it through the pulmonary artery to the pulmonary capillary bed for oxygenation. The newly oxygenated blood then travels through the pulmonary veins to the left atrium. Blood enters the left atrium and crosses the mitral (bicuspid) valve into the left ventricle. Blood is then pumped out of the aorta to the arterial circulation.

The heart's chambers are each separated by a valve that allows unidirectional blood flow to the next chamber or great vessel (refer to Figure 29–3). The atria are separated from the ventricles by the two atrioventricular (AV) valves; the tricuspid valve is on the right side, and the bicuspid (or mitral) valve is on the left. The flaps of each of these valves are anchored to the papillary muscles of the ventricles by the chordae tendineae. These structures control the movement of the AV valves to prevent backflow of blood. The ventricles are connected

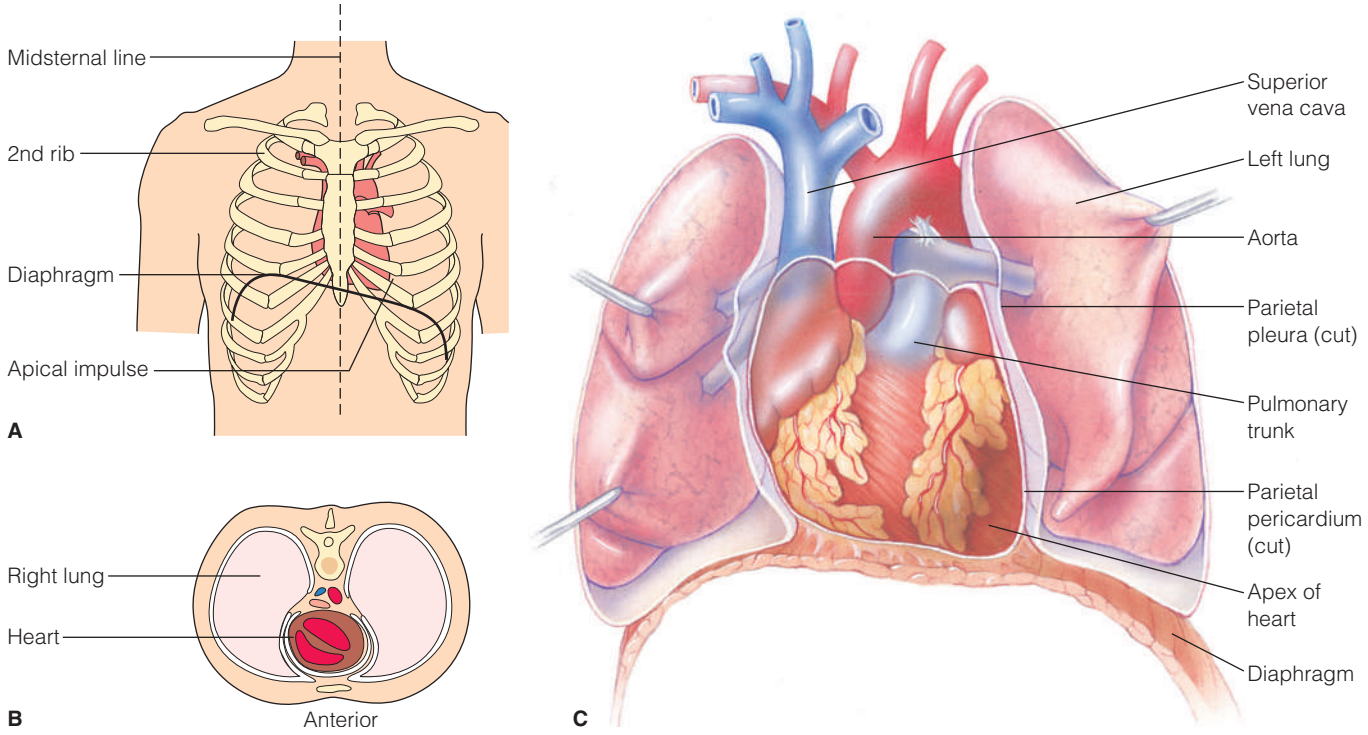

Figure 29–1 ■ Location of the heart in the mediastinum of the thorax. A, Relationship of the heart to the sternum, ribs, and diaphragm. B, Cross-sectional view showing relative position of the heart in the thorax. C, Relationship of the heart and great vessels to the lungs.

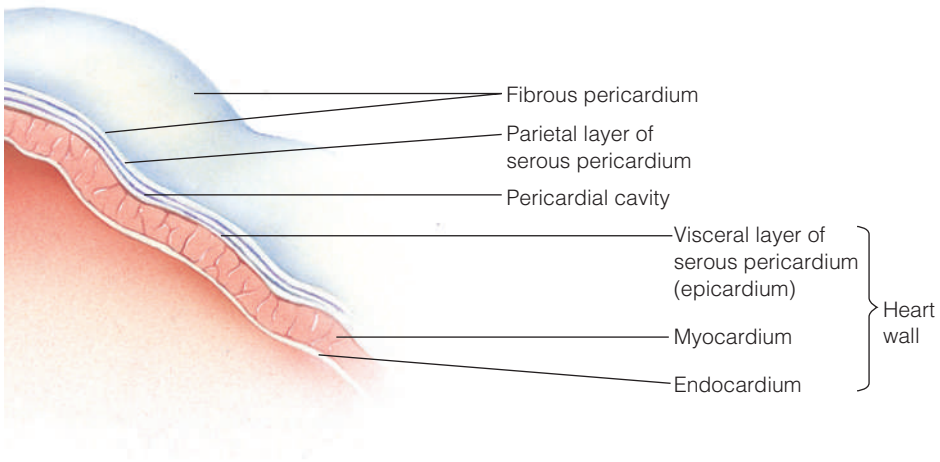

Figure 29–2 ■ Coverings and layers of the heart.

to their great vessels by the semilunar valves. On the right, the pulmonary (pulmonic) valve joins the right ventricle with the pulmonary artery. On the left, the aortic valve joins the left ventricle to the aorta. Closure of the AV valves at the onset of contraction (systole) produces the first heart sound, or S_1 (characterized by the syllable *lub*); closure of the semilunar valves at the onset of relaxation (diastole) produces the second heart sound, or S_2 (characterized by the syllable *dub*).

Systemic, Pulmonary, and Coronary Circulation

Because each side of the heart both receives and ejects blood, the heart is often described as a double pump. Blood enters the right atrium and moves to the pulmonary bed at almost the exact same time that blood is entering the left atrium. The circulatory system has two parts: the systemic circulation (a high-pressure system), which supplies blood to all other body tissues, and the pulmonary circulation (a low-pressure system). The systemic circulation consists of the left side of the heart, the aorta and its branches, the capillaries that supply the brain and peripheral tissues, the systemic venous system, and the vena cava. The pulmonary circulation consists of the right side of the heart, the pulmonary artery, the pulmonary capillaries, and the pulmonary vein. Pulmonary circulation begins with the right side of the heart. Deoxygenated blood from the venous system enters the right atrium through two large veins, the superior and inferior venae cavae, and is transported to the lungs via the pulmonary artery

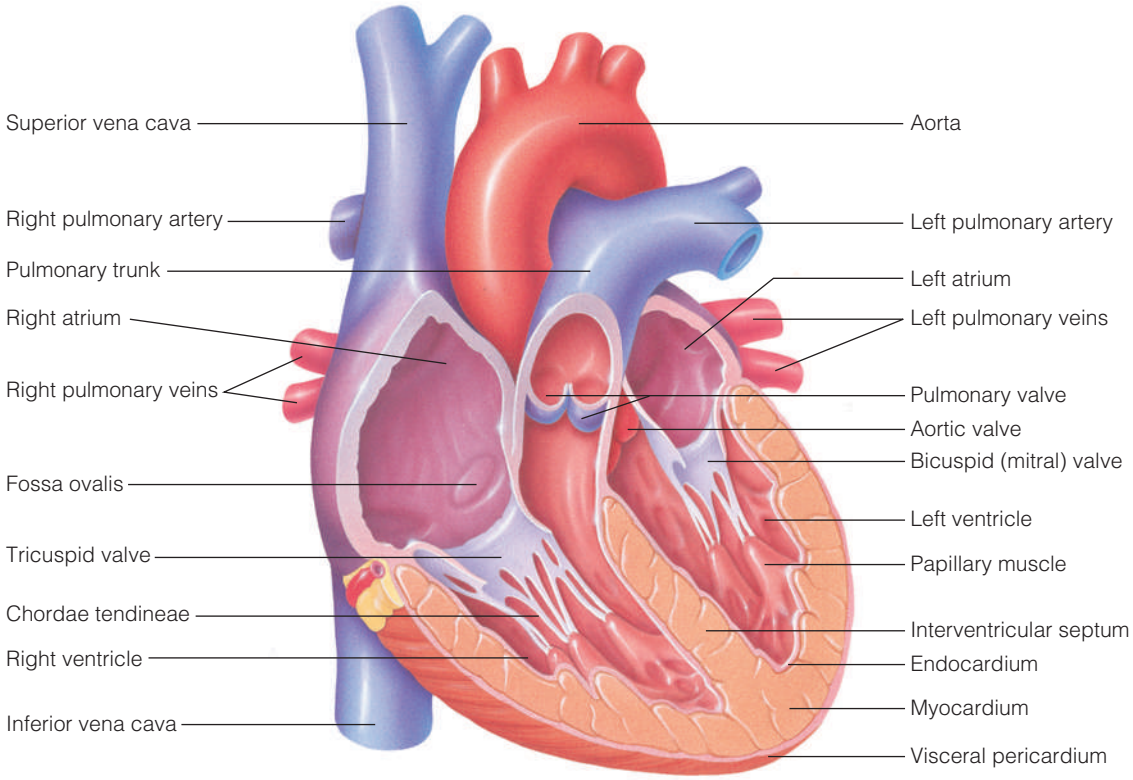

Figure 29–3 ■ The internal anatomy of the heart, frontal section.

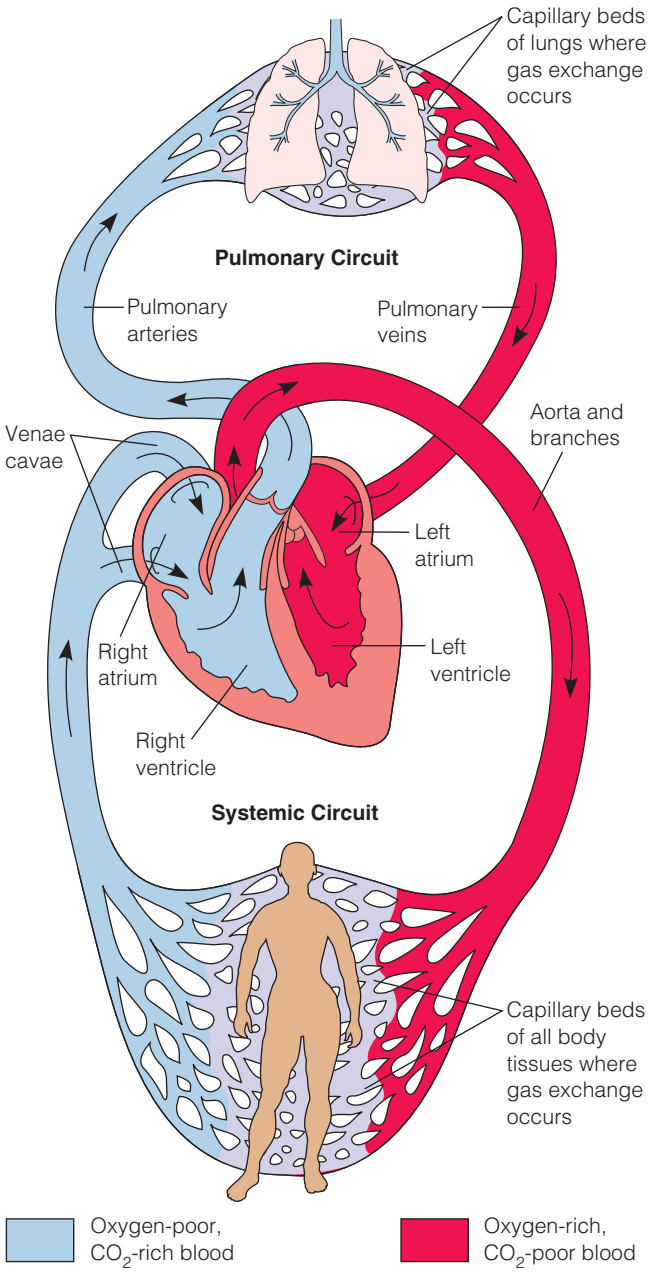

Figure 29–4 ■ Pulmonary and systemic circulation.

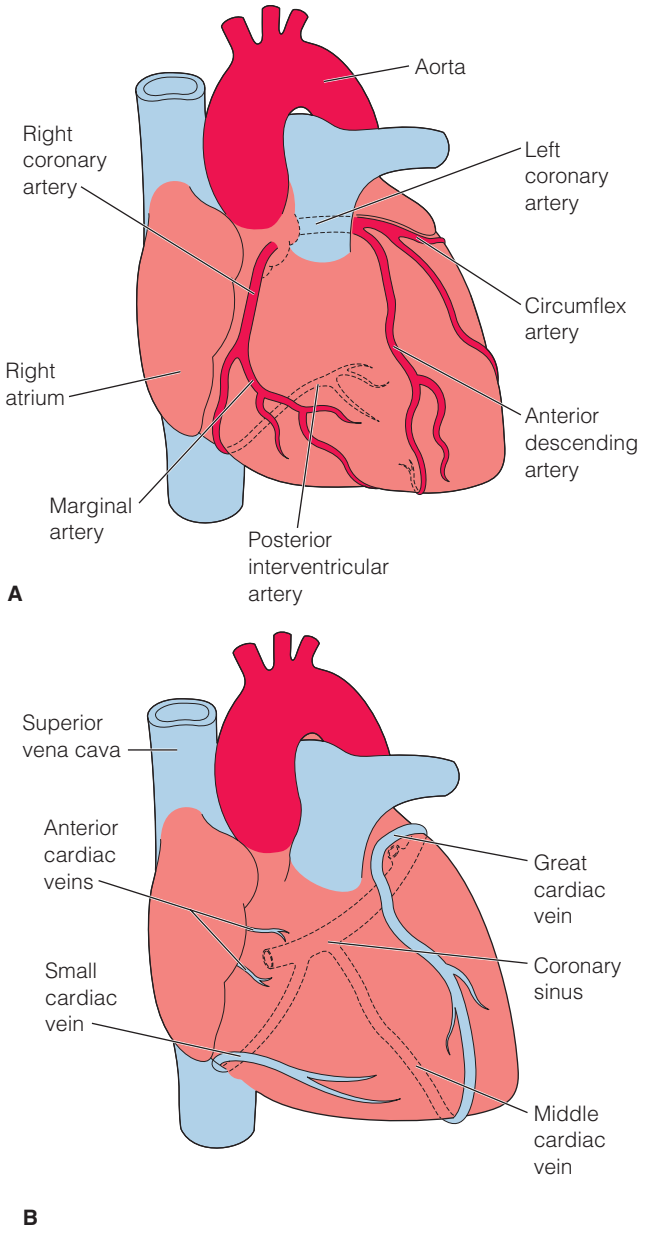

Figure 29–5 ■ Coronary circulation: A, coronary arteries; and B, coronary veins.

and its branches (Figure 29–4 ■). After oxygen and carbon dioxide are exchanged in the pulmonary capillaries, oxygen-rich blood returns to the left atrium through several pulmonary veins. Blood is then pumped out of the left ventricle through the aorta and its major branches to supply all body tissues by the systemic circulation.

Oxygen is supplied to the heart muscle by its own network of vessels through the coronary circulation. The left and right coronary arteries originate at the base of the aorta and branch out to encircle the myocardium (Figure 29–5A ■), supplying it with blood, oxygen, and nutrients. The left main coronary artery divides to form the anterior descending and circumflex arteries. The anterior descending artery supplies the anterior interventricular septum and the left ventricle. The circumflex branch supplies the left lateral wall of the left ventricle. The right coronary artery supplies the right ventricle and forms the posterior descending artery. The posterior descending artery supplies the posterior portion of the heart. While ventricular contraction delivers blood through the pulmonary circulation and the systemic circulation, it is during ventricular relaxation that the coronary arteries fill with oxygenated blood. After the blood perfuses the heart muscle, the cardiac veins drain the blood into the coronary sinus, which empties into the right atrium of the heart (Figure 29–5B). Blood flow through the coronary arteries is regulated by several factors. Aortic pressure is the primary factor. Other factors include the heart rate (most flow occurs during diastole, when the muscle is relaxed), metabolic activity of the heart, and blood vessel tone (constriction).

The Cardiac Cycle and Cardiac Output

The contraction and relaxation of the heart constitute one heartbeat and this process is called *the cardiac cycle* (Figure 29–6 ■). Ventricular filling is followed by ventricular systole, a phase during which the ventricles contract and eject blood into the pulmonary and systemic circuits. Systole is followed by a relaxation phase known as diastole, during which the ventricles refill, the atria contract, and the myocardium is perfused. Normally, the complete cardiac cycle occurs about 70 to 80 times per minute, measured as the heart rate (HR).

During diastole, the volume in the ventricles is increased to about 120 mL (the end-diastolic volume), and at the end of systole, about 50 mL of blood remains in the ventricles (the end-systolic volume). The difference between the end-diastolic volume and the end-systolic volume is called the stroke volume (SV). Stroke volume ranges from 60 to 100 mL/beat and averages about 70 mL/beat in an adult. The ejection fraction is the stroke volume divided by the end-diastolic volume and represents the fraction or percent of the diastolic volume that is ejected from the heart during systole (Huether & McCance, 2011). For example, an end-diastolic volume of 120 mL divided by a stroke volume of 80 mL equals an ejection fraction of 66%. The normal ejection fraction ranges from 50% to 70%.

The **cardiac output (CO)** is the amount of blood pumped by the ventricles into the pulmonary and systemic circulations in 1 minute. Multiplying the HR by the SV determines the cardiac output: HR × SV = CO. The average adult CO ranges from 4 to 8 L/min. Cardiac output is an indicator of how well the heart is functioning as a pump. If the heart cannot pump effectively, CO and tissue perfusion are decreased. Body tissues that do not receive enough blood and oxygen (carried in the blood on hemoglobin) become **ischemic** (deprived of oxygen). If the tissues do not receive enough blood flow to maintain the functions of the cells, the cells die, resulting in necrosis (infarction).

Activity level, metabolic rate, physiologic and psychologic stress responses, age, and body size all influence CO. In addition, CO is determined by the interaction of four major factors: heart rate, contractility, preload, and afterload. Changes in each of these variables influence CO intrinsically, and each can be manipulated to affect CO. The heart's ability to respond to the body's changing need for CO is called cardiac reserve.

HEART RATE

Heart rate is affected by both direct and indirect autonomic nervous system stimulation. Direct stimulation is accomplished through the innervation of the heart muscle by sympathetic and parasympathetic nerves. The sympathetic nervous system increases the heart rate, whereas the parasympathetic vagal tone slows the heart rate. Reflex regulation of the heart rate in response to systemic blood pressure also occurs through activation of baroreceptors (pressure receptors) located in the carotid sinus, aortic arch, venae cavae, and pulmonary veins.

If heart rate increases, CO increases (up to a point), even if there is no change in stroke volume. However, rapid heart rates decrease the amount of time available for ventricular filling during diastole. Cardiac output then falls because decreased filling time decreases stroke volume. Coronary artery perfusion also decreases because the coronary arteries fill primarily during diastole. Cardiac output decreases during bradycardia if stroke volume stays the same, because the number of cardiac cycles is decreased.

CONTRACTILITY

Contractility is the ability of the cardiac muscle fibers to shorten. Poor contractility of the heart muscle reduces the forward flow of blood from the heart, increases the ventricular pressures from accumulation of blood volume, and reduces CO. Increased contractility may stress the heart by increasing the SV in pathologic conditions.

PRELOAD

Preload is the amount of cardiac muscle fiber tension, or stretch, that exists at the end of diastole, just before contraction of the ventricles. Preload is influenced by venous return (volume) and the compliance of the ventricles (resulting pressure). Preload is based on ventricular end-diastolic volume (VEDV) and ventricular end-diastolic pressure (VEDP). It is related to the total volume of blood in the ventricles: The greater the volume, the greater the stretch of the cardiac muscle fibers, and the greater the force with which the fibers contract to accomplish

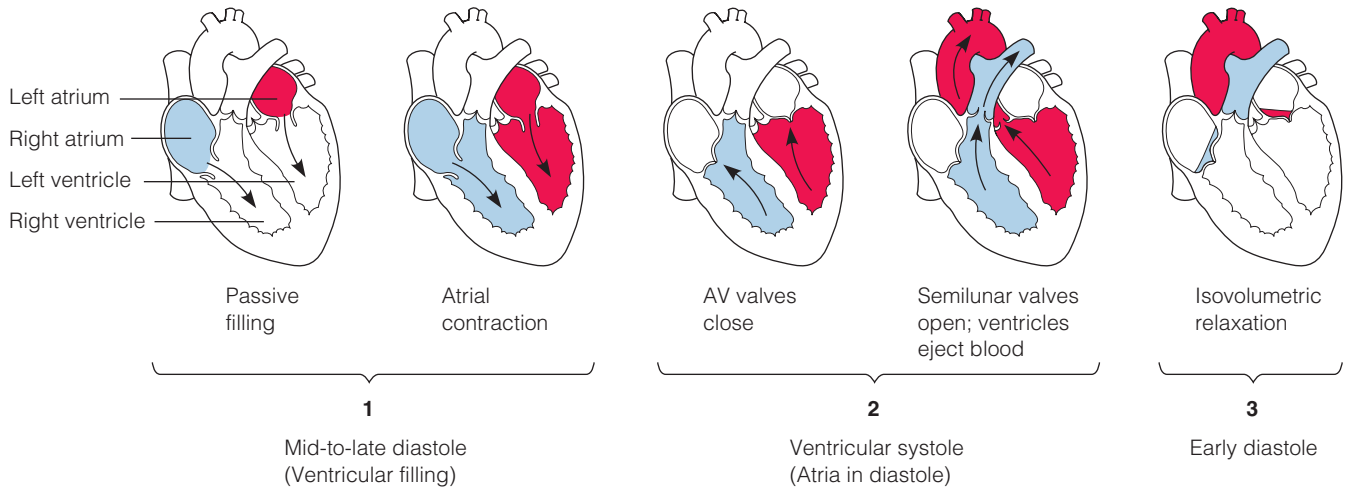

Figure 29–6 ■ The cardiac cycle has three events: (1) ventricular filling in mid-to-late diastole, (2) ventricular systole, and (3) isovolumetric relaxation in early diastole.

emptying. This principle is called *Starling's law of the heart*. Disorders such as renal disease and congestive heart failure result in sodium and water retention and increased preload. Vasoconstriction also increases venous return and preload.

MEMORY CUE

This mechanism has a physiologic limit. Just as continuous overstretching of a rubber band causes the band to relax and lose its ability to recoil, overstretching of the cardiac muscle fibers eventually results in ineffective contraction.

Too little circulating blood volume results in a decreased venous return and therefore a decreased preload. A decreased preload reduces stroke volume and thus cardiac output. Decreased preload may result from hemorrhage or misdistribution of blood volume, as occurs in third spacing (see Chapter 11).

AFTERLOAD

Afterload is the force the ventricles must overcome to eject their blood volume. It is the pressure in the arterial system ahead of the ventricles. The right ventricle must generate enough tension to open the pulmonary valve and eject its volume into the low-pressure pulmonary arteries. Right ventricle afterload is measured as pulmonary vascular resistance (PVR). The left ventricle, in contrast, ejects its load by overcoming the pressure behind the aortic valve. Afterload of the left ventricle is measured as systemic vascular resistance (SVR). Arterial pressures are much higher than pulmonary pressures; thus, the left ventricle has to work much harder than the right ventricle.

Alterations in vascular tone affect afterload and ventricular work. As the pulmonary or arterial blood pressure increases (e.g., through vasoconstriction), PVR and/or SVR increases, and the work of the ventricles increases. As workload increases, consumption of myocardial oxygen also increases. A compromised heart cannot effectively meet this increased oxygen demand, and a vicious cycle ensues. By contrast, a very low afterload decreases the forward flow of blood into the systemic circulation and the coronary arteries.

CLINICAL INDICATORS OF CARDIAC OUTPUT

For many critically ill patients, invasive hemodynamic monitoring catheters are used to measure CO in quantifiable numbers. However, advanced technology is not the only way to identify and assess compromised blood flow. Because CO perfuses the body's tissues, clinical indicators of low CO may be manifested by changes in organ function that result from compromised blood flow. For example, a decrease in blood flow to the brain presents as a change in level of consciousness. Other manifestations of decreased CO are discussed in Chapters 11 and 30.

Cardiac index (CI) is the CO adjusted for the patient's body size, also called the patient's body surface area (BSA). Because it takes into account the patient's BSA, the cardiac index provides more meaningful data about the heart's ability to perfuse the tissues and therefore is a more accurate indicator of the effectiveness of the circulation than the CO.

BSA is stated in square meters (m^2), and cardiac index is calculated as CO divided by BSA. Cardiac measurements are considered adequate when they fall within the range of 2.5 to 4.2 L/min/m^2. For example, two patients have a CO of 4 L/min. This parameter is within normal limits. However, one patient is 157 cm (5 ft, 2 in.) tall and weighs 54.5 kg (120 lb), with a BSA of 1.54 m^2. This patient's cardiac index is 4 ÷ 1.54, or 2.6 L/min/m^2. The second patient is 188 cm (6 ft, 2 in.) tall and weighs 81.7 kg (280 lb), with a BSA of 2.52 m^2. This patient's cardiac index is 4 ÷ 2.52, or 1.6 L/min/m^2. The cardiac index results show that the same CO of 4 L/min is adequate for the first patient but grossly inadequate for the second patient.

The Conduction System of the Heart

The cardiac cycle is perpetuated by a complex electrical circuit commonly known as *the intrinsic conduction system of the heart*. Cardiac muscle cells possess an inherent characteristic of self-excitation, which enables them to initiate and transmit impulses independent of a stimulus. However, specialized areas of myocardial cells typically exert a controlling influence in this electrical pathway.

One of these specialized areas is the sinoatrial (SA) node, located at the junction of the superior vena cava and right atrium (Figure 29–7 ■). The SA node acts as the normal "pacemaker" of the heart, usually generating an impulse 60 to 100 times per minute. This impulse travels across the atria via internodal pathways to the AV node, in the floor of the interatrial septum. The very small junctional fibers of the AV node slow the impulse, slightly delaying its transmission to the ventricles. It then passes through the bundle of His at the atrioventricular junction and continues down the interventricular septum through the right and left bundle branches and out to the Purkinje fibers in the ventricular muscle walls.

This path of electrical transmission produces a series of changes in ion concentration across the membrane of each cardiac muscle cell. The electrical stimulus increases the permeability of the cell membrane, creating an action potential (electrical potential). The result is an exchange of sodium, potassium, and calcium ions across the cell membrane, which changes the intracellular electrical charge to a positive state. This process of depolarization results in myocardial contraction. As the ion exchange reverses and the cell returns to its resting state of electronegativity, the cell is repolarized, and cardiac muscle relaxes. The cellular action potential serves as the basis for electrocardiography (ECG), a diagnostic test of cardiac function.

THE PERIPHERAL VASCULAR SYSTEM

The two components of the peripheral vascular system are the arterial network and the venous network. The arterial network begins with the major arteries that branch from the aorta. The major arteries of the systemic circulation are illustrated in Figure 29–8 ■. These major arteries branch into successively smaller arteries, which in turn subdivide into the smallest of the arterial vessels, called *arterioles*. The smallest arterioles feed into beds of hairlike capillaries in the body's organs and tissues.

In the capillary beds, oxygen and nutrients are exchanged for metabolic wastes, and deoxygenated blood moves back to the heart through venules, the smallest vessels of the venous network. Venules join the smallest of veins, which in turn join larger and larger veins. The blood transported by the veins empties into the superior and

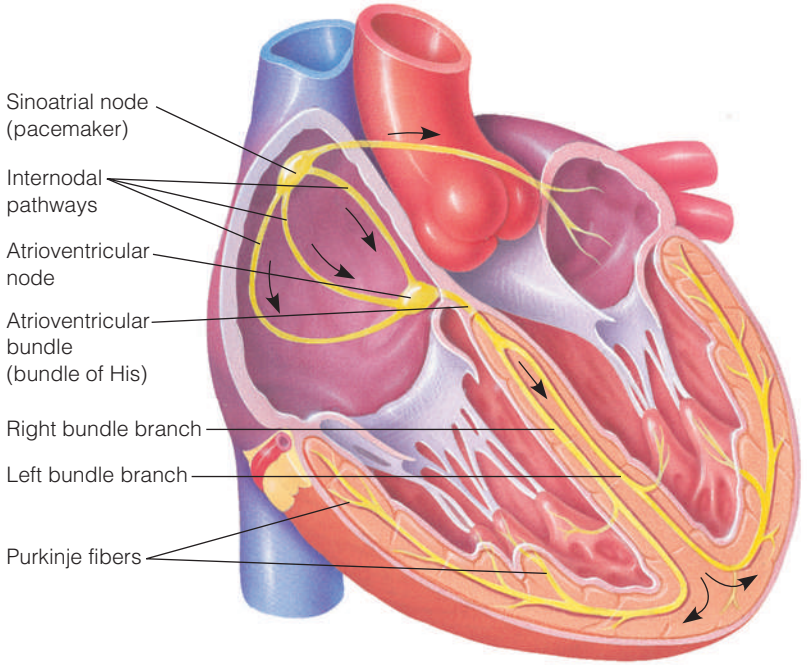

Figure 29–7 ■ The intrinsic conduction system of the heart.

inferior venae cavae entering the right side of the heart. The major veins of the systemic circulation are shown in Figure 29–9 ■.

Structure of Blood Vessels

The structure of blood vessels reflects their different functions within the circulatory system (Figure 29–10 ■). Except for the tiniest vessels, blood vessel walls have three layers: the tunica intima, the tunica media, and the tunica adventitia. The tunica intima, the innermost layer, is made of endothelium that provides a slick surface to facilitate the flow of blood. In arteries, the middle layer, or tunica media, is made of smooth muscle and is thicker than the tunica media of veins. This makes arteries more elastic than veins and allows the arteries to alternately expand and recoil as the heart contracts and relaxes with each beat, producing a pressure wave that can be felt as a pulse over an artery. The smaller arterioles are less elastic than arteries but contain more smooth muscle, which promotes their constriction and dilation. In fact, arterioles exert the major control over arterial blood pressure. The tunica adventitia, or outermost layer, is made of connective tissue and serves to protect and anchor the vessel. Veins have a thicker tunica adventitia than do arteries.

Blood in the veins travels at a much lower pressure than does blood in the arteries. Veins have thinner walls, a larger lumen, and greater capacity, and many are supplied with valves that help blood flow against gravity back to the heart. The "milking" action of skeletal muscle contraction supports venous return. When skeletal muscles contract against veins, the valves proximal to the contraction open, and blood is propelled toward the heart. The abdominal and thoracic pressure changes that occur with breathing also propel blood toward the heart.

The tiny capillaries, which connect the arterioles and venules, contain only one thin layer of tunica intima that is permeable to the gases and molecules exchanged between blood and tissue cells. Capillaries typically are found in interwoven networks. They filter and shunt blood from precapillary arterioles to postcapillary venules.

Arterial Circulation

The factors that affect arterial circulation are blood flow, peripheral vascular resistance, and blood pressure. Blood flow refers to the volume of blood transported in a vessel, in an organ, or throughout the entire circulation over a given period of time. It is commonly expressed as liters or milliliters per minute or cubic centimeters per second.

Peripheral vascular resistance (PVR) refers to the opposing forces or impedance to blood flow as the arterial channels become more and more distant from the heart. Peripheral vascular resistance is determined by three factors:

- *Blood viscosity:* The greater the viscosity, or thickness, of the blood, the greater its resistance to moving and flowing.
- *Length of the vessel:* The longer the vessel, the greater the resistance to blood flow.
- *Diameter of the vessel:* The smaller the diameter of a vessel, the greater the friction against the walls of the vessel and, thus, the greater the impedance to blood flow.

Blood pressure (BP) is the force exerted against the walls of the arteries by the blood as it is pumped from the heart. It is most accurately referred to as mean arterial pressure (MAP). The highest pressure exerted against the arterial walls at the peak of ventricular contraction (systole) is called the systolic BP. The lowest pressure exerted during ventricular relaxation (diastole) is the diastolic BP.

Mean arterial blood pressure is regulated mainly by cardiac output and peripheral vascular resistance, as represented in this formula: $MAP = CO \times PVR$. For clinical use, the MAP may be estimated by calculating the diastolic blood pressure plus one-third of the pulse pressure (the difference between the systolic and diastolic blood pressure).

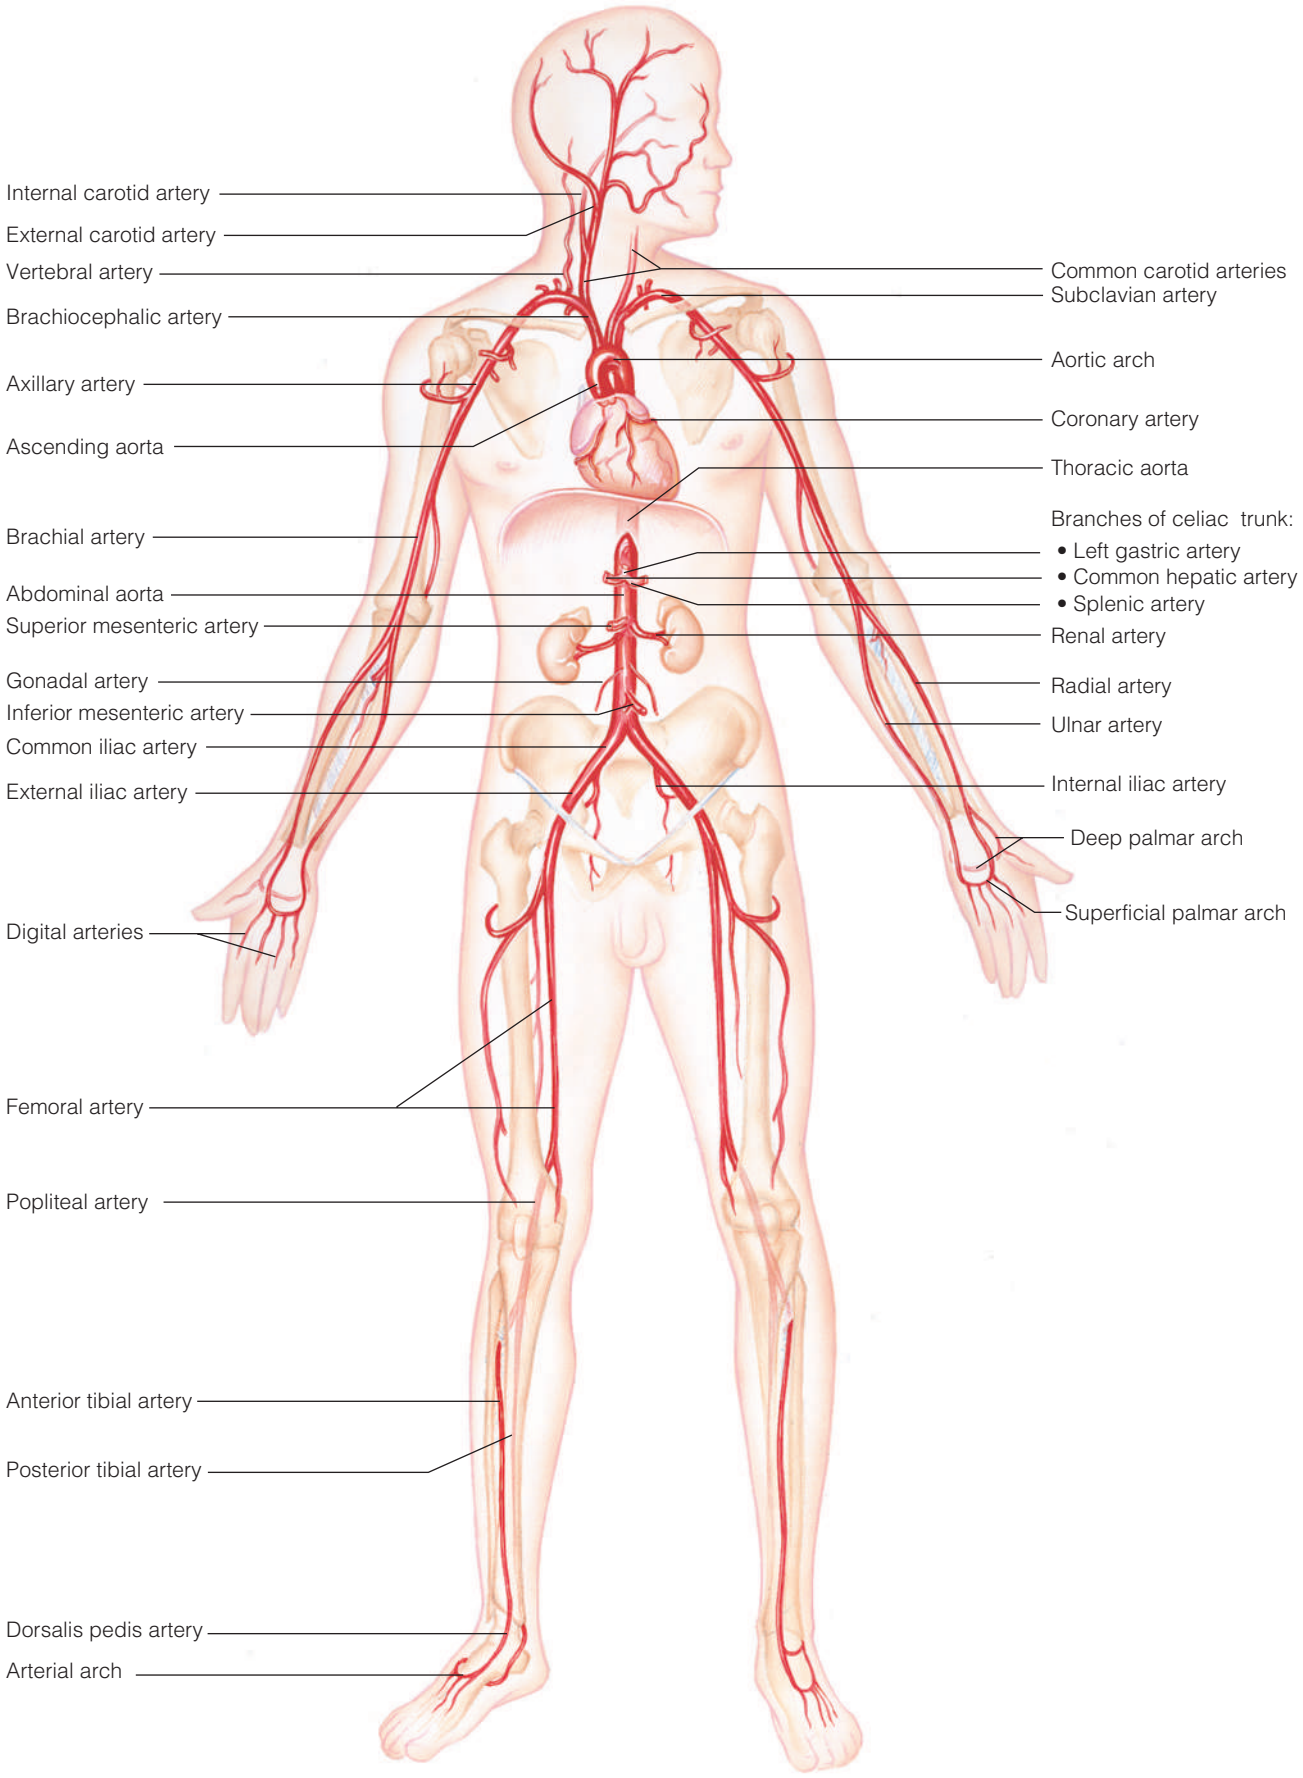

Figure 29–8 ■ Major arteries of the systemic circulation.

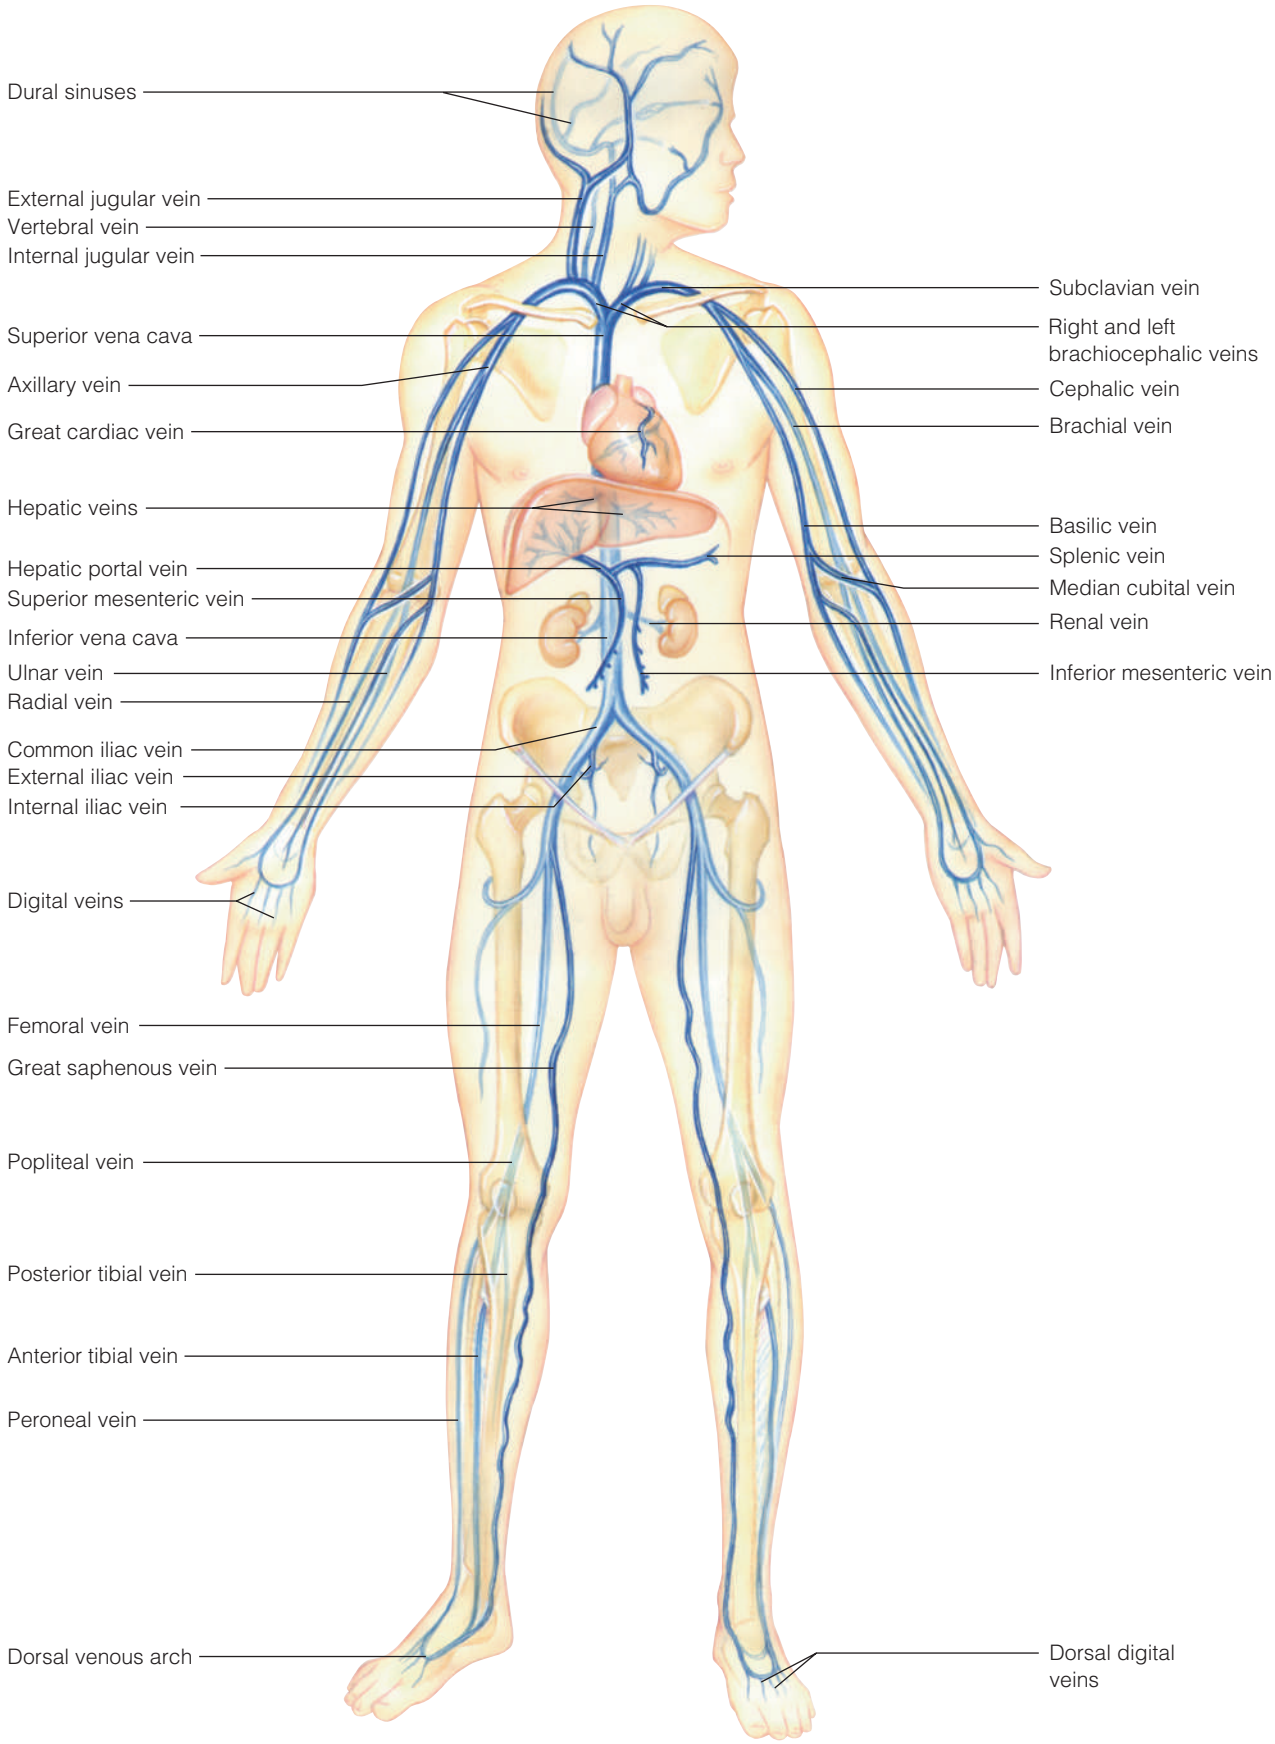

Figure 29–9 ■ Major veins of the systemic circulation.

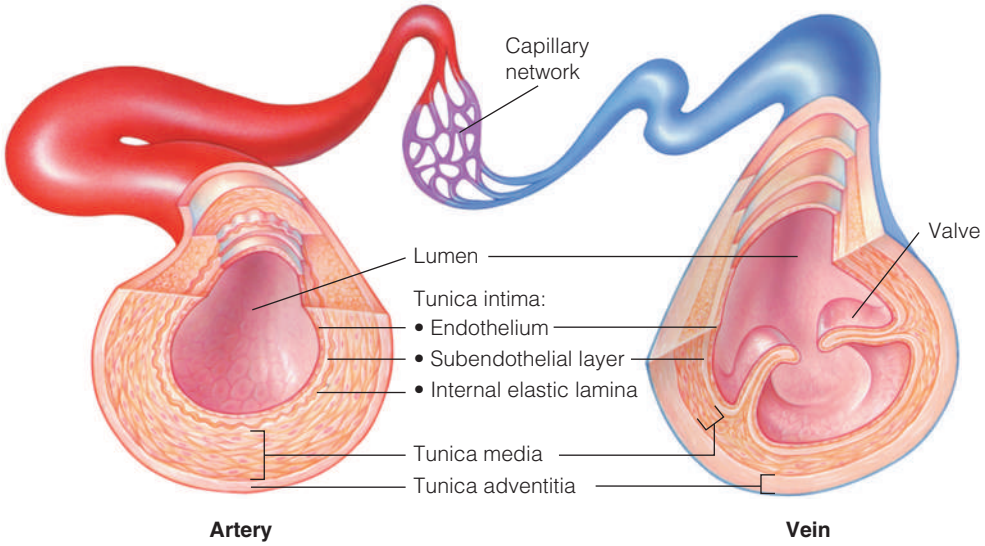

Figure 29–10 ■ Structure of arteries, veins, and capillaries. Capillaries are composed of only a fine tunica intima. Notice that the tunica media is thicker in arteries than in veins.

Factors Influencing Arterial Blood Pressure

Blood flow, peripheral vascular resistance, and BP, which influence arterial circulation, are in turn influenced by various factors, as follows:

- The sympathetic and parasympathetic nervous systems are the primary mechanisms that regulate BP. Stimulation of the sympathetic nervous system exerts a major effect on peripheral resistance by causing vasoconstriction of the arterioles, thereby increasing BP. Parasympathetic stimulation causes vasodilation of the arterioles, lowering BP.
- Baroreceptors and chemoreceptors in the aortic arch, carotid sinus, and other large vessels are sensitive to pressure and chemical changes and cause reflex sympathetic stimulation, resulting in vasoconstriction, increased heart rate, and increased BP.
- The kidneys help maintain BP by excreting or conserving sodium and water. When BP decreases, the kidneys initiate the renin–angiotensin mechanism. This stimulates vasoconstriction, resulting in the release of the hormone aldosterone from the adrenal cortex, increasing sodium ion reabsorption and water retention. In addition, pituitary release of antidiuretic hormone (ADH) promotes renal reabsorption of water. The net result is an increase in blood volume and a consequent increase in CO and BP.
- Temperatures may affect peripheral resistance: Cold causes vasoconstriction, whereas warmth produces vasodilation.
- Many chemicals, hormones, and drugs influence BP by affecting CO and/or PVR. For example, epinephrine causes vasoconstriction and increased heart rate; prostaglandins dilate blood vessel diameter (by relaxing vascular smooth muscle); endothelin, a chemical released by the inner lining of vessels, is a potent vasoconstrictor; nicotine causes vasoconstriction; and alcohol and histamine cause vasodilation.
- Dietary factors such as intake of salt, saturated fats, and cholesterol elevate BP by affecting blood volume and vessel diameter.
- Race, gender, age, weight, time of day, position, exercise, and emotional state may also affect BP. These factors influence the arterial pressure. Systemic venous pressure, though it is much lower, is also influenced by such factors as blood volume, venous tone, and right atrial pressure.

The Lymphatic System

The structures of the lymphatic system include the lymph, lymph nodes, spleen, thymus, tonsils, and the Peyer's patches of the small intestine. Lymph nodes are small aggregates of specialized cells that assist the immune system by removing foreign material, infectious organisms, and tumor cells from lymph. Lymph nodes are distributed along the lymphatic vessels, forming clusters in certain body regions such as the neck, axilla, and groin (see Figure 29–11 ■).

The spleen, the largest lymphoid organ, is in the upper left quadrant of the abdomen under the thorax. The main function of the spleen is to filter the blood by breaking down old red blood cells and storing or releasing to the liver their by-products (such as iron). The spleen also synthesizes lymphocytes, stores platelets for blood clotting, and serves as a reservoir of blood. The thymus gland is in the lower throat and is most active in childhood, producing hormones (such as thymosin) that facilitate the immune action of lymphocytes. The tonsils of the pharynx and Peyer's patches of the small intestine are lymphoid organs that protect the upper respiratory and digestive tracts from foreign pathogens.

The lymphatic vessels, or lymphatics, form a network around the arterial and venous channels and interweave at the capillary beds. They collect and drain excess tissue fluid, called *lymph*, that leaks from the cardiovascular system and accumulates at the venous end of the capillary bed. The lymphatics return this fluid to the heart through a one-way system of lymphatic venules and veins that eventually drain

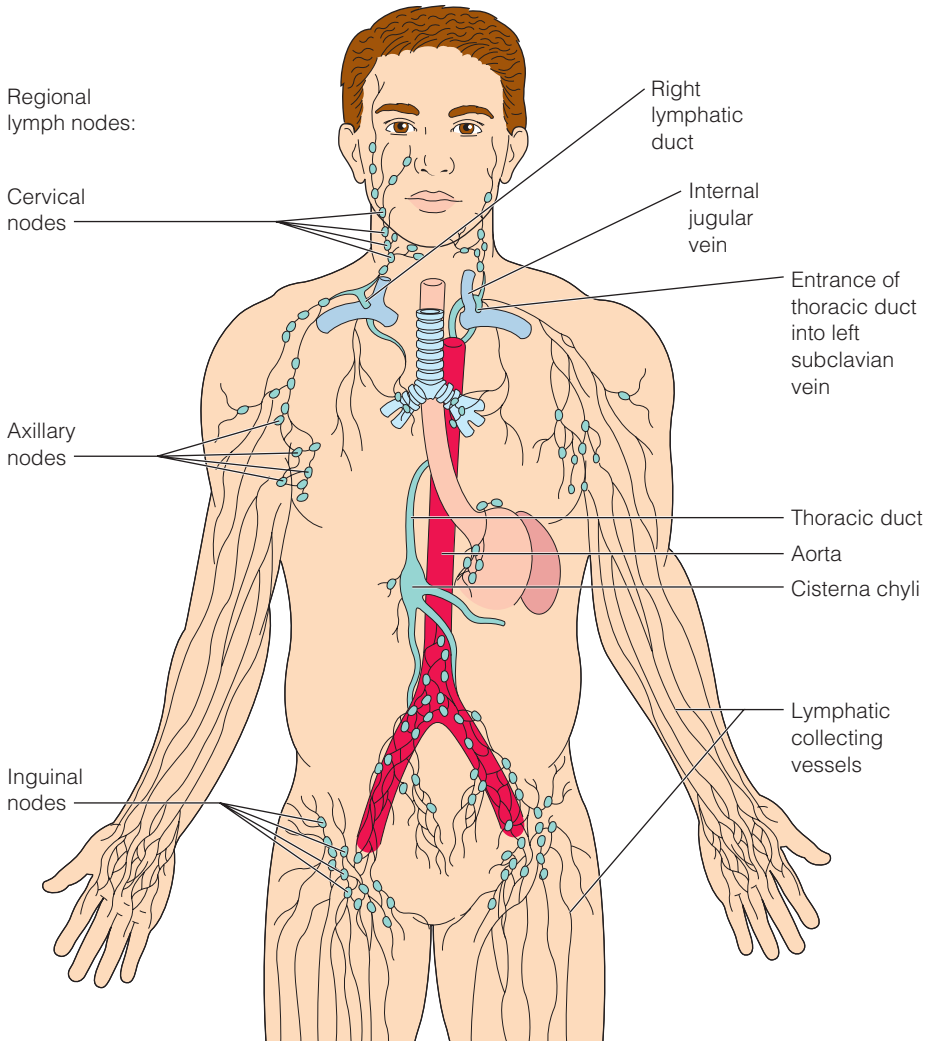

Figure 29–11 ■ The lymphatic system.

into the right lymphatic duct and left thoracic duct, both of which empty into their respective subclavian veins. Lymphatics are a low-pressure system without a pump; their fluid transport depends on the rhythmic contraction of their smooth muscle and the muscular and respiratory movements that assist venous circulation.

The Hematologic System

Blood consists of plasma, solutes (e.g., proteins, electrolytes, and organic constituents), red blood cells, white blood cells, and platelets (which are fragments of cells). The hematopoietic (blood-forming) system includes the bone marrow (myeloid) tissues, where blood cells form, and the lymphoid tissues of the lymph nodes, where white blood cells mature and circulate. All blood cells originate from cells in the bone marrow called stem cells, or hemocytoblasts. The origin of the cellular components of blood is illustrated in Figure 29–12 ■. Normal laboratory values for blood components are found in Table 29–1.

Regulatory mechanisms cause stem cells to differentiate into families of parent cells, each of which gives rise to one of the formed elements of the blood (red blood cells, platelets, and white blood cells). The functions of blood include transporting oxygen, nutrients, hormones, and metabolic wastes; protecting against invasion of pathogens; maintaining blood coagulation; and regulating fluids, electrolytes, acids, bases, and body temperature.

Red Blood Cells

Red blood cells (RBCs), or erythrocytes, are the most common type of blood cell. They are shaped like biconcave disks (Figure 29–13 ■). This unique shape increases the surface area of the cell and allows the cell to pass through very small capillaries without disrupting the cell membrane. RBCs and the hemoglobin molecules they contain transport oxygen to body tissues. Hemoglobin also binds with some carbon dioxide, carrying it to the lungs for excretion. Abnormal numbers of RBCs, changes in their size and shape, or altered hemoglobin content or structure can adversely affect health. Anemia, the most common RBC disorder, is an abnormally low RBC count or reduced hemoglobin content. Polycythemia is an abnormally high RBC count.

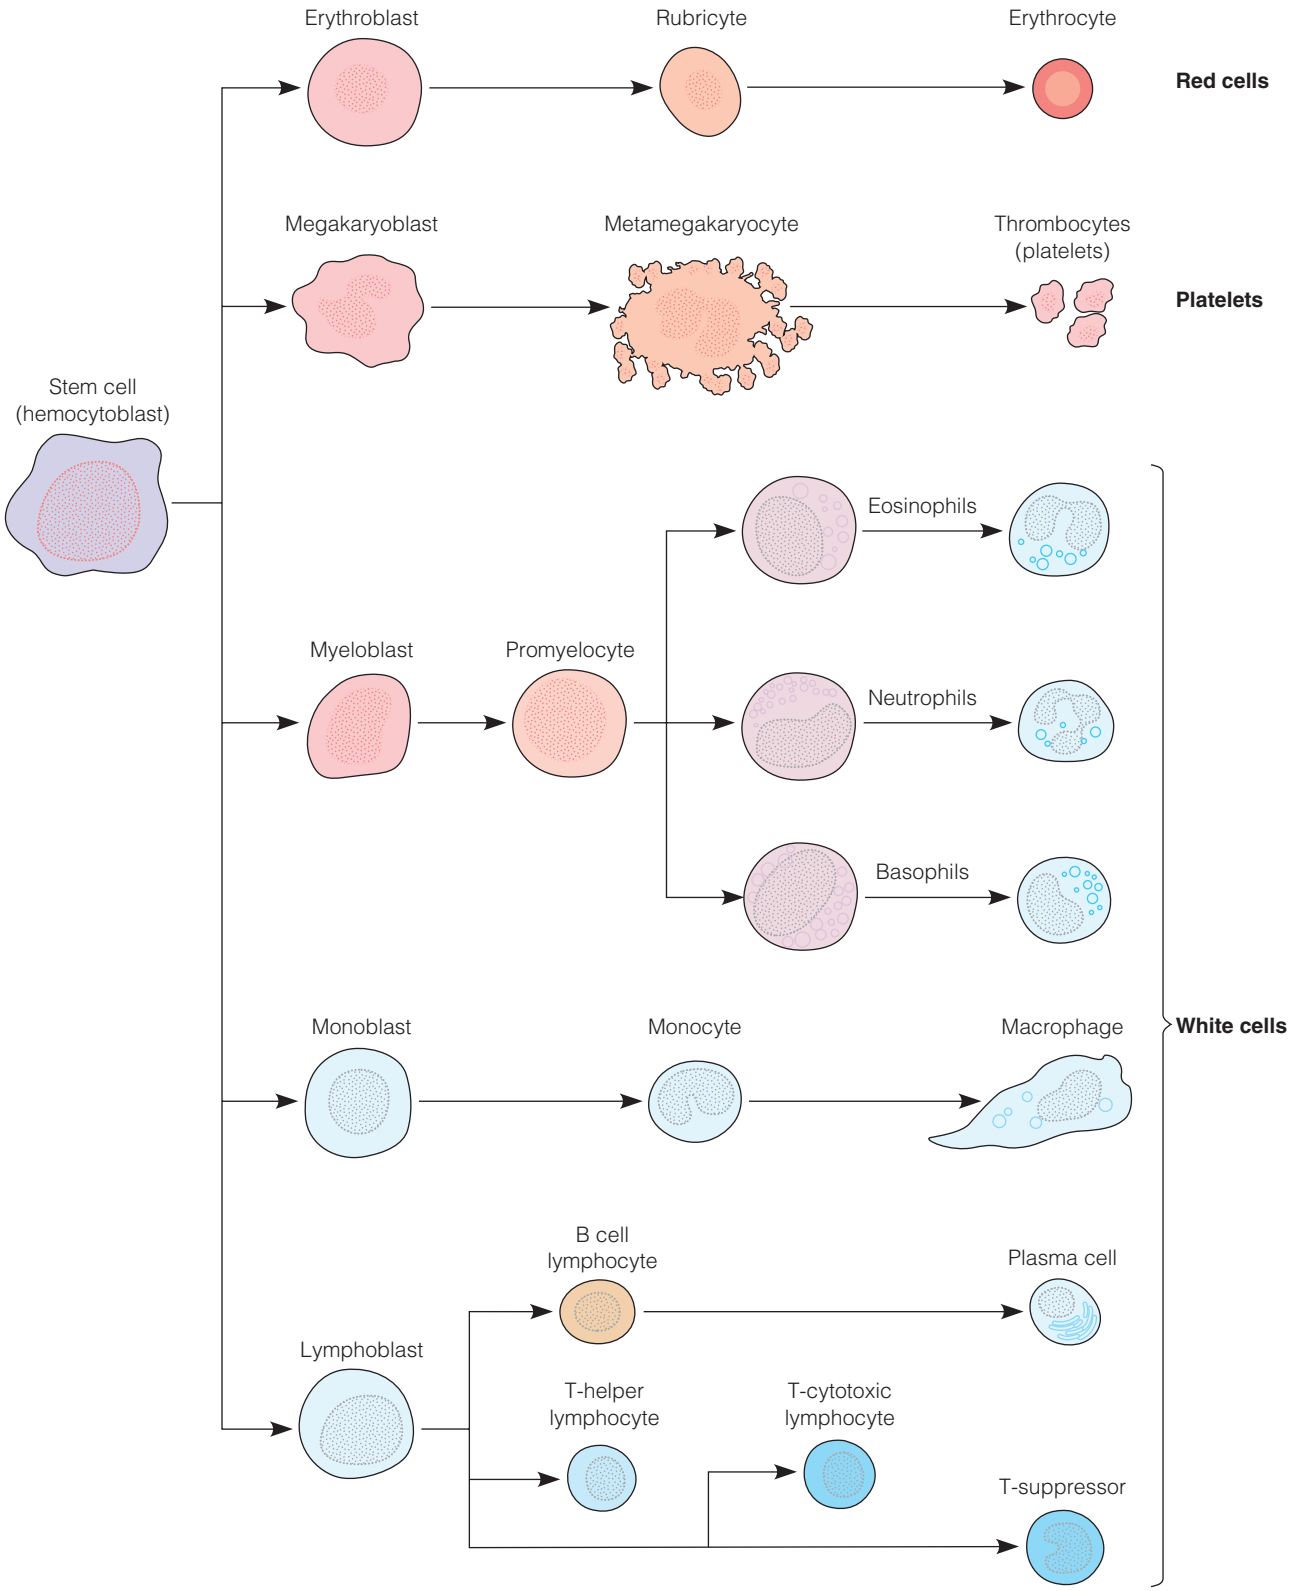

Figure 29–12 ■ Blood cell formation from stem cells. Regulatory factors control the differentiation of stem cells into blasts. Each of the five kinds of blasts is committed to producing one type of mature blood cell. Erythroblasts, for example, can differentiate only into RBCs; megakaryoblasts can differentiate only into platelets.

Hemoglobin, synthesized within the RBC, is the oxygen-carrying protein. It consists of the heme molecule and globin, a protein molecule. Globin is made of four polypeptide chains—two alpha chains and two beta chains (Figure 29–14 ■). Each of the four polypeptide chains has a heme unit that contains an iron atom. The iron atom binds reversibly with oxygen, allowing it to transport oxygen as oxyhemoglobin to the cells. The rate of synthesis depends on the availability of iron. The size, color, and shape of stained RBCs also

TABLE 29–1 Complete Blood Count (CBC)

Component	Purpose	Normal Values
Hemoglobin (Hb)	Measures the capacity of the hemoglobin to carry gases.	Women: 12–16 g/dL Men: 13.5–18 g/dL
Hematocrit (Hct)	Measures packed cell volume of RBCs, expressed as a percent of the total blood volume.	Women: 38%–47% Men: 40%–54%
Total RBC count	Counts number of circulating RBCs.	Women: 4–5 × 10^6/μL Men: 4.5–6 × 10^6/μL
Red cell indices: MCV 10^6MCH	Determines relative size of MCV (mean corpuscular volume). Measures average weight of Hb/RBC (MCH = mean corpuscular hemoglobin).	82–98 fl 27–29 pg
MCHC	Evaluates RBC saturation with Hb (MCHC = mean corpuscular hemoglobin concentration).	32%–36%
WBC count	Measures total number of leukocytes (total count) and whether each kind of WBC is present in proper proportion (differential).	Total WBC count: 4000–11,000/ μL (4–11 × 10^9/L) WBC differential: neutrophils: 50%–70%; eosinophils: 2%–4%; basophils: 0%–2%; lymphocytes: 20%–40%; monocytes: 4%–8%
Platelets	Measures number of platelets available to maintain clotting functions.	150,000–400,000/μL (150–400 × 10^9/L)

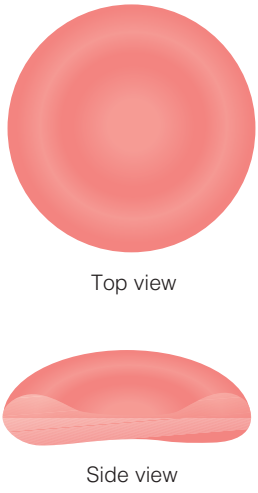

Figure 29–13 ■ Top and side view of a red blood cell (erythrocyte). Note the distinctive biconcave shape.

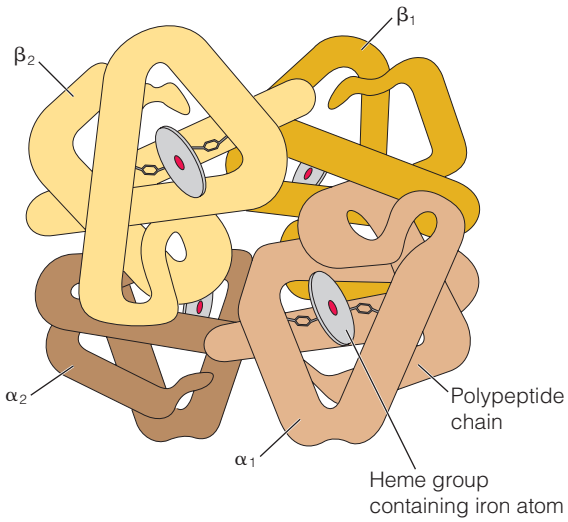

Figure 29–14 ■ The hemoglobin molecule includes globin (a protein) and heme, which contains iron. Globin is made of four subunits, two alpha and two beta polypeptide chains. A heme disk containing an iron atom (red dot) nests within the folds of each protein subunit. The iron atoms combine reversibly with oxygen, transporting it to the cells.

may be analyzed. RBCs may be normocytic (normal size), smaller than normal (microcytic), or larger than normal (macrocytic). Their color may be normal (normochromic) or diminished (hypochromic).

RED BLOOD CELL PRODUCTION AND REGULATION

In adults, RBC production (erythropoiesis) (Figure 29–15 ■) begins in the red bone marrow of the vertebrae, sternum, ribs, and pelvis, and is completed in the blood or spleen. Erythroblasts begin forming hemoglobin while they are in the bone marrow, a process that continues throughout the RBC life span. The cells enter the circulation as reticulocytes, which fully mature in about 48 hours. The complete sequence from stem cell to RBC takes 3 to 5 days.

The stimulus for increased RBC production is tissue hypoxia. The hormone *erythropoietin* is released by the kidneys in response to hypoxia. It stimulates the bone marrow to produce RBCs. However, the process of RBC production takes about 5 days to maximize. During periods of increased RBC production, the percentage of reticulocytes (immature RBCs) in the blood exceeds that of mature cells.

RED BLOOD CELL DESTRUCTION

RBCs have a life span of about 120 days. Old or damaged RBCs are lysed (destroyed) by phagocytes in the spleen, liver, bone marrow, and lymph nodes. The process of RBC destruction is called hemolysis. Phagocytes save and reuse amino acids and iron from heme units in the lysed RBCs. Most of the heme unit is converted to bilirubin, an orange-yellow pigment that is removed from the blood by

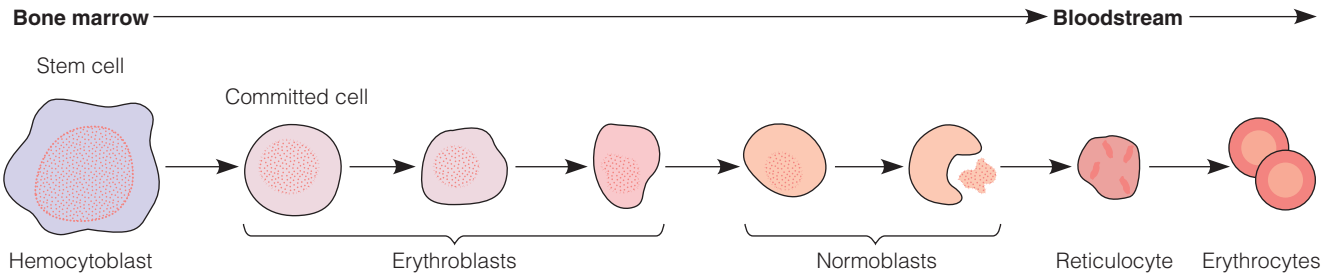

Figure 29–15 ■ Erythropoiesis. RBCs begin as erythroblasts within the bone marrow, maturing into normoblasts, which eventually eject their nucleus and organelles to become reticulocytes. Reticulocytes mature within the blood or spleen to become erythrocytes.

the liver and excreted in the bile. During disease processes causing increased hemolysis or impaired liver function, bilirubin accumulates in the serum, causing jaundice, a yellowish appearance of the skin and sclera.

White Blood Cells

White blood cells (WBCs), or leukocytes, originate from hemopoietic stem cells in the bone marrow and differentiate into the various types of white blood cells. They are a part of the body's defense against microorganisms. Leukocytosis is a higher-than-normal WBC count; leukopenia is a WBC count that is lower than normal.

The two basic types of WBCs are granular leukocytes (or granulocytes) and nongranular leukocytes. Stimulated by granulocyte-macrophage colony-stimulating factor (GM-CSF) and granulocyte colony-stimulating factor (G-CSF), granulocytes mature fully in the bone marrow before being released into the bloodstream. The three types of granulocytes are as follows:

- Neutrophils (also called polymorphonuclear [PMN] or segmented [segs] leukocytes) are active phagocytes, the first cells to arrive at a site of injury. Their numbers increase during inflammation. Immature forms of neutrophils (bands) are released during inflammation or infections, and are referred to as having a shift to the left (so named because immature cell frequencies appear on the left side of the graph) on a differential blood count. Neutrophils have a life span of only about 10 hours and are constantly being replaced.
- Eosinophils are found in large numbers in the mucosa of the intestines and lungs. Their numbers increase during allergic reactions and parasitic infestations.
- Basophils contain histamine, heparin, and other inflammatory mediators. Basophils increase in numbers during allergic and inflammatory reactions.

Nongranular WBCs (agranulocytes) include the monocytes and lymphocytes. They enter the bloodstream before final maturation. These cells are an active part of the inflammatory and immune responses and are discussed in Chapters 12 and 13.

Platelets

Platelets (thrombocytes) produce ATP and release mediators required for clotting. Platelets are formed in the bone marrow as pinched-off portions of large megakaryocytes. Platelet production is controlled by thrombopoietin, a protein produced by the liver, kidney, smooth muscle, and bone marrow. The number of circulating platelets controls thrombopoietin release. Platelets live up to 10 days in circulation. An excess of platelets is thrombocytosis. A deficit of platelets is thrombocytopenia.

Hemostasis

Platelet and coagulation disorders affect **hemostasis** (control of bleeding). Hemostasis is a series of complex interactions between platelets and clotting mechanisms that maintain a relatively steady state of blood volume, BP, and blood flow through injured vessels. The five stages of hemostasis are (1) vessel spasm, (2) formation of the platelet plug, (3) development of an insoluble fibrin clot, (4) clot retraction, and (5) clot dissolution.

VESSEL SPASM

When a blood vessel is damaged, thromboxane A_2 (TXA_2) is released from platelets and cells, causing vessel spasm. This spasm constricts the damaged vessel for about 1 minute, reducing blood flow.

FORMATION OF THE PLATELET PLUG

Platelets attracted to the damaged vessel wall change from smooth disks to spiny spheres. Receptors on the activated platelets bind with von Willebrand's factor (a protein molecule) and exposed collagen fibers at the site of injury to form the platelet plug (Figure 29–16 ■). The platelets release adenosine diphosphate (ADP) and TXA_2 to activate nearby platelets, adhering them to the developing plug. Activation of the clotting pathway on the platelet surface converts fibrinogen to fibrin. Fibrin, in turn, forms a meshwork that binds the platelets and other blood cells to form a stable plug.

DEVELOPMENT OF THE FIBRIN CLOT

The process of coagulation creates a meshwork of fibrin strands that cements the blood components to form an insoluble clot. Coagulation requires many interactive reactions and two clotting pathways (Figure 29–17 ■). The slower intrinsic pathway is activated when blood contacts collagen in the injured vessel wall; the faster extrinsic pathway is activated when blood is exposed to tissues. The final outcome of both pathways is fibrin clot formation. Each procoagulation substance is activated in sequence; the activation of one coagulation factor activates another in turn. Table 29–2 lists known factors, their origin, and their function or pathway. A deficiency of one or more factors or inappropriate inactivation of any factor alters normal coagulation.

CLOT RETRACTION

After the clot is stabilized (within about 30 minutes), trapped platelets contract. Platelet contraction squeezes the fibrin strands, pulling the broken portions of the ruptured blood vessel closer together.

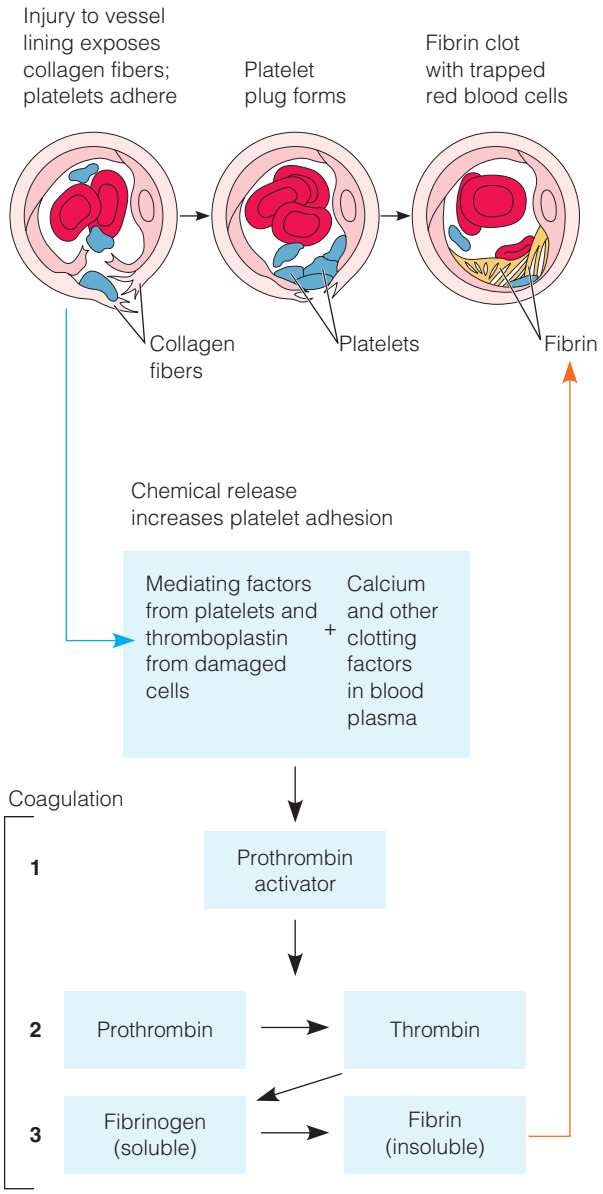

Figure 29–16 ■ Platelet plug formation and blood clotting. This flow diagram summarizes the events leading to fibrin clot formation. PF_3 (blue arrow) released from damaged tissue combines with other clotting factors to release prothrombin activator, the first step of coagulation. Second, prothrombin is converted into thrombin. Finally, thrombin transforms soluble fibrinogen into insoluble fibrin (red arrow) to form a clot.

Growth factors released by the platelets stimulate cell division and tissue repair of the damaged vessel.

CLOT DISSOLUTION

Fibrinolysis, the process of clot dissolution, begins shortly after the clot has formed, restoring blood flow and promoting tissue repair. Like coagulation, fibrinolysis requires a sequence of interactions between activator and inhibitor substances. Plasminogen, an enzyme that promotes fibrinolysis, is converted into plasmin, its active form, by chemical mediators released from vessel walls and the liver. Plasmin dissolves the clot's fibrin strands and certain coagulation factors. Stimuli such as exercise, fever, and vasoactive drugs promote plasminogen activator release. The liver and endothelium also produce fibrinolytic inhibitors.

ASSESSING CARDIOVASCULAR AND LYMPHATIC FUNCTION

Cardiovascular function is assessed by findings from diagnostic tests, a health assessment interview to collect subjective data, and a physical assessment to collect objective data.

Diagnostic Tests

The results of diagnostic tests of cardiac function are used to support the diagnosis of a specific disease, to provide information to identify or modify the appropriate medications or therapy used to treat the disease, and to help the interprofessional team monitor the patient's responses to treatment and nursing care interventions. Diagnostic tests to assess the structures and functions of the heart are described on page 841. More information is included in the discussion of specific disorders in Chapters 30 through 33.

Regardless of the type of diagnostic test, the nurse is responsible for explaining the procedure and any special preparation needed, ensuring the consent form is signed (if necessary), supporting the patient during the examination as necessary, documenting the procedure as appropriate, and monitoring the results of the test. The nurse is responsible for postprocedure care and patient teaching for self-care at home.

Genetic Considerations

When conducting a health assessment interview and physical assessment, it is important for the nurse to consider genetic influences on the health of the adult. Ask about family members with health problems affecting the cardiovascular system, such as high BP, high cholesterol levels, leukemia, or early-onset CAD. Depending on the racial and ethnic background of the patient, ask about any family members with sickle cell disease or thalassemia. During the physical assessment, assess for any manifestations that might indicate a genetic disorder (see the Genetic Considerations box on page 845). If data are found to indicate genetic risk factors or alterations, ask about genetic testing and refer for appropriate genetic counseling and evaluation. Chapter 8 provides further information about genetics in medical-surgical nursing.

The Health Assessment Interview

A health assessment interview to determine problems with cardiovascular or lymphatic structure and function may be conducted during a health screening, may focus on a chief complaint (such as chest pain or leg pain when walking), or may be part of a complete health assessment. If the patient has a problem with cardiovascular or lymphatic function, analyze its onset, characteristics, course, severity, precipitating and relieving factors, and any associated symptoms, noting the timing and circumstances. For example, ask the patient the following:

- What is the location of the chest pain you experienced? Did it move up to your jaw or into your left arm?
- Describe the type of activity that brings on your chest pain.
- Does the leg pain occur only with activities such as walking, or during rest or sleep?
- Have you felt light-headed during the times your heart is racing?

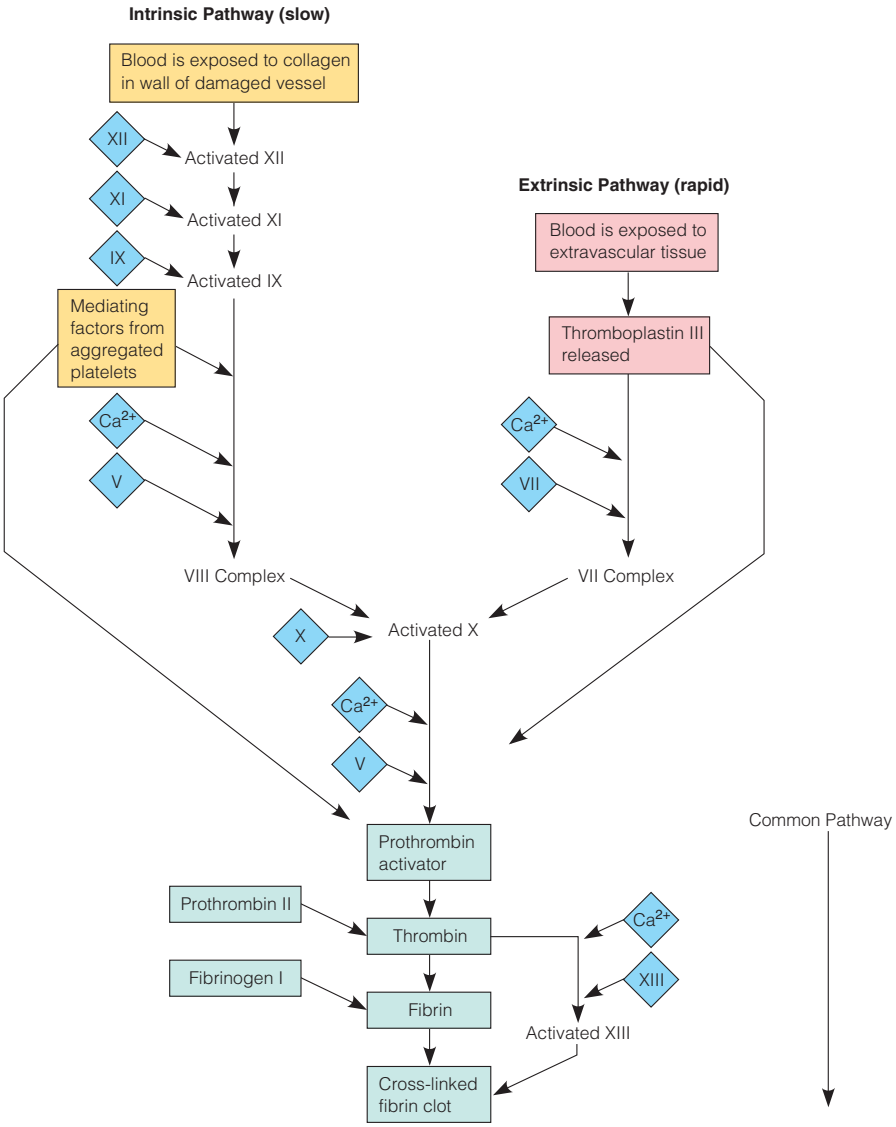

Figure 29–17 ■ Clot formation. Both the slower intrinsic pathway and the more rapid extrinsic pathway activate Factor X. Factor X then combines with other factors to form prothrombin activator. Prothrombin activator transforms prothrombin into thrombin, which then transforms fibrinogen into long fibrin strands. Thrombin also activates Factor XIII, which draws the fibrin strands together into a dense meshwork. The complete process of clot formation occurs within 3 to 6 minutes after blood vessel damage.

TABLE 29–2 Blood Coagulation Factors

Factor	Name	Function or Pathway
I	Fibrinogen	Converted to fibrin strands
II	Prothrombin	Converted to thrombin
III	Thromboplastin	Catalyzes conversion of thrombin
IV	Calcium ions	Needed for all steps of coagulation
V	Proaccelerin	Extrinsic/intrinsic pathways
VII	Serum prothrombin conversion accelerator	Extrinsic pathway
VIII	Antihemophilic factor	Intrinsic pathway
IX	Plasma prothrombin component	Intrinsic pathway
X	Stuart factor	Extrinsic/intrinsic pathways
XI	Plasma prothrombin antecedent	Intrinsic pathway
XII	Hageman factor	Intrinsic pathway
XIII	Fibrin stabilizing factor	Cross-links fibrin strands to form insoluble clot

DIAGNOSTIC TESTS of the Cardiovascular and Lymphatic System

THE HEART AND PERIPHERAL VASCULAR SYSTEM

Name of Test	Purpose and Description	Related Nursing Interventions
Blood pool imaging (gated scan or multigated acquisition scan [MUGA])	This test is useful for evaluation of cardiac status following myocardial infarction and congestive heart failure and effectiveness of cardiac medications. Also used to evaluate left ventricular (LV) function during rest and exercise. Following IV injection of technetium-99m pertechnetate, sequential evaluation of the heart can be performed for several hours. It can be done at the patient's bedside.	No special preparation is needed.
Cardiac catheterization (coronary angiography, coronary arteriography)	A cardiac catheterization may be performed to identify coronary artery disease (CAD) or cardiac valvular disease, to determine pulmonary artery or heart chamber pressures, to obtain a myocardial biopsy, to evaluate artificial valves, or to perform angioplasty or stent an area of CAD. The test is performed by inserting a long catheter into a vein or artery (depending on whether the right side or the left side of the heart is being examined) in the arm or leg. Using fluoroscopy, the catheter is then threaded to the heart chambers or coronary arteries or both. Contrast dye is injected and heart structures are visualized and heart activity filmed. The test is done in the hospital for diagnosis and before heart surgery. *Right cardiac catheterization:* The catheter is inserted into the brachial, subclavian, internal jugular or femoral vein and then threaded through the inferior vena cava into the right atrium to the pulmonary artery. Pressures are measured at each site and blood samples can be obtained for the right side of the heart. The functions of the tricuspid and pulmonary valves can be observed. *Left cardiac catheterization:* The catheter is inserted into the radial, brachial, or femoral artery and advanced retrograde through the aorta to the coronary arteries and/or left ventricle. The patency of the coronary arteries and/or functions of the aortic and mitral valves and left ventricle can be observed.	Inform the patient that food and fluids should not be taken for 6–8 h before the test. Assess for allergies to seafood, iodine, or iodine contrast dyes. If an allergic response to the dye is possible, antihistamines (such as Benadryl) or steroids may be administered the evening before and the morning of the test. Assess for use of aspirin or NSAIDs (risk of bleeding), Viagra (risk of heart problems), or history of kidney disease (dye used may be toxic to the kidneys). Take and record vital signs, including peripheral pulses. Explain that the patient is positioned on a padded table that tilts. A local anesthetic is used at the site of catheter insertion. ECG leads are applied and vital signs are monitored during the procedure. The patient lies supine and is asked to cough and deep breathe frequently. The procedure takes 0.5–3 h. After the procedure, monitor vital signs every 15 min for the first hour and then every 30 min until stable. Assess cardiac rhythm and rate for alterations. Assess peripheral pulses distal to the insertion site. Assess for chest heaviness, dyspnea, level of consciousness, and abdominal or groin pain. Monitor catheter insertion site for bleeding or hematoma. Administer pain medications as prescribed. Instruct patient to increase fluid intake and restrict activity as ordered.
Cardiolite scan	This test is used to evaluate blood flow in different parts of the heart. Cardiolite (technetium-99m sestamibi) is injected IV. In pharmacologic stress scans, dipyridamole (Persantine) or adenosine is injected to increase blood flow to coronary arteries. Additional pharmacologic stress scans can use dobutamine or arbutamine for their positive inotropic properties. These scans may be done in conjunction with a treadmill test.	See information in this table for treadmill test. Instruct the patient to avoid intake of caffeine (including chocolate) for 12–24 h before having a test with dipyridamole Cardiolite.
Cardiac computed tomography (CT) scan	A cardiac CT scan may be conducted to visualize the heart anatomy or coronary circulation or to quantify early calcium deposits in coronary arteries. The calcium score screening heart scan is used to evaluate risk for future coronary artery disease and coronary artery bypass graft patency. It does not require injection of IV iodine. If calcium is present, a score is generated that estimates the extent of coronary artery disease. A negative test does not rule out the potential for soft plaque atherosclerosis.	Assess for allergy to iodine or seafood if contrast medium is to be administered. If allergy exists, follow orders for times and types of medications. For IV contrast studies, instruct patient not to eat or drink for 4 h prior to the test. Assess medications: oral hypoglycemic agents are contraindicated for use with iodinated contrast. Request patient remove hairpins, earrings, and dentures.
Chest x-ray	An x-ray of the thorax can illustrate the contours, placement, and chambers of the heart. It may be done to identify heart displacement or hypertrophy, or fluid in the pericardial sac.	No special preparation is needed.

(*continued*)

DIAGNOSTIC TESTS of the Cardiovascular and Lymphatic System (*continued*)

Name of Test	Purpose and Description	Related Nursing Interventions
Echocardiogram • M-mode • Two-dimensional (2-D) • Spectral Doppler • Color Doppler • Three-dimensional (3-D) • Four-dimensional (4-D) • Stress echocardiogram	Echocardiograms use a transducer to record waves that are bounced off the heart, and to record the direction and flow of blood through the heart in audio and graphic data. An *M (motion)-mode echocardiogram* records the motion, wall thickness, and chamber size of the heart. A *2-D echocardiogram* provides a cross-sectional view of the heart. *Spectral Doppler* records blood flow through the chambers and septal wall defects.*Color Doppler* detects blood flow through the heart, valve function, and presence of shunting. *Three-dimensional echocardiography* combines 2-D echocardiography and ultrasound technology to evaluate the speed and direction of blood flow through the heart, which can identify pathology such as leaky valves. *Four-dimensional* echocardiography provides a moving picture of the 3D echo. *Stress echocardiography* combines a treadmill test with ultrasound images to evaluate segmental function and wall motion. If the patient is not physically able to exercise, IV dobutamine may be administered and ultrasound images taken.	No special preparation is needed; see related nursing care for the patient having a treadmill test for a stress echocardiogram.
Electrocardiogram (ECG)	See Boxes 29–1 and 29–2.	No special preparation is needed.
Lipids	Blood lipids are cholesterol, triglycerides, and phospholipids. They circulate bound to proteins, and so are known as lipoproteins. Lipids are measured to evaluate risk for CAD and to monitor effectiveness of anticholesterol medications. Normal values: Cholesterol: < 200 mg/dL Triglycerides: < 150 mg/dL HDL: Optimal: > 60 mg/dL Men: > 40 mg/dL Women: > 50 mg/dL LDL: < 100 mg/dL (*Note:* Normal values may vary by laboratory.)	Recommend a low-fat meal the evening prior to the test, then no food for 8–12 h. Instruct the patient to have no alcohol intake for 24 h prior to the test. Assess medications. Blood lipids may be increased by thyroxine, estrogens, aspirin, antibiotics (tetracycline and neomycin), nicotinic acid, heparin, and colchicine.
Magnetic resonance imaging (MRI)	An MRI may be used to identify and locate areas of myocardial infarction, perfusion of the heart, and patency of coronary arteries after coronary grafts, and to evaluate pericarditis and cardiac tumors.	Assess for any metallic implants (such as clips on brain aneurysms, pacemaker, body piercing, tattoos, and shrapnel). If present, notify physician. Remove transdermal medication patches (both OTC and prescribed) unless otherwise ordered. Replace the patch following the procedure. Tell the patient to inform the staff about the patch when making the appointment and when completing the admission information. Ask if patient is pregnant; if so the test is not performed. Ask about claustrophobia; if a problem exists, request patient to ask the referring physician for a relaxing medication prior to the MRI. If the patient is very claustrophobic, obese, or confused, an open MRI may be used. A contrast agent (gadolinium) may be used, especially in those allergic to dyes used in CT scanning.
Nuclear dobutamine stress test	Dobutamine is an adrenergic drug that increases myocardial contractility, heart rate, and systolic BP, which increases coronary oxygen consumption and thus increases coronary blood flow. The test is conducted in two parts: resting and stress. The test usually takes about 3.5–4 h.	Instruct the patient to not eat food or drink fluids other than water after midnight or during the test. Tell the patient to discontinue beta-blockers, calcium channel blockers, and ACE inhibitors for 36 h prior to the test. If hospitalized, do not administer nitrates for 6 h prior to the test.

DIAGNOSTIC TESTS of the Cardiovascular and Lymphatic System (*continued*)

Name of Test	Purpose and Description	Related Nursing Interventions
Nuclear dipyridamole (Persantine) stress test	This test is used when the patient is not physically able to walk on a treadmill. Dipyridamole (Persantine), given IV, dilates the coronary arteries and increases myocardial blood flow. Coronary arteries that are narrowed from CAD cannot dilate to increase myocardial perfusion.	Patient is NPO after midnight except for water. Food, fluids, and drugs that contain caffeine should be avoided for 24 h prior to the test, as should decaffeinated fluids. Some drugs, such as theophylline preparations, are discontinued for 36 h prior to the test.
Pericardiocentesis	This procedure is performed in the hospital to remove fluid from the pericardial sac for diagnostic or therapeutic purposes. It may also be done as an emergency procedure for the patient with cardiac tamponade (which may result in death). After local anesthetic, a large-gauge (16 to 18) needle is inserted to the left of the xiphoid process into the pericardial sac and excess fluid is withdrawn (Figure 29–18 ■).	Take and record baseline vital signs. Assess for history of cardiac problems. Explain to patient the need to remain still during the procedure, that the procedure takes about 30 min, and that a local anesthetic will be used at the needle insertion site. Monitor the ECG during and after the procedure and report abnormal findings to the physician. Monitor vital signs after the procedure as ordered. Notify the physician of changes in cardiac rhythm, BP, heart rate, or level of consciousness. If the procedure is to treat an emergency, monitor central venous pressure (CVP) and BP closely. As the effusion is relieved, CVP will decrease and BP will increase.
Positron emission tomography (PET)	Following injection of a radionuclide, two scans are performed (resting and chemically induced stress) and the resulting images are compared for myocardial perfusion and myocardial metabolic function. A stress test (treadmill) may be a part of the test. If the myocardium is ischemic or damaged, the images will be different. Normally, the images will be the same.	Assess the patient's blood glucose: For accurate metabolic activity images, the blood glucose level must be between 60 and 140 mg/dL. If exercise is included in the test, instruct the patient to be NPO and avoid smoking and caffeine for 24 h prior to the test.
Thallium/technetium stress test (myocardial imaging perfusion test, cardiac blood pool imaging)	*Thallium stress test:* Thallium-201, a radioisotope that accumulates in myocardial cells, is used during the stress test to evaluate myocardial perfusion. Second scans are done 2–3 h later when the heart is at rest; this is to differentiate between an ischemic area and an infarcted or scarred area of myocardium. *Exercise technetium perfusion test:* Technetium-99m–laced compounds are administered and a scan is done to evaluate cardiac perfusion, wall motion, and ejection fraction. This is probably the most useful noninvasive test to diagnose and monitor CAD.	Assess medications; those that affect the BP or heart rate should be discontinued for 24–36 h prior to the test (unless the test is being done to monitor the effectiveness of the medications). See treadmill test for other interventions.
Treadmill test (stress test)	Stress testing is based on the theory that coronary artery disease results in depression of the ST segment with exercise. Depression of the ST segment and depression or inversion of the T wave indicates myocardial ischemia. When the patient is walking on a treadmill machine, the work rate of the heart is changed every 3 min for 15 min by increasing the speed and degree of incline by 3% each time. Patients exercise until they are fatigued, develop symptoms, or reach their maximum predicted heart rate.	Ask the patient to wear comfortable shoes, and to avoid food, fluids, and smoking for 2–3 h before the test. Assess for events that contraindicate the tests: recent myocardial infarction; severe, unstable angina; controlled dysrhythmias; congestive heart failure; or recent pulmonary embolism.

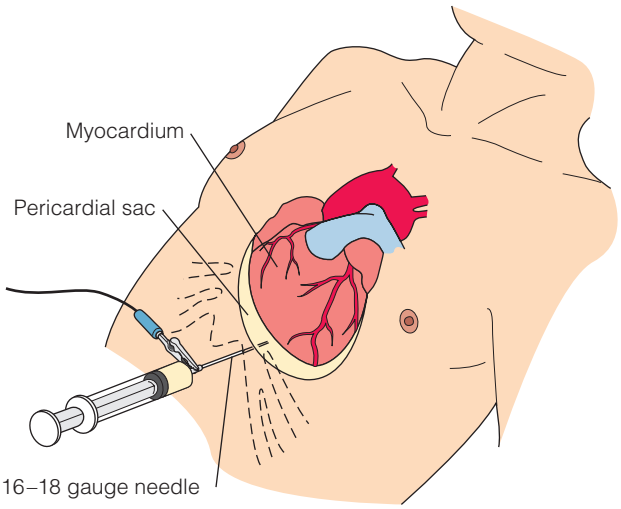

Figure 29–18 ■ Pericardiocentesis.

(*continued*)

DIAGNOSTIC TESTS of the Cardiovascular and Lymphatic System (*continued*)

Name of Test	Purpose and Description	Related Nursing Interventions
Transesophageal echocardiography (TEE)	A TEE allows visualization of adjacent cardiac and extracardiac structures to identify or monitor mitral and aortic valve pathology, left atrium intracardiac thrombus, acute dissection of the aorta, endocarditis, perioperative left ventricular function, and intracardiac repairs during surgery. A transducer (probe) attached to an endoscope is inserted into the esophagus, and images are taken. Concurrent IV contrast medium, Doppler ultrasound, and color flow imaging may be used.	Instruct the patient to not eat or drink fluids for 4 h before the test. Explain that a sedative will be given before the test. Take and record vital signs.

THE LYMPHATIC SYSTEM

Name of Test	Purpose and Description	Related Nursing Interventions
Abdominal or thoracic CT scan	A radiologic study used to assess the liver or spleen and enlarged lymph nodes in the mediastinum.	Tell the patient not to eat or drink for 4 h before the test. Oral hypoglycemic agents should not be taken if iodinated contrast is used. Assess for allergy to iodine products and notify physician if allergy is found. Administer oral contrast as prescribed. Following the test, tell the patient to increase oral intake of fluids to help flush out the dye, and to report any allergic reactions to the dye (such as skin rash, headache, vomiting, or kidney dysfunction).
Lymph node biopsy	A lymph node biopsy is done to obtain tissue for histologic examination for diagnosis and treatment. It may be open (performed in the operating room) or closed (needle) by needle aspiration of tissue from a lymph node.	Use sterile technique when changing dressings.
Lymphangiography (lymphangiogram)	This is an x-ray examination of the lymphatic vessels and lymph nodes, used to assess metastasis of the lymph nodes, to identify malignant lymphoma, and to identify the cause of lymphedema. An iodine contrast substance is injected at various sites and fluoroscopy is used to visualize lymphatic filling.	Ask the patient about allergies to seafood, iodine, or contrast medium used in a previous x-ray test. Tell the patient that the blue contrast dye discolors the urine and possibly the skin for a few days. Take and record vital signs. Ask patient to void before the test. After the test, monitor for dyspnea, pain, and hypotension; assess incision sites for manifestations of infection, and assess for leg edema. Elevate lower extremities as indicated.
Magnetic resonance imaging (MRI)—liver, spleen, lymph nodes	A radiologic study used to visualize the liver, spleen, and lymph nodes. It does not require injection of contrast medium.	Assess for any metallic implants (such as clips on brain aneurysms, pacemaker, body piercing, tattoos, and shrapnel). If present, notify physician. Remove transdermal medication patches (both OTC and prescribed) unless otherwise ordered (FDA, 2009). Replace the patch following the procedure. Tell the patient to inform the staff about the patch when making the appointment and when completing the admission information. Ask if patient is pregnant; if so the test is not performed. Ask about claustrophobia; if a problem exists, request patient to ask the referring physician for a relaxing medication prior to the MRI. If the patient is very claustrophobic, obese, or confused, an open MRI may be used.

DIAGNOSTIC TESTS of the Cardiovascular and Lymphatic System (*continued*)

THE HEMATOLOGIC SYSTEM

Name of Test	Purpose and Description	Related Nursing Interventions
Bone marrow examination	A bone marrow examination is conducted to evaluate blood-forming tissue; to diagnose multiple myeloma, leukemia, and some lymphomas; and to assess effectiveness of therapy for leukemia. Bone marrow specimens are obtained by either aspiration or biopsy. The preferred site for bone marrow aspiration is the posterior iliac crest; the sternum may also be used. The procedure is performed by inserting a needle into the bone and drawing out a sample of the blood in the marrow. A bone marrow biopsy is performed by making a small incision over the bone and screwing a core biopsy instrument into the bone to obtain a specimen. Bone marrow studies are used to diagnose leukemias, metastatic cancer, lymphoma, aplastic anemia, and Hodgkin's disease.	Explain that the procedure (either aspiration or biopsy) takes about 20 min, a sedative may be given prior to the procedure, and that it is important to remain very still during the procedure to prevent accidental injury. Tell the patient that although the area will be anesthetized with a local anesthetic, insertion of the needle will be painful for a short time. Taking deep breaths may make this part of the procedure less painful. The aspiration site may ache for 1 or 2 days. Take and record vital signs and ask the patient to void. If specimen is taken from the sternum or iliac crest place patient in the supine position; if the posterior iliac crest is used, place patient in the prone position. After the procedure apply pressure to the puncture site for 5–10 min. Apply a sterile dressing to the puncture site and monitor for bleeding for 24 h.
Complete blood count (CBC)	This is a blood test that measures blood components. Refer to Table 29–1.	None
Erythrocyte sedimentation rate (ESR)	This blood test is done as a measure of inflammation, and is increased in many illnesses, including cancer, heart disease, and kidney disease. Normal values: Women: 1–20 mm/h Men: 1–15 mm/h	None
Magnetic resonance angiography (MRA)	An MRA is used to visualize vascular occlusive disease and aneurysms of the abdominal aorta. The procedure is done by using a non–iodine-based contrast medium injected IV.	See MRI entry earlier in this table

GENETIC CONSIDERATIONS

Examples of Cardiovascular Disorders

- Familial hypercholesterolemia is a single-gene disorder that results in atherosclerosis and CAD, which may occur at an earlier age than in the general population (i.e., before age 55 in men and age 65 in women). However, increased cholesterol levels may also be inherited and are a risk factor for CAD in both men and women.
- Marfan's syndrome is an autosomal-dominant inherited disorder that affects the skeleton, the eyes, and the cardiovascular system. The cardiovascular effects are a dilation of the proximal aorta and aortic dissection associated with degeneration of the elastic fibers in the tunica media of the aorta. There may also be thoracic aortic aneurysms.
- Hypertrophic cardiomyopathy is a disease of the sarcomere proteins. More than 100 different mutations in 10 genes encoding contractile sarcomeres have been identified.
- Long QT syndrome (LQTS) is an inherited genetic disorder that results from structural abnormalities of the sodium, potassium, and calcium channels in the heart, leading to dysrhythmias. This can result in unconsciousness, and may cause sudden cardiac death in teenagers and young adults when exposed to stressors ranging from exercise to loud sounds.
- Sickle cell disease is the most common inherited blood disorder in the United States, affecting 1 in 500 people of African descent. It is characterized by episodes of pain, chronic hemolytic anemia, and severe infections.
- Gaucher disease, more common in descendants of Eastern European Jewish people, is an inherited illness caused by a gene mutation. The gene is responsible for an enzyme that breaks down a specific fat. When the fat is not broken down, it accumulates in the liver, spleen, and bone marrow, causing pain, fatigue, jaundice, bone damage, anemia, and even death.
- Hemophilia A is a hereditary blood disorder, primarily affecting males, characterized by a deficiency of the blood clotting factor, Factor VIII. Abnormal bleeding results.
- Chronic myeloid leukemia (CML), a cancer of blood cells, is characterized by replacement of bone marrow with malignant, leukemic cells. Leukemic cells also circulate in the blood, causing enlargement of the spleen, liver, and other organs. This leukemia is the result of chromosomal abnormality called the Philadelphia chromosome.
- Thalassemia, an inherited disease of faulty hemoglobin synthesis, is more often found in descendants of people living near the Mediterranean Sea, Africa, the Middle East, and Asia. It comprises a group of disorders that range from very mild blood abnormalities to severe or fatal anemia.

BOX 29–1 Electrocardiogram

The electrocardiogram (ECG) is a graphic record of the heart's activity. Electrodes applied to the body surface are used to obtain a graphic representation of cardiac electrical activity. These electrodes detect the magnitude and direction of electrical currents produced in the heart. They attach to the electrocardiograph by an insulated wire called a *lead*. The electrocardiograph converts the electrical impulses it receives into a series of waveforms that represent cardiac depolarization and repolarization. Placement of electrodes on different parts of the body allows different views of this electrical activity, much like turning the head while holding a camera provides different views of the scenery. ECG waveforms and patterns are examined to detect dysrhythmias as well as myocardial damage, the effects of drugs, and electrolyte imbalances.

ECG waveforms reflect the direction of electrical flow in relation to a positive electrode. Current flowing toward the positive electrode produces an upward (positive) waveform; current flowing away from the positive electrode produces a downward (negative) waveform. Current flowing perpendicular to the positive pole produces a biphasic (both positive and negative) waveform. Absence of electrical activity, called the *isoelectric line*, is represented by a straight line.

ECG waveforms are recorded by a heated stylus on heat-sensitive paper. The paper is marked at standard intervals that represent time and voltage or amplitude (see Figure 1). Each small box is 1 mm^2. The recording speed of the standard ECG is 25 mm/second, so each small box represents 0.04 second. Five small boxes horizontally and vertically make one large box, equivalent to 0.20 second. Five large boxes represent 1 full second. Measured vertically, each small box represents 0.1 mV.

Both bipolar and unipolar leads are used in recording the ECG. A bipolar lead uses two electrodes of opposite polarity (negative and positive). In a *unipolar* lead, one positive electrode and a negative reference point at the center of the heart are used. The electrical potential between the two monitoring points is graphically recorded as the ECG waveform.

The heart can be viewed from both the frontal plane and the horizontal plane (see Figure 2). Each plane provides a unique perspective of the heart muscle. The frontal plane is an imaginary cut through the body that views the heart from top to bottom (superior–inferior) and side to side (right–left). This perspective of the heart is analogous to a paper doll cutout. It provides information about the inferior and lateral walls of the heart. The horizontal plane is a cross-sectional view of the heart from front to back (anterior–posterior) and side to side (right–left). Information regarding the anterior, septal, and lateral walls of the heart, as well as the posterior wall, is obtained from this view.

A standard 12-lead ECG provides a simultaneous recording of six limb leads and six precordial leads (see Figure 3). The limb leads provide information about the heart in the frontal plane and

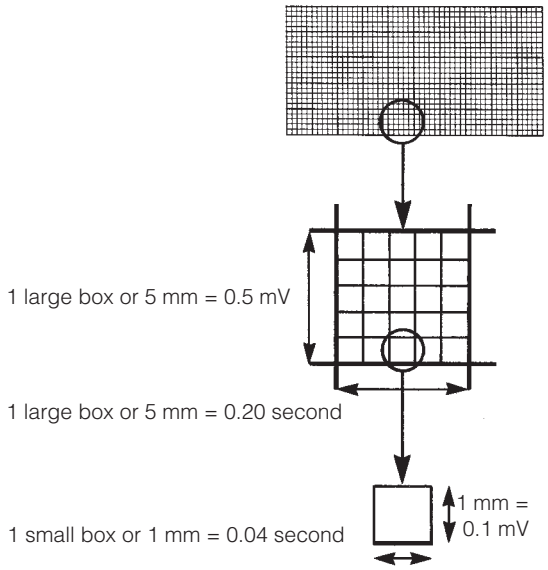

Figure 1 Time and speed voltage measurements on ECG paper at a recording speed of 25 mm/second.

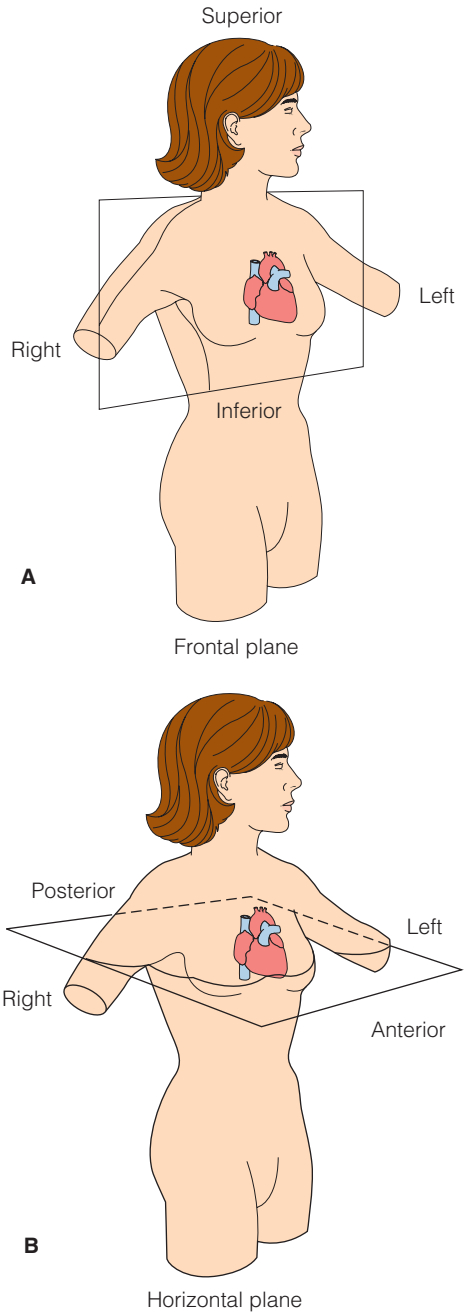

Figure 2 Planes of the heart: A, frontal plane; and B, horizontal plane.

BOX 29–1 Electrocardiogram (*continued*)

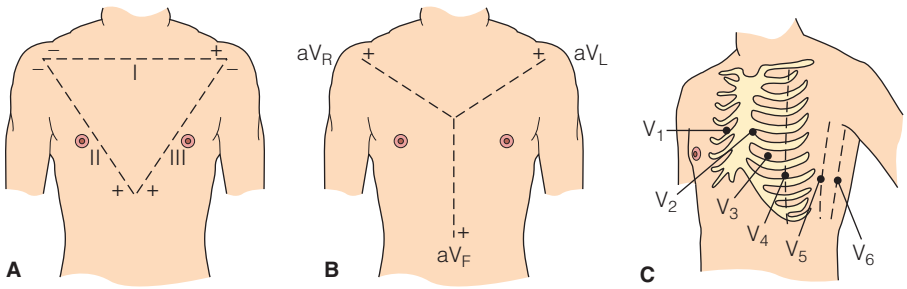

Figure 3 Leads of the 12-lead ECG: A, bipolar limb leads I, II, III; B, unipolar limb leads aV_R, aV_L, aV_F; and C, unipolar precordial leads V_1 to V_6.

include three bipolar leads (I, II, III) and three unipolar leads (aV_R, aV_L, and aV_F). The bipolar limb leads measure electrical activity between a negative lead on one extremity and a positive lead on another. The unipolar limb leads (called augmented leads) measure the electrical activity between a single positive electrode on a limb (right arm [R], left arm [L], or left leg [F for foot]), and the center of the heart.

The precordial leads, also known as chest leads or V leads, view the heart in the horizontal plane. They include six unipolar leads (V_1, V_2, V_3, V_4, V_5, and V_6), which measure electrical activity between the center of the heart and a positive electrode on the chest wall.

The cardiac cycle is depicted as a series of waveforms, the P, Q, R, S, and T waves (see Figure 4).

- The *P wave* represents atrial depolarization and contraction. The impulse is from the sinus node. The P wave precedes the QRS complex and is normally smooth, round, and upright. P waves may be absent when the SA node is not acting as the pacemaker. Atrial repolarization occurs during ventricular depolarization and usually is not seen on the ECG.
- The *PR interval* represents the time required for the sinus impulse to travel to the AV node and into the Purkinje fibers. This interval is measured from beginning of P wave to beginning of QRS complex. If no Q wave is seen, the beginning of the R wave is used. The PR interval is normally 0.12 to 0.20 second (up to 0.24 second is considered normal in patients over age 65). PR intervals greater than 0.20 second indicate a delay in conduction from the SA node to the ventricles.
- The *QRS complex* represents ventricular depolarization and contraction. The QRS complex includes three separate waves: The Q wave is the first negative deflection, the R wave is the positive or upright deflection, and the S wave is the first negative deflection after the R wave. Not all QRS complexes have all three waves; nonetheless, the complex is called a QRS complex. The normal duration of a QRS complex is from 0.06 to 0.10 second. QRS complexes greater than 0.10 second indicate delays in transmitting the impulse through the ventricular conduction system.
- The *ST segment* signifies the beginning of ventricular repolarization. The ST segment, the period from the end of the QRS complex to the beginning of the T wave, should be isoelectric. An abnormal ST segment is displaced (elevated or depressed) from the isoelectric line.
- The *T wave* represents ventricular repolarization. It normally has a smooth, rounded shape that is usually less than 10 mm tall. It usually points in the same direction as the QRS complex. Abnormalities of the T wave may indicate myocardial ischemia or injury, or electrolyte imbalances.
- The *QT interval* is measured from the beginning of the QRS complex to the end of the T wave. It represents the total time of ventricular depolarization and repolarization. Its duration varies with gender, age, and heart rate; usually, it is 0.32 to 0.44 second long. Prolonged QT intervals indicate a prolonged relative refractory period and a greater risk of dysrhythmias. Shortened QT intervals may result from medications or electrolyte imbalances.
- The *U wave* is not normally seen. It is thought to signify repolarization of the terminal Purkinje fibers. If present, the U wave follows the same direction as the T wave. It is most commonly seen in hypokalemia.

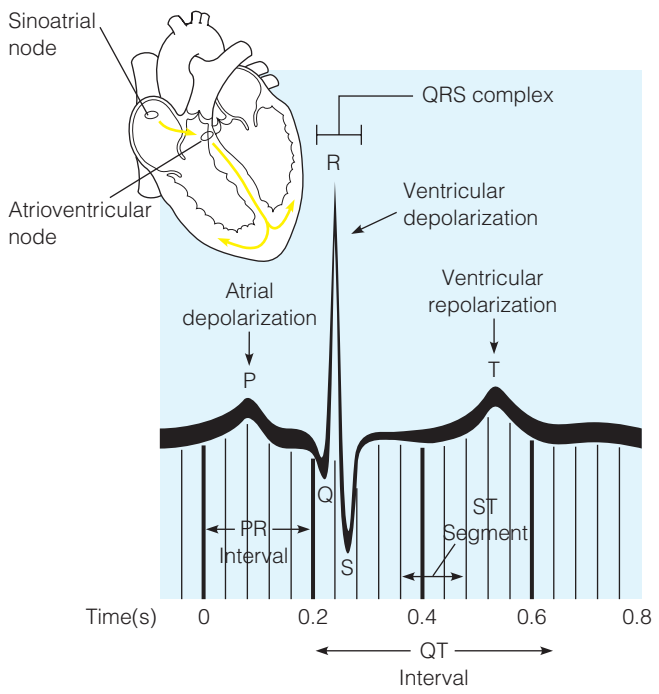

Figure 4 Normal ECG waveform and intervals.

The interview begins by exploring the patient's chief complaint (e.g., chest pain, leg pain, or fatigue). Describe the patient's chest pain or leg pain in terms of location, quality or character, timing, setting or precipitating factors, severity, aggravating and relieving factors, and associated symptoms (Table 29–3).

Explore the patient's medical history for any cardiovascular disorders such as angina, heart attack, congestive heart failure (CHF), stroke, hypertension (HTN), peripheral vascular disease (PVD), or other chronic illnesses (such as diabetes or bleeding disorders). Ask the patient about previous heart surgery or illnesses, such as rheumatic fever, scarlet fever, or recurrent streptococcal throat infections, and radiation treatment for breast cancer. Review the patient's family history for CAD, HTN, stroke, hyperlipidemia, diabetes, congenital heart disease, or sudden death.

Ask the patient about past or present occurrence of cardiovascular symptoms, such as chest pain, shortness of breath, difficulty breathing, cough, palpitations, fatigue, light-headedness or dizziness, fainting, heart murmur, blood clots, leg cramps or swelling, changes in skin color or temperature, varicose veins, or edema. Because cardiovascular function affects all other body systems, a full history may need to explore other related systems, such as respiratory function. Ask about past or present bleeding (from the nose, gums or mouth, or rectum) as well as associated symptoms (such as pallor, dizziness, fatigue), lymph node changes (swelling, pain, heat), swelling of extremities, and recurrent infections.

Review the patient's personal habits and nutritional history, including body weight; eating patterns; dietary intake of fats, salt, fluids; dietary restrictions; hypersensitivities or intolerances to food or medication; and the use of caffeine and alcohol. If the patient uses tobacco products, ask about type (cigarettes, pipe, cigars, snuff), duration, amount, and efforts to quit. If the patient uses street drugs, ask about type, method of intake (e.g., inhaled or injected), duration of use, and efforts to quit. Include questions about the patient's activity level and tolerance, recreational activities, and relaxation habits. Assess the patient's sleep patterns for interruptions in sleep due to dyspnea, cough, discomfort, urination, or stress. Ask how many pillows the patient uses when sleeping.

It is important to consider socioeconomic factors that may precipitate or aggravate circulatory problems, such as inadequate clothing, shoes, or shelter; and occupational levels such as prolonged sitting or standing, exposure to radiation, or extremes of temperature. Lifestyle, including intravenous drug use or sexual practices, may be significant in determining the risk for diseases associated with bleeding and impaired lymphatic function.

BOX 29–2 Interpreting an ECG

Interpreting an ECG strip to determine the cardiac rhythm is a skill that takes practice to learn and master. Many methods are used to analyze ECGs. It is important to use a consistent method for ECG analysis. Identifying and interpreting complex dysrhythmias requires advanced skills and knowledge obtained through further education. One method follows:

- *Step 1: Determine rate.* Assess heart rate. Use P waves to determine the atrial rate and R waves for the ventricular rate. Several approaches can determine the heart rate:
  - Count the number of complexes in a 6-second rhythm strip (the top margin of ECG paper is marked at 3-second intervals), and multiply by 10. This provides an estimate of the rate and is particularly valuable if rhythms are irregular.
  - Count the number of large boxes between two consecutive complexes, and divide by 300 (the number of large boxes in 1 minute). For example, there are 6 large boxes between two R waves; 300 divided by 6 equals a ventricular rate of 50 bpm. Memorize the following sequence for rapid rate determination: 300, 150, 100, 75, 60, 50, 43. One large box between complexes equals a rate of 300; two, a rate of 150; three, a rate of 100; and so on.
  - Count the number of small boxes between two consecutive complexes, and divide 1500 (the number of small boxes in 1 minute) by this number. For example, there are 19 small boxes between two R waves; 1500 divided by 19 equals a ventricular rate of 79 bpm. This is the most precise measurement of heart rate.
- *Step 2: Determine regularity.* Regularity is the consistency with which the P waves or QRS complexes occur. In a regular rhythm, all waves occur at a consistent rate. Rhythm regularity is determined by measuring the interval between consecutive waves. Place one point of an ECG caliper (a measuring device) on the peak of the P wave (for atrial rhythm) or the R wave (for ventricular rhythm). Adjust the other point to the peak of the next wave, P to P or R to R. Keeping the calipers set at this distance, evaluate intervals between consecutive waves. The rhythm is *regular* if all caliper points fall on succeeding wave peaks. Alternately, use a strip of blank paper on top of the ECG strip, marking the peaks of two or three consecutive waves. Then move the paper along the strip to consecutive waves. Wave peaks that vary by more than one to three small boxes (depending on the rate) are *irregular*. Irregular rhythms may be *irregularly irregular* (if the intervals have no pattern) or *regularly irregular* (if a consistent pattern to the irregularity can be identified).
- *Step 3: Assess P wave.* The presence or absence of P waves helps determine the origin of the rhythm. All the P waves should be alike in size and shape (*morphology*). If P waves are not seen or they differ in shape, the rhythm may not originate in the sinus node.
- *Step 4: Assess P to QRS relationship.* Determine the relationship between P waves and QRS complexes. There should be one and only one P wave for every QRS complex, because the normal stimulus for ventricular contraction originates in the sinus node.
- *Step 5: Determine interval durations.* To evaluate impulse transmission through the cardiac conduction system, measure the PR interval, QRS duration, and QT interval. To measure, count the number of small boxes from the beginning of the interval to the end, and multiply by 0.04 second. Then determine whether the interval duration is within its normal limits. For example, the PR interval is 3.5 small boxes wide, or 0.14 second. This is within the normal limits of 0.12 to 0.20 second. This interval should be consistent, not varying from beat to beat. A PR interval greater than 0.20 second or one that varies from beat to beat is abnormal.

  The QRS complex duration is normally between 0.06 and 0.10 second. A QRS complex greater than 0.12 second indicates delayed ventricular conduction.

  The QT interval is normally 0.32 to 0.44 second. It varies inversely with the heart rate: The faster the heart rate, the shorter the QT interval. As a general rule, the QT interval should be no more than half the previous R–R interval. A prolonged QT interval indicates a prolonged relative refractory period of the heart.
- *Step 6: Identify abnormalities.* Note the presence and frequency of *ectopic* (extra) beats, deviation of the ST segment above or below the baseline, and abnormalities in waveform shape and duration.

TABLE 29–3 Assessing Chest Pain

Characteristic	Examples
Location	Substernal, precordial, jaw (more common in women), back (more common in women) Localized or diffuse Radiation to neck, jaw, shoulder, arm, back between the shoulders
Character/quality	Pressure; tightness; crushing, burning, or aching quality; heaviness; dullness; "heartburn" or indigestion
Timing: onset, duration, and frequency	Onset: Sudden or gradual? Duration: How many minutes does the pain last? Frequency: Is the pain continuous or periodic?
Setting/precipitating factors	Awake, at rest, sleep interrupted? With activity? With eating, exertion, exercise, elimination, emotional upset?
Intensity/severity	Can range from 0 (no pain) to 10 (worst pain ever felt)
Aggravating factors	Activity, breathing, temperature
Relieving factors	Medication (nitroglycerin, antacid), rest; there may be no relieving factors
Associated symptoms	Fatigue, shortness of breath (more common in women), palpitations, nausea and vomiting (more common in women), sweating, anxiety, light-headedness or dizziness

Physical Assessment

Physical assessment of cardiovascular function may be performed either as part of a total assessment or alone for patients with suspected or known problems with heart, peripheral vascular, lymphatic, or hematologic function. The patient may sit or lie in the supine position. Before beginning the assessment, collect all required equipment and explain the techniques to the patient to decrease anxiety.

Assess the heart through inspection, palpation, and auscultation over the precordium (the area of the chest wall overlying the heart) (Figure 29–19 ■). Movements over the precordium may be more easily seen with tangential lighting (in which the light is directed at a right angle to the area being observed, producing shadows). A quiet environment is essential to hear and assess heart sounds accurately. Assess the heart and thorax for the following:

- The **apical impulse** is a normal, visible pulsation (**thrust**) in the area of the midclavicular line in the left fifth intercostal space. It can be seen on inspection in about half of the adult population. (The apical impulse was previously called the point of maximal impulse [PMI] but this term is no longer used because a maximal impulse may occur in other areas of the precordium as a result of abnormal conditions.)
- **Retraction** is a pulling in of the tissue of the precordium; a slight retraction just medial to the midclavicular line at the area of the apical impulse is normal and is more likely to be visible in thin patients.
- Pulsations (other than the normal apical pulsations), which may be called **heaves** or **lifts**, are considered abnormal. They may occur as the result of an enlarged ventricle.

The techniques used to assess the peripheral vascular and lymphatic systems include inspecting the skin for such changes as edema, ulcerations, or alterations in color and temperature; auscultating BP; and palpating the major pulse points of the body (Figure 29–20 ■)

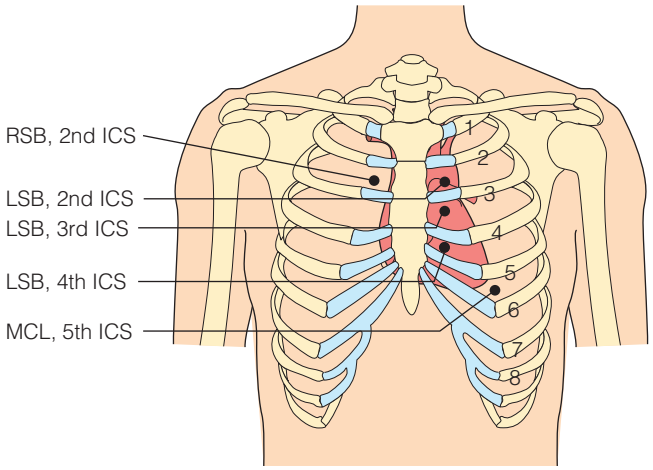

Figure 29–19 ■ Areas for inspection and palpation of the precordium, indicating the sequence for palpation.

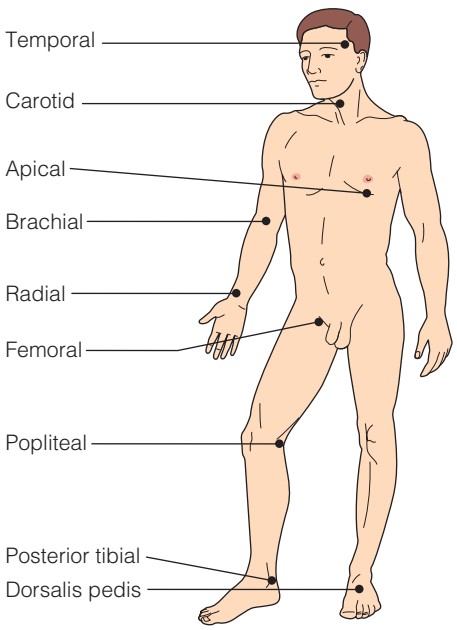

Figure 29–20 ■ Body sites at which peripheral pulses are most easily palpated.

and lymph nodes. The 5 Ps of peripheral vascular disease include pulselessness, pallor, pain, paresthesias, and paralysis. The patient may be assessed in the supine, sitting, and standing positions. Physical assessment of the lymphatic system, using inspection and palpation, is usually integrated into the assessment of other body systems. For example, the tonsils are inspected with the pharynx during the head and neck assessment; the regional lymph nodes are evaluated with corresponding body regions (e.g., occipital, auricular, and cervical nodes are evaluated with assessment of the head and neck, axillary nodes with assessment of the breast or thorax, epitrochlear node with assessment of the peripheral vascular exam of the arms, and inguinal nodes with assessment of the abdomen); and the spleen can be palpated during the abdominal assessment. Normal age-related findings for the older adult are summarized in the Nursing Care of the Older Adult box.

SAMPLE DOCUMENTATION

Assessment of Cardiac Function

56-year-old male admitted to cardiac critical care unit from ED to rule out myocardial infarction. States he has pain in the middle of his chest that is "like a heavy pressure"; 6 on a 10-point scale. Skin cool, slightly moist. BP 190/94 mmHg right arm and 186/92 mmHg left arm (both reclining). Apical pulse 92 bpm, regular and strong. No pulse deficit. Respirations 28/min. Apical impulse nonpalpable, no visible heaves or thrusts. S_1 and S_2 auscultated without murmurs or clicks. S_4 noted.

NURSING CARE OF THE OLDER ADULT

Age-Related Cardiovascular Changes

Age-Related Change	Significance
Myocardium: ↓ efficiency and contractibility.	• Decreased CO when under physiologic stress with resulting tachycardia that lasts longer. The person may require rest time between physical activities.
Sinus Node: ↑ in thickness of shell surrounding the node, and a ↓ in the number of pacemaker cells throughout the conduction system.	
Left ventricle: Slight hypertrophy, prolonged isometric contraction phase and relaxation time; ↑ time for diastolic filling and systolic emptying cycle.	• Stroke volume may increase to compensate for tachycardia, leading to increased BP.
Valves and blood vessels: Aorta is elongated and dilated, valves are thicker and more rigid, and resistance to peripheral blood flow increases by 1% per year.	• BP increases to compensate for increased peripheral resistance and decreased CO. • Baroreceptor response decreases.
Bone marrow: ↓ ability of bone marrow to respond to need for increased RBCs, WBCs, and platelets.	• Anemia may result.
Blood vessels:	
Tunica intima: fibrosis, calcium and lipid accumulation, cellular proliferation.	• As a result of age-related changes, the systolic BP rises. Decreased arterial elasticity results in vascular changes in the heart, kidneys, and pituitary gland. Decreased baroreceptor function results in postural hypotension. Vessels in the head, neck, and extremities are more prominent.
Tunica media: thins, elastin fibers calcify; increase in calcium results in stiffening. Baroreceptor function is impaired and peripheral resistance increases.	• Inefficient vasoconstriction, decreased CO, and reduced muscle mass and subcutaneous tissue lead to a reduced ability to respond to cold temperatures. • With a decrease in BP and changes in blood vessel walls, tissue perfusion may be inadequate, leading to edema, inflammation, pressure ulcers, and changes in effects of medications.
Immune system	• Increased risk for infection, with decreased manifestations of an actual infection.
Impaired function of B and T lymphocytes. ↓ production of antibodies.	• Increased incidence of cancers.

Cardiovascular Assessments

Technique/Normal Findings	Abnormal Findings
Apical Impulse Assessment	
First using the palmar surface and then repeating with finger pads, palpate the precordium for symmetry of movement and the apical impulse for location, size, amplitude, and duration. Refer to Figure 29–19 for the sequence for palpation. To locate the apical impulse, ask the patient to assume a left lateral recumbent position. Simultaneous palpation of the carotid pulse may also be helpful. *The apical impulse is not palpable in all patients. The apical impulse may be palpated in the mitral area, and has only a brief small amplitude.*	• An enlarged or displaced heart is associated with an apical impulse lateral to the midclavicular line (MCL) or below the fifth left intercostal space (ICS). • Increased size, amplitude, and duration of the apical impulse are associated with left ventricular volume overload (increased afterload) in conditions such as HTN and aortic stenosis, and with pressure overload (increased preload) in conditions such as aortic or mitral regurgitation. • Increased amplitude alone may occur with hyperkinetic states, such as anxiety, hyperthyroidism, and anemia. • Decreased amplitude is associated with a dilated heart in cardiomyopathy. • Displacement alone may also occur with dextrocardia, diaphragmatic hernia, gastric distention, or chronic lung disease. • A **thrill** (a palpable vibration over the precordium or an artery) may accompany severe valve stenosis. • A marked increase in amplitude of the apical impulse at the right ventricular area occurs with right ventricular volume overload in atrial septal defect. • An increase in amplitude and duration occurs with right ventricular pressure overload in pulmonic stenosis and pulmonary hypertension. A lift or heave may also be seen in these conditions (and in chronic lung disease). • A palpable thrill in this area occurs with ventricular septal defect.
Palpate the subxiphoid area with the index and middle finger. *No pulsations or vibrations should be palpated.*	• Right ventricular enlargement may produce a downward pulsation against the fingertips. • An accentuated pulsation at the pulmonary area may be present in hyperkinetic states. • A prominent pulsation reflects increased flow or dilation of the pulmonary artery. • A thrill may be associated with aortic or pulmonary stenosis, aortic stenosis, pulmonary HTN, or atrial septal defect. • Increased pulsation at the aortic area may suggest aortic aneurysm. • A palpable second heart sound (S_2) may be noted with systemic HTN.
Cardiac Rate and Rhythm Assessment	
Auscultate heart rate (Figure 29–21 ■). *The heart rate should be 60 to 100 beats per minute (bpm) with regular rhythm.*	• A heart rate exceeding 100 bpm is tachycardia. A heart rate less than 60 bpm is bradycardia.
Simultaneously palpate the radial pulse while listening to the apical pulse. *The radial and apical pulses should be equal.*	• If the radial pulse falls behind the apical rate, the patient has a pulse deficit, indicating weak, ineffective contractions of the left ventricle.
Auscultate heart rhythm. *The heart rhythm should be regular.*	• **Dysrhythmias** (abnormal heart rate or rhythm) may be regular or irregular in rhythm; their rates may be slow or fast. Irregular rhythms may occur in a pattern (e.g., an early beat every second beat, called bigeminy), sporadically, or with frequency and disorganization (e.g., atrial fibrillation). A pattern of gradual increase and decrease in heart rate that is within the normal heart rate and that correlates with inspiration and expiration is called sinus arrhythmia.

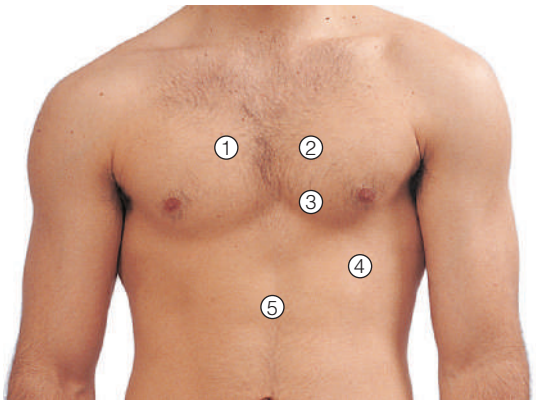

Figure 29–21 ■ Areas for auscultation of the heart.

(*continued*)

Cardiovascular Assessments (*continued*)

Technique/Normal Findings	Abnormal Findings

Heart Sounds Assessment

See guidelines for cardiac auscultation in Box 29–3.

BOX 29–3 Guidelines for Cardiac Auscultation

1. Locate the major auscultatory areas on the precordium (refer to Figure 29–21).
2. Choose a sequence of listening. Either begin from the apex and move upward along the sternal border to the base, or begin at the base and move downward to the apex. One suggested sequence is shown in Figure 29–21.
3. Listen first with the patient in the sitting or supine position. Then ask the patient to lie on the left side, and focus on the apex. Lastly, ask the patient to sit up and lean forward. These position changes bring the heart closer to the chest wall and enhance auscultation. Carry out the following steps when the patient assumes each of these positions:
   a. First, auscultate each area with the diaphragm of the stethoscope to listen for high-pitched sounds: S_1, S_2, murmurs, pericardial friction rubs.
   b. Next, auscultate each area with the bell of the stethoscope to listen for lower-pitched sounds: S_3, S_4, murmurs.
   c. Listen for the effect of respirations on each sound; while the patient is sitting up and leaning forward, ask him or her to exhale and hold the breath while you listen to heart sounds.

Identify S_1 (first heart sound) and note its intensity. At each auscultatory area, listen for several cardiac cycles. *S_1 is loudest at the apex of the heart.*	• An accentuated S_1 occurs with tachycardia, states in which CO is high (fever, anxiety, exercise, anemia, hyperthyroidism), complete heart block, and mitral stenosis. • A diminished S_1 occurs with first-degree heart block, mitral regurgitation, CHF, CAD, and pulmonary or systemic HTN. The intensity is also decreased with obesity, emphysema, and pericardial effusion. Varying intensity of S_1 occurs with complete heart block and grossly irregular rhythms.
Listen for splitting of S_1. *Splitting of S_1 may occur during inspiration.*	• Abnormal splitting of S_1 may be heard with right bundle branch block and premature ventricular contractions.
Identify S_2 (second heart sound) and note its intensity. *S_2 immediately follows S_1 and is loudest at the base of the heart.*	• An accentuated S_2 may be heard with HTN, exercise, excitement, and conditions of pulmonary HTN such as CHF and cor pulmonale. • A diminished S_2 occurs with aortic stenosis, a fall in systolic BP (shock), and increased anteroposterior chest diameter.
Listen for splitting of S_2. *No splitting of S_2 should be heard.*	• Wide splitting of S_2 is associated with delayed emptying of the right ventricle, resulting in delayed pulmonary valve closure (e.g., mitral regurgitation, pulmonary stenosis, and right bundle branch block). • Fixed splitting occurs when right ventricular output is greater than left ventricular output and pulmonary valve closure is delayed (e.g., with atrial septal defect and right ventricular failure). • Paradoxical splitting occurs when closure of the aortic valve is delayed (e.g., left bundle branch block).
Identify extra heart sounds in systole. *Extra heart sounds are not present in systole.*	• Ejection sounds (or clicks) result from the opening of deformed semilunar valves (e.g., aortic and pulmonary stenosis). • A midsystolic click is heard with mitral valve prolapse (MVP).
Identify the presence of extra heart sounds in diastole. *Extra heart sounds are not present in diastole.*	• An opening snap results from the opening sound of a stenotic mitral valve. • A pathologic S_3 (a third heart sound that immediately follows S_2, called a ventricular gallop) results from myocardial failure and ventricular volume overload (e.g., CHF, mitral or tricuspid regurgitation). • An S_4 (a fourth heart sound that immediately precedes S_1, called an atrial gallop) results from increased resistance to ventricular filling after atrial contraction (e.g., HTN, CAD, aortic stenosis, and cardiomyopathy). • A combined S_3 and S_4 is called a summation gallop and occurs with severe CHF. • A pericardial friction rub results from inflammation of the pericardial sac, as with pericarditis.

Murmur Assessment

Identify any murmurs. Note location, timing, presence during systole or diastole, and intensity. Use the following scale to grade murmurs: I = Barely heard II = Quietly heard III = Clearly heard	• Midsystolic murmurs are heard with semilunar valve disease (e.g., aortic and pulmonary stenosis) and with hypertrophic cardiomyopathy. • Pansystolic (holosystolic) murmurs are heard with AV valve disease (e.g., mitral and tricuspid regurgitation, ventricular septal defect). • A late systolic murmur is heard with MVP. • Early diastolic murmurs occur with regurgitant flow across incompetent semilunar valves (e.g., aortic regurgitation).

Cardiovascular Assessments (*continued*)

Technique/Normal Findings	Abnormal Findings
IV = Loud V = Very loud VI = Loudest; may be heard with stethoscope off the chest. A thrill may accompany murmurs of grade IV to grade VI. Note pitch (low, medium, high) and quality (harsh, blowing, or musical). Note pattern/shape, crescendo, decrescendo, and radiation/transmission (to axilla, neck). *No murmurs should be heard.*	• Mid-diastolic and presystolic murmurs, such as with mitral stenosis, occur with turbulent flow across the AV valves. • Continuous murmurs throughout systole and all or part of diastole occur with patent ductus arteriosus.

Blood Pressure and Pulse Pressure Assessment

See Box 29–4 for blood pressure measurement guidelines.

BOX 29–4 Guidelines for Blood Pressure Assessment

REVIEW OF KOROTKOFF'S SOUNDS

The first sound heard is the systolic pressure; at least two consecutive sounds should be clear. If the sound disappears and then is heard again 10 to 15 mm later, an auscultatory gap is present; this may be a normal variant, or it may be associated with hypertension. The first diastolic sound is heard as a muffling of the Korotkoff's sound and is considered the best approximation of the true diastolic pressure. The second diastolic sound is the level at which sounds are no longer heard.

The American Heart Association recommends documenting all three readings when measuring BP, for example, 120/72/64 mmHg. If only two readings are documented, the systolic and the second diastolic pressure are taken, for example, 120/64 mmHg.

TECHNIQUE REMINDERS

- Choose a cuff of an appropriate size: The cuff should snugly cover two-thirds of the upper arm, and the bladder should completely encircle the arm. The bladder should be centered over the brachial artery, with the lower edge 2 to 3 cm above the antecubital space.
- The patient's arm should be slightly flexed and supported (on a table or by the examiner) at heart level.
- To determine how high to inflate the cuff, palpate the brachial pulse, and inflate the cuff to the point on the manometer at which the pulse is no longer felt; then, add 30 mmHg to this reading, and use the sum as the target for inflation. Wait 15 seconds before reinflating the cuff to auscultate the BP.
- To recheck a BP, wait at least 30 seconds before attempting another inflation.
- Always inflate the cuff completely, and then deflate it. Once deflation begins, allow it to continue; do not try to reinflate the cuff if the first systolic sound is not heard or if the cuff inadvertently deflates.
- The bell of the stethoscope more effectively transmits the low-pitched sounds of BP.

SOURCES OF ERROR

- Falsely high readings can occur if the cuff is too small, too loose, or if the patient supports his or her own arm.
- Falsely low readings can occur if a standard cuff is used on a patient with thin arms.
- Inadequate inflation may result in underestimation of the systolic pressure or overestimation of the diastolic pressure if an auscultatory gap is present.
- Rapid deflation and repeated or slow inflations (causing venous congestion) can lead to underestimation of the systolic BP and overestimation of the diastolic BP.

FACTORS ALTERING BLOOD PRESSURE

- A change from the horizontal to upright position causes a slight decrease (5 to 10 mm) in systolic BP; the diastolic BP remains unchanged or rises slightly.
- BP taken in the arm is lower when the patient is standing.
- If the BP is taken with the patient in the lateral recumbent position, a lower BP reading may be obtained in both arms; this is especially apparent in the right arm with the patient in the left lateral position.
- Factors that increase BP include exercise, caffeine, tobacco use, cold environment, eating a large meal, painful stimuli, and emotions.
- Factors that lower BP include sleep (by 20 mmHg) and very fast, slow, or irregular heart rates.
- BP tends to be higher in taller or heavier patients.
- Legs should not be crossed when sitting, lying, or standing during BP measurement.

ALTERNATIVE METHODS OF BLOOD PRESSURE MEASUREMENT

- The palpatory method may be necessary if severe hypotension is present and the BP is inaudible. Palpate the brachial pulse, and inflate the cuff 30 mm above the point where the pulse disappears; deflate the cuff, and note the point on the manometer where the pulse becomes palpable again. Record this as the palpatory systolic BP.
- Leg BP measurement may be needed when there is injury of the arms or to rule out coarctation of the aorta or aortic insufficiency when arm diastolic BP is over 90 mmHg. Place the patient in the prone or supine position with the leg slightly flexed. Place a large leg cuff on the thigh with the bladder centered over the popliteal artery. Place the bell of the stethoscope over the popliteal space. Normal leg systolic BP is higher than arm BP; diastolic BP should be equal to or lower than arm BP. Abnormally low leg BP occurs with aortic insufficiency and coarctation of the aorta.

(*continued*)

Cardiovascular Assessments (*continued*)

Technique/Normal Findings	Abnormal Findings
Auscultate BP in each arm with the patient seated. *The normal BP is considered to be <120/<80 mmHg.*	• Consistent BP readings over 140/90 in adults under age 40 is considered hypertension. • BP under 90/60 is considered hypotension. • An auscultatory gap—a temporary disappearance of sound between the systolic and diastolic BP—may be a normal variation, or it may be associated with systolic HTN or a drop in diastolic BP due to aortic stenosis. • **Korotkoff's sounds** (refer to Box 29–4) may be heard down to zero with cardiac valve replacements, hyperkinetic states, thyrotoxicosis, and severe anemia, as well as after vigorous exercise. • The sounds of aortic regurgitation may obscure the diastolic BP. • A difference of more than 10 mmHg between arms suggests arterial compression on the side of the lower reading, aortic dissection, or coarctation of the aorta.
Auscultate BP in each arm with the patient standing. If orthostatic changes occur, measure the BP with the patient supine, legs dangling, and again with the patient standing, 1–3 min apart. *A decrease of systolic BP is expected, but should be <10 mmHg; diastolic BP should not drop on standing.*	• A decrease in systolic BP of more than 10–15 mmHg and a drop in diastolic BP on standing are called **orthostatic hypotension**. Causes include antihypertensive medications, volume depletion, PVD, prolonged bed rest, and aging. • A widened pulse pressure with an elevated systolic BP occurs with exercise, arteriosclerosis, severe anemia, thyrotoxicosis, and increased intracranial pressure. • A narrowed pulse pressure with a decreased systolic BP occurs with shock, cardiac failure, and pulmonary embolus.
Observe the pulse pressure. The pulse pressure is the difference between the systolic and diastolic BP. For example, if the BP is 140/80 mmHg, the pulse pressure is 60. *A normal pulse pressure is one-third the systolic measurement.*	**PRACTICE ALERT!** If unable to auscultate BP or palpate pulses, a Doppler ultrasound device may be used to evaluate blood flow. Apply a dime-sized amount of gel over the blood vessel to be assessed and lightly place the probe over the gel. Listen for a whooshing (artery) or rushing (vein) sound.
Skin Assessment	
Inspect the color of the skin. *The skin color should be appropriate to the patient's age and race.*	• Pallor reflects constriction of peripheral blood flow (e.g., due to syncope or shock) or decreased circulating oxyhemoglobin (e.g., due to hemorrhage or anemia). • Central cyanosis of the lips, earlobes, oral mucosa, and tongue suggests chronic cardiopulmonary disease. (See Box 29–5 for abnormal findings associated with peripheral vascular and lymphatic assessment.)

BOX 29–5 Abnormal Findings Associated with Peripheral Vascular and Lymphatic Assessment

- *Pallor* is an absence of color of the skin. The degree of pallor depends on the patient's normal skin color and health status. Dark skin may appear ashen or have a yellowish tinge.
- *Cyanosis* is a bluish discoloration of the skin and mucous membranes in people with light skin. In people with dark skin, cyanosis may be difficult to observe. Inspect the nail beds and conjunctiva.
- *Edema* is an abnormal accumulation of fluid in the interstitial spaces of body tissues. It is often most apparent in the lower extremities.
- *Varicose veins* are tortuous and dilated veins that have incompetent valves. The saphenous veins of the legs are most commonly affected.
- *Enlarged lymph nodes* result from infection or malignancy.
- *Atrophic changes* are changes in the size or activity of body tissues as a result of pathology or injury. Decreased blood flow and oxygenation of the lower extremities often cause atrophic changes of loss of hair, thickened toenails, changes in pigmentation, and ulcerations.
- *Gangrene* is the necrosis (or death) of tissue, most often the result of loss of blood supply and infection. Gangrene often begins in the most distal of the tissues of the extremities.
- *Pressure ulcers*, also called decubitus ulcers or bed sores, are the result of ischemia and hypoxia of tissue following prolonged pressure. These ulcers often are located over bony prominences. If untreated, the tissue changes proceed from red skin to deep, crater-like ulcers.

Inspect the skin of the extremities and over the regional lymph nodes, noting any edema, erythema, red streaks, or skin lesions. *There should be no edema, redness, or lesions over the regional lymph nodes.*	• Lymphangitis (inflammation of a lymphatic vessel) may produce a red streak with induration (hardness) following the course of the lymphatic collecting duct; infected skin lesions may be present, particularly between the digits. • **Lymphedema** (swelling due to lymphatic obstruction) occurs with congenital lymphatic anomaly (Milroy's disease) or with trauma to the regional lymphatic ducts from surgery or metastasis (e.g., arm lymphedema after radical mastectomy with axillary node removal). • Edema of lymphatic origin is usually not pitting, and the skin may be thickened; one example is the taut swelling of the face and body that occurs with myxedema, associated with hypothyroidism.

Cardiovascular Assessments (*continued*)

Technique/Normal Findings	Abnormal Findings
Artery and Vein Assessment	
Palpate the temporal arteries. *There should be no redness, swelling, nodules, or variations in pulse amplitude.*	• Redness, swelling, nodularity, and variations in pulse amplitude may occur with temporal arteritis.
Inspect and palpate the carotid arteries. Note symmetry, the pulse rate, rhythm, volume, and amplitude. *Note any variation with respiration. Describe all pulses as increased, normal, diminished, or absent. Scales ranging from 0 to 4+ are sometimes used as follows:* 0 = Absent 1+ = Diminished 2+ = Normal 3+ = Increased 4+ = Bounding	
Pulse waveforms are shown in Figure 29–22 ■. *The carotid pulses should be bilaterally equal in rate, rhythm, volume, and amplitude.*	• A unilateral pulsating bulge is seen with a tortuous or kinked carotid artery. • Alterations in pulse rate or rhythm are due to cardiac dysrhythmias. • An absent pulse indicates arterial occlusion. • A hypokinetic (weak) pulse is associated with decreased stroke volume (Figure 29–22B). This may be due to congestive heart failure (CHF), aortic stenosis, or hypovolemia; to increased peripheral resistance, which may result from cold temperatures; or to arterial narrowing, commonly found with atherosclerosis. • A hyperkinetic (bounding) pulse occurs with increased stroke volume and/or decreased peripheral resistance (Figure 29–22C). This may result from states in which CO is high or from aortic regurgitation. It also may occur with anemia, hyperthyroidism, bradycardia, or reduced compliance, as with atherosclerosis. • A bigeminal pulse is marked by decreased amplitude of every second beat (Figure 29–22D). This may be due to premature contractions (usually ventricular). • Pulsus alternans is a regular pulse with alternating strong and weak beats (Figure 29–22E). This may be due to left ventricular failure and severe HTN.
Auscultate the carotid arteries, using the bell of the stethoscope. *No bruits should be heard.*	• A murmuring or blowing sound heard over stenosed peripheral vessels is known as a *bruit*. A bruit heard over the middle to upper carotid artery suggests atherosclerosis.
Inspect and palpate the internal and external jugular veins for venous pressure. *See* Box 29–6 *for guidelines for assessing jugular venous pressure (JVP).*	• An increase in jugular venous pressure (JVP) over 3 cm and located above the sternal angle reflects increased right atrial pressure. This occurs with right ventricular failure or, less commonly, with constrictive pericarditis, tricuspid stenosis, and superior venae cavae obstruction.
If venous pressure is elevated, assess the hepatojugular reflex. (Compress the liver in the right upper abdominal quadrant with the palm of the hand for 30–60 sec while observing the jugular veins.)	• A decrease in venous pressure reflects reduced left ventricular output or blood volume. • Unilateral neck vein distention suggests local compression or anatomic anomaly. • A rise in the column of neck vein distention over 1 cm with liver compression indicates right heart failure.

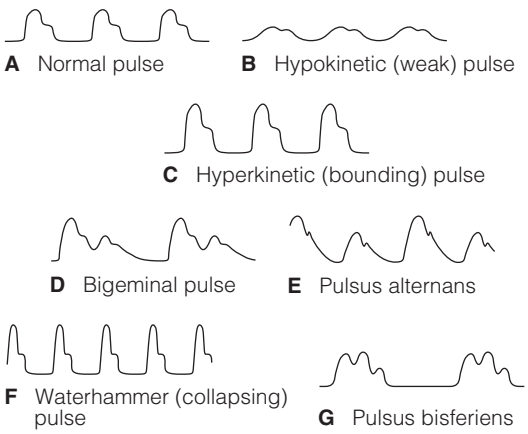

Figure 29–22 ■ Types of pulse patterns.

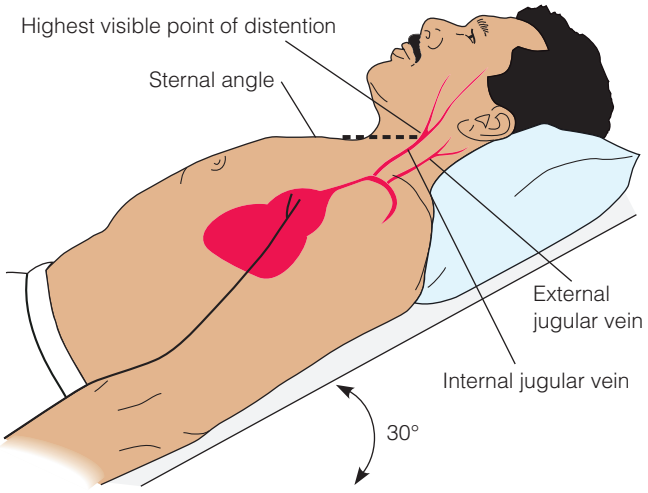
(*continued*)



Cardiovascular Assessments (*continued*)

Technique/Normal Findings	Abnormal Findings
Upper Extremity Assessment	
Inspect and palpate the arms and hands, noting size and symmetry, skin color, and temperature. *Arms and hands should be symmetrical in size and shape, warm, and of appropriate skin color.*	• Unilateral swelling with venous prominence occurs with venous obstruction. • Cyanosis of the nail beds reflects chronic cardiopulmonary disease. • Unilateral swelling with venous prominence occurs with venous obstruction. • Cold temperature of the hands and fingers occurs with vasoconstriction.
Palpate the nail beds for capillary refill. (Apply pressure to the patient's fingertips. Watch for blanching of the nail beds. Release the pressure. Note the time it takes for capillary refill, indicated by the return of pink color on release of the pressure.) *Capillary refill should be less than 2 seconds (i.e., immediate).*	• Capillary refill that takes less than 3 sec reflects circulatory compromise, such as hypovolemia or anemia.
Assess venous pattern and pressure. (Elevate one of the patient's arms over the head for a few seconds. Slowly lower the arm. Observe the filling of the patient's hand veins.) *Hand veins should fill equally and immediately.*	• Distention of hand veins at elevations over 9 cm above heart level reflects an increase in systemic venous pressure.

BOX 29–6 Assessing Jugular Venous Pressure

When a patient with normal venous pressure lies in the supine position, full neck veins are normally visible, but as the head of the bed is elevated, the pulsations disappear. In the patient with greatly elevated venous pressure, visible pulsations of the jugular vein are present even in the upright position. To conduct the inspection, do the following:

1. Remove clothing from the patient's neck and chest. Elevate the head of the bed 30 to 45 degrees, and turn the patient's head to the opposite side. Shine a light tangentially across the neck to increase shadows. If the external jugular veins are distended, they will be visible vertically between the mandible and outer clavicle.
2. If jugular distention is present, assess the jugular venous pressure by measuring from the highest point of visible distention to the sternal angle (the point at which the clavicles meet) on both sides of the neck (see the accompanying figure). Bilateral measurements above 3 cm are considered elevated and indicate increased venous pressure; distention on only one side may indicate obstruction.

Assessment of the highest point of jugular vein distention.

Palpate the radial and brachial pulses. Note rate, rhythm, volume amplitude, symmetry, and variations with respiration. (Refer to Figure 29–22 for pulse patterns.) *Radial and brachial pulses should have equal and normal rate, be strong, and not vary with respirations.*	• Alterations in pulse rate or rhythm are due to cardiac dysrhythmias (such as atrial fibrillation, atrial flutter, and premature ventricular contractions). A pulse rate over 100 bpm is tachycardia; a pulse rate below 60 bpm is bradycardia. • A pulse deficit (slower radial rate than apical rate) occurs with dysrhythmias and CHF. • Irregularities of rhythm produce early beats and pauses (skipped beats) in the pulse, which may be regular in pattern, sporadic, or grossly irregular. • Diminished or absent radial pulses may be due to thromboangiitis obliterans (Buerger's disease) or acute arterial occlusion. • A weak and thready pulse, often with tachycardia, reflects decreased CO. • A bounding pulse occurs with hyperkinetic states and atherosclerosis. • Unequal pulses between extremities suggest arterial narrowing or obstruction on one side. • In sinus dysrhythmia (a normal variant, especially in young adults), the pulse rate increases with inspiration and decreases with expiration.

Cardiovascular Assessments (*continued*)

Technique/Normal Findings	Abnormal Findings
If arterial insufficiency is suspected, palpate the ulnar pulse and perform the Allen test: • Have the patient make a tight fist. • Compress both the radial and ulnar arteries. • Have the patient open the hand to a slightly flexed position. • Observe for pallor and manifestations of pain. • Release the ulnar artery and observe for the return of pink color within 3–5 sec. • Repeat the procedure on the radial artery. *Color should return within 3–5 sec in both the ulnar and the radial arteries.*	• The normal ulnar artery may or may not have a palpable pulse. • Persistent pallor with the Allen test suggests ulnar artery occlusion.
Lower Extremity Assessment	
Inspect and palpate each leg, noting size, shape, and symmetry; arterial pattern; skin color, temperature, and texture; hair pattern; pigmentation; rashes; ulcers, sensation; and capillary refill. *Legs should be symmetric in size and shape, arterial pattern, appropriate color, warm, without lesions. Capillary refill on toenails should be immediate.*	• Chronic arterial insufficiency may be due to arteriosclerosis or autonomic dysfunction, or to acute occlusion resulting from thrombosis, embolus, or aneurysm. • Signs of arterial disruption include pallor, dependent rubor (dusky redness); cool to cold temperature; and atrophic changes, such as hair loss with shiny and smooth texture, thickened nails, sensory loss, slow capillary refill, and muscle atrophy. • Ulcers with symmetric margins, a deep base, black or necrotic tissue, and absence of bleeding may occur at pressure points on or between the toes, on the heel, on the lateral malleolar or tibial area, over the metatarsal heads, or along the side or sole of the foot. • Gangrene due to complete arterial occlusion presents as black, dry, hard skin; pregangrenous color changes include deep cyanosis and purple-black discoloration.
With the patient supine, assess the venous pattern of the legs. Repeat with the patient standing. *Venous pattern on both legs should be symmetric, and there should be no edema, cyanosis, or lesions.*	• Signs of venous insufficiency include swelling, thickened skin, cyanosis, stasis dermatitis (brown pigmentation, erythema, and scaling), and superficial ankle ulcers located predominantly at the medial malleolus with uneven margins, ruddy granulation tissue, and bleeding. • Varicose veins appear as dilated, tortuous, and thickened veins, which are more prominent in a dependent position.
Palpate the femoral, popliteal, posterior tibial, and dorsalis pedis pulses for volume, amplitude, and symmetry (refer to Figure 29–20). *All lower extremity pulses should be strong and equal in amplitude.*	• Diminished or absent leg pulses suggest partial or complete arterial occlusion of the proximal vessel and are often due to arteriosclerosis obliterans. • Increased and widened femoral and popliteal pulsations suggest aneurysm. • Absence of a posterior tibial pulse with signs and symptoms of arterial insufficiency is usually due to acute occlusion by thrombosis or embolus. • Diminished or absent pedal pulses are often due to popliteal occlusion associated with diabetes mellitus.
If pulses are diminished, observe for postural color changes. Elevate both legs 60 degrees, and observe the color of the soles of the feet. Have the patient sit and dangle the legs; note the return of color to the feet.	• Extensive pallor on elevation is suggestive of arterial insufficiency. • Rubor (dusky redness) of the toes and feet along with delayed venous return (over 45 sec) suggests arterial insufficiency.
If arterial insufficiency is suspected, auscultate the femoral arteries. *No bruits should be heard.*	• Femoral bruits suggest arterial narrowing due to arteriosclerosis.
Inspect and gently palpate the calves. *There should be no redness or swelling, heat, or pain in the calves of the legs.*	• Redness, warmth, swelling, tenderness, and cords along a superficial vein suggest thrombophlebitis or deep venous thrombosis.
Inspect and palpate for edema. Use your thumb to compress the dorsum of the patient's foot, around the ankles, and along the tibia (Figure 29–23A ■). A depression in the skin that does not immediately refill is called pitting edema. *Normally, there is no edema.*	Edema can be graded on a scale from 1+ to 4+ (Figure 29–23B): 1+ (−2-mm depression): no visible change in the leg; slight pitting 2+ (−4-mm depression): no marked change in the shape of the leg; pitting slightly deeper 3+ (−6-mm depression): leg visibly swollen; pitting deep 4+ (−8-mm depression): leg very swollen; pitting very deep • Edema may be caused by disease of the cardiovascular system such as CHF; by renal, hepatic, or lymphatic problems; or by infection. • Venous distention suggests venous insufficiency or incompetence.

(*continued*)

Cardiovascular Assessments (*continued*)

Technique/Normal Findings	Abnormal Findings

Abdominal Assessment

Inspect and palpate the abdominal aorta. Note size, width, and any visible pulsations or bulging. *Abdominal aorta should be of appropriate size without visible pulsations or bulging.*

- A pulsating mass in the upper abdomen suggests an aortic aneurysm, particularly in the older adult.
- An aorta greater than 2.5–3 cm in width reflects pathologic dilation, most likely due to arteriosclerosis.

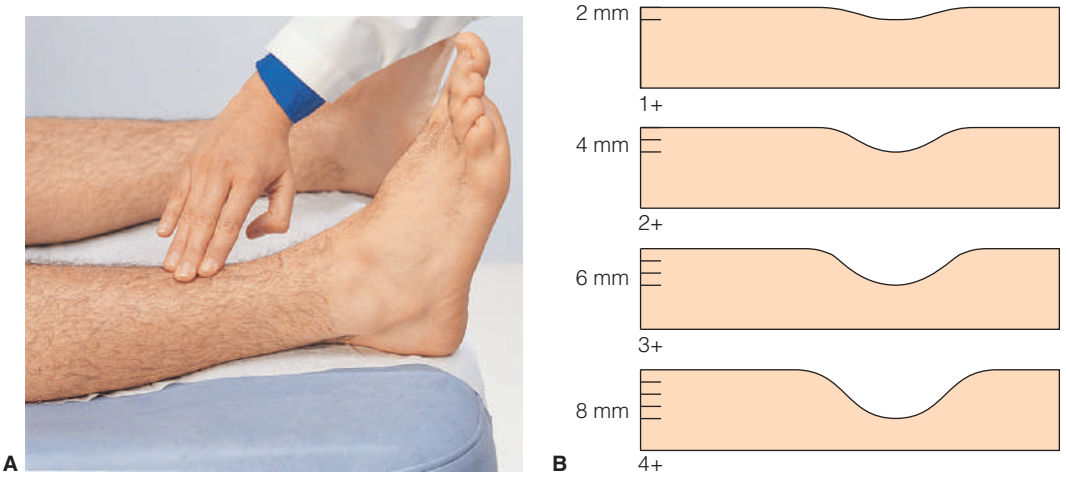


Figure 29–23 ■ Evaluation of edema: A, palpating for edema over the tibia; and B, four-point scale for grading edema.

Auscultate the epigastrium and each abdominal quadrant, using the bell of the stethoscope (Figure 29–24 ■). *No bruits should be heard over the abdominal aorta.*

- Abdominal bruits reflect turbulent blood flow associated with partial arterial occlusion.
- A bruit heard over the aorta suggests an aneurysm.
- A bruit heard over the epigastrium and radiating laterally, especially with HTN, suggests renal artery stenosis.
- Bruits heard in the lower abdominal quadrants suggest partial occlusion of the iliac arteries.

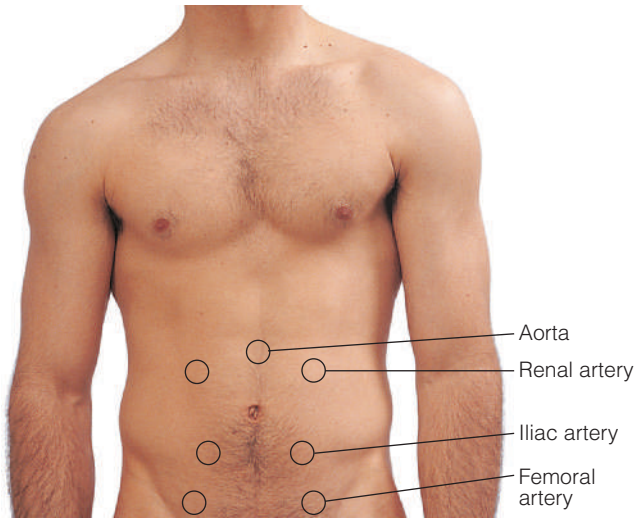

Figure 29–24 ■ Auscultation sites of the abdominal aorta and its branches.

Lymph Node Assessment

Palpate the regional lymph nodes of the head and neck, axillae, arms, and groin. Use firm, circular movements of the finger pads and note size, shape, symmetry, consistency, delineation, mobility, tenderness, sensation, and condition of overlying skin. *Nodes should not be enlarged or painful.*

- **Lymphadenopathy** refers to the enlargement of lymph nodes (over 1 cm) with or without tenderness. It may be caused by inflammation, infection, or malignancy of the nodes or the regions drained by the nodes.
- Lymph node enlargement with tenderness suggests inflammation (*lymphadenitis*). With bacterial infection, the nodes may be warm and matted with localized swelling.
- Malignant or metastatic nodes may be hard, indicating lymphoma; rubbery, indicating Hodgkin's disease; or fixed to adjacent structures. Usually they are not tender.
- Ear infections and scalp and facial lesions, such as acne, may cause enlargement of the preauricular and cervical nodes.
- Anterior cervical nodes are enlarged and infected with streptococcal pharyngitis and mononucleosis.

Cardiovascular Assessments (*continued*)

Technique/Normal Findings	Abnormal Findings
	• Lymphadenitis of the cervical and submandibular nodes occurs with herpes simplex lesions. • Enlargement of supraclavicular nodes, especially the left, is highly suggestive of metastatic disease from abdominal and thoracic cancer. • Axillary lymphadenopathy is associated with breast cancer. • Lesions of the genitals may produce enlargement of the inguinal nodes. • Persistent generalized lymphadenopathy is associated with acquired immunodeficiency syndrome (AIDS) and AIDS-related complex.
Spleen Assessment	
Palpate for the spleen, in the upper left quadrant of the abdomen. *The spleen is normally not palpable.*	A palpable spleen in the left upper abdominal quadrant of an adult may indicate abnormal enlargement (splenomegaly) and may be associated with cancer, blood dyscrasias, and viral infection, such as mononucleosis.
Percuss for splenic dullness in the lowest left intercostal space (ICS) at the anterior axillary line or in the 9th to 10th ICS at the midaxillary line (Figure 29–25 ■). *Normally, tympany is heard.*	A dull percussion note in the lowest left ICS at the anterior axillary line or below the tenth rib at the midaxillary line suggests splenic enlargement.

Figure 29–25 ■ Percussing the spleen.

CHAPTER HIGHLIGHTS

- Normal anatomy, physiology, and functions of the heart, blood vessels, and lymphatic system are the basis for assessment.
- Both general health and focused cardiovascular and lymphatic system assessments can detect dysfunction, injury, and disorders.
- **Assessment of the cardiovascular and lymphatic systems includes diagnostic tests, genetic considerations, a health interview, and a physical assessment.**

TEST YOURSELF NCLEX-RN® REVIEW

1. A patient who is hemorrhaging has decreased preload. What physiologic effect should the nurse expect to occur with this patient?
1. increased afterload
2. decreased cardiac output
3. decreased action potential
4. increased ejection fraction

2. The nurse is preparing to assess a patient who is experiencing chest pain. Which question should the nurse ask to learn more information about the intensity of the pain?
1. "Did the pain move into your left arm?"
2. "Was the pain a pressure, a burning, or tightness?"
3. "Was your pain relieved by resting or worse when you were busy?"
4. "On a scale of 0 (no pain) to 10 (worst pain), what number is your pain?"

3. The nurse is preparing to assess a patient's apical impulse. Which anatomic location should the nurse use to make this assessment?
   1. right nipple line, any intercostal space
   2. left substernal line, sixth intercostal space
   3. left midclavicular line, fifth intercostal space
   4. right midaxillary line, second intercostal space
4. The nurse assesses a patient's heart rate as being 50 beats per minute. How should the nurse document this finding?
   1. bradycardia
   2. tachycardia
   3. hypotension
   4. hypertension
5. A patient's laboratory values indicate a low red blood cell count. What subjective data should the nurse expect to assess that is consistent with this data?
   1. fatigue
   2. nausea
   3. chest pain
   4. sore throat
6. A patient is being admitted for a low platelet count. Which finding should the nurse expect when conducting a physical assessment of this patient?
   1. varicose veins
   2. excessive bruising
   3. enlarged lymph nodes
   4. changes in pulse pressure
7. The nurse determines that an older patient would benefit from interventions to address peripheral vascular resistance. What manifestations did the nurse assess in this patient? (Select all that apply.)
   1. joint pain
   2. sunken eyeballs
   3. distant bowel sounds
   4. elevated blood pressure
   5. lower extremity fatigue
8. The nurse is preparing to assess a patient's carotid arteries. Which techniques should the nurse use for this assessment? (Select all that apply.)
   1. Palpate for pulse rate.
   2. Inspect for pulsations.
   3. Auscultate for rhythm.
   4. Percuss for arterial wall density.
   5. Palpate deeply for arterial wall integrity.
9. During the physical examination of a patient's abdomen, the nurse auscultates a blowing sound over the aorta. How should the nurse document this finding?
   1. bruit
   2. dysrhythmia
   3. bigeminal pulse
   4. hypokinetic pulse
10. A patient has been admitted with severe leg pain. The limb is cyanotic, cool to the touch, and peripheral pulses are absent. What should the nurse do first after this assessment?
    1. Document the findings.
    2. Teach relaxation techniques.
    3. Notify the physician immediately.
    4. Ask how long the limb has been hurting.

See Test Yourself answers in Appendix B.

30 Nursing Care of Patients with Coronary Heart Disease

LEARNING OUTCOMES

1. Discuss the coronary circulation and electrical properties of the heart.
2. Compare and contrast the pathophysiology and manifestations of coronary heart disease and common cardiac dysrhythmias.
3. Describe interprofessional and nursing care for patients with coronary heart disease and/or cardiac dysrhythmias.
4. Relate the outcomes of diagnostic tests and procedures to the pathophysiology of cardiac disorders and implications for patient responses to the disorder.
5. Discuss nursing implications for medications and treatments used to prevent and treat coronary heart disease and dysrhythmias.
6. Describe nursing care for the patient undergoing diagnostic testing, an interventional procedure, or surgery for coronary heart disease or a dysrhythmia.

CLINICAL COMPETENCIES

1. Assess functional health status of patients with coronary heart disease and/or a dysrhythmia, including the impact of the disorder on the patient's ability to perform activities of daily living and usual tasks.
2. Use knowledge of the normal anatomy and physiology of the heart in caring for patients with coronary heart disease.
3. Monitor patients with coronary heart disease or dysrhythmias for expected and unexpected manifestations, reporting and recording findings as indicated.
4. Use assessed data to select nursing diagnoses, determine priorities of care, and develop and implement individualized nursing interventions for patients with coronary heart disease and dysrhythmias.
5. Administer medications and treatments for patients with coronary heart disease and dysrhythmias safely and knowledgably.
6. Integrate interprofessional care into nursing care planning and implementation for patients with coronary heart disease and dysrhythmias.
7. Provide appropriate teaching for prevention, health promotion, and self-care related to coronary heart disease and dysrhythmias.
8. Evaluate the effectiveness of nursing interventions, revising or modifying the plan of care as needed to promote, maintain, or restore functional health for patients with coronary heart disease or dysrhythmias.

MAJOR CHAPTER CONCEPTS

- Atherosclerosis is the primary underlying process in coronary heart disease resulting from both modifiable and nonmodifiable risk factors.
- Therapeutic lifestyle changes such as smoking cessation, exercise, diet modification, and weight loss are the primary treatment measures for coronary heart disease.
- Acute coronary syndrome or unstable angina is characterized by increasingly severe chest pain that occurs unpredictably, often requiring aggressive intervention.
- Myocardial infarction, necrosis of myocardial tissue, results from complete blockage of a coronary artery. Prompt restoration of blood flow is necessary to preserve functional muscle tissue.
- Cardiac dysrhythmias may arise anywhere in conductive tissue of the myocardium.

KEY TERMS

acute coronary syndrome (ACS), *878*
acute myocardial infarction (AMI), *882*
angina pectoris, *873*
atherosclerosis, *862*
atrial kick, *897*
cardiac arrest, *903*
cardiac rehabilitation, *892*
cardiovascular disease (CVD), *862*
collateral channels, *862*
coronary heart disease (CHD), *862*
dysrhythmia, *887*
ectopic beats, *897*
heart block, *897*
ischemia, *873*
pacemaker, *907*
paroxysmal, *901*
sudden cardiac death (SCD), *913*

Impaired blood flow to the myocardium, changes in the conduction of electrical impulses through the heart, and structural changes in the heart itself affect the heart's ability to fulfill its major purpose: to pump enough blood to meet the body's demand for oxygen and nutrients. Impaired cardiac function, no matter what the underlying cause, affects the patient's ability to participate in exercise and activities and to fulfill life roles. Disruptions in cardiac function affect other organ systems as well, potentially leading to organ system failure and death.

Cardiovascular disease (CVD) is a generic term for disorders of the heart and blood vessels. CVD is the leading cause of death and disability in the United States. About 80 million people (or 1 in 3) have some type of cardiovascular disease. The direct CVD costs in 2011 were estimated to be $312.6 billion (American Heart Association [AHA], 2013).

This chapter focuses on disorders of myocardial blood flow (coronary heart disease) and cardiac rhythm. Disorders of cardiac structure and function are discussed in Chapter 31. Review the normal anatomy and physiology and nursing assessment of the heart in Chapter 29 before proceeding with this chapter.

FAST FACTS

- It's estimated that more than 83.6 million American adults have at least one type of cardiovascular disease, which is more than 1 in 3 adults.
- Heart disease accounted for about 2150 deaths every day, translating to one death every 40 seconds on average.
- Heart disease death rates declined by about 32.7% between 1999 and 2009, now accounting for 1 in 3 deaths in the United States.
- In 2009, more women in the United States died of CVD than cancer, chronic lung diseases, and Alzheimer's disease combined.
- If all major forms of CVD were eliminated, life expectancy would rise by about 7.2 years.

Public education aimed at reducing fat intake, increasing exercise, and lowering cholesterol levels have made people more aware of risk factors associated with CVD.

Source: American Heart Association, 2013.

Disorders of Myocardial Perfusion

THE PATIENT WITH CORONARY HEART DISEASE

Coronary heart disease (CHD), or *coronary artery disease (CAD)*, affects 16.3 million people in the United States and causes more than 405,000 deaths annually (AHA, 2013). CHD is caused by impaired blood flow to the myocardium. Accumulation of atherosclerotic plaque in the coronary arteries is the usual cause. CHD may be asymptomatic, or may lead to angina pectoris, acute coronary syndrome, myocardial infarction (MI or heart attack), dysrhythmias, heart failure, and even sudden death.

Physiology Review

The two main coronary arteries, the left and the right, supply blood, oxygen, and nutrients to the myocardium. They originate in the root of the aorta, just outside the aortic valve. The *left main coronary artery* divides to form the anterior descending and circumflex arteries. The *anterior descending artery* supplies the anterior interventricular septum and the left ventricle, including the apex of the heart. The *circumflex* branch supplies the lateral wall of the left ventricle. The *right coronary artery* supplies the right ventricle and forms the posterior descending artery. The *posterior descending* artery supplies the posterior portion of the heart (refer to Figure 29–5).

Blood flow through the coronary arteries is primarily regulated by aortic pressure. Other factors include the heart rate (most flow occurs during diastole, when the muscle is relaxed), metabolic activity of the heart, blood vessel tone (constriction), and collateral circulation. Although there are no connections between the large coronary arteries, small arteries are joined by **collateral channels**. If large vessels are gradually occluded, these channels enlarge, providing alternative routes for blood flow (Huether & McCance, 2011).

Pathophysiology

Coronary atherosclerosis is the most common cause of reduced coronary blood flow.

ATHEROSCLEROSIS

Atherosclerosis is a progressive disease characterized by *atheroma* (plaque) formation, which affects the intimal and medial layers of large and midsize arteries. See the Pathophysiology Illustrated feature.

Atherosclerosis is initiated by unknown precipitating factors that cause lipoproteins and fibrous tissue to accumulate in the arterial wall. Although the precise mechanisms are unknown, abnormal lipid metabolism and injury to or inflammation of endothelial cells lining the artery appear to be key to its development.

In the bloodstream, lipids are transported attached to proteins called *apoproteins*. High levels of certain *lipoproteins*, a type of apoprotein, increase the risk of atherosclerosis. *Low-density lipoproteins*, which are high in cholesterol, carry cholesterol to peripheral tissues where some of it is released to be taken up and incorporated into cells for use in producing energy. *Very-low-density lipoproteins*, large molecules primarily composed of triglycerides and cholesterol, carry triglycerides to muscle and fat cells. When the triglycerides are released into these tissues, the remainder of the molecule is a low-density lipoprotein. *High-density lipoproteins*, in contrast, attract cholesterol, returning it from peripheral tissues to the liver.

Hyperlipidemia itself may damage arterial endothelium. Other potential mechanisms of vessel injury include excessive pressures within the arterial system (hypertension), toxins found in cigarette smoke, infections, and inflammation. Endothelial damage promotes platelet adhesion and aggregation, and attracts leukocytes to the area.

At the site of injury, *atherogenic* (atherosclerosis-promoting) lipoproteins collect in the intimal lining of the artery, binding to the extracellular portion of the vessel endothelium. Macrophages migrate to the injured site as part of the inflammatory process. Contact with platelets, cholesterol, and other blood components stimulate abnormal proliferation of smooth muscle cells and connective tissue within the vessel wall. Although blood flow is not affected at this stage, this early lesion appears as a yellowish fatty streak on the inner lining of the artery. Fibrous plaque develops as smooth muscle cells enlarge, collagen fibers proliferate, and blood lipids accumulate. The lesion

protrudes into the arterial lumen and is fixed to the inner wall of the intima. It may invade the muscular media layer of the vessel as well. The developing plaque not only gradually occludes the vessel lumen but also impairs the vessel's ability to dilate in response to increased oxygen demands. Fibrous plaque lesions often develop at arterial bifurcations or curves or in areas of narrowing. As the plaque expands, it can produce severe stenosis or total occlusion of the artery.

The final stage of the process is the development of *atheromas*, complex lesions consisting of lipids, fibrous tissue, collagen, calcium, cellular debris, and capillaries. These calcified lesions can ulcerate or rupture, stimulating thrombosis. The vessel lumen may be rapidly occluded by the thrombus, or it may embolize to occlude a distal vessel.

Plaque formation may be *eccentric*, located in a specific, asymmetric region of the vessel wall, or *concentric*, involving the entire vessel circumference. Manifestations of the process usually do not appear until about 75% of the arterial lumen has been occluded.

Atherosclerosis tends to develop where arteries *bifurcate* or branch. Certain vessels have a higher likelihood of being affected, including the coronary arteries (the left anterior descending artery in particular), the renal arteries, the bifurcation of the carotid arteries, and branching sections of peripheral arteries. In addition to obstructing or occluding blood flow, atherosclerosis weakens arterial walls and is a major cause of aneurysm in vessels such as the aorta and iliac arteries.

MYOCARDIAL ISCHEMIA

Myocardial cells become ischemic when the oxygen supply is inadequate to meet metabolic demands. The critical factors in meeting the metabolic demands of cardiac cells are coronary perfusion and myocardial workload. Coronary perfusion can be affected by several different mechanisms:

- One or more vessels may be partially occluded by large, stable areas of plaque.
- Platelets can aggregate in narrowed vessels, forming a thrombus.
- Normal or already narrowed vessels may spasm.
- A drop in blood pressure may lead to inadequate flow through coronary vessels.
- Normal autoregulatory mechanisms that increase flow to working muscles may fail.

Workload is affected by the heart rate, myocardial contractility, preload (the amount of blood in the ventricles just prior to systole), and afterload (the peripheral pressure that must be overcome to move blood out of the heart into the circulation). The oxygen content of the blood and hematocrit are contributing factors to myocardial ischemia. Table 30–1 lists factors that may lead to myocardial ischemia.

Myocardial cells have a limited supply of adenosine triphosphate (ATP). When myocardial workload increases or the supply of blood and oxygen falls, cellular ATP stores are quickly depleted, affecting contractility. Cellular metabolism switches from an efficient aerobic process to anaerobic metabolism. Lactic acid accumulates, and cells are damaged. If blood flow is restored within 20 minutes, aerobic metabolism and contractility are restored, and cellular repair begins. Continued ischemia results in cell necrosis and death (infarction).

Coronary heart disease is generally divided into two categories, chronic ischemic heart disease and acute coronary syndromes. *Chronic ischemic heart disease* includes stable and vasospastic angina, and silent myocardial ischemia. In women, fatigue is the most common presenting symptom of CHD. *Acute coronary syndromes* range from unstable angina to myocardial infarction. Acute coronary syndromes and myocardial infarction are the most common presenting symptoms of CHD in men. These disorders are discussed in the following sections of this chapter.

Incidence and Prevalence

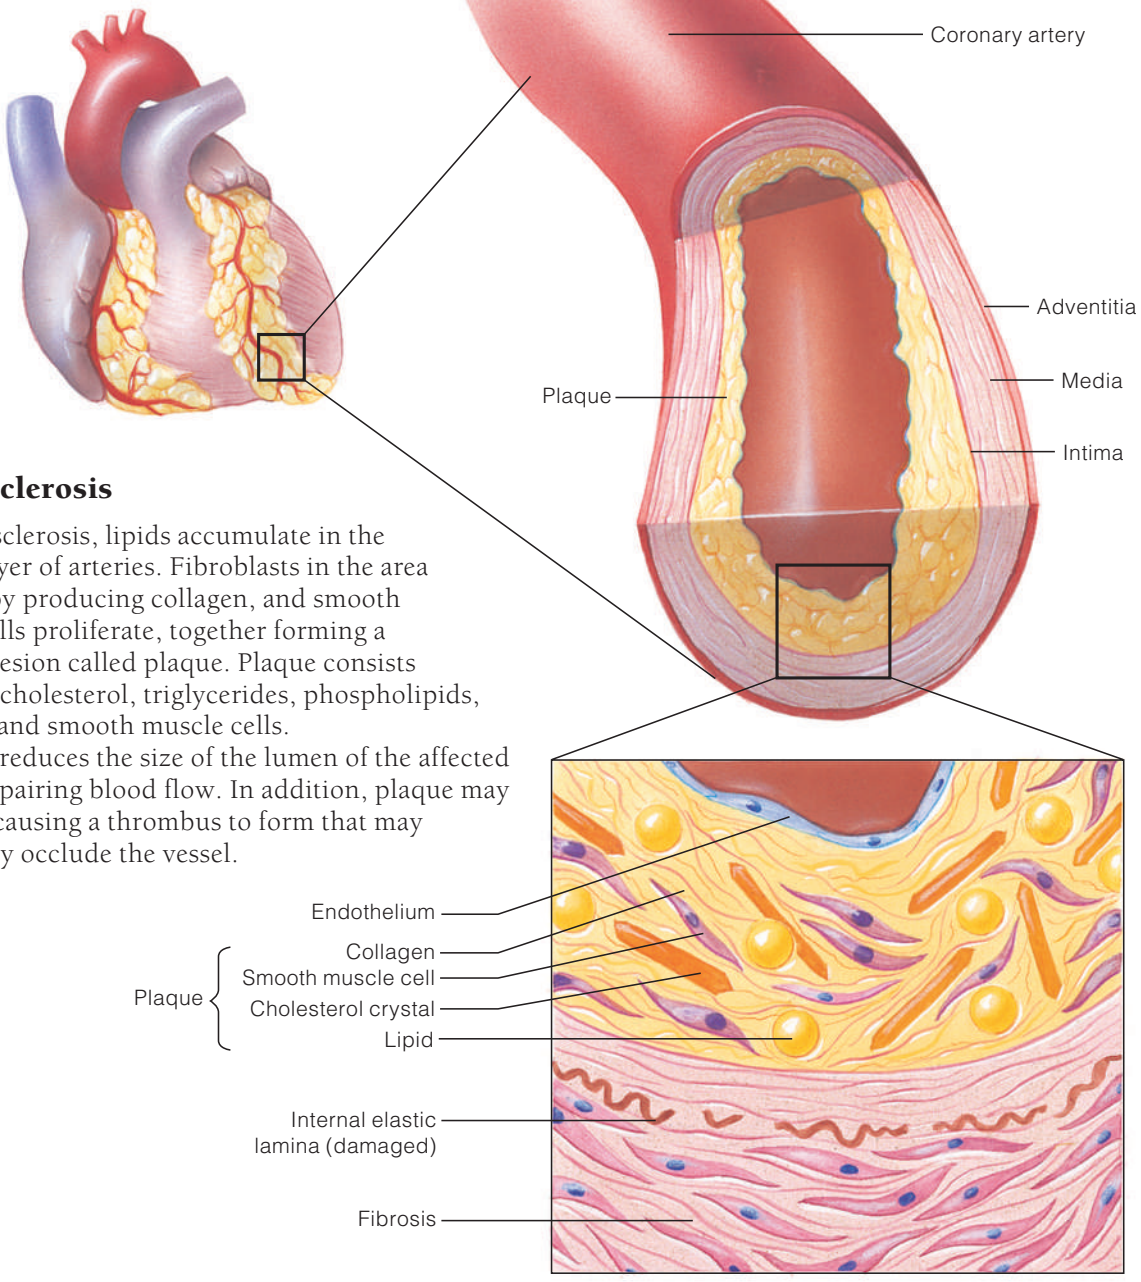
Many risk factors for CHD can be controlled through lifestyle modification. In fact, with increased public awareness of risk factors related to CHD, mortality rates are declining by about 3.3% per year. Nevertheless, CHD remains a major public health problem. Heart disease is the leading cause of death for all U.S. ethnic groups except Asian females (AHA, 2013). See the accompanying Focus on Cultural Diversity box. Nurses are in a prime position to encourage and support positive lifestyle changes by teaching and promoting healthy living practices. Individual choices can and do affect health.

The highest incidence of CHD is in the Western world, mainly in White males ages 45 and older. Both men and women are affected by coronary heart disease; in women, however, the onset is about 10 years later. After menopause, women's risk is equal to that of men.

FOCUS ON CULTURAL DIVERSITY

Heart Disease

- Native Americans (American Indians and Alaska Natives) have the highest prevalence of coronary heart disease (7.2%), followed by Caucasians (6.3%), African Americans (6.9%), Mexican Americans (5.9%), and Asian Americans (4.3%).
- People with less than a high school diploma have the highest rate of CHD; people with a bachelor's degree or higher have the lowest.
- Economic status is a factor. People with a family income of less than $35,000 per year have a significantly higher rate than those with incomes greater than $75,000 per year.
- Regionally, the rate of CHD is highest in the South and lowest in the West.



Source: (AHA, 2013).

TABLE 30–1 Factors Contributing to Myocardial Ischemia

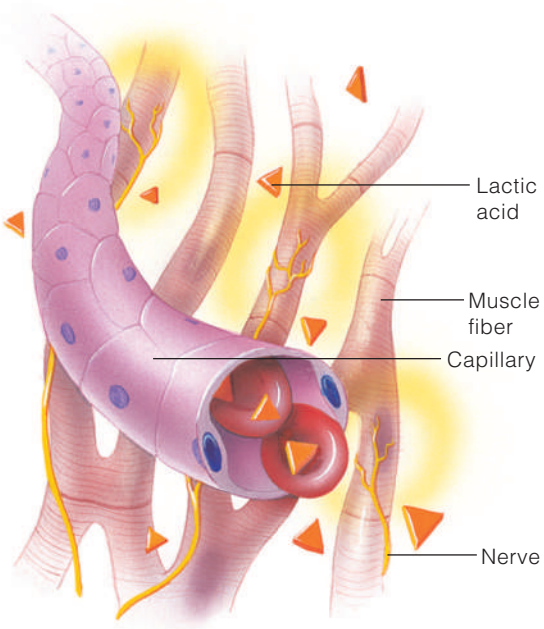
Coronary Perfusion	Myocardial Workload	Blood Oxygen Content
• Atherosclerosis • Thrombosis • Vasospasm • Poor perfusion pressure	• Rapid heart rate • Increased preload, afterload, or contractility • Increased metabolic demands (e.g., hyperthyroidism)	• Reduced atmospheric oxygen pressure • Impaired gas exchange • Low red blood cells and hemoglobin content

PATHOPHYSIOLOGY ILLUSTRATED
Coronary Heart Disease

Coronary heart disease usually is due to *atherosclerosis*, occlusion of the coronary arteries by fibrous, fatty plaque. Coronary heart disease is manifested by *angina pectoris, acute coronary syndrome,* and/or *myocardial infarction*. Risk factors for coronary heart disease include age (over 50 years), heredity, smoking, obesity, high serum cholesterol levels, hypertension, and diabetes mellitus. Other factors, such as diet and lack of exercise, also contribute to the risk of CHD.

Atherosclerosis

In atherosclerosis, lipids accumulate in the intimal layer of arteries. Fibroblasts in the area respond by producing collagen, and smooth muscle cells proliferate, together forming a complex lesion called plaque. Plaque consists mostly of cholesterol, triglycerides, phospholipids, collagen, and smooth muscle cells.

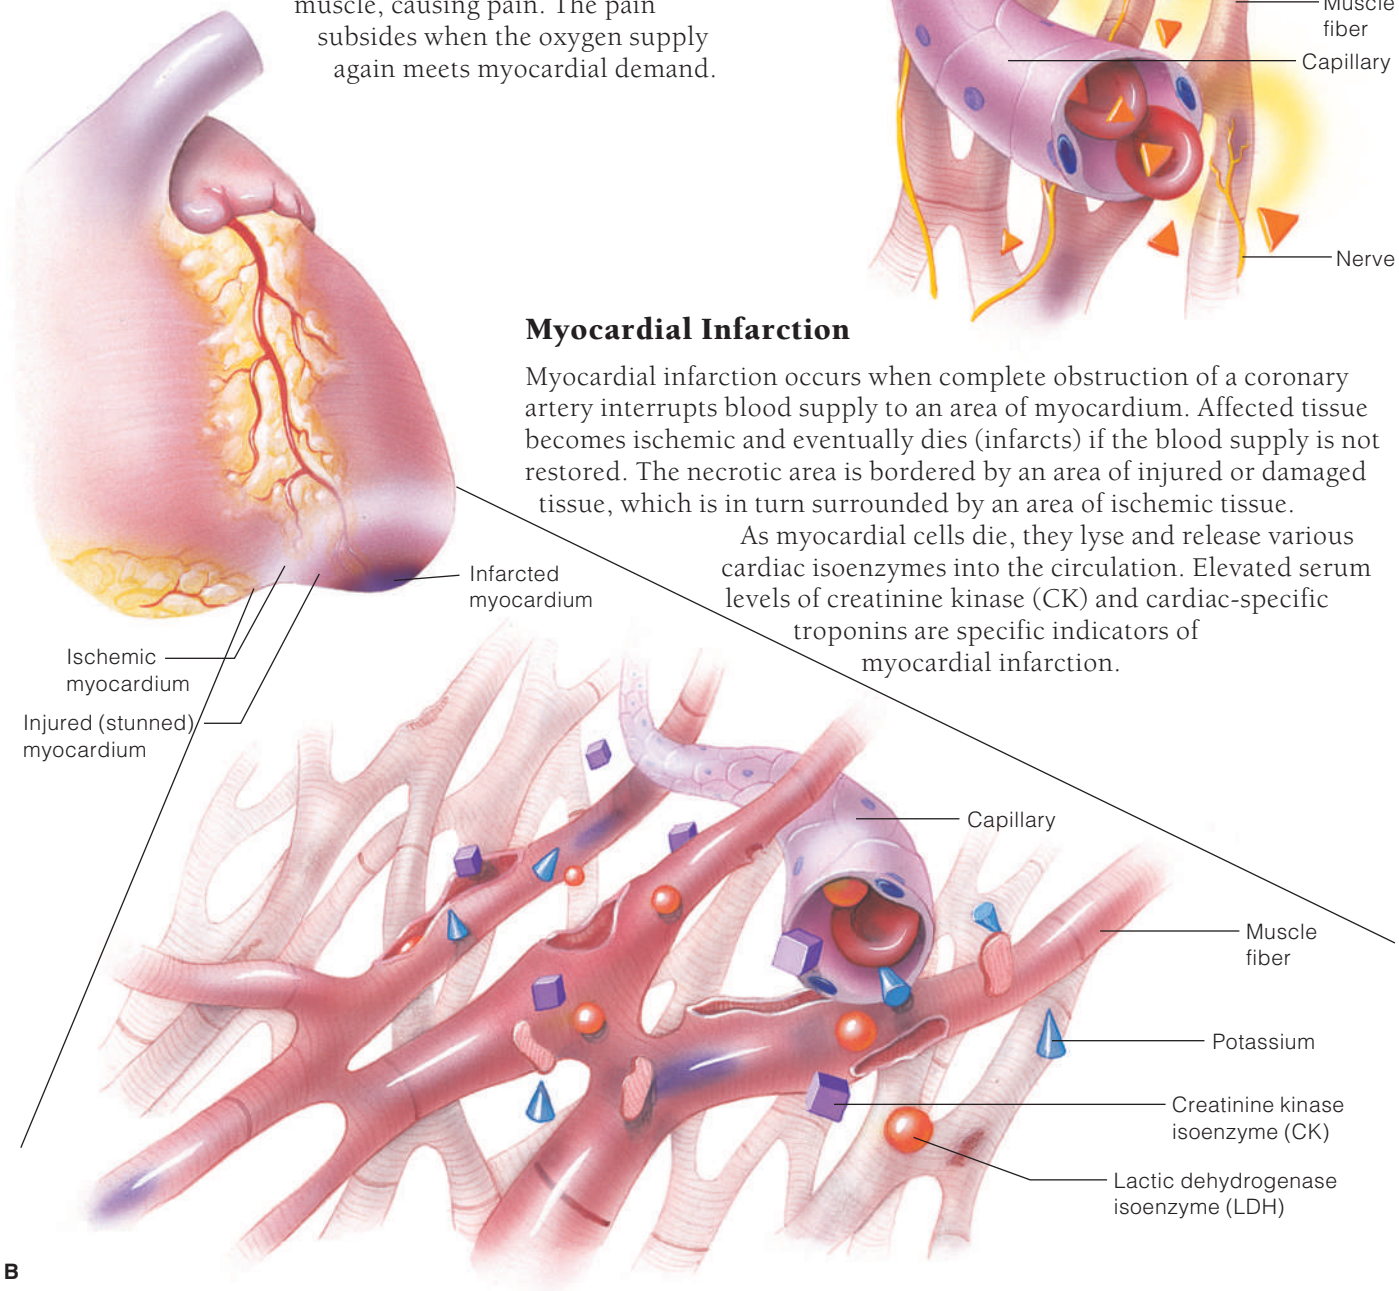


Plaque reduces the size of the lumen of the affected artery, impairing blood flow. In addition, plaque may ulcerate, causing a thrombus to form that may completely occlude the vessel.

A

Angina Pectoris

Angina is characterized by episodes of chest pain, usually precipitated by exercise and relieved by rest. When myocardial oxygen needs are greater than partially occluded vessels can supply, myocardial cells become ischemic and shift to anaerobic metabolism.



Anaerobic metabolism produces lactic acid that stimulates nerve endings in the muscle, causing pain. The pain subsides when the oxygen supply again meets myocardial demand.

Myocardial Infarction

Myocardial infarction occurs when complete obstruction of a coronary artery interrupts blood supply to an area of myocardium. Affected tissue becomes ischemic and eventually dies (infarcts) if the blood supply is not restored. The necrotic area is bordered by an area of injured or damaged tissue, which is in turn surrounded by an area of ischemic tissue.

As myocardial cells die, they lyse and release various cardiac isoenzymes into the circulation. Elevated serum levels of creatinine kinase (CK) and cardiac-specific troponins are specific indicators of myocardial infarction.

B

BOX 30–1 The Framingham Heart Study

The Framingham Heart Study (FHS) is an ongoing, significant clinical research study that has provided data about cardiovascular disease for over 50 years. The study was initiated in 1948 with an original study group of 5209 participants in the town of Framingham, Massachusetts. Every 2 years, this original group is evaluated for cardiovascular events via their medical history, physical findings, and diagnostic testing. Children of the original group have also been studied as part of the Framingham Offspring Study. It was in reports of the FHS that the term *risk factor* first appeared.

Implications for Nursing

The data collected from both the FHS and the Framingham Offspring Study provide a rich database from which to develop evidence-based approaches for patients with heart disease. A major application of these research findings to practice is in primary preventive education, for example, through community cardiovascular health programs. As noted in the text, although research shows that increased public awareness of cardiovascular risk factors has lowered morbidity and mortality from heart disease, heart disease remains the number-one killer in the United States. Education about the effects of lifestyle on the cardiovascular system must begin in the early school years and be reinforced throughout the formative years. When healthy choices become habit, cardiac disease will be reduced.

A second application of these findings is in collaborative treatment. Nurses should keep up to date on the latest strategies for medical treatment so that they can provide accurate rationales to patients and formulate effective nursing treatment plans that complement medical management strategies. The result is better communication, a sense of collegiality and teamwork, and positive patient outcomes.

Moving Knowledge into Action

1. What kinds of strategies can be used in elementary school settings to teach cardiovascular health in a fun, informative manner?
2. Which healthcare providers should be included in a multidisciplinary effort to encourage patients to modify their lifestyles?
3. What changes do you need to make in your lifestyle to role model heart-healthy living?

Risk Factors

The causes of atherosclerosis are not known, but certain risk factors have been linked with the development of atherosclerotic plaques. The Framingham Heart Study provided vital research into the relationship between risk factors and the development of heart disease (Box 30–1). Research into CHD is ongoing, looking at causative factors, manifestations, and protective measures for many populations.

Risk factors for CHD are frequently classified as *nonmodifiable*, or factors that cannot be changed, and *modifiable*, those factors that can be changed (Table 30–2).

NONMODIFIABLE RISK FACTORS

Age is a nonmodifiable risk factor. Over 50% of heart attack victims are age 65 or older; 80% of deaths due to MI occur in this age group. Gender and genetic factors also are nonmodifiable risk factors for CHD. Men are affected by CHD at an earlier age than women. A family history of CHD in a male first-degree relative younger than age 55 or a female first-degree relative younger than 65 years is identified as a risk factor for CHD (National Cholesterol Education Program [NCEP], 2013). Chromosome p921.3 has been associated with CHD. The region containing this chromosome also contains gene sequences for cyclin-dependent kinase inhibitors, which are implicated in the pathogenesis of atherosclerosis.

MODIFIABLE RISK FACTORS

Modifiable risk factors include lifestyle factors and pathologic conditions that predispose the patient to developing CHD. Disease conditions that contribute to CHD include hypertension, diabetes mellitus, and hyperlipidemia. Although these conditions are not a matter of choice, they are modifiable risk factors that can often be controlled through medication, weight control, diet, and exercise.

Behavioral or lifestyle factors can be controlled or completely eliminated. Behavioral factors such as underlying anxiety have been identified as an independent risk factor for CHD and

TABLE 30–2 Risk Factors for Coronary Heart Disease

Nonmodifiable	Modifiable	
	Pathophysiologic	**Lifestyle**
Age	Hyperlipidemia	Cigarette smoking
Men ≥ 45 years	Elevated LDL cholesterol	Obesity
Women ≥ 55 years	Elevated triglycerides	Physical inactivity
	Low HDL cholesterol	Atherogenic diet
Gender	Hypertension	Women only: use of oral contraceptives, hormone replacement therapy
Heredity	Diabetes mellitus	
Behavioral	Chronic stress Social isolation Anxiety and depression	
	Emerging risk factors: Elevated homocysteine levels Thrombogenic factors Inflammatory factors Impaired fasting glucose	

Moving Evidence into Action

Relationship of Anxiety to Morbidity and Mortality in Patients with CHD

Although the prevalence of anxiety is high in patients with coronary heart disease, the effect of anxiety symptoms on cardiac events is not well described. Although cardiac rehabilitation has been shown to improve function and survival while reducing costs, it remains severely underused. A study conducted at the University of Kentucky compared anxiety symptom scores of patients defined as persistent anxiety, nonpersistent anxiety, or nonanxious to hospitalization and all-cause mortality. Because anxiety can have multiple influences, relevant sociodemographic, comorbidity, risk factor, and psychologic covariates were controlled for in analysis. The authors found that symptoms of persistent anxiety were a strong, independent predictor of cardiac event–free survival (Moser et al., 2011).

Implications for Nursing

Nurses often are in a position to advise and counsel patients about psychologic symptoms, including anxiety. Although everyone has some degree of anxiety, nurses who have close relationships with their patients can educate them about, advocate for, and support the use of appropriate psychologic professional interventions when indicated by high levels of anxiety.

Moving Knowledge into Action

1. In this study, the increased risk for CHD was related to persistent anxiety. Will this data affect your advice to patients diagnosed with CHD? If so, how?
2. How does your role as the nurse impact how you approach the CHD patient with anxiety? How does this impact your patient education? Your plan of care?

cardiac mortality. Lifestyle changes require significant commitment by the patient; ongoing support from the healthcare team is vital for success.

HYPERTENSION *Hypertension* is consistent blood pressure readings greater than 140 mmHg systolic or 90 mmHg diastolic. Hypertension is common, affecting more than one-third of people over age 50 in the United States. Its prevalence is higher in African Americans than in Hispanics, and higher in Hispanics than in Caucasian Americans. Hypertension damages the endothelial cells of arteries, possibly by excess pressure and altered characteristics of blood flow. This damage can stimulate the development of atherosclerotic plaque.

DIABETES *Diabetes mellitus* contributes to CHD in several ways. Diabetes is associated with higher blood lipid levels, a higher incidence of hypertension, and obesity—all risk factors in their own right. In addition, diabetes affects the endothelium of blood vessels, contributing to the process of atherosclerosis. Hyperglycemia and hyperinsulinemia, altered platelet function, elevated fibrinogen levels, and inflammation also are thought to play a role in the development of atherosclerosis in people with diabetes.

ABNORMAL BLOOD LIPIDS *Hyperlipidemia* is an abnormally high level of blood lipids and lipoproteins. Lipoproteins carry cholesterol in the blood. Low-density lipoproteins (LDLs) are the primary carriers of cholesterol. High levels of LDL promote atherosclerosis because LDL deposits cholesterol on artery walls. Table 30–3 lists desirable and high-risk levels for total and LDL cholesterol. In contrast, high-density lipoproteins (HDLs) help clear cholesterol from the arteries, transporting it to the liver for excretion. HDL levels above 35 mg/dL have a protective effect, reducing the risk of CHD; in contrast, HDL levels lower than 35 mg/dL are associated with an increased risk for CHD. Triglycerides, compounds of fatty acids bound to glycerol and used for fat storage by the body, are carried on very-low-density lipoprotein (VLDL) molecules. Elevated triglycerides also contribute to the risk for CHD.

MEMORY CUE

LDLs = less desirable lipoproteins
HDLs = highly desirable lipoproteins

CIGARETTE SMOKING Cigarette smoking is an independent risk factor for CHD. It is responsible for more deaths from CHD than from lung cancer or pulmonary disease. The effects of smoking on the cardiovascular system are dose dependent (NCEP, 2013). The male cigarette smoker has two to three times the risk of developing heart disease than the nonsmoker; the female who smokes has up to four times the risk. The risk of mortality from CHD is reduced by half for both men and women who stop smoking. Secondhand (or environmental) tobacco smoke also increases the risk of death from CHD by as much as 30%. Tobacco smoke promotes CHD in several ways. Carbon monoxide damages vascular endothelium, promoting cholesterol deposition. Nicotine stimulates catecholamine release, increasing blood pressure, heart rate, and myocardial oxygen use. Nicotine also constricts arteries, limiting tissue perfusion (blood flow and oxygen delivery). Furthermore, nicotine reduces HDL levels and increases platelet aggregation, increasing the risk of thrombus formation.

TABLE 30–3 Classification of Serum Cholesterol and Triglyceride Values*

	Total Cholesterol (mg/dL)	LDL Cholesterol (mg/dL)	Triglyceride (mg/dL)
Optimal		< 100	
Desirable	< 200	100–129	< 150
Borderline	200–239	130–159	150–199
High	≥ 240	160–189	200–499
Very high		≥ 190	≥ 500

Note: *As defined by the National Blood, Lung, and Heart Institute's National Cholesterol Education Program.

FAST FACTS

Cigarette smoking is the leading independent risk factor for coronary heart disease and a primary target of risk factor management.

OBESITY Obesity (excess adipose tissue), generally defined as a body mass index (BMI) of 30 kg/m^2 or greater, and fat distribution affect the risk for CHD. People with obesity have higher rates of hypertension, diabetes, and hyperlipidemia. In the Framingham study, men over age 50 who were obese had twice the incidence of CHD and acute MI of those who were within 10% of their ideal weight. Central obesity, or intra-abdominal fat, is associated with an increased risk for CHD. The best indicator of central obesity is the waist circumference. A waist-to-hip ratio of greater than 0.8 (women) or 0.9 (men) increases the risk for CHD.

PHYSICAL INACTIVITY Physical inactivity is associated with higher risk of CHD. Research data indicate that people who maintain a regular program of physical activity are less prone to developing CHD than sedentary people. Cardiovascular benefits of exercise include increased availability of oxygen to the heart muscle, decreased oxygen demand and cardiac workload, and increased myocardial function and electrical stability. Other positive effects of regular physical activity include decreased blood pressure, blood lipids, insulin levels, platelet aggregation, and weight.

DIET Diet is a risk factor for CHD, independent of fat and cholesterol intake. Diets high in fruits, vegetables, whole grains, and unsaturated fatty acids appear to have a protective effect. The underlying factors are not clear, but probably relate to nutrients such as antioxidants, folic acid, other B vitamins, omega-3 fatty acids, and other unidentified micronutrients.

EMERGING RISK FACTORS Recent research demonstrates a link between elevated serum *homocysteine levels* and CHD. Until menopause, women have lower homocysteine levels than men, which may partially explain their lower risk for CHD. Homocysteine levels are negatively correlated with serum folate and dietary folate intake; that is, increasing folate intake lowers homocysteine levels.

Based on evidence that aspirin and antiplatelet therapies reduce the risk for myocardial infarction, *clot-promoting factors* are identified as CHD risk factors. Inflammation also has recently been identified as a risk factor. Inflammatory processes may increase the development of atherosclerotic plaque, and are implicated in plaque rupture (NCEP, 2013). Inflammation also promotes clot formation at the site of ruptured plaque. Although identified as risk factors, it is not generally recommended that patients routinely be tested for these factors.

METABOLIC SYNDROME The *metabolic syndrome*, a group of metabolic risk factors occurring in an individual, is a strong risk factor for CHD (Box 30–2). The metabolic syndrome has emerged as a risk factor for premature CHD that is equal to that of cigarette smoking. Three underlying causes of metabolic syndrome have been identified: overweight/obesity, physical inactivity, and genetic factors. It is closely associated with *insulin resistance*, impaired tissue responses to insulin. Genetic factors play a role in insulin resistance, as do the acquired factors of abdominal obesity and physical inactivity (NCEP, 2013).

BOX 30–2 Characteristics of the Metabolic Syndrome

- Abdominal obesity
- Abnormal blood lipids (low HDL, high triglycerides)
- Hypertension
- Elevated fasting blood glucose
- Clotting tendency
- Inflammatory factors

RISK FACTORS UNIQUE TO WOMEN Risk factors unique to women include *premature menopause*, *oral contraceptive use*, and *hormone replacement therapy (HRT)*. At menopause, serum HDL levels drop and LDL levels rise, increasing the risk of CHD. Early menopause (natural or surgically induced) increases the risk of CHD and MI. Women who have a bilateral oophorectomy before age 35 without hormone replacement are eight times more likely to have an MI than women experiencing natural menopause. Estrogen replacement therapy reduces the risk of CHD and MI in these women. Oral contraceptives, by contrast, increase the risk for MI, particularly in women who also smoke. This increased risk is due to the tendency of oral contraceptives to promote clotting and to increase blood pressure, serum lipids, and glucose tolerance. The Women's Health Initiative randomized trial of HRT showed an increased risk for CHD in previously healthy women taking a commonly prescribed combination of estrogen and progestin. This well-controlled research study was terminated early when it showed a small but significant increased risk for CHD, stroke, pulmonary embolism, and invasive breast cancer in women taking HRT.

FAST FACTS

- Risk factors for coronary heart disease are those factors that promote atherosclerosis and plaque development.
- Angina pectoris, acute coronary syndromes, and myocardial infarction are the manifestations of myocardial ischemia and coronary heart disease due to atherosclerosis.
- Atherosclerosis also is the primary underlying cause of stroke and peripheral vascular disease; therefore, the risk factors for atherosclerosis also are the risk factors for coronary heart disease, including angina, acute coronary syndromes, and myocardial infarction.

●○● INTERPROFESSIONAL CARE

Care of patients with coronary heart disease focuses on aggressive risk factor management to slow the atherosclerotic process and maintain myocardial perfusion. Until manifestations of chronic or acute ischemia are experienced, the diagnosis often is presumptive, based on history and the presence of risk factors.

DIAGNOSIS

Laboratory testing assesses for risk factors such as an abnormal blood lipid profile (elevated triglyceride and LDL levels and decreased HDL levels).

- *Total serum cholesterol* is elevated in hyperlipidemia. A *lipid profile* includes triglyceride, HDL, and LDL levels, and enables calculation of the ratio of HDL to total cholesterol. The ratio should be at least 1:5, with 1:3 being the ideal ratio. Elevated lipid levels are associated with an increased risk of atherosclerosis (refer to

Table 30–3). In patients with a strong family history of premature CHD or familial hypercholesterolemia, *lipoprotein Lp(a)* also may be measured. Elevated levels of Lp(a) may independently increase the risk of CHD. Other subsets of blood lipids may also be measured in selected patients. See the Diagnostic Tests table in Chapter 29 for nursing care related to lipid profile studies.

Diagnostic tests to identify subclinical (asymptomatic) CHD may be indicated when multiple risk factors are present.

- *C-reactive protein* is a serum protein associated with inflammatory processes. Recent evidence suggests that elevated blood levels of this protein may be predictive of CHD.
- The *ankle–brachial blood pressure index (ABI)* is an inexpensive, noninvasive test for peripheral vascular disease that may be predictive of CHD. Doppler is used to measure the systolic blood pressure in the brachial, posterior tibial, and dorsalis pedis arteries. An ABI of <0.9 in either leg indicates the presence of peripheral arterial disease and a significant risk for CHD.
- *Exercise ECG testing* assesses the cardiac response to increased workload induced by exercise. The test is considered positive for CHD if myocardial ischemia is detected on the ECG (depression of the ST segment by greater than 3 mm; see Figure 30–1 later in the chapter), the patient develops chest pain, or the test is stopped due to excess fatigue, dysrhythmias, or other symptoms before the predicted maximal heart rate is achieved.
- *Electron beam computed tomography (EBCT)* creates a three-dimensional image of the heart and coronary arteries that can reveal coronary artery calcification and other abnormalities. A coronary artery calcium score can be calculated from this test, providing additional important information in the diagnosis of CHD. This noninvasive test requires no special preparation, and can identify patients at risk for developing myocardial ischemia.
- *Myocardial perfusion imaging* (see the section on angina that follows) evaluates myocardial blood flow and perfusion, both at rest and during stress testing (exercise or mental stress).

These diagnostic tests are further explained in Chapter 29 and the later section on angina. Perfusion imaging studies are costly, and therefore not recommended for routine CHD risk assessment.

RISK FACTOR MANAGEMENT

Conservative management of CHD focuses on risk factor modification, including smoking, diet, exercise, and management of comorbidities.

SMOKING Smoking cessation reduces the risk for CHD within months after quitting and improves cardiovascular status. People who quit reduce their risk by 50%, regardless of how long they smoked before quitting. For women, the risk becomes equivalent to that of a nonsmoker within 3 to 5 years of smoking cessation In addition, stopping smoking improves HDL levels, lowers LDL levels, and reduces blood viscosity. All smokers are advised to quit with health promotion activities focused on prevention.

DIET The National Cholesterol Education Program (2013) recommends reduced saturated fat and cholesterol intake with strategies to lower LDL levels (Table 30–4). Most fats are a mixture of saturated and unsaturated fatty acids. The highest proportions of saturated fat are found in whole-milk products, red meats, and coconut oil. Recommended proteins include nonfat dairy products, fish, and poultry. Solidified vegetable fats (e.g., margarine, shortening) contain trans fatty acids, which behave more like saturated fats. Soft margarines and vegetable oil spreads contain low levels of trans fatty acids, and should be used instead of butter, stick margarine, and shortening. Monounsaturated fats, found in olive, canola, and peanut oils, actually lower LDL and cholesterol levels. Certain cold-water fish, such as tuna, salmon, and mackerel, contain high levels of omega-3 (or Ω-3) fatty acids, which help raise HDL levels and decrease serum triglycerides, total serum cholesterol, and blood pressure.

TABLE 30–4 Dietary Recommendations to Reduce Total Cholesterol, LDL Levels, and CHD Risk

Nutrient	Recommendation
Calories	Adjusted to attain/maintain desirable body weight
Total fat	20%–35% of total calories
• Saturated fats	• < 10% of total calories
• Polyunsaturated fat	• Up to 10% of total calories
• Monounsaturated fat	• Up to 20% of total calories
• Cholesterol	• < 200 mg/day
Carbohydrate (primarily complex carbohydrates, such as whole grains, fruits, and vegetables)	45%–65% of total calories
Dietary fiber	20–30 g/day
Protein	About 10%–35% of total calories
Sodium	Less than 2300 mg/day, and up to 1500 mg for those ages 51 and older or those who have hypertension, diabetes, chronic kidney disease, or are African American

Source: Compiled from U.S. Department of Agriculture and U.S. Department of Health and Human Services. (2010, December). *Dietary guidelines for Americans, 2010* (7th ed.). Washington, DC: U.S. Government Printing Office.

In addition, increased intake of soluble fiber (found in oats, psyllium, pectin-rich fruit, and beans) and insoluble fiber (found in whole grains, vegetables, and fruit) is recommended. Folic acid and vitamins B_6 and B_{12} affect homocysteine metabolism, reducing serum levels. Leafy green vegetables (e.g., spinach and broccoli) and legumes (e.g., black-eyed peas, dried beans, and lentils) are rich sources of folate. Meat, fish, and poultry are rich in vitamins B_6 and B_{12}. Vitamin B_6 also is found in soy products; B_{12} is in fortified cereals. Increased intake of antioxidant nutrients (vitamin E, in particular) and foods rich in antioxidants (fruits and vegetables) appears to increase HDL levels and has a protective effect on CHD.

In middle-aged and older adults, moderate alcohol intake may reduce the risk for CHD (NCEP, 2013). Consumption of no more than two drinks per day for men or one drink per day for women is recommended. A drink is 5 ounces of wine, 12 ounces of beer, or 1 1/2 ounces of whiskey. People who do not drink alcohol, however, should not be encouraged to start consuming it as a heart-protective measure.

People who are overweight or obese are encouraged to lose weight through a combination of reduced calorie intake (maintaining a nutritionally sound diet) and increased exercise. High-protein, high-fat weight loss programs are not recommended for weight reduction.

EXERCISE Regular physical exercise reduces the risk for CHD in several ways. It lowers VLDL, LDL, and triglyceride levels, and raises HDL levels. Regular exercise reduces blood pressure and insulin resistance. Unless contraindicated, all patients are encouraged to participate in at least 30 minutes of moderate-intensity physical activity 5 to 6 days each week. To achieve weight loss and prevent weight gain, 60 to 90 minutes of moderate intensity exercise daily is recommended.

HYPERTENSION Although hypertension often cannot be prevented or cured, it can be controlled. Hypertension control (maintaining a blood pressure lower than 140/90 mmHg) is vital to reduce atherosclerosis-promoting effects and to reduce the workload of the heart. Management strategies include reducing sodium intake, increasing calcium intake, regular exercise, stress management, and medications. Hypertension management is discussed in Chapter 32.

DIABETES Diabetes increases the risk of CHD by accelerating the atherosclerotic process. Weight loss (if appropriate), reduced fat intake, and exercise are particularly important for patients with diabetes. Because hyperglycemia apparently contributes to atherosclerosis, consistent blood glucose management is vital. See Chapter 20 for a detailed discussion about diabetes and blood glucose management.

MEDICATIONS

Medication to lower total serum cholesterol and LDL levels and to raise HDL levels is an integral part of CHD management. Based on the patient's overall risk for CHD, drug therapy is used in conjunction with diet and other lifestyle changes.

Drugs used to treat hyperlipidemia act specifically by lowering LDL levels. The goal of treatment is to achieve an LDL level of < 130 mg/dL (NCEP, 2013). Medications to treat hyperlipidemia are not inexpensive; the cost–benefit ratio needs to be considered, because long-term treatment may be required. The four major classes of cholesterol-lowering drugs are statins, bile acid sequestrants, nicotinic acid, and fibrates. The nursing implications and patient teaching for these drug classes are outlined in the Medication Administration box on page 871.

The statins, including lovastatin (Mevacor), pravastatin (Pravachol), simvastatin (Zocor), and others, are first-line drugs for treating hyperlipidemia. They effectively lower LDL levels and may increase HDL levels. The statins can cause myopathy; all patients are instructed to report muscle pain and weakness or brown urine. Liver function tests are monitored during therapy, because these drugs may increase liver enzyme levels.

The other cholesterol-lowering drugs, such as the bile acid sequestrants, nicotinic acid, and fibrates, are primarily used when combination therapy is required to lower serum cholesterol levels. They also may be used for selected patients, such as younger adults, women who wish to become pregnant, or to specifically lower triglyceride levels.

Patients at high risk for MI are often started on prophylactic low-dose aspirin therapy. The dose ranges from 80 to 325 mg/day. In women, the benefit of low-dose aspirin in reducing the risk for CHD is not clear prior to age 65. Aspirin is contraindicated for patients who have a history of aspirin sensitivity, bleeding disorders, or active peptic ulcer disease. Angiotensin-converting enzyme (ACE) inhibitors or angiotensin receptor blockers also may be prescribed for high-risk patients, including people with diabetes who have other CHD risk factors.

BOX 30–3 Complementary Therapies: Diet for CHD

Two diet programs have been shown to have a beneficial effect on CHD. The Pritikin diet is basically vegetarian, high in complex carbohydrates and fiber, low in cholesterol, and extremely low in fat (< 10% of daily calories). Egg whites and limited amounts of nonfat dairy or soy products are allowed. In updates, the Pritikin diet also suggests awareness of caloric density. The Pritikin program requires 45 minutes of walking daily and recommends multivitamin supplements, including vitamins C and E and folate.

The Ornish diet also is vegetarian, although egg whites and a cup of nonfat milk or yogurt per day are allowed. No oil or fat is permitted, even for cooking. Two ounces of alcohol a day are permitted. The Ornish program also calls for stress reduction, emotional social support systems, daily stretching, and walking for 1 hour three times a week.

Hypertension is a major, modifiable risk factor for CHD. When used with other lifestyle changes, the DASH (Dietary Approaches to Stop Hypertension) eating plan can help to prevent high blood pressure. The diet is heavy on grains (six to eight servings daily), vegetables (four to five servings daily), and fruits (four to five servings daily) and limits sodium (1500 to 2300 mg/day), fats, meats, and sweets. Refer to the U.S. Department of Health and Human Services website for a complete brochure.

COMPLEMENTARY THERAPIES

Diet and exercise programs that emphasize physical conditioning and a low-fat diet rich in antioxidants have been shown to be effective in managing CHD (Box 30–3). Supplements of vitamins C, E, B_6, B_{12}, and folic acid may be beneficial. Other potentially helpful complementary therapies include red wine or grape juice, foods containing bioflavonoids, green tea, nuts, and herbals and garlic (effective only for hypertension). Emphasize the need for patients to talk to their physician prior to taking any herbal preparations, as interactions with prescribed drugs are common. Behavioral therapies of benefit for patients with CHD include relaxation and stress management; guided imagery; treatment of depression; anger/hostility management; and meditation, tai chi, and yoga.

●○● NURSING CARE

Nurses are instrumental in educating adults about their risk for coronary heart disease, promoting participation in screening programs to identify that risk, and teaching all patients measures to reduce their risk for CHD.

Health Promotion

Information on healthy lifestyle habits can be presented to community and religious groups, schoolchildren (grades K through 12), and through the media. Work with local governments and organizations to create venues and opportunities that promote a healthy lifestyle. Walking and bicycle lanes are a safe alternative to driving that incorporates exercise into the daily routine. Lobby with smoking prevention/cessation groups against tobacco advertising aimed at youth. While promoting a healthy diet, work with school systems to remove high-fructose drinks and fat-laden snacks from school vending machines.

MEDICATION ADMINISTRATION

Cholesterol-Lowering Drugs

STATINS

atorvastatin (Lipitor)

fluvastatin (Lescol)

lovastatin (Mevacor)

pravastatin (Pravachol)

rosuvastatin (Crestor)

simvastatin (Zocor)

Statins inhibit the enzyme HMG-CoA reductase in the liver, lowering LDL synthesis and serum levels. The statins are first-line treatment for elevated LDL, used in conjunction with diet and lifestyle changes. Although their side effects are minimal, they may cause increased serum liver enzyme levels and myopathy. Rhabdomyolysis is a rare side effect resulting in the breakdown of muscle fibers.

Nursing Responsibilities

- Monitor serum cholesterol and liver enzyme levels before and during therapy (12 weeks and then at least yearly thereafter). Report elevated liver enzyme levels.
- Assess for muscle pain and tenderness. Monitor CPK level if present.
- If taking digoxin concurrently, monitor for and report digoxin toxicity.

Health Education for the Patient and Family

- Promptly report muscle pain, tenderness, or weakness; skin rash or hives, or changes in skin color; abdominal pain, nausea, or vomiting.
- Do not use these drugs if you are pregnant or plan to become pregnant.
- Inform your physician if you are taking any other medications concurrently.

BILE ACID SEQUESTRANTS

cholestyramine (Questran)

colestipol (Colestid)

colesevelam (Welchol)

Bile acid sequestrants lower LDL levels by binding bile acids in the intestine, reducing its reabsorption and cholesterol production in the liver. They are used in combination therapy regimens and for women who are considering pregnancy. Their primary disadvantages are inconvenience of administration due to bulk and gastrointestinal side effects such as constipation.

Nursing Responsibilities

- Mix cholestyramine and colestipol powders with 4 to 6 oz of water or juice; administer once or twice a day as ordered with meals.
- Store in a tightly closed container.

Health Education for the Patient and Family

- Promptly report constipation, severe gastric distress with nausea and vomiting, unexplained weight loss, black or bloody stools, or sudden back pain to your physician.
- Drinking ample amounts of fluid while taking these drugs reduces problems of constipation and bloating.
- Do not omit doses as this may affect the absorption of other drugs you are taking.

CHOLESTEROL ABSORPTION INHIBITORS

ezetimibe (Zetia)

Cholesterol absorption inhibitors block absorption in the small intestine. Their use is contraindicated with acute liver disease or hepatic insufficiency.

Nursing Responsibilities

- Can initially increase liver enzymes when used with statins; resolves with continued use.
- Can be taken without regard to meals.

NICOTINIC ACID

niacin (Nicobid, Nicolar, Niaspan, others)

Nicotinic acid in both prescription and nonprescription forms lowers total and LDL cholesterol and triglyceride levels. The crystalline form and Niaspan, a prescription extended-release tablet, also raise HDL levels. Because the doses required to achieve significant cholesterol-lowering effects are associated with multiple side effects, nicotinic acid generally is used in combination therapy, particularly with the statin drugs.

Nursing Responsibilities

- Give oral preparations with meals and accompanied by a cold beverage to minimize GI effects.
- Administer with caution to patients with active liver disease, peptic ulcer disease, gout, or type 2 diabetes.
- Monitor blood glucose, uric acid levels, and liver function tests during treatment.

Health Education for the Patient and Family

- Flushing of face, neck, and ears may occur within 2 hours following dose; these effects generally subside as treatment continues. Alcohol use during nicotinic acid therapy may worsen this effect.
- Report weakness or dizziness with changes in posture (lying to sitting; sitting to standing) to your physician. Change positions slowly to reduce the risk of injury.

FIBRIC ACID DERIVATIVES

gemfibrozil (Lopid)

fenofibrate (TriCor, Lipofen)

clofibrate (Atromid-S)

The fibrates are used to lower serum triglyceride levels; they have only a slight to modest effect on LDL levels. They affect lipid regulation by blocking triglyceride synthesis. They are used to treat very high triglyceride levels, and may be used in combination with statins.

Nursing Responsibilities

- Monitor serum LDL and VLDL levels, electrolytes, glucose, liver enzymes, renal function tests, and CBC during therapy. Report abnormal values.
- Up to 2 months of treatment may be required to achieve a therapeutic effect; rebound, with decreasing benefit, may occur in the second or third month of treatment.

Health Education for the Patient and Family

- Take with meals if the drug causes gastric distress.
- Promptly report flu-like symptoms (fatigue, muscle aching, soreness, or weakness) to your physician.
- Do not use this drug if you are pregnant or plan to become pregnant. Use reliable birth control measures while taking this drug.
- Contact your physician before stopping this drug and before taking any over-the-counter preparations.

Note: Drugs identified in *italics* are among the 200 most commonly prescribed medications in the U.S.

Be a model of healthy lifestyle habits, taking care of yourself, exercising, and eating right. In promoting healthy lifestyle habits, nurses can positively affect the incidence, morbidity, and mortality from CHD.

Strongly encourage all patients to avoid smoking in the first place, and to stop all forms of tobacco use. Discuss the adverse effects of smoking and the benefits of quitting. Provide information about dietary recommendations to maintain a healthy weight and optimal cholesterol levels. Discuss the benefits and importance of regular exercise. Finally, encourage patients with cardiovascular risk factors to undergo regular screening for hypertension, diabetes, and abnormal blood lipids.

Assessment

See the Course and Manifestations and Interprofessional Care sections for the assessment of the patient with coronary heart disease. Nursing assessment for CHD focuses on identifying risk factors:

- *Health history:* current manifestations such as chest pain or heaviness, shortness of breath, weakness; current diet, exercise patterns, and medications; smoking history and pattern of alcohol intake; history of heart disease, hypertension, or diabetes; family history of CHD or other cardiac problems
- *Physical assessment:* current weight and its appropriateness for height; body mass index; waist-to-hip ratio; blood pressure; strength and equality of peripheral pulses.

Priorities of Care

Collaborating with the interprofessional team to ensure adequate treatment of the underlying process while providing care that supports the physical and psychologic responses to the disorder is a priority.

Diagnoses, Outcomes, and Interventions

Imbalanced Nutrition: More Than Body Requirements

This nursing diagnosis may be appropriate for patients who are obese, have a waist-to-hip ratio greater than 0.8 (female) or 0.9 (male), or whose diet history or serum cholesterol levels indicate a need to reduce fat and cholesterol intake. See Chapters 21 and 22 for more information about assessing obesity.

Expected Outcome: Patient's weight will be within normal limits as a result of the application of therapeutic lifestyle changes.

- Encourage assessment of food intake and eating patterns to help identify areas that can be improved. *Patients often are unaware of their fat and cholesterol intake, particularly when many meals are eaten away from home. Careful assessment increases awareness and allows the patient to make conscious changes.*
- Discuss AHA and therapeutic lifestyle change (TLC) dietary recommendations, emphasizing the role of diet in heart disease. Provide guidance regarding specific food choices with healthy alternatives. Specific diet information and suggestions help the patient make better food choices.
- Refer to clinical dietitian for diet planning and further teaching. Suggest cookbooks that offer low-fat recipes to encourage healthier eating, and provide AHA and American Cancer Society recipe pamphlets and information on low-fat eating. *These resources provide tools for the patient to use as eating patterns change.*
- Encourage gradual but progressive dietary changes. *Drastic changes in eating patterns may cause frustration and discourage the patient from maintaining a healthy diet over the long term.*
- Discourage use of high-fat, low-carbohydrate, or other fad diets for weight loss. *These diets may adversely affect serum cholesterol and triglyceride levels, and often are too drastic to maintain over the long term.*
- Encourage reasonable goals for weight loss (e.g., 1.0 to 1.5 lb per week and a 10% weight loss over 6 months). Provide information about weight loss programs and support groups such as Weight Watchers and Take Off Pounds Sensibly (TOPS). *Gradual but steady weight loss is more likely to be sustained. Recognized programs that emphasize healthy eating provide support and incentive for making lifetime dietary changes.*

Ineffective Health Maintenance

Patients with risk factors for CHD may be unable to identify or independently manage their risk factors.

Expected Outcome: Patient will be independent in identifying and managing modifiable risk factors for CHD.

- Discuss risk factors for CHD, stressing that changing or managing those factors that can be modified reduces the patient's overall risk for the disease. *Patients with significant nonmodifiable risk factors may be discouraged, reducing their ability to eliminate or control modifiable risk factors.*
- Discuss the immediate benefits of smoking cessation. Provide resource materials from the AHA, the American Lung Association, and the American Cancer Society. Refer to a structured smoking cessation program to increase the likelihood of success in quitting. *Long-time smokers may assume that the damage from smoking has already been done, and quitting would not be worth the effort.*
- Help the patient identify specific sources of psychosocial and physical support for smoking cessation, dietary, and lifestyle changes. *Support persons, groups, and aids such as nicotine patches help the patient achieve success and provide encouragement during difficult times (such as withdrawal symptoms).*
- Discuss the benefits of regular exercise for cardiovascular health and weight loss. Help identify favorite forms of exercise or physical activity. Encourage planning for 30 minutes of continuous aerobic activity (i.e., walking, running, bicycling, swimming) most days of the week. Encourage identification of an exercise buddy to help maintain motivation. *Engaging in preferred activities with a partner maintains motivation and increases the likelihood of maintaining an exercise program. Encourage continuation of the plan, even when days are missed.*
- Provide information and teaching about prescribed medications such as cholesterol-lowering drugs. Discuss the relationship between hypertension, diabetes, and CHD. *Teaching is important to promote understanding of and compliance with the prescribed drug regimen.*

Delegating Nursing Care Activities

As appropriate and allowed by the designated duties and responsibilities of unlicensed assistive personnel, the nurse may delegate nursing care activities such as measuring fluid intake and output, collecting vital signs (including orthostatic vital signs), encouraging oral or enteral fluid intake, and nonpharmacologic skin care.

Continuity of Care

Encourage participation in some form of cardiac rehabilitation program. Formal programs provide comprehensive assessment of, interventions for, and teaching of patients with cardiac disease. Monitoring exercise and providing information about risk factors help patients identify ways to lower their risk for CHD.

Because patients themselves are primarily responsible for maintaining the lifestyle changes necessary to reduce the risk of CHD, provide teaching and support as outlined in the previous section. Assist the patient to make healthy choices and reinforce positive changes. Emphasize the importance of regular follow-up appointments to monitor progress.

THE PATIENT WITH ANGINA PECTORIS

Angina pectoris (angina) is chest pain resulting from reduced coronary blood flow, which causes a temporary imbalance between myocardial blood supply and demand. The imbalance may be due to coronary heart disease, atherosclerosis, or vessel constriction that impairs myocardial blood supply. Hypermetabolic conditions such as exercise, thyrotoxicosis, stimulant abuse (e.g., cocaine), hyperthyroidism, and emotional stress can increase myocardial oxygen demand, precipitating angina. Anemia, heart failure, ventricular hypertrophy, or pulmonary diseases may affect blood and oxygen supplies as well, causing angina.

Pathophysiology

The imbalance between myocardial blood supply and demand causes temporary and reversible myocardial ischemia. **Ischemia**, deficient blood flow to tissue, may be caused by partial obstruction of a coronary artery, coronary artery spasm, or a thrombus. Obstruction of a coronary artery deprives cells in the region of the heart normally supplied by that vessel of oxygen and nutrients needed for metabolic processes. Cellular processes are compromised as ATP stores are depleted. Reduced oxygen causes cells to switch from aerobic metabolism to anaerobic metabolism. Anaerobic metabolism causes lactic acid to build up in the cells. It also affects cell membrane permeability, releasing substances such as histamine, kinins, and specific enzymes that stimulate terminal nerve fibers in the cardiac muscle and send pain impulses to the central nervous system. The pain radiates to the upper body because the heart shares the same dermatome as this region. Return of adequate circulation provides the nutrients needed by cells, and clears the waste products. More than 30 minutes of ischemia irreversibly damages myocardial cells (necrosis).

Three types of angina have been identified:

- *Stable angina* is the most common and predictable form of angina. It occurs with a predictable amount of activity or stress, and is a common manifestation of CHD. Stable angina usually occurs when the work of the heart is increased by physical exertion, exposure to cold, or by stress. Stable angina is relieved by rest and nitrates.
- *Prinzmetal's (variant) angina* is atypical angina that occurs unpredictably (unrelated to activity) and often at night. It is caused by coronary artery spasm with or without an atherosclerotic lesion. The exact mechanism of coronary artery spasm is unknown. It may result from hyperactive sympathetic nervous system responses, altered calcium flow in smooth muscle, or reduced prostaglandins that promote vasodilation.
- *Unstable angina* occurs with increasing frequency, severity, and duration. Pain is unpredictable and occurs with decreasing levels of activity or stress and may occur at rest. Patients with unstable angina are at risk for myocardial infarction. Unstable angina is discussed further in the section on acute coronary syndromes.

Silent myocardial ischemia, or asymptomatic ischemia, is thought to be common in people with CHD. Silent ischemia may occur with either activity or with mental stress. Mental stress increases the heart rate and blood pressure, increasing myocardial oxygen demand (Huether & McCance, 2011). Like symptomatic angina, silent myocardial ischemia is associated with an increased chance of myocardial infarction and death.

FAST FACTS

- Stable angina occurs with a predictable amount of activity or stress.
- Unstable angina occurs with increasing frequency and severity; it may occur at times unrelated to activity or stress.
- Prinzmetal's angina is the only type of angina not necessarily related to coronary heart disease and atherosclerosis, developing due to coronary artery spasm.

Course and Manifestations

The cardinal manifestation of angina is chest pain. The pain typically is precipitated by an identifiable event, such as physical activity, strong emotion, stress, eating a heavy meal, or exposure to cold. The classic sequence of angina is activity–pain, rest–relief. The patient may describe the pain as a tight, squeezing, heavy pressure, or constricting sensation. It characteristically begins beneath the sternum and may radiate to the jaw, neck, shoulder, or arm. Less characteristically, the pain may be felt in the jaw, epigastric region, or back. Anginal pain usually occurs in a *crescendo–decrescendo* pattern (increasing to a peak, then gradually decreasing) typically lasting 2 to 5 minutes; it is generally relieved by rest. Additional manifestations of angina include dyspnea, pallor, tachycardia, and great anxiety and fear.

Women frequently present with atypical symptoms of angina, including fatigue, indigestion or nausea, vomiting, and upper back pain. The manifestations of angina are summarized in the accompanying box.

The severity of angina can be graded by the degree to which it limits the patient's activities. Class I angina does not occur with ordinary physical activities. It is prompted by strenuous, rapid, or

MANIFESTATIONS OF ANGINA

- Chest pain: substernal or precordial (across the chest wall); may radiate to neck, arms, shoulders, or jaw
- Quality: tight, squeezing, constricting, or heavy sensation; may also be described as burning, aching, choking, dull, or constant
- Associated manifestations: dyspnea, pallor, tachycardia, anxiety, and fear
- Atypical manifestations: indigestion, nausea, vomiting, upper back pain
- Precipitating factors: exercise or activity, strong emotion, stress, cold, heavy meal
- Relieving factors: rest, position change, nitroglycerin

prolonged physical exertion. Class II angina may develop with rapid or prolonged walking or stair climbing, whereas Class III angina significantly limits ordinary physical activities. The patient with Class IV angina may have angina at rest, as well as with physical activity.

●○● INTERPROFESSIONAL CARE

The management of stable angina focuses on maintaining coronary blood flow and cardiac function. Stable angina often can be managed by medical therapy. Measures to restore coronary blood flow are discussed in the section on acute coronary syndrome. As for CHD, risk factor management is a vital component of care for the patient with angina (see the preceding section of this chapter).

DIAGNOSIS

The diagnosis of angina is based on past medical history and family history, a comprehensive description of the chest pain, and physical assessment findings. Laboratory tests may confirm the presence of risk factors, such as an abnormal blood lipid profile and elevated blood glucose. Diagnostic tests provide information about overall cardiac function.

Common diagnostic tests to assess for coronary heart disease and angina include electrocardiography, stress testing, nuclear medicine studies, echocardiography (ultrasound), and coronary angiography.

ELECTROCARDIOGRAPHY A resting ECG may be normal, may show nonspecific changes in the ST segment and T wave, or may show evidence of previous myocardial infarction. Characteristic ECG changes are seen during anginal episodes. During periods of ischemia, the ST segment is depressed or downsloping, and the T wave may flatten or invert (Figure 30–1 ■). These changes reverse when ischemia is relieved. For more details about the ECG, its waveforms, and its uses, see Chapter 29.

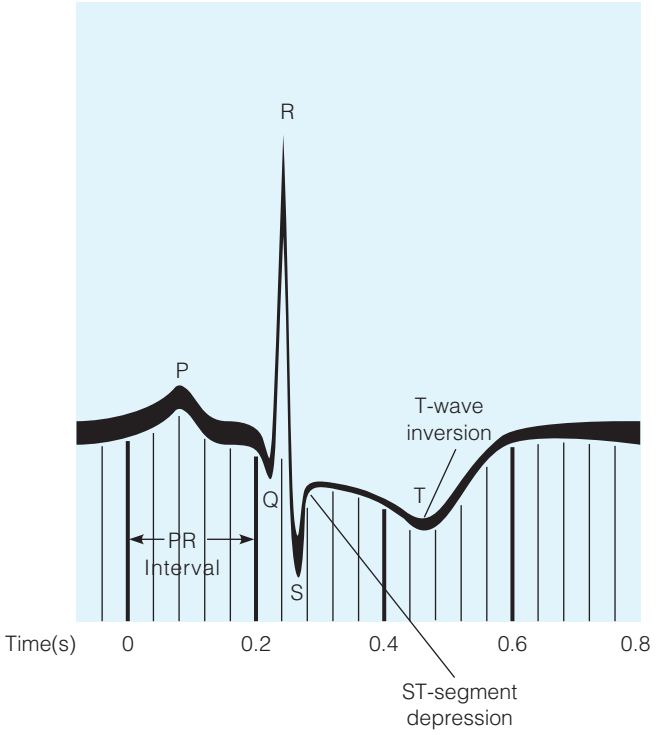


Figure 30–1 ■ ECG changes during an episode of angina. Note characteristic T-wave inversion and ST-segment depression of myocardial ischemia.

STRESS ELECTROCARDIOGRAPHY Stress electrocardiography (exercise stress test) uses ECGs to monitor the cardiac response to an increased workload during progressive exercise. See the Diagnostic Tests table in Chapter 29 for more information about exercise stress tests.

RADIONUCLIDE TESTING Radionuclide testing is a safe, noninvasive technique to evaluate myocardial perfusion and left ventricular function. The amount of radioisotope injected is very small; no special radiation precautions are required during or after the scan. Thallium-201 or a technetium-based radiocompound is injected intravenously, and the heart is scanned with a radiation detector. Ischemic or infarcted cells of the myocardium do not take up the substance normally, appearing as a "cold spot" on the scan. If the ischemia is transient, these spots gradually fill in, indicating the reversibility of the process. With severe ischemia or a myocardial infarction, these areas remain devoid of radioactivity.

Left ventricular function can also be evaluated. Whereas the ejection fraction (portion of blood ejected from the left ventricle during systole) normally increases during exercise, it may actually decrease in coronary heart disease and stress-induced ischemia.

Radionuclide testing may be combined with pharmacologic stress testing for patients who are physically unable to exercise or to detect subclinical myocardial ischemia. A vasodilator is injected to induce the same ischemic changes that occur with exercise in the diseased heart. Coronary arteries unaffected by atherosclerosis dilate in response to the drugs, increasing blood flow to already well-perfused tissue. This reduces flow to ischemic muscle, called *myocardial steal syndrome*.

ECHOCARDIOGRAPHY *Echocardiography* is a noninvasive test that uses ultrasound to evaluate cardiac structure and function. It may be done at rest, during supine exercise, or immediately following upright exercise to evaluate movement of the myocardial wall and assess for possible ischemia or infarction.

Transesophageal echocardiography (TEE) uses ultrasound to identify abnormal blood flow patterns as well as cardiac structures. In TEE, the probe is on the tip of an endoscope inserted into the esophagus, positioning it close to the posterior heart (especially the left atrium and the aorta). It avoids interference by breasts, ribs, or lungs. See the Diagnostic Tests table in Chapter 29 for more information about these tests and the nursing implications.

CORONARY ANGIOGRAPHY *Coronary angiography* is the gold standard for evaluating the coronary arteries. Guided by fluoroscopy, a catheter introduced into the femoral or brachial artery is threaded into the coronary artery. Dye is injected into each coronary opening, allowing visualization of the main coronary branches and any abnormalities, such as stenosis or obstruction. Narrowing of the vessel lumen by more than 50% is considered significant; most lesions that cause symptoms involve more than 70% narrowing. Vessel obstructions are noted on a coronary artery map that provides a guide for tracking disease progression and for elective treatment with angioplasty or cardiac surgery. During angiogram, the drug ergonovine maleate may be injected to induce coronary artery spasm and diagnose Prinzmetal's angina. Nursing care of the patient

undergoing a coronary angiogram is summarized in the box titled "Having PCR" on page 883.

MEDICATIONS

Drugs may be used for both acute and long-term relief of angina. The goal of drug treatment is to reduce oxygen demand and increase oxygen supply to the myocardium. Three main classes of drugs are used to treat angina: nitrates, beta-blockers, and calcium channel blockers.

NITRATES Nitrates, including nitroglycerin and longer-acting nitrate preparations, are used to treat acute anginal attacks and prevent angina.

Sublingual nitroglycerin is the drug of choice to treat acute angina. It acts within 1 to 2 minutes, decreasing myocardial work and oxygen demand through venous and arterial dilation, which in turn reduce preload and afterload. It may also improve myocardial oxygen supply by dilating collateral blood vessels and reducing stenosis. Rapid-acting nitroglycerin is also available as a buccal spray in a metered system. For some patients, this may be easier to handle than small nitroglycerin tablets.

PRACTICE ALERT!

Sublingual nitroglycerin tablets and nitroglycerin spray are the only medications appropriate to treat an acute anginal attack.

Longer-acting nitroglycerin preparations (oral tablets, ointments, or transdermal patches) are used to prevent attacks of angina, not to treat an acute attack. The primary problem with long-term nitrate use is the development of *tolerance*, a decreasing effect from the same dose of medication. Tolerance can be limited by a dosing schedule that allows a nitrate-free period of at least 8 to 10 hours daily. This is usually scheduled at night, when angina is less likely to occur.

Headache is a common side effect of nitrates, and may limit their usefulness. Nausea, dizziness, and hypotension are also common effects of therapy.

BETA-BLOCKERS Beta-blockers, including propranolol, metoprolol, nadolol, and atenolol, are considered first-line drugs to treat stable angina. They block the cardiac-stimulating effects of norepinephrine and epinephrine, preventing anginal attacks by reducing heart rate, myocardial contractility, and blood pressure, thus reducing myocardial oxygen demand. Beta-blockers may be used alone or with other medications to prevent angina.

Beta-blockers are contraindicated for patients with asthma or severe chronic obstructive pulmonary disease (COPD) (see Chapter 37) because they may cause severe bronchospasm. They are not used in patients with significant bradycardia, or AV conduction blocks, and are used cautiously in heart failure. Beta-blockers are not used to treat Prinzmetal's angina because they may make it worse.

CALCIUM CHANNEL BLOCKERS Calcium channel blockers reduce myocardial oxygen demand and increase myocardial blood and oxygen supply. These drugs, which include verapamil, diltiazem, and nifedipine, lower blood pressure, reduce myocardial contractility, and, in some cases, lower the heart rate, decreasing myocardial oxygen demand. They are also potent coronary vasodilators, effectively increasing oxygen supply. Like beta-blockers, calcium channel blockers act too slowly to effectively treat an acute attack of angina; they are used for long-term prophylaxis. Because they may actually increase ischemia and mortality in patients with heart failure or left ventricular dysfunction, these drugs are not usually prescribed in the initial treatment of angina. They are used cautiously in patients with dysrhythmias, heart failure, or hypotension.

The nursing implications of antianginal medications are summarized in the Medication Administration box on page 876.

ASPIRIN The patient with angina, particularly unstable angina, is at risk for myocardial infarction because of significant narrowing of the coronary arteries. Low-dose aspirin (80 to 325 mg/day) is often prescribed to reduce the risk of platelet aggregation and thrombus formation.

●○● NURSING CARE

The focus of nursing care for patients with angina is similar to the collaborative care focus: to reduce myocardial oxygen demand and improve the oxygen supply. Angina usually is treated in community settings; the primary nursing focus is education.

Health Promotion

In addition to health promotion measures, emphasize the importance of active CHD risk factor management to slow progression of the disease. Encourage patients to stop smoking. Discuss the use of cholesterol-lowering drug therapy with patients who have hypercholesterolemia. Encourage regular aerobic exercise and a diet based on AHA or NCEP guidelines.

Assessment

Focused assessment data for the patient with angina includes the following:

- *Health history:* chest pain, including type, intensity, duration, frequency, aggravating factors and relief measures; associated symptoms; history of other cardiovascular disorders, peripheral vascular disease, or stroke; current medications and treatment; usual diet, exercise, and alcohol intake patterns; smoking history; use of other recreational drugs
- *Physical assessment:* vital signs and heart sounds; strength and equality of peripheral pulses; skin color and temperature (central and peripheral); physical appearance during pain episode (e.g., shortness of breath, apparent anxiety, color, diaphoresis).

Priorities of Care

Collaborating with the interprofessional team to ensure adequate treatment of the cardiac perfusion limitations while providing care that supports circulatory support (including appropriate precautions) is a nursing priority. Teaching the patient and, as appropriate, caregivers strategies to identify early signs and symptoms of acute cardiac events and optimize safe home and work environments is another nursing priority. The nurse also focuses on promoting comfort and prevention of cardiac event recurrence.

Diagnoses, Outcomes, and Interventions

High-priority nursing diagnoses for patients with angina include ineffective cardiac tissue perfusion and management of the prescribed therapeutic regimen.

MEDICATION ADMINISTRATION

Antianginal Medications

ORGANIC NITRATES

nitroglycerin (Nitropaste, Nitro-Dur, Nitro-Bid, Nitrol, Transderm-Nitro, Nitrogard, Nitrodisc, Tridil)

isosorbide dinitrate (Isordil)

isosorbide mononitrate (ISMO)

amyl nitrite

Nitrates dilate both arterial and venous vessels, depending on the dose. Coronary artery vasodilation increases blood flow and myocardial oxygen supply. Venous dilation allows peripheral blood pooling, reducing venous return, preload, and cardiac work. Arterial dilation reduces vascular resistance and afterload, also reducing cardiac work. Sublingual nitroglycerin (NTG) tablets are used to treat and prevent acute anginal attacks (when taken prophylactically before activity). Nitrates are administered sublingually, by buccal spray, or intravenously for immediate effect, or orally or topically for sustained effect.

Nursing Responsibilities

- Dilute intravenous nitroglycerin before infusing; use only glass bottles for the mixture. Nitroglycerin adheres to PVC bags and tubing, affecting the amount of drug that is delivered. Use non-PVC infusion tubing.
- Wear gloves when applying nitroglycerin paste or ointment to prevent absorbing the drug through the skin. Measure dose carefully and spread evenly in a 2 × 3-inch area.
- Remove nitroglycerin patches or ointment at night to help prevent tolerance.

Health Education for the Patient and Family

- Use only the sublingual, buccal, and spray forms of nitrates to treat acute angina.
- If the first nitrate dose does not relieve angina within 5 minutes, take a second dose. After 5 more minutes, you may take a third dose if needed. If the pain is unrelieved or lasts for 20 minutes or longer, seek medical assistance immediately.
- Carry a supply of nitroglycerin tablets with you. Dissolve sublingual nitroglycerin tablets under the tongue or between the upper lip and gum. Do not eat, drink, or smoke until the tablet is completely dissolved.
- Keep sublingual tablets in their original amber glass bottle to protect them from heat, light, and moisture. Replace your supply every 6 months.
- You may experience a burning or tingling sensation under the tongue and develop a transient headache when you take the drug. These are expected; the headache will diminish over time.
- Use caution when standing from a sitting position; nitroglycerin may make you light-headed.
- Rotate ointment or transdermal patch application sites. Apply to a hairless area; spread ointment evenly without rubbing or massaging. Remove the patch or residual ointment at bedtime daily. Apply a fresh dose in the morning.
- If you are using a long-acting nitrate, keep a supply of immediate-acting nitrates to treat acute angina.

BETA-BLOCKERS

atenolol (Tenormin)

carvedilol (Coreg)

metoprolol (Lopressor, Toprol)

nadolol (Corgard)

propranolol (Inderal)

Beta-blockers decrease cardiac workload by blocking beta-receptors on the heart muscle, decreasing heart rate, contractility, myocardial oxygen consumption, and blood pressure. Beta-blockers also reduce *reflex tachycardia* (an increased heart rate in response to stimuli such as increased sympathetic nervous system [SNS] activity or vasodilation), which may develop with other antianginal drugs. Beta-blockers are frequently prescribed as antianginal and antihypertensive agents.

Nursing Responsibilities

- Document heart rate and blood pressure before administering the medication. Withhold drug if the heart rate is below 50 bpm or the blood pressure is below prescribed limits. Notify the physician.
- Assess for and report possible contraindications to therapy, including heart failure, bradycardia, AV block, asthma, or COPD.
- Concurrent use of beta-blockers and calcium channel blockers increases the risk for heart failure; notify the physician if these drugs are prescribed together.
- Do not abruptly discontinue these drugs after long-term therapy, as this can increase heart rate, contractility, and blood pressure, and cause fatal dysrhythmia, myocardial infarction, or stroke.

Health Education for the Patient and Family

- Beta-blockers help prevent angina but will not relieve an acute attack. Keep a supply of fast-acting nitrates on hand for acute anginal attacks.
- Do not suddenly stop taking this medication. Discuss discontinuing this medication with your physician.
- Take your pulse daily. Do not take the drug, and contact your physician if your heart rate is below 50 bpm. Check your blood pressure frequently.
- Report a slow or irregular pulse, swelling or weight gain, or difficulty breathing to your physician.

CALCIUM CHANNEL BLOCKERS

amlodipine (Norvasc)

bepridil (Vascor)

diltiazem (Cardizem)

felodipine (Plendil)

isradipine (DynaCirc)

nicardipine (Cardene)

nifedipine (Adalat, Procardia)

nimodipine (Nimotop)

verapamil (Isoptin, Calan)

Calcium channel blockers are used to control angina, hypertension, and dysrhythmias. By blocking the entry of calcium into cells, these drugs reduce contractility, slow the heart rate and conduction, and cause vasodilation. Calcium channel blockers increase myocardial oxygen supply by dilating the coronary arteries; they decrease the workload of the heart by lowering vascular resistance and oxygen demand. Calcium channel blockers are often prescribed for patients with coronary artery spasm (Prinzmetal's angina).

Nursing Responsibilities

- Do not mix verapamil in any solution containing sodium bicarbonate. Administer IV push verapamil over 2 to 3 minutes.
- Document blood pressure and heart rate before administering the drug. Withhold the drug if the heart rate is below 50 bpm. Notify the physician.
- Use caution when giving a calcium channel blocker with other cardiac depressants, such as beta-blockers.

MEDICATION ADMINISTRATION (*continued*)

Concomitant administration with nitrates may cause excessive vasodilation.
- Manifestations of toxicity include nausea, generalized weakness, signs of decreased cardiac output, hypotension, bradycardia, and AV block. Report these findings immediately. Maintain intravenous access, and slowly administer intravenous calcium chloride. Do not infuse large volumes of fluid to treat hypotension as heart failure may result.

Health Education for the Patient and Family
- Take your pulse before taking the drug. If your heart rate drops below 50 bpm, do not take the drug and notify your physician.
- Keep a fresh supply of immediate-acting nitrate available to treat acute anginal attacks. Calcium channel blockers will not work fast enough to relieve an acute attack.

Note: Drugs identified in *italics* are among the 200 most commonly prescribed medications in the U.S.

Ineffective Tissue Perfusion: Cardiac

Anginal pain results from impaired blood flow and oxygen supply to the myocardium. Nursing interventions can both prevent ischemia and shorten the duration of pain.

Expected Outcome: Patient will experience adequate cardiac perfusion as evidenced by freedom from chest pain related to angina and freedom from arrhythmias.

- Keep prescribed nitroglycerin tablets at the patient's side so one can be taken at the onset of pain. *Anginal pain indicates myocardial ischemia. Nitroglycerin reduces cardiac work and may improve myocardial blood flow, relieving ischemia and pain.*
- Start oxygen at 4 to 6 L/min per nasal cannula or as prescribed. *Supplemental oxygen reduces myocardial hypoxia.*
- Space activities to allow rest between them. *Activity increases cardiac work and may precipitate angina. Spacing of activities allows the heart to recover.*
- Teach about prescribed medications to maintain myocardial perfusion and reduce cardiac work. Emphasize that long-acting nitrates, beta-blockers, and calcium channel blockers are used to prevent anginal attacks, not to treat an acute attack. *It is important for the patient to understand the purpose and use of prescribed drugs to maintain optimal myocardial perfusion.*
- Instruct to take sublingual nitroglycerin before engaging in activities that precipitate angina (e.g., climbing stairs, sexual intercourse). *This prophylactic dose of nitroglycerin helps maintain cardiac perfusion when increased work is anticipated, preventing ischemia and chest pain.*
- Encourage to implement and maintain a progressive exercise program under the supervision of the primary care provider or a cardiac rehabilitation professional. *Exercise slows the atherosclerotic process and helps develop collateral circulation to the heart muscle.*
- Refer to a smoking cessation program as indicated. *Nicotine causes vasoconstriction and increases the heart rate, decreasing myocardial perfusion and increasing cardiac workload.*

Risk for Ineffective Therapeutic Regimen Management

Denial may be strong in the patient with angina pectoris. Because many people think of the heart as the locus of life itself, problems such as angina remind people of their mortality, an uncomfortable fact. Denial may lead to forgetting to take prescribed medications or to attempting activities that will precipitate angina. Some patients, by contrast, may become afraid to engage in activities because of anticipated chest pain. Their inactivity may actually hasten the atherosclerotic process and inhibit collateral circulation development, worsening angina.

Expected Outcome: Patient will be knowledgeable about therapies used to manage angina as evidenced by verbalized understanding of the underlying pathophysiology of angina, correct medication plan, and early identification of the onset of anginal episodes.

- Assess knowledge and understanding of angina. *Assessment allows tailoring of teaching and interventions to the needs of the patient.*
- Teach about angina and atherosclerosis as needed, building on current knowledge base. *This can help the patient understand that angina is a manageable disease and that pain can usually be controlled and the disease progress slowed.*
- Provide written and verbal instructions about prescribed medications and their use. *Written instructions reinforce teaching and are available to the patient for future reference.*
- Stress the importance of taking chest pains seriously while maintaining a positive attitude. *Although it is vital to recognize the significance of chest pain and deal with it appropriately, it is also important to maintain a positive outlook.*
- Refer patient to a cardiac rehabilitation program or other organized activities and support groups for patients with coronary artery disease. *Programs such as these help the patient develop risk factor management strategies, maintain a program of supervised activity, and gain coping skills.*

Delegating Nursing Care Activities

As appropriate and allowed by designated duties and responsibilities of assistive personnel, the nurse may delegate nursing care activities such as collecting vital signs (including orthostatic vital signs), measuring fluid intake and output, encouraging oral or enteral fluid intake, and skin care.

Continuity of Care

Many patients with stable angina manage their pain effectively, continuing to live active and productive lives. To promote effective management of this disorder, include the following topics in teaching for home care:

- Coronary heart disease and the processes that cause chest pain, including the relationship between the pain and reduced blood flow to the heart muscle.
- Use and effects (desired and adverse) of prescribed medications; importance of not discontinuing medications abruptly.
- Nitroglycerin use for acute angina: Always carry several tablets (not the entire supply); prophylactic use before activities that often cause chest pain; take tablet at first indication of pain rather than waiting to see if the pain develops; seek immediate medical assistance if three nitroglycerin tablets over 15 to 20 minutes do

not relieve the pain. Instruct patient to not continue the series of nitroglycerin if dizziness or light-headedness develops but to seek immediate medical assistance.
- The importance of calling 911 or going to the emergency department immediately for unrelieved chest pain.
- Appropriate storage of nitroglycerin: This unstable compound needs to be stored in a cool, dry, dark place; no more than a 6-month supply should be kept on hand.

For the patient who has undergone cardiac surgery, also include the following:

- Respiratory care, activity, and pain management
- The importance of actively participating in rehabilitation
- Manifestations of infection or other potential complications and their management.

THE PATIENT WITH ACUTE CORONARY SYNDROME

Acute coronary syndrome (ACS) is a condition of unstable cardiac ischemia. ACS includes unstable angina and acute myocardial ischemia with or without significant injury of myocardial tissue. Although the term ACS may, in some cases, be applied to acute myocardial infarction (myocardial tissue death), myocardial infarction is discussed separately in the next section of this chapter. An estimated 1.5 million Americans are admitted to the hospital annually with ACS (AHA, 2013).

FAST FACTS

- Acute coronary syndrome (severe cardiac ischemia), a common cause of hospital admission, includes unstable angina and acute myocardial infarction.
- Unstable angina is characterized by injury to myocardial cells; with prompt restoration of blood flow, muscle tissue recovers.
- Myocardial infarction is characterized by necrosis and death of myocardial cells; scar tissue forms and functional muscle is lost.
- ACS is the most common identified cause of sudden cardiac death (AHA, 2013).

Pathophysiology

ACS is a dynamic state in which coronary blood flow is acutely reduced, but not fully occluded. Myocardial cells are injured by the acute ischemia that results. Most people affected by ACS have significant stenosis of one or more coronary arteries.

ACS is precipitated by one or more of the following processes: (1) rupture or erosion of atherosclerotic plaque with formation of a blood clot that does not fully occlude the vessel; (2) coronary artery spasm (e.g., Prinzmetal's angina); (3) progressive vessel obstruction by atherosclerotic plaque or restenosis following a percutaneous revascularization (PCR) procedure; (4) inflammation of a coronary artery; or (5) increased myocardial oxygen demand and/or decreased supply (e.g., acute blood loss or anemia). Of these, ruptured or eroded plaque is the predominant pathophysiology underlying ACS. Plaque rupture often is triggered by hemodynamic factors such as increased heart rate, blood flow, and blood pressure in response to a surge of sympathetic nervous system activity. Increased SNS activity also is thought to contribute to the higher incidence of plaque rupture within the first hour of arising from bed in the morning.

When atherosclerotic plaque ruptures or erodes, the exposed lipid core of the plaque stimulates platelet aggregation and the extrinsic clotting pathway. Thrombin is generated and fibrin is deposited, forming a clot that severely impairs or obstructs blood flow to tissue distal to the area of plaque rupture. As a result, these cells become ischemic.

Injured myocardial cells contract less effectively, potentially reducing cardiac output if a large area of myocardium is affected. Lactic acid released from ischemic cells stimulates pain receptors, causing chest pain. Ischemia and injury affect electrical impulse conduction, producing inversion of the T wave and possibly elevation of the ST segment on the ECG.

Manifestations

The cardinal manifestation of ACS is chest pain, usually substernal or epigastric. The pain often radiates to the neck, left shoulder, and/or left arm. The pain may occur at rest and typically lasts longer than 10 to 20 minutes. In ACS, the chest pain is more severe and prolonged than that previously experienced by the patient. It may be a new onset of pain, or may represent a pattern of increasing frequency and severity of anginal pain. Dyspnea, diaphoresis, pallor, and cool skin may be present. Tachycardia and hypotension may occur. The patient may be nauseated or feel light-headed. Table 30–5 compares the features of stable angina, ACS, and acute myocardial infarction.

●○● INTERPROFESSIONAL CARE

The patient with ACS generally presents at the emergency department or physician's office with complaints of severe chest pain. The pain may be unrelieved by nitroglycerin or may be more severe and of longer duration than previous anginal episodes. The ECG is used in conjunction with blood levels of cardiac markers to differentiate between unstable angina and acute myocardial infarction. Patients with unstable angina generally are admitted to the acute care unit on bed rest with cardiac monitoring for 12 to 24 hours. Coronary revascularization procedures may be performed within 48 hours if significant CHD is identified.

DIAGNOSIS

The ECG and serum cardiac markers are the primary tests used to establish the diagnosis of ACS. Serum cardiac markers, proteins released from injured and necrotic heart muscle, can be measured (see the following section on acute myocardial infarction and Table 30–6 for more information about serum cardiac markers).

- Cardiac muscle troponins, *cardiac-specific troponin T (cT_nT)* and *cardiac-specific troponin I (cT_nI)*, are sensitive indicators of myocardial damage. Troponins may be elevated in ACS or may be within normal limits if chest pain is due to unstable angina.
- Creatine kinase (CK) and CK-MB (specific to myocardial muscle) levels are likely to be within normal limits or demonstrate transient elevation, returning to normal levels within 12 to 24 hours.

The ECG, particularly when done during the acute episode of chest pain, is a valuable diagnostic tool for ACS. ST-segment changes (elevation or depression) during chest pain that resolve when the pain abates usually indicate acute myocardial ischemia and severe underlying CHD.

TABLE 30–5 Comparing Stable Angina, Acute Coronary Syndrome, and Acute Myocardial Infarction

	Stable Angina	Acute Coronary Syndrome	Acute Myocardial Infarction
Pathophysiology	Myocardial ischemia occurs with increased workload (e.g., during exercise) due to stable atherosclerotic plaque narrowing coronary arteries.	Coronary artery spasm or partial occlusion by unstable plaque and thrombus formation occur, with increasing myocardial ischemia.	Obstruction of a coronary artery by a thrombus blocks blood supply to a portion of the myocardium, resulting in necrosis.
Chest pain	Stable and predictable, occurring with exertion or emotion	Occurs at rest; increasing frequency and severity	Begins abruptly, unrelated to rest or exercise
	Crescendo–decrescendo pattern	Lasts 10 min or longer	Severe, "crushing"
	May radiate to neck, shoulder, arms	Radiates to neck, left shoulder, and arm	Unrelieved by rest or nitroglycerin
	Usually lasts 5–10 min, relieved by rest	Lasts longer than 10 min	Radiates to arms, neck, jaw
Other manifestations	Indigestion, nausea	Epigastric pain	Epigastric pain, nausea
	Possible shortness of breath	Dyspnea	Dyspnea
	Anxiety	Tachycardia, hypotension	Pallor, diaphoresis
		Cool, pale skin	Tachycardia or bradycardia, hyper- or hypotension
Diagnosis	ECG: T-wave inversion during anginal episodes	ECG: ST-segment depression, T-wave inversion	ECG: ST-segment elevation, possible Q wave
	Cardiac markers: within normal range	Cardiac markers: within normal range or transient elevation	Cardiac markers: elevated

MEDICATIONS

Medications include drugs to reduce myocardial ischemia and those to reduce the risk for blood clotting. Fibrinolytic drugs (drugs that break down the fibrin in blood clots) may be given prior to or on admission to the emergency department. These drugs restore blood flow to ischemic cardiac muscle and can prevent permanent damage. (See the section on myocardial infarction and the Nursing Care of the Patient Receiving Fibrinolytic Therapy box later in this chapter for more information about fibrinolytic drugs and their nursing implications.)

Nitrates and beta-blockers are used to restore blood flow to the ischemic myocardium and reduce the workload of the heart. Nitroglycerin is given by sublingual tablet or buccal spray. If chest pain is unrelieved after three doses 5 minutes apart, an intravenous nitroglycerin infusion is initiated. The infusion may be continued until the chest pain is relieved or for 12 to 24 hours. Topical or oral nitrates are then initiated. Beta-adrenergic blockers are initially given intravenously, followed by oral beta-blockers. Refer to the Medication Administration box on page 876 for the nursing implications of these drugs.

Aspirin, other antiplatelet drugs, and heparin are given to inhibit blood clotting and reduce the risk of thrombus formation. Aspirin and clopidogrel (Plavix) are given to patients with ACS who do not have an excessive bleeding risk. Aspirin and clopidogrel suppress platelet aggregation, interrupting the process of forming a stable blood clot. Both increase the risk of serious hemorrhage; for most patients, however, the benefit outweighs the risk. Intravenous antiplatelet drugs such as abciximab (ReoPro), eptifibatide (Integrilin), or tirofiban (Aggrastat) may be used when an invasive coronary revascularization procedure is anticipated in the immediate or near future. Nursing implications for the antiplatelet drugs are outlined in the accompanying Medication Administration box.

REVASCULARIZATION PROCEDURES

Several procedures may be used to restore blood flow and oxygen to ischemic tissue. Nonsurgical techniques include transluminal coronary angioplasty, laser angioplasty, coronary atherectomy, and intracoronary stents. Coronary artery bypass grafting (CABG) is a surgical procedure that may be used.

PERCUTANEOUS CORONARY REVASCULARIZATION *Percutaneous coronary revascularization (PCR)* procedures are used to restore blood flow to the ischemic myocardium in patients with CHD. Approximately 600,000 PCR procedures are done annually in the United States. PCR is used to treat patients with the following:

- Moderately severe, chronic stable angina unrelieved by medical therapy
- Unstable angina
- Acute myocardial infarction
- Significant stenosis of the left anterior descending coronary artery
- Stenosis of a coronary artery bypass graft.

PCR procedures are similar to the procedure used for coronary angiography. A catheter introduced into the arterial circulation is guided into the opening of the narrowed coronary artery. A flexible guide wire is inserted through the catheter lumen into the affected vessel. The guide wire is then used to thread an angioplasty balloon, arterial stent, or other therapeutic device into the narrowed segment of the artery. The procedure is performed in the cardiac catheterization laboratory using local anesthesia. The hospital stay is short (1 to 2 days), minimizing costs.

In a *percutaneous transluminal coronary angioplasty (PTCA)*, a balloon-tipped catheter is threaded over the guide wire, with the balloon positioned across the area of narrowing (Figure 30–2 ■). The balloon is inflated in a step-by-step fashion for about 30 seconds to 2 minutes to compress the plaque against the arterial wall, with the goal of reducing the vessel obstruction to less than 50% of the arterial lumen. PTCA typically is accompanied by placement of a stent. *Intracoronary stents* are metallic scaffolds used to maintain an open arterial lumen. Stents reduce the rate of restenosis following angioplasty by about one-third, and are now used in the majority of all

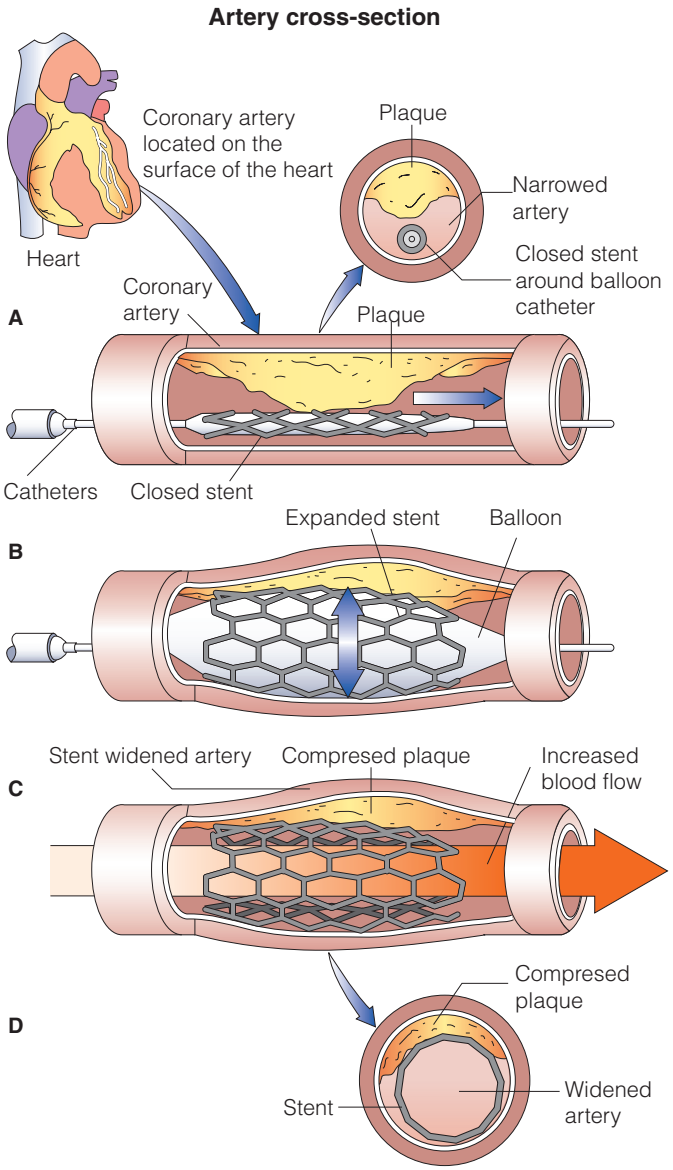

Figure 30–2 ■ Percutaneous coronary revascularization. A, The balloon catheter with the stent is threaded into the affected coronary artery. B, C, The stent is positioned across the blockage and expanded. D, The balloon is deflated and removed, leaving the stent in place.

PCR procedures. The stent is placed over a balloon catheter, guided into position, and expanded as the balloon is inflated. It then remains in the artery as a prop after the balloon is removed. Endothelial cells will completely line the inner wall of the stent to produce a smooth inner lining. Antiplatelet medications (aspirin and ticlopidine) are given following stent insertion to reduce the risk of thrombus formation at the site.

In contrast to stent procedures that enlarge the artery by displacing plaque, *atherectomy* procedures remove plaque from the identified lesion. The directional atherectomy catheter shaves the plaque off vessel walls using a rotary cutting head, retaining the fragments in its housing and removing them from the vessel. Rotational atherectomy catheters pulverize plaque into particles small enough to pass through the coronary microcirculation. Laser atherectomy devices use laser energy to remove plaque.

Complications following PCR procedures include hematoma at the catheter insertion site, pseudoaneurysm, embolism, hypersensitivity to contrast dye, dysrhythmias, bleeding, vessel perforation, and restenosis, reocclusion of the treated vessel, or stroke.

Nursing care of the patient undergoing PCR is outlined in the box on page 883.

CORONARY ARTERY BYPASS GRAFTING Surgery for coronary heart disease involves using a section of a vein or an artery to create a connection (or bypass) between the aorta and the coronary artery beyond the obstruction (Figure 30–3 ■). This then allows blood to perfuse the ischemic portion of the heart. The internal mammary artery in the chest and the saphenous vein from the leg are the vessels most commonly used for coronary artery bypass grafting (CABG).

Bypass grafts are safe and effective. Angina is totally relieved or significantly reduced in 90% of patients who undergo complete revascularization. Although anginal pain may recur within 3 years, it is rarely as severe as before surgery. CABG has a positive effect on mortality in many cases. It is recommended for patients who have multiple-vessel disease and impaired left ventricular function or diabetes, and for patients who have significant obstruction of the left main coronary artery (Perrin & MacLeod, 2012).

A median sternotomy commonly is used to access the heart. The heart is usually stopped during surgery. The *cardiopulmonary bypass (CPB) pump* is used to maintain perfusion to the rest of the organs during open-heart surgery. Venous blood is removed from the body through a cannula placed in the right atrium or the superior and inferior venae cavae. Blood then circulates through the CPB pump, where it is oxygenated, its temperature is regulated, and it is filtered. Oxygenated blood is returned to the body through a cannula in the ascending aorta (Figure 30–4 ■). Cardiopulmonary bypass enables surgeons to operate on a quiet heart and a relatively bloodless field. Hypothermia can be maintained to reduce the metabolic rate and decrease oxygen demand during surgery.

Newer techniques have been developed that allow surgeons to perform CABG without cardioplegia (stopping the heart) and CPB. Off-pump coronary artery bypass (OPCAB) allows use of a smaller

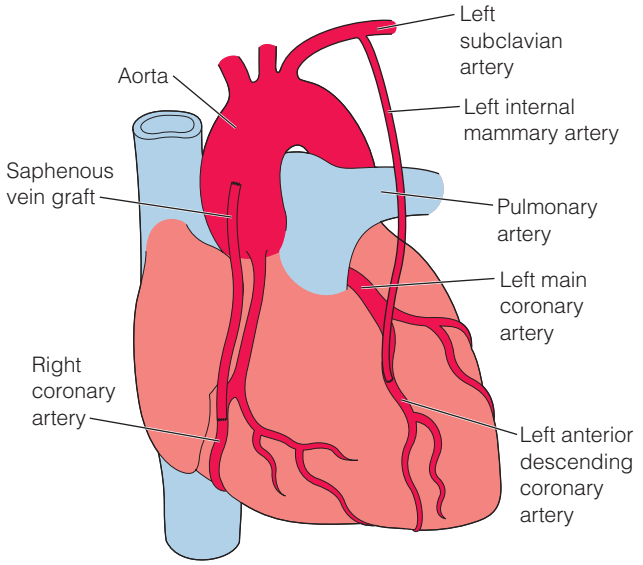

Figure 30–3 ■ Coronary artery bypass grafting using the internal mammary artery and a saphenous vein graft.

MEDICATION ADMINISTRATION

Antiplatelet Drugs

ORAL ANTIPLATELET DRUGS

aspirin

clopidogrel (Plavix)

dipyridamole (Persantine)

ticlopidine (Ticlid)

cilostazol (Pletal)

Antiplatelet drugs suppress platelet aggregation in arteries, preventing the development of an arterial thrombus. Aspirin, clopidogrel, and dipyridamole block different platelet activation pathways to inhibit platelet aggregation and clot formation. Ticlopidine alters the function of platelet membranes. The dose of aspirin given to achieve antiplatelet effects is low, typically 80 to 325 mg/day.

Nursing Responsibilities

- Inquire about a history of intracranial hemorrhage, upper gastrointestinal bleeding, peptic ulcer disease, or known bleeding tendency.
- Observe for and report increased bruising, petechiae, purpura, and apparent or occult bleeding (e.g., melena, hematemesis, hematuria, nosebleeds, bleeding from IV sites).
- Avoid needlesticks after administration.
- If a Foley catheter is ordered, insert prior to medication administration
- Only dipyridamole can be used concurrently with warfarin (Coumadin).

Health Education for the Patient and Family

- Take as directed. Take aspirin with food or milk; clopidogrel may be taken at any time of day.
- Do not use nonsteroidal anti-inflammatory drugs (NSAIDs) or other over-the-counter drugs that may contain aspirin or an NSAID unless prescribed by your physician.
- Check with your physician before taking any herbal remedies such as evening primrose oil, feverfew, garlic, ginkgo biloba, or grapeseed extract while taking these medications.
- Report unusual bruising or excessive bleeding.
- Inform all care providers (including dental professionals) of use of these drugs.

INTRAVENOUS ANTIPLATELET DRUGS

abciximab (ReoPro)

eptifibatide (Integrilin)

tirofiban (Aggrastat)

These intravenously administered antiplatelet drugs block the final common pathway of platelet activation and, thus, are more effective than oral antiplatelet drugs. However, the risk of bleeding is greater than with the orally administered antiplatelet drugs.

Nursing Responsibilities

- Determine history of bleeding disorders, intracranial hemorrhage, recent trauma, or surgery.
- Inquire about recent use of oral antiplatelet or anticoagulant drugs.
- Monitor CBC including hemoglobin, hematocrit, and platelet count; clotting studies, including PT, INR, PTT; vital signs; and ECG during therapy.
- Maintain a separate intravenous line for blood draws and administration of other drugs during infusion.
- Closely observe for and immediately report anaphylaxis or bleeding uncontrolled by pressure. Keep resuscitation equipment readily available.
- Maintain bed rest during infusion.

Health Education for the Patient and Family

- This drug is given to reduce the risk of clotting and myocardial infarction. It helps maintain blood flow through the affected vessel following angioplasty and stent placement.
- Immediately report any chest tightness, difficulty breathing, shortness of breath, or itching that develops during the infusion.
- Your risk of bleeding should return to normal within about 2 days following the infusion.
- Immediately report any unusual bruising or bleeding to your physician.

Note: Drugs identified in *italics* are among the 200 most commonly prescribed medications in the U.S.

incision for access. Although cardiopulmonary bypass is employed for the majority of coronary artery bypass procedures, OPCAB is a promising alternative. Controlled studies demonstrate lower mortality and morbidity rates and faster recovery for patients undergoing OPCAB as compared to CABG with cardiopulmonary bypass.

When the saphenous vein is used, it is excised from its normal attachments in the leg, flushed with a cold heparinized saline solution, and then reversed so that its valves do not interfere with blood flow. When appropriate, a laparoscopic approach may be used to remove the vein. The vein is *anastomosed* (grafted) to the aorta and the coronary artery, distal to the occlusion (refer to Figure 30–3). This provides a bridge or conduit for blood flow past the obstruction. If the internal mammary artery (IMA) is used, its distal end is excised and anastomosed to the coronary artery distal to the obstruction. The IMA often is used to revascularize the left coronary artery because of the greater oxygen demand of the left ventricle.

Once grafting is completed, cardiopulmonary bypass is discontinued and the patient is rewarmed. Rewarming stimulates the heart to resume beating. Temporary pacing wires are sutured in place and passed through the chest wall in case temporary pacing is necessary. Chest tubes are placed in the pleural space and mediastinum to drain blood and reestablish negative pressure in the thoracic cavity. The sternum is closed using heavy wires and bone wax, the skin is closed with sutures or staples, and sterile dressings are applied over sternal and leg incisions.

Pre- and postoperative nursing care and teaching for the patient having a coronary artery bypass graft or other open-heart surgery are outlined on page 884.

MINIMALLY INVASIVE CORONARY ARTERY SURGERY *Minimally invasive coronary artery surgery* is a potential future alternative to CABG. Two approaches may be used: *Port-access coronary artery bypass* uses several small holes, or ports, in the chest wall to access vessels for connection to the CPB pump and the surgical site; alternatively, the femoral artery and femoral vein may be used for CPB. CPB is avoided altogether using the *minimally invasive direct coronary artery bypass (MIDCAB)* approach. With MIDCAB, a small surgical incision and several chest wall ports are used to graft a chest wall artery to the affected coronary vessel while the heart continues to beat.

TRANSMYOCARDIAL LASER REVASCULARIZATION A new development in myocardial revascularization techniques is called

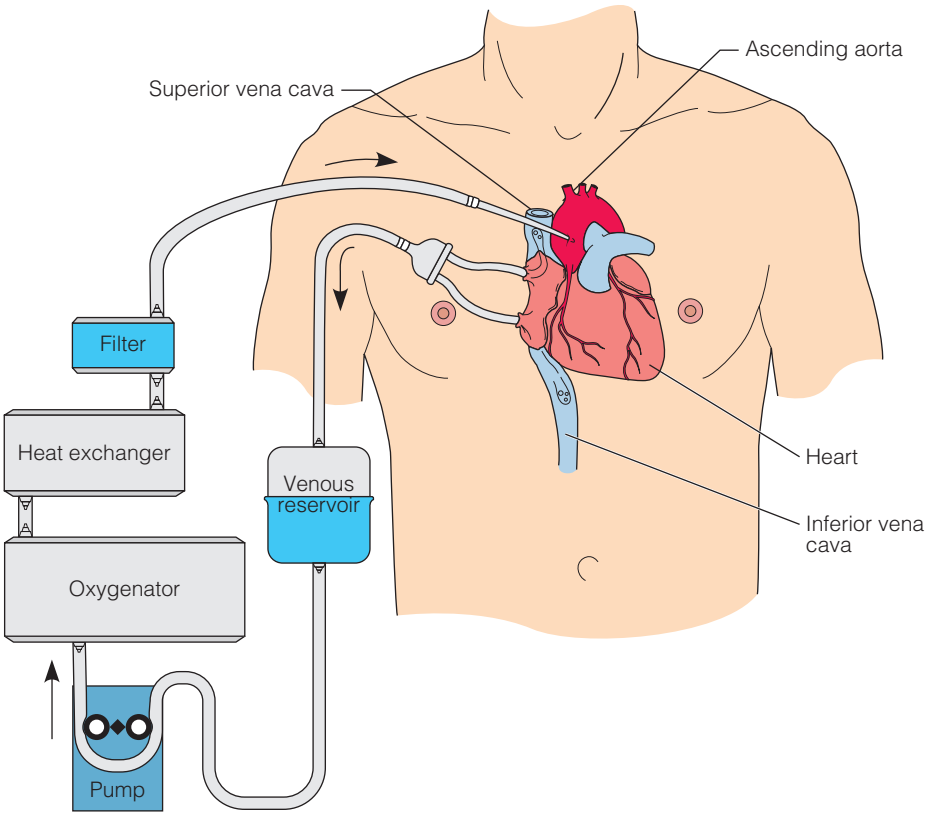

Figure 30–4 ■ A diagrammatic representation of cardiopulmonary bypass. A cannula in the superior and inferior venae cavae removes venous blood, which is then pumped through an oxygenator and heat exchanger. After filtering, oxygenated blood is returned to the ascending aorta.

transmyocardial laser revascularization (TMLR). In this procedure, a laser is used to drill tiny holes into the myocardial muscle itself to provide collateral blood flow to ischemic muscle. Patients whose coronary artery obstructions are too diffuse to bypass are candidates for this new surgical treatment.

●○● NURSING CARE

Health promotion, assessment, nursing diagnoses, and interventions for the patient with ACS are similar to those identified for patients with angina and with acute myocardial infarction. See the preceding and subsequent sections of this chapter for specific nursing care activities, as well as the Case Study & Nursing Care Plan that follows.

THE PATIENT WITH ACUTE MYOCARDIAL INFARCTION

An **acute myocardial infarction (AMI)**, necrosis (death) of myocardial cells, is a life-threatening event. If circulation to the affected myocardium is not promptly restored, loss of functional myocardium affects the heart's ability to maintain an effective cardiac output. This may ultimately lead to cardiogenic shock and death.

Heart disease remains the leading cause of death in the United States. Of the major heart diseases, myocardial infarction (MI) or *heart attack*, and other forms of ischemic heart disease cause the majority of deaths. Annually, approximately 785,000 people in the United States experience their first MI; another 470,000 suffer an MI subsequent to the initial one. It is estimated that 195,000 silent attacks occur each year (AHA, 2013).

The majority of deaths from MI occur during the initial period after symptoms begin: approximately 60% within the first hour, and 40% prior to hospitalization. Heightening public awareness of the manifestations of MI, the importance of seeking immediate medical assistance, and training in cardiopulmonary resuscitation (CPR) techniques is vital to decrease deaths due to MI.

Myocardial infarction rarely occurs without preexisting coronary heart disease. Although no specific cause has been identified, the risk factors for MI are those for coronary heart disease: age, gender, heredity, race, smoking, obesity, hyperlipidemia, hypertension, diabetes, sedentary lifestyle, diet, and others. See the previous section of this chapter on coronary heart disease for further discussion of these risk factors.

Evidence for Nursing Care

The Patient with Acute Coronary Syndrome

Selected resources that nurses may find helpful when planning evidence-based nursing care follow.

- Berra, K., Fletcher, B. J., & Handberg, E. (2011). Antiplatelet therapy in acute coronary syndromes: Implications for nursing practice. *Journal of Cardiovascular Nursing, 26*(3), 239–249.
- Kuhn, L., Page, K., Davidson, P. M., & Worrall-Carter, L. (2011). Triaging women with acute coronary syndrome: A review of the literature. *Journal of Cardiovascular Nursing, 26*(5), 395–407.

NURSING CARE OF THE PATIENT

Having PCR

BEFORE THE PROCEDURE

- Assess knowledge of the procedure and expectations of treatment. *This allows information to be tailored to the patient's needs and provides an opportunity to clarify misconceptions.*
- Describe the cardiac catheterization laboratory and the planned PCR procedure, including the following:
  - Preoperative preparation (refer to Chapter 4)
  - Planned anesthesia or sedation to be used
  - Drugs that may be given during the procedure, such as anticoagulants to reduce the risk of thrombus formation, and intravenous nitroglycerin and a calcium channel blocker to dilate coronary arteries and prevent anginal pain
- Discuss possible sensations during the procedure, including flushing or warmth and a metallic taste in the mouth as the contrast dye is injected, and a feeling of pressure or chest pain during balloon inflation. *Advanced preparation for expected sensations reduces anxiety and improves outcomes.*
- Perform a comprehensive assessment, including hydration status (skin and mucous membrane moisture, turgor) and peripheral circulation (color, warmth, sensation, pulses, and capillary refill).

AFTER THE PROCEDURE

- Complete a head-to-toe assessment. Note any complaints of chest pain, or evidence of decreased cardiac output or myocardial infarction. *Assessment provides a baseline for subsequent assessments and allows early identification of possible complications.*
- Monitor vital signs and cardiac rhythm continuously. Treat dysrhythmias as ordered. Obtain a 12-lead ECG if signs of ischemia develop, and notify physician. *Vital signs reflect cardiac output. Dysrhythmias may develop with reperfusion of the ischemic myocardium. ECG changes may indicate infarction or restenosis of the affected vessel.*
- Maintain intravenous nitroglycerin infusion. Administer anticoagulant and antiplatelet medications, nitrates, and calcium channel blockers as ordered. *These drugs decrease oxygen demand and increase oxygen supply by dilating the coronary arteries and systemic vasculature. They also reduce the risk of thrombus formation.*
- Monitor for and treat or report chest pain as indicated. *Chest pain may indicate ischemia and possible myocardial infarction.*
- Maintain bed rest as ordered with the head of the bed at 30 degrees or less. Prevent flexion of the leg on the affected side. Following sheath removal, follow protocol for pressure dressing or device or sandbag placement. *A large puncture wound occurs at the insertion site. Immobilization allows the wound to seal; a pressure dressing helps prevent bleeding.*
- Monitor distal pulses, color, movement, sensation, and temperature of the affected leg, and insertion site every 15 minutes for the first hour, every 30 minutes for the next hour, every hour for the next 8 hours, and then every 4 hours. *A clot may form at the site, reducing perfusion of the affected leg. The site and dressing are monitored for excessive bleeding, hematoma formation, or pseudoaneurysm. Pseudoaneurysm occurs as a result of inadequate hemostasis after catheter removal.*
- Monitor intake and output, serum electrolytes, blood urea nitrogen (BUN), creatinine, complete blood count (CBC), partial thromboplastin time (PTT), and cardiac enzymes. Report abnormal results to the physician. *Contrast dye causes osmotic diuresis and may cause renal damage or a hypersensitivity reaction. Electrolyte imbalances increase the risk of dysrhythmias. Cardiac enzymes are monitored for indications of possible myocardial damage during the procedure. The PTT monitors the effectiveness of heparin therapy.*
- Monitor for bradycardia, light-headedness, hypotension, diaphoresis, and loss of consciousness during sheath removal. Keep atropine at bedside during sheath removal. *Bradycardia and signs of decreased cardiac output may occur during sheath removal because of a vasovagal reaction. Atropine decreases vagal tone and increases heart rate.*
- Monitor neurovascular status (level of consciousness, pupil size and reactivity, motor function). *A reduced level of consciousness may indicate development of stroke due to migration of clot particulates during PCR.*

Pathophysiology

Atherosclerotic plaque may form stable or unstable lesions. *Stable* lesions progress by gradually occluding the vessel lumen, whereas *unstable* (or *complicated*) lesions are prone to rupture and thrombus formation. Stable lesions often cause angina; unstable lesions often lead to acute coronary syndromes or acute ischemic heart diseases. Acute coronary syndromes include unstable angina, myocardial infarction, and sudden cardiac death.

Myocardial infarction occurs when blood flow to a portion of cardiac muscle is completely blocked, resulting in prolonged tissue ischemia and irreversible cell damage. Coronary occlusion is usually caused by ulceration or rupture of a complicated atherosclerotic lesion. When an atherosclerotic lesion ruptures or ulcerates, substances are released that stimulate platelet aggregation, thrombin generation, and local vasomotor tone. As a result, the vessel constricts, and a thrombus (clot) forms, occluding the vessel and interrupting blood flow to the myocardium distal to the obstruction.

Cellular injury occurs when the cells are denied adequate oxygen and nutrients. With prolonged ischemia lasting more than 20 to 45 minutes, irreversible hypoxemia causes cellular death and tissue necrosis. Oxygen, glycogen, and ATP stores of ischemic cells are rapidly depleted. Cellular metabolism shifts to an anaerobic process, producing hydrogen ions and lactic acid. Cellular acidosis increases cells' vulnerability to further damage with release of intracellular enzymes through the damaged cell membranes.

Cellular acidosis, electrolyte imbalances, and hormones released in response to cellular ischemia affect impulse conduction and myocardial contractility. Myocardial contractility decreases, increasing the risk for dysrhythmias, subsequently reducing stroke volume, cardiac output, blood pressure, and tissue perfusion.

Within 20 minutes of injury, the subendocardium, being most susceptible to changes in coronary blood flow, suffers the initial damage. If blood flow is restored at this point, the infarction is limited to subendocardial tissue (a *subendocardial* or *non-Q-wave infarction*). The damage progresses to the epicardium within 1 to 6 hours. When all layers of the myocardium are affected, it is known as a *transmural infarction*. A significant Q wave develops with a transmural infarction, so this also may be called a *Q-wave MI*. Complications such as heart failure are more frequently associated with Q-wave MIs; however, patients with non-Q-wave MIs frequently experience recurrent ischemia or subsequent MI within weeks or months of the event (Woods et al., 2009).

NURSING CARE OF THE PATIENT

Having a Coronary Artery Bypass Graft

PREOPERATIVE CARE

- Provide routine preoperative care and teaching as outlined in Chapter 4.
- Verify presence of laboratory and diagnostic test results in the chart, including CBC, coagulation profile, urinalysis, chest x-ray, and coronary angiogram. *These baseline data are important for comparison of postoperative results and values*.
- Type and crossmatch four or more units of blood as ordered. *Blood is made available for use during and after surgery as needed*.
- Provide specific patient and family teaching related to the procedure and postoperative care. Include the following topics:
  - Cardiac recovery unit; sensory stimuli, personnel; noise and alarms; visiting policies
  - Tubes, drains, and general appearance
  - Monitoring equipment, including cardiac and hemodynamic monitoring systems
  - Respiratory support: ventilator, endotracheal tube, suctioning; communication while intubated
  - Incisions and dressings
  - Pain management.

Preoperative teaching reduces anxiety and prepares the patient and family for the postoperative environment and expected sensations.

POSTOPERATIVE CARE

- Provide routine postoperative care as outlined in Chapter 4. In addition to the care needs of all patients having major surgery, the cardiac surgery patient has specific care needs related to open-heart and thoracic surgery. These are outlined under the nursing diagnoses identified next.

Decreased Cardiac Output

Cardiac output may be compromised postoperatively due to bleeding and fluid loss; depression of myocardial function by drugs, hypothermia, and surgical manipulation; dysrhythmias; increased vascular resistance; and a potential complication, *cardiac tamponade*, compression of the heart due to collected blood or fluid in the pericardium.

- Monitor vital signs, oxygen saturation, and hemodynamic parameters every 15 minutes. Note trends and report significant changes to the physician. *Initial hypothermia and bradycardia are expected; the heart rate should return to the normal range with rewarming. The blood pressure may fall during rewarming as vasodilation occurs. Hypotension and tachycardia, however, may indicate low cardiac output. Pulmonary artery pressure (PAP), pulmonary artery wedge pressure (PAWP), cardiac output, and oxygen saturation are monitored to evaluate fluid volume, cardiac function, and gas exchange*. Hemodynamic monitoring is further discussed in Chapter 31.
- Auscultate heart and breath sounds on admission and at least every 4 hours. *A ventricular gallop, or S_3, is an early sign of heart failure; an S_4 sound may indicate decreased ventricular compliance. Muffled heart sounds may be an early indication of cardiac tamponade. Adventitious breath sounds (wheezes, crackles, or rales) may be a manifestation of heart failure or respiratory compromise*.
- Assess skin color and temperature, peripheral pulses, and level of consciousness with vital signs. *Pale, mottled, or cyanotic coloring, cool and clammy skin, and diminished pulse amplitude are indicators of decreased cardiac output*.
- Continuously monitor and document cardiac rhythm. *Dysrhythmias are common, and may interfere with cardiac filling and contractility, decreasing the cardiac output*.
- Measure intake and output hourly. Report urine output less than 30 mL/h for 2 consecutive hours. *Intake and output measurements help evaluate fluid volume status. A fall in urine output may be an early indicator of decreased cardiac output*.
- Record chest tube output hourly. *Chest tube drainage greater than 70 mL/h or that is warm, red, and free flowing indicates hemorrhage and may necessitate a return to surgery. A sudden drop in chest tube output may indicate impending cardiac tamponade*.
- Monitor hemoglobin, hematocrit, and serum electrolytes. *A drop in hemoglobin and hematocrit may indicate hemorrhage that is not otherwise obvious. Electrolyte imbalances, potassium, calcium, and magnesium in particular, affect cardiac rhythm and contractility*.
- Administer intravenous fluids, fluid boluses, and blood transfusions as ordered. *Fluid and blood replacement helps ensure adequate blood volume and oxygen-carrying capacity*.
- Administer medications as ordered. *Medications ordered in the early postoperative period to maintain the cardiac output include inotropic drugs (e.g., dopamine, dobutamine) to increase the force of myocardial contractions; vasodilators (e.g., nitroprusside or nitroglycerin) to decrease vascular resistance and afterload; and antidysrhythmics to correct dysrhythmias that affect cardiac output*.
- Keep a temporary pacemaker at the bedside; initiate pacing as indicated. *Temporary pacing may be needed to maintain the cardiac output with bradydysrhythmias, such as high-level AV blocks*.

PRACTICE ALERT!

Assess for signs of cardiac tamponade: increased heart rate, decreased BP, decreased urine output, increased central venous pressure, a sudden decrease in chest tube output, muffled/distant heart sounds, and diminished peripheral pulses. Notify physician immediately. Cardiac tamponade is a life-threatening complication that may develop postoperatively. Cardiac tamponade interferes with ventricular filling and contraction, decreasing cardiac output. Untreated, cardiac tamponade leads to cardiogenic shock and possible cardiac arrest.

Hypothermia

Hypothermia is maintained during cardiac surgery to reduce the metabolic rate and protect vital organs from ischemic damage. Although rewarming is instituted on completion of the surgery, the patient often remains hypothermic on admission to cardiac recovery. Gradual rewarming is necessary to prevent peripheral vasodilation and hypotension.

- Monitor core body temperature (e.g., tympanic membrane, pulmonary artery, bladder) for the first 8 hours following surgery. *Oral and rectal temperature measurements are not reliable indicators of core body temperature during this period.*
- Institute rewarming measures (e.g., warmed intravenous solutions or blood transfusion, warm blankets, warm inspired gases, radiant heat lamps) as needed to maintain a temperature above 96.8°F (36°C). Administer Thorazine, morphine, or diltiazem as ordered to relieve shivering. *Low body temperature may cause shivering, increasing oxygen demand and consumption. Hypothermia also increases the risk for hypoxia, metabolic acidosis, vasoconstriction and increased cardiac work, altered clotting, and dysrhythmias.*

Acute Pain

Following a CABG, pain is experienced due to both the thoracic incision and removal of the saphenous vein from the leg. Dissection of the internal mammary artery (usually the left IMA) from the chest wall also causes chest pain on the affected side. Chest tube sites are

NURSING CARE OF THE PATIENT (*continued*)

also uncomfortable. The leg from which the saphenous vein graft was obtained may be more painful than the chest incision.

- Frequently assess for pain, including its location and character. Document its intensity using a standard pain scale. Assess for verbal and nonverbal indicators of pain. Validate pain cues with the patient. *Pain is subjective, and differs among individuals. Incisional pain is expected; however, anginal pain also may develop. It is important to differentiate the type of pain.*

PRACTICE ALERT!

Promptly report anginal or cardiac pain. Cardiac pain may indicate a perioperative or postoperative myocardial infarction.

- Administer analgesics on a scheduled basis, by PCA, or by continuous infusion for the first 24 to 48 hours. *Research demonstrates that adequate pain management in the immediate postoperative period reduces complications from sympathetic stimulation and allows faster recovery. Pain causes muscle tension and vasoconstriction, impairing circulation and tissue perfusion, slowing wound healing, and increasing cardiac work.*
- Premedicate 30 minutes before activities or planned procedures. *Premedication and the subsequent reduction of pain improve patient participation and cooperation with care.*

Ineffective Airway Clearance/Impaired Gas Exchange

Atelectasis due to impaired ventilation and airway clearance is a common pulmonary complication of cardiac surgery. Gas exchange may also be affected by blood loss and decreased oxygen-carrying capacity following surgery. Phrenic nerve paralysis is a potential complication of cardiac surgery that may also contribute to impaired ventilation and gas exchange.

- Evaluate respiratory rate, depth, effort, symmetry of chest expansion, and breath sounds frequently. *Pain, anxiety, excess fluid volume, surgical injury, narcotics and anesthesia, and altered homeostasis can affect respiratory rate, depth, and effort postoperatively. Decreased chest expansion or asymmetrical movement may indicate impaired ventilation of one lung, and needs further evaluation.*
- Note endotracheal tube (ETT) placement on chest x-ray. Mark tube position and secure in place. Insert an oral airway if an oral ETT is used. *The chest x-ray documents correct ETT placement above the bifurcation to the right and left mainstem bronchus. Marking its appropriate placement allows evaluation of potential tube movement. Secure the tube firmly in place to prevent slippage or inadvertent removal. An oral airway helps prevent obstruction of an oral ETT by biting.*
- Maintain ventilator settings as ordered. Monitor arterial blood gases (ABGs) as ordered. *Mechanical ventilation promotes optimal lung expansion and oxygenation postoperatively. ABGs are used to evaluate oxygenation and acid–base balance.*
- Suction as needed. *Suctioning is performed only as indicated to clear airway secretions.*
- Prepare for ventilator weaning and extubation, as appropriate. *The patient is removed from the ventilator and extubated as soon as possible to reduce complications associated with mechanical ventilation and intubation.*
- After extubation, teach use of the incentive spirometer, and encourage use every 2 hours. Encourage deep breathing; advise against vigorous coughing. Teach use of a cough pillow to splint chest incision and decrease pain. Frequently turn and encourage movement. Dangle on postoperative day 1. *Deep breathing, controlled coughing, and position changes improve ventilation and airway clearance and help prevent complications. Vigorous coughing may excessively increase intrathoracic pressure and cause sternal instability.*

Risk for Infection

Following an open-chest procedure, a sternal infection may develop that can progress to involve the mediastinum. Incisions for removal of the saphenous vein also may become infected. Patients with IMA grafts, who are diabetic, older, or malnourished are at high risk: Harvesting of IMA disrupts blood supply to the sternum, and these patients have impaired immune responses and healing.

- Assess sternal incision and leg wounds every shift. Document redness, warmth, swelling, and/or drainage from the site. Note wound approximation. *These assessments provide indicators of inflammation and healing.*
- Maintain a sterile dressing for the first 48 hours, and then leave the incision open to air. Use Steri-Strips as needed to maintain approximation of the wound edges. *The sterile dressing prevents early contamination of the wound, whereas exposing the incision after 48 hours promotes healing.*
- Report signs of wound infection: a swollen, reddened area that is hot and painful to the touch, drainage from the wound, impaired healing, or healed areas that reopen. *Evidence of infection or impaired healing requires further evaluation and treatment.*
- Culture wound drainage as indicated. *Identifying the infective organism facilitates the choosing of appropriate antibiotic therapy.*
- Collaborate with the dietitian to promote nutrition and fluid intake. *Good nutritional status is vital to healing and immune function.*

Disturbed Thought Processes

Many factors affect neuropsychologic function after CABG, including the length of cardiopulmonary bypass, age, presurgery organic brain dysfunction, severity of illness, and decreased cardiac output. Sensory overload and deprivation, sleep disruption, and numerous drugs also affect thinking and mental clarity.

- Frequently reorient during initial recovery period. State that surgery is over and that the patient is in the recovery area. *Frequent reorientation provides emotional support and reality checks.*
- Explain all procedures before performing them. Speak in a clear, calm voice. Encourage questions, and give honest answers. *These measures provide information, decrease anxiety, and establish trust.*
- Secure all intravenous lines and invasive catheters/tubes (e.g., ETT, Foley catheter, nasogastric tube). *Disoriented patients may tug or pull at invasive equipment, disrupting them and increasing the risk of injury.*
- Note verbal responses to questions. Correct misconceptions immediately (e.g., "Mr. Snow, look at all the special equipment in this room. Does this room look like your bedroom at home?"). *Helping the patient recognize differences in the hospital environment offers a basis for continual reality checks.*
- Maintain a calendar and clock within the patient's view. *This provides current information regarding day, date, and time.*
- Involve family members in providing reorientation. Place familiar objects and photographs within view. Encourage family presence. *The family provides reassurance and contact with the familiar, assisting with orientation.*
- Promote patient participation in care and decision making as appropriate. *This allows the patient to maintain a degree of power and control and enables the patient to take an active role in recovery.*
- Report signs of hallucinations, delusions, depression, or agitation. *These may indicate progressive deterioration of mental status.*
- Administer sedatives cautiously. *Mild sedation may help prevent injury. Some sedatives may, however, have adverse effects, increasing confusion and disorientation.*
- Reevaluate neurologic status every shift. *These data allow evaluation of the effect of interventions.*

CASE STUDY & NURSING CARE PLAN A Patient with Coronary Artery Bypass Surgery

Six weeks ago, John Clements, age 50, was discharged from the hospital after emergency triple bypass surgery. Despite having emergency surgery, his postoperative recovery was uneventful, and he was discharged 6 days after admission. He returns to the clinic for a postoperative stress test and to discuss his cardiac rehabilitation program. Anne Wagner, RN, CNS, a cardiac clinical nurse specialist and the program coordinator, meets Mr. Clements to obtain specific information regarding his medical status.

ASSESSMENT

Mr. Clements's medical history reveals significant CHD, an anterior wall myocardial infarction that led to his emergency triple bypass, and hyperlipidemia. Current medications include Cardizem, Isordil, Ecotrin, and Transderm Nitro 5. The ECG reveals sinus rhythm with some ST-segment and T-wave flattening. Resting heart rate 68 bpm, and blood pressure 136/84 mmHg.

Mr. Clements has a strong family history of CHD. He does not smoke, but does use alcohol occasionally in social situations. He enjoys "good Southern-style cooking" and watching television. Mr. Clements states his only regular exercise used to be an evening of dancing with his wife and friends about once a month, "But I get short of breath walking around the block now, so I guess I can't go dancing anymore!"

Mr. Clements owns his own contracting business and states that he typically works about 50 to 60 hours per week. He tells Ms. Wagner, "I don't know what this program is supposed to do for me. I have got to get back to work! You just can't sit around in my business—you have to make sure that the work is getting done on time, and you have to check on supplies and equipment and the like. But I feel like a weakling—I need to get my energy back!"

DIAGNOSES

- *Activity Intolerance* related to general weakness and fatigue
- *Ineffective Role Performance* related to health crisis

EXPECTED OUTCOMES

- Patient will verbalize an understanding of the definition and components of his structured cardiac rehabilitation program.
- Patient will verbalize a desire to make lifestyle changes.
- Patient will identify resources available in the community to assist with lifestyle changes.
- Patient will participate in his activity program without suffering any complications.
- Patient will verbalize an increase in energy after 6 weeks on the program.
- Patient will accept the reality of the temporary change in his usual work responsibilities.

PLANNING AND IMPLEMENTATION

- Define the purpose and components of a cardiac rehabilitation program.
- Enroll in "heart health" classes, including cardiac anatomy, physiology, and coronary heart disease; exercise and activity prescriptions; lifestyle modifications, including diet counseling and stress management; emotional reactions to CAD; sexual activity; use of cardiac medications; and self-responsibility for health.
- Plan an exercise program based on stress test results, physical examination, and interview.
- Encourage to schedule rest periods before and after activity/exercise.
- Review signs and symptoms of overexertion.
- Provide information about community resources for emotional and educational support.
- Assist to identify strategies for dealing with concerns about his business role.

EVALUATION

Mr. Clements decides to "give the rehab program a try." Ms. Wagner and an exercise physiologist work with him to plan an individualized exercise/activity program. A registered dietitian provides dietary counseling. Ms. Wagner emphasizes stress management strategies. Mr. Clements is able to list manifestations of overexertion and states that he realizes the need for gradual activity progression.

After 6 weeks, Mr. Clements has reported a significant increase in energy and strength. "I am feeling much stronger, and have been sleeping better. Mary and I are taking evening walks around the neighborhood. My chest soreness is also gone." He has completed the 12-week cardiac rehabilitation program, and another stress test indicates that his cardiac function is adequate. Mr. Clements has joined the local Mended Hearts support group and states that he is now incorporating heart-healthy considerations into his daily routines.

Clinical Reasoning in Patient Care

1. Develop a personalized risk factor reduction plan for Mr. Clements.
2. How might denial affect Mr. Clements's ability to (a) accept the need for cardiac rehabilitation, (b) comply with the proposed lifestyle changes, and (c) make permanent adjustments to his daily life?
3. How does spousal support influence a patient's compliance with a structured cardiac rehabilitation program?
4. Mr. Clements tells you that since the surgery, his wife has been afraid that sexual activity will induce another heart attack. How would you respond to these concerns?

See Evaluating Your Response in Appendix B.

The necrotic, infarcted tissue is surrounded by regions of injured and ischemic tissues. Tissue in the ischemic area is potentially viable; restoration of blood flow minimizes the amount of tissue lost. The surrounding tissue also undergoes metabolic changes. It may be *stunned*, its contractility impaired for hours to days following reperfusion, or *hibernating*, a process that protects myocytes until perfusion is restored. *Myocardial remodeling* may occur, with cellular hypertrophy and loss of contractility in regions distant from the infarction. Rapid restoration of blood flow limits these changes (Huether & McCance, 2011).

When a larger artery is compromised, collateral vessels connecting smaller arteries in the coronary system dilate to maintain blood flow to the cardiac muscle. The degree of collateral circulation helps determine the extent of myocardial damage from ischemia. Acute occlusion of a coronary artery without any collateral flow results in massive tissue damage and possible death. Progressive narrowing of the larger coronary arteries allows collateral vessels to develop and enlarge, meeting the demand for blood flow. Good collateral circulation can limit the size of an MI.

MI usually affects the left ventricle because it is the major workhorse of the heart; its muscle mass is greater, as are its oxygen demands.

MIs are described by the damaged area of the heart. The coronary artery that is occluded determines the area of damage. Occlusion of the left anterior descending (LAD) artery affects blood flow to the anterior wall of the left ventricle (an anterior MI) and part of the interventricular septum. Occlusion of the left circumflex artery (LCA) causes a lateral MI. Right ventricular, inferior, and posterior infarcts involve occlusions of the right coronary artery (RCA) and posterior descending artery (PDA). Occlusion of the left main coronary artery

Meeting Individualized Needs

Recognizing a Myocardial Infarction in Women and Older Adults

Women and older adults often present with atypical manifestations of MI. However, heart disease is the number one cause of death in both groups, making early recognition and aggressive treatment vital.

Women are more likely than men to have a silent or unrecognized heart attack, or to present in cardiac arrest or with cardiogenic shock. Women often experience epigastric pain and nausea, causing them to blame their discomfort on heartburn. Shortness of breath is common, as is fatigue and weakness of the shoulders and upper arms.

Older people often seek treatment for vague complaints of difficulty breathing, confusion, fainting, dizziness, abdominal pain, or cough. They often attribute their symptoms to a stroke. The prevalence of silent ischemia is greater in older adults.

Stress the importance of seeking medical help promptly for atypical manifestations of MI. Prompt diagnosis and intervention reduce the mortality and morbidity of MI in women and older adults, just as they do in men. Despite this fact, both women and older adults are more likely to delay seeking treatment and are less likely to be accurately diagnosed and aggressively treated for CHD. Younger women are a particularly important group to reach; their mortality rate when MI occurs is twice that of men.

is the most devastating, causing ischemia of the entire left ventricle, and a grave prognosis. Identifying the infarct site helps predict possible complications and determine appropriate therapy.

COCAINE-INDUCED MI

AMI may develop due to cocaine intoxication. Cocaine increases SNS activity by both increasing the release of catecholamines from central and peripheral stores and interfering with the reuptake of catecholamines. This increased catecholamine concentration stimulates the heart rate and increases its contractility, increases the automaticity of cardiac tissues and the risk of dysrhythmias, and causes vasoconstriction and hypertension. The patient with cocaine-induced MI may present with an altered level of consciousness, confusion and restlessness, seizure activity, tachycardia, hypotension, increased respiratory rate, and respiratory crackles.

Manifestations

Pain is a classic manifestation of MI. Chest pain due to MI is more severe than anginal pain. However, it is not the intensity of the chest pain that distinguishes MI from angina or acute coronary syndrome, but its duration and its continuous nature. The onset of pain is sudden and usually is not associated with activity. In fact, most MIs occur in the early morning. Patients with a history of angina may have more frequent anginal attacks in the days or weeks prior to an MI (unstable angina or ACS). Chest pain may be described as crushing and severe; as a pressure, heavy, or squeezing sensation; or as chest tightness or burning. The pain often begins in the center of the chest (*substernal*), and may radiate to the shoulders, neck, jaw, or arms. It lasts more than 15 to 20 minutes and is not relieved by rest or nitroglycerin.

Women and older adults often experience atypical chest pain, presenting with complaints of indigestion, heartburn, nausea, and vomiting (see the accompanying box). Up to 25% of patients with AMI deny chest discomfort (Woods et al., 2009).

Compensatory mechanisms cause many of the other symptoms of MI. SNS stimulation causes anxiety, tachycardia, and vasoconstriction, producing cool, clammy, mottled skin. Pain and blood chemistry changes stimulate the respiratory center, causing tachypnea. The patient often has a sense of impending doom and death. Tissue necrosis causes an inflammatory reaction that increases the white blood cell (WBC) count and elevates the temperature. Serum cardiac enzyme levels rise as enzymes are released from necrotic cardiac cells.

Other manifestations may vary, depending on the location and amount of infarcted tissue. Hypertension, hypotension, or signs of heart failure may develop. Vagal stimulation may cause nausea and vomiting, bradycardia, and hypotension. Hiccupping may develop due to diaphragmatic irritation. If a large vessel is occluded, the first sign of MI may be sudden death. Typical manifestations of MI are listed in an accompanying box.

Complications

The risk of complications associated with MI is related to its size and location.

DYSRHYTHMIAS

Dysrhythmias, disturbances or irregularities of heart rhythm, are the most frequent complication of MI. Dysrhythmias are discussed in detail in the next section of this chapter.

Infarcted tissue is *arrhythmogenic*; that is, it alters the generation and conduction of electrical impulses in the heart, increasing the risk of dysrhythmias. Premature ventricular contractions (PVCs) are common following an MI, developing in more than 90% of patients with an AMI. Although not dangerous in themselves, they may be predictive of more dangerous dysrhythmias such as ventricular tachycardia or ventricular fibrillation. Ventricular fibrillation (VF) is a frequent cause of sudden cardiac death. The risk of VF is greatest in the first hour after MI, declining with time. Infarction around a conduction pathway will affect electrical conduction. Atrioventricular (AV) block may occur following anterior wall infarction. First-degree and Mobitz I (Wenckebach) blocks are most common, although complete heart block can occur. Bradydysrhythmias (abnormal slow rhythms) may develop when the inferior wall of the ventricle is affected.

MANIFESTATIONS OF ACUTE MYOCARDIAL INFARCTION

- Chest pain: substernal or precordial (across the entire chest wall); may radiate to neck, jaw, shoulder(s), or left arm
- Tachycardia, tachypnea
- Dyspnea, shortness of breath
- Nausea and vomiting
- Anxiety, sense of impending doom
- Diaphoresis
- Cool, mottled skin; diminished peripheral pulses
- Hypotension or hypertension
- Palpitations, dysrhythmias
- Signs of left heart failure
- Decreased level of consciousness

Moving Evidence into Action

Women Following Myocardial Infarction

CHD is the leading killer of women in the United States. The risk of death and disability resulting from AMI is higher in women than in men. Part of the problem is the vague symptomatology and warning signs of AMI in women. Sleep disturbances may be one such warning sign.

Cole and colleagues (2012) described the prevalence and related factors of pre-AMI sleep disturbances reported by women. A secondary analysis of 1270 women who experienced AMI found that 672 (50.2%) of those respondents reported new or worsening sleep disturbance before the MI occurred. Although the sleep disturbances were similar across racial groups, these changes were more prevalent in older ($p < 0.03$), heavier ($p < 0.001$) women. Other related warning signs were determined using logistic regression and included reported severe cognitive changes (adjusted odds ratio: 2.69), new or increasing anxiety (2.21), and unusual fatigue (2.16). Other significant symptoms and comorbid conditions included leg pain, arm ache, back pain, headache, and/or gastroesophageal reflux disease (GERD).

Implications for Nursing

This study describes the possible relationship between sleep disturbance prior to AMI in women.

It is important for nurses to understand the vague symptoms and complaints that may occur prior to AMI in women. With the findings of this study, nursing assessment, patient education, and interventions that focus on alternative symptoms that occur in women related to this life-threatening event may be developed and used. It is important for the nurse to focus on the individual patient's reported symptoms because these symptoms are very individualized. The authors caution that this retrospective report may be subject to recall bias and that the data did not address the presence of sleep disorders such as sleep apnea or restless leg syndrome.

Moving Knowledge into Action

1. Why do women report different AMI symptoms than men?
2. Identify some health history questions the nurse might ask that address vague or uncommon symptoms that are related to AMI in women.
3. Identify patient education topics to address the lack of reporting of vague and uncommon symptoms that are related to AMI in women.

PUMP FAILURE

MI reduces myocardial contractility, ventricular wall motion, and compliance. Impaired contractility and filling may produce heart failure. The risk of heart failure is greatest when large portions of the left ventricle are infarcted. Severity of heart failure is dependent on the location and amount of myocardial damage. Anterior infarcts, affecting the left ventricle, result in more severe failure. Loss of 20% to 30% of the left ventricular muscle mass may cause manifestations of left-sided heart failure, including dyspnea, fatigue, weakness, and respiratory crackles on auscultation. Inferior or right ventricular MI may lead to right-sided heart failure with manifestations such as neck vein distention and peripheral edema. Hemodynamic monitoring is often initiated for patients with evidence of heart failure. Heart failure and its manifestations are discussed in greater depth in Chapter 31.

CARDIOGENIC SHOCK *Cardiogenic shock*, impaired tissue perfusion due to pump failure, results when functioning myocardial muscle mass decreases by more than 40%. The heart is unable to pump enough blood to meet the needs of the body and maintain organ function. Low cardiac output due to cardiogenic shock also impairs perfusion of the coronary arteries and myocardium, further increasing tissue damage. Mortality from cardiogenic shock is greater than 70%, although this can be reduced by prompt intervention with revascularization procedures. Refer to Chapter 11 for a more extensive discussion of cardiogenic shock.

INFARCT EXTENSION

Approximately 10% of patients experience extension or reinfarction in the area of the original infarction during the first 10 to 14 days after an MI. Extension of the MI is characterized by increased myocardial necrosis from continued blood flow impairment and ongoing injury. Expansion of the MI is described as a permanent expansion of the infarcted area from thinning and dilation of the muscle. Infarct extension and expansion may cause manifestations such as continuing chest pain, hemodynamic compromise, and worsening heart failure.

STRUCTURAL DEFECTS

Necrotic muscle is replaced by scar tissue that is thinner than the ventricular muscle mass. This can lead to such complications as ventricular aneurysm, rupture of the interventricular septum or papillary muscle, and myocardial rupture. A *ventricular aneurysm* is an outpouching of the ventricular wall. It may develop when a large section of the ventricle is replaced by scar tissue. Because it does not contract during systole, stroke volume decreases. Blood may pool within the aneurysm, causing clots to form. Ischemia of the papillary muscle or chordae tendineae may cause structural damage leading to papillary muscle dysfunction or rupture. Impaired AV valve function (usually the mitral valve) causes *regurgitation*, backflow of blood into the atria during systole. The interventricular septum may perforate or rupture due to ischemia and infarction. Myocardial rupture is a risk between days 4 and 7 after MI, when the injured tissue is soft and weak. This potential complication of MI is often fatal.

PERICARDITIS

Tissue necrosis prompts an inflammatory response. *Pericarditis*, inflammation of the pericardial tissue surrounding the heart, may complicate AMI, usually within 2 to 3 days. Pericarditis causes chest pain that may be aching or sharp and stabbing, aggravated by movement or deep breathing. A *pericardial friction rub* may be heard on auscultation of heart sounds.

Dressler's syndrome, thought to be a hypersensitivity response to necrotic tissue or an autoimmune disorder, may develop days to weeks after AMI. It is a symptom complex characterized by fever, chest pain, and dyspnea. Dressler's syndrome may spontaneously resolve or recur over several months, causing significant discomfort and distress.

FAST FACTS

- Dysrhythmias are the most common complication of AMI.
- Heart failure also is a common complication or consequence of myocardial infarction, developing due to loss of functional muscle tissue.

●○● INTERPROFESSIONAL CARE

Immediate treatment goals for the MI patient are as follows:

- Relieve chest pain.
- Reduce the extent of myocardial damage.
- Maintain cardiovascular stability.
- Decrease cardiac workload.
- Prevent complications.

Slowing the process of CHD and reducing the risk of future MI is a major long-term management goal for the patient.

Rapid assessment and early diagnosis are important in treating AMI. "Time is muscle" is a medical truism for the patient with AMI. The evolution of an AMI is dynamic: The quicker the artery is reopened (medically, surgically, or spontaneously), the more myocardium can be salvaged. Survival and long-term outcomes following AMI are improved by rapidly restoring blood flow to the "stunned" myocardium surrounding the infracted tissue, reducing myocardial oxygen demand and limiting the accumulation of toxic by-products of necrosis and reperfusion. The AHA recommends initiation of definitive treatment within 1 hour of entry into the healthcare system as every minute of delay in treating patients with AMI affects the mortality risk during the first year.

The major problem interfering with timely reperfusion is delay in seeking medical care following the onset of symptoms. Up to 44% of patients with symptoms of chest discomfort or pain wait more than 4 hours before seeking treatment. Many factors are cited as reasons for treatment delay, including advanced age, the perception of the seriousness of symptoms, denial, access to medical care, the availability of an emergency response system, and in-hospital delays. Immediate evaluation of the patient presenting with manifestations of myocardial infarction is essential to early diagnosis and treatment.

DIAGNOSIS

Diagnostic testing is used to establish the diagnosis of AMI.

Serum cardiac markers are proteins released from necrotic heart muscle. The proteins most specific for diagnosis of MI are the creatine kinase (CK, or creatine phosphokinase, CPK) and cardiac-specific troponins (Table 30–6).

- *Creatine kinase* is an important enzyme for cellular function found principally in cardiac and skeletal muscle and the brain. CK levels rise rapidly with damage to these tissues, appearing in the serum 4 to 6 hours after AMI, peaking within 12 to 24 hours, and then declining during the next 48 to 72 hours. The CK level correlates with the size of the infarction; the greater the amount of infarcted tissue, the higher the serum CK level.
- *CK-MB* (also called *MB-bands*) is a subset of CK specific to cardiac muscle. This isoenzyme of CK is considered the most sensitive indicator of MI. Elevated CK alone is not specific for MI; elevated CK-MB greater than 5% is considered a positive indicator of MI. CK-MB levels do not normally rise with chest pain from angina or causes other than MI.
- Cardiac muscle troponins, *cardiac-specific troponin T (cT_nT)* and *cardiac-specific troponin I (cT_nI)*, are proteins released during myocardial infarction that are sensitive indicators of myocardial damage. These proteins are part of the actin-myosin unit in cardiac muscle and normally are not detectable in the blood. With necrosis of cardiac muscle, troponins are released and blood levels rise. The specificity of cT_nT and cT_nI to cardiac muscle necrosis makes these markers particularly useful when skeletal muscle trauma contributes to elevated CK levels (e.g., when CPR has been performed or traumatic injury occurred at the time of the MI). They are sensitive enough to detect very small infarctions that do not cause significant CK elevation. Both cT_nT and cT_nI remain in the blood for 10 to 14 days after an MI, making them useful for diagnosing MI when medical treatment is delayed.

Serum levels of cardiac markers are ordered on admission and for 3 succeeding days. Serial blood levels help establish the diagnosis and determine the extent of myocardial damage.

Other laboratory tests may include the following:

- *Myoglobin* is one of the first cardiac markers to be detectable in the blood after an MI. It is released within a few hours of symptom onset. Its lack of specificity to cardiac muscle and rapid excretion (blood levels return to normal within 24 hours) limit its use (Perrin & MacLeod, 2012).
- *Complete blood count (CBC)* shows an elevated WBC count due to inflammation of the injured myocardium. The *erythrocyte sedimentation rate (ESR)* also rises because of inflammation.
- *Arterial blood gases (ABGs)* may be ordered to assess blood oxygen levels and acid–base balance.

Electrocardiography, echocardiography, and myocardial nuclear scans are the most common diagnostic tests performed when AMI is suspected. With the exception of the ECG, the timing of these tests depends on the patient's immediate condition. Hemodynamic monitoring may be initiated in the unstable patient following MI.

TABLE 30–6 Cardiac Markers

				Changes Occurring with MI		
Marker	**Normal Level**	**Primary Tissue Location**	**Significance of Elevation**	**Appears**	**Peaks**	**Duration**
CK (CPK)	Male: 12–80 units/L Female: 10–70 units/L	Cardiac muscle, skeletal muscle, brain	Injury to muscle cells	3–6 h	12–24 h	24–48 h
CK-MB	0%–3% of total CK	Cardiac muscle	MI, cardiac ischemia, myocarditis, cardiac contusion, defibrillation	4–8 h	18–24 h	72 h
cT_nT	< 0.2 mcg/L	Cardiac muscle	Acute MI, unstable angina	2–4 h	24–36 h	10–14 days
cT_nI	< 3.1 mcg/L	Cardiac muscle	Acute MI, unstable angina	2–4 h	24–36 h	7–10 days

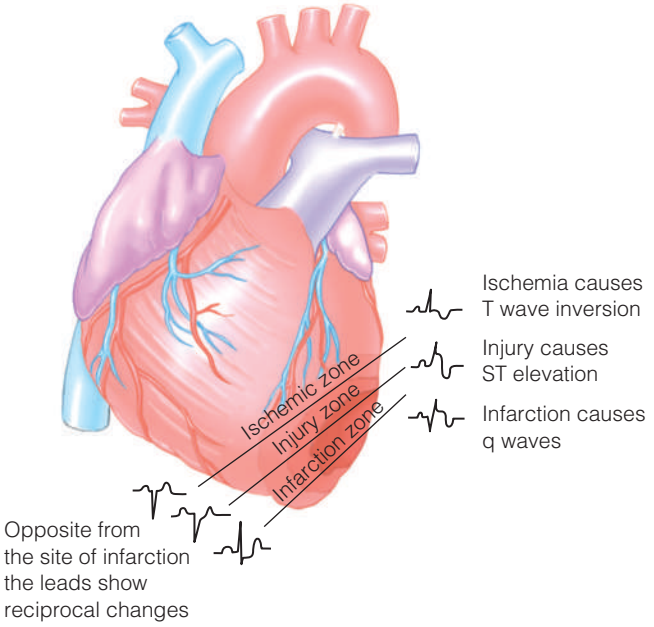

Figure 30–5 ■ ECG changes characteristic of MI.

- The *electrocardiogram* reflects changes in conduction due to myocardial ischemia and necrosis. Classic ECG changes seen in AMI include T-wave inversion, ST-segment elevation, and formation of a Q wave. Ischemic changes in the heart are seen as depression of the ST segment or inversion of the T wave (refer to Figure 30–2). With myocardial injury, elevation of the ST segment occurs (Figure 30–5 ■). Significant Q-wave development indicates a transmural, or full-thickness infarction. Myocardial damage can be localized using the 12-lead ECG. See Chapter 29 for more information about ECGs.
- *Echocardiography* is done to evaluate cardiac wall motion and left ventricular function. Stunned and infarcted tissue does not contract as effectively (if at all) as healthy myocardium.
- *Radionuclide imaging* studies may be done to evaluate myocardial perfusion. These studies cannot differentiate between an acute MI and old scar tissue, but do help identify the specific area of myocardial ischemia and damage.
- *Hemodynamic monitoring* may be initiated when AMI significantly affects cardiac output and hemodynamic status. These invasive procedures are described in Chapter 31.

MEDICATIONS

Aspirin, a platelet inhibitor, is now considered an essential part of AMI treatment. A 160- to 325-mg aspirin tablet is given by emergency personnel, with the instructions that it is to be chewed (for buccal absorption). This initial dose is followed by a daily oral dose of 160 to 325 mg of aspirin. Fibrinolytic agents, analgesics, and antidysrhythmic agents are among the principal classes of drugs used in treating AMI.

ANALGESIA Pain relief is vital in treating the patient with AMI. Pain stimulates the sympathetic nervous system, increasing the heart rate and blood pressure and, in turn, myocardial workload. Sublingual nitroglycerin may be given (up to three 0.4-mg doses at 5-minute intervals). Intravenous nitroglycerin may be continued for the first 24 to 48 hours to reduce myocardial work. In addition to pain relief, nitroglycerin decreases myocardial oxygen demand and may increase the supply of oxygen to the myocardium. Nitroglycerin is a peripheral and arterial vasodilator that reduces afterload. It dilates coronary arteries and collateral channels in the heart, increasing coronary blood flow to save myocardial tissue at risk. Nitrates may, however, cause reflex tachycardia or excessive hypotension, so close monitoring is necessary during administration. It also is important to ask the patient about use of sildenafil (Viagra) within the previous 24 hours before administering nitroglycerin, as the combination can precipitate a significant drop in blood pressure. See the Medication Administration box on page 881 for the nursing implications of nitroglycerin and other drugs given to reduce myocardial work following AMI.

Morphine sulfate is the drug of choice for pain unrelieved by nitroglycerin and for sedation. Following an initial intravenous dose of 4 to 8 mg, small doses (2 to 4 mg) may be repeated intravenously every 5 minutes until pain is relieved. It is important to assess frequently for pain relief and possible adverse effects of analgesia, such as excessive sedation. Pain unrelieved by expected or usual doses should be reported to the physician as it may indicate a complication such as extension of the infarct. Refer to Chapter 9 for more details about morphine administration. Antianxiety agents such as diazepam (Valium) may also be administered to promote rest.

FIBRINOLYTIC THERAPY Fibrinolytic agents, drugs that dissolve or break up blood clots, are first-line drugs used to treat acute MI when access to a cardiac catheterization lab for revascularization procedures is not immediately available. Fibrinolytic drugs activate the fibrinolytic system to *lyse* or destroy the clot, restoring blood flow to the obstructed artery. Early fibrinolytic administration (within the first 6 hours of MI onset) limits infarct size, reduces heart damage, and improves outcomes. Activation of the fibrinolytic system can cause multiple complications; approximately 0.5% to 5% of patients receiving fibrinolytic drugs experience serious bleeding complications. Not every patient is a candidate for fibrinolytic therapy; for example, it is contraindicated in patients with known bleeding disorders, history of cerebrovascular disease, uncontrolled hypertension, pregnancy, or recent trauma or surgery to the head or spine.

Several fibrinolytic agents are commonly used today. Among these, little difference in effectiveness has been demonstrated; there are, however, big differences in cost. Streptokinase, a biologic agent derived from group C *Streptococcus* organisms, is the least expensive of the drugs. Its primary drawback is the risk of a severe hypersensitivity reaction, including anaphylaxis. Streptokinase is administered by intravenous infusion. Anisoylated plasminogen-streptokinase activator complex (APSAC) is a related drug that can be administered by bolus over 2 to 5 minutes. It has many of the same effects as streptokinase, but is considerably more expensive. Tissue plasminogen activator (t-PA), tenecteplase (TNK), and reteplase (rPA) are more effective in reestablishing myocardial perfusion, especially when the pain developed more than 3 hours previously. These drugs, however, are the most expensive. Nursing care of the patient receiving a fibrinolytic agent is outlined on page 891.

ANTIDYSRHYTHMICS Dysrhythmias are a common complication of AMI, particularly in the first 12 to 24 hours. Antidysrhythmic medications are used as needed to treat dysrhythmias. They also may be given prophylactically to prevent dysrhythmias. Ventricular

dysrhythmias are treated with a Class I or Class III antidysrhythmic drug (see the Medication Administration box on page 906). Symptomatic bradycardia (bradycardia with associated hypotension and other signs of low cardiac output) is treated with intravenous atropine, 0.5 to 1 mg. Intravenous verapamil or the short-acting beta-blocker esmolol (Brevibloc) may be ordered to treat atrial fibrillation or other supraventricular tachydysrhythmias.

OTHER MEDICATIONS Beta-blockers such as propranolol (Inderal), atenolol (Tenormin), and metoprolol (Lopressor) reduce pain, limit infarct size, and decrease the incidence of serious ventricular dysrhythmias in AMI. These drugs decrease the heart rate, reducing cardiac work and myocardial oxygen demand. Initial doses are given intravenously. Oral beta-blocker therapy is continued to reduce the risk of reinfarction and death related to cardiovascular causes.

Angiotensin-converting enzyme (ACE) inhibitors also reduce mortality associated with AMI. These drugs reduce ventricular remodeling following an MI, reducing the risk for subsequent heart failure. They also may reduce the risk of reinfarction.

Anticoagulants and antiplatelet medications often are prescribed to maintain coronary artery patency following thrombolysis or a revascularization procedure. Abciximab (ReoPro) suppresses platelet aggregation and reduces the risk of reocclusion following angioplasty. It also improves vessel opening with fibrinolytic therapy, permitting lower doses of fibrinolytic drugs. Standard or low-molecular-weight heparin preparations often are given to patients with AMI. Heparin helps establish and maintain patency of the affected coronary artery. It also is used, along with long-term warfarin, to prevent systemic or pulmonary embolism in patients with significant left ventricular impairment or atrial fibrillation following AMI. See the Medication Administration box on page 881 for the nursing implications of antiplatelet drugs, and Chapter 34 for more information about anticoagulant therapy.

Patients with pump failure and hypotension may receive intravenous dopamine, a vasopressor. At low doses (less than 5 mg/kg/min), it improves blood flow to the kidneys, preventing renal ischemia and possible acute renal failure (refer to Chapter 28). With increasing doses, dopamine increases myocardial contractility and causes vasoconstriction, improving blood pressure and cardiac output.

Antilipemic agents are used for the patient with hyperlipidemia. A stool softener such as docusate sodium is prescribed to maintain normal bowel function and reduce straining.

TREATMENTS

The patient with a suspected or confirmed MI is monitored continuously. Care is provided in the intensive coronary care unit for the first

NURSING CARE OF THE PATIENT

Receiving Fibrinolytic Therapy

PREINFUSION CARE

- Obtain nursing history, and perform a physical assessment. *Information obtained from the history and physical exam helps determine whether fibrinolytic therapy is appropriate. The goal is to initiate fibrinolytic therapy within 30 minutes of arrival.*
- Evaluate for contraindications to fibrinolytic therapy: recent surgery or trauma (including prolonged CPR), bleeding disorders or active bleeding, cerebrovascular accident, neurosurgery within the last 2 months, gastrointestinal ulcers, diabetic hemorrhagic retinopathy, and uncontrolled hypertension. *Fibrinolytic agents dissolve clots and therefore may precipitate intracranial, internal, or peripheral bleeding.*
- Inform the patient of the purpose of the therapy. Discuss the risk of bleeding and the need to keep the extremity immobile during and after the infusion. *Minimal movement of the extremity is necessary to prevent bleeding from the infusion site.*

DURING THE INFUSION

- Assess and record vital signs and the infusion site for hematoma or bleeding every 15 minutes for the first hour, every 30 minutes for the next 2 hours, and then hourly until the intravenous catheter is discontinued. Assess pulses, color, sensation, and temperature of both extremities with each vital sign check. *Vital signs and the site are frequently assessed to detect possible complications.*
- Remind the patient to keep the extremity still and straight. Do not elevate head of bed above 15 degrees. *Extremity immobilization helps prevent infusion site trauma and bleeding. Hypotension may develop; keeping the bed flat helps maintain cerebral perfusion.*
- Maintain continuous cardiac monitoring during the infusion. Keep antidysrhythmic drugs and the emergency cart readily available for treatment of significant dysrhythmias. *Ventricular dysrhythmias commonly occur with reperfusion of the ischemic myocardium.*

POSTINFUSION CARE

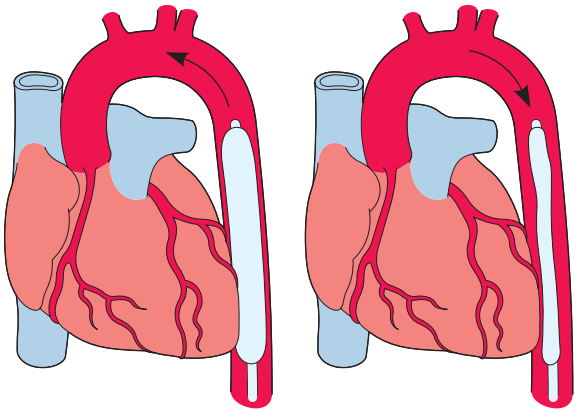
- Assess vital signs, distal pulses, and infusion site frequently as needed. *The patient remains at high risk for bleeding following fibrinolytic therapy.*
- Evaluate response to therapy: normalization of ST segment, relief of chest pain, reperfusion dysrhythmias, and early peaking of the CK and CK-MB levels. *These are signs that the clot has been dissolved and the myocardium is being reperfused.*
- Maintain bed rest for 6 hours. Keep the head of the bed at or below 15 degrees. Reinforce the need to keep the extremity straight and immobile. Avoid any injections for 24 hours after catheter removal. *Precautions such as these are important to prevent bleeding.*
- Assess puncture sites for bleeding. On catheter removal hold direct pressure over the site for at least 30 minutes. Apply a pressure dressing to any venous or arterial sites as needed. Perform routine care in a gentle manner to avoid bruising or injury. *Fibrinolytic therapy disrupts normal coagulation. Peripheral bleeding may occur at puncture sites, and there may not be sufficient fibrin to form a clot. Direct or indirect pressure may be needed to control the bleeding.*
- Assess body fluids, including urine, vomitus, and feces, for evidence of bleeding; frequently assess for changes in level of consciousness and manifestations of increased intracranial pressure, which may indicate intracranial bleeding. Assess surgical sites for bleeding. Monitor hemoglobin and hematocrit levels, prothrombin time (PT), and partial thromboplastin time (PTT). *These provide additional means of assessing for bleeding.*
- Administer platelet-modifying drugs (e.g., aspirin, dipyridamole) as ordered. *Platelet inhibitors decrease platelet aggregation and adhesion and are used to prevent reocclusion of the artery.*
- Report manifestations of reocclusion, including changes in the ST segment, chest pain, or dysrhythmias. *Early recognition of reocclusion is vital to save myocardial tissue.*

24 to 48 hours, after which time less intensive monitoring (e.g., telemetry) may be required. An intravenous line is established to allow rapid administration of emergency medications.

Bed rest is prescribed for the first 12 hours to reduce the cardiac workload. The bedside commode generally is allowed; studies have shown this to be less stressful than using a bedpan. If the patient's condition is stable, sitting in a chair at the bedside is permitted after 12 hours. Activities are gradually increased as tolerated. A quiet, calm environment with limited outside stimuli is preferred. Visitors are limited to promote rest. Oxygen is administered by nasal cannula at 2 to 5 L/min to improve oxygenation of the myocardium and other tissues.

A liquid diet may be prescribed for the first 4 to 12 hours to reduce gastric distention and myocardial work. Following that, a low-fat, low-cholesterol, reduced-sodium diet is allowed. Sodium restrictions may be lifted after 2 to 3 days if no evidence of heart failure is present. Small, frequent feedings are often recommended. Drinks containing caffeine and very hot and cold foods may also be limited.

REVASCULARIZATION PROCEDURES



Many patients with AMI are treated with immediate or early percutaneous coronary revascularization (PCR) such as angioplasty and stent placement. PCR may follow fibrinolytic therapy or be used in place of fibrinolytic therapy to restore blood flow to ischemic myocardium. When compared with fibrinolytic therapy, prompt PCR reduces hospital mortality. In some cases, CABG surgery may be performed. The choice of procedure depends on the patient's age and immediate condition, the time elapsed from the onset of manifestations, and the extent of myocardial disease and damage. These procedures and related nursing care are covered in more depth in the preceding section on acute coronary syndrome.

OTHER INVASIVE PROCEDURES

For patients with large MIs and evidence of pump failure, invasive devices may be used to temporarily take over the function of the heart, allowing the injured myocardium to heal. The intra-aortic balloon pump is widely used to augment cardiac output. Ventricular assist devices are indicated for patients requiring more or longer term artificial support than the intra-aortic balloon pump provides.

INTRA-AORTIC BALLOON PUMP The *intra-aortic balloon pump (IABP)*, also called intra-aortic balloon counterpulsation, is a mechanical circulatory support device that may be used after cardiac surgery or to treat cardiogenic shock following AMI. The IABP temporarily supports cardiac function, allowing the heart gradually to recover by decreasing myocardial workload and oxygen demand and increasing perfusion of the coronary arteries.

A catheter with a 30- to 40-mL balloon is introduced into the aorta, usually via the femoral artery. The balloon catheter is connected to a console that regulates the inflation and deflation of the balloon. The IABP catheter inflates during diastole, increasing perfusion of the coronary and renal arteries, and deflates just prior to systole, decreasing afterload and cardiac workload (Figure 30–6 ■). The inflation–deflation sequence is triggered by the ECG pattern. During the most acute period, the balloon inflates and deflates with each heart beat (1:1 ratio), providing maximal assistance to the heart. As the patient's condition improves, the IABP is weaned to inflate–deflate at varying intervals (e.g., 1:2, 1:4, 1:8). This provides a continually decreasing amount of support as the heart muscle recovers. When mechanical assistance is no longer required, the IABP catheter is removed.

A Diastole **B** Systole

Figure 30–6 ■ The intra-aortic balloon pump. A, When inflated during diastole, the balloon supports cerebral, renal, and coronary artery perfusion. B, The balloon deflates during systole, so cardiac output is unimpeded.

VENTRICULAR ASSIST DEVICES Use of *ventricular assist devices (VADs)* to aid the failing heart is becoming more common with advances in technology. Whereas the IABP can supplement cardiac output by approximately 10% to 15%, the VAD temporarily takes partial or complete control of cardiac function, depending on the type of device. VADs may be used as temporary or complete assist devices in AMI and cardiogenic shock when there is a chance for recovery of normal heart function after a period of cardiac rest. The device also may be used as a bridge to heart transplant. Nursing care for the patient with a VAD is supportive and includes assessing hemodynamic status and for complications associated with the device. Patients with VAD are at considerable risk for infection; strict aseptic technique is used with all invasive catheters and dressing changes. Pneumonia also is a risk due to immobility and ventilatory support. Mechanical failure of the VAD is a life-threatening event that requires immediate intervention (Perrin & MacLeod, 2012).

CARDIAC REHABILITATION

Cardiac rehabilitation is a long-term program of medical evaluation, exercise, risk factor modification, education, and counseling designed to limit the physical and psychologic effects of cardiac illness and improve the patient's quality of life. Cardiac rehabilitation begins with admission for a cardiac event such as AMI or a revascularization procedure. Phase 1 of the program is the inpatient phase. A thorough assessment of the patient's history, current status, risk factors, and motivation is obtained. During this phase, activity progresses from bed rest to independent performance of activities of daily living (ADLs) and ambulation within the facility. Both subjective and objective responses to increasing activity levels are evaluated. Excess fatigue, shortness of breath, chest pain, tachypnea, tachycardia, or cool, clammy skin indicate activity intolerance. Phase 2, immediate outpatient cardiac rehabilitation, begins within 3 weeks of the cardiac event. The goals for the outpatient program are to increase activity level, participation, and capacity; improve psychosocial status and treat anxiety or depression; and provide education and support for

risk factor reduction. Continuation programs, phase 3 of cardiac rehabilitation, are directed at providing a transition to independent exercise and exercise maintenance. During this final phase, the patient may check in every 3 months for evaluation of risk factors, quality of life, and exercise habits.

●○● NURSING CARE

Nursing care of the patient with an acute myocardial infarction focuses on reducing cardiac work, identifying and treating complications in a timely manner, and preparing the patient for rehabilitation. See also the Case Study & Nursing Care Plan for a patient with an AMI.

Health Promotion

Health promotion activities to prevent AMI are those outlined for CHD and angina in previous sections of this chapter. In addition, discuss risk factor management, use of prescribed medications, and cardiac rehabilitation to reduce the risk of complications or future infarctions.

Assessment

Nursing assessment for the patient with AMI must be both timely and ongoing. Assessment data related to AMI includes the following:

- *Health history:* complaints of chest pain, including its location, intensity, character, radiation, and timing; associated symptoms such as nausea, heartburn, shortness of breath, and anxiety; treatment measures taken since onset of pain; past medical history, especially cardiac related; chronic diseases; current medications and any known allergies to medications; smoking history and use of recreational drugs and alcohol
- *Physical assessment:* general appearance including obvious signs of distress; vital signs; peripheral pulses; skin color, temperature, moisture; level of consciousness; heart and breath sounds; cardiac rhythm (on beside monitor); bowel sounds, abdominal tenderness.

Priorities of Care

Collaborating with the interprofessional team to ensure adequate treatment of the underlying process while providing care that supports the physical and psychologic responses to the acute cardiac event is a nursing priority.

Evidence for Nursing Care

The Patient with Acute Myocardial Infarction

Selected resources that nurses may find helpful when planning evidence-based nursing care follow.

- Dechant, L. M. (2012). UA/NSTEM: Are you following the latest guidelines? *Nursing 2012, 42*(9), 26–34.
- Leeper, B., Cyr, A., Lambert, C., & Martin, K. (2011). Acute coronary syndrome. *Critical Care Nursing Clinics of North America, 23*(4), 547–557.
- Metcalfe, M. (2012). Improving the safety of oxygen therapy in the treatment of acute myocardial infarctions. *International Emergency Nursing, 20*(2), 94–97.

Diagnoses, Outcomes, and Interventions

Priorities of nursing care include relieving chest pain, reducing cardiac work, and promoting oxygenation. Psychosocial support is especially important because an AMI can be devastating, bringing the patient face to face with his or her own mortality for the first time.

Acute Pain

Chest pain occurs when the oxygen supply to the heart muscle does not meet the demand. Pain is caused by myocardial ischemia, infarction, and reperfusion of an ischemic area following fibrinolytic therapy or emergent PTCA. Pain stimulates the sympathetic nervous system, increasing cardiac work. Pain relief is a priority of care for the patient with AMI.

Expected Outcome: Patient's post-event pain will be controlled as evidenced by patient self-report of adequate pain management and reduction in pain-related behaviors.

- Assess for verbal and nonverbal signs of pain. Document characteristics and the intensity of the pain, using a standard pain scale. Verify nonverbal indicators of pain with the patient. *Frequent, careful pain assessment allows early intervention to reduce the risk of further damage. Pain is a subjective experience; its expression may vary with location and intensity, previous experiences, and cultural and social background. Pain scales provide an objective tool for measuring pain and a way to assess pain relief or reduction.*
- Administer oxygen at 2 to 5 L/min per nasal cannula. *Supplemental oxygen increases oxygen supply to the myocardium, decreasing ischemia and pain.*
- Promote physical and psychologic rest. Provide information and emotional support. *Rest decreases cardiac workload and sympathetic nervous system stimulation, promoting comfort. Information and emotional support help decrease anxiety and provide psychologic rest.*
- Titrate intravenous nitroglycerin as ordered to relieve chest pain, maintaining a systolic blood pressure greater than 100 mmHg. *Nitroglycerin decreases chest pain by dilating peripheral vessels, reducing cardiac work, and dilating coronary vessels, including collateral channels, thus improving blood flow to ischemic tissue.*

SAFETY ALERT

Intravenous nitroglycerin causes peripheral vasodilation, which may lead to hypotension, reduced coronary blood flow, and tachycardia. Reduce the nitro flow rate and notify the physician if this occurs.

- Administer 2 to 4 mg morphine by intravenous push for chest pain as needed. *Morphine is an effective narcotic analgesic for chest pain. It decreases pain and anxiety, acts as a venodilator, and decreases the respiratory rate. The resulting reduction in preload and SNS stimulation reduces cardiac work and oxygen consumption.*

PRACTICE ALERT!

Reassess for relief of chest pain. The goal of care is to achieve pain relief, not simply a reduction in pain to a manageable level.

Ineffective Tissue Perfusion

Cardiac muscle damage affects its compliance, contractility, and the cardiac output. The extent of the effect on tissue perfusion depends

on the location and amount of damage. Anterior wall infarcts have a greater effect on cardiac output than do right ventricular infarcts. Infarcted muscle increases the risk for cardiac dysrhythmias, affecting the delivery of blood and oxygen to the tissues.

Expected Outcome: Patient will exhibit adequate cardiac perfusion as evidenced by freedom from chest pain related to angina and freedom from arrhythmias.

- Assess and document vital signs. Report increases in heart rate and changes in rhythm, blood pressure, and respiratory rate. *Decreased cardiac output activates compensatory mechanisms that may cause tachycardia and vasoconstriction, increasing cardiac work.*
- Assess for changes in level of consciousness (LOC); decreased urine output; moist, cool, pale, mottled, or cyanotic skin; dusky or cyanotic mucous membranes and nail beds; diminished/absent peripheral pulses; and delayed capillary refill. *These are manifestations of impaired tissue perfusion. A change in LOC is often the first manifestation of altered perfusion because brain tissue and cerebral function depend on a continuous supply of oxygen.*
- Auscultate heart and breath sounds. Note abnormal heart sounds (e.g., an S_3 or S_4 gallop or a murmur) or adventitious lung sounds. *Abnormal heart sounds or adventitious lung sounds may indicate impaired cardiac filling or output, increasing the risk for decreased tissue perfusion.*
- Monitor ECG rhythm continuously. *Dysrhythmias can further impair cardiac output and tissue perfusion.*
  - Obtain a 12-lead ECG to assess complaints of chest pain. Report marked changes to the physician. Continued or unrelieved chest pain may indicate further myocardial ischemia and extension of the infarct; an ECG during episodes of chest pain provides a valuable diagnostic tool to assess myocardial perfusion.
- Monitor oxygen saturation levels. Administer oxygen as ordered. Obtain and assess ABGs as indicated. *Oxygen saturation is an indicator of gas exchange, tissue perfusion, and the effectiveness of oxygen administration. ABGs provide a more precise measurement of blood oxygen levels and allow assessment of acid–base balance.*
- Administer antidysrhythmic medications as needed. *Dysrhythmias affect tissue perfusion by altering cardiac output.*
- Obtain serial CK, isoenzyme, and troponin levels as ordered. *Levels of cardiac markers, CK isoenzymes in particular, correlate with the extent of myocardial damage.*
- Plan for invasive hemodynamic monitoring. *Hemodynamic monitoring facilitates AMI management and treatment evaluation by providing a means of assessing pressures in the systemic and pulmonary arteries, the relationship between oxygen supply and demand, cardiac output, and cardiac index.*

SAFETY ALERT

Continuously evaluate the response to interventions such as fibrinolytic therapy, drugs to improve cardiac output and tissue perfusion, and drugs to reduce cardiac work. Adverse effects of therapy may reduce the effectiveness of treatment. Bleeding due to fibrinolytic therapy may affect vascular volume and cardiac output; reperfusion dysrhythmias may affect cardiac output. Drugs used to improve cardiac output may increase cardiac work, whereas those given to reduce cardiac work may significantly affect contractility and cardiac output.

Ineffective Coping

Coping mechanisms help an individual deal with a life-threatening event or with acute changes in health. However, certain coping mechanisms may be detrimental to restoring health, particularly if the patient relies on them for a prolonged period. Denial, for example, is a common coping mechanism among post-MI patients. In the initial stages, denial can reduce anxiety. Continued denial, however, can interfere with learning and compliance with treatment.

Expected Outcome: Patient will use effective coping behaviors as evidenced by decreased report of stress symptoms and verbalization and utilization of positive coping behaviors.

- Establish an environment of caring and trust. Encourage the patient to express feelings. *Establishing a trusting nurse–patient relationship provides a safe environment for the patient to discuss feelings of helplessness, powerlessness, anxiety, and hopelessness. The nurse may then be able to provide additional resources to meet the patient's needs.*
- Accept denial as a coping mechanism, but do not reinforce it. *Denial may initially help by diminishing the psychologic threat to health, decreasing anxiety. However, its prolonged use can interfere with acceptance of reality and cooperation, possibly delaying treatment and hindering recovery.*
- Note aggressive behaviors, hostility, or anger. Document any failure to comply with treatments. *These signs can indicate anxiety and denial.*
- Help the patient identify positive coping skills used in the past (e.g., problem-solving skills, verbalization of feelings, asking for help, prayer). Reinforce use of positive coping behaviors. *Coping behaviors that have been successful in the past can help the patient deal with the current situation. These familiar methods can decrease feelings of powerlessness.*
- Provide opportunities for the patient to make decisions about the plan of care, as possible. *This promotes self-confidence and independence. Participating in care planning gives the patient a sense of control and the opportunity to use positive coping skills.*
- Provide privacy for the patient and significant other to share their questions and concerns. *Privacy provides an opportunity for the patient and partner to share their feelings and fears, offer support and encouragement to one another, relieve anxiety, and establish effective coping methods.*

Fear

The fear of death and disability can be a paralyzing emotion that adversely affects the patient's recovery from AMI.

Expected Outcome: Patient will demonstrate reduced fear as evidenced by verbal and nonverbal indicators reflecting understanding by the patient and family of the current clinical condition.

- Identify the patient's level of fear, noting verbal and nonverbal signs. *This information enables the nurse to plan appropriate interventions. Patients may not voice concerns; attention to nonverbal indicators is important. Controlling fear helps decrease SNS responses and catecholamine release that may increase feelings of fear and anxiety.*
- Acknowledge the patient's perception of the situation. Allow to verbalize concerns. *A sudden change in health status causes anxiety and fear of the unknown. Verbalizing these fears may help the patient cope with change and allow the healthcare team to provide information and correct misconceptions.*

- Encourage questions and provide consistent, factual answers. Repeat information as needed. *Accurate and consistent information can reduce fear. Honest explanations help strengthen the nurse–patient relationship and help the patient develop realistic expectations. Anxiety and fear decrease the ability to concentrate and retain information; therefore, information may need to be repeated.*
- Encourage self-care. Allow the patient to make decisions regarding the plan of care. *This promotes personal responsibility for health and allows some control over the situation. Patients' confidence increases as their dependence decreases.*
- Administer antianxiety medications as ordered. *These medications promote rest and relaxation and decrease feelings of anxiety, which may act as barriers to health restoration.*
- Teach nonpharmacologic methods of stress reduction (e.g., relaxation techniques, mental imagery, music therapy, breathing exercises, meditation, and massage). *Stress management techniques can help reduce tension and anxiety, provide a sense of control, and enhance coping skills.*

Delegating Nursing Care Activities

As appropriate and allowed by the designated duties and responsibilities of unlicensed assistive personnel, the nurse may delegate nursing care activities such as measuring fluid intake and output, collecting vital signs (including orthostatic vital signs), encouraging oral or enteral fluid intake, and nonpharmacologic skin care.

Continuity of Care

Cardiac rehabilitation begins with admission to the healthcare facility and continues through the inpatient stay and after discharge into the rehabilitative period. The emphasis is on realistic application of information to maintain lifestyle changes.

Assessing readiness to learn is an important first step in preparing for home care. The patient in strong denial may not identify any relevance to the information being taught. Evaluate ability to learn, assessing physiologic and psychologic health, beliefs regarding personal responsibility for health, and expectations of the healthcare system. Also assess developmental level, ability to perform psychomotor skills, cognitive function, learning disabilities, existing knowledge base, and the influence of previous learning experiences. Provide written material to supplement teaching and encourage questions.

Include the following topics in teaching for home care:

- The normal anatomy and physiology of the heart, and the specific area of heart damage
- The process of CHD and implications of MI
- Purposes and side effects of prescribed medications.
- The importance of complying with the medical regimen and cardiac rehabilitation program and of keeping follow-up appointments
- Information about community resources, such as the local chapter of the AHA.

After discharge, follow up by telephone within 1 week and periodically thereafter during the recovery period. Provide telephone numbers of resource personnel who are available to respond to questions and concerns after discharge. While depressive symptoms can increase following AMI, research demonstrates that patients may report positive psychologic effects after AMI.

Because the patient who has had an MI is at high risk for sudden cardiac death, encourage family members to learn CPR and provide information about community resources for CPR training.

Cardiac Rhythm Disorders

Heart muscle contracts in response to electrical stimulation. In the normal heart, electrical stimulation produces a synchronized, rhythmic heart muscle contraction that propels blood into the vascular system. Changes in cardiac rhythm affect this synchronized activity and the heart's ability to effectively pump blood to body tissues.

THE PATIENT WITH A CARDIAC DYSRHYTHMIA

A cardiac dysrhythmia is a disturbance or irregularity in the electrical system of the heart. Cardiac dysrhythmias may be benign or have lethal consequences. Prompt recognition of a lethal dysrhythmia and quick action can save lives.

Dysrhythmias develop for many reasons. Not all are pathologic; some alterations in cardiac rhythm occur in response to events such as exercise or fear. For example, a rapid heart rate due to exercise, fever, or excitement is a normal response to the body's demand for oxygen or to stimulation of the SNS. Slow heart rates also may be normal. *Athletic heart syndrome*, which results from long-term training on the heart muscle, allows the heart to beat more slowly and forcefully while maintaining cardiac output and tissue perfusion. Many athletes have a heart rate of less than 60 bpm. Aging affects cardiac rhythm as well (see the Nursing Care of the Older Adult box).

Regardless of cause, a dysrhythmia can significantly affect cardiac output, depending on heart muscle health. The patient's response to the dysrhythmia is key in determining the urgency and type of treatment needed. Treat the patient, not the monitor.

Physiology Review

The unique properties of cardiac cells allow effective heart function. Four properties are electrical; the fifth is the cardiac muscle's mechanical response to electrical stimulation.

- *Automaticity* is the ability of pacemaker cells to spontaneously initiate an electrical impulse (action potential). The sinoatrial (SA) node (also called the *sinus node*) is the dominant pacemaker, generating impulses at 60 to 100 times a minute. Myocardial muscle cells do not possess this ability.
- *Excitability* is the ability of myocardial cells to respond to stimuli generated by pacemaker cells.
- *Conductivity* is the ability to transmit an impulse from cell to cell. When one cell is stimulated, the impulse rapidly spreads throughout the heart muscle.
- *Refractoriness* is the inability of cardiac cells to respond to additional stimuli immediately following depolarization. In the absolute refractory period, depolarization will not occur in response

CASE STUDY & NURSING CARE PLAN A Patient with Acute Myocardial Infarction

Betty Williams, a 62-year-old psychologist, is admitted to the emergency department (ED) with complaints of severe substernal chest pain. Mrs. Williams states that the pain began after lunch, about 4 hours ago. She initially attributed the pain to indigestion. She described the pain, which now radiates to her jaw and left arm, as "really severe heartburn." It is accompanied by a "choking feeling," severe shortness of breath, and diaphoresis. The pain is unrelieved by rest, antacids, or three sublingual nitroglycerin tablets (0.4 mg).

Oxygen is started per nasal cannula at 5 L/min. Central and peripheral intravenous lines are inserted. A 12-lead ECG and the following lab work are obtained: cardiac troponins, CK and CK isoenzymes, ABGs, CBC, and a chemistry panel. Morphine sulfate relieves Mrs. Williams's pain.

Mrs. Williams's medical history includes type 2 diabetes, angina, and hypertension. She has a 45-year history of cigarette smoking, averaging 1.5 to 2 packs per day. Family history reveals that Mrs. Williams's father died at age 42 of AMI, and her paternal grandfather died at age 65 of AMI. Mrs. Williams is taking the following medications: tolbutamide (Orinase), hydrochlorothiazide, and isosorbide (Isordil).

Based on ECG changes and cardiac markers, an acute anterior MI is diagnosed. Mrs. Williams has no contraindications to fibrinolytic therapy and is deemed a good candidate. Intravenous alteplase (t-PA, Activase) is given by bolus followed by intravenous infusions of alteplase and heparin. She is transferred to the coronary care unit (CCU).

ASSESSMENT

Dan Morales, RN, is Mrs. Williams's primary care nurse. Mrs. Williams is alert and oriented to person, place, and time. Vital signs are T 99.6° F (37.5°C), P 118 bpm, R 24/min with adequate depth, and BP 172/92 mmHg. Auscultation reveals an S_4 and fine crackles in the bases of both lungs. The ECG shows sinus tachycardia with occasional PVCs. Her skin is cool and slightly diaphoretic. Capillary refill is less than 3 seconds, and peripheral pulses are strong and equal. Her nail beds are pink.

A triple-lumen central line is in place. Nitroglycerin is infusing at 200 mcg/min in the distal lumen, the alteplase infusion is in the middle lumen, and a heparin infusion is in the proximal lumen. The peripheral intravenous line has a saline lock. Mrs. Williams states, "The pain is better since the nurse in the ED gave me a shot. But it has been coming and going. I would rate it a four right now, but it was terrible before. The doctor told me that this drug I'm getting will quickly open up the artery that is blocked. I hope it works! Do many people get this drug?"

DIAGNOSES

- *Acute Pain* related to ischemic myocardial tissue
- *Anxiety* and *Fear* related to change in health status
- *Ineffective Protection* related to the risk of bleeding secondary to fibrinolytic therapy
- *Risk for Decreased Cardiac Output* related to altered cardiac rate and rhythm

EXPECTED OUTCOMES

- Patient will rate chest pain as 2 or lower on a pain scale of 0 to 10.
- Patient will verbalize reduced anxiety and fear.
- Patient will demonstrate no signs of internal or external bleeding.
- Patient will maintain adequate cardiac output during and following reperfusion therapy.

PLANNING AND IMPLEMENTATION

The following interventions are planned and implemented during the immediate phase of Mrs. Williams's hospitalization:

- Instruct to report all chest pain. Monitor and evaluate pain using a scale of 0 to 10. Titrate intravenous nitroglycerin infusion for chest pain; stop infusion if systolic BP is below 100 mmHg. Administer 2 to 4 mg morphine intravenously for chest pain unrelieved by nitroglycerin infusion.
- Encourage verbalization of fears and concerns. Respond honestly, and correct misconceptions about the disease, therapeutic interventions, or prognosis.
- Assess knowledge of CHD. Explain the purpose of fibrinolytic therapy to dissolve the fresh clot and reperfuse the heart muscle, limiting heart damage.
- Explain the need for frequent monitoring of vital signs and potential bleeding.
- Assess for manifestations of internal or intracranial bleeding: complaints of back or abdominal pain, headache, decreased level of consciousness, dizziness, bloody secretions or excretions, or pallor. Test all stools, urine, and vomitus for occult blood. Notify physician immediately of any abnormal findings.
- Monitor for signs of reperfusion: decreased chest pain, return of ST segment to baseline, reperfusion dysrhythmias (e.g., PVCs, bradycardia, and heart block).
- Continuously monitor ECG for changes in cardiac rate, rhythm, and conduction. Assess vital signs.
- Treat dangerous dysrhythmias or other cardiac events per protocol. Notify the physician.
- Discuss continuing cardiac care and rehabilitation.

EVALUATION

The initial morphine dose reduces Mrs. Williams's chest pain from a rating of 8 to 4. The nitroglycerin infusion and fibrinolytic therapy further reduce her pain to 2. The nitroglycerin infusion is gradually discontinued after 24 hours. As her pain subsides, Mrs. Williams states that she feels "much better now that the pain is gone. I was afraid it would just get worse." She verbalizes an understanding of fibrinolytic therapy to limit myocardial damage. Bleeding problems are not noted. Reperfusion is indicated by relief of chest pain, return of the ST segment to baseline on the ECG, early peaking of CK levels, and increased frequency of PVCs but no significant dysrhythmias. Mrs. Williams remains in CCU for 36 hours and is transferred to the floor.

Clinical Reasoning in Patient Care

1. How would the initial plan of care have changed if Mrs. Williams were not a candidate for fibrinolytic therapy?
2. Two days after her initial therapy, Mrs. Williams complains of palpitations. You notice frequent PVCs on the ECG monitor. What do you do?
3. What health promotion topics would you teach Mrs. Williams before discharge?
4. Mrs. Williams states, "I've been smoking for over 45 years, and I'm not going to stop now! Besides, it calms me down when I'm anxious." How would you respond to this statement?

See Evaluating Your Response in Appendix B.

to any stimulus. A stronger than normal stimulus is required to initiate depolarization during the relative refractory period. This is followed by the supernormal period, during which a mild stimulus will cause depolarization.

- *Contractility* is the ability of myocardial fibers to shorten in response to a stimulus. Heart muscle responds in an all-or-nothing manner: Stimulation of one muscle fiber causes the entire muscle mass to contract to its fullest extent as one unit.

NURSING CARE OF THE OLDER ADULT

Cardiac Dysrhythmias

Aging affects the heart and the cardiac conduction system, increasing the incidence of dysrhythmias and conduction defects. Older adults may experience dysrhythmias even when no evidence of heart disease is found.

Older adults have a higher incidence than younger people of both ventricular and supraventricular dysrhythmias without detrimental effects. Ectopic beats, including short runs of ventricular tachycardia, occur more commonly during exercise in older adults. These dysrhythmias do not affect cardiac morbidity or mortality. Fibrosis of the bundle branches can lead to atrioventricular blocks; a prolonged PR interval is common in patients over the age of 65. Older adults also have a higher incidence of diseases that may affect heart rhythm. An older patient with hyperthyroidism, for example, may present with atrial fibrillation, syncope, and confusion instead of the usual manifestations of goiter, tremor, and exophthalmoses.

ASSESSING FOR HOME CARE

Assessment of older adults for problems related to cardiac dysrhythmias focuses on the effect of the dysrhythmia on functional health status:

- Ask about a history of cardiovascular disease and current medications.
- Inquire about symptoms such as episodes of dizziness, lightheadedness, fainting, palpitations, chest pain, or shortness of breath.
- Ask about the relationship of symptoms such as palpitations to intake of certain foods and caffeine-containing beverages.
- Evaluate for other contributing factors such as smoking or alcohol intake.
- Inquire about a history of falls, particularly those occurring without apparent reason.

TEACHING FOR HOME CARE

Teach measures to reduce the risk of cardiac dysrhythmias and the potential adverse consequences of dysrhythmias:

- Emphasize the importance of taking medications as prescribed. Discuss possible effects of over-the-counter medications on the heart.
- Encourage reducing or eliminating caffeine intake. Caffeine increases the risk of ectopic beats and rapid heart rates.
- Encourage participation in a smoking cessation program and reduce or eliminate alcohol intake if appropriate.
- Encourage engaging in regular exercise. Discuss the beneficial effects of exercise to maintain muscle mass, including cardiac muscle, and cardiovascular health.
- Instruct to contact primary care provider for evaluation of symptoms such as dizziness, fainting, frequent palpitations, shortness of breath, unexplained falls, or chest pain.

Electrical activity of the heart is normally controlled by the cardiac conduction system (refer to Figure 29–7). The SA node, the primary pacemaker of the heart, usually generates impulses at a regular rate of 60 to 100 bpm. The impulse spreads through the atria, is briefly delayed at the AV node, and then spreads through conduction pathways of the ventricles and to ventricular muscle. The AV nodal delay allows the atria to contract, delivering an extra bolus of blood to the ventricles before they contract (the **atrial kick**). The AV node also controls the number of impulses that reach the ventricles, preventing extremely rapid heart rates.

Pathophysiology

Dysrhythmias arise through disruption of the very properties that stimulate and control the heartbeat: automaticity, excitability, conductivity, and refractoriness.

Dysrhythmias due to altered impulse formation include changes in rate and rhythm and the development of ectopic beats. This category includes *tachydysrhythmias* (rapid heart rates), *bradydysrhythmias* (slow heart rates), and ectopic rhythms. These dysrhythmias result from a change in the automaticity of cardiac cells. The rate of impulse formation may abnormally increase or decrease. Aberrant (abnormal) impulses may originate outside normal conduction pathways, causing **ectopic beats**. Ectopic beats interrupt the normal conduction sequence and may not initiate a normal muscle contraction. Depending on the site and timing of abnormal impulses, they may have little effect on the patient or may pose a significant threat.

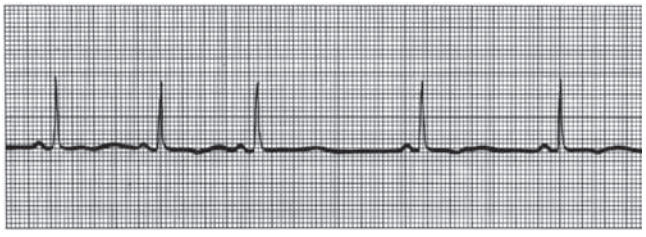
Ischemia, injury, and infarction of myocardial tissue affect its excitability and ability to conduct and respond to an electrical stimulus. Conduction abnormalities cause varying degrees of **heart block**, a block in the normal conduction pathways. Myocardial injury or infarction can obstruct or delay impulse conduction. Bundle branch blocks are common in acute myocardial infarction.

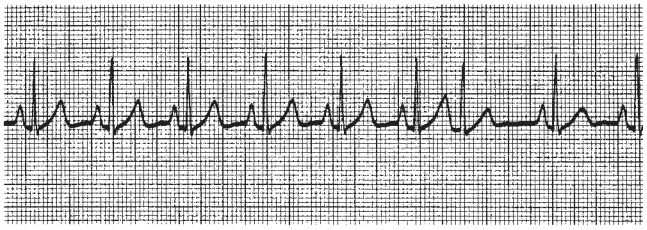
The *reentry phenomenon*, a phenomenon of normal and slow conduction, is a major cause of tachydysrhythmias. A stimulus such as an ectopic beat triggers the reentry phenomenon. The impulse is delayed in one area of the heart (e.g., an area of ischemia or injury), but conducted normally through the rest. Muscle that has been depolarized by the normally conducted impulse is repolarized by the time the impulse traveling through the area of slow conduction reaches it, thus initiating another cycle of depolarization (Huether & McCance, 2011). The result is a dysrhythmia that propagates itself.

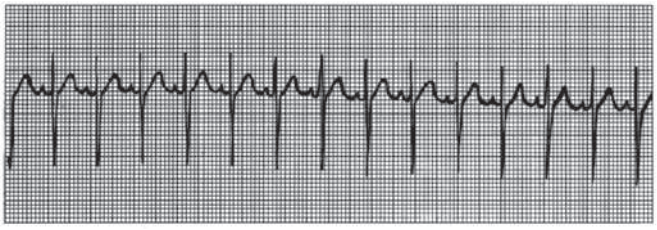
Several forms of reentry may occur. The impulse may travel through a set pathway to reenter repolarized tissue. Many atrial dysrhythmias follow this pattern, including atrial flutter. In functional reentry, local differences in the conduction of an impulse interrupt the normal wave of depolarization, sending it back on itself in a spiral pattern and setting up a permanent rotation. This type of pattern suppresses normal pacemaker activity and can lead to atrial fibrillation (Huether & McCance, 2011).

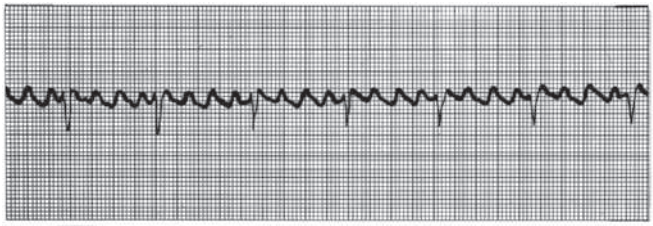
Cardiac rhythms are classified according to the site of impulse formation or the site and degree of conduction block. *Supraventricular rhythms* arise above the ventricles. These rhythms usually produce a QRS complex within the normal range. Sinus rhythms, atrial rhythms, and junctional (arising from the AV junction) rhythms are all supraventricular rhythms. *Ventricular rhythms* originate in the ventricles and may prove fatal if left untreated. *AV conduction blocks* result from a defect in impulse transmission from the atria to the ventricles. The major normal and abnormal cardiac rhythms are summarized in Table 30–7.

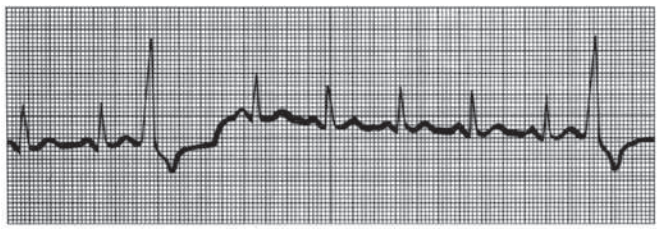
TABLE 30–7 Characteristics of Selected Cardiac Rhythms and Dysrhythmias

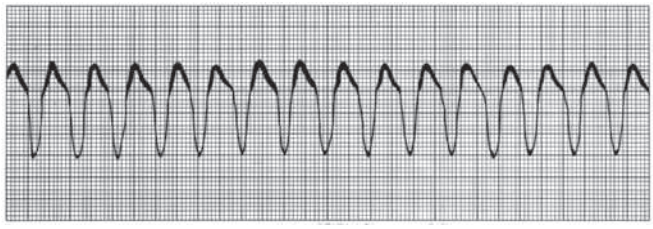


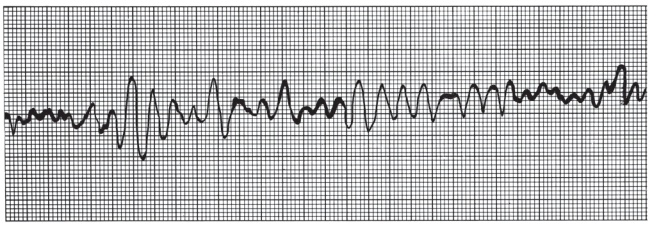


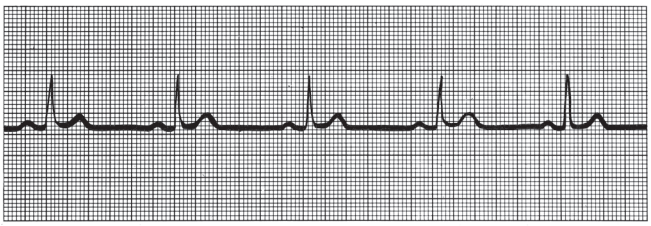


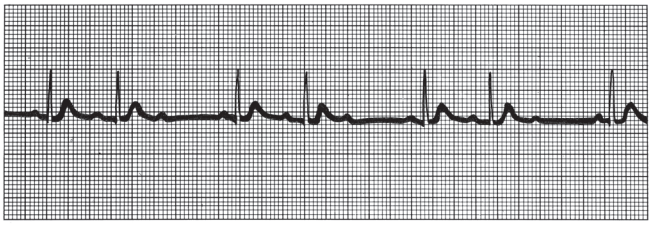


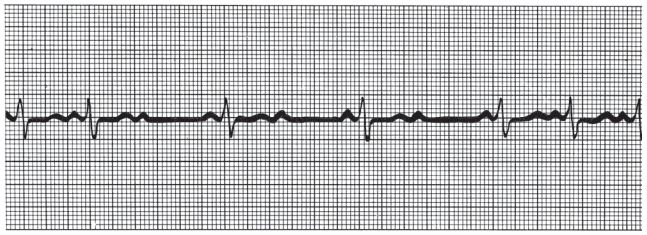


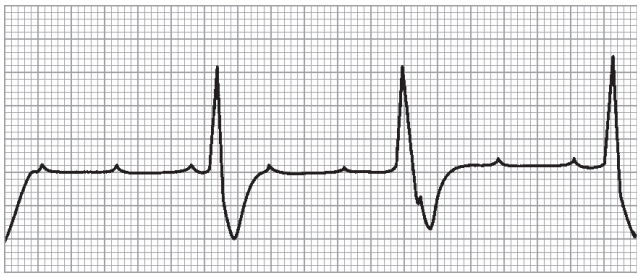












Rhythm/ECG Appearance	ECG Characteristics	Management
SUPRAVENTRICULAR RHYTHMS		
Normal sinus rhythm (NSR) 	Rate: 60–100 bpm Rhythm: regular P:QRS: 1:1 PR interval: 0.12–0.20 sec QRS complex: 0.6–0.10 sec	None; heart rhythm is normal.
Sinus arrhythmia 	Rate: 60–100 bpm Rhythm: irregular, varying with respirations P:QRS: 1:1 PR interval: 0.12–0.20 sec QRS complex: 0.6–0.10 sec	Generally none; considered a normal rhythm in the very young and very old.
Sinus tachycardia 	Rate: 101–150 bpm Rhythm: regular P:QRS: 1:1 (With very fast rates, P wave may be hidden in preceding T wave.) PR interval: 0.12–0.20 sec QRS complex: 0.6–0.10 sec	Treated only if symptomatic or patient is at risk for myocardial damage. Treat underlying cause (e.g., hypovolemia, fever, pain). Beta-blockers or verapamil may be used.
Sinus bradycardia 	Rate: < 60 bpm Rhythm: regular P:QRS: 1:1 PR interval: 0.12–0.20 sec QRS complex: 0.6–0.10 sec	Treated only if symptomatic. Intravenous atropine or isoproterenol, and/or pacemaker therapy may be used.
Premature atrial contractions (PACs) 	Rate: variable Rhythm: irregular, with normal rhythm interrupted by early beats arising in the atria P:QRS: 1:1 PR interval: 0.12–0.20 sec, but may be prolonged QRS complex: 0.6–0.10 sec	Usually require no treatment. Advise to reduce alcohol and caffeine intake, to reduce stress, and to stop smoking. Beta-blocker may be prescribed.
Paroxysmal supraventricular tachycardia (PSVT) 	Rate: 100–280 bpm (usually 150–200 bpm) Rhythm: regular P:QRS: P waves often not identifiable PR interval: not measured QRS complex: 0.6–0.10 sec	Treat if symptomatic. Treatment may include vagal maneuvers (Valsalva, carotid sinus massage); oxygen therapy; adenosine or a beta-blocker; temporary pacing, or synchronized cardioversion.

TABLE 30–7 Characteristics of Selected Cardiac Rhythms and Dysrhythmias (*continued*)

Rhythm/ECG Appearance	ECG Characteristics	Management
Atrial flutter 	Rate: atrial 240–360 bpm; ventricular rate depends on degree of AV block and usually is < 150 bpm. Rhythm: atrial regular; ventricular usually regular P:QRS: 2:1, 4:1, 6:1; may vary PR interval: not measured QRS complex: 0.6–0.10 sec	Synchronized cardioversion; medications to slow ventricular response such as a beta-blocker or calcium channel blocker, followed by a Class I antidysrhythmic agent or amiodarone.
Atrial fibrillation 	Rate: atrial 300–600 bpm (too rapid to count); ventricular 100–180 bpm in untreated patients Rhythm: irregularly irregular P:QRS: variable PR interval: not measured QRS complex: 0.06–0.10 sec	Synchronized cardioversion; medications to reduce ventricular response rate: metoprolol, diltiazem, or digoxin; anticoagulant therapy to reduce risk of clot formation and stroke.
Junctional escape rhythm 	Rate: 40–60 bpm; junctional tachycardia 60–140 bpm Rhythm: regular P:QRS: P waves may be absent, inverted, and immediately preceding or succeeding QRS complex, or hidden in QRS complex. PR interval: < 0.10 sec QRS complex: 0.06–0.10 sec	Treat cause if symptomatic.
VENTRICULAR RHYTHMS		
Premature ventricular contractions (PVCs) 	Rate: variable Rhythm: irregular, with PVC interrupting underlying rhythm and followed by a compensatory pause P:QRS: no P wave noted before PVC PR interval: absent with PVC QRS complex: wide (> 0.12 sec) and bizarre in appearance; differs from normal QRS complex	Treat if symptomatic or in presence of severe heart disease. Advise against stimulant use (caffeine, nicotine). Beta-blockers, or Class I or III antidysrhythmic agents (see the box on page 906) may be used for patients with severe heart disease who are symptomatic.
Ventricular tachycardia (VT or V tach) 	Rate: 100–250 bpm Rhythm: regular P:QRS: P waves usually not identifiable PR interval: not measured QRS complex: 0.12 sec or greater; bizarre shape	Treat if VT is sustained, symptomatic, or associated with organic heart disease. Treatment includes DC cardioversion or intravenous procainamide, lidocaine, or a Class III antidysrhythmic agent if hemodynamic instability is present. Surgical ablation or antitachycardia pacing with an implanted cardioverter/defibrillator (ICD) is used for repeated episodes.

(*continued*)

TABLE 30–7 Characteristics of Selected Cardiac Rhythms and Dysrhythmias (*continued*)

Rhythm/ECG Appearance	ECG Characteristics	Management
Ventricular fibrillation (VF, V fib) 	Rate: too rapid to count Rhythm: grossly irregular P:QRS: no identifiable P waves PR interval: none QRS: bizarre, varying in shape and direction	Immediate defibrillation.
ATRIOVENTRICULAR CONDUCTION BLOCKS		
First-degree AV block 	Rate: usually 60–100 bpm Rhythm: regular P:QRS: 1:1 PR interval: > 0.21 sec QRS complex: 0.06–0.10 sec	None required.
Second-degree AV block, type I (Mobitz I, Wenckebach) 	Rate: 60–100 bpm Rhythm: atrial regular; ventricular irregular P:QRS: 1:1 until P wave blocked with no subsequent QRS complex PR interval: progressively lengthens in a regular pattern QRS complex: 0.06–0.10 sec; sudden absence of QRS complex	Monitoring and observation; rarely progresses to a higher degree of block or requires treatment.
Second-degree AV block, type II (Mobitz II) 	Rate: atrial 60–100 bpm; ventricular < 60 bpm Rhythm: atrial regular; ventricular irregular P:QRS: typically 2:1, may vary PR interval: constant PR interval for each conducted QRS complex QRS complex: 0.06–0.10 sec	Atropine or isoproterenol; pacemaker therapy.
Third-degree AV block (complete heart block) 	Rate: atrial 60–100 bpm; ventricular 15–60 bpm Rhythm: atrial regular; ventricular regular P:QRS: No relationship between P waves and QRS complexes; independent rhythms PR interval: not measured QRS complex: 0.06–0.10 sec if junctional escape rhythm; > 0.12 sec if ventricular escape rhythm	Immediate pacemaker therapy.

FAST FACTS

- The normal sinus rate is 60 to 100 bpm. Each complex includes a P wave, QRS, and T wave.
- Supraventricular dysrhythmias arise in the SA node or the atria. A P wave may be present; the QRS appears normal, and a T wave may be seen.
- Junctional dysrhythmias arise in tissue just above or just below the AV node. The P wave may be inverted, and may precede, follow, or be buried in the QRS complex. The QRS usually appears normal and is followed by a T wave.
- Ventricular dysrhythmias arise in ventricular myocardium. They do not reset the SA node or activate the atria. QRS complexes are wide and bizarre.

SUPRAVENTRICULAR RHYTHMS

NORMAL SINUS RHYTHM Normal sinus rhythm (NSR) is the normal heart rhythm, in which impulses originate in the SA node and travel through all normal conduction pathways without delay. All waveforms are of normal configuration, look alike, and have consistent (fixed) durations. The rate is between 60 and 100 bpm.

SINUS NODE DYSRHYTHMIAS Sinus node dysrhythmias may occur as a normal compensatory response (e.g., to exercise) or because of altered automaticity. In these rhythms, as in a normal sinus rhythm (NSR), the initiating impulse is from the sinus node. They differ from NSR in rate or regularity of the rhythm. Sinus dysrhythmias include sinus arrhythmia, sinus tachycardia, and sinus bradycardia.

SINUS ARRHYTHMIA *Sinus arrhythmia* is a sinus rhythm in which the rate varies with respirations, causing an irregular rhythm. The rate increases during inspiration and decreases with expiration. Sinus arrhythmia is common in the very young and the very old. It can be caused by an increase in vagal tone, by digitalis toxicity, or by morphine administration.

SINUS TACHYCARDIA *Sinus tachycardia* has all of the characteristics of NSR, except that the rate is greater than 100 bpm. Tachycardia arises from enhanced automaticity in response to changes in the internal environment. SNS stimulation or blocked vagal (parasympathetic) activity increases the heart rate. Tachycardia is a normal response to any condition or event that increases the body's demand for oxygen and nutrients, such as exercise or hypoxia. In the patient on bed rest, tachycardia is an ominous sign. Sinus tachycardia may be an early sign of cardiac dysfunction, such as heart failure. Tachycardia is detrimental in patients with cardiac disease because it increases cardiac work and oxygen use.

Common causes of sinus tachycardia include exercise, excitement, anxiety, pain, fever, hypoxia, hypovolemia, anemia, hyperthyroidism, myocardial infarction, heart failure, cardiogenic shock, pulmonary embolism, caffeine intake, and certain drugs, such as atropine, epinephrine (Adrenalin), or isoproterenol (Isuprel).

Manifestations of sinus tachycardia include a rapid pulse rate. The patient may complain of feeling that the heart is racing, shortness of breath, and dizziness. In the presence of heart disease, sinus tachycardia may precipitate chest pain.

SINUS BRADYCARDIA *Sinus bradycardia* has all of the characteristics of NSR, but the rate is less than 60 bpm. Sinus bradycardia may result from increased vagal (parasympathetic) activity or from depressed automaticity due to injury or ischemia to the sinus node. Sinus bradycardia may be normal (e.g., in patients with athletic heart syndrome). The heart rate normally slows during sleep because the parasympathetic nervous system is dominant at this time. Other causes of sinus bradycardia include pain, increased intracranial pressure, sinus node disease, acute myocardial infarction (especially with inferior wall damage), hypothermia, acidosis, and certain drugs.

Sinus bradycardia may be asymptomatic; it is important to assess the patient before treating the rhythm. Manifestations of decreased cardiac output, such as decreased level of consciousness, syncope (faintness), or hypotension, indicate a need for intervention.

SICK SINUS SYNDROME *Sick sinus syndrome (SSS)* results from SA node disease or dysfunction that causes problems with impulse formation, transmission, and conduction. Sick sinus syndrome is often found in older adults. It may be caused by direct injury to sinus tissue, fibrosis of conduction fibers associated with aging, and such drugs as digitalis, beta-blockers, and calcium channel blockers.

ECG characteristics of SSS include sinus bradycardia, sinus arrhythmia, sinus pauses or arrest, and atrial tachydysrhythmias such as atrial fibrillation, atrial flutter, or atrial tachycardia. Bradycardia-tachycardia syndrome, characterized either by **paroxysmal** (abrupt onset and termination) atrial tachycardia followed by prolonged sinus pauses or alternating periods of bradycardia and tachycardia, also may indicate sinus node dysfunction.

Manifestations of sinus node dysfunction often are intermittent, related to a drop in cardiac output caused by the irregular rhythm. Fatigue, dizziness, light-headedness, and syncope are common. The heart rate may not increase in response to stressors such as exercise or fever.

SUPRAVENTRICULAR DYSRHYTHMIAS When an action potential originates in atrial tissue outside the sinus node, the resulting rhythm is classified as a *supraventricular rhythm*. In these dysrhythmias, an ectopic pacemaker takes over, or overrides, the SA node. They may occur when the SA node fails; an *escape rhythm* develops as a fail-safe mechanism to maintain the heart rate. The most common supraventricular dysrhythmias are premature atrial contractions, paroxysmal supraventricular tachycardia, atrial flutter, and atrial fibrillation. These rhythms may be paroxysmal; that is, they may occur in bursts with an abrupt beginning and end.

PREMATURE ATRIAL CONTRACTIONS A *premature atrial contraction (PAC)* is an ectopic atrial beat that occurs earlier than the next expected sinus beat. PACs can arise anywhere in the atria. They are usually asymptomatic and benign, but they may initiate paroxysmal supraventricular tachycardia in susceptible individuals. PACs are common in older adults, often occurring without an obvious cause. Strong emotions, excessive alcohol intake, tobacco, and stimulants such as caffeine can precipitate PACs. They also may be associated with MI, heart failure and other cardiac disorders, hypoxemia, pulmonary embolism, digitalis toxicity, and electrolyte or acid–base imbalances. In patients with underlying heart disease, PACs may precede a more serious dysrhythmia.

The ECG tracing shows interruption of the underlying rhythm by a premature complex that looks similar to the underlying beats. The ectopic impulse of the PAC is usually conducted normally, leading to depolarization of cardiac muscle and a normal QRS complex. Because the impulse arises above the ventricles, it follows normal conduction pathways through the ventricles. The QRS complex is

narrow or matches those of the underlying rhythm. The shape of the P wave of a PAC differs from normal P waves because its impulse arises outside the sinus node. A *noncompensatory pause* usually follows, as the PAC resets the SA node rhythm. Occasionally, the ectopic impulse may not be conducted through the heart, resulting in a lone P wave without a QRS, or a nonconducted PAC.

PACs cause few manifestations. If frequent, they may cause palpitations or a fluttering sensation in the chest. Early beats may be noted on auscultating or palpating the pulse.

PAROXYSMAL SUPRAVENTRICULAR TACHYCARDIA *Paroxysmal supraventricular tachycardia (PSVT)* is tachycardia of sudden onset and termination. PSVT is usually initiated by a reentry loop in or around the AV node; that is, an impulse reenters the same section of tissue over and over, causing repeated depolarizations.

PSVT occurs more frequently in women. Sympathetic nervous system stimulation and stressors such as fever, sepsis, and hyperthyroidism may precipitate PSVT. It also may be associated with heart diseases such as CHD, MI, rheumatic heart disease, myocarditis, or acute pericarditis. Abnormal conduction pathways associated with Wolff-Parkinson-White (WPW) or Lown-Ganong-Levine (LGL) may account for PSVT.

PSVT affects ventricular filling and cardiac output, and decreases coronary artery perfusion. Its manifestations include complaints of palpitations and a racing heart, anxiety, dizziness, dyspnea, anginal pain, diaphoresis, extreme fatigue, and polyuria (urine output may reach up to 3 L in the first few hours after PSVT onset).

ATRIAL FLUTTER *Atrial flutter* is a rapid and regular atrial rhythm thought to result from an intra-atrial reentry mechanism. Causes include sympathetic nervous system stimulation due to anxiety, caffeine and alcohol intake, thyrotoxicosis, CHD, or MI; pulmonary embolism; and abnormal conduction syndromes such as WPW or LGL syndromes. Older individuals with rheumatic heart disease and/or valvular disease are especially vulnerable.

Two types of atrial flutter have been identified. Type I atrial flutter has an atrial rate of 240 to 340 bpm. It develops due to a reentry mechanism in the right atrium. The mechanism leading to type II atrial flutter has not been identified. In this type of flutter, the atrial rate is faster, 350 to 350 bpm.

Patients with atrial flutter may complain of palpitations or a fluttering sensation in the chest or throat. If the ventricular rate is rapid, manifestations of decreased cardiac output, such as decreased level of consciousness, hypotension, decreased urinary output, and cool clammy skin, may be noted. The atrial kick (additional ventricular filling with atrial contraction) is lost because of inadequate atrial filling.

ECG characteristics include what is commonly called a *sawtooth* or *picket fence* appearance of P waves, which are labeled flutter (F) waves. The atrial rate is rapid, often around 300 bpm. As a protective mechanism, many impulses are blocked at the AV node, and the ventricular rate is rarely greater than 150 to 170 bpm. Usually, atrial impulses are evenly conducted through the AV node, for example, two impulses to one QRS complex (2:1), four impulses to one QRS complex (4:1), or six impulses to one QRS complex (6:1). A constant conduction ratio results in a regular ventricular rhythm; the ventricular rhythm is irregular if the conduction ratio varies. The ventricular rate usually ranges from 150 to 170 bpm in 2:1 conduction and 60 to 75 bpm for lower conduction ratios. The T wave is usually hidden by overriding F waves; some F waves may be hidden in the QRS complex.

ATRIAL FIBRILLATION *Atrial fibrillation* is a common dysrhythmia characterized by disorganized atrial activity without discrete atrial contractions. Multiple small reentry circuits develop in the atria. Atrial cells cannot repolarize in time to respond to the next stimulus (Huether & McCance, 2011). Extremely rapid atrial impulses bombard the AV node, resulting in an irregularly irregular ventricular response. Atrial fibrillation may occur suddenly and recur, or it may persist as a chronic dysrhythmia. Atrial fibrillation is commonly associated with heart failure, rheumatic heart disease, CHD, hypertension, and hyperthyroidism.

Manifestations of atrial fibrillation relate to the rate of the ventricular response. With rapid response rates, manifestations of decreased cardiac output such as hypotension, shortness of breath, fatigue, and angina may develop. Patients with extensive heart disease may develop syncope or heart failure. Peripheral pulses are irregular and of variable amplitude (strength).

The specific ECG characteristics of atrial fibrillation include an irregularly irregular rhythm and the absence of identifiable P waves. The atrial rate is so rapid that it is not measurable. The ventricular rate varies.

Atrial fibrillation increases the risk for formation of thromboemboli. Organ infarction may occur as a result; the incidence of stroke is high.

JUNCTIONAL DYSRHYTHMIAS

Rhythms that originate in AV nodal tissue are termed *junctional*. The AV junction includes the AV node and the bundle of His, which branches into the right and left bundle branches. An impulse arising from the AV junction may occur in response to failure of higher pacemakers, as in a *junctional escape rhythm*, or it may result from an abnormal mechanism, such as altered automaticity. An impulse arising from the AV junction may or may not be conducted back up to the atria. This conduction against the normal flow or pattern is called *retrograde conduction*. The resulting atrial wave, called a P′ wave, may be found before, during, or after the QRS complex, depending on the speed of conduction. The P′ wave is inverted in some ECG leads because the impulse moves from the AV node up to the atria instead of from the SA node down toward the AV node. In addition, the P′R interval is shorter than normal (less than 0.12 second). The QRS complex is typically narrow.

A junctional rhythm may be due to drug toxicity (e.g., digitalis, beta-blockers, or calcium channel blockers), or other causes such as hypoxemia, hyperkalemia, increased vagal tone or damage to the AV node, MI, and heart failure. Loss of synchronized atrial contraction and the atrial kick may affect cardiac output, leading to manifestations of decreased cardiac output and impaired myocardial tissue perfusion. Heart failure may develop.

Premature junctional contractions (PJCs) occur before the next expected beat of the underlying rhythm. Isolated PJCs may occur in healthy people and are insignificant. *Junctional tachycardia* is a junctional rhythm with a rate greater than 60 bpm. It is caused by increased automaticity of AV nodal tissue. The ventricular rate is usually less than 140 bpm. Both rhythms are most commonly associated with digitalis toxicity, hypoxia, ischemia, or electrolyte imbalances.

VENTRICULAR DYSRHYTHMIAS

Ventricular dysrhythmias originate in the ventricles. Because the ventricles pump blood into the pulmonary and systemic vasculature,

any disruption of their rhythm affects cardiac output and tissue perfusion. A wide and bizarre QRS complex (greater than 0.12 second) is a characteristic feature of ventricular dysrhythmias. This occurs because ventricular ectopic impulses begin and travel outside normal conduction pathways. Other characteristics include no relationship of the QRS complex to a P wave, increased amplitude of the QRS complex, an abnormal ST segment, and a T wave deflected in the opposite direction from the QRS complex.

PREMATURE VENTRICULAR CONTRACTIONS *Premature ventricular contractions (PVCs)* are ectopic ventricular beats that occur before the next expected beat of the underlying rhythm. They usually do not reset the atrial rhythm and are followed by a full compensatory pause. PVCs often have no significance in people without heart disease. Frequent, recurrent, or multifocal PVCs may be associated with an increased risk for lethal dysrhythmias. PVCs result from either enhanced automaticity or a reentry phenomenon. They may be triggered by anxiety or stress; tobacco, alcohol, or caffeine use; hypoxia, acidosis, and electrolyte imbalances; sympathomimetic drugs; coronary heart disease, heart failure, or mechanical stimulation of the heart (e.g., the insertion of a cardiac catheter); or reperfusion after fibrinolytic therapy. The incidence and significance of PVCs is greatest after MI.

PVCs may be isolated or occur in a specific pattern. Two PVCs in a row are called a *couplet* or *paired* PVCs. Three consecutive PVCs (a *triplet* or *salvo*) is a short run of ventricular tachycardia. *Ventricular bigeminy* is characterized by a PVC following each normal beat; a PVC noted every third beat is called *ventricular trigeminy*. When the ventricular impulse arises from one ectopic site, all PVCs look the same (*monomorphic*) and are called *unifocal* PVCs. *Multifocal* PVCs arise from different ectopic sites and appear different from one another on the ECG (*polymorphic*).

The frequency and patterns of PVCs can be indicative of myocardial irritability and the risk for a lethal dysrhythmia. The following are considered warning signs in the patient with acute heart disease (e.g., an acute MI):

- PVCs that develop within the first 4 hours of an MI
- Frequent PVCs (six or more per minute)
- Couplets or triplets
- Multifocal PVCs
- R-on-T phenomenon (PVCs falling on the T wave).

In people without heart disease, isolated PVCs usually are insignificant and do not require treatment. Patients may complain of feeling their hearts skip a beat or of palpitations. In patients with preexisting heart disease, PVCs may indicate drug toxicity or an increased risk for lethal dysrhythmias and cardiac arrest. The risk is greatest following acute MI.

VENTRICULAR TACHYCARDIA *Ventricular tachycardia (VT, V tach)* is a rapid ventricular rhythm defined as three or more consecutive PVCs. Ventricular tachycardia may occur in short bursts, or runs, or may persist for more than 30 seconds (sustained ventricular tachycardia). The rate is greater than 100 bpm, and the rhythm is usually regular. Reentry is the usual electrophysiologic mechanism responsible for VT. Myocardial ischemia and infarction are the most common predisposing factors for VT. It also is associated with cardiac structural disorders such as valvular disease, rheumatic heart disease, or cardiomyopathy. VT may occur in the absence of heart disease, with anorexia nervosa, metabolic disorders, and drug toxicity.

Nonsustained VT may occur paroxysmally and convert back to an effective rhythm spontaneously. The patient may experience a fluttering sensation in the chest or complain of palpitations and brief shortness of breath. Patients in sustained VT generally develop signs and symptoms of decreased cardiac output and hemodynamic instability, including severe hypotension, a weak or nonpalpable pulse, and loss of consciousness. Allowed to continue, VT can deteriorate into ventricular fibrillation. Sustained ventricular tachycardia is a medical emergency that requires immediate intervention, particularly in patients with cardiac disease.

Torsades de pointes is a type of ventricular tachycardia associated with *long QT syndrome*, a prolongation of the QT interval. Long QT syndrome may be genetic or acquired, occurring secondarily to electrolyte disruptions, MI, cocaine use, liquid protein diets, medications, or other conditions. In torsades de pointes, the QRS complexes vary in size, shape, and amplitude (Figure 30–7 ■). Patients with torsades de pointes may have multiple bursts or episodes of VT or may develop ventricular fibrillation and sudden cardiac death (Heuther & McCance, 2011; Perrin & MacLeod, 2012).

VENTRICULAR FIBRILLATION *Ventricular fibrillation (VF, V fib)* is extremely rapid, chaotic ventricular depolarization causing the ventricles to quiver and cease contracting; there is no cardiac output. This is known as **cardiac arrest**; it is a medical emergency requiring immediate intervention with CPR. Death will follow the onset of VF within 4 minutes if the rhythm is not recognized and terminated and an effective perfusing rhythm reestablished.

VF is usually triggered by severe myocardial ischemia or infarction. It occurs without warning 50% of the time. It is the terminal event in many disease processes or traumatic conditions. VF may be precipitated by a single PVC or may follow VT. Other causes of VF include digitalis toxicity, reperfusion therapy, antidysrhythmic drugs, hypokalemia and hyperkalemia, hypothermia, metabolic acidosis, mechanical stimulation (as with the insertion of cardiac catheters or pacing wires), and electric shock.

Clinically, loss of ventricular contractions results in the absence of a palpable or audible pulse. The patient loses consciousness and stops breathing as perfusion ceases. The ECG shows grossly irregular, bizarre complexes with no discernible rate or rhythm.

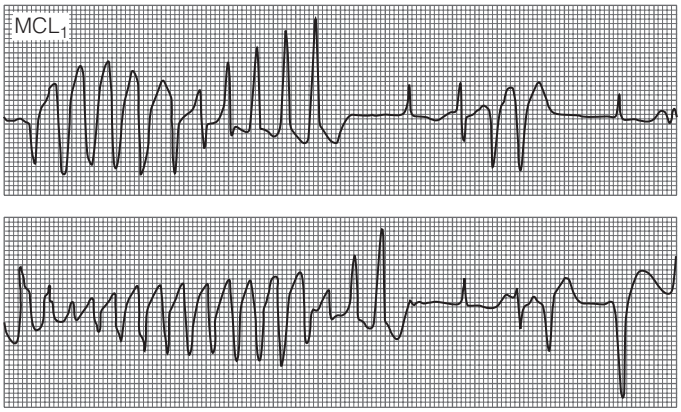


Figure 30–7 ■ Torsades de pointes. Note the wide and bizarre QRS complexes of varying size, shape (morphology), and amplitude.

ATRIOVENTRICULAR CONDUCTION BLOCKS

Conduction defects that delay or block transmission of the sinus impulse through the AV node are called *atrioventricular (AV) conduction blocks*. Impaired conduction may result from tissue injury or disease, increased vagal (parasympathetic) tone, drug effects, or a congenital defect. AV conduction blocks vary in severity from benign to severe.

FAST FACTS

- First-degree AV block = delayed conduction through the AV node and a long PR interval
- Second-degree AV block = complete blockage of *some* impulses through the AV node; some P waves are not followed by a QRS complex
- Third-degree AV block = complete blockage of *all* impulses through the AV node; no relationship between P waves and QRS complexes

FIRST-DEGREE AV BLOCK *First-degree AV block* is a benign conduction delay that generally poses no threat, has no symptoms, and requires no treatment. Impulse conduction through the AV node is slowed, but all atrial impulses are conducted to the ventricles. It may result from injury or infarct of the AV node, other cardiac diseases, or drug effects. The ECG shows all characteristics of NSR; however, the PR interval is greater than 0.20 second.

SECOND-DEGREE AV BLOCK *Second-degree AV block* is characterized by failure to conduct one or more impulses from the atria to the ventricles. Two patterns of second-degree AV block are identified: type I and type II.

SECOND-DEGREE AV BLOCK—TYPE I *Type I second-degree AV block (Mobitz type I* or *Wenckebach phenomenon)* is characterized by a repeating pattern of increasing AV conduction delays until an impulse fails to conduct to the ventricles. On the ECG, PR intervals progressively lengthen until one QRS complex is not conducted, or dropped. The ventricular rate remains adequate to maintain cardiac output, and the patient usually is asymptomatic. Mobitz type I AV block usually is transient, associated with AMI or drug intoxication (e.g., digitalis, beta-blockers, or calcium channel blockers). It rarely progresses to complete heart block.

SECOND-DEGREE AV BLOCK—TYPE II *Type II second-degree AV block (Mobitz type II)* involves intermittent failure of the AV node to conduct an impulse to the ventricles without preceding delays in conduction. The PR interval remains constant, but not all P waves are followed by QRS complexes (e.g., there may be two P waves for every QRS). Conduction through the His-Purkinje system usually is delayed as well, causing a widened QRS complex. Mobitz type II block is frequently associated with acute anterior wall MI and a high rate of mortality (Huether & McCance, 2011). Manifestations of Mobitz type II block depend on the ventricular rate. Pacemaker therapy may be required to maintain the cardiac output.

THIRD-DEGREE AV BLOCK *Third-degree AV block (complete heart block)* occurs when atrial impulses are completely blocked at the AV node and fail to reach the ventricles. As a result, the atria and ventricles are controlled by different and independent pacemakers, with separate rates and rhythms. The ventricular impulse arises from either junctional fibers (with a rate of 40 to 60 bpm) or a ventricular pacemaker at a rate of less than 40 bpm. The width of the QRS complex depends on the location of the escape pacemaker. The QRS is wide and the rate is slow when the rhythm arises distal to the bundle of His.

Third-degree block is frequently associated with an inferior or anteroseptal myocardial infarction. Other causes include congenital conditions, acute or degenerative cardiac disease or damage, drug effects, and electrolyte imbalances. The slow escape rhythm significantly affects cardiac output, causing manifestations such as syncope (known as a *Stokes-Adams attack*), dizziness, fatigue, exercise intolerance, and heart failure. Third-degree AV block is life threatening and requires immediate intervention to maintain adequate cardiac output.

AV DISSOCIATION Complete dissociation of atrial and ventricular rhythms can occur in conditions other than third-degree AV block. The two primary factors leading to AV dissociation are severe sinus bradycardia and a lower pacemaker (junctional or ventricular) that competes with or exceeds the normal sinus rhythm. AV dissociation may result from acute myocardial ischemia or infarction, cardiac surgery, or drug effects. The ECG shows separate and competing atrial (P waves) and ventricular (QRS complexes) rhythms.

INTRAVENTRICULAR CONDUCTION BLOCKS

Once the impulse enters the ventricles, its conduction through the right and left bundle branches may be impaired (*bundle branch block*). As a result, the impulse is conducted more slowly than normal through the ventricles. On the ECG, the QRS complex is prolonged. Its appearance varies, depending on the affected bundle (right or left). Typically, no clinical manifestations are associated with bundle branch block unless it occurs in conjunction with an AV block.

●○● INTERPROFESSIONAL CARE

Cardiac dysrhythmias may be either benign or critical: Recognizing lethal dysrhythmias is a matter of life and death. Major goals of care include identifying the dysrhythmia, evaluating its effect on physical and psychosocial well-being, and treating underlying causes. This may involve correcting fluid and electrolyte or acid–base imbalances; treating hypoxia, pain, or anxiety; administering antidysrhythmic medications; or mechanical and surgical interventions.

DIAGNOSIS

Diagnostic tests for dysrhythmias include the electrocardiogram, cardiac monitoring, and electrophysiology studies. Laboratory tests such as serum electrolytes, drug levels, and arterial blood gases may be done to help identify the cause of the dysrhythmia.

ELECTROCARDIOGRAM The 12-lead ECG may be required to accurately diagnose a dysrhythmia. It also provides information about underlying disease processes, such as MI or other cardiac disease. The ECG may also be used to monitor the effects of treatment. Refer to Chapter 29 for more information about the 12-lead ECG.

CARDIAC MONITORING Cardiac monitoring allows continuous observation of the cardiac rhythm. It is used in many different circumstances (Box 30–4). Different types of ECG monitoring are employed for different situations.

BOX 30–4 Indications for Cardiac Monitoring

- Perioperative monitoring of heart rate and rhythm
- Detecting and identifying dysrhythmias
- Monitoring the effects of cardiac and noncardiac diseases on the heart
- Monitoring patients with potentially life-threatening conditions:
  a. Major trauma (especially cardiac trauma)
  b. Dissecting aneurysm
  c. Acute myocardial infarction
  d. Heart failure
  e. Shock
  f. Other emergency conditions
- Evaluating responses to procedures and interventions:
  a. Drug therapies
  b. Diagnostic procedures
  c. Ablative techniques
  d. Angioplasty or cardiac catheterization
  e. Cardiac surgery
  f. Pacemaker function
  g. Automatic implantable cardioverter/defibrillator function

CONTINUOUS CARDIAC MONITORING Continuous monitoring of the cardiac rhythm is provided by bedside and central monitoring stations. Electrodes placed on the patient's chest attach to cables connected to a monitor. The heart rate and rhythm are visually displayed on a bedside monitor connected to a central monitoring station. The central station allows simultaneous monitoring of multiple patients within a nursing unit. Alarms on both bedside and central monitors warn of potential problems such as very rapid or very slow heart rates. Alarm limits are preset by the nurse for the individual patient.

Telemetry may be used in acute care settings when the patient is ambulatory. Chest electrodes are connected to a portable transmitter worn around the neck or waist; the ECG is transmitted electronically to a central monitoring station for continuous monitoring.

HOME MONITORING Patients often complain of palpitations or other heart symptoms but are asymptomatic during evaluation in a hospital or community-based setting. Ambulatory or Holter monitoring may be used to identify intermittent dysrhythmias, to detect silent ischemia, to monitor the effects of treatment, and to assess pacemaker or automatic cardioverter/defibrillator function. Electrodes are applied and the leads attached to the portable telemetry monitor that records and stores all electrical activity. Patients are instructed to leave the electrode pads in place during monitoring, record any cardiac symptoms or events in a journal (such as chest pain, palpitations, syncope), and are told when to return to the clinic. After the prescribed period, usually 48 to 72 hours, the patient returns and the monitor is removed. Diary entries are compared to the recorded heart rhythms to identify the effects of dysrhythmias.

ELECTROPHYSIOLOGY STUDIES Diagnostic cardiac *electrophysiology (EP) procedures* are used to identify dysrhythmias and their causes. EP studies are used to analyze components of the conduction system, identify sites of ectopic stimulation, and evaluate the effectiveness of treatment. EP procedures can be used for both diagnosis and as a therapeutic intervention.

In the electrophysiology laboratory, electrode catheters are guided by fluoroscopy into the heart through the femoral or brachial vein. The timing and sequence of electrical activation during normal and abnormal (aberrant) rhythms is observed and measured. Electrical stimulation may be used to induce dysrhythmias similar to the patient's clinical dysrhythmia. Following diagnosis, an EP procedure may be used to treat the dysrhythmia, for example, by overdrive pacing (stimulating the patient's heart rate to a rate faster than that of the tachydysrhythmia) to break the dysrhythmia's cycle, or to perform ablative therapy to destroy the ectopic site. See the section on ablative techniques for further information.

Nursing care for the patient undergoing an EP procedure is similar to that for a coronary angiogram (refer to the box on page 883). The procedure and expected sensations are explained. The patient remains awake during the procedure; antianxiety medications or sedatives are given to reduce apprehension. Intravenous heparin may be given during the procedure to reduce the risk of thromboembolism.

Complications of EP procedures are infrequent, but include fatal ventricular fibrillation, cardiac perforation, and major venous thrombosis. Careful postprocedure monitoring is vital.

MEDICATIONS

The goal of drug therapy is to suppress dysrhythmia formation. No drug has been found to be completely safe and effective. Antidysrhythmic drugs are primarily used for acute treatment of dysrhythmias, although they may also be used to manage chronic conditions. The overall goal of therapy is to maintain an effective cardiac output by stabilizing cardiac rhythm.

It is important to remember that virtually all antidysrhythmic drugs also have *prodysrhythmic* effects; that is, they can worsen existing dysrhythmias and precipitate new ones. Antidysrhythmic medications are used sparingly because of this tendency and because of studies that demonstrate higher mortality rates in patients receiving antidysrhythmic medications and the increasing safety and availability of interventional techniques..

Most antidysrhythmic drugs are classified by their effects on the cardiac action potential. Most are Class I drugs, or fast sodium channel blockers. By blocking sodium channels, these drugs slow impulse conduction in the atria and ventricles. This class is further divided into subclasses A, B, and C. Class II drugs are beta-blockers, which decrease SA node automaticity, AV conduction velocity, and myocardial contractility. Class III agents block potassium channels, delaying repolarization and prolonging the relative refractory period. Class IV drugs are calcium channel blockers. Their effect is similar to that of beta-blockers. Adenosine and digoxin do not fit within the major classes. Both drugs reduce SA node automaticity and slow AV conduction. Ibutilide and magnesium also fall outside the major classes, but are used to treat dysrhythmias. The Medication Administration box on page 906 identifies common antidysrhythmic drugs within each class and the nursing implications in caring for patients receiving these drugs.

Drugs that affect the autonomic nervous system may also be used to treat dysrhythmias. Sympathomimetics, such as epinephrine, stimulate the heart, increasing both heart rate and contractility. Anticholinergic agents such as atropine are used to decrease vagal tone and increase the heart rate. Magnesium sulfate is an unclassified drug that has been shown to be safe and effective in treating ventricular tachycardias.

COUNTERSHOCK

Countershock is used to interrupt cardiac rhythms that compromise cardiac output and the patient's welfare. Delivery of a direct

MEDICATION ADMINISTRATION

Antidysrhythmic Drugs

CLASS I DRUGS: SODIUM CHANNEL BLOCKERS

Class IA

quinidine (Cardioquin, Quinidex, Quinaglute)

procainamide (Pronestyl, Procan SR)

disopyramide (Norpace, Norpace CR)

moricizine (Ethmozine)

Class IA drugs decrease the flow of sodium into the cell and prolong the action potential. This decreases automaticity, slows the rate of impulse conduction, and prolongs refractiveness. They are used to treat both supraventricular and ventricular tachycardias.

Class IB

lidocaine (Xylocaine)

mexiletine (Mexitil)

tocainide (Tonocard)

phenytoin (Dilantin)

Class IB, or lidocaine-like, drugs decrease the refractory period but have little effect on automaticity. Drugs in this class are used primarily to treat ventricular dysrhythmias, including PVCs and ventricular tachycardia.

Class IC

flecainide (Tambocor)

propafenone (Rythmol)

Class IC drugs slow impulse conduction velocity but have little effect on refractoriness. They are used to reduce or eliminate tachydysrhythmias associated with reentry. Their significant prodysrhythmic effects limit their usefulness, but they may be used to treat supraventricular tachycardia.

CLASS II DRUGS: BETA-BLOCKERS

atenolol (Tenormin)

carvedilol (Coreg)

esmolol (Brevibloc)

metoprolol (Lopressor, Toprol)

nadolol (Corgard)

propranolol (Inderal)

Class II drugs are beta-blockers that decrease automaticity and conduction through the AV node. They also reduce the heart rate and myocardial contractility. They are used to treat supraventricular tachycardia and to slow the ventricular response rate to atrial fibrillation. These drugs may cause bronchospasm and are contraindicated for patients with asthma, chronic obstructive pulmonary disease (COPD), or other restrictive or obstructive lung diseases.

CLASS III DRUGS: POTASSIUM CHANNEL BLOCKERS

amiodarone (Cordarone)

bretylium (Bretylol)

dofetilide (Tikosyn)

ibutilide (Corvert)

sotalol (Betapace)

Class III drugs block potassium channels, prolonging repolarization and the refractory period. Drugs in this class are used primarily to treat ventricular tachycardia and ventricular fibrillation. Amiodarone may also be used for supraventricular tachycardias.

CLASS IV DRUGS: CALCIUM CHANNEL BLOCKERS

amlodipine (Norvasc)

verapamil (Calan, Isoptin, Verelan)

diltiazem (Cardizem, Dilacor XR)

Calcium channel blockers decrease automaticity and AV nodal conduction. They are used to manage supraventricular tachycardias. Like the beta-blockers, calcium channel blockers reduce myocardial contractility.

OTHER DRUGS

adenosine (Adenocard)

digoxin (Lanoxin)

Adenosine and digoxin decrease conduction through the AV node and are used to treat supraventricular tachycardias.

Nursing Responsibilities

- Obtain baseline data including vital signs, cardiac rhythm (including rate, PR and QT intervals, and QRS duration), and physical assessment (especially cardiac, neurologic, and respiratory status).
- Assess medication regimen to identify drugs that may interfere with antidysrhythmic therapy.
- Monitor ECG to evaluate the effectiveness of therapy and to assess for possible dysrhythmias precipitated by treatment.
- Immediately report manifestations of drug toxicity:
  - Procainamide: signs of heart failure; conduction delays or ventricular dysrhythmias; skin rash, myalgias or arthralgias, flu-like symptoms
  - Disopyramide: urinary retention, heart failure, eye pain
  - Lidocaine: changes in neurologic status, such as agitation, confusion, dizziness, nervousness
  - Amiodarone: pulmonary fibrosis (increasing dyspnea, cough, hepatic dysfunction—changes in liver function tests, jaundice); vision changes, photosensitivity
  - Digoxin: anorexia, nausea, vomiting; blurred or double vision; yellow green halos; new-onset dysrhythmias.
- Use an infusion pump to administer intravenous infusions. Monitor the dose and assess its appropriateness (in mg/min or mcg/kg/min).

Health Education for the Patient and Family

- Take the drug exactly as prescribed. Do not skip or double doses. Check with your physician if a dose is missed.
- Take your pulse and record the rate daily before rising. Count the pulse for 1 full minute. Bring the record with you to each office or clinic visit.
- Report the following to the physician: irregular pulse rate or rhythm, dizziness, eye pain, changes in vision, skin rashes or color changes, wheezing or other respiratory problems, changes in behavior.

Note: Drugs identified in *italics* are among the 200 most commonly prescribed medications in the U.S

current charge depolarizes all cardiac cells at the same time. This simultaneous depolarization may stop a tachydysrhythmia and allow the sinus node to recover control of impulse formation. There are two types of countershock: synchronized cardioversion and defibrillation.

SYNCHRONIZED CARDIOVERSION *Synchronized cardioversion* delivers direct electrical current synchronized with the patient's heart rhythm. Synchronization of the shock with the QRS complex prevents ventricular fibrillation by avoiding current delivery during the vulnerable period of repolarization. Cardioversion is usually

Figure 30–8 ■ Placement of paddles for defibrillation.

done as an elective procedure to treat supraventricular tachycardia, atrial fibrillation, atrial flutter, or hemodynamically stable ventricular tachycardia.

The nurse assists with cardioversion by preparing the patient before the procedure; obtaining any laboratory tests ordered; obtaining and documenting ECG strips prior to, during, and after treatment; setting up the equipment; and monitoring the patient's response.

Patients in atrial fibrillation are at high risk for thromboembolism following cardioversion. Loss of atrial contractions with atrial fibrillation leads to blood pooling in the atria, increasing the risk of clot formation. When the atria begin to contract following successful cardioversion, clots may be dislodged, embolizing to the pulmonary or systemic circulation. If possible, anticoagulants are given for several weeks before cardioversion is attempted.

DEFIBRILLATION Unlike carefully synchronized cardioversion, *defibrillation* is an emergency procedure that delivers direct current without regard to the cardiac cycle. Ventricular fibrillation is immediately treated as soon as the dysrhythmia is recognized. Early defibrillation has been shown to improve survival in patients experiencing VF.

Defibrillation can be delivered by external or internal paddles or pads. Conductive gel pads or paste is applied, and external paddles or pads are placed on the chest wall at the apex and base of the heart (Figure 30–8 ■). Internal paddles are applied directly on the heart, and may be used in surgery, the emergency department, or critical care. Internal defibrillation is done only by a physician; external defibrillation may be performed by any healthcare provider who has been trained in the procedure. Automatic external defibrillators (AEDs) are available on most hospital units to allow early defibrillation for cardiac arrest.

PACEMAKER THERAPY

A **pacemaker** is a pulse generator used to provide an electrical stimulus to the heart when the heart fails to generate or conduct its own at a rate that maintains the cardiac output. The pulse generator is connected to *leads* (insulated wires) passed intravenously into the heart or sutured directly to the epicardium. The leads sense the intrinsic electrical activity of the heart and provide an electrical stimulus to the heart when necessary (pacing).

Pacemakers are used to treat both acute and chronic conduction defects such as third-degree AV block. They also may be used to treat bradydysrhythmias and tachydysrhythmias.

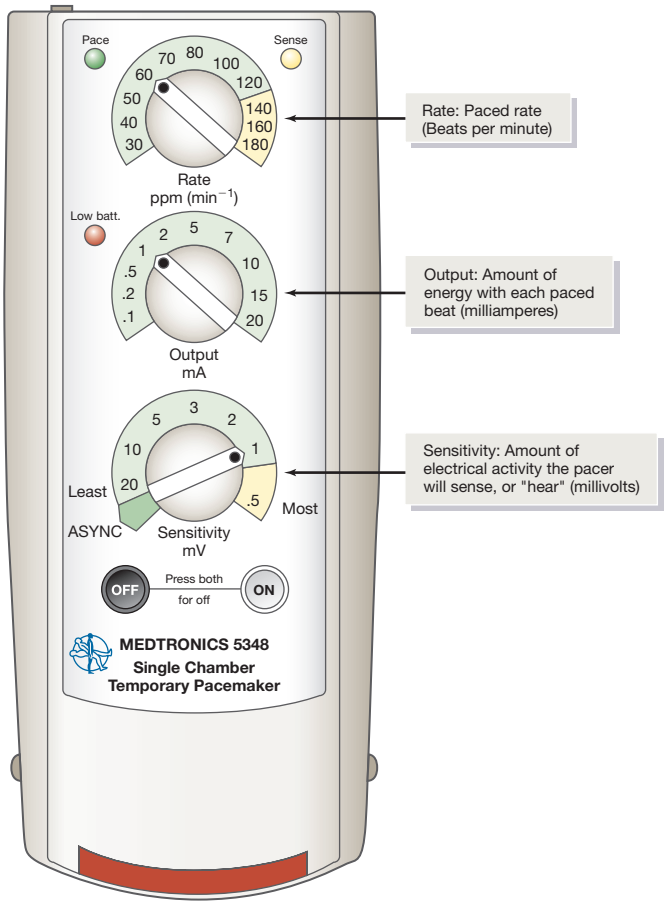

Figure 30–9 ■ Programmable settings on a temporary pacemaker.

Temporary pacemakers use an external pulse generator (Figure 30–9 ■) attached to a lead threaded intravenously into the right ventricle, to temporary pacing wires implanted during cardiac surgery, or to external conductive pads placed on the chest wall for emergency pacing.

Permanent pacemakers use an internal pulse generator placed in a subcutaneous pocket in the subclavian space or abdominal wall. The generator connects to leads sewn directly onto the heart (*epicardial*) or passed transvenously into the heart (*endocardial*). Epicardial pacemakers (Figure 30–10 ■) require surgical exposure of the heart. Leads may be placed during cardiac surgery or using a small subxiphoid incision to expose the heart. Transvenous pacemaker leads are positioned in the right heart via the cephalic, subclavian, or jugular vein (Figure 30–11 ■). Local anesthesia can be used for permanent pacer insertion.

Pacemakers are programmed to stimulate the atria or the ventricles (*single-chamber pacing*), or both (*dual-chamber pacing*). Table 30–8 defines terms used to describe pacemaker modes and functions. The most commonly used pacemakers either (1) sense activity in and pace the ventricles only, or (2) sense activity in and pace both the atria and the ventricles. Dual-chamber or *atrioventricular sequential pacing* stimulates both chambers of the heart in sequence. AV pacing imitates the normal sequence of atrial contraction followed by ventricular contraction, improving cardiac output.

Pacing is detected on the ECG strip by the presence of a pacing artifact (Figure 30–12 ■). A sharp spike is noted before the P wave

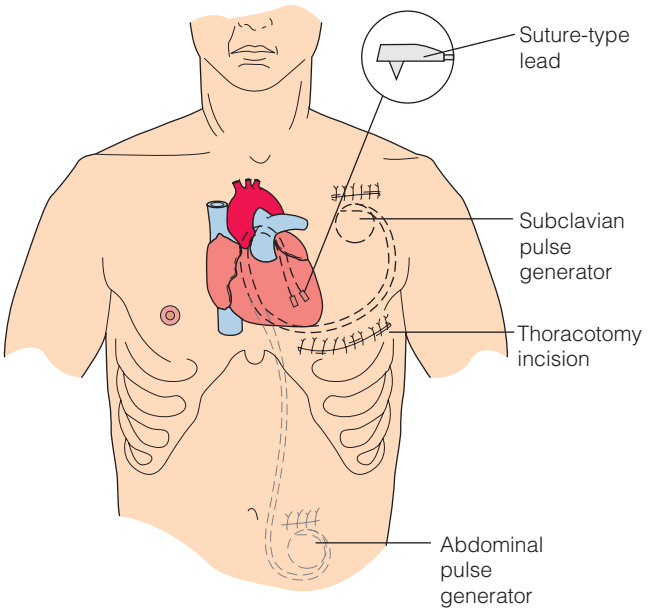

Figure 30–10 ■ A permanent epicardial pacemaker. The pulse generator may be placed in subcutaneous pockets in the subclavian or abdominal regions.

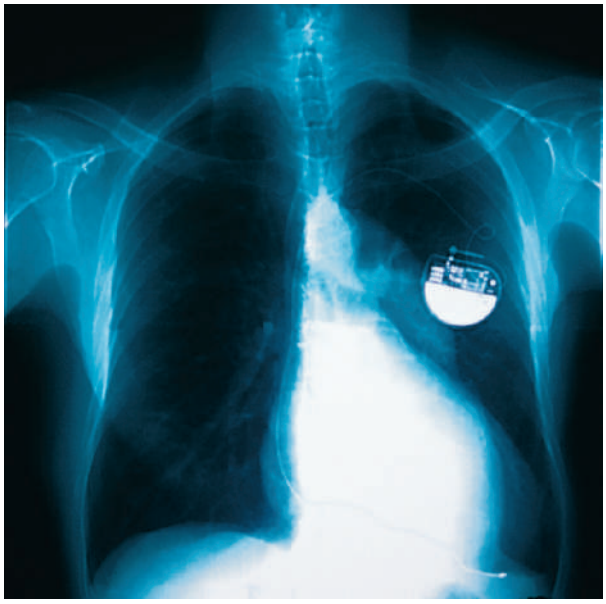

Figure 30–11 ■ A permanent transvenous (endocardial) pacemaker with the lead placed in the right ventricle via the subclavian vein.
Source: Photo Researchers, Inc.

with atrial pacing, and before the QRS complex with ventricular pacing. Pacing spikes are seen before both the P wave and QRS complex in AV sequential pacing. Capture is noted if there is a contraction of the chamber immediately following the pacer spike. Problems in sensing, pacing, and capture are noted in Table 30–9.

Care of the patient with a temporary or permanent pacemaker focuses on monitoring for pacemaker malfunctioning, maintaining safety (Box 30–5), and preventing infection and postoperative complications. Nursing care for the patient having a pacemaker implant is outlined on page 911.

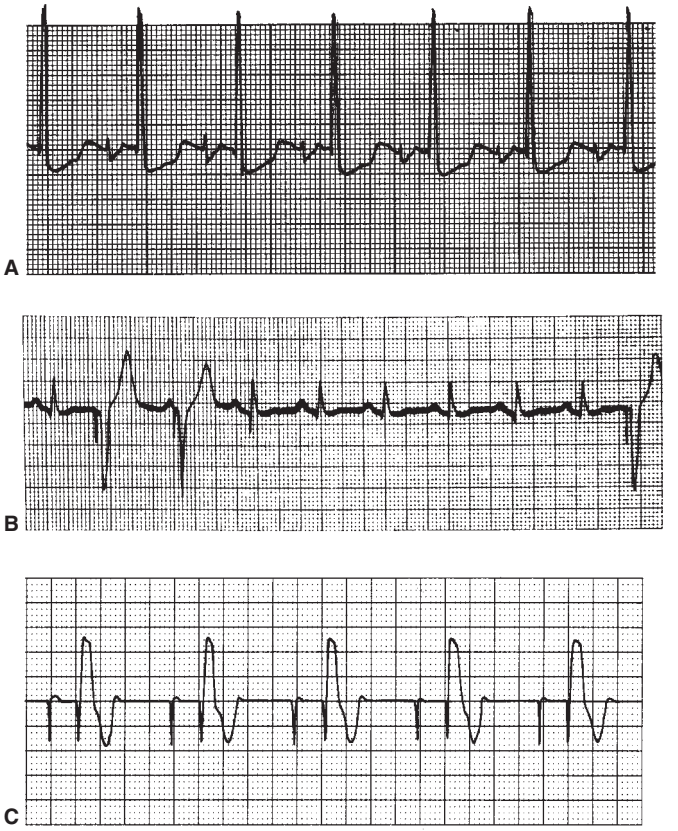

Figure 30–12 ■ Pacing artifacts. A, Atrial pacing and ventricular sensing. Note the pacer spike preceding the P wave. B, Ventricular demand pacing. Note the absence of pacer spikes when the patient's natural rhythm dominates. C, Atrioventricular pacing. Note the pacer spikes preceding both P waves and QRS complexes.

BOX 30–5 Safety Measures for Patients with a Temporary Pacemaker

- Ensure that all electrical equipment in use has a grounded plug; do not use adapters or extension cords.
- Encourage the use of battery-powered equipment (e.g., electric razor).
- Remove any damaged electrical equipment from the unit, including equipment
  a. that has been abused (e.g., has been dropped or in which liquid has been spilled).
  b. from which anyone has received a shock.
  c. that has frayed, worn, or otherwise damaged electrical cords or plugs.
  d. that has other evidence of impaired function, such as a hot smell during use or control knobs that are loose or do not consistently produce the expected response.
- Wear gloves when handling pacer electrodes or wires.
- Insulate pacemaker terminals and pacing wires with nonconductive, moisture-proof material (e.g., a rubber glove).
- Test the pacemaker battery prior to use.
- Keep a spare pacemaker, cable, batteries, and battery tester available at all times.
- Immediately report any apparent deviation from expected pacemaker function.

TABLE 30–8 Terms Used to Describe Pacemaker Functions

Term	Definition
Asynchronous pacing	Pacemaker delivers a pacing stimulus at a set rate regardless of intrinsic cardiac activity.
Base rate	Rate at which the pacemaker paces when no cardiac activity is sensed.
Capture	The ability of the pacing stimulus to generate a cardiac depolarization.
Demand pacing	Pacemaker delivers a pacing stimulus only when the intrinsic rate falls below the pacemaker's base rate.
Dual-chamber pacing	Allows both the atria and the ventricles to be paced; most frequently used permanent pacing mode.
Lead	An insulated wire that senses intrinsic cardiac activity and delivers a pacing stimulus as programmed.
Output	The electrical stimulus delivered by the pulse generator.
Pacing spike	A small vertical spike noted on the ECG with every pacemaker stimulus.
Sensing	The pacemaker's ability to identify and respond to intrinsic cardiac activity.
Single-chamber pacing	Pacing of only the atria or the ventricles, not both; most common temporary pacing mode used.

Note: Adapted from Woods, S. L., Froelicher, E. S. S., Motzer, S. A., & Bridges, E. J. (2009). *Cardiac nursing* (6th ed.). Philadelphia, PA: Lippincott.

IMPLANTABLE CARDIOVERTER/DEFIBRILLATOR

Sudden cardiac death claims more than 300,000 lives per year in the United States. The *implantable cardioverter/defibrillator (ICD)* detects life-threatening changes in the cardiac rhythm and automatically delivers an electric shock to convert the dysrhythmia back into a normal rhythm. ICDs are used for sudden death survivors, patients with recurrent ventricular tachycardia, and patients with demonstrated risk factors for sudden death. ICDs can deliver a shock as needed, provide pacing on demand, and store ECG records of tachycardic episodes.

A pulse generator connected to lead electrodes for rhythm detection and current delivery is implanted in the left pectoral region. The lead is threaded transvenously to the apex of the right ventricle. The ICD is programmed to sense a change in heart rate or rhythm. When it detects a potentially lethal rhythm, it shocks the heart to convert the rhythm. The device can be programmed or reprogrammed at the bedside as necessary. The ICD may be tested prior to discharge.

Local or general anesthesia is used, and the patient may be discharged within 24 hours. The lithium-powered battery must be surgically replaced every 5 years. Complications and nursing care are similar to that for a patient having a permanent pacemaker implant (see the Nursing Care box on page 911).

The patient may briefly lose consciousness before the device discharges, typically regaining consciousness quickly after the episode. Some patients report significant discomfort with ICD discharge (like a blow to the chest). An individual in direct contact with the patient when the device discharges may experience a tingling sensation.

CARDIAC MAPPING AND CATHETER ABLATION

Cardiac mapping and catheter ablation are used to locate and destroy an ectopic focus. These diagnostic and therapeutic measures use electrophysiology techniques, and can be performed in the cardiac catheterization laboratory. *Cardiac mapping* is used to identify the site of earliest impulse formation in the atria or the ventricles. Intracardiac and extracardiac catheter electrodes and computer technology are used to pinpoint the ectopic site on a map of the heart. These same catheters can be used to deliver the ablative intervention.

Ablation destroys, removes, or isolates an ectopic focus. In most instances, radio-frequency energy produced by high-frequency alternating current is used to create heat as it passes through tissue. Catheter ablation is used to treat supraventricular tachycardias, atrial fibrillation and flutter, and, in some cases, paroxysmal ventricular tachycardia.

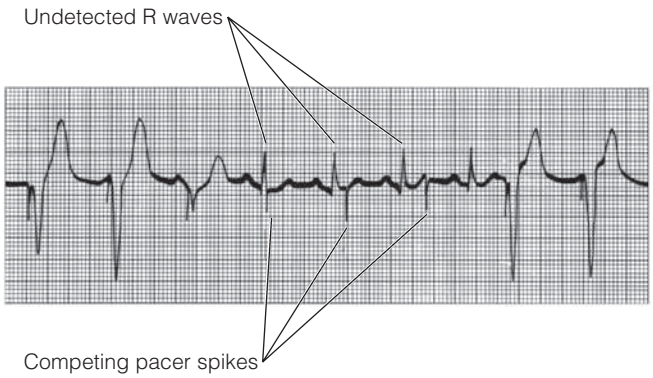
Anticoagulant therapy may be started after catheter ablation to reduce the risk of clot formation at the ablation site.

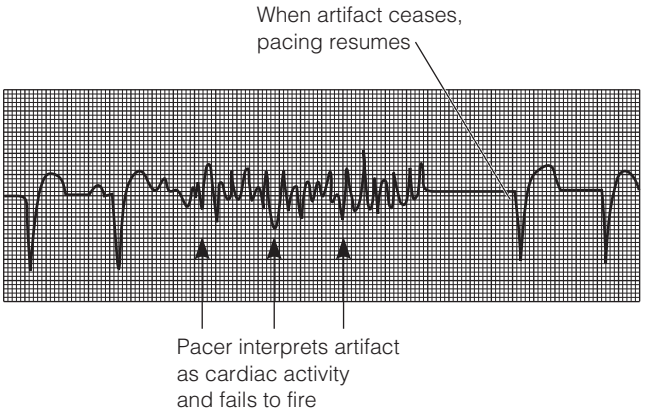
OTHER THERAPIES

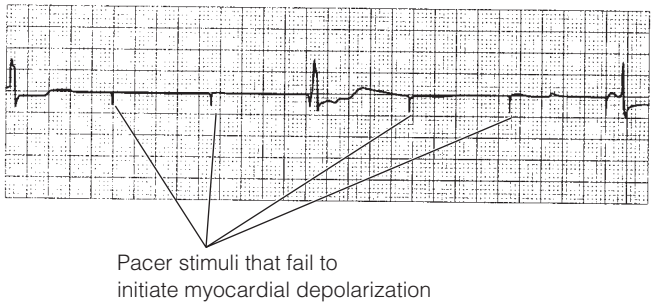
In addition to medications and interventional techniques, other measures may be used to treat selected dysrhythmias. Vagal maneuvers that stimulate the parasympathetic nervous system may be used to slow the heart rate in supraventricular tachycardias. These maneuvers include *carotid sinus massage* and the *Valsalva maneuver*. Carotid sinus massage is performed only by a physician during continuous cardiac monitoring. Excessive slowing of the heart rate may result. The Valsalva maneuver, forced exhalation against a closed glottis (e.g., bearing down), increases intrathoracic pressure and vagal tone, slowing the pulse rate.

●○● NURSING CARE

Caring for the patient with cardiac dysrhythmias requires the ability to recognize, identify, and promptly treat the dysrhythmia. The urgency of intervention is determined by the effects of the dysrhythmia on the patient. Nursing care focuses on maintaining cardiac output, monitoring the response to therapy, and teaching. See the Case Study & Nursing Care Plan for a patient with supraventricular tachycardia.







Health Promotion

Health promotion measures to prevent CHD also reduce the risk for dysrhythmias. In most cases, dysrhythmias develop as a result of ischemic or structural changes in the heart, rather than in isolation. Advise patients who are at risk or who complain of occasional palpitations or flutters in their chest to reduce their intake of caffeine and other SNS stimulants, such as excess chocolate.

Assessment

Assessment is vital before treating any suspected dysrhythmia. What appears to be ventricular tachycardia on the monitor may be the patient scratching or brushing his or her teeth. Apparent asystole on the

TABLE 30–9 Potential Pacemaker Problems and Corrective Strategies

Problem	Possible Causes	Corrective Measures
UNDERSENSING		
Device fails to detect existing cardiac depolarizations; therefore, it competes with the native rhythms.	Lead disconnected from pacer or from viable myocardium. Sensitivity set too low. Lead fracture. Low battery.	Check connection of lead to pacer. Increase sensitivity. Reposition or change lead. Change battery.
		
OVERSENSING		
Device detects noncardiac electrical events and interprets them as cardiac depolarizations; therefore, it is wrongly inhibited from pacing.	Sensitivity set too high.	Decrease sensitivity (turn sensing control to a LARGER number).
	Interference from electrical sources (ungrounded equipment, short circuits) is detected and misinterpreted by the device. Lead disconnected from pacer or from viable myocardium.	Remove all ungrounded electrical equipment or have it evaluated by hospital engineers. Check connection of lead to pacer.
NONCAPTURE		
Device emits stimuli that fail to depolarize the myocardium.	Output set too low in the noncaptured chamber. Lead fracture. High pacing threshold due to medication or metabolic changes. Low battery.	Increase output in the noncaptured chamber. Reposition or change lead. Alter medication regimen, correct metabolic changes. Change battery.
		

monitor may be due to a loose electrode patch. Similarly, a heart rate of 52 bpm may not affect the overall cardiac output in some patients. Review Chapter 29 for complete assessment of the patient with a cardiac problem.

- *Health history:* complaints of palpitations (ask for further definition of palpitations), fluttering sensations, or a sensation of the heart racing; episodes of dizziness, light-headedness, or syncope (fainting); timing (duration, time of day); correlation with food or beverage intake, activity; presence of chest pain, shortness of breath, or other associated symptoms; history of heart or endocrine disease (such as hyperthyroidism); current medications
- *Physical assessment:* level of consciousness (LOC); vital signs, including apical pulse for a full minute; regularity and amplitude of peripheral pulses; color; presence of dyspnea, adventitious lung sounds; ECG rhythm analysis; oxygen saturation levels.

NURSING CARE OF THE PATIENT

Having a Permanent Pacemaker Implant

PREOPERATIVE CARE

- Provide routine preoperative care and teaching as outlined in Chapter 4.
- Assess knowledge and understanding of the procedure, clarifying and expanding on existing knowledge as needed. *Clarifying knowledge, providing information, and conveying emotional support reduce anxiety and fear and allow the patient to develop a realistic outlook regarding pacer therapy.*
- Place ECG monitor electrodes away from potential incision sites. *This helps preserve skin integrity.*
- Teach range-of-motion (ROM) exercises for the affected side. *ROM exercises of the affected arm and shoulder prevent stiffness and impaired function following pacemaker insertion.*

POSTOPERATIVE CARE

- Provide postoperative monitoring, analgesia, and care as outlined in Chapter 4.
- Obtain a chest x-ray as ordered. *A postoperative chest x-ray is used to identify lead location and detect possible complications, such as pneumothorax or pleural effusion.*
- Position for comfort. Minimize movement of the affected arm and shoulder during the initial postoperative period. *Restricting movement minimizes discomfort on the operative side and allows the leads to become anchored, reducing the risk of dislodging.*
- Assist with gentle ROM exercises at least three times daily, beginning 24 hours after pacemaker implantation. *ROM exercises help restore normal shoulder movement and prevent contractures on the affected side.*
- Monitor pacemaker function with cardiac monitoring or intermittent ECGs. Report pacemaker problems to the physician:
  - Failure to pace. *This may indicate battery depletion, damage or dislodgement of pacer wires, or inappropriate sensing.*
  - Failure to capture (the pacemaker stimulus is not followed by ventricular depolarization). *The electrical output of the pacemaker may not be adequate, or the lead may be dislodged.*
  - Improper sensing (the pacemaker is firing or not firing, regardless of the intrinsic rate). *This increases the risk for decreased cardiac output and dysrhythmias.*
  - Runaway pacemaker (a pacemaker firing at a rapid rate). *This may be due to generator malfunction or problems with sensing.*
  - Hiccups. *A lead positioned near the diaphragm can stimulate it, causing hiccups. Hiccups may occur in extremely thin patients or may indicate a medical emergency with perforation of the right ventricle by the pacing electrode tip.*
- Assess for dysrhythmias and treat as indicated. *Until the catheter is "seated" or adheres to the myocardium, its movement may cause myocardial irritability and dysrhythmias. Fibrotic tissue develops within 2 to 3 days.*
- Document the date of pacemaker insertion, the model and type, and settings. *This information is important for future reference.*
- Immediately report signs of potential complications, including myocardial perforation, cardiac tamponade, pneumothorax, hemothorax, emboli, skin breakdown, bleeding, infection, endocarditis, or poor wound healing (see Chapter 31 for more information about cardiac tamponade and endocarditis, and Chapter 36 for pneumothorax and hemothorax). *Early identification of complications allows for aggressive intervention.*
- Provide a pacemaker identification card including the manufacturer's name, model number, mode of operation, rate parameters, and expected battery life. *This card provides a reference for the patient and future healthcare providers.*

HOME CARE

Provide appropriate teaching for the patient and family about the following:

- Placement of the pacemaker generator and leads in relation to the heart.
- How the pacemaker works and the rate at which it is set.
- Battery replacement. Most pacemaker batteries last 6 to 12 years. Replacement requires outpatient surgery to open the subcutaneous pocket and replace the battery.
- Notify healthcare provider of weakness, dizziness, or light-headedness.
- How to take and record the pulse rate. Instruct to assess pulse daily before arising and notify the physician if 5 or more bpm slower than the preset pacemaker rate.
- Incision care and signs of infection. Bruising may be present following surgery.
- Signs of pacemaker malfunction to report, including dizziness, fainting, fatigue, weakness, chest pain, or palpitations.
- Activity restrictions as ordered. This usually is limited to contact sports (which may damage the generator) and avoiding heavy lifting for 2 months after surgery.
- Resume sexual activity as recommended by the physician. Avoid positions that cause pressure on the site.
- Avoid tight-fitting clothing over the pacemaker site to reduce irritation and avoid skin breakdown.
- Carry the pacemaker identification card at all times, and wear a medical alert bracelet or tag.
- Notify all care providers of the pacemaker.
- Do not hold or use certain electrical devices over the pacemaker site, including household appliances or tools, garage door openers, antitheft devices, or burglar alarms. Do not perform arc-welding. A pacemaker will set off airport security detectors; notify security officials of its presence.
- Maintain follow-up care with the physician as recommended.

Priorities of Care

Collaborating with the interprofessional team to ensure adequate treatment of the cardiac perfusion limitations while providing care that supports circulation (including appropriate precautions) as well as, teaching the patient and, as appropriate, caregivers strategies to identify early signs and symptoms of acute cardiac events and optimize safe home and work environments, should be considered priority nursing actions. The nurse also focuses on promoting comfort and prevention of cardiac event recurrence.

Diagnoses, Outcomes, and Interventions

The effect of the dysrhythmia on cardiac output is the priority of nursing care. Other potential nursing diagnoses related to dysrhythmias may include *Ineffective Tissue Perfusion*, *Activity Intolerance*, and *Fear* or *Anxiety*.

Decreased Cardiac Output

Dysrhythmias can affect cardiac output. Bradycardias decrease cardiac output if the stroke volume does not increase to compensate for

CASE STUDY & NURSING CARE PLAN A Patient with Supraventricular Tachycardia

Elisa Vasquez, 53 years old, is admitted to the cardiac unit with complaints of palpitations, light-headedness, and shortness of breath. Her history reveals rheumatic fever at age 12 with subsequent rheumatic heart disease and mitral stenosis. An intravenous line is in place and she is receiving oxygen. Marcia Lewin, RN, is assigned to Ms. Vasquez.

ASSESSMENT

Ms. Lewin's assessment reveals that Ms. Vasquez is moderately anxious. Her ECG shows supraventricular tachycardia (SVT) with a rate of 154. Vital signs: T 98.8° F (37.1°C), R 26/min, BP 95/60 mmHg. Peripheral pulses weak but equal, mucous membranes pale pink, skin cool and dry. Fine crackles noted in both lung bases. A loud S_3 gallop and a diastolic murmur are noted. Ms. Vasquez is still complaining of palpitations and tells Ms. Lewin, "I feel so nervous and weak and dizzy." Ms. Vasquez's cardiologist orders 2.5 mg of verapamil to be given slowly via intravenous push and tells Ms. Lewin to prepare to assist with synchronized cardioversion if drug therapy does not control the ventricular rate.

DIAGNOSIS

- *Decreased Cardiac Output* related to inadequate ventricular filling associated with rapid tachycardia
- *Ineffective Tissue Perfusion: Cerebral/Cardiopulmonary/Peripheral* related to decreased cardiac output
- *Anxiety* related to unknown outcome of altered health state

EXPECTED OUTCOMES

- Patient will maintain adequate cardiac output and tissue perfusion.
- Patient will demonstrate a ventricular rate within normal limits and stable vital signs.
- Patient will verbalize reduced anxiety.
- Patient will verbalize an understanding of the rationale for the treatment measures to control the heart rate.

PLANNING AND IMPLEMENTATION

- Provide oxygen per nasal cannula at 4 L/min.
- Continuously monitor ECG for rate, rhythm, and conduction. Assess vital signs and associated symptoms with changes in ECG. Report findings to physician.
- Explain the importance of rapidly reducing the heart rate. Explain the cardioversion procedure and encourage questions.
- Encourage verbalization of fears and concerns. Answer questions honestly, correcting misconceptions about the disease process, treatment, or prognosis.
- Administer intravenous diazepam as ordered before cardioversion.
- Document pretreatment vital signs, LOC, and peripheral pulses.
- Place emergency cart with drugs and airway management supplies in patient unit.
- Assist with cardioversion as indicated.
- Assess LOC, level of sedation, cardiovascular and respiratory status, and skin condition following cardioversion.
- Document procedure and postcardioversion rhythm, and response to intervention.

EVALUATION

Intravenous verapamil lowers Ms. Vasquez's heart rate to 138 for a short time, after which it increases to 164 with BP of 82/64. Her cardiologist, Dr. Mullins, performs carotid sinus massage. The ventricular rate slows to 126 for 2 minutes, revealing atrial flutter waves, and then returns to a rate of 150. Dr. Mullins explains the treatment options, including synchronized cardioversion. Ms. Vasquez agrees to the procedure.

Ms. Vasquez is lightly sedated and synchronized cardioversion is performed. One countershock converts Ms. Vasquez to regular sinus rhythm at 96 bpm with BP 112/60.

Ms. Vasquez is sleepy from the sedation but recovers without incident. She states that she feels "much better," and her vital signs return to her normal levels. She remains in NSR with a rate of 86 to 92 beats per minute for the remainder of her hospital stay. Dr. Mullins places Ms. Vasquez on furosemide to treat manifestations of mild heart failure.

Clinical Reasoning in Patient Care

1. What is the scientific basis for using carotid massage to treat supraventricular tachycardias? Was this an appropriate maneuver in the case of Ms. Vasquez?
2. What other treatment options might the physician have used to treat Ms. Vasquez's supraventricular tachycardia if she had been asymptomatic with stable vital signs?
3. Develop a teaching plan for Ms. Vasquez related to her prescription for furosemide.

See Evaluating Your Response in Appendix B.

the slow heart rate. Tachycardia reduces diastolic filling time, affecting stroke volume and coronary artery perfusion. Loss of the atrial kick in junctional rhythms, atrial fibrillation, and AV blocks also decreases ventricular filling and cardiac output. In ventricular fibrillation, loss of ventricular contractions causes cardiac arrest and no cardiac output.

Expected Outcome: Patient will demonstrate adequate cardiac output as evidenced by blood pressure and pulse rate and rhythm within normal limits.

PRACTICE ALERT!

Before treating any dysrhythmia, assess the patient, not just the monitor! Loose electrode pads, disconnected leads or cables, and muscle movement can simulate critical dysrhythmias. The patient's condition is the best indicator of the need for treatment.

- Assess for decreased cardiac output: decreased LOC; tachycardia; tachypnea; hypotension; low oxygen saturation; diaphoresis; low urine output; cool, clammy, mottled skin; pallor or cyanosis; and diminished peripheral pulses. *Initial signs of decreased cardiac output may be subtle, such as decreased LOC. Early recognition of the dysrhythmia's effect on cardiac output facilitates appropriate treatment and may prevent further adverse effects.*
- Monitor ECG; post ECG strip every shift and when rhythm changes occur. *Documenting cardiac rhythm provides a record of disease progression and treatment effectiveness.*

PRACTICE ALERT!

Assess vital signs, ECG, and oxygen saturation every 5 to 15 minutes during acute dysrhythmic episodes and during antidysrhythmic drug infusions. These data provide a record of cardiac output during the dysrhythmia. Antidysrhythmic drugs can adversely affect heart rate, rhythm, and blood pressure, further decreasing cardiac output.

- Assess for underlying causes of dysrhythmias, such as hypovolemia, hypoxia, anemia, electrolyte imbalance, vagal stimulation, or

medications. *Sinus tachycardia often develops in response to tissue hypoxia. Vagal stimulation (such as the Valsalva maneuver) can precipitate bradycardia.*

- Assess serum electrolytes (especially potassium, calcium, and magnesium) and digitalis and antidysrhythmic drug levels as indicated. Report abnormal values. *Electrolyte imbalances affect cardiac depolarization and repolarization and may cause dysrhythmias. Toxic levels of digitalis and antidysrhythmic drugs can precipitate further dysrhythmias. Impaired renal or hepatic function increases the risk for toxicity, as does aging.*
- Be prepared to administer antidysrhythmic medications as indicated. Implement Advanced Cardiac Life Support (ACLS) protocols as needed. *Emergency drugs should be readily available, especially on units with high-risk patients. Refer to Table 30–7 and the Medication Administration box on page 906 for drugs used to treat common dysrhythmias that may affect cardiac output.*
- If appropriate, instruct to perform the Valsalva maneuver (bear down as if straining or coughing) for supraventricular tachycardia or ventricular tachycardia without angina. *Vagal maneuvers stimulate the parasympathetic system and may terminate some dysrhythmias. The Valsalva maneuver is contraindicated if chest pain occurs with the dysrhythmia.*
- Prepare to assist with cardioversion. Prepare the patient per orders or hospital protocol. Explain the procedure to reduce anxiety. Have emergency equipment readily available. *Elective or emergency cardioversion is a treatment of choice for certain dysrhythmias.*

PRACTICE ALERT!

On recognizing ventricular fibrillation and cardiac arrest, begin emergency procedures. Call for help. Obtain defibrillator and immediately defibrillate. If the defibrillator will be brought by another healthcare provider, begin CPR. Initiate ACLS protocols and assist with resuscitation measures as directed. Cardiac output ceases with ventricular fibrillation. Immediate or early defibrillation has been shown to have the greatest impact on survival following cardiac arrest.

- After cardiac arrest, transfer to critical care. Perform and document head-to-toe assessment; obtain laboratory tests, 12-lead ECG, and chest x-ray as ordered; monitor and maintain oxygenation and intravenous infusions; and monitor vital signs and cardiac rhythm. *The period following resuscitation is critical, necessitating careful monitoring. Postarrest assessment allows comparison of the patient's condition with prearrest status and may identify CPR-related injuries. Correcting electrolyte disturbances, hypoxia, and acid–base imbalances is important to prevent further dysrhythmias and potential adverse effects on cardiac output. Intravenous access is crucial to maintain drug infusions. Hemodynamic monitoring may be instituted. The 12-lead ECG documents myocardial status, and the chest x-ray provides information about pulmonary status and possible thoracic injury due to CPR.*
- Notify the family of significant changes in the patient's condition or cardiac arrest, providing up-to-date information. Prepare family members prior to visits by explaining interventions (such as invasive tubes, a ventilator, or additional equipment) implemented since the last visit. *Concern for the family and significant others is part of holistic nursing. Researchers studying the needs of families have found that one of the most important needs was information about their loved one's condition. Patients and families need and appreciate honest communication and compassionate care. Preparing the family for critical changes in the patient's condition and plan of care helps them to cope with a situational crisis.*

Continuity of Care

Dysrhythmias have a significant physical and psychologic impact on the patient and all family members. Many of these patients and their families are under a great deal of stress from frequent hospitalizations, experimentation with therapies, frustration, and the fear of sudden cardiac death. A major teaching effort focuses on coping strategies and lifestyle changes, as well as specific management of prescribed therapies. Include the following topics as appropriate when teaching the patient and family for home care:

- Function, maintenance, precautions, and signs of malfunction or complications of any implanted device such as a pacemaker or ICD
- Monitoring pulse rate and rhythm
- Activity or dietary restrictions, and any potential effects of the dysrhythmia or its treatment on lifestyle
- Medication management to reduce the risk of dysrhythmias, including the desired and potential adverse effects of antidysrhythmic drugs
- Specific instructions related to planned diagnostic tests or procedures
- The importance of follow-up visits with the cardiologist
- The importance of and where to obtain CPR training for the patient and family members.

In addition, discuss fears related to treatment or implanted devices, such as that of shocking a significant other during close contact or sexual activity. Explain that if a shock occurs, the partner may feel a slight buzz or tingling but should not be harmed. Refer to and encourage the patient and family to attend a peer support group for the specific condition.

THE PATIENT WITH SUDDEN CARDIAC DEATH

Sudden cardiac death (SCD) is defined as unexpected death occurring within 1 hour of the onset of cardiovascular symptoms. It usually is caused by ventricular fibrillation and cardiac arrest. *Cardiac arrest* is the sudden collapse, loss of consciousness, and cessation of effective circulation that precedes biologic death. Worldwide, fewer than 6% of out-of-hospital cardiac arrest victims survive. In communities of North America that have organized lay rescuer and automated AED programs, the survival rate is significantly better, ranging from 49% to 74% when a witnessed arrest due to ventricular fibrillation occurs (AHA, 2013).

Almost 50% of all deaths due to CHD are attributed to SCD. CHD causes up to 80% of all sudden cardiac deaths in the United States. Other cardiac pathologies such as cardiomyopathy and valvular disorders also may lead to SCD. Noncardiac causes of sudden death include electrocution, pulmonary embolism, and rapid blood loss from a ruptured aortic aneurysm.

Ventricular fibrillation is the most common dysrhythmia associated with SCD, accounting for 65% to 80% of cardiac arrests. Sustained severe bradydysrhythmias, *asystole* or cardiac standstill, and pulseless electrical activity (organized cardiac electrical activity without a mechanical response) are responsible for most remaining

BOX 30–6 Selected Causes of Sudden Cardiac Death

CARDIAC CAUSES
- Coronary heart disease
- Reperfusion following ischemia
- Myocardial hypertrophy
- Cardiomyopathy
- Inflammatory myocardial disorders
- Valve disorders
- Primary electrical disorders
- Dissecting or ruptured aortic or ventricular aneurysm
- Cardiac drug toxicity

NONCARDIAC CAUSES
- Pulmonary embolism
- Cerebral hemorrhage
- Autonomic dysfunction
- Choking
- Electrical shock
- Electrolyte and acid–base imbalances

SCDs. Selected cardiac and noncardiac causes of sudden cardiac death are listed in Box 30–6.

Risk factors for SCD are those associated with CHD. Advancing age and male gender are powerful risk factors. After age 65, the gap between male and female incidence of SCD narrows. Patients with dysrhythmias such as recurrent VT may have a higher risk of SCD. Women with AMI, however, are more likely to present with cardiac arrest and cardiogenic shock than with ventricular tachycardia.

Pathophysiology

Evidence of CHD with significant atherosclerosis and narrowing of two or more major coronary arteries is found in 75% of SCD victims. Although most have had a prior MI, only 20% to 30% have had a recent AMI. An acute change in cardiovascular status precedes cardiac arrest by up to 1 hour; however, often the onset is instantaneous or abrupt. Tachycardia develops, and the number of PVCs increases. This is followed by a run of VT that deteriorates into VF (Perrin & MacLeod, 2012).

Abnormalities of myocardial structure or function also contribute. Structural abnormalities include infarction, hypertrophy, myopathy, and electrical anomalies. Functional deviations are caused by such factors as ischemia followed by reperfusion, altered homeostasis, autonomic nervous system and hormone interactions, and toxic effects. The interactions of the two cause myocardial instability and may precipitate fatal dysrhythmias.

Manifestations

SCD may be preceded by typical manifestations of ACS or MI, including severe chest pain, dyspnea or orthopnea, and palpitations or light-headedness. The event itself is abrupt, with complete loss of consciousness and death within minutes. If VT precedes cardiac arrest, consciousness and mentation may be impaired prior to collapse and loss of consciousness.

●○● INTERPROFESSIONAL CARE

The goal of care is to restore cardiac output and tissue perfusion. Treatment measures are initiated as soon as clinical cardiac arrest is verified by the absence of respirations and carotid or femoral pulses. Basic and advanced cardiac life support measures must be instituted within 2 to 4 minutes of cardiac arrest to prevent permanent neurologic damage and ischemic injury to other organs.

BASIC LIFE SUPPORT

Basic life support (BLS) begins with identification of the cardiac arrest and initiation of an emergency response.

Providers trained in the use of the *automated external defibrillator (AED)* should immediately defibrillate the patient in VF. Self-adhesive conductive pads attached to connecting cables are positioned on the chest (Figure 30–13 ■). The AED analyzes the rhythm and advises the provider to charge the device if VF is detected. After warning all personnel to stand clear, the shock button is depressed to deliver a shock. Following the shock, CPR is immediately initiated. After approximately 2 minutes or five cycles of CPR, the rhythm is evaluated and circulation checked. The sequence of analysis, shock, and CPR is continued and ACLS protocols are initiated.

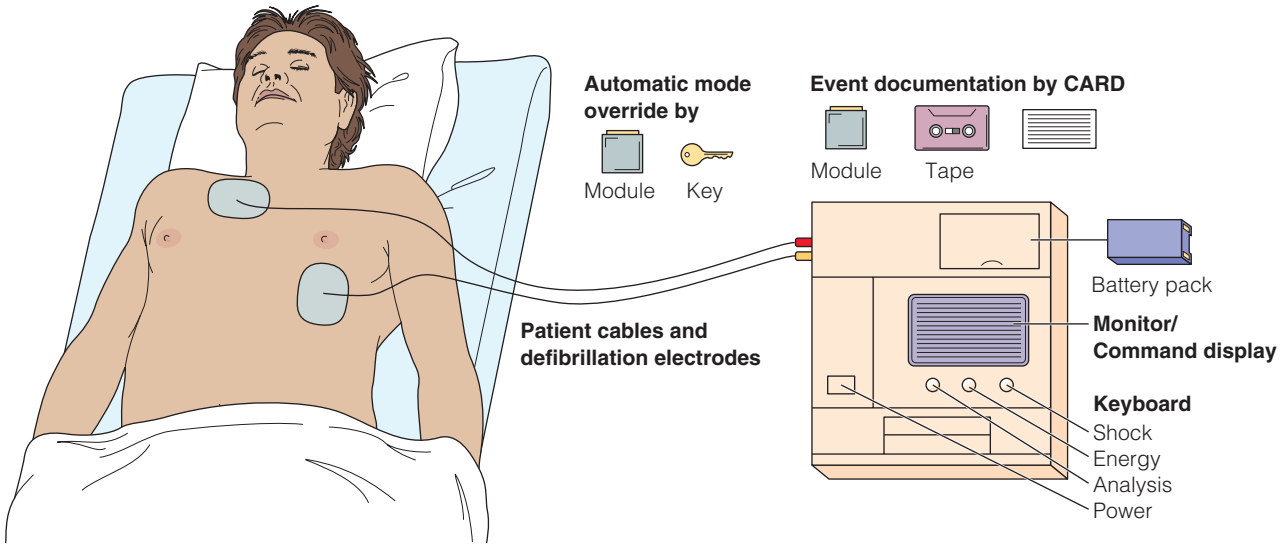


Figure 30–13 ■ Schematic of an automated external defibrillator (AED) attached to a patient.

Cardiopulmonary resuscitation (CPR) is a mechanical attempt to maintain tissue perfusion using external cardiac compressions. All healthcare providers need to be proficient in CPR. The technique, as updated in 2014, should be performed according to AHA or American Red Cross guidelines and hospital protocol (see Box 30–7). Research demonstrates clear benefit from sustained, effective chest compressions, yet compressions often are interrupted for ventilation, assessment of pulses, and other measures. Many patients are excessively ventilated and under-perfused during CPR.

CPR carries a high risk for both cardiac and noncardiac trauma. CPR-related complications include injuries to the skin, thorax, upper airway, abdomen, lungs, heart, and great vessels. These complications can be minimized by adhering to accepted CPR techniques.

ADVANCED LIFE SUPPORT

Advanced life support (ALS), provided by specially trained healthcare personnel, includes advanced airway support (insertion of a laryngeal mask airway [LMA], esophageal-tracheal Combitube, or endotracheal intubation) to maintain the airway and oxygenation, use of intravenous drugs following specific protocols, and additional interventions such as repeated defibrillation procedures and cardiac pacing. Epinephrine, vasopressin, sodium bicarbonate, and antidysrhythmic drugs such as amiodarone, lidocaine, procainamide, magnesium sulfate, and atropine are used to attempt to restore and maintain an effective cardiac rhythm.

POSTRESUSCITATION CARE

Patients who are resuscitated following a cardiac arrest that associated with ventricular fibrillation and acute MI have the best prognosis. The patient is transferred to a coronary care unit and MI treatment measures are instituted. Antidysrhythmic drugs may be continued for 24 to 48 hours to reduce the risk of subsequent episodes of VF.

Because the risk for recurrent cardiac arrest is significant in survivors, extensive diagnostic testing and interventions such as angioplasty or surgical revascularization of the myocardium, ablation, or an implantable cardioverter/defibrillator may be indicated.

●○● NURSING CARE

Priorities of Care

Nursing care of the patient experiencing SCD requires prompt recognition of the event and immediate initiation of BLS and ALS protocols. As noted before, fast and effective cardiac compressions and early defibrillation of unstable VT and VF are the most important

BOX 30–7 Cardiopulmonary Resuscitation

1. Assess for responsiveness; shake the patient and shout.
2. Call for help. Dial 911 (if outside the healthcare facility) or initiate the institutional code or cardiac arrest procedure.
3. Initiate hard and fast cardiac compressions, pressing straight down to depress the sternum at least 2 inches, keeping the elbows locked and positioning the shoulders directly over the hands (part A of the figure). Release pressure completely between compressions but do not lift the hands from the chest. The rate should be at least 100 compressions per minute (part B of the figure).
4. After 30 compressions, open the airway using the head tilt/chin lift by simultaneously pressing down on the forehead with one hand while lifting the chin upward with the other and deliver 2 ventilations (part C of the figure).
5. Continue to compress the chest at a rate of at least 100 times per minute; continue CPR until help arrives.
6. When any rescuer witnesses an out-of-hospital arrest and an AED is immediately available on-site, the rescuer should start CPR with chest compressions and use the AED as soon as possible

A Placement of hands on the sternum between nipples.

B Arm, hand, and shoulder position for cardiac massage.

C Head-tilt/chin-lift maneuver and use of a bag-valve-mask unit.

Source: American Red Cross. (2014). Retrieved from http://www.cprcertificationonlinehq.com/american-red-cross-official-guidelines-cpr-2014/.

keys to survival of cardiac arrest victims. Important concepts of emergency cardiac care follow:

- Treat the patient, not the monitor. Recognize signs and symptoms of cardiac compromise early.
- Activate the emergency medical services system (i.e., call a code or call 911).
- Begin and continue basic cardiac life support principles throughout the resuscitation effort.
- Continually assess the effectiveness of emergency interventions.
- Defibrillate pulseless VT or VF as soon as possible.
- Initiate ALS protocols early.

The family is not forgotten during resuscitation. If family members are present, they are usually offered a private consultation room in which to await the outcome. If the family is not present, they are notified that their family member is not doing well and asked to come to the hospital as soon as possible. The situation is presented in a careful manner to prevent the family from racing to the hospital, precipitating an automobile crash. Pastoral care or the family's choice of spiritual support is offered to help during this difficult time. Attendance of family members during resuscitation efforts is controversial, and depends on institutional protocols and family desires.

After successful resuscitation, the nurse provides care specific to the patient's underlying disease processes and needs. Intravenous infusions such as lidocaine or dopamine may be ordered to prevent further dysrhythmias and maintain hemodynamic stability.

If the patient does not survive the arrest, the nurse provides postmortem care and emotional and spiritual support to the family.

Nursing diagnoses to consider for the patient experiencing cardiac arrest include the following:

- *Ineffective Tissue Perfusion: Cerebral* related to ineffective cardiac output
- *Impaired Spontaneous Ventilation* related to cardiac arrest
- *Spiritual Distress* related to unexplained sudden cardiac death
- *Disturbed Thought Processes* related to compromised cerebral circulation
- *Fear* related to risk for future episodes of near sudden cardiac death

The risk for a future episode of near SCD requires careful and effective teaching for home care prior to discharge. Discuss the following topics with the patient and family:

- Risk factor reduction for CHD
- Planned diagnostic studies to identify the cause of SCD, and possible interventions
- The risks and benefits of an ICD if appropriate
- The importance of carrying a card at all times listing all current medications and contact information for the patient's healthcare provider
- Early manifestations or warning signs of cardiac arrest
- The importance of CPR training and maintaining proficiency in performing CPR (Provide referral to local CPR training providers or scheduled classes through the American Heart Association or American Red Cross.).

Nurses can impact death rates from cardiac arrest through community teaching as well. Survival rates from cardiac arrest related to SCD improve in communities in which a significant portion of the population is trained in CPR and early response by EMS agencies is stressed. Work with community groups and individuals can help create a population of people able to perform effective CPR.

CHAPTER HIGHLIGHTS

- **Atherosclerosis is the primary underlying process in coronary heart disease, impaired perfusion of myocardial tissue.**
- The risk factors for coronary heart disease are those for atherosclerosis: age, gender, and genetic factors; hypertension, diabetes, abnormal blood lipids; cigarette smoking, obesity, physical inactivity, and diet; and emerging risk factors such as the metabolic syndrome and homocysteine levels.
- **Smoking cessation, exercise, diet modification, weight loss, medications to achieve desired blood lipid values, and effective hypertension and diabetes management are the primary treatment measures for coronary heart disease.**
- Atherosclerosis of coronary vessels impairs the supply of blood, oxygen, and nutrients to the myocardium. Myocardial ischemia results in the manifestations of coronary heart disease, angina pectoris, acute coronary syndrome, and myocardial infarction.
- Stable angina develops with a predictable amount of activity or stress, and typically follows an activity–pain, rest–relief pattern. Stable angina often can be managed effectively by medications and risk factor modification. The nursing focus is on education.
- **Acute coronary syndrome or unstable angina is characterized by increasingly severe chest pain that occurs unpredictably. Acute coronary syndrome often requires aggressive interventions such as percutaneous coronary revascularization or coronary artery bypass surgery.**
- **Myocardial infarction, necrosis of myocardial tissue, results from complete blockage of a coronary artery, usually due to atherosclerotic plaque rupture and thrombus formation. Prompt restoration of blood flow through a revascularization procedure or administration of a fibrinolytic drug to dissolve the blood clot is necessary to preserve functional muscle tissue.**

- The nursing focus for patients with acute coronary syndrome and myocardial infarction is on reducing myocardial work through measures such as pain relief and activity limitation, promoting blood flow and oxygenation through medication and oxygen administration and positioning, and early recognition and treatment of complications.
- **Cardiac dysrhythmias may arise anywhere in conductive tissue of the myocardium. Dysrhythmias may be either benign or fatal, depending on their effect on cardiac output.**
- Tachycardias increase the workload of the heart and may interfere with cardiac output if ventricular filling is impaired by the rapid rate.
- Bradycardias can affect cardiac output when the rate is too slow to meet the metabolic needs of the body.
- Atrial fibrillation is a common dysrhythmia that can lead to formation of blood clots within the heart and subsequent stroke if these clots lodge in cerebral blood vessels.
- Frequent ventricular dysrhythmias may indicate an increased risk for ventricular fibrillation and cardiac arrest.
- AV conduction blocks interfere with conduction of the sinus or atrial impulse through the AV node and to the ventricles.
- Although many antidysrhythmic medications are available, all increase the risk of dysrhythmia development, so they are used sparingly.
- The nurse's role in caring for patients with cardiac dysrhythmias focuses on prompt identification of the rhythm disruption, assessment of its effect on the patient, administration of medications and other treatment measures, and institution of life support procedures as indicated.

TEST YOURSELF NCLEX-RN® REVIEW

1. The nurse instructs a patient about modifiable risk factors for coronary artery disease. Which statements indicate that teaching has been effective? (Select all that apply.)
1. "I should stop smoking to reduce my risk of heart disease."
2. "Restricting my activity reduces the onset of heart disease."
3. "I should drink alcohol because this prevents heart disease."
4. "There is not much that can be done to prevent heart disease."
5. "Obesity is a risk factor that I can change to reduce the onset of heart disease."

2. A patient is prescribed lovastatin (Mevacor) for hyperlipidemia. What should the nurse instruct the patient about this medication?
1. Abstain from alcohol use while taking this drug.
2. Take the drug with meals to minimize gastric distress.
3. Promptly report muscle pain or tenderness to the physician.
4. Consume a diet that includes no more than 20% of calories from saturated fat.

3. The nurse is caring for a patient with stable angina. Which assessment finding would be consistent with this medical diagnosis?
1. persistent ECG changes
2. increasing nocturnal pain
3. correlation between activity level and pain
4. evidence of impaired cardiac output such as weak peripheral pulses

4. The nurse is caring for a patient with acute coronary syndrome. Which nursing diagnosis should be the priority for this patient?
1. *Anxiety* related to unknown outcome of disorder
2. *Decreased Cardiac Output* related to myocardial ischemia
3. *Ineffective Health Maintenance* related to lack of knowledge about coronary heart disease
4. *Ineffective Tissue Perfusion: Cardiopulmonary* related to underlying coronary heart disease

5. The nurse is caring for a patient recovering from a coronary angioplasty with stent placement. Which intervention is a priority for the patient at this time?
1. securing chest tubes to bedding
2. maintaining leg extension on the affected side
3. discontinuing intravenous lines when taking oral fluids
4. treating chest pain with intravenous morphine as needed

6. The nurse is planning care for a patient with acute myocardial infarction. What goals should the nurse use to guide this patient's care? (Select all that apply.)
1. Relieve chest pain.
2. Prevent complications.
3. Reduce blood viscosity.
4. Decrease cardiac workload.
5. Reduce myocardial damage.

7. The nurse is determining nursing diagnoses appropriate for a patient scheduled for fibrinolytic therapy. Which nursing diagnosis would be a priority for this patient?
1. *Anxiety*
2. *Ineffective Protection*
3. *Risk for Powerlessness*
4. *Ineffective Health Maintenance*

8. The nurse is reviewing laboratory results for a patient admitted with acute chest pain. Which laboratory value should cause the nurse the most concern?
1. AST 65 units/L
2. CK 320 units/L
3. Hematocrit 35%
4. APTT 35 seconds

9. The nurse recognizes that a patient has developed second-degree AV block, type II (Mobitz II). Which action should the nurse take at this time?
1. Record the finding in the chart.
2. Places the patient in Fowler's position.
3. Prepare for temporary pacemaker insertion.
4. Administer a Class IB antidysrhythmic drug.

10. The nurse identifies that a patient has sinus bradycardia with a heart rate at 45 bpm. What should the nurse do first?
1. Assess mental status and blood pressure.
2. Prepare to administer intravenous atropine.
3. Assess peripheral pulses on all four extremities.
4. Determine if an apical-radial pulse deficit is present.

See Test Yourself answers in Appendix B.

31 Nursing Care of Patients with Cardiac Disorders

LEARNING OUTCOMES

1. Compare and contrast the etiology, pathophysiology, and manifestations of common cardiac disorders, including heart failure, structural disorders, and inflammatory disorders.
2. Explain risk factors and preventive measures for cardiac disorders such as heart failure, inflammatory disorders, and valve disorders.
3. Discuss indications for and management of patients with hemodynamic monitoring.
4. Discuss the effects and nursing implications for medications commonly prescribed for patients with cardiac disorders.
5. Describe nursing care for the patient undergoing cardiac surgery or cardiac transplant.

CLINICAL COMPETENCIES

1. Apply knowledge of normal cardiac anatomy and physiology and assessment techniques in caring for patients with cardiac disorders.
2. Assess the functional health status of patients with cardiac disorders, documenting and reporting deviations for expected findings.
3. Based on patient assessment and knowledge of the disorder, determine priority nursing diagnoses.
4. Plan, prioritize, and provide evidence-based, individualized care for patients with cardiac disorders.
5. Safely and knowledgeably administer prescribed medications and treatments to patients with cardiac disorders.
6. Actively participate in planning and coordinating interprofessional care for patients with cardiac disorders.
7. Provide appropriate teaching and community-based care for patients with cardiac disorders and their families.
8. Evaluate the effectiveness of nursing care, revising the plan of care as needed to promote, maintain, or restore the functional health status of patients with cardiac disorders.

MAJOR CHAPTER CONCEPTS

- Heart failure, the most common cardiac disorder, is a condition in which the heart is unable to pump effectively to meet the body's needs for blood and oxygen to the tissues.
- Heart failure is due to *impaired myocardial contraction* or *excessive workload.*
- Goals of heart failure management are to reduce the workload and improve its function. Medical management includes medication use including ACE inhibitors, beta-blockers, diuretics, and vasodilators to reduce the cardiac workload.
- Nursing care of the patient with heart failure is primarily supportive and educative, providing the patient and family with the necessary knowledge and resources to manage this chronic condition.

Cardiac disorders affect the structure and/or function of the heart. These disorders interfere with the heart's primary purpose: to pump enough blood to meet the body's demand for oxygen and nutrients. Disruptions in cardiac function affect the functioning of other organs and tissues, potentially leading to organ system failure and death. Emergence of symptoms (fatigue, dyspnea, chest pain) is common with the progression of cardiac disorders. The New York Heart Association (NYHA) classification is commonly used to describe the severity of exertional symptoms observed (see Table 31–1).

TABLE 31–1 New York Heart Association Classification

Class	Severity of Symptoms
I	No limitation in physical activity/asymptomatic
II	Symptoms with strenuous activity
III	Symptoms with mild activity
IV	Symptoms at rest

Heart failure is the most common cardiac disorder. Other cardiac disorders discussed in this chapter include structural cardiac disorders, such as valve disorders and cardiomyopathy, and inflammatory cardiac disorders, such as endocarditis and pericarditis. Before continuing with this chapter, please review the heart's anatomy and physiology, nursing assessment, and diagnostic tests in Chapter 29.

Heart Failure

Heart failure is a complex syndrome resulting from cardiac disorders that impair the ventricles' ability to fill with and effectively pump blood. In heart failure, the heart is unable to pump enough blood to meet the metabolic demands of the body. It is the end result of many conditions. Frequently, it is a long-term effect of coronary heart disease and myocardial infarction (MI) when left ventricular damage is extensive enough to impair cardiac output (refer to Chapter 29). Other diseases of the heart also may cause heart failure, including structural and inflammatory disorders. In normal hearts, failure can result from excessive demands placed on the heart. Heart failure may be acute or chronic.

THE PATIENT WITH HEART FAILURE

As mentioned, heart failure develops when the heart cannot effectively fill or contract with adequate strength to function as a pump to meet the needs of the body. As a result, cardiac output falls, leading to decreased tissue perfusion. The body initially adjusts to reduced cardiac output by activating inherent compensatory mechanisms to restore tissue perfusion. These normal mechanisms may result in vascular congestion—hence, the commonly used term *congestive heart failure (CHF)*. As these mechanisms are exhausted, heart failure ensues, with increased morbidity and mortality.

Heart failure is a disorder of cardiac function. It frequently is due to *impaired myocardial contraction*, which may result from coronary heart disease and myocardial ischemia or infarct or from a primary cardiac muscle disorder such as cardiomyopathy or myocarditis. Structural cardiac disorders, such as valve disorders or congenital heart defects, and hypertension also can lead to heart failure when the heart muscle is damaged by the long-standing *excessive workload* associated with these conditions. Other patients without a primary abnormality of myocardial function may present with manifestations of heart failure due to *acute excess demands* placed on the myocardium, such as volume overload, hyperthyroidism, and massive pulmonary embolus (see Table 31–2). Hypertension and coronary heart disease are the leading causes of heart failure in the United States. The high prevalence of hypertension in African Americans contributes significantly to their risk for and incidence of heart failure.

Incidence, Prevalence, and Risk Factors

More than 6.6 million people in the United States are currently living with heart failure; approximately 550,000 new cases of heart failure are diagnosed annually (American Heart Association [AHA], 2013). Estimates predict an additional 3 million people will have heart failure by 2030. Its incidence and prevalence increase with age: Fewer than 5% of people between ages 55 and 64 have heart failure, whereas 6% to 10% of people ages 65 to 74 are affected. There is a rapid rise in heart failure prevalence after age 65. Those ages 75 to 84 have a 14.8 to 22.3/1000 person (per) years incidence, while those older than 85 years have a 32.7 to 41.9/1000 person-years incidence (see Nursing Care of the Older Adult box). At age 40, the lifetime risk of developing heart failure is one in five (AHA, 2013). The estimated direct and indirect cost of heart failure in the United States in 2011 was $34.4 billion. The prevalence and mortality rate for heart failure is higher in African Americans than in Whites. See the accompanying Focus on Cultural Diversity box.

Ischemic heart disease (coronary heart disease) is the leading risk factor for heart failure. Up to 75% of individuals with heart failure have a history of hypertension.

The prognosis for a patient with heart failure depends on its underlying cause and how effectively precipitating factors can be treated. Most patients with heart failure die within 8 years of the diagnosis. The risk for sudden cardiac death is dramatically increased, occurring at a rate six to nine times that of the general population. In 2009, one in nine death certificates in the United States mentioned heart failure as the primary or a contributing cause of death (AHA, 2013).

Physiology Review

The mechanical pumping action of cardiac muscle propels the blood it receives to the pulmonary and systemic vascular systems for reoxygenation and delivery to the tissues. *Cardiac output (CO)* is the amount

TABLE 31–2 Selected Causes of Heart Failure

Impaired Myocardial Function	Increased Cardiac Workload	Acute Noncardiac Conditions
• Coronary heart disease	• Hypertension	• Volume overload
• Cardiomyopathies	• Valve disorders	• Hyperthyroidism
• Rheumatic fever	• Anemias	• Fever, infection
• Infective endocarditis	• Congenital heart defects	• Massive pulmonary embolus

FOCUS ON CULTURAL DIVERSITY

Heart Disease

- Up to 6.6 million Americans have heart failure. Of these, about 800,000 (15%) are African Americans.
- In African Americans:
  - Manifestations of heart failure develop at an earlier age.
  - The disease progresses more rapidly.
  - More hospital visits are attributed to heart failure.
  - The mortality rate is higher than in White men and women.

of blood pumped from the ventricles in 1 minute. Cardiac output is used to assess cardiac performance, especially left ventricular function. Effective cardiac output depends on adequate functional muscle mass and the ability of the ventricles to work together. Cardiac output normally is regulated by the oxygen needs of the body: As oxygen use increases, cardiac output increases to maintain cellular function. *Cardiac reserve* is the ability of the heart to increase CO to meet metabolic demand. Ventricular damage reduces the cardiac reserve.

Cardiac output is a product of heart rate and stroke volume. *Heart rate* affects cardiac output by controlling the number of ventricular contractions per minute. It is influenced by the autonomic nervous system, catecholamines, and thyroid hormones. Activation of a stress response (e.g., hypovolemia or fear) stimulates the sympathetic nervous system, increasing the heart rate and its contractility. Elevated heart rates increase cardiac output. Very rapid heart rates, however, shorten ventricular filling time (diastole), reducing stroke volume and cardiac output. On the other hand, a slow heart rate reduces cardiac output simply because of fewer cardiac cycles.

Stroke volume, the volume of blood ejected with each heartbeat, is determined by preload, afterload, and myocardial contractility. *Preload* is the volume of blood in the ventricles at end-diastole (just prior to contraction). The blood in the ventricles exerts pressure on the ventricle walls, stretching muscle fibers. The greater the blood volume, the greater the force with which the ventricle contracts to expel the blood. End diastolic volume (EDV) depends on the amount of blood returning to the ventricles (*venous return*), and the distensibility or stiffness of the ventricles (*compliance*). (See Box 31–1.)

BOX 31–1 Explaining Physiologic Terms Using Practical Examples

The concepts of preload, the Frank-Starling mechanism, compliance, and afterload can be difficult to understand and to explain to patients. Use common analogies to make these concepts easier to understand:

- *Preload:* Think about a new rubber band. As you stretch the rubber band and then release it, it snaps back into shape with great force.
- *Frank-Starling mechanism:* When you repeatedly stretch that rubber band beyond a certain limit, it loses some elasticity and fails to return to its original shape and size.
- *Compliance:* Use a new rubber balloon to illustrate this concept. A new balloon is not very compliant—it takes a lot of work (force) to inflate it. As the balloon is repeatedly stretched, it becomes more compliant, expanding easily with less force.
- *Afterload:* When a hose is crimped or plugged, more force is required to eject a stream of water out its end.

Afterload is the force needed to eject blood into the circulation. This force must be great enough to overcome arterial pressures within the pulmonary and systemic vascular systems. The right ventricle must generate enough force to open the pulmonary valve and eject its blood into the pulmonary artery. The left ventricle ejects its blood into the systemic circulation by overcoming the arterial resistance behind the aortic valve. Increased systemic vascular resistance (e.g., hypertension) increases afterload, impairing stroke volume and increasing myocardial work.

Contractility is the natural ability of cardiac muscle fibers to shorten during systole. Contractility is necessary to overcome arterial pressures and eject blood during systole. Impaired contractility affects cardiac output by reducing stroke volume. The *ejection fraction (EF)* is the percentage of blood in the ventricle that is ejected during systole. A normal ejection fraction is approximately 60%.

NURSING CARE OF THE OLDER ADULT

Heart Failure

Heart failure is common in older adults, affecting nearly 10% of people over the age of 75 years.

Aging affects cardiac function. Diastolic filling is impaired by decreased ventricular compliance. With aging, the heart is less responsive to SNS stimulation. As a result, maximal heart rate, cardiac reserve, and exercise tolerance are reduced. Concurrent health problems such as arthritis that affect stamina or mobility often contribute to a more sedentary lifestyle, further decreasing the heart's ability to respond to increased stress.

ASSESSING FOR HOME CARE

The older adult with heart failure may not be dyspneic, instead presenting with weakness and fatigue, somnolence, confusion, disorientation, or worsening dementia. Dependent edema and respiratory crackles may or may not indicate heart failure in older adults.

Assess the diet of the older adult. Decreased taste may lead to increased use of salt to bring out food flavors. Limited mobility or visual acuity may cause the older adult to rely on prepared foods that are high in sodium such as canned soups and frozen meals. Discuss normal daily activities and assess sleep and rest patterns. It is also important to assess the environment for the following:

- Safe roads or neighborhoods for walking
- Access to pharmacy, medical care, and assistive services such as a cardiac rehabilitation program or structured exercise programs designed for older adults.

PATIENT AND FAMILY TEACHING

Teaching for the older adult with heart failure focuses on maintaining function and promptly identifying and treating episodes of heart failure. Teach patients how to adapt to changes in cardiovascular function associated with aging, such as the following:

- Allowing longer warm-up and cool-down periods during exercise
- Engaging in regular exercise such as walking five or more times a week
- Resting with feet elevated (e.g., in a recliner) when fatigued
- Maintaining adequate fluid intake
- Preventing infection through pneumococcal and influenza immunizations.

TABLE 31–3 Compensatory Mechanisms Activated in Heart Failure

Mechanism	Physiology	Effect on Body Systems	Complications
Frank-Starling mechanism	The greater the stretch of cardiac muscle fibers, the greater the force of contraction.	• Increased contractile force leading to increased CO	• Increased myocardial oxygen demand • Limited by overstretching
Neuroendocrine response	Decreased CO stimulates the sympathetic nervous system and catecholamine release.	• Increased HR, BP, and contractility • Increased vascular resistance • Increased venous return	• Tachycardia with decreased filling time and decreased CO • Increased vascular resistance • Increased myocardial work and oxygen demand
	Decreased CO and decreased renal perfusion stimulate renin–angiotensin system.	• Vasoconstriction and increased BP	• Increased myocardial work • Renal vasoconstriction and decreased renal perfusion
	Angiotensin stimulates aldosterone release from adrenal cortex.	• Salt and water retention by the kidneys • Increased vascular volume	• Increased preload and afterload • Pulmonary congestion
	ADH is released from posterior pituitary. Atrial natriuretic factor is released.	• Water excretion inhibited • Increased sodium excretion • Diuresis	• Fluid retention and increased preload and afterload
	Blood flow is redistributed to vital organs (heart and brain).	• Decreased perfusion of other organ systems • Decreased perfusion of skin and muscles	• Renal failure • Anaerobic metabolism and lactic acidosis
Ventricular hypertrophy	Increased cardiac workload causes myocardial muscle to hypertrophy and ventricles to dilate.	• Increased contractile force to maintain CO	• Increased myocardial oxygen demand • Cellular enlargement

Pathophysiology

When the heart begins to fail, mechanisms are activated to compensate for the impaired function and maintain the cardiac output. The primary compensatory mechanisms are (1) the Frank-Starling mechanism, (2) neuroendocrine responses including activation of the sympathetic nervous system (SNS) and the renin–angiotensin–aldosterone system (RAAS), and (3) ventricular hypertrophy. These mechanisms and their effects are summarized in Table 31–3.

Decreased cardiac output initially stimulates aortic baroreceptors, which in turn stimulate the SNS. SNS stimulation produces both cardiac and vascular responses through the release of norepinephrine. Norepinephrine increases heart rate and contractility by stimulating cardiac beta-receptors. Cardiac output improves as both heart rate and stroke volume increase. Norepinephrine also causes arterial and venous vasoconstriction, increasing venous return to the heart. Increased venous return increases ventricular filling and myocardial stretch, increasing the force of contraction (the Frank-Starling mechanism). Overstretching the muscle fibers past their physiologic limit results in an ineffective contraction.

Blood flow is redistributed to the brain and the heart to maintain perfusion of these vital organs. Decreased renal perfusion causes renin to be released from the kidneys. Activation of the RAAS produces additional vasoconstriction and stimulates the adrenal cortex to produce aldosterone and the posterior pituitary to release antidiuretic hormone (ADH). Aldosterone stimulates sodium reabsorption in renal tubules, promoting water retention. ADH acts on the distal tubule to inhibit water excretion and causes vasoconstriction. The effect of these hormones is significant vasoconstriction and salt and water retention, with a resulting increase in vascular volume. Increased ventricular filling increases the force of contraction, improving cardiac output. The increased vascular volume and venous return also increase atrial pressures, stimulating the release of an additional hormone, *atrial natriuretic factor (ANF)* or *atriopeptin*. ANF balances the effects of the other hormones to a certain extent, promoting sodium and water excretion and inhibiting the release of norepinephrine, renin, and ADH. This hormone is thought to be a natural preventive that delays severe cardiac decompensation.

Ventricular remodeling occurs as the heart chambers and myocardium adapt to fluid volume and pressure increases. The chambers dilate to accommodate excess fluid resulting from increased vascular volume and incomplete emptying. Initially, this additional stretch causes more effective contractions. *Ventricular hypertrophy* occurs as existing cardiac muscle cells enlarge, increasing their contractile elements (actin and myosin) and force of contraction.

Although these responses may help in the short-term regulation of cardiac output, it is now recognized that they hasten the deterioration of cardiac function. The onset of heart failure is heralded by *decompensation*, the loss of effective compensation. Heart failure progresses due to the very mechanisms that initially maintained circulatory stability.

The rapid heart rate shortens diastolic filling time, compromises coronary artery perfusion, and increases myocardial oxygen demand. Resulting ischemia further impairs cardiac output. Beta-receptors in the heart become less sensitive to continued SNS stimulation, decreasing heart rate and contractility. As the beta-receptors become less sensitive, norepinephrine stores in the cardiac muscle become depleted. In contrast, alpha-receptors on peripheral blood vessels become increasingly sensitive to persistent stimulation, promoting vasoconstriction and increasing afterload and cardiac work.

Initially, ventricular hypertrophy and dilation increase cardiac output, but chronic distention causes the ventricular wall eventually to thin and degenerate. The purpose of hypertrophy is thus defeated. In addition, chronic overloading of the dilated ventricle eventually stretches the fibers beyond the optimal point for effective contraction. The ventricles continue to dilate to accommodate the excess fluid, but the heart loses the ability to contract forcefully. The heart muscle may eventually become so large that the coronary blood supply is inadequate, causing ischemia.

Chronic distention exhausts atrial stores of ANF. The effects of norepinephrine, renin, and ADH prevail, and the renin–angiotensin pathway is continually stimulated. This mechanism ultimately raises the hemodynamic stress on the heart by increasing both preload and afterload. As heart function deteriorates, less blood is delivered to the tissues and to the heart itself. Ischemia and necrosis of the myocardium further weaken the already failing heart, and the cycle repeats.

In normal hearts, the cardiac reserve allows the heart to adjust its output to meet metabolic needs of the body, increasing the cardiac output by up to five times the basal level during exercise. Patients with heart failure have minimal to no cardiac reserve. At rest, they may be unaffected; however, any stressor (e.g., exercise, illness) taxes their ability to meet the demand for oxygen and nutrients. Manifestations of activity intolerance when the person is at rest indicate a critical level of cardiac decompensation.

Classifications and Manifestations of Heart Failure

Heart failure is commonly classified in several different ways, depending on the underlying pathology. Classifications include systolic versus diastolic failure, left-sided versus right-sided failure, low-output versus high-output failure, and acute versus chronic failure.

FAST FACTS

Terms used to describe or classify heart failure are as follows:

- Systolic or diastolic failure
- Left ventricular (or sided) or right ventricular (or sided) failure
- Low-output or high-output failure
- Acute or chronic failure
- Forward or backward effects

SYSTOLIC VERSUS DIASTOLIC FAILURE

Systolic failure occurs when the ventricle fails to contract adequately to eject a sufficient blood volume into the arterial system. Systolic function is affected by loss of myocardial cells due to ischemia and infarction, cardiomyopathy, or inflammation. The manifestations of systolic failure are those of decreased cardiac output: weakness, fatigue, and decreased exercise tolerance.

Diastolic failure results when the heart cannot completely relax in diastole, disrupting normal filling. Passive diastolic filling decreases, increasing the importance of atrial contraction to preload. Diastolic dysfunction results from decreased ventricular compliance due to hypertrophic and cellular changes and impaired relaxation of the heart muscle. Its manifestations result from increased pressure and congestion behind the ventricle: shortness of breath, tachypnea, and respiratory crackles if the left ventricle is affected; distended neck veins, liver enlargement, anorexia, and nausea if the right ventricle is affected. Many patients have components of both systolic and diastolic failure.

LEFT-SIDED VERSUS RIGHT-SIDED FAILURE

Depending on the pathophysiology involved, either the left or the right ventricle may be primarily affected. In chronic heart failure, however, both ventricles typically are impaired to some degree. Coronary heart disease and hypertension are common causes of *left-sided heart failure*, whereas *right-sided heart failure* often is caused by conditions that restrict blood flow to the lungs, such as acute or chronic pulmonary disease. Left-sided heart failure also can lead to right-sided failure as pressures in the pulmonary vascular system increase with congestion behind the failing left ventricle.

As left ventricular function fails, cardiac output falls. Pressures in the left ventricle and atrium increase as the amount of blood remaining in the ventricle after systole increases. These increased pressures impair filling, causing congestion and increased pressures in the pulmonary vascular system. Increased pressures in this normally low-pressure system increase fluid movement from the blood vessels into interstitial tissues and the alveoli (Figure 31–1 ■).

The manifestations of left-sided heart failure result from pulmonary congestion (*backward effects*) and decreased cardiac output (*forward effects*). Fatigue and activity intolerance are common early manifestations. Dizziness and syncope also may result from decreased cardiac output. Pulmonary congestion causes dyspnea, shortness of

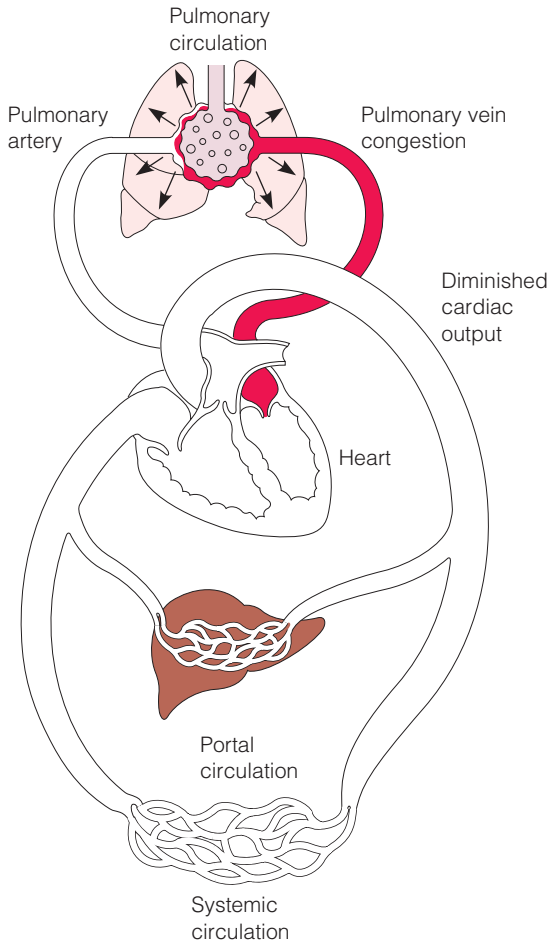

Figure 31–1 ■ The hemodynamic effects of left-sided heart failure.

breath, and a cough. The patient may develop **orthopnea** (difficulty breathing while lying down), prompting use of two or three pillows or a recliner for sleeping. Cyanosis from impaired gas exchange may be noted. On auscultation of the lungs, inspiratory crackles (rales) and wheezes may be heard in lung bases. An S_3 gallop may be present, reflecting the heart's attempts to fill an already distended ventricle.

In right-sided heart failure, increased pressures in the pulmonary vasculature or right ventricular muscle damage impair the right ventricle's ability to pump blood into the pulmonary circulation. The right ventricle and atrium become distended, and blood accumulates in the systemic venous system. Increased venous pressures cause abdominal organs to become congested and peripheral tissue edema to develop (Figure 31–2 ■).

Dependent tissues tend to be affected because of the effects of gravity; edema develops in the feet and legs, or if the patient is bedridden, in the sacrum. Congestion of gastrointestinal tract vessels causes anorexia and nausea. Right upper quadrant pain may result from liver engorgement. Neck veins distend and become visible even when the patient is upright due to increased venous pressure.

LOW-OUTPUT VERSUS HIGH-OUTPUT FAILURE

Patients with heart failure due to coronary heart disease, hypertension, cardiomyopathy, and other primary cardiac disorders develop *low-output failure* and manifestations such as those previously described. Patients in hypermetabolic states (e.g., hyperthyroidism, infection, anemia, or pregnancy) require increased cardiac output to maintain blood flow and oxygen to the tissues. If the increased blood flow cannot meet the oxygen demands of the tissues, compensatory mechanisms are activated to further increase cardiac output, which in turn further increases oxygen demand. Thus, even though cardiac output is high, the heart is unable to meet increased oxygen demands. This condition is known as *high-output failure*.

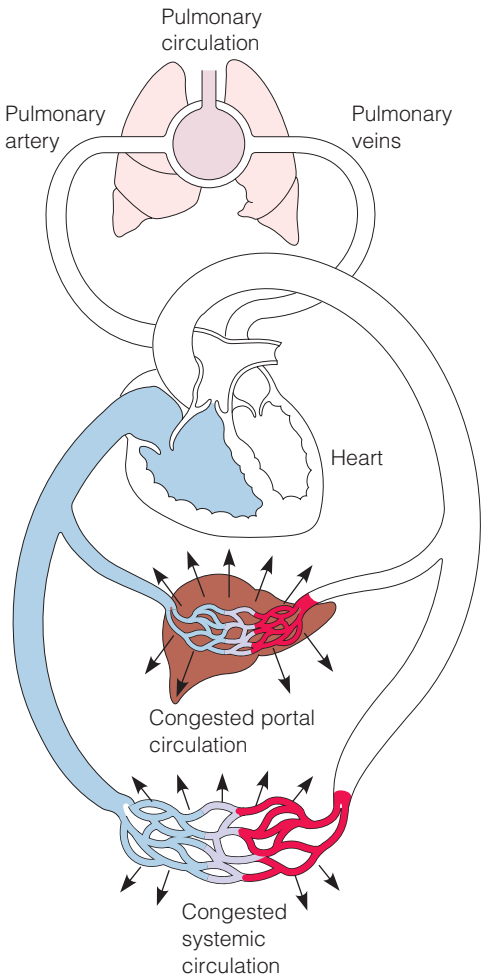

Figure 31–2 ■ The hemodynamic effects of right-sided heart failure.

ACUTE VERSUS CHRONIC FAILURE

Acute failure is the abrupt onset of a myocardial injury (such as a massive MI) resulting in suddenly decreased cardiac function and signs of decreased cardiac output. *Chronic failure* is a progressive deterioration of the heart muscle due to cardiomyopathies, valvular disease, or coronary heart disease (CHD).

OTHER MANIFESTATIONS

In addition to the previous manifestations for the various classifications of heart failure, other signs and symptoms commonly are seen.

A fall in cardiac output activates mechanisms that cause increased salt and water retention. This causes weight gain and further increases pressures in the capillaries, resulting in edema. *Nocturia*, voiding more than one time at night, develops as edema fluid from dependent tissues is reabsorbed when the patient is supine. **Paroxysmal nocturnal dyspnea (PND)**, a frightening condition in which the patient awakens at night acutely short of breath, also may develop. PND occurs when edema fluid that has accumulated during the day is reabsorbed into the circulation at night, causing fluid overload and pulmonary congestion. Severe heart failure may cause dyspnea at rest as well as with activity, signifying little or no cardiac reserve. Both an S_3 and an S_4 gallop may be heard on auscultation.

See the Multisystem Effects of Heart Failure feature on page 925.

Complications

The compensatory mechanisms initiated in heart failure can lead to complications in other body systems. Congestive hepatomegaly and splenomegaly caused by engorgement of the portal venous system result in increased abdominal pressure, ascites, and gastrointestinal problems. With prolonged right-sided heart failure, liver function may be impaired. Myocardial distention can precipitate dysrhythmias, further impairing cardiac output. Pleural effusions and other pulmonary problems may develop. Major complications of severe heart failure are cardiogenic shock (described in Chapter 11) and acute pulmonary edema, a medical emergency described in the next section of this chapter.

●○● INTERPROFESSIONAL CARE

The main goals for care of heart failure are to slow its progression, reduce cardiac workload, improve cardiac function, and control fluid retention. Treatment strategies are based on the evolution and progression of heart failure (Table 31–4).

DIAGNOSIS

Diagnosis of heart failure is based on the history, physical examination, and diagnostic findings.

- *Atrial natriuretic factor (ANF)*, also called *atrial natriuretic hormone (ANH)*, and *brain natriuretic peptide (BNP)* are hormones released by the heart muscle in response to changes in blood volume.

MULTISYSTEM EFFECTS OF
Heart Failure

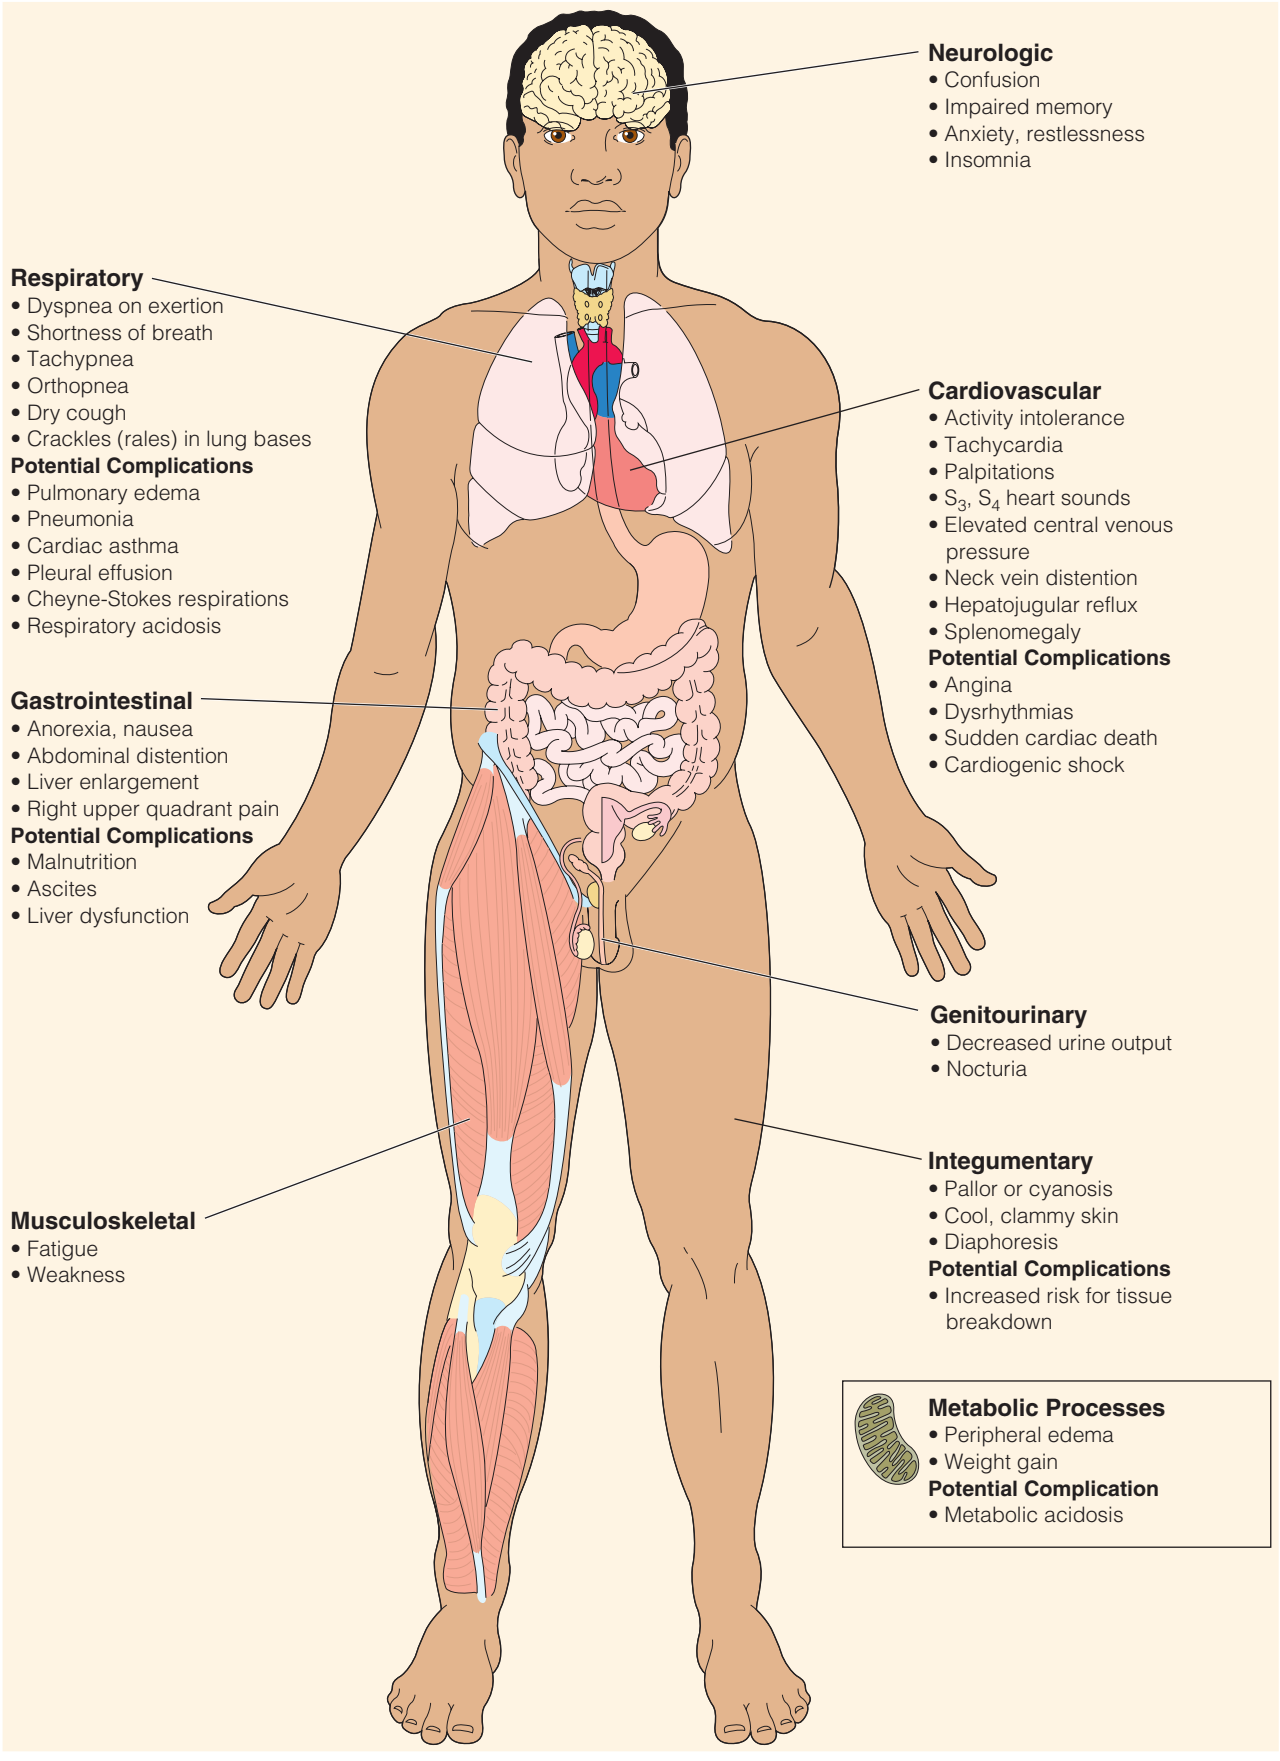

TABLE 31–4 Stages of Heart Failure

Stage	Description	Recommended Treatment Measures
A	Patients at high risk for developing heart failure, but without structural heart disease or symptoms of heart failure (patients with hypertension, CHD, diabetes, obesity, metabolic syndrome, or who have a family history of cardiomyopathy, or who are taking cardiotoxic drugs)	Treat underlying risk factors (e.g., hypertension) including lipid disorders Angiotensin-converting enzyme (ACE) inhibitor or angiotensin-receptor blocker (ARB) therapy as appropriate Exercise Salt restriction Smoking cessation Discourage alcohol, illicit drug use Control blood glucose in patients with metabolic syndrome
B	Patients with structural heart disease but no manifestations of heart failure (patients with previous MI, asymptomatic valve disease, or left ventricular dysfunction)	As for stage A ACE inhibitor or ARB therapy as appropriate Beta-blocker therapy if indicated
C	Patients with structural heart disease and current or prior symptoms of heart failure (shortness of breath, fatigue, decreased exercise tolerance)	As for stages A and B Drug therapy with a diuretic, ACE inhibitor, and/or beta-blocker Additional drugs as indicated, such as an aldosterone antagonist, ARB, digitalis, hydralazine, nitrates Ventricular pacing or an implanted cardioverter/defibrillator (ICD) as indicated
D	Refractory heart failure (patients with manifestations of heart failure at rest despite aggressive treatment)	As for stages A, B, and C as appropriate Hospice care Hemodynamic monitoring Continual infusion of positive inotropic agents Valve replacement, cardiac transplant as indicated Permanent mechanical support; experimental surgery or drug therapy

Note: Adapted from Yancy, C. W., Jessup, M., Bozkurt, B., Butler, J., Casey, D. E., Drazner, M. H., . . . Wilkoff, B. L. (2013). 2013 ACCF/AHA Guideline for the management of heart failure: A report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines. *Circulation, 128*, e240–e327. Retrieved from http://circ.ahajournals.org/content/128/16/e240.full.pdf+html.

N-terminal prohormone of brain natriuretic peptide (NT-proBNP) is a rapid test (readable in 15 minutes) for BNP (Kee, 2014). Blood levels of these hormones increase in heart failure, however, it is important to remember that BNP levels may be elevated in women and in people over age 60 who do not have heart failure. Therefore, an elevated BNP cannot be used alone to diagnose heart failure.

- *Serum electrolytes* are measured to evaluate fluid and electrolyte status. Serum osmolality may be low due to fluid retention. Sodium, potassium, and chloride levels provide a baseline for evaluating the effects of treatment; serum calcium and magnesium are measured as well.
- *Urinalysis, blood urea nitrogen (BUN)*, and *serum creatinine* are obtained to evaluate renal function.
- *Liver function tests*, including ALT, AST, LDH, serum bilirubin, and total protein and albumin levels, are obtained to evaluate possible effects of heart failure on liver function.
- Thyroid function tests, including TSH and TH levels, are obtained because both hyperthyroidism and hypothyroidism can be either a primary or a contributing cause of heart failure.
- In acute heart failure, *arterial blood gases (ABGs)* are drawn to evaluate gas exchange in the lungs and tissues.
- *Chest x-ray* may show pulmonary vascular congestion and cardiomegaly in heart failure.
- *Electrocardiography* is used to identify ECG changes associated with ventricular enlargement and to detect dysrhythmias, myocardial ischemia, or infarction.
- *Echocardiography with Doppler flow studies* are performed to evaluate left ventricular function. Either *transthoracic echocardiography* or *transesophageal echocardiography* may be used.
- *Radionuclide imaging* is used to evaluate ventricular function and size.

Refer to Chapter 29 for more information and the nursing implications of these tests.

HEMODYNAMIC MONITORING

Hemodynamics is the study of forces involved in blood circulation. Hemodynamic monitoring is used to assess cardiovascular function in patients who are critically ill or unstable. The main goals of invasive hemodynamic monitoring are to evaluate cardiac and circulatory function and the response to interventions.

Hemodynamic parameters include heart rate, arterial blood pressure, central venous or right atrial pressure, pulmonary pressures, and cardiac output. *Direct* hemodynamic parameters are obtained straight from the monitoring device (e.g., heart rate, arterial and venous pressures). *Indirect* or *derived* measurements are calculated using the direct data (e.g., the cardiac index, mean arterial blood pressure, and stroke volume). Invasive hemodynamic monitoring is routinely used in critical care units.

Hemodynamic monitoring systems measure the pressure within a vessel and convert this signal into an electrical waveform that is amplified and displayed. The electrical signal may be graphically recorded on graph paper and displayed digitally on the monitor. System components include an invasive catheter threaded into an artery or vein connected to a transducer by stiff, high-pressure tubing. The pressure transducer translates pressures into an electrical signal that is relayed to the monitor. Additional components of the system include stopcocks and a continuous flush system with normal saline or heparinized saline and an infusion pressure bag to prevent clots

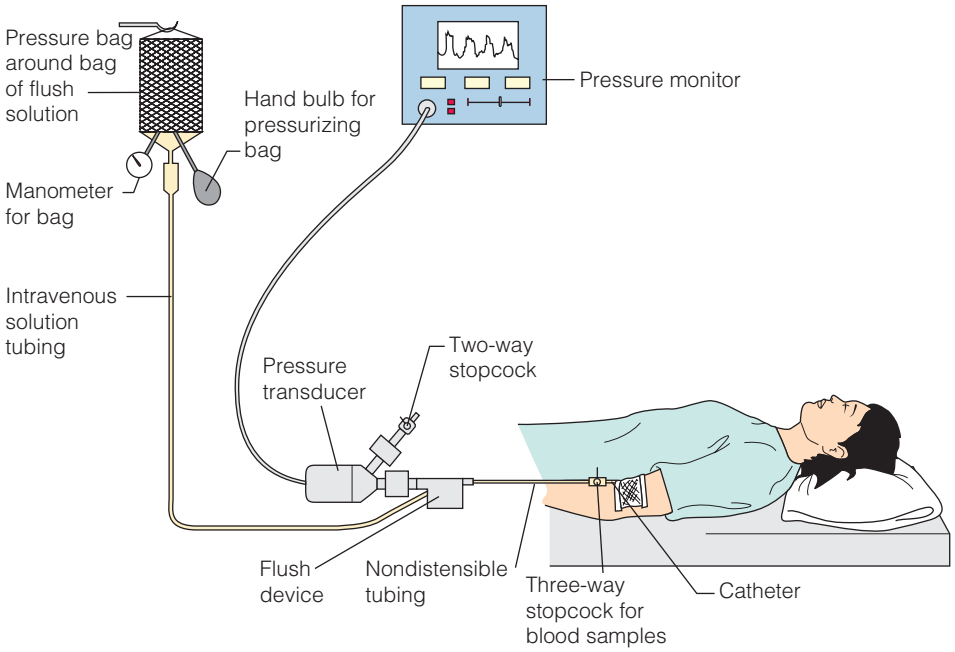

Figure 31–3 ■ A hemodynamic monitoring setup.

from forming in the catheter. Figure 31–3 ■ illustrates a pressure transducer and typical hemodynamic monitoring system.

Hemodynamic pressure monitoring may be used to measure peripheral arterial pressures, or central pressures, such as central venous pressure (CVP) or right atrial pressure (RAP) and pulmonary artery pressure (PAP). Although the information obtained from invasive monitoring is valuable, the procedure is not without risk. Nursing care of the patient undergoing hemodynamic monitoring is outlined on page 928. Box 31–2 lists potential complications of central pressure monitoring. Pressure monitoring systems require calibration, leveling, and zeroing of the transducer to the level of the patient's left atrium. This is called the phlebostatic axis.

INTRA-ARTERIAL PRESSURE MONITORING Intra-arterial pressure monitoring is commonly used in intensive and coronary care units. An indwelling arterial line, commonly called an *art line* or an *A line*, allows direct and continuous monitoring of systolic, diastolic, and mean arterial blood pressure and provides easy access for arterial blood sampling. Arterial lines are used to assess blood volume, monitor the effects of vasoactive drugs, and obtain frequent ABG determinations. Because the invasive catheter is inserted directly into the artery, it offers immediate access for blood gas measurements and blood testing.

BOX 31–2 Potential Complications of Central Catheters

- Bleeding
- Hematoma
- Pneumothorax
- Hemothorax
- Arterial puncture
- Dysrhythmias
- Venospasm
- Infection
- Air embolism
- Thromboembolism
- Brachial nerve injury
- Thoracic duct injury

The arterial blood pressure reflects the cardiac output and the resistance to blood flow created by the elastic arterial walls (*systemic vascular resistance, SVR*). Cardiac output is determined by the blood volume and the ability of the ventricles to fill and effectively pump that blood. SVR is primarily determined by vessel diameter and distensibility (compliance). Factors such as SNS input, circulating hormones (e.g., epinephrine, norepinephrine, atrial natriuretic factor, and vasopressin), and the RAAS affect SVR.

The systolic blood pressure, normally about 120 mmHg in healthy adults, reflects the pressure generated during ventricular systole. During diastole, elastic arterial walls keep a minimum pressure within the vessel (diastolic blood pressure) to maintain blood flow through the capillary beds. The average diastolic pressure in a healthy adult is 80 mmHg. The **mean arterial pressure (MAP)** is the average pressure in the arterial circulation throughout the cardiac cycle. It reflects the driving pressure, or perfusion pressure, an indicator of tissue perfusion. The formula MAP = CO × SVR often is used to show the relationships between factors determining the blood pressure. Mean arterial pressure can be calculated by adding one-third of the pulse pressure (PP) to the diastolic blood pressure (DBP): MAP = DBP + PP/3. For example, a blood pressure of 120/80 results in a mean arterial pressure of 93. Mean arterial pressures of 70 to 90 mmHg are desirable. Perfusion to vital organs is severely jeopardized at MAPs of 50 mmHg or less; MAPs greater than 105 mmHg may indicate hypertension or vasoconstriction.

VENOUS PRESSURE MONITORING *Central venous pressure (CVP)* and *right atrial pressure (RAP)* are measures of blood volume and venous return. They also reflect right heart filling pressures. Pressures are elevated in right-sided heart failure. CVP and RAP are primarily used to monitor fluid volume status. To measure venous and atrial pressures, a catheter is inserted in the internal jugular or

NURSING CARE OF THE PATIENT

Undergoing Hemodynamic Monitoring

- Calibrate and level the system at least once a shift using the right atrium as a constant reference level. Relevel the transducer after a change in position. Mark the right atrial position (at the fourth intercostal space, midaxillary line) on the chest wall, and use this as a reference point for all readings. *Calibration and leveling ensure that accurate pressures are recorded. Marking the right atrial level provides a consistent reference point for all caregivers.*
- Measure all pressures between breaths. *This ensures that intrathoracic pressure does not influence pressure readings.*
- Maintain 300 mmHg of pressure on the flush solution at all times. *This ensures a continuous flow of flush solution through the pressure tubing and catheter to prevent clot formation and catheter occlusion.*
- Monitor pressure trends rather than individual readings. *Individual readings may not reflect the patient's true status. Trends in pressure readings along with clinical observations provide a better overall picture of the patient's status.*
- Obtain a chest x-ray before infusing intravenous fluid into any newly placed central line. *Chest x-ray verifies the location of the catheter and helps prevent pulmonary complications of incorrect catheter placement such as pneumothorax.*
- Set alarm limits for monitored hemodynamic variables. Turn alarms on. *Alarms warn of hemodynamic instability. Always investigate alarms. They may be temporarily silenced to change tubing or draw blood but should never be turned off.*
- Use aseptic technique during catheter insertion and site care. *Aseptic technique is important to prevent infection.*
- Assess and document appearance of the insertion site at least every shift; observe for signs of infiltration, infection, or phlebitis. *Frequent assessment allows early detection and prompt treatment of complications.*
- Change intravenous solutions every 24 hours, site dressing every 48 hours, and tubing to the insertion site every 72 hours. Label solution, tubing, and dressing with date and time of change. *These measures help prevent infection.*
- Thoroughly flush stopcock ports after drawing blood samples from the pressure line. *Flushing prevents colonization of bacteria and occlusion of the catheter.*
- Assess pulse and perfusion distal to the monitoring site. *Frequent assessment is vital to ensure perfusion of the distal extremity.*
- When discontinuing the pressure line, apply manual pressure to the insertion site as soon as the catheter tip is out. Hold pressure for 5 to 15 minutes or until the bleeding stops. *This is particularly important for arterial lines to prevent bleeding and hematoma formation.*
- Secure all connections and stopcocks. *This is done to prevent disconnection of the invasive line and potential hemorrhage.*
- Ensure that electrical equipment is grounded, intact, and operating as expected. *This helps prevent electrical injury.*
- Loosely restrain the affected extremity if the patient pulls on the catheter or connections. *Restraints may be necessary to prevent injury from accidental or intentional disconnection or discontinuation of invasive lines (i.e., if the patient has dementia or is agitated).*
- Keep tubing free of kinks and tension. This prevents the catheter from becoming clotted or inadvertently dislodged.

subclavian vein. The distal tip of the catheter is positioned in the superior vena cava just above or just inside the right atrium. CVP may be measured in either centimeters of water (cm H_2O) or in millimeters of mercury (mmHg). A water manometer is a clear tube with calibrated markings that is attached between a central catheter and an intravenous fluid bag. Pressure in the venous system causes fluid in the manometer to rise or fall. The CVP is recorded by noting the fluid level in the manometer. If the central line is connected to a pressure transducer, venous pressure is displayed digitally in millimeters of mercury.

The normal range for CVP is 2 to 8 cm H_2O or 2 to 6 mmHg, but CVP varies in individual patients. Hypovolemia and shock decrease the CVP; fluid overload, vasoconstriction, and cardiac tamponade increase CVP.

PULMONARY ARTERY PRESSURE MONITORING The pulmonary artery (PA) catheter is a flow-directed, balloon-tipped catheter first used in the early 1970s. The PA catheter is often called a *Swan-Ganz catheter*, after the physicians who developed it. The PA catheter is used to evaluate left ventricular and overall cardiac function. The PA catheter is inserted into a central vein, usually the internal jugular or subclavian vein, and threaded into the right atrium. A small balloon at the tip of the catheter allows the catheter to be drawn into the right ventricle and from there into the pulmonary artery (Figure 31–4 ■). The inflated balloon carries the catheter forward until the balloon wedges in a small branch of pulmonary vasculature. Once in place, the balloon is deflated, and multiple lumens of the catheter allow measurement of pressures in the right atrium, pulmonary artery, and left ventricle. The normal PA pressure is around 25/10 mmHg; normal mean pulmonary artery pressure is about 15 mmHg (Figure 31–5A ■). Pulmonary artery pressure is increased in left-sided heart failure.

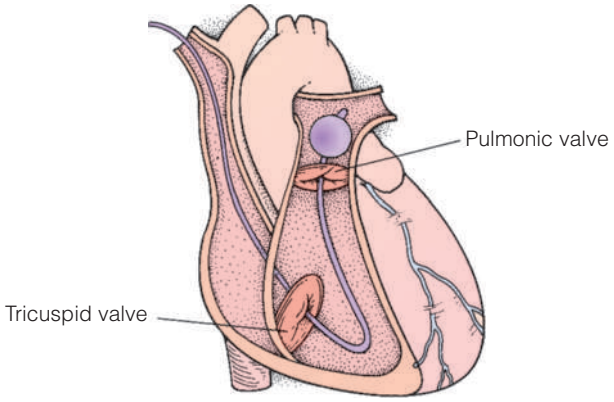

Figure 31–4 ■ Inflation of the balloon on the flow-directed catheter allows it to be carried through the pulmonic valve into the pulmonary artery.

Inflation of the balloon effectively blocks pressure from behind the balloon and allows measurement of pressures generated by the left ventricle. This is known as pulmonary artery wedge pressure (PAWP or PWP) and is used to assess left ventricular function. The normal pulmonary artery wedge pressure is 8 to 12 mmHg (Figure 31–5B). PAWP is increased in left ventricular failure and pericardial tamponade, and decreased in hypovolemia.

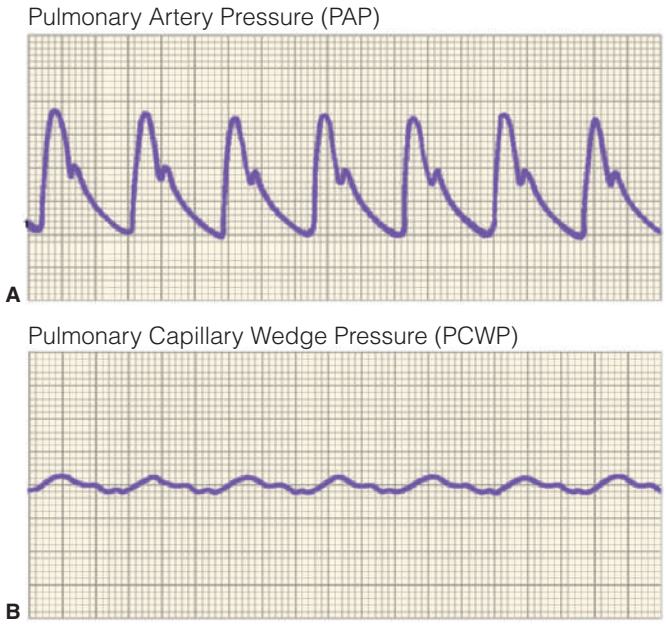

Figure 31–5 ■ Typical waveforms seen when measuring A, pulmonary artery pressure, and B, pulmonary wedge pressure.

Cardiac output also can be measured with the PA catheter using a technique called thermodilution. Cardiac output and the cardiac index are used to assess the heart's ability to meet the body's oxygen demands. Because body size affects overall cardiac output, the cardiac index is a more precise measure of heart function. The *cardiac index* is a calculation of cardiac output per square meter of body surface area. The normal cardiac index is 2.8 to 4.2 L/min/m^2.

MEDICATIONS

Patients with heart failure often receive multiple medications to reduce cardiac work and improve cardiac function. The main drug classes used to treat heart failure are the angiotensin-converting enzyme (ACE) inhibitors, angiotensin II receptor blockers (ARBs), beta-blockers, diuretics, inotropic medications (including digitalis, sympathomimetic agents, and phosphodiesterase inhibitors), direct vasodilators, and antidysrhythmic drugs. Nursing implications for ACE inhibitors and ARBs, diuretics, and inotropic medications are found in the Medication Administration box on page 930.

ACE inhibitors, ARBs, and beta-blockers interfere with the neurohormonal mechanisms of sympathetic activation and the RAAS. ACE inhibitors interrupt the conversion of angiotensin I to angiotensin II by inhibiting the enzyme that mediates the conversion (angiotensin-converting enzyme). Angiotensin II causes intense vasoconstriction, increasing afterload and ventricular wall stress and increasing preload and ventricular dilation. It also stimulates aldosterone and ADH production, causing fluid retention. ACE inhibitors block this RAAS activity, decreasing cardiac work and increasing cardiac output. They reduce the progression and manifestations of heart failure, thus reducing the number and frequency of hospital admissions, decreasing mortality rates, and preventing cardiac complications. However, ACE inhibitors should be used with caution in African Americans due to increased risk for developing angioedema.

In contrast to ACE inhibitors, ARBs do not block the production of angiotensin II; instead, they block its action. The pharmacologic effect is similar, and they also are used in heart failure to slow its progression, reduce manifestations, and prevent cardiac complications.

Beta-blockers improve cardiac function in heart failure by inhibiting SNS activity. This prevents the long-term deleterious effects of sympathetic stimulation. Because beta-blockers reduce the force of myocardial contraction and may actually worsen symptoms, they are used in low doses. Beta-blockers are indicated for all classes of patients with heart failure. The combination of ACE inhibitors and beta-blockers improves patient outcomes. Beta-blockers are discussed further in Chapter 30.

Patients with symptomatic heart failure often are treated with diuretics as well. Diuretics relieve symptoms related to fluid retention. They may, however, cause significant electrolyte imbalances and rapid fluid loss. Patients with severe heart failure are often treated with a loop, or high-ceiling, diuretic such as furosemide (Lasix), bumetanide (Bumex), torsemide (Demadex), or ethacrynic acid (Edecrin). These drugs have a rapid onset of action, inhibiting chloride reabsorption in the ascending loop of Henle, which prompts sodium and water excretion. Their major drawback is their efficacy in promoting diuresis; loss of vascular volume can stimulate the SNS. Thiazide diuretics may be used for patients with less severe manifestations of heart failure. These agents promote fluid excretion by blocking sodium reabsorption in the terminal loop of Henle and the distal tubule.

Vasodilators relax smooth muscle in blood vessels, causing dilation. Arterial dilation reduces peripheral vascular resistance and afterload, reducing myocardial work. Venous dilation reduces venous return and preload. Pulmonary vascular relaxation reduces pulmonary capillary pressure, allowing reabsorption of fluid from interstitial tissues and the alveoli. Vasodilators include nitrates, hydralazine, and prazosin, an alpha-adrenergic blocker. See Chapter 32 for more information about vasodilators.

Nitrates produce both arterial and venous vasodilation. They may be given by nasal spray or by a sublingual, oral, or intravenous route. Sodium nitroprusside is a potent vasodilator that may be used to treat acute heart failure. It can cause excessive hypotension, so it is often given along with dopamine or dobutamine to maintain the blood pressure. Isosorbide or nitroglycerin ointment may be used in long-term management of heart failure (refer to Chapter 30, page 876).

BiDil, a combination of two vasodilators, hydralazine and isosorbide, in fixed doses is an option for treatment of heart failure in African Americans. In African Americans with severe heart failure, BiDil improved symptoms and significantly reduced the number of hospitalizations and deaths attributed to heart failure. The accompanying box on cultural diversity discusses the nursing implications for BiDil.

Digitalis glycosides are used judiciously in symptomatic heart failure. Digitalis has a *positive inotropic effect* on the heart, increasing the strength of myocardial contraction by increasing the intracellular calcium concentrations. Digitalis also decreases SA node automaticity and slows conduction through the AV node, increasing ventricular filling time.

Digitalis has a narrow therapeutic index; in other words, therapeutic levels are very close to toxic levels. Early manifestations of digitalis toxicity include anorexia, nausea and vomiting, headache, altered vision, and confusion. A number of cardiac dysrhythmias are also associated with digitalis toxicity, including sinus arrest, supraventricular and ventricular tachycardias, and high levels of AV block.

MEDICATION ADMINISTRATION

Heart Failure

ANGIOTENSIN-CONVERTING ENZYME (ACE) INHIBITORS

enalapril (Vasotec)
captopril (Capoten)
moexipril (Univasc)
quinapril (Accupril)
trandolapril (Mavik)
lisinopril (Prinivil, Zestril)
fosinopril (Monopril)
perindopril (Aceon)
ramipril (Altace)

ANGIOTENSIN II RECEPTOR BLOCKERS (ARBS)

candesartan (Atacand)
losartan (Cozaar)
telmisartan (Micardis)
irbesartan (Avapro)
nesiritide (Natrecor)
valsartan (Diovan)

ACE inhibitors and ARBs prevent acute coronary events and reduce mortality in heart failure. ACE inhibitors interfere with production of angiotensin II, resulting in vasodilation, reduced blood volume, and prevention of its effects in the heart and blood vessels. In heart failure, ACE inhibitors reduce afterload and improve cardiac output and renal blood flow. They also reduce pulmonary congestion and peripheral edema. ACE inhibitors suppress myocyte growth and reduce ventricular remodeling in heart failure. Although the pharmacologic effect of ARBs is similar, they block the action of angiotensin II at the receptor rather than interfering with its production.

Nursing Responsibilities

- Do not give these drugs to women in the second and third trimesters of pregnancy.
- Carefully monitor patients who are volume depleted or who have impaired renal function (assess BUN and creatinine).
- Use an infusion pump when administering ACE inhibitors intravenously.
- Monitor blood pressure closely for 2 hours following first dose and as indicated thereafter.
- Monitor serum potassium levels; ACE inhibitors can cause hyperkalemia (this is less of a concern with ARBs).
- Monitor white blood cell (WBC) count for potential neutropenia. Report to the physician.

Health Education for the Patient and Family

- Take the drug at the same time every day to ensure a stable blood level.
- Monitor your blood pressure and weight weekly. Report significant changes to your doctor.
- Avoid making sudden position changes; for example, rise from bed slowly. Lie down if you become dizzy or light-headed, particularly after the first dose.
- Report any signs of easy bruising and bleeding, sore throat or fever, edema, or skin rash. Immediately report swelling of the face, lips, or eyelids, and itching or breathing problems.
- A persistent, dry cough may develop if you are taking an ACE inhibitor. Contact your doctor if this becomes a problem.
- Take captopril or moexipril 1 hour before meals.

DIURETICS

chlorothiazide (Diuril)
furosemide (Lasix)
ethacrynic acid (Edecrin)
bumetanide (Bumex)
torsemide (Demadex)
hydrochlorothiazide (HydroDIURIL)
spironolactone (Aldactone)
triamterene (Dyrenium)
amiloride (Midamor)
acetazolamide (Diamox)
metolazone (Zaroxolyn)

Diuretics act on different portions of the kidney tubule to inhibit the reabsorption of sodium and water and promote their excretion. With the exception of the potassium-sparing diuretics—spironolactone, triamterene, and amiloride—diuretics also promote potassium excretion, increasing the risk of hypokalemia. Spironolactone, an aldosterone receptor blocker, reduces symptoms and slows the progression of heart failure. Aldosterone receptors in the heart and blood vessels promote myocardial remodeling and fibrosis, activate the sympathetic nervous system, and promote vascular fibrosis (which decreases compliance) and baroreceptor dysfunction.

Nursing Responsibilities

- Obtain baseline weight and vital signs.
- Monitor blood pressure, intake and output, weight, skin turgor, and edema as indicators of fluid volume status.
- Assess for volume depletion, particularly with loop diuretics (furosemide, ethacrynic acid, and bumetanide): dizziness, orthostatic hypotension, tachycardia, and muscle cramping.
- Report abnormal serum electrolyte levels to the physician. Replace electrolytes as indicated.
- Do not administer potassium replacements to patients receiving a potassium-sparing diuretic.
- Evaluate renal function by assessing urine output, BUN, and serum creatinine.
- Administer intravenous furosemide slowly, no faster than 20 mg/min. Evaluate for signs of ototoxicity. Do not administer this drug or ethacrynic acid concurrently with aminoglycoside antibiotics (e.g., gentamicin), which are also ototoxic.

Health Education for the Patient and Family

- Drink at least six to eight glasses of water per day.
- Take your diuretic at times that will be the least disruptive to your lifestyle, usually in the morning and early afternoon if a second dose is ordered. Take with meals to decrease gastric upset.
- Monitor your blood pressure, pulse, and weight weekly. Report significant weight changes to your doctor.
- Report any of the following to your doctor: severe abdominal pain, jaundice, dark urine, abnormal bleeding or bruising, flu-like symptoms, signs of hypokalemia, hyponatremia, and dehydration (thirst, salt craving, dizziness, weakness, rapid pulse). See Chapter 10 for manifestations of electrolyte imbalances.
- Avoid sudden position changes. You may experience dizziness, light-headedness, or feelings of faintness.
- Unless you are taking a potassium-sparing diuretic, integrate foods rich in potassium into your diet. Limit sodium use.

POSITIVE INOTROPIC AGENTS

Digitalis Glycosides

digoxin (Lanoxin)

Digitalis improves myocardial contractility by interfering with ATPase in the myocardial cell membrane and increasing the amount of calcium available for contraction. The increased force of contraction causes the heart to empty more completely, increasing stroke volume and cardiac output. Improved cardiac output improves renal perfusion, decreasing renin secretion. This decreases preload and afterload, reducing cardiac work. Digitalis also has electrophysiologic

MEDICATION ADMINISTRATION (*continued*)

effects, slowing conduction through the AV node. This decreases the heart rate and reduces oxygen consumption.

Nursing Responsibilities

- Assess apical pulse before administering. Withhold digitalis and notify the physician if heart rate is below 60 bpm and/or manifestations of decreased cardiac output are noted. Record apical rate on medication record.
- Evaluate ECG for scooped (spoon-shaped) ST segment, AV block, bradycardia, and other dysrhythmias (especially premature ventricular contractions [PVCs] and atrial tachycardias).
- Report manifestations of digitalis toxicity: anorexia, nausea, vomiting, abdominal pain, weakness, vision changes (diplopia, blurred vision, yellow-green or white halos seen around objects), and new-onset dysrhythmias.
- Assess potassium, magnesium, calcium, and serum digoxin levels before giving digitalis. Hypokalemia can precipitate toxicity even when the serum digitalis level is in the normal range.
- Monitor patients with renal insufficiency or renal failure and older adults carefully for digitalis toxicity.
- Prepare to administer digoxin immune fab (Digibind) for digoxin toxicity.

Health Education for the Patient and Family

- Take your pulse daily before taking your digoxin. Do not take the digoxin if your pulse is below 60 bpm or if you are weak, fatigued, light-headed, dizzy, short of breath, or having chest pain. Notify your physician immediately.
- Contact your doctor if you develop manifestations of digitalis toxicity: palpitations, weakness, loss of appetite, nausea, vomiting, abdominal pain, blurred or colored vision, or double vision.
- Avoid using antacids and laxatives; they decrease digoxin absorption.
- Notify your physician immediately if you develop manifestations of potassium deficiency: weakness, lethargy, thirst, depression, muscle cramps, or vomiting.
- Incorporate foods high in potassium into your diet: fresh orange or tomato juice, bananas, raisins, dates, figs, prunes, apricots, spinach, cauliflower, and potatoes.

Sympathomimetic Agents

dopamine (Intropin)

dobutamine (Dobutrex)

Sympathomimetic agents stimulate the heart, improving the force of contraction. Dobutamine is preferred in managing heart failure because it does not increase the heart rate as much as dopamine, and it has a mild vasodilatory effect. These drugs are given by intravenous infusion and may be titrated to obtain their optimal effects.

Phosphodiesterase Inhibitors

inamrinone (Inocor)

milrinone (Primacor)

Phosphodiesterase inhibitors are used in treating acute heart failure to increase myocardial contractility and cause vasodilation. The net effects are an increase in cardiac output and a decrease in afterload.

Nursing Responsibilities

- Use an infusion pump to administer these agents. Monitor hemodynamic parameters carefully.
- Avoid discontinuing these drugs abruptly.
- Change solutions and tubing every 24 hours.
- Inamrinone is given as an intravenous bolus over 2 to 3 minutes, followed by an infusion of 5 to 10 mg/kg/min.
- Inamrinone may be infused full strength or diluted in normal saline or half-strength saline. Do not mix this drug with dextrose solutions. After dilution, inamrinone can be piggybacked into a line containing a dextrose solution.
- Monitor liver function and platelet counts; inamrinone may cause hepatotoxicity and thrombocytopenia.
- Do not confuse with amiodarone (Inocor).

Health Education for the Patient and Family

- Notify the nursing staff if you experience abdominal pain or notice a skin rash or bruising.

Note: Drugs identified in *italics* are among the 200 most commonly prescribed medications in the U.S.

Low serum potassium levels increase the risk of digitalis toxicity, as do low magnesium and high calcium levels. Older adults are at particular risk for digitalis toxicity. The AHA's heart failure guidelines (Yancy et al., 2013) note that the risk of toxicity outweighs the benefits of this class of drug. Digitalis levels may be affected by a number of other drugs; check for potential interactions.

Dysrhythmias are common in patients with heart failure. Although PVCs may be frequent, they are often not associated with an increased risk of ventricular tachycardia and fibrillation. Because many antidysrhythmic medications depress left ventricular function, PVCs are frequently left untreated in heart failure. Amiodarone is the drug of choice to treat nonsustained ventricular tachycardia, which is associated with a poor prognosis. (Refer to Chapter 30.)

NUTRITION AND ACTIVITY

A sodium-restricted diet is recommended to minimize sodium and water retention. Intake is generally limited to 1.5 to 2 g of sodium per day, a moderate restriction. Box 10–2 in Chapter 10 includes patient teaching regarding a sodium-restricted diet.

Exercise intolerance, decreased ability to participate in activities using large skeletal muscles due to fatigue or dyspnea, is a common early manifestation of heart failure. Activity may be restricted to bed rest during acute episodes of heart failure to reduce cardiac workload and allow the heart to compensate. Prolonged bed rest and continued activity limitations, however, are not recommended. A moderate, progressive activity program is prescribed to improve myocardial function. Exercise should be performed 3 to 5 days per week, and each session should include a 10- to 15-minute warm-up period, 20 to 30 minutes of exercise at the recommended intensity, and a cool-down period. Walking is encouraged on nontraining days. As of November 21, 2013, the Centers for Medicare and Medicaid Services announced a proposed decision memo that would extend cardiac rehabilitation service coverage for patients with chronic heart failure (defined as patients with left ventricular ejection fraction of 35% or less and NYHA class II to IV symptoms despite being on optimal heart failure therapy for at least 6 weeks).

OTHER TREATMENTS

In end-stage heart failure, devices to provide circulatory assistance or surgery may be required. Surgery may be used to treat the underlying cause of failure (e.g., replacement of diseased valves) or to improve quality of life. Valve replacement is discussed later in this chapter. Heart transplant is currently the only clearly effective surgical

FOCUS ON CULTURAL DIVERSITY

BiDil for Treating Heart Failure in African Americans

BiDil, a fixed-dose combination of two vasodilators (hydralazine and isosorbide), is indicated as an adjunctive treatment in African Americans with heart failure. It has been shown to reduce symptoms, decrease the number of hospitalizations, and prolong life in Blacks. The recommended dose is one to two tablets three times per day, although the dose may be as low as 1/2 tablet three times a day if side effects are intolerable. The approval of this combination drug has raised the ethical issue of race-specific FDA approval.

NURSING IMPLICATIONS

- Assess vital signs and fluid volume status before administering this drug, because hypotension (orthostatic hypotension in particular) is a common effect.
- Notify the physician if manifestations of systemic lupus erythematosus, glomerulonephritis, or peripheral neuropathy develop.
- Use caution when administering concurrently with MAO inhibitors.
- Closely monitor for hypotension when administered concurrently with any potent parenteral antihypertensive agent.

PATIENT AND FAMILY TEACHING

- Take this drug as prescribed.
- Headache is a common adverse effect of this drug, particularly when first starting therapy. Headaches tend to subside with continued treatment.
- Notify your doctor if headaches continue after the first few weeks of therapy, or if you develop chest pain or palpitations while taking this drug.
- This drug can cause a drop in blood pressure, particularly when changing positions from lying to sitting or sitting to standing. Change positions slowly and use caution to prevent falls.
- Do not use drugs such as sildenafil (Viagra, Revatio), vardenafil (Levitra), or tadalafil (Cialis) while taking this medication because the combination may cause an extreme drop in blood pressure leading to fainting, chest pain, or a heart attack.

treatment for end-stage heart failure; its use is limited by the availability of donor hearts.

CIRCULATORY ASSISTANCE Devices such as the intra-aortic balloon pump or a left-ventricular assist device may be used when the patient is expected to recover or as a bridge to transplant (refer to Chapter 30). Newer devices that will allow longer term support outside the hospital are in the developmental stages. These devices will serve either as a bridge to transplant or allow the myocardium to heal over an extended period of time.

CARDIAC TRANSPLANTATION Heart transplant is the treatment of choice for end-stage heart disease. Survival rates are good: 83% at 1 year and 76% at 3 years. More than 90% of patients return to normal, unrestricted functional abilities following transplant. The most frequently used transplant procedure leaves the posterior walls of the atria, the superior and inferior vena cavae, and the pulmonary veins of the recipient intact (Figure 31–6A ■). The atrial walls of the donor heart are then anastomosed to the recipient's atria (Figure 31–6B). The donor pulmonary artery and aorta are anastomosed to the recipient's vessels (Figure 31–6C). Care is taken to avoid damaging the sinus node of the donor heart and to ensure integrity of the suture line to prevent postoperative bleeding. Donor organs are obtained from people with no evidence of cardiac trauma.

Nursing care of the heart transplant patient is similar to care of any cardiac surgery patient (refer to Chapter 30). Bleeding is a major concern in the early postoperative period. Chest tube drainage is frequently monitored (initially every 15 minutes), as are the cardiac output, pulmonary artery pressures, and CVP. Cardiac tamponade (compression of the heart) can develop, presenting as either a sudden event or a gradual process. Chest tubes are gently milked (not stripped) as needed to maintain patency. Atrial dysrhythmias are relatively common following cardiac transplant. Temporary pacing wires are placed during surgery because surgical manipulation or postoperative swelling may disrupt the conduction system. Hypothermia is induced during surgery; postoperatively, the patient is gradually rewarmed over a 1- to 2-hour period. Prevention of rapid rewarming and shivering is important to maintain hemodynamic stability and reduce oxygen consumption. Cardiac function is impaired in up to 50% of transplanted hearts during the early postoperative period. Inotropic agents such as low-dose dopamine, dobutamine, or milrinone may be required to support cardiac function and circulation.

Infection and rejection are major postoperative concerns; these are the chief causes of mortality in transplant patients. Rejection may

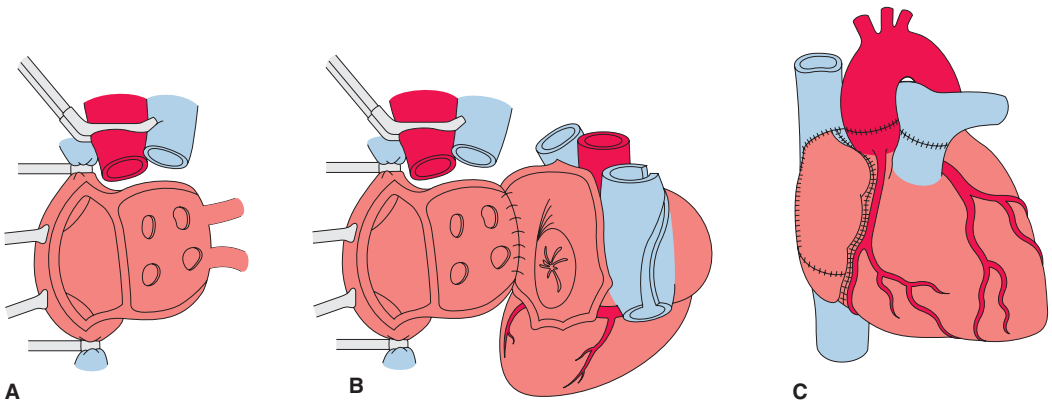

Figure 31–6 ■ Cardiac transplantation. A, The heart is removed, leaving the posterior walls of the atria intact. The donor heart is anastomosed to the atria, B, and the great vessels, C.

develop immediately after transplant (a rare occurrence), within weeks to months, or years after the transplant. Acute rejection usually presents within weeks of the transplant, developing when the transplanted organ is recognized by the immune system as foreign. Lymphocytes infiltrate the organ, and myocardial cell necrosis can be detected on biopsy. Acute rejection often can be treated using immunosuppressive drugs. These drugs are also given to prevent rejection of the transplanted organ, even when the tissue match is good (refer to Chapter 12). Although immunosuppressive medications help prevent organ rejection, they impair the patient's defenses against infection. Early postoperative infections commonly are bacterial or fungal (*candida*). Multiple invasive lines, prolonged ventilator support, and immunosuppressive therapy contribute to the transplant recipient's risk for infection. Aggressive nursing care directed at prevention of infection is vital: limiting visitors with communicable diseases and practicing pulmonary hygiene measures, early ambulation, and strict aseptic technique.

The donor heart is denervated during the transplant procedure. Lack of innervation by the autonomic nervous system affects the heart rate (usually between 90 and 110 bpm in transplanted hearts), its response to position changes, stress, exercise, and certain drugs.

OTHER PROCEDURES Other surgical procedures such as cardiomyoplasty and ventricular reduction surgery do not improve the prognosis or quality of life in patients with end-stage heart failure. *Cardiomyoplasty* involves wrapping the latissimus dorsi muscle around the heart to support the failing myocardium. The muscle is stimulated in synchrony with the heart, providing a more forceful contraction and increasing cardiac output. In ventricular reduction surgery (or *partial ventriculectomy*), a portion of the anteriolateral left ventricular wall is resected to improve cardiac function.

COMPLEMENTARY THERAPIES

Evidence supports the use of several complementary therapies for heart failure. Hawthorn, a shrubby tree, contains natural cardiotonic ingredients in its blossoms, leaves, and fruit. It increases the force of myocardial contraction, dilates blood vessels, and has a natural ACE inhibitor. Hawthorn should never be used without consulting an experienced herb practitioner and advising the physician. Nutritional supplements of coenzyme Q10, magnesium, and thiamine may be used in conjunction with other treatments. Coenzyme Q10 improves mitochondria function and energy production. It can be lost with use of antilipemics.

END-OF-LIFE CARE

Unless a cardiac transplant is performed, chronic heart failure is ultimately a terminal disease. The patient and family need honest discussions about the anticipated course of the disease and treatment options. It is important to discuss advance directives such as a living will and medical power of attorney, differentiating potential acute events from which recovery would be anticipated (e.g., reversible exacerbation of heart failure, sudden cardiac arrest) from prolonged life support without reasonable expectation of functional recovery. Hospice services are available for patients with heart failure, and should be offered when appropriate. Severe dyspnea is common in the final stages of the disease. It may be managed with narcotic analgesics or with frequent intravenous diuretics and continuous infusion of a positive inotropic agent.

●○● NURSING CARE

Health Promotion

Health promotion activities to reduce the risk for and incidence of heart failure are directed at the risk factors. Teach patients about coronary heart disease, the primary underlying cause of heart failure. Discuss CHD risk factors, and ways to reduce those risk factors (see Chapter 30).

Hypertension also is a major cause of heart failure. Routinely screen patients for elevated blood pressure, and refer patients to a primary care provider as indicated. Discuss the importance of effectively managing hypertension to reduce the future risk for heart failure. Likewise, stress the relationship between effective diabetes management and reduced risk of heart failure.

Assessment

See the Manifestations and Interprofessional Care sections for the assessment of the patient with heart failure.

Obtain both subjective and objective data when assessing the patient with heart failure.

- *Health history:* complaints of increasing shortness of breath, dyspnea with exertion, decreasing activity tolerance, or paroxysmal nocturnal dyspnea; number of pillows used for sleeping; recent weight gain; presence of a cough; chest or abdominal pain; anorexia or nausea; history of cardiac disease, previous episodes of heart failure; other risk factors such as hypertension or diabetes; current medications; usual diet and activity and recent changes. Determine patient's NYHA class.
- *Physical assessment:* general appearance; ease of breathing, conversing, changing positions; apparent anxiety; vital signs including apical pulse; color of skin and mucous membranes; neck vein distention, peripheral pulses, capillary refill, presence and degree of edema; heart and breath sounds; abdominal contour, bowel sounds, tenderness; right upper abdominal tenderness, liver enlargement.

Priorities of Care

Collaborating with the interprofessional team to ensure adequate treatment of the underlying process while providing care that supports the physical and psychologic responses to the disorder is a priority of nursing care.

Diagnoses, Outcomes, and Interventions

Heart failure impacts quality of life, interfering with such daily activities as self-care and role performance. Reducing the oxygen demand of the heart is a major nursing care goal for the patient in acute heart failure. This includes providing rest and carrying out prescribed treatment measures to reduce cardiac work, improve contractility,

Evidence for Nursing Care

The Patient with Heart Failure

A selected resource that nurses may find helpful when planning evidence-based nursing care follows.

- Pere, K. (2012). Developing nursing expertise in caring for older advanced stage heart failure patients and their families—palliative and end-of-life care. *Canadian Journal of Cardiovascular Nursing, 22*(3), 12–17.

and manage symptoms. See also the accompanying Case Study & Nursing Care Plan for additional nursing diagnoses and interventions for the patient with heart failure.

Decreased Cardiac Output

As the heart fails as a pump, stroke volume and tissue perfusion decrease.

Expected Outcome: Patient will demonstrate adequate cardiac output as evidenced by blood pressure and pulse rate and rhythm within normal limits.

- Monitor vital signs and oxygen saturation as indicated. *Decreased cardiac output stimulates the SNS to increase the heart rate in an attempt to restore CO. Tachycardia at rest is common. Diastolic blood pressure may initially be elevated because of vasoconstriction; in late stages, compensatory mechanisms fail, and BP falls. Oxygen saturation levels provide a measure of gas exchange and tissue perfusion.*
- Auscultate heart and breath sounds regularly. *S_1 and S_2 may be diminished if cardiac function is poor. A ventricular gallop (S_3) is an early sign of heart failure; atrial gallop (S_4) may also be present. Crackles are often heard in the lung bases; increasing crackles, dyspnea, and shortness of breath indicate worsening failure.*

SAFETY ALERT

Report manifestations of decreased cardiac output and tissue perfusion: changes in mentation; decreased urine output; cool, clammy skin; diminished pulses; pallor or cyanosis; or dysrhythmias. These are manifestations of decreased tissue perfusion to organ systems.

- Administer supplemental oxygen as needed. *This improves oxygenation of the blood, decreasing the effects of hypoxia and ischemia.*
- Administer prescribed medications as ordered. *Drugs are used to decrease the cardiac workload and increase the effectiveness of contractions.*
- Encourage rest, explaining the rationale. Elevate the head of the bed to reduce the work of breathing. Provide a bedside commode, and assist with ADLs. Instruct to avoid the Valsalva maneuver. *These measures reduce cardiac workload.*

Excess Fluid Volume

As cardiac output falls, compensatory mechanisms cause salt and water retention, increasing blood volume. This increased fluid volume places additional stress on the already failing ventricles, making them work harder to move the fluid load.

Expected Outcome: Patient will maintain normal fluid volume as evidenced by weight loss and decreases in edema, jugular venous distention, and abdominal distention.

- Assess respiratory status and auscultate lung sounds at least every 4 hours. Notify the physician of significant changes in condition. *Declining respiratory status indicates worsening left heart failure.*

SAFETY ALERT

Immediately notify the physician if the patient develops air hunger, an overwhelming sense of impending doom or panic, tachypnea, severe orthopnea, or a cough productive of large amounts of pink, frothy sputum. Acute pulmonary edema, a medical emergency, can develop rapidly, necessitating immediate intervention to preserve life.

- Monitor intake and output. Notify the physician if urine output is less than 30 mL/h. Weigh daily. *Careful monitoring of fluid volume is important during treatment of heart failure. Diuretics may reduce circulating volume, producing hypovolemia despite persistent peripheral edema. A fall in urine output may indicate significantly reduced cardiac output and renal ischemia. Weight is an objective measure of fluid status: 1 L of fluid is equal to 2.2 lb of weight.*
- Record abdominal girth every shift. Note complaints of a loss of appetite, abdominal discomfort, or nausea. *Venous congestion can lead to ascites and may affect gastrointestinal function and nutritional status.*
- Monitor and record hemodynamic measurements. Report significant changes and negative trends. *Hemodynamic measurements provide a means of monitoring the patient's condition and response to treatment.*
- Restrict fluids as ordered. Allow choices of fluid type and timing of intake, scheduling most fluid intake during morning and afternoon hours. Offer ice chips and frequent mouth care; provide hard candies if allowed. *Providing choices increases the patient's sense of control. Ice chips, hard candies, and mouth care relieve dry mouth and thirst and promote comfort.*

Activity Intolerance

Patients with heart failure have little or no cardiac reserve to meet increased oxygen demands. As the disease progresses and cardiac function is further compromised, activity intolerance increases. The low cardiac output and inability to participate in activities may hinder self-care.

Expected Outcome: Patient will participate in physical activity as tolerated.

PRACTICE ALERT!

Monitor vital signs and cardiac rhythm during and after activities. Tachycardia, dysrhythmias, increasing dyspnea, changes in blood pressure, diaphoresis, pallor, complaints of chest pain, excessive fatigue, or palpitations indicate activity intolerance. Instruct to rest if manifestations are noted. The failing heart is unable to increase cardiac output to meet the increased oxygen demands associated with activity. Assessing response to activities helps evaluate cardiac function. Decreasing activity tolerance may signal deterioration of cardiac function, not overexertion.

- Organize nursing care to allow rest periods. *Grouping activities together allows adequate time to rest and recharge.*
- Assist with ADLs as needed. Encourage independence within prescribed limits. *Assisting with ADLs helps ensure that care needs are met while reducing cardiac workload. Involving the patient promotes a sense of control and reduces helplessness.*
- Plan and implement progressive activities. Use passive and active ROM exercises as appropriate. Consult with physical therapist on activity plan. *Progressive activity slowly increases exercise capacity by strengthening and improving cardiac function without strain. Activity also helps prevent skeletal muscle atrophy. ROM exercises prevent complications of immobility in severely compromised patients.*
- Provide written and verbal information about activity after discharge. *Written information provides a reference for important information. Verbal information allows for clarification and validation of the material.*

Deficient Knowledge: Low-Sodium Diet

Diet is an important part of long-term management of heart failure to manage fluid retention.

Expected Outcome: Patient will comply with sodium restrictions prescribed as evidenced by reduction in fluid retention and edema.

- Discuss the rationale for sodium restrictions. *Understanding fosters compliance with the prescribed diet.*
- Consult with dietitian to plan and teach a low-sodium and, if necessary for weight control, low-kilocalorie diet. Provide a list of high-sodium, high-fat, high-cholesterol foods to avoid. Provide American Heart Association materials. *Dietary planning and teaching increase the patient's sense of control and participation in disease management. Food lists are useful memory aids.*
- Teach how to read food labels for nutritional information. Many processed foods contain hidden sodium, which can be identified by careful label reading. *Knowledge about hidden sodium can improve dietary selections.*
- Assist the patient to construct a 2-day meal plan choosing foods low in sodium. *This allows for learning assessment, clarification of misunderstandings, and reinforcement of teaching.*
- Encourage small, frequent meals rather than three heavy meals per day. *Small, frequent meals provide continuing energy resources and decrease the work required to digest a large meal.*

Delegating Nursing Care Activities

As appropriate and allowed by the designated duties and responsibilities of unlicensed assistive personnel, the nurse may delegate nursing care activities such as measuring fluid intake and output, collecting vital signs (including orthostatic vital signs), encouraging oral or enteral fluid intake, and ensuring nonpharmacologic skin care.

Continuity of Care

Heart failure is a chronic condition requiring active participation by the patient and family for effective management. In teaching for home care, include the following topics:

- The disease process and its effects on the patient's life
- Warning signals of cardiac decompensation that require treatment
- Desired and adverse effects of prescribed drugs; monitoring for effects; importance of compliance with drug regimen to prevent acute and long-term complications of heart failure
- Prescribed diet and sodium restriction; practical suggestions for reducing salt intake; recommend American Heart Association materials and recipes
- Exercise recommendations to strengthen the heart muscle and improve aerobic capacity (Box 31–3)
- The importance of keeping scheduled follow-up appointments to monitor disease progression and effects of therapy.

Provide referrals for home healthcare and household assistance (shopping, transportation, personal needs, and housekeeping) as indicated. Referrals to community agencies, such as local cardiac rehabilitation programs, heart support groups, or the AHA, can provide additional materials and psychosocial support.

THE PATIENT WITH PULMONARY EDEMA

Pulmonary edema is an abnormal accumulation of fluid in the interstitial tissue and alveoli of the lung. Both cardiac and noncardiac disorders can cause pulmonary edema. Cardiac causes include acute myocardial infarction, acute heart failure, and valvular disease. *Cardiogenic pulmonary edema*, the focus of this section, is a sign of severe cardiac decompensation. Noncardiac causes of pulmonary edema include primary pulmonary disorders, such as acute respiratory distress syndrome (ARDS), trauma, sepsis, drug overdose, or neurologic sequelae. Pulmonary edema due to ARDS is discussed in Chapter 37.

FAST FACTS

- Cardiogenic pulmonary edema is a severe form of heart failure. Risk factors are those associated with heart failure, and treatment focuses on maintaining oxygenation and improving cardiac function.
- Noncardiogenic pulmonary edema is a primary or secondary lung disorder. It usually occurs secondarily to a critical event such as major trauma, shock, or DIC. Treatment focuses on maintaining oxygenation and the primary, underlying disorder.

BOX 31–3 Home Activity Guidelines for the Patient with Heart Failure

- Perform as many activities as independently as you can.
- Space your meals and activities.
  a. Eat six small meals a day.
  b. Allow time during the day for periods of rest and relaxation.
- Perform all activities at a comfortable pace.
  a. If you get tired during any activity, stop what you are doing and rest for 15 minutes.
  b. Resume activity only if you feel up to it.
- Stop any activity that causes chest pain, shortness of breath, dizziness, faintness, excessive weakness, or sweating. Rest. Notify your physician if your activity tolerance changes and if symptoms continue after rest.
- Avoid straining. Do not lift heavy objects. Eat a high-fiber diet and drink plenty of water to prevent constipation. Use laxatives or stool softeners, as approved by your physician, to avoid constipation and straining during bowel movements.
- Begin a graded exercise program. Walking is good exercise that does not require any special equipment (except a good pair of walking shoes). Plan to walk twice a day at a comfortable, slow pace for the first couple of weeks at home, and then gradually increase the distance and pace. A suggested schedule is provided next—but progress at your own speed. Take your time. Aim for walking at least three times per week (every other day) (American College of Sports Medicine, 2013).

Week 1	200–400 ft (1/4 mile)	Twice a day, slow leisurely pace
Week 2	1/4 mile	15 min, minimum of 3 times per week
Weeks 2–3	1/2 mile	30 min, minimum of 3 times per week
Weeks 3–4	1 mile	30 min, minimum of 3 times per week
Weeks 4–5	1 1/2 miles	30 min, minimum of 3 times per week
Weeks 5–6	2 miles	40 min, minimum of 3 times per week

CASE STUDY & NURSING CARE PLAN A Patient with Heart Failure

One year ago, Arthur Jackson, 67 years old, had a large anterior wall MI and underwent subsequent coronary artery bypass surgery. On discharge, he was started on a regimen of enalapril (Vasotec), digoxin, furosemide (Lasix), warfarin (Coumadin), and a potassium chloride supplement. He is now in the cardiac unit complaining of severe shortness of breath, hemoptysis, and poor appetite for 1 week. He is diagnosed with acute heart failure.

ASSESSMENT

Mr. Jackson refuses to settle in bed, preferring to sit in the bedside recliner in high-Fowler's position. He states, "Lately, this is the only way I can breathe." Mr. Jackson states that he has not been able to work in his garden without getting short of breath. He complains of his shoes and belt being too tight.

When Mr. Jackson's nurse, Ms. Takashi, RN, obtains his nursing history, Mr. Jackson insists that he takes his medications regularly. He states that he normally works in his garden for light exercise. In his diet history, Mr. Jackson admits a fondness for bacon and Chinese food and sheepishly admits to snacking between meals "even though I need to lose weight."

Mr. Jackson's vital signs are BP 95/72 mmHg, HR 124 bpm and irregular, R 28/min and labored, and T 97.5°F (36.5°C). The cardiac monitor shows atrial fibrillation. An S_3 is noted on auscultation; the cardiac impulse is left of the midclavicular line. He has crackles and diminished breath sounds in the bases of both lungs. Significant jugular venous distention, 3+ pitting edema of feet and ankles, and abdominal distention are noted. Liver size is within normal limits by percussion. Skin cool and diaphoretic. Chest x-ray shows cardiomegaly and pulmonary infiltrates.

DIAGNOSES

- *Excess Fluid Volume* related to impaired cardiac pump and salt and water retention
- *Activity Intolerance* related to impaired cardiac output
- *Impaired Health Maintenance* related to lack of knowledge about diet restrictions

EXPECTED OUTCOMES

- Patient will demonstrate loss of excess fluid by weight loss and decreases in edema, jugular venous distention, and abdominal distention.
- Patient will demonstrate improved activity tolerance.
- Patient will verbalize understanding of diet restrictions.

PLANNING AND IMPLEMENTATION

- Take hourly vital signs and hemodynamic pressure measurements.
- Administer and monitor effects of prescribed diuretics and vasodilators.
- Weigh daily; strict intake and output.
- Enforce fluid restriction of 1500 mL/24 hours: 600 mL day shift, 600 mL evening shift, 300 mL at night.
- Auscultate heart and breath sounds every 4 hours and as indicated.
- Administer oxygen per nasal cannula at 2 L/min. Monitor oxygen saturation continuously. Notify physician if less than 94%.
- Place in high-Fowler's or other position of comfort.
- Notify physician of significant changes in laboratory values.
- Teach about all medications and how to take and record pulse. Provide information about anticoagulant therapy and signs of bleeding.
- Design an activity plan with Mr. Jackson that incorporates preferred activities and scheduled rest periods.
- Instruct about sodium-restricted diet. Allow meal choices within allowed limits.
- Consult dietitian for planning and teaching Mr. and Mrs. Jackson about low-sodium diet.

EVALUATION

Mr. Jackson is discharged after 3 days in the cardiac unit. He has lost 8 pounds during his stay and states it is much easier to breathe and his shoes fit better. He is able to sleep in semi-Fowler's position with only one pillow. His peripheral edema has resolved. Mr. and Mrs. Jackson met with the dietitian, who helped them develop a realistic eating plan to limit sodium, sugar, and fats. The dietitian also provided a list of high-sodium foods to avoid. Mr. Jackson is relieved to know that he can still enjoy Chinese food prepared without monosodium glutamate (MSG) or added salt. Ms. Takashi and the physical therapist designed a progressive activity plan with Mr. Jackson that he will continue at home. He remains in atrial fibrillation, a chronic condition. His knowledge of digoxin and Coumadin has been assessed and reinforced. Ms. Takashi confirms that he is able to accurately check his pulse and can list signs of digoxin toxicity and excessive bleeding.

Clinical Reasoning in Patient Care

1. Mr. Jackson's medication regimen remains the same after discharge. What specific teaching does he need related to potential interactions of these drugs?
2. Mr. Jackson tells you, "Talk to my wife about my medications—she's Tarzan and I'm Jane now." How would you respond?
3. Design an exercise plan for Mr. Jackson to prevent deconditioning and conserve energy.
4. Mr. Jackson tells you, "Sometimes I forget whether I have taken my aspirin, so I'll take another just to be sure. After all, they are only baby aspirin. One or two extra a day shouldn't hurt, right?" What is your response?
5. Mr. Jackson is admitted to the neuro unit 6 months later with a cerebrovascular accident (CVA). What is the probable cause of his stroke?

See Evaluating Your Response in Appendix B.

Pulmonary edema is a medical emergency: The patient is literally drowning in the fluid in the alveolar and interstitial pulmonary spaces. Its onset may be acute or gradual, progressing to severe respiratory distress. Immediate treatment is necessary.

Pathophysiology

In cardiogenic pulmonary edema, the contractility of the left ventricle is severely impaired. The ejection fraction falls as the ventricle is unable to eject the blood that enters it, causing a sharp rise in end-diastolic volume and pressure. Pulmonary hydrostatic pressures rise, ultimately exceeding the osmotic pressure of the blood. As a result, fluid leaking from the pulmonary capillaries congests interstitial tissues, decreasing lung compliance and interfering with gas exchange. As capillary and interstitial pressures increase further, the tight junctions of the alveolar walls are disrupted, and the fluid enters the alveoli, along with large red blood cells and protein molecules. Ventilation and gas exchange are severely disrupted, and hypoxia worsens.

Manifestations

The patient with acute pulmonary edema presents with classic manifestations (see the accompanying box). Dyspnea, shortness of breath, and labored respirations are acute and severe, accompanied

MANIFESTATIONS OF PULMONARY EDEMA

RESPIRATORY
- Tachypnea
- Labored respirations
- Dyspnea
- Orthopnea
- Paroxysmal nocturnal dyspnea
- Cough productive of frothy, pink sputum
- Crackles, wheezes

CARDIOVASCULAR
- Tachycardia
- Hypotension
- Cyanosis
- Cool, clammy skin
- Hypoxemia
- Ventricular gallop

NEUROLOGIC
- Restlessness
- Anxiety
- Feeling of impending doom

by orthopnea, the inability to breathe when lying down. Cyanosis is present, and the skin is cool, clammy, and diaphoretic. A productive cough with pink, frothy sputum develops due to fluid, RBCs, and plasma proteins in the alveoli and airways. Crackles are heard throughout the lung fields on auscultation. As the condition worsens, lung sounds become harsher. The patient often is restless and highly anxious, although severe hypoxia may cause confusion or lethargy.

As noted earlier, pulmonary edema is a medical emergency. Without rapid and effective intervention, severe tissue hypoxia and acidosis will lead to organ system failure and death.

●○● INTERPROFESSIONAL CARE

Immediate treatment for acute pulmonary edema focuses on restoring effective gas exchange and reducing fluid and pressure in the pulmonary vascular system. The patient is placed in an upright sitting position with the legs dangling to reduce venous return by trapping some excess fluid in the lower extremities. This position also facilitates breathing.

Diagnostic testing is limited to assessment of the acute situation. *Arterial blood gases (ABGs)* are drawn to assess gas exchange and acid–base balance. Oxygen tension (PaO_2) is usually low. Initially, carbon dioxide levels ($PaCO_2$) may also be reduced because of rapid respirations. As the condition progresses, the $PaCO_2$ rises and respiratory acidosis develops (see Chapter 10). *Oxygen saturation* levels also are continuously monitored. The *chest x-ray* shows pulmonary vascular congestion and alveolar edema. Provided the patient's condition allows, *hemodynamic monitoring* is instituted. In cardiogenic pulmonary edema, the pulmonary artery wedge pressure (PAWP) is elevated, usually over 25 mmHg. Cardiac output may be decreased.

Morphine is administered intravenously to relieve anxiety and improve the efficacy of breathing. It also is a vasodilator that reduces venous return and lowers left atrial pressure. Although morphine is very effective for patients with cardiogenic pulmonary edema, naloxone, its antidote, is kept readily available in case respiratory depression occurs.

Oxygen is administered using a positive pressure system that can achieve a 100% oxygen concentration. A continuous positive airway pressure (CPAP) mask system may be used, or the patient may be intubated and mechanical ventilation employed (see Chapter 37). Positive pressure increases alveolar pressures and gas exchange while decreasing fluid diffusion into the alveoli.

Potent loop diuretics such as furosemide, ethacrynic acid, or bumetanide are administered intravenously to promote rapid diuresis. Furosemide is also a venous dilator, reducing venous return to the heart. Vasodilators such as intravenous nitroprusside are given to improve cardiac output by reducing afterload. Dopamine or dobutamine and possibly digoxin are administered to improve the myocardial contractility and cardiac output. Intravenous aminophylline may be used cautiously to reduce bronchospasm and decrease wheezing.

When the patient's condition has stabilized, further diagnostic tests may be done to determine the underlying cause of pulmonary edema, and specific treatment measures directed at the cause instituted.

●○● NURSING CARE

Nursing care of the patient with acute pulmonary edema focuses on relieving the pulmonary effects of the disorder. Interventions are directed toward improving oxygenation, reducing fluid volume, and providing emotional support.

Assessment

See the Manifestations and Interprofessional Care sections for the assessment of the patient with acute pulmonary edema.

The nurse often is instrumental in recognizing early manifestations of pulmonary edema and initiating treatment. As with many critical conditions, emergent care is directed toward the ABCs: airway, breathing, and circulation.

Priorities of Care

Collaborating with the interprofessional team to ensure adequate treatment of the underlying process while providing care that supports the physical and psychologic responses to the disorder is a priority of nursing care.

Diagnoses, Outcomes, and Interventions

Promoting effective gas exchange and restoring an effective cardiac output are the priorities for nursing and interprofessional care of the patient with cardiogenic pulmonary edema. The experience of acute dyspnea and shortness of breath is terrifying for the patient; the nurse is instrumental in providing emotional support and reassurance.

Impaired Gas Exchange

Accumulated fluid in the alveoli and airways interferes with ventilation of the lungs. As a result, alveolar oxygen levels fall and carbon dioxide levels may rise. Reduced alveolar oxygen decreases diffusion of the gas into pulmonary capillaries. In addition, pulmonary edema increases the distance over which gases must diffuse to cross the alveolar-capillary membrane, further reducing oxygen levels in the blood and oxygen delivery to the tissues.

Expected Outcome: Patient will experience improved ventilation and adequate oxygenation as evidenced by blood gas levels within normal limits for the individual patient

- Ensure airway patency. *A patent airway is absolutely vital for pulmonary function, including ventilation and gas exchange.*
- Assess the effectiveness of respiratory efforts and airway clearance. *Pulmonary edema increases the work of breathing. This increased effort can lead to fatigue and decreased respiratory effort.*
- Assess respiratory status frequently, including rate, effort, use of accessory muscles, sputum characteristics, lung sounds, and skin color. *The status of a patient in acute pulmonary edema can change rapidly for the better or worse.*
- Place in high-Fowler's position with the legs dangling. *The upright position facilitates breathing and decreases venous return.*
- Administer oxygen as ordered by mask, CPAP mask, or ventilator. *Supplemental oxygen promotes gas exchange; positive pressure increases the pressure within the alveoli, airways, and thoracic cavity, decreasing venous return, pulmonary capillary pressure, and fluid leak into the alveoli.*
- Encourage patient to cough up secretions; provide nasotracheal suctioning if necessary. *Coughing moves secretions from smaller airways into larger airways where they can be suctioned out if necessary.*

SAFETY ALERT

Have emergency equipment readily available in case of respiratory arrest. Be prepared to assist with intubation and initiation of mechanical ventilation. Fatigue, impaired gas exchange, and respiratory acidosis can lead to respiratory and cardiac arrest.

Decreased Cardiac Output

Cardiogenic pulmonary edema usually is caused by either an acute decrease in myocardial contractility or increased workload that exceeds the ability of the left ventricle. The significant decrease in cardiac output increases pressure within the pulmonary vascular system and triggers compensatory mechanisms that increase the heart rate and blood volume. These compensatory mechanisms further increase the workload of the failing heart.

Expected Outcome: Patient will demonstrate adequate cardiac output as evidenced by blood pressure and pulse rate and rhythm within normal limits.

- Monitor vital signs, hemodynamic status, and rhythm continuously. *Acute pulmonary edema is a critical condition, and cardiovascular status can change rapidly.*
- Assess heart sounds for possible S_3, S_4, or murmurs. *These abnormal heart sounds may be due to excess work or may indicate the cause of the acute pulmonary edema.*
- Initiate an intravenous line for medication administration. Administer morphine, diuretics, vasodilators, bronchodilators, and positive inotropic medications (e.g., digoxin) as ordered. *These drugs reduce cardiac work and improve contractility.*
- Insert an indwelling catheter as ordered; record output hourly. *Urine output of less than 30 mL/h indicates impaired renal perfusion due to severely impaired cardiac output and a risk for renal failure or other complications.*
- Keep accurate intake and output records. Restrict fluids as ordered. *Fluids may be restricted to reduce vascular volume and cardiac work.*

Fear

Acute pulmonary edema is a very frightening experience for everyone (including the nurse).

Expected Outcome: Patient will demonstrate reduced fear as evidenced by verbal and nonverbal indicators that reflect understanding by the patient and family of the current clinical condition.

- Provide emotional support for the patient and family members. *Fear and anxiety stimulate the sympathetic nervous system, which can lead to ineffective respiratory patterns and interfere with cooperation with care measures.*
- Explain all procedures and the reasons for the procedures to the patient and family members. Keep information brief and to the point. Use short sentences and a reassuring tone. *Anxiety and fear interfere with the ability to assimilate information; brief, factual information and reassurance reduce anxiety and fear.*
- Maintain close contact with the patient and family, providing reassurance that recovery from acute pulmonary edema is often as dramatic as its onset.
- Answer questions, and provide accurate information in a caring manner. *Knowledge reduces the anxiety and psychologic stress associated with this critical condition.*

Delegating Nursing Care Activities

As appropriate and allowed by the designated duties and responsibilities of unlicensed assistive personnel, the nurse may delegate nursing care activities such as measuring fluid intake and output, collecting vital signs (including orthostatic vital signs), encouraging oral or enteral fluid intake, and ensuring nonpharmacologic skin care.

Continuity of Care

During the acute period, teaching is limited to immediate care measures. Once the acute episode of pulmonary edema has resolved, teach the patient and family about its underlying cause and prevention of future episodes. If pulmonary edema follows an acute myocardial infarction (AMI), include information related to CHD and the AMI, as well as information related to heart failure. Review the teaching and home care for patients with these disorders for further information.

Inflammatory Heart Disorders

Any layer of cardiac tissue—the endocardium, myocardium, or pericardium—can become inflamed, thus damaging the heart valves, heart muscle, or pericardial lining. Manifestations of inflammatory heart disorders range from very mild to life threatening. This section discusses the causes and management of rheumatic heart disease, endocarditis, myocarditis, and pericarditis.

THE PATIENT WITH RHEUMATIC FEVER AND RHEUMATIC HEART DISEASE

Rheumatic fever is a systemic inflammatory disease caused by an abnormal immune response to pharyngeal infection by group A beta-hemolytic streptococci. Rheumatic fever usually is a self-limiting disorder, although it may become recurrent or chronic. Although the heart commonly is involved in the acute inflammatory process, only about 10% of people with rheumatic fever develop rheumatic heart disease. Rheumatic heart disease frequently damages the heart valves and is a major cause of the mitral and aortic valve disorders discussed in the next section of this chapter.

Incidence, Prevalence, and Risk Factors

In the United States and other industrialized nations, rheumatic fever and its sequelae are rare. The peak incidence of rheumatic fever is between ages 5 and 15; although it is rare after age 40, it may affect people of any age. About 3% of people with untreated group A streptococcal pharyngitis develop rheumatic fever. Rheumatic fever and rheumatic heart disease remain significant public health problems in many developing countries. Highly virulent strains of group A streptococci have caused scattered outbreaks in the United States in recent years.

Risk factors for streptococcal infections of the pharynx include environmental and economic factors such as crowded living conditions, malnutrition, immunodeficiency, and poor access to healthcare. Evidence also suggests an unknown genetic factor in susceptibility to rheumatic fever.

FAST FACTS

- The peak incidence of rheumatic fever is in children ages 5 to 15.
- Young adults (in late adolescence and the early 20s) are the primary adult population affected by rheumatic fever.
- People past age 40 rarely develop the disease, unless it is a case of recurrent rheumatic fever.
- Although crowded living conditions and lower socioeconomic status are risk factors, a relatively recent outbreak in the United States occurred in people with ready access to healthcare.

Pathophysiology

The pathophysiology of rheumatic fever is not yet totally understood. It is thought to result from an abnormal immune response to M proteins on group A beta-hemolytic streptococcal bacteria. These antigens can bind to cells in the heart, muscles, and brain. They also bind with receptors in synovial joints, provoking an autoimmune response. The resulting immune response to the bacteria also leads to inflammation in tissues containing these M proteins. Inflammatory lesions develop in connective tissues on the heart, joints, and skin. The antibodies may remain in the serum for up to 6 months following the initiating event. Refer to Chapters 11 and 12 for more information about the immune system and inflammatory response.

Carditis, inflammation of the heart, develops in about 50% of people with rheumatic fever. The inflammatory process usually involves all three layers of the heart—the pericardium, myocardium, and endocardium. *Aschoff bodies*, localized areas of tissue necrosis surrounded by immune cells, develop in cardiac tissues. Pericardial and myocardial inflammation tends to be mild and self-limiting. Endocardial inflammation, however, causes swelling and erythema of valve structures and small vegetative lesions on valve leaflets. As the inflammatory process resolves, fibrous scarring occurs, causing deformity.

Rheumatic heart disease (RHD) is a slowly progressive valvular deformity that may follow acute or repeated attacks of rheumatic fever. Valve leaflets become rigid and deformed; commissures (openings) fuse, and the chordae tendineae fibrose and shorten. This results in stenosis or regurgitation of the valve. In **stenosis**, a narrowed, fused valve obstructs forward blood flow. **Regurgitation** occurs when the valve fails to close properly (an *incompetent* valve), allowing blood to flow back through it. Valves on the left side of the heart are usually affected; the mitral valve is most frequently involved.

Manifestations

Manifestations of rheumatic fever typically follow the initial streptococcal infection by about 2 to 3 weeks. Fever and migratory joint pain are often initial manifestations. The knees, ankles, hips, and elbows are common sites of swelling and inflammation. *Erythema marginatum* is a temporary nonpruritic skin rash characterized by red lesions with clear borders and blanched centers usually found on the trunk and proximal extremities. Neurologic symptoms of rheumatic fever, although rare in adults, may range from irritability and an inability to concentrate to clumsiness and involuntary muscle spasms.

Manifestations of carditis include chest pain, tachycardia, a pericardial friction rub, or evidence of heart failure. On auscultation, an S_3, S_4, or a heart murmur may be heard. Cardiomegaly or pericardial effusion may develop. Other manifestations of rheumatic fever are listed in the accompanying box.

●○● INTERPROFESSIONAL CARE

Management of the patient with rheumatic heart disease focuses on eradicating the streptococcal infection and managing the manifestations of the disease. Carditis and resulting heart failure are treated with measures to reduce the inflammatory process and manage the heart failure. Activities are limited, but bed rest is not generally ordered.

MANIFESTATIONS OF RHEUMATIC FEVER

CARDIAC
- Chest pain
- Friction rub
- Heart murmur

MUSCULOSKELETAL
- *Migratory polyarthritis:* redness, heat, swelling, pain, and tenderness of more than one joint
- Usually affects large joints of extremities

SKIN
- *Erythema marginatum:* transitory pink, nonpruritic, macular lesions on trunk or inner aspect of upper arms or thighs
- *Subcutaneous nodules* over extensors of wrist, elbow, ankle, and knee joints

NEUROLOGIC
- *Sydenham's chorea:* irritability; behavior changes; sudden, jerky, involuntary movements

TABLE 31–5 Diagnostic Tests for Rheumatic Heart Disease

Test	Values Characteristic of Rheumatic Heart Disease
White blood cell count (WBC)	> 10,000/mm^3
Red blood cell (RBC) count	< 4 million/mm^3
Erythrocyte sedimentation rate (ESR)	> 20 mm/h
C-reactive protein	Positive
Antistreptolysin (ASO) titer	> 250 International Units/mL
Throat culture	Usually positive for group A beta-hemolytic streptococci
Cardiac enzymes	Elevated in severe carditis
ECG changes	Prolonged PR interval
Chest x-ray	May show cardiac enlargement
Echocardiogram	May show valvular damage, enlarged chambers, decreased ventricular function, or pericardial effusion

DIAGNOSIS

In addition to the history and physical examination, a number of laboratory and diagnostic tests may be ordered for the patient with suspected rheumatic fever. Table 31–5 identifies tests and values indicative of carditis associated with rheumatic fever.

- *Complete blood count (CBC)* and *erythrocyte sedimentation rate (ESR)* are indicators of the inflammatory process. The WBC count is elevated, and the number of red blood cells may be low due to the inflammatory inhibition of erythropoiesis. The ESR, a general indicator of inflammation, is elevated.
- *C-reactive protein (CRP)* is positive in an active inflammatory process.
- *Antistreptolysin (ASO) titer* is a test for streptococcal antibodies. It rises within 2 months of onset and is positive in most patients with rheumatic fever.
- Throat culture is positive for group A beta-hemolytic streptococcus in only 25% to 40% of patients with acute rheumatic fever.

MEDICATIONS

As soon as rheumatic fever is diagnosed, antibiotics are started to eliminate the streptococcal infection. Penicillin is the antibiotic of choice to treat group A streptococci. Antibiotics are prescribed for at least 10 days. Erythromycin or clindamycin is used if the patient is allergic to penicillin. Prophylactic antibiotic therapy is continued for 5 to 10 years to prevent recurrences. Recurrences after 5 years or age 25 are rare. Penicillin G, 1.2 million units injected intramuscularly every 3 to 4 weeks, is the prophylaxis of choice. Oral penicillin, amoxicillin, sulfadiazine, or erythromycin may also be used.

Joint pain and fever are treated with salicylates (e.g., aspirin), ibuprofen, or another nonsteroidal anti-inflammatory drug (NSAID); corticosteroids may be used for severe pain due to inflammation or carditis. Refer to Chapter 9 for information about the use of these anti-inflammatory medications.

●○● NURSING CARE

Health Promotion

Rheumatic fever is preventable. Prompt identification and treatment of streptococcal throat infections help decrease spread of the pathogen and the risk for rheumatic fever. Characteristics of streptococcal sore throat include a red, fiery-looking throat, pain with swallowing, enlarged and tender cervical lymph nodes, fever range of 38.3° to 40.0°C (101° to 104°F), and headache. Emphasize the importance of finishing the complete course of medication to eradicate the pathogen.

Assessment

See the Manifestations and Interprofessional Care sections for the assessment of the patient with rheumatic fever/rheumatic heart disease. Assess patients at risk for rheumatic fever (prolonged, untreated, or recurrent pharyngitis) for possible manifestations.

- *Health history:* complaints of recent sore throat with fever, difficulty swallowing, and general malaise; treatment measures; previous history of strep throat or rheumatic fever; history of heart murmur or other cardiac problems; current medications
- *Physical assessment:* vital signs including temperature; skin color, presence of rash on trunk or proximal extremities; mental status; evidence of inflamed joints; heart and lung sounds.

Priorities of Care

Collaborating with the interprofessional team to ensure adequate treatment of the underlying process while providing care that supports the physical and psychologic responses to the disorder is a priority of nursing care.

Diagnoses, Outcomes, and Interventions

The nursing care focus for the patient with RHD is on providing supportive care and preventing complications. Teaching to prevent recurrence of rheumatic fever is extremely important. *Pain* and *Activity Intolerance* are priority nursing diagnoses for the patient with rheumatic fever and RHD.

Acute Pain

Joint and chest pain due to acute inflammation is common in rheumatic fever. Pain and inflammation may interfere with rest and healing.

Expected Outcome: Patient will achieve adequate pain control as evidenced by physical well-being.

- Administer anti-inflammatory drugs as ordered. Promptly report manifestations of aspirin toxicity, including tinnitus, vomiting, and gastrointestinal bleeding. Give aspirin and other NSAIDs with food, milk, or antacids to minimize gastric irritation. *Joint pain and fever may be treated with anti-inflammatory agents such as aspirin and NSAIDs. Steroids may be prescribed for severe carditis.*
- Provide warm, moist compresses for local pain relief of acutely inflamed joints. *Moist heat helps relieve pain associated with inflamed joints by reducing inflammation.*
- Auscultate heart sounds as indicated (every shift or each home visit). Notify the physician if a pericardial friction rub or a new murmur develops. *A friction rub is produced as inflamed pericardial surfaces rub against each other. This also stimulates pain receptors, and may increase discomfort.*

Activity Intolerance

The patient with acute carditis or RHD may develop heart failure if the heart is unable to supply enough oxygen to meet the body's demand. Manifestations of fatigue, weakness, and dyspnea on exertion may result.

Expected Outcome: The patient will participate in physical activity as tolerated.

- Explain the importance of activity limitations and reinforce teaching as needed. *Activities are limited during the acute phase of carditis to reduce the workload of the heart. Understanding the rationale improves cooperation with the limitations.*
- Encourage social and diversional activities such as visits with friends and family, reading, playing cards or board games, watching television, and listening to music or audio books. *Diversional activities provide a focus for the patient whose physical activities must be limited.*
- Encourage gradual increases in activity, monitoring for evidence of intolerance or heart failure. Consult a cardiac rehabilitation specialist to help design an activity progression schedule. *Gradual activity progression is encouraged as the patient's condition improves. Activity tolerance is monitored and activities modified as needed.*

Delegating Nursing Care Activities

As appropriate and allowed by the designated duties and responsibilities of unlicensed assistive personnel, the nurse may delegate nursing care activities such as measuring fluid intake and output, collecting vital signs (including orthostatic vital signs), encouraging oral or enteral fluid intake, and ensuring nonpharmacologic skin care.

Continuity of Care

Most patients with rheumatic fever and carditis do not require hospitalization. Teaching for home care focuses on both acute care and preventing recurrences and further tissue damage. Include the following topics:

- The importance of completing the full course of antibiotic therapy and continuing antibiotic prophylaxis as prescribed for the patient with chronic RHD; include the importance of antibiotic prophylaxis for invasive procedures (e.g., dental care, endoscopy, or surgery) to prevent bacterial endocarditis. Pamphlets on endocarditis prevention are helpful reminders, and are available from the American Heart Association.
- Preventive dental care and good oral hygiene to maintain oral health and prevent gingival infections, which can lead to recurrence of the disease.
- Early recognition of streptococcal sore throat and appropriate treatment for both the patient and family members.
- Early manifestations of heart failure to report to the physician.
- Prescribed medications, including their dosage, route, intended and potential adverse effects, and manifestations to report to the physician.
- Dietary sodium restriction if ordered or recommended. A high-carbohydrate, high-protein diet may be recommended to facilitate healing and combat fatigue.

Refer for home health services or household assistance as indicated.

THE PATIENT WITH INFECTIVE ENDOCARDITIS

Endocarditis, inflammation of the endocardium, can involve any portion of the endothelial lining of the heart. The valves usually are affected. Endocarditis is usually infectious in nature, characterized by colonization or invasion of the endocardium and heart valves by a pathogen.

FAST FACTS

- Subacute bacterial endocarditis develops more slowly and usually occurs in people with previous heart valve damage.
- Acute bacterial endocarditis has an abrupt onset and typically affects people with no previous history of heart problems.

Incidence and Risk Factors

Endocarditis is relatively uncommon, with an incidence of 1.5 to 6.2 cases per 100,000 people in developed countries. The greatest risk factor for endocarditis is previous heart damage. Lesions develop on deformed valves, on valve prostheses, or in areas of tissue damage due to congenital deformities or ischemic disease. The left side of the heart, the mitral valve in particular, is usually affected. Intravenous drug use also is a significant risk factor. The right side of the heart usually is affected in these patients. Other risk factors include invasive catheters (e.g., a central venous catheter, hemodynamic monitoring, or an indwelling urinary catheter), dental procedures or poor dental health, and recent heart surgery.

Prosthetic valve endocarditis (PVE) may occur in patients with a mechanical or tissue valve replacement. This infection may develop in the early postoperative period (within 2 months after surgery) or later. Prosthetic valve endocarditis accounts for 10% to 20% of endocarditis cases. It usually affects males over the age of 60, and is more frequently associated with aortic valve prostheses than with mitral valve replacements. Early PVE is usually due to prosthetic valve contamination during surgery or perioperative bacteremia. Its course often is rapid, and mortality is high. Late-onset PVE more closely resembles subacute endocarditis.

Pathophysiology

Entry of pathogens into the bloodstream is required for infective endocarditis to develop. Bacteria may enter through oral lesions, during dental work or invasive procedures, such as intravenous catheter insertion, surgery, or urinary catheterization; during intravenous

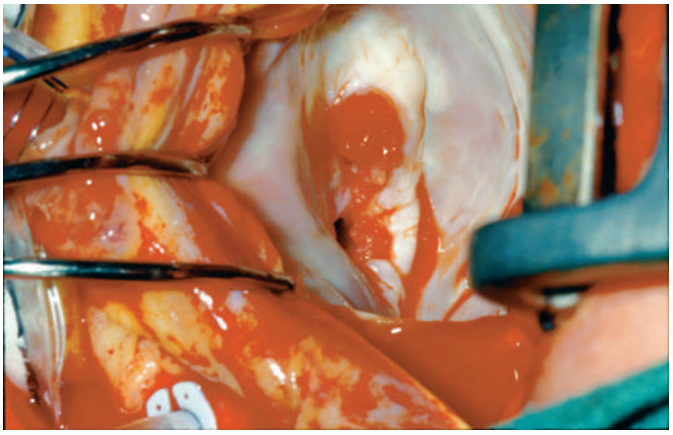

Figure 31–7 ■ A vegetative lesion of bacterial endocarditis.
Source: M. English/Custom Medical Stock Photo, Inc.

drug use; or as a result of infectious processes such as urinary tract or upper respiratory infection.

The initial lesion is a sterile platelet-fibrin vegetation formed on damaged endothelium (Figure 31–7 ■). In acute infective endocarditis, these lesions develop on healthy valve structures, although the mechanism is unknown. In subacute endocarditis, they usually develop on already damaged valves or in endocardial tissue that has been damaged by abnormal pressures or blood flow within the heart.

Organisms that have invaded the blood colonize these vegetations. The vegetation enlarges as more platelets and fibrin are attracted to the site and cover the infecting organism. This covering "protects" the bacteria from quick removal by immune defenses such as phagocytosis by neutrophils, antibodies, and complement. Vegetations may be singular or multiple. They expand while loosely attached to edges of the valve. Friable vegetations can break or shear off, embolizing and traveling through the bloodstream to other organ systems. When they lodge in small vessels, they may cause hemorrhages, infarcts, or abscesses. Ultimately, the vegetations scar and deform the valves and cause turbulence of blood flowing through the heart. Heart valve function is affected, either obstructing forward blood flow, or closing incompletely.

Endocarditis is classified by its acuity and disease course (Table 31–6). *Acute infective endocarditis* has an abrupt onset and is a rapidly progressive, severe disease. Although almost any organism can cause infective endocarditis, virulent organisms such as *Staphylococcus aureus* cause a more abrupt onset and destructive course. *S. aureus* is commonly the infective organism in acute endocarditis. In contrast, *subacute infective endocarditis* has a more gradual onset, with predominant systemic manifestations. It is more likely to occur in patients with preexisting heart disease. *Streptococcus viridans*, enterococci, other gram-negative and gram-positive bacilli, yeasts, and fungi tend to cause the subacute forms of endocarditis (Huether & McCance, 2011).

Manifestations

The manifestations of infective endocarditis often are nonspecific (see the accompanying box). A temperature above 39.4°C (101.5°F) and flu-like symptoms develop, accompanied by cough, shortness of breath, and joint pain. The presentation of acute staphylococcal endocarditis is more severe, with a sudden onset, chills, and a high fever. Heart murmurs are heard in 90% of persons with infective endocarditis. An existing murmur may worsen, or a new murmur may develop.

Splenomegaly is common in chronic disease. Peripheral manifestations of infective endocarditis result from microemboli or circulating immune complexes. These manifestations include the following:

- *Petechiae:* small, purplish-red hemorrhagic spots on the trunk, conjunctiva, and mucous membranes
- *Splinter hemorrhage:* hemorrhagic streaks under the fingernails or toenails
- *Osler's nodes:* small, reddened, painful raised growths on finger and toe pads
- *Janeway lesions:* small, nontender, purplish-red macular lesions on the palms of the hands and soles of the feet
- *Roth's spots:* small, whitish spots (cotton-wool spots) seen on the retina.

Complications

Embolization of vegetative fragments may affect any organ system, particularly the lungs, brain, kidneys, and the skin and mucous membranes, with resulting organ infarction. Other common complications of infective endocarditis include heart failure, abscess, and aneurysms due to infiltration of the arterial wall by organisms. Without treatment, endocarditis is almost universally fatal; fortunately, antibiotic therapy is usually effective to treat this disease.

TABLE 31–6 Classifications of Infective Endocarditis

	Acute Infective Endocarditis	Subacute Infective Endocarditis
Onset	Sudden	Gradual
Usual organism	*Staphylococcus aureus*	*Streptococcus viridans*, enterococci, gram-negative and gram-positive bacilli, fungi, yeasts
Risk factors	Usually occurs in previously normal heart; intravenous drug use, infected intravenous sites	Usually occurs in damaged or deformed hearts; dental work, invasive procedures, and infections
Pathologic process	Rapid valve destruction	Valve destruction leading to regurgitation; embolization of friable vegetations
Presentation	Abrupt onset with spiking fever and chills; manifestations of heart failure	Gradual onset of febrile illness with cough, dyspnea, arthralgias, abdominal pain

MANIFESTATIONS OF INFECTIVE ENDOCARDITIS

- Chills and fever
- General malaise, fatigue
- Arthralgias
- Cough, dyspnea
- Heart murmur
- Anorexia, abdominal pain
- Petechiae, splinter hemorrhages
- Splenomegaly

●○● INTERPROFESSIONAL CARE

Eradicating the infecting organism and minimizing valve damage and other adverse consequences of infective endocarditis are the priorities of care.

DIAGNOSIS

There are no definitive tests for infective endocarditis, but diagnostic tests help establish the diagnosis.

- *Blood cultures* usually are positive for bacteria or other pathogens. Blood cultures are considered positive when a typical infecting organism is identified from two or more separate blood cultures (drawn from different sites and/or at different times, e.g., 12-hour intervals).
- *Echocardiography* (either transthoracic or transesophageal) to visualize vegetations can be diagnostic for infective endocarditis when combined with positive blood cultures. See Chapter 29 for more information about echocardiography.
- *Serologic immune testing* for circulating antigens to assess for typical infective organisms may be done.

Other diagnostic tests may include CBC, ESR, and serum creatinine levels; chest x-ray; and an electrocardiogram.

MEDICATIONS

Preventing endocarditis in patients at high risk is important. Antibiotics are commonly prescribed for patients with preexisting valve damage or heart disease prior to high-risk procedures. In 2008, the AHA significantly altered the recommendations for endocarditis prophylaxis, reducing the groups of patients who require antibiotics prior to procedures (Nishimura et al., 2008) (see Table 31–7).

Antibiotic therapy effectively treats infective endocarditis in most cases. The goal of therapy is to eradicate the infecting organism from the blood and vegetative lesions in the heart. The fibrin covering that protects colonies of organisms from immune defenses also protects them from antibiotic therapy. Therefore, an extended course of multiple intravenous antibiotics is required.

Following blood cultures, antibiotic therapy is initiated with drugs known to be effective against the most common infecting organisms: staphylococci, streptococci, and enterococci. The initial regimen may include nafcillin or oxacillin, penicillin or ampicillin, and gentamicin. Once the organism has been identified, therapy is tailored to that organism. Staphylococcal and enterococcal infections are treated with a combination of penicillin and gentamicin. If the patient is allergic to penicillin, ceftriaxone, cefazolin, or vancomycin may be used. Staphylococcal infections are treated with nafcillin or oxacillin and gentamicin; cefazolin or vancomycin may be used if penicillin allergy is present. Intravenous drug therapy is continued for 2 to 8 weeks, depending on the infecting organism, the drugs used, and the results of repeat blood cultures. Refer to Chapter 12 for the nursing implications for antibiotic therapy.

The patient with prosthetic valve endocarditis requires extended treatment, usually 6 to 8 weeks. Combination therapy using vancomycin, rifampin, and gentamicin is used to treat these resistant infections.

SURGERY

Some patients with infective endocarditis require the following from surgery:

- Replace severely damaged valves.
- Remove large vegetations at risk for embolization.
- Remove a valve that is a continuing source of infection that does not respond to antibiotic therapy.

The most common indication for surgery is valvular regurgitation that causes heart failure and does not respond to medical therapy. When the infection has not responded to antibiotic therapy within 7 to 10 days, the infected valve may be replaced to facilitate eradication of the organism. Patients with fungal endocarditis usually require surgical intervention. More information on valve replacement surgery is provided in the section on valve disorders.

TABLE 31–7 Updated Recommendations for Antibiotic Prophylaxis for Infective Endocarditis

Indications for Prophylaxis	Selected Procedures for Which Prophylaxis Is Recommended	Suggested Antibiotics
Prosthetic valves Previous episode(s) of infective endocarditis Congenital heart disease Unrepaired, cyanotic Completely repaired up to 6 months postrepair Repaired with residual defects Cardiac transplant	Dental procedures in which bleeding is likely, including cleaning Most surgeries Bronchoscopy (only with incision of the respiratory tract mucosa) Cystoscopy Urinary catheterization when infection is present Incision and drainage of infected tissue Vaginal delivery if infection is present	*Amoxicillin* Erythromycin Ampicillin Clindamycin Vancomycin (recommended for MRSA) (*Note:* Choice of antibiotic depends on procedure.)

Note: Drugs identified in *italics* are among the 200 most commonly prescribed medications in the U.S.

●○● NURSING CARE

Health Promotion

Prevention of endocarditis is vital in susceptible people. Education is a key part of prevention. Use every opportunity to educate individuals and the public about the risks of intravenous drug use, including endocarditis. Discuss preventive measures with all patients with specific risk factors, such as a history of valve replacement, congenital heart defects, or cardiac transplantation (Nishimura et al., 2008).

Assessment

See the Manifestations and Interprofessional Care sections for the assessment of the patient with endocarditis.

Assessment related to ineffective endocarditis includes identifying risk factors and manifestations of the disease.

- *Health history:* complaints of persistent flu-like symptoms, fatigue, shortness of breath, and activity intolerance; history of recent dental work or other invasive procedures; known heart murmur, valve or other heart disorder; recent intravenous drug use
- *Physical assessment:* vital signs including temperature; apical pulse and heart sounds; rate and ease of respirations, lung sounds; skin color, temperature, and presence of petechiae or splinter hemorrhages.

Priorities of Care

Collaborating with the interprofessional team to ensure adequate treatment of the underlying process while providing care that supports the physical and psychologic responses to the disorder is a priority of nursing care.

Diagnoses, Outcomes, and Interventions

Nursing care focuses on managing the manifestations of endocarditis, administering antibiotics, and teaching the patient and family members about the disorder. In addition to the diagnoses identified next, nursing diagnoses and interventions for heart failure also may be appropriate for patients with infective endocarditis.

Risk for Imbalanced Body Temperature

Fever is common in patients with infective endocarditis. It may be acutely elevated and accompanied by chills, particularly with acute infective endocarditis. The inflammatory process initiates a cycle of events that affects the regulation of temperature and causes discomfort.

Expected Outcome: The patient's body temperature will be within normal limits as evidenced by measurements within normal range and skin warm and dry.

- Record temperature every 2 to 4 hours. Report temperature above 39.4°C (101.5°F). Assess for complaints of discomfort. *Fever is usually low grade (below 39.4°C [101.5°F]) in infective endocarditis; higher temperatures may cause discomfort. The temperature usually returns to normal within 1 week after initiation of antibiotic therapy. Continued fever may indicate a need to modify the treatment regimen.*
- Obtain blood cultures as ordered, before initial antibiotic dose. *Initial blood cultures are obtained before antibiotic therapy is started to obtain adequate organisms to culture and identify. Follow-up cultures are used to assess the effectiveness of therapy.*
- Provide anti-inflammatory or antipyretic agents as prescribed. *Fever may be treated with anti-inflammatory or antipyretic agents such as aspirin, ibuprofen, or acetaminophen.*
- Administer antibiotics as ordered; obtain peak and trough drug levels as indicated. *Intravenous antibiotics are given to eradicate the pathogen. Peak and trough levels are used to evaluate the dose effectiveness in maintaining a therapeutic blood level.*

Risk for Ineffective Tissue Perfusion

Embolization of vegetative lesions can threaten tissue and organ perfusion. Vegetations from the left heart may lodge in arterioles or capillaries of the brain, kidneys, or peripheral tissues, causing infarction or abscess. A large embolism can cause manifestations of stroke or transient ischemic attack, renal failure, or tissue ischemia. Emboli from the right side of the heart become entrapped in pulmonary vasculature, causing manifestations of pulmonary embolism.

Expected Outcome: Patient's tissue perfusion will be adequate as evidenced by adequate arterial flow as seen by strong peripheral pulses and freedom from dyspnea.

- Assess for, document, and report manifestations of decreased organ system perfusion:
  - Neurologic: changes in level of consciousness, numbness or tingling in extremities, hemiplegia, visual disturbances, or manifestations of stroke
  - Renal: decreased urine output, hematuria, elevated BUN or creatinine
  - Pulmonary: dyspnea, hemoptysis, shortness of breath, diminished breath sounds, restlessness, sudden chest or shoulder pain
  - Cardiovascular: chest pain radiating to jaw or arms, tachycardia, anxiety, tachypnea, hypotension.

  All major organs and tissues, and the microcirculation, may be affected by emboli when vegetations break off due to turbulent blood flow. Emboli may cause manifestations of organ dysfunction. The most devastating effects of emboli are in the brain and the myocardium, with resulting infarctions. Intravenous drug users have a high risk of pulmonary emboli as a result of right-sided endocardial fragments.
- Assess and document skin color and temperature, quality of peripheral pulses, and capillary refill. *Peripheral emboli affect tissue perfusion, with a risk for tissue necrosis and possible extremity loss.*

Ineffective Health Maintenance

The patient with endocarditis often is treated in the community. Teaching about disease management and prevention of possible recurrences of endocarditis is vital.

Expected Outcome: Patient will be knowledgeable about management of endocarditis as evidenced by patient being able to describe the components and rationale for the treatment plan.

- Demonstrate intravenous catheter site care and intermittent antibiotic administration if the patient and family will manage therapy. Have the patient and/or significant other redemonstrate appropriate techniques. *Intermittent antibiotic infusions may be managed by the patient or family members, or the patient may go to an outpatient facility to receive the infusions. Appropriate site care is necessary to reduce the risk of trauma and infection.*
- Explain the actions, doses, administration, and desired and adverse effects of prescribed drugs. Identify manifestations to be reported

to the physician. Provide practical information about measures to reduce the risk of superinfection (e.g., consuming 8 oz of yogurt or buttermilk containing live bacterial cultures daily). *Careful compliance with prescribed drug therapy is vital to eradicate the infecting organism. Antibiotic therapy can, however, cause superinfections such as candidiasis due to elimination of normal body flora.*

- Teach about the function of heart valves and the effects of endocarditis on heart function. Include a simple definition of endocarditis, and explain the risk for its recurrence. *Information helps the patient and family understand endocarditis, its treatment, and its effects. Understanding increases compliance.*
- Describe the manifestations of heart failure to be reported to the physician. *Evidence of heart failure may necessitate modification of the treatment regimen or replacement of infected valves.*
- Stress the importance of notifying all care providers of valve disease, heart murmur, or valve replacement before undergoing invasive procedures. *Invasive procedures provide a portal of entry for bacteria. A history of valve disease increases the risk for the development or recurrence of endocarditis.*
- Encourage good dental hygiene and mouth care and regular dental checkups. Teach how to prevent bleeding from the gums and avoid developing mouth ulcers (e.g., gentle tooth brushing, ensuring that dentures fit properly, and avoiding toothpicks, dental floss, and high-flow water devices). *The oropharynx harbors streptococci, which are common causes of endocarditis. Bleeding gums offer an opportunity for bacteria to enter the bloodstream.*
- Encourage the patient to avoid people with upper respiratory infections. *Streptococci are normal pathogens in the upper respiratory tract; exposure to people with upper respiratory infections may increase the risk of infection.*
- If anticoagulant therapy is ordered, explain its actions, administration, and major side effects. Identify manifestations of bleeding to be promptly reported to the physician. *Patients with valve disease or a prosthetic valve following infective endocarditis may require continued anticoagulant therapy to prevent thrombi and emboli. Knowledge is vital for appropriate management of anticoagulant therapy and prevention of complications.*

Delegating Nursing Care Activities

As appropriate and allowed by designated duties and responsibilities of assistive personnel, the nurse may delegate nursing care activities such as measuring fluid intake and output, collecting vital signs (including orthostatic vital signs), encouraging oral or enteral fluid intake, and ensuring nonpharmacologic skin care.

Continuity of Care

When preparing the patient with infective endocarditis for home care, provide teaching as outlined for the nursing diagnosis *Ineffective Health Maintenance.* In addition, discuss the following topics:

- Although serious and frightening, infective endocarditis can usually be treated effectively with intravenous antibiotics.
- The importance of promptly reporting any unusual manifestation, such as a change in vision, sudden pain, or weakness, so that interventions to control complications can be promptly implemented.
- The rationale for all treatments and procedures.
- Preventing recurrences of infective endocarditis.
- The importance of maintaining contact with the physician for follow-up care and monitoring for long-term effects such as progressive valve damage and dysfunction.
- If appropriate, explain the risks associated with intravenous drug use.

Provide educational materials on infective endocarditis from the American Heart Association. Refer as appropriate to home health or home intravenous therapy services. Refer the patient and family members or significant others as appropriate to a drug or substance abuse treatment program or facility. Provide follow-up care to ensure compliance with the referral and treatment plan.

THE PATIENT WITH MYOCARDITIS

Myocarditis is inflammation of the heart muscle. It usually results from an infectious process, but also may occur as an immunologic response, or due to the effects of radiation, toxins, or drugs. In the United States, myocarditis is usually viral, caused by coxsackievirus B. Approximately 10% of people with HIV disease develop myocarditis due to infiltration of the myocardium by the virus. Bacterial myocarditis, much less common, may be associated with endocarditis caused by *Staphylococcus aureus*, or with diphtheria. Parasitic infections caused by *Trypanosoma cruzi* (Chagas disease) are common in Central and South America.

Incidence and Risk Factors

Myocarditis may occur at any age, and it is more common in men than women. Factors that alter immune response (e.g., malnutrition, alcohol use, immunosuppressive drugs, exposure to radiation, stress, and advanced age) increase the risk for myocarditis. It also is a common complication of rheumatic fever and pericarditis.

Pathophysiology

In myocarditis, myocardial cells are damaged by an inflammatory process that causes local or diffuse swelling and damage. Infectious agents infiltrate interstitial tissues, forming abscesses. Autoimmune injury may occur when the immune system destroys not only the invading pathogen but also myocardial cells. The extent of damage to cardiac muscle ultimately determines the long-term outcome of the disease. Viral myocarditis usually is self-limited; it may progress, however, to become chronic, leading to dilated cardiomyopathy. Severe myocarditis may lead to heart failure.

Manifestations

The manifestations of myocarditis depend on the degree of myocardial damage. The patient may be asymptomatic. Nonspecific manifestations of inflammation such as fever, fatigue, general malaise, dyspnea, palpitations, arthralgias, and sore throat may be present. A nonspecific febrile illness or upper respiratory infection often precedes the onset of myocarditis symptoms. Abnormal heart sounds such as muffled S_1, an S_3, murmur, and pericardial friction rub may be heard. In some cases, manifestations of myocardial infarction, including chest pain, may occur.

●○● INTERPROFESSIONAL CARE

Myocarditis treatment focuses on resolving the inflammatory process to prevent further damage to the myocardium.

DIAGNOSIS

Diagnostic studies may be ordered to help diagnose myocarditis.

- *Electrocardiography* may show transient ST segment and T-wave changes, as well as dysrhythmias and possible heart block.
- *Cardiac markers*, such as the creatinine kinase, troponin T, and troponin I, may be elevated, indicating myocardial cell damage.
- *Endomyocardial biopsy* to examine myocardial cells is necessary to establish a definitive diagnosis; patchy cell necrosis and the inflammatory process can be identified.

MEDICATIONS

If appropriate, antimicrobial therapy is used to eradicate the infecting organism. Antiviral therapy with interferon-α may be instituted. Immunosuppressive therapy with corticosteroids or other immunosuppressive agents (refer to Chapter 13) may be used to minimize the inflammatory response. Heart failure is treated as needed, using ACE inhibitors and drugs. Patients with myocarditis often are particularly sensitive to the effects of digitalis, so it is used with caution. Other medications used in treating myocarditis include antidysrhythmic agents to control dysrhythmias and anticoagulants to prevent emboli.

Bed rest and activity restrictions are ordered during the acute inflammatory process to reduce myocardial work and prevent myocardial damage. Activities may be limited for as long as 6 months to a year.

●○● NURSING CARE

Nursing care is directed at decreasing myocardial work and maintaining cardiac output. Both physical and emotional rest are indicated, because anxiety increases myocardial oxygen demand. Hemodynamic parameters and the ECG are monitored closely, especially during the acute phase of the illness. Activity tolerance, urine output, and heart and breath sounds are frequently assessed for manifestations of heart failure. Consider the following nursing diagnoses for the patient with myocarditis:

- *Activity Intolerance* related to impaired cardiac muscle function
- *Decreased Cardiac Output* related to myocardial inflammation
- *Fatigue* related to inflammation and impaired cardiac output
- *Anxiety* related to possible long-term effects of the disorder
- *Excess Fluid Volume* related to compensatory mechanisms for decreased cardiac output.

Continuity of Care

Include the following topics when preparing the patient with myocarditis for home care:

- Activity restrictions and other prescribed measures to reduce cardiac workload
- Early manifestations of heart failure to report to the physician
- The importance of following the prescribed treatment regimen
- Any recommended dietary modifications (such as a low-sodium diet for heart failure)
- Prescribed medications, their purpose, doses, and possible adverse effects
- The importance of adhering to the treatment plan and recommended follow-up appointments to reduce the risk of long-term consequences such as cardiomyopathy.

THE PATIENT WITH PERICARDITIS

The pericardium is the outermost layer of the heart. It is a two-layered membranous sac with a thin layer of serous fluid (normally no more than 30 to 50 mL) separating the layers. It protects and cushions the heart and the great vessels, provides a barrier to infectious processes in adjacent structures, prevents displacement of the myocardium and blood vessels, and prevents sudden distention of the heart.

Pericarditis is the inflammation of the pericardium. Pericarditis may be a primary disorder or develop secondarily to another cardiac or systemic disorder. Some possible causes of pericarditis are listed in Box 31–4. Acute pericarditis is usually viral and affects men (usually under the age of 50) more frequently than women. Pericarditis affects 40% to 50% of patients with end-stage renal disease and uremia. Postmyocardial infarction pericarditis and postcardiotomy (following open-heart surgery) pericarditis also are common.

Pathophysiology

Pericardial tissue damage triggers an inflammatory response. Inflammatory mediators released from the injured tissue cause vasodilation, hyperemia, and edema. Capillary permeability increases, allowing plasma proteins, including fibrinogen, to escape into the pericardial space. White blood cells amass at the site of injury to destroy the causative agent. Exudate is formed, usually fibrinous or serofibrinous (a mixture of serous fluid and fibrinous exudate). In some cases, the exudate may contain red blood cells or, if infectious, purulent material. The inflammatory process may resolve without long-term effects, or scar tissue and adhesions may form between the pericardial layers.

Fibrosis and scarring of the pericardium may restrict cardiac function. Pericardial effusions may develop as serous or purulent exudate (depending on the causative agent) collects in the pericardial sac. Pericardial effusion may be recurrent. Chronic inflammation causes the pericardium to become rigid.

Manifestations

Classic manifestations of acute pericarditis include chest pain, a pericardial friction rub, and fever. Chest pain, the most common

BOX 31–4 Selected Causes of Pericarditis

INFECTIOUS
- Viruses
- Bacteria
- Tuberculosis
- Syphilis
- Parasites

NONINFECTIOUS
- Myocardial and pericardial injury
- Rheumatic fever
- Uremia
- Neoplasms
- Radiation
- Trauma or surgery
- Myxedema
- Autoimmune disorders
- Connective tissue diseases
- Prescription and nonprescription drugs
- Postcardiac injury

symptom, has an abrupt onset. It is caused by inflammation of nerve fibers in the lower parietal pericardium and pleura covering the diaphragm. The pain is usually sharp, may be steady or intermittent, and may radiate to the back or neck. The pain can mimic myocardial ischemia; careful assessment is important to rule out myocardial infarction. Pericardial pain is aggravated by respiratory movements (i.e., deep inspiration and/or coughing), changes in body position, or swallowing. Sitting upright and leaning forward reduces the discomfort by moving the heart away from the diaphragmatic side of the lung pleura.

Although not always present, a *pericardial friction rub* is the characteristic sign of pericarditis. A pericardial friction rub is a leathery, grating sound produced by the inflamed pericardial layers rubbing against the chest wall or pleura. It is heard most clearly at the left lower sternal border with the patient sitting up or leaning forward. The rub is usually heard on expiration and may be constant or intermittent.

A low-grade fever (below 38.4°C [100°F]) often develops due to the inflammatory process. Dyspnea and tachycardia are common.

Complications

Pericardial effusion, cardiac tamponade, and constrictive pericarditis are possible complications of acute pericarditis.

PERICARDIAL EFFUSION

A *pericardial effusion* is an abnormal collection of fluid between the pericardial layers that threatens normal cardiac function. The fluid may consist of pus, blood, serum, lymph, or a combination. The manifestations of a pericardial effusion depend on the rate at which the fluid collects. Although the pericardium normally contains about 30 to 50 mL of fluid, the sac can stretch to accommodate a gradual accumulation of fluid. Over time, the pericardial sac can accommodate up to 2 L of fluid without immediate adverse effects. Conversely, a rapid buildup of pericardial fluid (as little as 100 mL) does not allow the sac to stretch and can compress the heart, interfering with myocardial function. This compression of the heart is known as **cardiac tamponade**. Slowly developing pericardial effusion is often painless and has few manifestations. Heart sounds may be distant or muffled. The patient may have a cough or mild dyspnea.

CARDIAC TAMPONADE

Cardiac tamponade is a medical emergency that must be aggressively treated to preserve life. Cardiac tamponade may result from pericardial effusion, trauma, cardiac rupture, or hemorrhage. Rapid collection of fluid in the pericardial sac interferes with ventricular filling and pumping, critically reducing cardiac output.

Classic manifestations of cardiac tamponade result from rising intracardiac pressures, decreased diastolic filling, and decreased cardiac output. A hallmark of cardiac tamponade is a paradoxical pulse, or *pulsus paradoxus.* A paradoxical pulse markedly decreases in amplitude during inspiration. Intrathoracic pressure normally drops during inspiration, enhancing venous return to the right heart. This draws more blood into the right side of the heart than the left, causing the interventricular septum to bulge slightly into the left ventricle. When ventricular filling is impaired by excess fluid in the pericardial sac, this bulging of the interventricular septum decreases cardiac output during inspiration (Figure 31–8 ■). On palpation of the carotid or femoral artery, the pulse is diminished or absent during inspiration. A drop in systolic blood pressure of more than 10 mmHg during inspiration also indicates pulsus paradoxus.

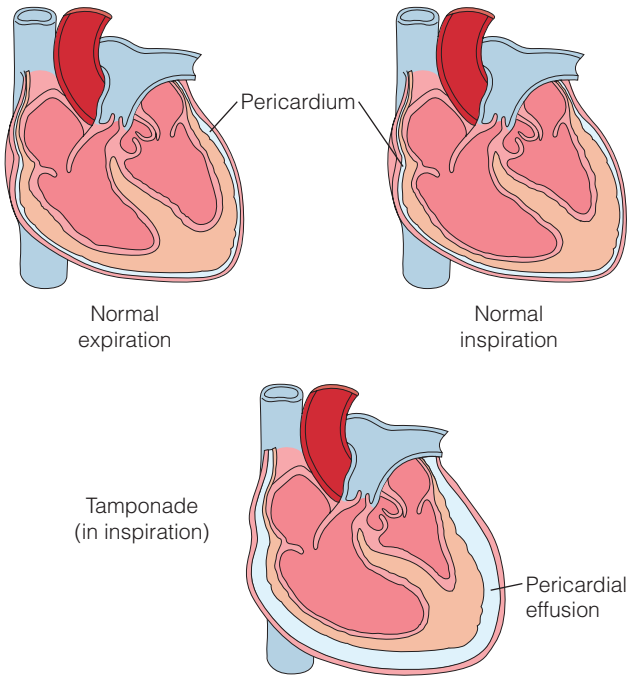

Figure 31–8 ■ Cardiac tamponade. Note increased volume in the right ventricle during inspiration in both the normal heart and the heart affected by a pericardial effusion. In tamponade, fluid in the pericardial sac and the distended right ventricle restrict filling of the left ventricle and, consequently, cardiac output.

Other manifestations of cardiac tamponade include muffled heart sounds, dyspnea and tachypnea, tachycardia, a narrowed pulse pressure, and distended neck veins (see the accompanying box).

CHRONIC CONSTRICTIVE PERICARDITIS

Chronic pericardial inflammation can lead to scar tissue formation between the pericardial layers. This scar tissue eventually contracts, restricting diastolic filling and elevating venous pressure. Constrictive pericarditis may follow viral infection, radiation therapy, or heart surgery. Its manifestations include progressive dyspnea, fatigue, and weakness. Ascites is common; peripheral edema may develop. Neck veins are distended, and may be particularly noticeable during inspiration (*Kussmaul's sign*). This occurs because the right atrium is unable to dilate to accommodate increased venous return during inspiration. See Figure 31–9 ■.

MANIFESTATIONS OF CARDIAC TAMPONADE

- Paradoxical pulse
- Narrowed pulse pressure, hypotension
- Tachycardia
- Weak peripheral pulses
- Distant, muffled heart sounds
- Jugular venous distention
- High central venous pressure
- Decreased level of consciousness
- Low urine output
- Cool, mottled skin

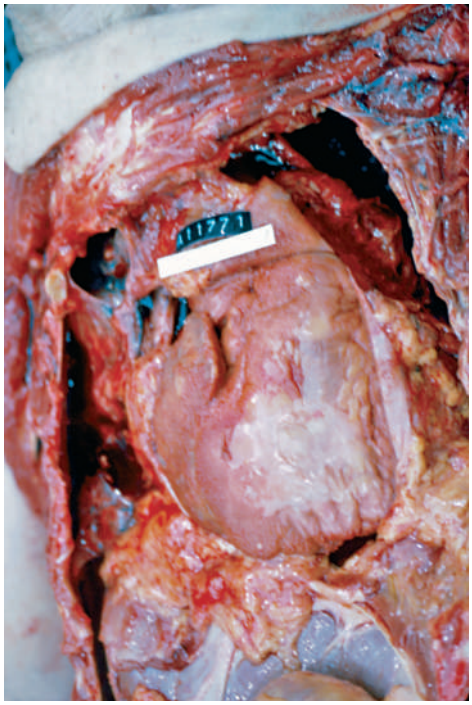

Figure 31–9 ■ Constrictive pericarditis.

●○● INTERPROFESSIONAL CARE

Care for the patient with pericarditis focuses on identifying its cause if possible, reducing inflammation, relieving symptoms, and preventing complications. The patient is closely monitored for early manifestations of cardiac tamponade so that it can be treated promptly.

DIAGNOSIS

There are no specific laboratory tests to diagnose pericarditis, but tests are often performed to differentiate pericarditis from myocardial infarction.

- *CBC* shows elevated WBCs and an ESR greater than 20 mm/h indicating acute inflammation.
- *Cardiac enzymes* may be slightly elevated because the inflammatory process extends to involve the epicardial surface of the heart. Cardiac enzymes are typically much lower in pericarditis than in myocardial infarction.
- *Electrocardiography* shows typical changes associated with pericarditis, such as diffuse ST-segment elevation in all leads. This resolves more quickly than changes of AMI and is not associated with the QRS-complex and T-wave changes typically seen in MI. With a large pericardial effusion, the QRS amplitude may be decreased. Atrial dysrhythmias may occur in acute pericarditis.
- *Echocardiography* is used to assess heart motion, for pericardial effusion, and the extent of restriction.
- *Hemodynamic monitoring* may be used in acute pericarditis or pericardial effusion to assess pressures and cardiac output. Elevated pulmonary artery pressures and venous pressures occur with impaired filling due to pericardial effusion or constrictive pericarditis.
- *Chest x-ray* may show cardiac enlargement if a pericardial effusion is present.
- *Computed tomography (CT scan)* or *magnetic resonance imaging (MRI)* may be used to identify pericardial effusion or constrictive pericarditis.

MEDICATIONS

Drug treatment for pericarditis addresses its manifestations. Aspirin and acetaminophen may be used to reduce fever. NSAIDs are used to reduce inflammation and promote comfort. In severe cases or with recurrent pericarditis, corticosteroids may be given to suppress the inflammatory response.

PERICARDIOCENTESIS

Pericardiocentesis may be done to remove fluid from the pericardial sac for diagnostic or therapeutic purposes (refer to Figure 29–18). The physician inserts a large (16- to 18-gauge) needle into the pericardial sac and withdraws excess fluid. The needle is attached to an ECG monitoring lead to help determine if the needle is touching the epicardial surface, which helps prevent piercing the myocardium. Pericardiocentesis may be an emergency procedure for the patient with cardiac tamponade. Nursing implications for pericardiocentesis are outlined in the box on page 843 of Chapter 29.

SURGERY

For recurrent pericarditis or recurrent pericardial effusion, a rectangular piece of the pericardium, or "window," may be excised to allow collected fluid to drain into the pleural space. Constrictive pericarditis may necessitate a partial or total *pericardiectomy*, removal of part or all of the pericardium, to relieve the ventricular compression and allow adequate filling.

●○● NURSING CARE

Health Promotion

Although it may not yet be possible to identify many patients at risk for acute pericarditis or to prevent it, early identification and treatment of the disorder can reduce the risk of complications. Promptly report a pericardial friction rub or other manifestations of pericarditis in patients with recent AMI, cardiac surgery, or systemic diseases associated with a risk for pericarditis.

Assessment

See the Manifestations and Interprofessional Care sections for the assessment of the patient with pericarditis.

Assessment data to collect from the patient with suspected pericarditis includes the following:

- *Health history:* complaints of acute substernal or precordial chest pain, effect of movement and breathing on discomfort, pain radiation, associated symptoms; recent AMI, heart surgery, or other cardiac disorder; current medications; chronic conditions such as renal failure or a connective tissue or autoimmune disorder
- *Physical assessment:* vital signs including temperature, variation in systolic BP with respirations; strength of peripheral pulses, variations with respiratory movement; apical pulse, clarity, changes with respiratory movement, presence of a friction rub; neck vein distention; level of consciousness, skin color, and other indicators of cardiac output.

Priorities of Care

Collaborating with the interprofessional team to ensure adequate treatment of the underlying process while providing care that supports the physical and psychologic responses to the disorder is a priority of nursing care.

Diagnoses, Outcomes, and Interventions

Nursing care for the patient with pericarditis may occur in the acute or community setting. Closely observe for early manifestations of increasing effusion or cardiac tamponade. Priority nursing diagnoses relate to comfort, the risk for tamponade, and effects of the acute inflammatory process.

Acute Pain

Inflamed pericardial layers rubbing against each other and the lung pleura stimulate phrenic nerve pain fibers in the lower portion of the parietal pericardium. Pain is usually acute and may be severe until inflammation resolves.

Expected Outcome: Patient will experience adequate pain control as evidenced by physical well-being.

- Assess chest pain using a standard pain scale and noting the quality and radiation of the pain. Note nonverbal cues of pain (grimacing, guarding behaviors), and validate with the patient. *Careful assessment helps identify the cause of pain. The pain of pericarditis may radiate to the neck or back and is aggravated by movement, coughing, or deep breathing. A pain scale allows evaluation of the effectiveness of interventions.*
- Auscultate heart sounds every 4 hours. *Presence of a pericardial friction rub often correlates with the location and severity of the pain.*
- Administer NSAIDs on a regular basis as prescribed with food. Document effectiveness. *NSAIDs reduce fever, inflammation, and pericardial pain. They are most effective when administered around the clock on a consistent basis. Administering the medications with food helps decrease gastric distress.*
- Maintain a quiet, calm environment, and position of comfort. Offer back rubs, heat/cold therapy, diversional activity, and emotional support. *Supportive interventions enhance the effects of the medication, may decrease pain perception, and convey a sense of caring.*

Ineffective Breathing Pattern

Respiratory movement intensifies pericardial pain. In an effort to decrease pain, the patient often breathes shallowly, increasing the risk for pulmonary complications.

- Document respiratory rate, effort, and breath sounds every 2 to 4 hours. Report adventitious or diminished breath sounds. *Shallow, guarded respirations may lead to increased respiratory rate and effort. Poor ventilation of peripheral alveoli may lead to congestion or atelectasis.*
- Encourage deep breathing and use of the incentive spirometer. Provide pain medication before respiratory therapy, as needed. *Deep breathing and an incentive spirometer promote alveolar ventilation and prevent atelectasis. Analgesia prior to respiratory treatments improves their effectiveness by decreasing guarding.*
- Administer oxygen as needed. *Supplementary oxygen promotes optimal gas exchange and tissue oxygenation.*
- Place in Fowler's or high-Fowler's position. Assist to a position of comfort. *Appropriate positioning reduces the work of breathing and decreases chest pain due to pericarditis.*

Risk for Decreased Cardiac Output

The acute inflammatory process of pericarditis can lead to significant pericardial effusion and cardiac tamponade. This potentially fatal complication can also occur with chronic pericardial effusion if the amount of fluid exceeds the ability of the pericardial sac to expand. Constrictive pericarditis increases the risk for decreased cardiac output because of restricted cardiac filling.

Expected Outcome: Patient will demonstrate adequate cardiac output as evidenced by blood pressure and pulse rate and rhythm within normal limits.

- Document vital signs hourly during the acute inflammatory processes. *Frequent assessment allows early recognition of manifestations of decreased cardiac output, such as tachycardia, hypotension, or changes in pulse pressure.*

SAFETY ALERT

Assess heart sounds and peripheral pulses, and observe for neck vein distention and paradoxical pulse hourly. Promptly report distant, muffled heart sounds, new murmurs or extra heart sounds, decreasing quality of peripheral pulses, and distended neck veins. Acute pericardial effusion interferes with normal cardiac filling and pumping, causing venous congestion and decreased cardiac output. As the amount of fluid increases in the pericardial sac, heart sounds are obscured. A drop in systolic blood pressure of more than 10 mmHg on inspiration signifies an abnormal response to changes in intrathoracic pressure.

- Report significant changes or trends in hemodynamic parameters and dysrhythmias. *Compression of the heart interferes with venous return, increasing CVP and right atrial pressures; dysrhythmias may also occur.*
- Promptly report other signs of decreased cardiac output: decreased level of consciousness; decreased urine output; cold, clammy, mottled skin; delayed capillary refill; and weak peripheral pulses. *These signs of decreased organ and tissue perfusion indicate a significant drop in cardiac output.*
- Maintain at least one patent intravenous access site. *The patient in cardiac tamponade may require rapid intravenous fluid infusion to restore blood volume and administration of emergency drugs to support the circulation.*
- Prepare for emergency pericardiocentesis and/or surgery as necessary. Provide appropriate explanations and reassurance. Observe for adverse responses during pericardiocentesis. *Excess pericardial fluid must be rapidly evacuated to prevent further compromise of cardiac output and death. Emotional support and explanations reduce the patient's and family's anxiety and promote a caring atmosphere.*

Activity Intolerance

In chronic constrictive pericarditis, pericardial adhesions and scarring restrict pericardial compliance, which in turn restricts heart filling and movement. Restricted filling and ineffective cardiac contraction decrease the cardiac output. The heart cannot compensate for increased metabolic demands by increasing cardiac output, and cardiac reserve falls significantly.

Expected Outcome: Patient will participate in an activity program without suffering any complications

- Document vital signs, cardiac rhythm, skin color, and temperature before and after activity. Note any subjective complaints of fatigue, shortness of breath, chest pain, palpitations, or other symptoms with activity. *These parameters help determine the response to increased cardiac work. Increased heart rate and respiratory rate and*

effort, decreased blood pressure, and dysrhythmias are indicators of activity intolerance. Pallor or cyanosis and cool, clammy, mottled skin are signs of decreased tissue perfusion. Complaints of weakness, shortness of breath, fatigue, dizziness, or palpitations are further evidence of activity intolerance.

- Work with the patient and physical therapist to develop a realistic, progressive activity plan. Monitor response. Encourage independence, but provide assistance as needed. *Patient involvement in planning increases the likelihood of success, as well as the patient's self-esteem and sense of control. Promoting self-care provides additional control and independence and enhances self-image. Activity that significantly increases the heart rate (more than 20 bpm over resting) should be stopped and reassessed for intensity.*
- Plan interventions and care activities to allow uninterrupted rest and sleep. *This supports healing and restoration of physical and emotional health.*

Delegating Nursing Care Activities

As appropriate and allowed by the designated duties and responsibilities of unlicensed assistive personnel, the nurse may delegate nursing care activities such as measuring fluid intake and output, collecting vital signs (including orthostatic vital signs), encouraging oral or enteral fluid intake, and ensuring nonpharmacologic skin care.

Continuity of Care

Include the following topics when teaching the patient and family in preparation for home care:

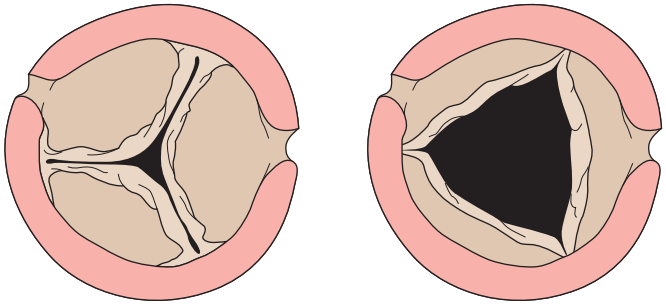
- The importance of continuing anti-inflammatory medications as ordered. Advise to take NSAIDs with food, milk, or antacids to minimize gastric distress, and to notify the physician if unable to tolerate the drug. Instruct to avoid aspirin or preparations containing aspirin while taking NSAIDs because it may interfere with activity.
- Prescribed medications, including dose, desired and possible adverse effects, and interactions with other drugs or food.
- Monitoring weight twice weekly because NSAIDs may cause fluid retention.
- Maintaining fluid intake of at least 2500 mL/day to minimize the risk of renal toxicity due to NSAID use.
- Measures to maintain activity restriction if ordered. Activity will be gradually increased once the inflammatory process has resolved.
- Manifestations of recurrent pericarditis, and the importance of reporting these manifestations promptly to the physician.

Disorders of Cardiac Structure

THE PATIENT WITH VALVULAR HEART DISEASE

Proper heart valve function ensures one-way blood flow through the heart and vascular system. **Valvular heart disease** interferes with blood flow to and from the heart. Acquired valvular disorders can result from acute conditions, such as infective endocarditis, or from chronic conditions, such as rheumatic heart disease. Rheumatic heart disease is the most common cause of valvular disease (Huether & McCance, 2011). Acute myocardial infarction also can damage heart valves, causing tearing, ischemia, or damage to the papillary muscles that affects valve leaflet function. Congenital heart defects may affect the heart valves, often with no manifestations until adulthood. Aging affects heart structure and function, and also increases the risk for valvular disease.

Physiology Review



The heart valves direct blood flow within and out of the heart. The valves are fibroelastic tissue supported by a ring of fibrous tissue (the annulus) that provides support.

The atrioventricular (AV) valves, the **mitral** (or *bicuspid*) **valve** on the left and the **tricuspid valve** on the right, separate the atria from the ventricles. These valves normally are fully open during diastole, allowing blood to flow freely from the atria into the ventricles. Rising pressure within the ventricles at the onset of systole (contraction) closes the AV valves, creating the S_1 heart sound ("lub"). The leaflets of the AV valves are connected to ventricular papillary muscles by fibrous *chordae tendineae*. The chordae tendineae prevent the valve leaflets from bulging back into the atria during systole.

The semilunar valves, the **aortic** and **pulmonic valves**, separate the ventricles from the great vessels. They open during systole, allowing blood to flow out of the heart with ventricular contraction. As the ventricle relaxes and intraventricular pressure falls at the beginning of diastole, the higher pressure within the great vessels (the aorta and pulmonary artery) closes these valves, creating the S_2 heart sound ("dub").

Pathophysiology

Valvular heart disease occurs as two major types of disorders: stenosis and regurgitation. Stenosis occurs when valve leaflets fuse together and cannot fully open or close. The valve opening narrows and becomes rigid (Figure 31–10A ■). Scarring of the valves (from endocarditis or infarction) and calcium deposits can lead to stenosis. Stenotic valves impede the forward flow of blood, decreasing cardiac output because of impaired ventricular filling or ejection and stroke

A Thickened and stenotic valve leaflets

B Retracted fibrosed valve openings

Figure 31–10 ■ Valvular heart disorders. A, Stenosis of a heart valve. B, An incompetent or regurgitant heart valve.

volume. Because stenotic valves also do not close completely, some backflow of blood occurs when the valve should be fully closed.

Regurgitant valves (called *insufficient* or *incompetent* valves) do not close completely (Figure 31–10B). This allows regurgitation, or backflow of blood, through the valve into the area it just left. Regurgitation can result from deformity or erosion of valve cusps caused by the vegetative lesions of bacterial endocarditis, by scarring or tearing from myocardial infarction, or by cardiac dilation. As the heart enlarges, the valve *annulus* (supporting ring of the valve) is stretched, and the valve edges no longer meet to allow complete closure.

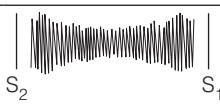
Valvular disease causes hemodynamic changes both in front of and behind the affected valve. Blood volume and pressures are reduced in front of the valve, because flow is obstructed through a stenotic valve and backflow occurs through a regurgitant valve. By contrast, volumes and pressures characteristically increase behind the diseased valve. These hemodynamic changes may lead to pulmonary complications or heart failure. Higher pressures and compensatory changes to maintain cardiac output lead to remodeling and hypertrophy of the heart muscle.

Stenosis increases the work of the chamber behind the affected valve as the heart attempts to move blood through the narrowed opening. Excess blood volume behind regurgitant valves causes dilation of the chamber. In mitral stenosis, for example, the left atrium hypertrophies to generate enough pressure to open and deliver its blood through the narrowed mitral valve. Not all of the blood is delivered before the valve closes, leaving blood to accumulate in the left atrium. This chamber dilates to accommodate the excess volume.

Eventually, cardiac output falls as compensatory mechanisms become less effective. The normal balance of oxygen supply and demand is upset, and the heart begins to fail. Increased muscle mass and size increase myocardial oxygen consumption. The size and workload of the heart exceed its blood supply, causing ischemia and chest pain. Eventually, necrosis occurs and functional muscle is lost. Contractile force, stroke volume, and cardiac output decrease. High pressures on the left side of the heart are reflected backward into the pulmonary system, causing pulmonary edema, pulmonary hypertension, and, eventually, right ventricular failure.

Valvular disorders interfere with the smooth flow of blood through the heart. The flow becomes turbulent, causing a **murmur**, a characteristic manifestation of valvular disease. Table 31–8 describes the murmurs associated with various types of valvular disorders.

Blood forced through the narrowed opening of a stenotic valve or regurgitated from a higher pressure chamber through an incompetent valve creates a jet stream effect (much like water spurting out of a partially occluded hose opening). The physical force of this jet stream damages the endocardium of the receiving chamber, increasing the risk for infective endocarditis.



The higher pressures on the left side of the heart subject its valves (the mitral and aortic valves) to more stress and damage than those on the right side of the heart (the tricuspid and pulmonic). Pulmonic valve disease is the least common of the valvular disorders.

MITRAL STENOSIS

Mitral stenosis narrows the mitral valve, obstructing blood flow from the left atrium into the left ventricle during diastole. It is usually caused by rheumatic heart disease or bacterial endocarditis; it rarely results from congenital defects. It affects females more frequently (66%) than males. Mitral stenosis is chronic and progressive.

In mitral valve stenosis, fibrous tissue replaces normal valve tissue, causing valve leaflets to stiffen and fuse. Resulting changes in blood flow through the valve lead to calcification of the valve leaflets. As calcium is deposited in and on the valve, the leaflets become

TABLE 31–8 Heart Murmur Timing and Characteristics

Murmur	Cardiac Cycle Timing	Auscultation Site	Configuration of Sound	Continuity
Mitral stenosis	Diastole	Apical		Rumble that increases in sound toward the end, continuous
Mitral regurgitation	Systole	Apex		Holosystolic (occurs throughout systole), continuous
Aortic stenosis	Midsystolic	2nd intercostal space (ICS), right sternal border (RSB)		Crescendo–decrescendo, continuous
Aortic regurgitation	Diastole (early)	3rd ICS, left sternal border (LSB)		Decrescendo, continuous
Tricuspid stenosis	Diastole	Lower LSB		Rumble that increases in sound toward the end, continuous
Tricuspid regurgitation	Systole	4th ICS, LSB		Holosystolic, continuous

more rigid and narrow the opening further. As the valve leaflets become less mobile, the chordae tendineae fuse, thicken, and shorten. Thromboemboli may form on the calcified leaflets.

The narrowed mitral opening impairs blood flow into the left ventricle, reducing end-diastolic volume and pressure, and decreasing stroke volume. The narrowed opening also forces the left atrium to generate higher pressure to deliver blood to the left ventricle. This leads to left atrial hypertrophy. The left atrium also dilates as obstructed blood flow increases its volume. As the resistance to blood flow increases, high atrial pressures are reflected back into the pulmonary vessels, increasing pulmonary pressures (Figure 31–11 ■). Pulmonary hypertension increases the workload of the right ventricle, causing it to dilate and hypertrophy. Eventually, heart failure occurs.

MANIFESTATIONS Mitral stenosis may be asymptomatic or cause severe impairment. Its manifestations depend on cardiac output and pulmonary vascular pressures. Dyspnea on exertion (DOE) is typically the earliest manifestation. Others include cough, hemoptysis, frequent pulmonary infections such as bronchitis and pneumonia, paroxysmal nocturnal dyspnea, orthopnea, weakness, fatigue, and palpitations. As the stenosis worsens, manifestations of right heart failure, including jugular venous distention, hepatomegaly, ascites, and peripheral edema, develop. Crackles may be heard in the lung bases. In severe mitral stenosis, cyanosis of the face and extremities may be noted. Chest pain is rare but may occur.

On auscultation, a loud S_1, a split S_2, and a mitral opening snap may be heard. The opening snap reflects high left atrial pressure. The murmur of mitral stenosis occurs during diastole, and is typically a low-pitched, rumbling, crescendo–decrescendo sound. It is heard best with the bell of the stethoscope in the apical region. It may be accompanied by a palpable thrill (vibration).

COMPLICATIONS Atrial dysrhythmias, particularly atrial fibrillation, are common due to chronic atrial distention. Thrombi may form and subsequently embolize to the brain, coronary arteries, kidneys, spleen, and extremities—potentially devastating complications.

Women with mitral stenosis may be asymptomatic until pregnancy. As the heart tries to compensate for increased circulating volume (30% more in pregnancy) by increasing cardiac output, left atrial pressures rise, tachycardia reduces ventricular filling and stroke volume, and pulmonary pressures increase. Sudden pulmonary edema and heart failure may threaten the lives of the mother and fetus.

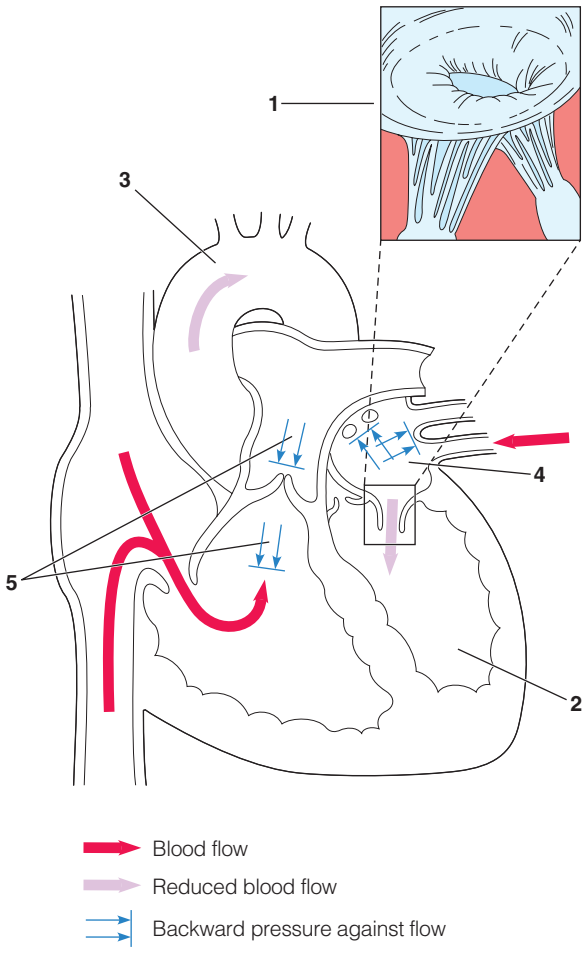


Figure 31–11 ■ Mitral stenosis. Narrowing of the mitral valve orifice (1) reduces blood volume to left ventricle (2), which reduces cardiac output (3). Rising pressure in the left atrium (4) causes left atrial hypertrophy and pulmonary congestion. Increased pressure in the pulmonary vessels (5) causes hypertrophy of the right ventricle and right atrium.

MITRAL REGURGITATION

Mitral regurgitation or *insufficiency* allows blood to flow back into the left atrium during systole because the valve does not close fully. Rheumatic heart disease is a common cause of mitral regurgitation. Men develop mitral regurgitation more frequently than women. Degenerative calcification of the mitral annulus may cause mitral regurgitation in older women. Processes that dilate the mitral annulus or affect the supporting structures, papillary muscles, or the chordae tendineae may cause mitral regurgitation (e.g., left ventricular hypertrophy and MI). Congenital defects also may cause mitral regurgitation.

In mitral regurgitation, blood flows into both the systemic circulation and back into the left atrium through the deformed valve during systole. This increases left atrial volume (Figure 31–12 ■). The left atrium dilates to accommodate its extra volume, pulling the posterior valve leaflet further away from the valve opening and worsening the defect. The left ventricle dilates to accommodate its increased preload and low cardiac output, further aggravating the problem.

MANIFESTATIONS Mitral regurgitation may be asymptomatic or cause symptoms such as fatigue, weakness, exertional dyspnea, and orthopnea. In severe or acute regurgitation, manifestations of left-sided heart failure develop, including pulmonary congestion and edema. High pulmonary pressures may lead to manifestations of right-sided heart failure.

The murmur of mitral regurgitation is usually loud, high pitched, rumbling, and holosystolic (occurring throughout systole). It is often accompanied by a palpable thrill and is heard most clearly at the cardiac apex. It may be characterized as a cooing or gull-like sound or as having a musical quality.

MITRAL VALVE PROLAPSE

Mitral valve prolapse (MVP) is a type of mitral insufficiency that occurs when one or both mitral valve cusps billow into the atrium during ventricular systole. MVP is more common in young women between ages 14 and 30; its incidence declines with age. Its cause often is unclear. It also can result from acute or chronic rheumatic damage,

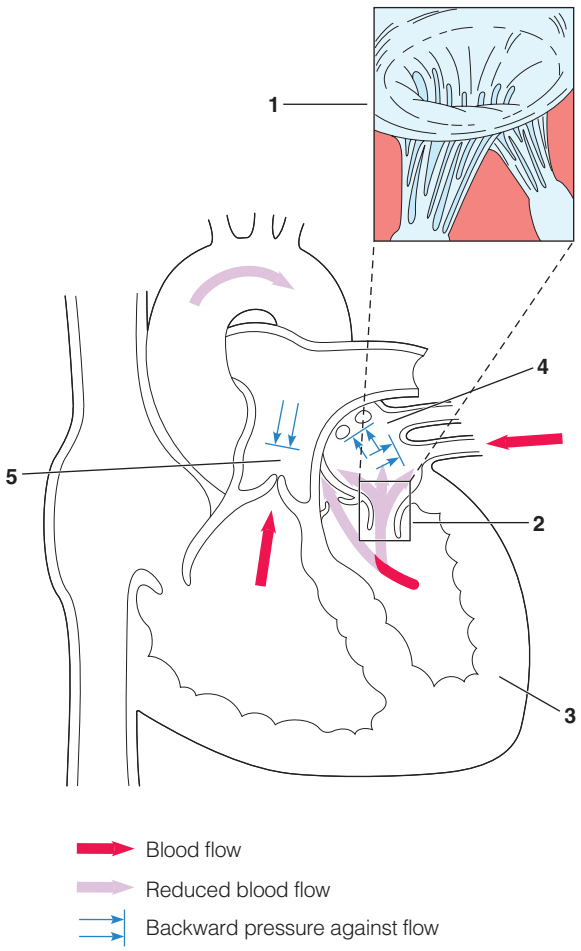

Figure 31–12 ■ Mitral regurgitation. The mitral valve closes incompletely (1), allowing blood to regurgitate during systole from the left ventricle to the left atrium (2). Cardiac output falls; to compensate, the left ventricle hypertrophies (3). Rising left atrial pressure (4) causes left atrial hypertrophy and pulmonary congestion. Elevated pulmonary artery pressure (5) causes slight enlargement of the right ventricle.

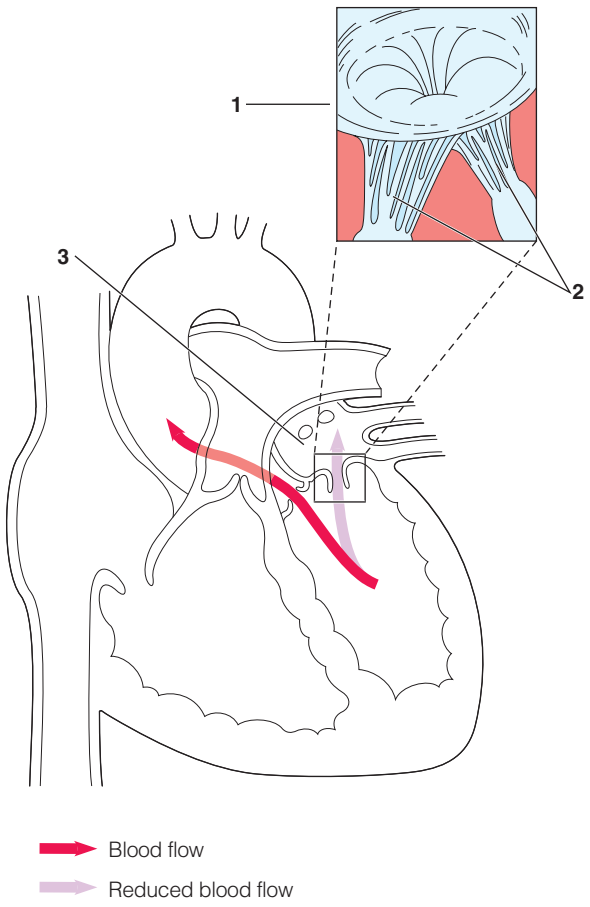

Figure 31–13 ■ Mitral valve prolapse. Excess tissue in the valve leaflets (1) and elongated cordae tendineae (2) impair mitral valve closure during systole. Some ventricular blood regurgitates into the left atrium (3).

ischemic heart disease, or other cardiac disorders. It commonly affects people with inherited connective tissue disorders such as Marfan syndrome (see the Genetic Considerations box). Mitral valve prolapse usually is benign, but about 0.01% to 0.02% of people with MVP have thickened mitral leaflets and a significant risk of morbidity and sudden death.

Excess collagen tissue in the valve leaflets and elongated chordae tendineae impair closure of the mitral valve, allowing the leaflets to billow into the left atrium during systole. Some ventricular blood volume regurgitates into the left atrium (Figure 31–13 ■).

MANIFESTATIONS AND COMPLICATIONS Mitral valve prolapse usually is asymptomatic. A midsystolic ejection click or murmur may be audible. A high-pitched late systolic murmur, sometimes described as a "whoop" or "honk," due to the regurgitation of blood through the valve, may develop in MVP. Atypical chest pain is the most common symptom of MVP. It may be left sided or substernal, and is frequently related to fatigue, not exertion. Tachydysrhythmias may develop with MVP, causing palpitations, light-headedness, and syncope. Increased sympathetic nervous system tone may cause a sense of anxiety.

GENETIC CONSIDERATIONS

Patients with Marfan Syndrome

Marfan syndrome is a genetic (autosomal dominant) connective tissue disorder that affects the skeleton, eyes, and cardiovascular system. Skeletal characteristics include a long, thin body, with long extremities and long, tapering fingers, sometimes called *arachnodactyly* (spider fingers). Joints are hyperextensible, and skeletal deformities such as kyphosis, scoliosis, pigeon chest, or pectus excavatum are common. The potentially life-threatening cardiovascular effects of Marfan syndrome include mitral valve prolapse, progressive dilation of the aortic valve ring, and weakness of arterial walls. People with Marfan syndrome frequently die young, between the ages of 30 and 40, often due to dissection and rupture of the aorta (Huether & McCance, 2011).

Mitral valve prolapse increases the risk for bacterial endocarditis. Progressive worsening of regurgitation can lead to heart failure. Thrombi may form on prolapsed valve leaflets; embolization may cause transient ischemic attacks (TIAs).

AORTIC STENOSIS

Aortic stenosis obstructs blood flow from the left ventricle into the aorta during systole. Aortic stenosis is more common in males (80%) than females. Aortic stenosis may be idiopathic, or due to a congenital defect, rheumatic damage, or degenerative changes. When rheumatic

heart disease is the cause, mitral valve deformity is also often present. Rheumatic heart disease destroys aortic valve leaflets, with fibrosis and calcification causing rigidity and scarring. In the older adult, calcific aortic stenosis may result from degenerative changes associated with aging. Constant wear and tear on this valve can lead to fibrosis and calcification. Idiopathic calcific stenosis generally is mild and does not impair cardiac output.

As aortic stenosis progresses, the valve annulus decreases in size, increasing the work of the left ventricle to eject its volume through the narrowed opening into the aorta. To compensate, the ventricle hypertrophies to maintain an adequate stroke volume and cardiac output (Figure 31–14 ■). Left ventricular compliance also decreases. The additional workload increases myocardial oxygen consumption, which can precipitate myocardial ischemia. Coronary blood flow may also decrease in aortic stenosis. As left ventricular end-diastolic pressure increases because of reduced stroke volume, left atrial pressures increase. These pressures also affect the pulmonary vascular system; pulmonary vascular congestion and pulmonary edema may result.

COURSE AND MANIFESTATIONS Aortic stenosis may be asymptomatic for many years. As the disease progresses and compensation fails, usually between ages 50 and 70, obstructed cardiac output causes manifestations of left ventricular failure. Dyspnea on exertion, angina pectoris, and exertional syncope are classic manifestations of aortic stenosis. Pulse pressure, an indicator of stroke volume, narrows to 30 mmHg or less. Hemodynamic monitors show increased left atrial pressure and pulmonary artery wedge pressure, as well as decreased stroke volume and cardiac output.

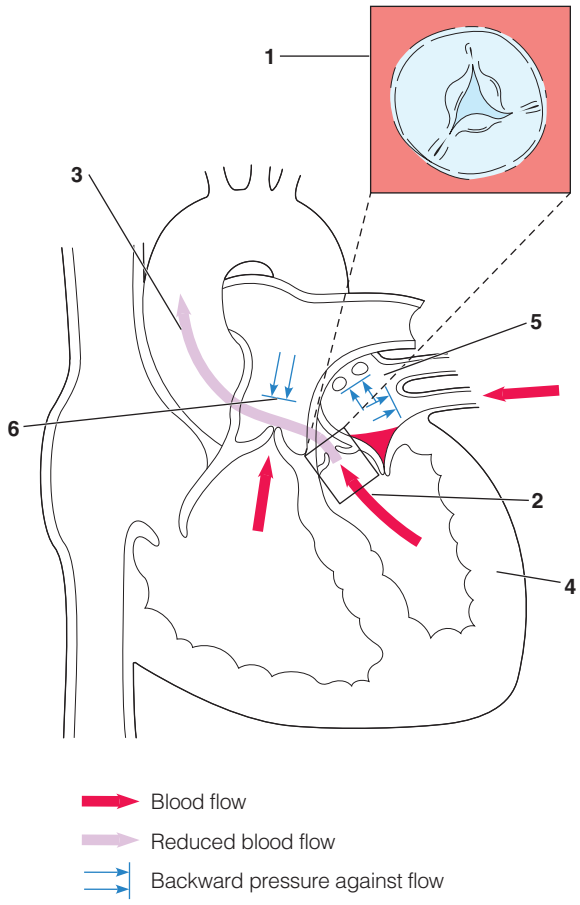

Figure 31–14 ■ Aortic stenosis. The narrowed aortic valve orifice (1) decreases the left ventricular ejection fraction during systole (2) and cardiac output (3). The left ventricle hypertrophies (4). Incomplete emptying of the left atrium (5) causes backward pressure through pulmonary veins and pulmonary hypertension. Elevated pulmonary artery pressure (6) causes right ventricular strain.

Aortic stenosis produces a harsh systolic murmur best heard in the second intercostal space to the right of the sternum. This crescendo–decrescendo murmur is produced by turbulence of blood entering the aorta through the stenotic valve. A palpable thrill is often felt. The murmur may radiate to the carotid arteries. Ventricular hypertrophy displaces the cardiac impulse to the left of the midclavicular line. As aortic stenosis progresses, S_3 and S_4 heart sounds may be heard, indicating heart failure and reduced left ventricular compliance.

As cardiac output falls, tissue perfusion decreases. Late in the disease, pulmonary hypertension and right ventricular failure develop. Untreated, symptomatic aortic stenosis has a poor prognosis; 10% to 20% of these patients experience sudden cardiac death.

AORTIC REGURGITATION

Aortic regurgitation, also called *aortic insufficiency*, allows blood to flow back into the left ventricle from the aorta during diastole. It is more common in males (75%) in its "pure" form; in females, it is commonly associated with coexisting mitral valve disease. Most aortic regurgitation (67%) results from rheumatic heart disease. Other causes include congenital disorders, infective endocarditis, blunt chest trauma, aortic aneurysm, syphilis, Marfan syndrome, and chronic hypertension.

In aortic regurgitation, thickened and contracted valve cusps, scarring, fibrosis, and calcification impede complete valve closure. Chronic hypertension and aortic aneurysm may dilate and stretch the aortic valve opening, increasing the degree of regurgitation.

In aortic regurgitation, volume overload affects the left ventricle as blood from the aorta adds to blood received from the atrium during diastole. This increases diastolic left ventricular pressure. Increased preload causes more forceful contractions and a high stroke volume (Figure 31–15 ■). With time, muscle cells hypertrophy to compensate for increased cardiac work and afterload; eventually this hypertrophy compromises cardiac output and increases regurgitation.

High left-ventricular pressures increase left atrial workload and pressure. This pressure is transmitted to the pulmonary vessels, causing pulmonary congestion. The workload of the right ventricle increases as a result, and right-sided heart failure may develop. Acute aortic regurgitation from traumatic injury or infective endocarditis causes a rapid decline in hemodynamic status from acute heart failure and pulmonary edema, because compensatory mechanisms do not have time to develop.

MANIFESTATIONS Aortic regurgitation may be asymptomatic for many years, even when severe. The increased stroke volume may cause complaints of persistent palpitations, especially when recumbent. A throbbing pulse may be visible in arteries of the neck; the force of contraction may cause a characteristic head bob (Musset's sign) and shake the whole body. Other symptoms include dizziness and exercise intolerance.

Fatigue, exertional dyspnea, orthopnea, and paroxysmal nocturnal dyspnea are common in aortic regurgitation. Anginal pain may

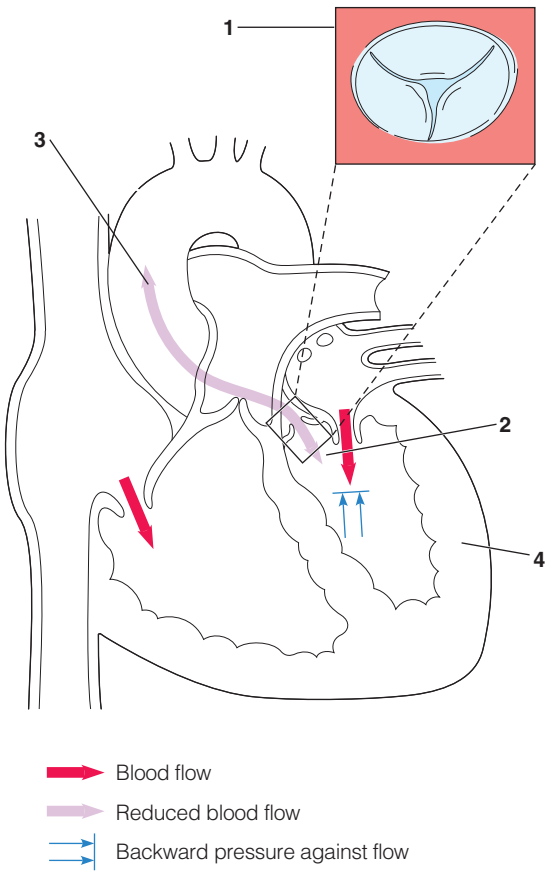

Figure 31–15 ■ Aortic regurgitation. The cusps of the aortic valve widen and fail to close during diastole (1). Blood regurgitates from the aorta into the left ventricle (2) increasing left ventricular volume and decreasing cardiac output (3). The left ventricle dilates and hypertrophies (4) in response to the increase in blood volume and workload.

result from excessive cardiac work and decreased coronary perfusion. Unlike CAD, angina often occurs at night and may not respond to conventional therapy.

The murmur of aortic regurgitation is heard during diastole as blood flows back into the left ventricle from the aorta. It is described as a blowing, high-pitched sound heard most clearly at the third left intercostal space. A palpable thrill and ventricular heave may be noted. An S_3 and S_4 may be heard as the heart fails and ventricular compliance diminishes. The apical impulse is displaced to the left.

High systolic and low diastolic pressures cause a widened pulse pressure. The arterial pressure waveform has a rapid upstroke and quickly collapsing downstroke, known as a *water-hammer pulse.* It is caused by the force of rapid and early delivery of the stroke volume into the aorta.

TRICUSPID VALVE DISORDERS

Tricuspid stenosis obstructs blood flow from the right atrium to the right ventricle. It usually results from rheumatic heart disease; mitral stenosis often occurs concurrently with tricuspid stenosis.

Fibrosed, retracted tricuspid valve cusps and fused leaflets narrow the valve orifice and prevent complete closure. Right ventricular filling is impaired during diastole, and during systole, some blood regurgitates back into the right atrium. Pressure in the right atrium increases, and it enlarges in response to the increased pressure and workload. This increased right atrial pressure is reflected backward into the systemic circulation. Right ventricular stroke volume decreases, reducing the volume delivered to the pulmonary system and left heart. Stroke volume, cardiac output, and tissue perfusion fall.

Manifestations of tricuspid stenosis relate to systemic congestion and right-sided heart failure. They include increased central venous pressure, jugular venous distention, ascites, hepatomegaly, and peripheral edema. Low cardiac output causes fatigue and weakness. The low-pitched, rumbling diastolic murmur of tricuspid stenosis is most clearly heard in the fourth intercostal space at the left sternal border or over the xiphoid process.

Tricuspid regurgitation usually occurs secondarily to right ventricular dilation. Stretching distorts the valve and its supporting structures, preventing complete valve closure. Left ventricular failure is the usual cause of right ventricular overload; pulmonary hypertension is another cause. The valve may be damaged by rheumatic heart disease, infective endocarditis, inferior MI, trauma, or other conditions.

Tricuspid regurgitation allows blood to flow back into the right atrium during systole, increasing right atrial pressures. Increased right atrial pressure causes manifestations of right-sided heart failure, including systemic venous congestion and low cardiac output. Atrial fibrillation due to atrial distention is common. The retrograde flow of blood over the deformed tricuspid valve causes a high-pitched, blowing systolic murmur heard over the tricuspid or xiphoid area.

PULMONIC VALVE DISORDERS

Pulmonic stenosis obstructs blood flow from the right ventricle into the pulmonary system. It usually is a congenital disorder, although rheumatic heart disease or cancer also may cause pulmonic stenosis. The right ventricle hypertrophies to generate the pressure needed to pump blood into the pulmonary system. The right atrium also hypertrophies to overcome the high pressures generated in the right ventricle. Right-sided heart failure occurs when the ventricle can no longer generate adequate pressure to force blood past the narrowed valve opening.

Pulmonic stenosis typically is asymptomatic unless severe. Dyspnea on exertion and fatigue are early signs. As the condition progresses, right-sided heart failure develops, with peripheral edema, ascites, hepatomegaly, and increased venous pressures. Turbulent blood flow caused by the narrowed valve generates a harsh, systolic crescendo–decrescendo murmur heard in the pulmonic area, the second left intercostal space.

Pulmonic regurgitation is more common than pulmonary stenosis. It is a complication of pulmonary hypertension, which stretches and dilates the pulmonary orifice, causing incomplete valve closure. Infective endocarditis, pulmonary artery aneurysm, and syphilis also may cause pulmonic regurgitation.

Incomplete valve closure allows blood to flow back into the right ventricle during diastole, decreasing blood flow to the pulmonary circuit. The extra blood increases right ventricular end-diastolic volume. When the ventricle can no longer compensate for the increased volume, right-sided heart failure develops. The murmur of pulmonic regurgitation is a high-pitched, decrescendo, blowing sound heard along the left sternal border during diastole.

●○● INTERPROFESSIONAL CARE

A heart murmur identified during routine physical examination often is the initial indication of valvular disease. If no symptoms are present, close observation for disease progression and prophylactic therapy to prevent infection of the diseased heart may be the only treatment.

Manifestations of heart failure are treated with diet and medications. When medical management is no longer effective, surgery is considered.

DIAGNOSIS

The following diagnostic tests help to identify and diagnose valvular disease. See Chapter 30 for more information about these tests and related nursing care.

- *Echocardiography* is used routinely to diagnose valvular disease. Thickened valve leaflets, vegetations or growths on valve leaflets, myocardial function, and chamber size can be determined, and pressure gradients across valves and pulmonary artery pressures can be estimated. Either transthoracic or transesophageal echocardiography may be used.
- *Chest x-ray* can identify cardiac hypertrophy, chamber and great vessel enlargement, and dilation of the pulmonary vasculature. Calcification of the valve leaflets and annular openings may also be visible.
- *Electrocardiography* can demonstrate atrial and ventricular hypertrophy, conduction defects, and dysrhythmias associated with valvular disease.
- *Cardiac catheterization* may be used to assess contractility and to determine the pressure gradients across the heart valves, in the heart chambers, and in the pulmonary system. It is used prevalvular surgery to assess CAD risk.
- *Exercise testing* should be used only with asymptomatic patients to assess for exercise-induced symptoms and abnormal blood pressure response. It is contraindicated for symptomatic aortic stenosis patients.

MEDICATIONS

Heart failure resulting from valvular disease is treated with diuretics, ACE inhibitors, vasodilators, and possibly digitalis glycosides. Digitalis increases the force of myocardial contraction to maintain cardiac output. Diuretics, ACE inhibitors, and vasodilators reduce preload and afterload. (See the Medication Administration box on page 930.)

In patients with valvular disorders, atrial distention often causes atrial fibrillation. Digitalis or small doses of beta-blockers are given to slow the ventricular response (see Chapter 32 for information about atrial fibrillation and its treatment). Anticoagulant therapy is added to prevent clot and embolus formation, a common complication of atrial fibrillation as blood pools in the noncontracting atria. Anticoagulant therapy also is required following insertion of a mechanical heart valve. See Chapter 33 for information about anticoagulant therapy.

Valvular damage increases the risk for infective endocarditis as altered blood flow allows bacterial colonization. Antibiotics are prescribed prophylactically prior to any dental work, invasive procedures, or surgery to minimize the risk of bacteremia (bacteria in the blood) and subsequent endocarditis.

PERCUTANEOUS BALLOON VALVOTOMY

A *percutaneous balloon valvotomy* is an invasive procedure performed in the cardiac catheterization laboratory. A balloon catheter similar to that used in coronary angioplasty procedures is inserted into the femoral vein or artery. Guided by fluoroscopy, the catheter is advanced into the heart and positioned with the balloon straddling the stenotic valve. The balloon is then inflated for approximately 90 seconds to divide the fused leaflets and enlarge the valve orifice (Figure 31–16 ■). Balloon valvotomy is the treatment of choice for symptomatic mitral valve stenosis. It is used to treat children and young adults with aortic stenosis, and may be indicated for older adults who are poor surgical risks, and as a "bridge to surgery" when heart function is severely compromised. Nursing care of the patient with a balloon valvotomy is similar to that of the patient following coronary revascularization (refer to Chapter 30).

SURGERY

Surgery to repair or replace the diseased valve may be done to restore valve function, alleviate symptoms, and prevent complications and death. Ideally, diseased valves are repaired or replaced before cardiopulmonary function is severely compromised. The diseased valve is repaired when possible, because the risk for surgical mortality and complications is lower than with valve replacement.

RECONSTRUCTIVE SURGERY *Valvuloplasty* is a general term for reconstruction or repair of a heart valve. Methods include patching the perforated portion of the leaflet, resecting excess tissue, debriding vegetations or calcifications, and other techniques. Valvuloplasty may be used for stenotic or regurgitant mitral and tricuspid valves, mitral valve prolapse, and aortic stenosis. Common valvuloplasty procedures include the following:

- *Open commissurotomy*, surgical division of fused valve leaflets, is done to open stenotic valves. Fused commissures (junctions

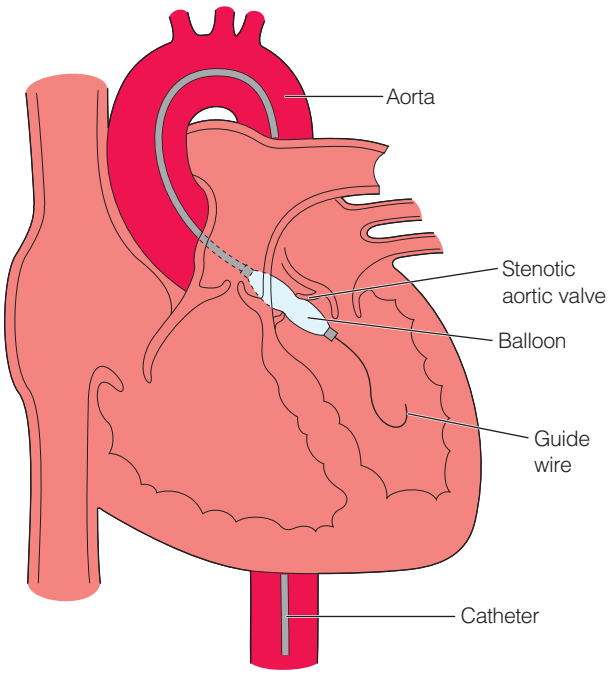

Figure 31–16 ■ Balloon valvotomy. The balloon catheter is guided into position straddling the stenosed valve. The balloon is then inflated to increase the size of the valve opening.

between valve leaflets or cusps) are incised, and calcium deposits are debrided as needed.

- *Annuloplasty* repairs a narrowed or an enlarged or dilated valve annulus, the supporting ring of the valve. A prosthetic ring may be used to resize the opening, or stitches and purse-string sutures may be used to reduce and gather excess tissue. Annuloplasty may be used for either stenotic or regurgitant valves.

VALVE REPLACEMENT Valve replacement is indicated when manifestations of valve dysfunction develop, preferably before left heart function is seriously impaired. In general, three factors determine the outcome of valve replacement surgery: (1) heart function at the time of surgery, (2) intraoperative and postoperative care, and (3) characteristics and durability of the replacement valve.

Many different prosthetic heart valves are available, including mechanical and biologic tissue valves. Selection depends on the valve hemodynamics, resistance to clot formation, ease of insertion, anatomic suitability, and patient acceptance. The patient's age, underlying condition, and contraindications to anticoagulation (such as a desire to become pregnant) also are considered in selecting the appropriate prosthesis. Table 31–9 lists the advantages and disadvantages of biologic and mechanical valves.

Biologic tissue valves may be *heterografts*, excised from a pig or made of calf pericardium, or *homografts* from a human (obtained from a cadaver or during heart transplant). Biologic valves allow more normal blood flow and have a low risk of thrombus formation. As a result, long-term anticoagulation rarely is necessary. They are less durable, however, than mechanical valves. Up to 50% of biologic valves must be replaced by 15 years.

Mechanical prosthetic valves have the major advantage of long-term durability. These valves are frequently used when life expectancy exceeds 10 years. Their major disadvantage is the need for lifetime anticoagulation to prevent the development of clots on the valve.

Most mechanical valves have either a tilting disk or a ball-and-cage design. The tilting-disk valve designs are frequently used because they have a lower profile than the ball-and-cage types, allowing blood to flow through the valve with less obstruction (Figure 31–17 ■). The St. Jude bileaflet design has good hemodynamics and low risk for clot formation. Both biologic and mechanical valves increase the risk of endocarditis, although its incidence is fairly low.

●○● NURSING CARE

Health Promotion

Preventing rheumatic heart disease is a key element in preventing heart valve disorders. Rheumatic heart disease is a consequence of rheumatic fever (see the previous section of this chapter), an immune process that may be a sequela to beta-hemolytic streptococcal infection of the pharynx (strep throat). Early treatment of strep throat prevents rheumatic fever. Teach individual patients, families, and communities about the importance of timely and effective treatment of strep throat. Emphasize the importance of completing the full prescription of antibiotics to prevent development of resistant bacteria. Prophylactic antibiotic therapy before invasive procedures to prevent infectious endocarditis is an important health promotion measure for patients with preexisting heart disease.

Assessment

See the Manifestations and Interprofessional Care sections for the assessment of the patient with valvular heart disease.

Assessment data related to valvular heart disease includes the following:

- *Health history:* complaints of decreasing exercise tolerance, dyspnea on exertion, palpitations; history of frequent respiratory

TABLE 31–9 Advantages and Disadvantages of Prosthetic Heart Valves

Category	Types	Advantages	Disadvantages
Mechanical valves	Ball and cage Tilting disk	Long-term durability Good hemodynamics	Lifetime anticoagulation Audible click Risk of thromboembolism Infections are harder to treat
Biologic tissue valves	Porcine heterograft Bovine heterograft Human aortic homograft	Low incidence of thromboembolism No long-term anticoagulation Good hemodynamics Quiet Infections are easier to treat	Prone to deterioration Frequent replacement is required

infections; previous history of rheumatic heart disease, endocarditis, or a heart murmur
- *Physical assessment:* vital signs; skin color and temperature, evidence of clubbing or peripheral edema; neck vein distention; breath sounds; heart sounds and presence of S_3, S_4, or murmur; timing, grade, and characteristics of any murmur; palpate for cardiac heave and thrills; abdominal contour, liver and spleen size.

Priorities of Care

Collaborating with the interprofessional team to ensure adequate treatment of the underlying process while providing care that supports the physical and psychologic responses to the disorder is a priority of nursing care.

Diagnoses, Outcomes, and Interventions

Nursing priorities include maintaining cardiac output, managing manifestations of the disorder, teaching about the disease process and its management, and preventing complications. Nursing care of the patient undergoing valve surgery is similar to that of the patient having other types of open-heart surgery (refer to Chapter 30), with increased attention to anticoagulation and preventing endocarditis.

Decreased Cardiac Output

Nearly all valve disorders affect ventricular filling and/or emptying, reducing cardiac output. Stenosis of the AV valves impairs ventricular filling and increases atrial pressures. Regurgitation of these valves reduces cardiac output as a portion of the blood in the ventricle regurgitates into the atria during systole. Stenosis of the semilunar valves obstructs ventricular outflow to the great vessels; regurgitation allows blood to flow back into the ventricles, creating higher filling pressures. When compensatory measures fail, heart failure develops.

Expected Outcome: Patient will demonstrate adequate cardiac output as evidenced by blood pressure and pulse rate and rhythm within normal limits.

- Monitor vital signs and hemodynamic parameters, reporting changes from the baseline. *A fall in systolic blood pressure and tachycardia may indicate decreased cardiac output. Increasing pulmonary artery and pulmonary wedge pressures may also indicate decreased cardiac output, causing increased congestion and pressure in the pulmonary vascular system.*

PRACTICE ALERT!

Promptly report changes in level of consciousness; distended neck veins; dyspnea or respiratory crackles; urine output less than 30 mL/h; cool, clammy, or cyanotic skin; diminished peripheral pulses; or slow capillary refill. These findings indicate decreased cardiac output and impaired tissue and organ perfusion.

- Monitor intake and output; weigh daily. Report weight gain of 1.4 to 2.3 kg (3 to 5 lb) within 24 hours. *Fluid retention is a compensatory mechanism that occurs when cardiac output decreases; 1 kg (2.2 lb) of weight equals 1 L of fluid.*
- Restrict fluids as ordered. *Fluid intake may be restricted to reduce cardiac workload and pressures within the heart and pulmonary circuit.*
- Monitor oxygen saturation continuously and ABGs as ordered. Report oxygen saturation less than 95% (or as specified) and abnormal ABG results. *Oxygen saturation levels and ABGs allow assessment of oxygenation.*

Evidence for Nursing Care

The Patient with Valvular Heart Disease

A selected resource that nurses may find helpful when planning evidence-based nursing care follows.
- Hull, C. L. (2012). Treating calcific aortic stenosis: An evolving science. *MedSurg Nursing, 21*(2), 82–88.

- Elevate the head of the bed. Administer supplemental oxygen as ordered. *These measures improve alveolar ventilation and oxygenation.*
- Provide for physical, emotional, and mental rest. *Physical and psychologic rest decreases the cardiac workload.*
- Administer prescribed medications as ordered to reduce cardiac workload. *Diuretics, ACE inhibitors, and direct vasodilators may be prescribed to reduce fluid volume and afterload, reducing cardiac work.*

Activity Intolerance

Altered blood flow through the heart impairs delivery of oxygen and nutrients to the tissues. As the heart muscle fails and is unable to compensate for altered blood flow, tissue perfusion is further compromised. Dyspnea on exertion is often an early symptom of valvular disease.

Expected Outcome: Patient will participate in physical activity as tolerated.

- Monitor vital signs before and during activities. *A change in heart rate of more than 20 bpm, a change of 20 mmHg or more in systolic BP, and complaints of dyspnea, shortness of breath, excessive fatigue, chest pain, diaphoresis, dizziness, or syncope may indicate activity intolerance.*
- Encourage self-care and gradually increasing activities as allowed and tolerated. Provide for rest periods, uninterrupted sleep, and adequate nutritional intake. *Gradual progression of activities avoids excessive cardiac stress. Encouraging self-care increases the patient's self-esteem and sense of power. Adequate rest and nutrition facilitate healing, decrease fatigue, and increase energy reserves.*
- Provide assistance as needed. Suggest use of a shower chair, sitting while brushing hair or teeth, and other energy-saving measures. *Reducing energy expenditure helps maintain a balance of oxygen supply and demand.*
- Consult with a cardiac rehabilitation specialist or physical therapist for in-bed exercises and an activity plan. *In-bed exercises may help improve strength.*
- Discuss ways to conserve energy at home. *Information provides practical ways to deal with activity limitations and empowers the patient to manage these limitations.*

Risk for Infection

Damaged and deformed valve leaflets and turbulent blood flow through the heart significantly increase the risk of infective endocarditis. Invasive diagnostic and monitoring lines (e.g., cardiac catheterization, hemodynamic monitoring) and disrupted skin with surgery also increase the risk of infection.

Expected Outcome: The patient will exhibit effective infection management as evidenced by skin integrity and body temperature within normal range.

- Use aseptic technique for all invasive procedures. *Invasive procedures breach the body's protective mechanisms, potentially allowing bacteria to enter. Aseptic technique reduces this risk.*
- Record temperature every 4 hours; notify physician if temperature exceeds 38.5°C (100.5°F). *Fever may be an early indication of infection.*

- Assess wounds and catheter sites for redness, swelling, warmth, pain, or evidence of drainage. *These signs of inflammation may signal infection.*
- Administer antibiotics as ordered. Ensure completion of the full course. *Antibiotics are used to prevent and treat infection. Completion of the full course of therapy prevents drug-resistant organisms from multiplying.*
- Monitor WBC and differential. Notify physician of leukocytosis or leukopenia. *A high WBC and increased percentage of immature WBCs (bands) may indicate bacterial infection; a low WBC count may indicate an impaired immune response and increased susceptibility to infection.*

Ineffective Protection

Anticoagulant therapy commonly is prescribed for patients with chronic atrial fibrillation, a history of emboli, and following valve replacement surgery. Although chronic anticoagulant therapy decreases the risk of clots and emboli, it increases the risk for bleeding and hemorrhage.

Expected Outcome: Patient will remain free of any evidence of new bleeding and take precautions to prevent bleeding.

SAFETY ALERT

Monitor the International Normalized Ratio (INR) or prothrombin time (PT or protime). Report an INR > 3.5 or a PT > 2.5 times the normal to the physician. An excessively high INR or PT indicates excessive anticoagulation and an increased risk for bleeding.

- Test stools and vomitus for occult blood. *Bleeding due to excessive anticoagulation may not be apparent.*
- Instruct to avoid using aspirin or other NSAIDs. Encourage reading ingredient labels on over-the-counter drugs; many contain aspirin. *Aspirin and other NSAIDs interfere with clotting and may potentiate the effects of the anticoagulant therapy.*
- Advise using a soft-bristled toothbrush, electric razor, and gentle touch when cleaning fragile skin. These measures decrease the risk of skin or gum trauma and bleeding.

PRACTICE ALERT!

Monitor hemoglobin, hematocrit, and platelet count as ordered. Notify the physician of decreasing hemoglobin and hematocrit levels or if the platelet count falls below 50,000/mm^3. Low hemoglobin and hematocrit indicate blood loss. Platelet counts below 50,000/mm^3 significantly increase the risk of bleeding.

Delegating Nursing Care Activities

As appropriate and allowed by the designated duties and responsibilities of unlicensed assistive personnel, the nurse may delegate nursing care activities such as measuring fluid intake and output, collecting vital signs (including orthostatic vital signs), encouraging oral or enteral fluid intake, and ensuring nonpharmacologic skin care.

Continuity of Care

For most patients, valvular disease is a chronic condition. The patient has primary responsibility for managing the effects of the disorder. To prepare the patient and family for home care, discuss the following topics:

- Management of symptoms, including any necessary activity restrictions or lifestyle changes
- The importance of adequate rest to prevent fatigue
- Diet restrictions to reduce fluid retention and symptoms of heart failure
- Information about prescribed medications, including purpose, desired and possible adverse effects, scheduling, and possible interactions with other drugs
- The importance of keeping follow-up appointments to monitor the disease and its treatment
- Notifying all healthcare providers about valve disease or surgery to facilitate prescription of prophylactic antibiotics before invasive procedures or dental work
- Manifestations to immediately report to the healthcare provider: increasing severity of symptoms, especially of worsening heart failure or pulmonary edema; signs of transient ischemic attacks or other embolic events; evidence of bleeding, such as joint pain, easy bruising, black and tarry stools, bleeding gums, or blood in the urine or sputum.

Provide referrals to community resources such as home maintenance services, home health services, and structured cardiac rehabilitation programs. Refer the patient and family (especially the primary food preparer) to a dietitian or nutritionist for teaching and assistance with menu planning. See the accompanying Case Study & Nursing Care Plan for additional nursing care and teaching for a patient with mitral valve prolapse.

THE PATIENT WITH CARDIOMYOPATHY

Cardiomyopathies are disorders that affect the heart muscle itself. They are a diverse group of disorders that affect both systolic and diastolic functions. Cardiomyopathies may be either primary or secondary in origin. Primary cardiomyopathies are idiopathic; their cause is unknown. Secondary cardiomyopathies occur as a result of other processes, such as ischemia, infectious disease, exposure to toxins, connective tissue disorders, metabolic disorders, or nutritional deficiencies. In many cases, the cause of cardiomyopathy is unknown. Close to 27,000 deaths annually are directly attributed to cardiomyopathy. Mortality associated with cardiomyopathy is higher in older adults, men, and African Americans (AHA, 2013).

Pathophysiology

The cardiomyopathies are categorized by their pathophysiology and presentation into three groups: dilated, hypertrophic, and restrictive. Table 31–10 compares the causes, pathophysiology, manifestations, and management of the cardiomyopathies.

DILATED CARDIOMYOPATHY

Dilated cardiomyopathy is the most common type of cardiomyopathy, accounting for 87% of cases (AHA, 2013). Dilated cardiomyopathy also is a common cause of heart failure, accounting for about one in three cases. It is primarily a disease of middle age males; African American males have a higher risk than Whites.

CASE STUDY & NURSING CARE PLAN A Patient with Mitral Valve Prolapse

Julie Snow, a 22-year-old college student, sees a nurse practitioner at the college health clinic for a physical examination after experiencing palpitations, fatigue, and a headache during midterm examinations. Ms. Snow tells Lakisha Johnson, FNP, "I'm scared that something is wrong with me."

During the past few months, Ms. Snow has had occasional palpitations that she describes as "feeling like my heart is doing flip-flops." Rarely, these palpitations have been accompanied by a sharp, stabbing pain in her chest that lasts only a few seconds. She initially attributed her symptoms to stress, but she is increasingly concerned because the "attacks" are becoming more frequent. Ms. Snow states that she has "always been healthy," does not smoke, uses alcohol socially, and exercises, albeit intermittently. Ms. Snow admits that she has been drinking a lot of coffee and cola and eating a lot of junk food lately.

ASSESSMENT

Ms. Johnson's assessment of Ms. Snow documents the following: height 168 cm (66 in.), weight 63.6 kg (140 lb), T 37.4°C (99.3°F), BP 118/64 mmHg, P 82 bpm, and R 18/min. Slightly anxious but in no acute distress. Systolic click and soft crescendo murmur grade II/VI noted on auscultation. Apical impulse at 5th ICS left MCL. Lungs clear to auscultation. Review of remaining systems reveals no apparent abnormalities. An ECG shows sinus rhythm with occasional PACs. Based on the admission history, manifestations, and physical assessment, Ms. Johnson suspects mitral valve prolapse (MVP).

DIAGNOSES

- *Anxiety* related to fear of heart disease and implications for lifestyle
- *Powerlessness* related to unpredictability of symptoms
- *Risk of Infection (endocarditis)* related to altered valve function

EXPECTED OUTCOMES

- Patient will verbalize an understanding of MVP and its management.
- Patient will discuss ways to decrease or relieve MVP symptoms.
- Patient will acknowledge the risk for endocarditis and identify precautions to prevent it.

PLANNING AND IMPLEMENTATION

- Consult with and refer to the cardiologist for continued monitoring and follow-up.
- Teach about MVP, including heart valve anatomy, physiology, and function, common manifestations of MVP, and treatment rationale.
- Discuss symptoms of progressive mitral regurgitation, and the need to report these to the cardiologist.
- Discuss recommended follow-up care and its rationale.
- Allow to verbalize feelings and share concerns about MVP. Encourage to attend an MVP support group meeting.
- Discuss the prognosis for MVP, emphasizing that most patients live normal lives using diet and lifestyle management.
- Instruct to keep a weekly record of symptoms and their frequency for 1 month.
- Discuss lifestyle changes to manage symptoms: aerobic exercise with warm-up and cool-down periods; maintaining adequate fluid intake, especially during hot weather or exercise; relaxation techniques (e.g., meditation, deep-breathing exercises, music therapy, yoga, guided imagery, heat therapy, or progressive muscle relaxation) to perform daily; avoiding caffeine and crash diets; forming healthy eating habits.
- Teach about infective endocarditis risk and prevention with prophylactic antibiotics. Encourage notifying dentist and other healthcare providers of MVP before dental or any other invasive procedures.

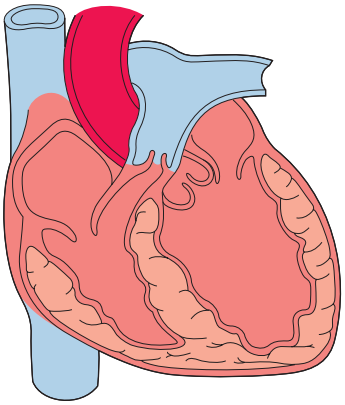
EVALUATION

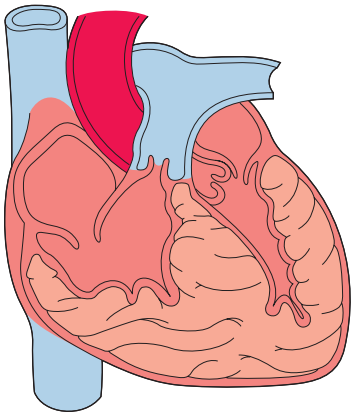
After several educational sessions at the college health clinic, Ms. Snow verbalizes an understanding of MVP by explaining heart valve function, listing common manifestations of MVP, and describing indications of deteriorating heart function. She states she will report these manifestations to her cardiologist if they occur. She is given a booklet on MVP for additional reading. She verbalizes understanding of the risk of endocarditis, and states that she will notify her doctors of her MVP and the need for antibiotics before invasive procedures. Ms. Snow is attending a monthly MVP support group (led by a cardiology clinical nurse specialist) on campus and states, "I am so glad to know I'm not alone! It really helps to know that others are living well with MVP." Her weekly symptom log shows her symptoms are associated with late-night studying and drinking large amounts of coffee and cola. Ms. Snow has moderated her caffeine intake and increased her fluids, relieving her symptoms. In addition, Ms. Snow is taking a relaxation music therapy class. Ms. Snow states that she realizes that she has "the ability to control my life through the choices I make."

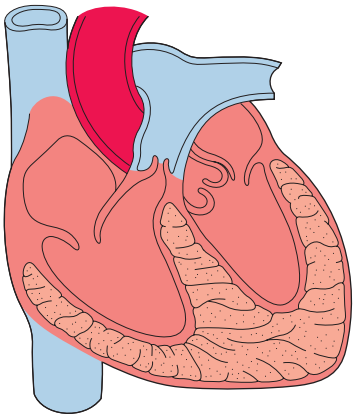
Clinical Reasoning in Patient Care

1. Develop an action plan for Ms. Snow that outlines specific activities she can use to manage symptoms of MVP.
2. Why are patients with symptomatic MVP encouraged to include regular exercise in their health habits?
3. How does the support of family, friends, and other people with MVP assist MVP patients in managing their condition?
4. What manifestations would indicate a progressive worsening of Ms. Snow's mitral regurgitation?

See Evaluating Your Response in Appendix B.







The cause of dilated cardiomyopathy is unknown, although it appears to frequently result from toxins, metabolic conditions, or infection. Reversible dilated cardiomyopathy may develop due to alcohol and cocaine abuse, chemotherapeutic drug use, pregnancy, and systemic hypertension. Up to 20% of cases of dilated cardiomyopathy may be genetic in origin, most commonly transmitted in an autosomal dominant pattern, although autosomal recessive, X-linked, and mitochondrial patterns of inheritance also are seen.

In dilated cardiomyopathy, heart chambers dilate and ventricular contraction is impaired. Both end-diastolic and end-systolic volumes increase, and the left ventricular ejection fraction is substantially reduced, decreasing cardiac output. Left ventricular dilation is prominent; left ventricular hypertrophy is usually minimal. The right ventricle also may be enlarged. Extensive interstitial fibrosis (scarring) is evident; necrotic myocardial cells also may be seen.

MANIFESTATIONS AND COURSE Manifestations of dilated cardiomyopathy develop gradually. Heart failure often presents years after the onset of dilation and pump failure. Both right- and left-sided failure occur, with dyspnea on exertion, orthopnea, paroxysmal nocturnal dyspnea, weakness, fatigue, peripheral edema, and ascites. Both S_3 and S_4 heart sounds are commonly heard, as well as an AV regurgitation murmur. Dysrhythmias are common, including supraventricular tachycardias, atrial fibrillation, and complex ventricular tachycardias. Untreated dysrhythmias can lead to sudden death. Mural thrombi (blood clots in the heart wall) may form in the left ventricular apex and embolize to other parts of the body.

The prognosis of dilated cardiomyopathy is grim; most patients get progressively worse and 50% die within 5 years after the diagnosis; 75% die within 10 years (AHA, 2013).

TABLE 31–10 Classifications of Cardiomyopathy

	Dilated	Hypertrophic	Restrictive
			
Causes	Usually idiopathic; may be secondary to chronic alcoholism or myocarditis	Hereditary; may be secondary to chronic hypertension	Usually secondary to amyloidosis, radiation, or myocardial fibrosis
Pathophysiology	Scarring and atrophy of myocardial cells Thickening of ventricular wall Dilation of heart chambers Impaired ventricular pumping Increased end-diastolic and end-systolic volumes Mural thrombi common	Hypertrophy of ventricular muscle mass Small left ventricular volume Septal hypertrophy may obstruct left ventricular outflow Left atrial dilation	Excess rigidity of ventricular walls restricts filling Myocardial contractility remains relatively normal
Manifestations	Heart failure Cardiomegaly Dysrhythmias S_3 and S_4 gallop; murmur of mitral regurgitation	Dyspnea, anginal pain, syncope Left ventricular hypertrophy Dysrhythmias Loud S_4 Sudden death	Dyspnea, fatigue Right-sided heart failure Mild to moderate cardiomegaly S_3 and S_4 heart sounds Mitral regurgitation murmur
Management	Management of heart failure ICD as needed Cardiac transplantation	Beta-blockers Calcium channel blockers Antidysrhythmic agents ICD, dual-chamber pacing Surgical excision of part of the ventricular septum	Management of heart failure Exercise restriction

HYPERTROPHIC CARDIOMYOPATHY

Hypertrophic cardiomyopathy is characterized by decreased compliance of the left ventricle and hypertrophy of the ventricular muscle mass. This impairs ventricular filling, leading to small end-diastolic volumes and low cardiac output. About half of all patients with hypertrophic cardiomyopathy have a family history of the disease. It is genetically transmitted in an autosomal dominant pattern.

The pattern of left ventricular hypertrophy is unique in that the muscle may not hypertrophy equally. In a majority of patients, the interventricular septal mass, especially the upper portion, increases to a greater extent than the free wall of the ventricle. The enlarged upper septum narrows the passageway of blood into the aorta, impairing ventricular outflow. For this reason, this disorder is also known as *idiopathic hypertrophic subaortic stenosis (IHSS)* or *hypertrophic obstructive cardiomyopathy (HOCM).*

MANIFESTATIONS AND COURSE Hypertrophic cardiomyopathy may be asymptomatic for many years. Symptoms typically occur when increased oxygen demand causes increased ventricular contractility. They may develop suddenly during or after physical activity; in children and young adults, sudden cardiac death may be the first sign of the disorder. Hypertrophic cardiomyopathy is the probable or definite cause of death in 36% of young athletes who die suddenly (AHA, 2013). It is hypothesized that sudden cardiac death is due to ventricular dysrhythmias or hemodynamic factors. Predictors of sudden cardiac death in this population include age of less than 30 years, a family history of sudden death, syncopal episodes, severe ventricular hypertrophy, and ventricular tachycardia seen on ambulatory ECG monitoring. For a brief synopsis of a nursing research study regarding family presence during CPR and invasive procedures, see the Moving Evidence into Action box.

The usual manifestations of hypertrophic cardiomyopathy are dyspnea, angina, and syncope. Angina may result from ischemia due to overgrowth of the ventricular muscle, coronary artery abnormalities, or decreased coronary artery perfusion. Syncope may occur when the outflow tract obstruction severely decreases cardiac output and blood flow to the brain. Ventricular dysrhythmias are common;

Moving Evidence into Action

Sudden Cardiac Death

When cardiac arrest occurs or invasive procedures are performed, family members typically are asked to leave the patient's care unit. The traditional rationale for this practice is fear of disrupted clinical interventions, trauma of the witnesses, and risk for increased hospital liability. However, in 1995, the Emergency Nurses Association (ENA) adopted a position supporting family presence during invasive procedures, including resuscitation efforts (CPR), as a means of maintaining family integrity and dignity. This position statement (updated in 2010) evaluated the responses of families, nurses, and physicians to family presence during invasive procedures and CPR.

Results of the response evaluation showed that families saw their presence as a positive experience and their right. They viewed themselves as active care partners, and being present met their needs for information and providing comfort and connection with the patient. Nurses overwhelmingly supported family presence; attending physicians also demonstrated a positive response. Physician residents were the least supportive of family presence.

Implications for Nursing
Family members often are asked to leave the patient's side during invasive procedures and CPR with the intention of protecting them from the trauma of witnessing painful or distressing events. This study clearly showed being present as a positive experience, even when the ultimate outcome was the patient's death.

Offering the opportunity to be present and providing information and psychologic and emotional support to an appropriate family member during invasive procedures and CPR supports the family unit and the patient during times of crisis. Screening is important: It is probably not appropriate to allow people who are combative, emotionally unstable, or have altered mental status (e.g., dementia, alcohol intoxication) to be present during such procedures. It also is important to allow families to decline the invitation without guilt.

Moving Knowledge into Action

1. Identify procedures and situations in which family members are often asked to leave the patient's side. When would it be appropriate to allow at least one significant other to remain with the patient?
2. How would you present the option and prepare a family member for being present during a traumatic event such as CPR following the sudden death of a young adult with undiagnosed hypertrophic cardiomyopathy?
3. You support family presence during traumatic events and procedures, but your charge nurse does not. What steps might you use to effect a change in policy on your unit?

Reference: Emergency Nurses Association. (2010). https://www.ena.org/SiteCollectionDocuments/Position%20Statements/FamilyPresence.pdf.

atrial fibrillation also may develop. Other manifestations of hypertrophic cardiomyopathy include fatigue, dizziness, and palpitations. A harsh, crescendo–decrescendo systolic murmur of variable intensity heard best at the lower left sternal border and apex is characteristic in hypertrophic cardiomyopathy. An S_4 may also be noted on auscultation.

RESTRICTIVE CARDIOMYOPATHY

The least common form of cardiomyopathy, *restrictive cardiomyopathy*, is characterized by rigid ventricular walls that impair diastolic filling. Causes of restrictive cardiomyopathy include myocardial fibrosis and infiltrative processes, such as amyloidosis. Fibrosis of the myocardium and endocardium causes excessive stiffness and rigidity of the ventricles. Decreased ventricular compliance impairs filling, with decreased ventricular size, elevated end-diastolic pressures, and decreased cardiac output. Contractility is unaffected, and the ejection fraction is normal.

MANIFESTATIONS AND COURSE The manifestations of restrictive cardiomyopathy are those of heart failure and decreased tissue perfusion. Dyspnea on exertion and exercise intolerance are common. Jugular venous pressure is elevated, and the presence of S_3 and S_4 heart sounds is common. The prognosis for restrictive cardiomyopathy is poor. Most patients die within 3 years, and the systemic nature of the underlying disease process precludes effective treatment.

●○● INTERPROFESSIONAL CARE

With the exception of treating an underlying cause, little can be done to treat either dilated or restrictive cardiomyopathies. For these disorders, treatment focuses on managing heart failure and treating dysrhythmias. Refer to the section of this chapter on heart failure and Chapter 30 for specific treatment strategies. Treatment of hypertrophic cardiomyopathy focuses on reducing contractility and preventing sudden cardiac death. Strenuous physical exertion is restricted, because it may precipitate dysrhythmias or sudden cardiac death. Dietary and sodium restrictions may help diminish the manifestations.

DIAGNOSIS

Diagnosis begins with a history and physical assessment to rule out known causes of heart failure. Other tests may include the following:

- *Echocardiography* is done to assess chamber size and thickness, ventricular wall motion, valvular function, and systolic and diastolic function of the heart.
- *Electrocardiography* and *ambulatory ECG monitoring* demonstrate cardiac enlargement and detect dysrhythmias.
- *Chest x-ray* shows cardiomegaly, enlargement of the heart, and any pulmonary congestion or edema.
- *Hemodynamic studies* are used to assess cardiac output and pressures in the cardiac chambers and pulmonary vascular system.
- *Radionuclear scans* help identify changes in ventricular volume and mass, as well as perfusion deficits.
- *Cardiac catheterization* and *coronary angiography* may be done to evaluate coronary perfusion, the cardiac chambers, valves, and great vessels for function and structure, pressure relationships, and cardiac output.
- *Myocardial biopsy* uses the transvenous route to obtain myocardial tissue for biopsy. The cells are examined for infiltration, fibrosis, or inflammation.

MEDICATIONS

The drug regimen used to treat heart failure also is used for dilated or restrictive cardiomyopathy. This includes ACE inhibitors,

vasodilators, and digitalis (see the previous section of this chapter). Beta-blockers also may be used with caution in patients with dilated cardiomyopathy. Anticoagulants are given to reduce the risk of thrombus formation and embolization. Antidysrhythmic drugs are avoided if possible due to their tendency to precipitate further dysrhythmias.

Beta-blockers are the drugs of choice to reduce anginal symptoms and syncopal episodes associated with hypertrophic cardiomyopathy. The negative inotropic effects of beta-blockers and calcium channel blockers decrease the myocardial contractility, decreasing obstruction of the outflow tract. Beta-blockers also decrease heart rate and increase ventricular compliance, increasing diastolic filling time and cardiac output. Vasodilators, digitalis, nitrates, and diuretics are contraindicated. Amiodarone may be used to treat ventricular dysrhythmias.

SURGERY

Without definitive treatment, patients with cardiomyopathy develop end-stage heart failure. Cardiac transplant is the definitive treatment for dilated cardiomyopathy. Ventricular assist devices may be used to support cardiac output until a donor heart is available. Transplantation is not a viable option for restrictive cardiomyopathy because transplantation does not eliminate the underlying process causing infiltration or fibrosis, and eventually the transplanted organ is affected as well. See the section on heart failure for more information about cardiac transplantation.

In severely symptomatic patients with obstructive hypertrophic cardiomyopathy, excess muscle may be surgically resected from the aortic valve outflow tract. The septum is incised, and tissue is removed. This procedure provides lasting improvement in about 75% of patients.

An implantable cardioverter–defibrillator (ICD) often is inserted to treat potentially lethal dysrhythmias, reducing the need for antidysrhythmic medications. A dual-chamber pacemaker also may be used to treat hypertrophic cardiomyopathy.

●○● NURSING CARE

Nursing assessment and care for patients with dilated and restrictive cardiomyopathy are similar to those provided to patients with heart failure. Teaching about the disease process and its management is vital. Some degree of activity restriction often is necessary; assist to conserve energy while encouraging self-care. Support coping skills and adaptation to required lifestyle changes. Provide information and support for decision making about cardiac transplantation if that is an option. Discuss the toxic and vasodilator effects of alcohol, and encourage abstinence. See the Nursing Care section for heart failure earlier in this chapter for nursing diagnoses and suggested interventions.

The patient with hypertrophic cardiomyopathy requires care similar to that provided for myocardial ischemia; nitrates and other vasodilators, however, are avoided. If surgery is performed, nursing care is similar to that for any patient undergoing open-heart surgery or cardiac transplant. Discuss the genetic transmission of hypertrophic cardiomyopathy, and suggest screening of close relatives (parents and siblings).

Provide pre- and postoperative care and teaching as appropriate for patients undergoing invasive procedures or surgery for cardiomyopathy.

Nursing diagnoses that may be appropriate for patients with cardiomyopathy include the following:

- *Decreased Cardiac Output* related to impaired left ventricular filling, contractility, or outflow obstruction
- *Fatigue* related to decreased cardiac output
- *Ineffective Breathing Pattern* related to heart failure
- *Fear* related to risk for sudden cardiac death
- *Ineffective Role Performance* related to decreasing cardiac function and activity restrictions
- *Anticipatory Grieving* related to poor prognosis.

Delegating Nursing Care Activities

As appropriate and allowed by the designated duties and responsibilities of unlicensed assistive personnel, the nurse may delegate nursing care activities such as measuring fluid intake and output, collecting vital signs (including orthostatic vital signs), encouraging oral or enteral fluid intake, and ensuring nonpharmacologic skin care.

Continuity of Care

Cardiomyopathies are chronic, progressive disorders generally managed in home and community care settings unless surgery or a transplant is planned or end-stage heart failure develops. When teaching the patient and family for home care, include the following topics:

- Activity restrictions and dietary changes to reduce manifestations and prevent complications
- Prescribed drug regimen, its rationale, intended and possible adverse effects
- The disease process, its expected ultimate outcome, and treatment options
- Cardiac transplantation, including the procedure, the need for lifetime immunosuppression to prevent transplant rejection, and the risks of postoperative infection and long-term immunosuppression
- Symptoms to report to the physician or for which immediate care is needed
- Cardiopulmonary resuscitation procedures and available training sites.

Refer the patient and family for home and social services and counseling as indicated. Provide information about community resources such as support groups or the AHA.

CHAPTER HIGHLIGHTS

- **Heart failure is the most common cardiac disorder, a condition in which the heart is unable to pump effectively to meet the body's need to provide blood and oxygen to the tissues.**
- **Heart failure is due to *impaired myocardial contraction* and is most commonly caused by coronary heart disease and myocardial ischemia or infarct.**
- Heart failure can also occur due to long-standing *excessive workload* of the heart muscle such as in hypertension or valvular disorders.
- When the heart starts to fail, compensatory mechanisms are activated to help maintain tissue perfusion. Although these mechanisms, including increased contractile force, vasoconstriction, sodium and water retention, and remodeling of the heart, effectively maintain cardiac output in the short term, in the long term they hasten deterioration of heart function.
- **Goals of heart failure management are to reduce the workload and improve its function. Medical management includes medication use including ACE inhibitors, beta-blockers, diuretics, and vasodilators to reduce the cardiac workload.**
- As of 2009, the AHA guideline recommendation reflected that digitalis was no longer recommended as a first-line therapy due to the risk for digitalis toxicity outweighing the benefit due to the narrow therapeutic window.
- **Nursing care of the patient with heart failure is primarily supportive and educative, providing the patient and family with the necessary knowledge and resources to manage this chronic condition.**
- Cardiogenic pulmonary edema, a manifestation of severe cardiac decompensation, is a medical emergency, requiring immediate and effective treatment to preserve life. The nurse's role in managing pulmonary edema focuses on supporting respiratory and cardiac function through careful assessment and early intervention, administering prescribed medications, and providing reassurance to the patient and family.
- Inflammatory and infectious processes, such as rheumatic fever, endocarditis, myocarditis, and pericarditis, can affect any layer of the heart. While some, such as myocarditis and pericarditis, typically are mild and self-limiting, others can have long-term effects on cardiac structure and function.
- Processes such as rheumatic heart disease, endocarditis, and congenital conditions can affect the structure and function of the heart valves, resulting in either stenosis (narrowing) of the valve and restricted flow through it, or regurgitation, backflow of blood through a valve that does not fully close. The mitral and aortic valves are commonly affected due to the higher pressures and increased workload of the left side of the heart.
- Valve disorders may be mild, producing a heart murmur but no functional impairment for the patient, or severe, causing symptoms of heart failure even at rest. Repair or replacement of the valve may ultimately be required.
- Cardiomyopathies affect the heart muscle and its ability to stretch during filling and to contract effectively. Dilated cardiomyopathy, the most common type, is progressive, ultimately necessitating heart transplant. Hypertrophic cardiomyopathy affects both ventricular filling and outflow through the aortic valve. Surgical resection of excess tissue may relieve its manifestations.

TEST YOURSELF NCLEX-RN® REVIEW

1. A patient with heart failure has an ejection fraction of 25%. What does this information indicate to the nurse about the patient's health status?
   1. Ventricular function is severely impaired.
   2. Cardiac output is greater than normal, which overtaxes the heart.
   3. The amount of blood being ejected from the ventricles is within normal limits.
   4. Twenty-five percent of the blood entering the ventricle remains in the ventricle after systole.

2. A patient admitted 24 hours previously with heart failure has lost 1 kg (2.2 lb) of weight, has a heart rate of 88, which was 105 on admission, and now has crackles only in the bases of the lungs. How should the nurse interpret these assessment findings?
   1. More aggressive treatment is needed.
   2. The patient's condition is unchanged from admission.
   3. The treatment regimen is achieving the desired effect.
   4. No further treatment is required at this time because the failure has resolved.

3. A patient is diagnosed with left ventricular failure. Which findings should the nurse recognize as being consistent with this diagnosis? (Select all that apply.)
   1. fatigue
   2. substernal chest pain during exercise
   3. 5 cm jugular vein distention at 30 degrees
   4. bilateral inspiratory crackles to midscapulae
   5. complaints of shortness of breath with minimal exertion

4. The nurse is caring for a patient undergoing pulmonary artery pressure monitoring. What should the nurse include when caring for this patient? (Select all that apply.)
   1. Maintain flush solution flow by gravity.
   2. Calibrate and level the system every shift.
   3. Secure the intravenous line to the bed linens.
   4. Change tubing to the insertion site every 72 hours.
   5. Report waveform dampening during wedge pressure measurements.

5. A patient experiencing acute pulmonary edema is prescribed morphine sulfate 2 to 5 mg IV as needed for pain and dyspnea. What action should the nurse take with this prescribed medication?
   1. Administer the drug as ordered, monitoring respiratory status.
   2. Withhold the drug until the patient's respiratory status improves.
   3. Question the order because no time intervals have been specified.
   4. Administer the drug only when the patient complains of chest pain.

6. The nurse notes a grating heart sound when auscultating the apical pulse of a patient with pericarditis. What should the nurse do with this assessment data?
   1. Obtain an electrocardiogram.
   2. Initiate resuscitation measures.
   3. Immediately notify the physician.
   4. Note the finding in the patient's medical record.

7. The nurse is planning care for a patient with acute infective endocarditis. What would be an appropriate goal of nursing care for this patient?
   1. Resume usual activities within 1 week of treatment.
   2. Relate the benign and self-limiting nature of the disease.
   3. Consider cardiac transplantation as a viable treatment option.
   4. State the importance of continuing intravenous antibiotic therapy as ordered.
8. The nurse is assessing heart sounds of a patient scheduled for mitral valve replacement surgery. Which sound should the nurse expect to auscultate in this patient?
   1. cardiac heave
   2. muffled heart sounds
   3. S_3 and S_4 heart sounds
   4. diastolic murmur heard at the apex
9. A patient considering heart valve replacement asks if a biologic or mechanical valve is better to use. How should the nurse respond to the patient?
   1. Biologic valves tend to be more durable than mechanical valves.
   2. The need to take drugs to prevent rejection of biologic tissue is a major consideration.
   3. Clotting is a risk with mechanical valves, necessitating anticoagulant drug therapy after insertion.
   4. Endocarditis is a risk following valve replacement that is more easily treated with mechanical valves.
10. The parents of a young athlete who collapsed and died due to hypertrophic cardiomyopathy ask how it is possible that their son had no symptoms of this disorder before experiencing sudden cardiac death. How should the nurse respond to the parents?
    1. "It is likely that your son had symptoms of the disorder before he died, but he may not have thought them important enough to tell someone about."
    2. "In this type of cardiomyopathy, the ventricle does not fill normally. During exercise, the heart may not be able to meet the body's needs for blood and oxygen."
    3. "Cardiomyopathy results in destruction and scarring of cardiac muscle cells. As a result, the ventricle may rupture during strenuous exercise, leading to sudden death."
    4. "Exercise causes the heart to contract more forcefully, and can lead to changes in the heart's rhythm or the outflow of blood from the heart in people with hypertrophic cardiomyopathy."

32 Nursing Care of Patients with Vascular and Lymphatic Disorders

LEARNING OUTCOMES

1. Compare and contrast the manifestations and effects of disorders affecting large and small vessels, arteries, and veins.
2. Explain risk factors for and measures to prevent peripheral vascular disorders and their complications.
3. Explain the nursing implications for medications and other interprofessional treatments used for patients with peripheral vascular disorders.
4. Describe preoperative and postoperative nursing care of patients having vascular surgery.
5. Relate the manifestations and diagnostic test results to the etiology and pathophysiology of common peripheral vascular and lymphatic disorders.

CLINICAL COMPETENCIES

1. Assess patients with peripheral vascular disorders, using data to select and prioritize appropriate nursing diagnoses and identify desired outcomes of care.
2. Identify the effects of peripheral vascular disorders on the functional health status of assigned patients.
3. Use research and an evidence-based plan to provide individualized care for patients with peripheral vascular disorders.
4. Collaborate with the interprofessional care team in planning and providing care for patients with peripheral vascular disorders.
5. Safely and knowledgably administer medications and prescribed treatments for patients with peripheral vascular disorders.
6. Provide patient and family teaching to promote, maintain, and restore health in patients with common peripheral vascular disorders.

MAJOR CHAPTER CONCEPTS

- Hypertension, blood pressure of 140/90 mmHg or higher with no clearly identified cause, rarely causes symptoms but is a major risk factor for coronary heart disease, heart failure, stroke, and renal insufficiency.
- Aneurysms, abnormal dilation of a blood vessel, commonly affect the aorta and the iliac arteries, particularly in older men.
- Peripheral vascular disease, obstruction or occlusion of peripheral arteries by atherosclerotic plaque, is common and a leading cause of disability and amputation.
- Venous thrombosis, particularly of the deep veins of the legs and pelvis, develop as a result of venous stasis, blood vessel damage, and increased coagulability of the blood.
- Lymphadenopathy (enlarged lymph nodes), lymphangitis (inflammation of the lymph vessels), and lymphedema (extremity edema due to accumulation of lymph) are the most common disorders affecting the lymph system.

KEY TERMS

aneurysm, *980*

varicose veins, *1005*
vasoconstriction, *987*
vasodilation, *987*
venous thrombosis, *997*

The major processes that interfere with peripheral blood flow and that of lymphatic fluid include constriction, obstruction, inflammation, and vasospasm. These conditions lead to disorders of blood pressure regulation, aortic structure, peripheral artery function, venous circulation, and lymphatic circulation.

A holistic approach is important when caring for patients with disorders of the peripheral vascular and lymphatic systems. The focus of care is on teaching long-term care measures, pain relief, improving peripheral blood and lymphatic circulation, preventing tissue damage, and promoting healing. The prescribed treatment may have emotional, social, and economic effects on the patient and family.

Disorders of Blood Pressure Regulation

Blood flows through the circulatory system from areas of higher pressure to areas of lower pressure. The amount of pressure in any portion of the vascular system is affected by a number of factors, including blood volume, vascular resistance, and cardiac output. The **blood pressure (BP)** is the tension or pressure exerted by blood against arterial walls. A certain amount of pressure within the system is necessary to maintain open vessels, capillary perfusion, and oxygenation of all body tissues. Excess pressure, however, has harmful effects, increasing the workload of the heart, altering the structure of the vessels, and affecting sensitive body tissues such as the kidneys, eyes, and central nervous system.

This section focuses on **hypertension**, or excess pressure in the arterial portion of systemic circulation. Excessively low blood pressure, *hypotension*, is discussed in the shock section of Chapter 11. Altered pulmonary vascular pressures are discussed in Chapter 37.

Physiology Review

Blood flow through the circulatory system requires *sufficient blood volume* to fill the blood vessels and *pressure differences* within the system that allow blood to move forward. The arterial, or supply side of the circulation, has relatively high pressures created by the thick elastic walls of the arteries and arterioles. The venous, or return side of the system, on the other hand, is a low-pressure system of thin-walled, distensible veins. Blood flows through the capillaries linking these two systems from the higher pressure arterial side to the lower pressure venous side.

The arterial blood pressure is created by the ejection of blood from the heart during systole (*cardiac output* or *CO*) and the tension, or resistance to blood flow, created by the elastic arterial walls (*systemic vascular resistance* or *SVR*). The blood pressure rises as the heart contracts during systole, ejecting its blood. This pressure wave, or the **systolic blood pressure**, is felt as the peripheral pulse and heard as the Korotkoff's sounds during blood pressure measurement. In healthy adults the average systolic pressure is less than 120 mmHg. During diastole, or cardiac relaxation and filling, elastic arterial walls maintain a minimum pressure, the **diastolic blood pressure**, to maintain blood flow through the capillary beds. The average diastolic pressure in a healthy adult is less than 80 mmHg. The difference between the systolic and diastolic pressure, normally about 40 mmHg, is known as the **pulse pressure**. The **mean arterial pressure (MAP)** is the average pressure in the arterial circulation throughout the cardiac cycle. It can be calculated using the formula [systolic BP + 2 (diastolic BP)] / 3.

FAST FACTS

- Cardiac output and systemic (or peripheral) vascular resistance are the primary factors that determine blood pressure.
- A decrease in cardiac output (e.g., due to hemorrhage) or decreased peripheral vascular resistance (e.g., systemic vasodilation) causes the blood pressure to fall.

Increased cardiac output (e.g., during exercise) or increased peripheral vascular resistance (e.g., vasoconstriction due to drug administration) cause the blood pressure to rise. Cardiac output is determined by the blood volume and the ability of the ventricles to fill and effectively pump that blood. A number of factors contribute to systemic vascular resistance, including vessel length, blood viscosity, and vessel diameter and distensibility (compliance). While vessel length and blood viscosity remain relatively constant, vessel diameter and compliance are subject to normal regulatory activities and disease.

The arterioles normally determine the SVR as their diameter changes in response to a variety of stimuli:

- *Sympathetic nervous system (SNS)* stimulation. Baroreceptors in the aortic arch and carotid sinus signal the SNS via the cardiovascular control center in the medulla when the MAP changes. A drop in MAP stimulates the SNS, increasing the heart rate, cardiac output, and constricting arterioles (except in skeletal muscle). As a result, BP rises. A rise in MAP has the opposite effect, decreasing the heart rate and cardiac output, and causing arteriolar vasodilation.
- *Circulating epinephrine* and *norepinephrine* from the adrenal cortex (e.g., the fight-or-flight response) have the same effect as SNS stimulation.
- The *renin–angiotensin–aldosterone system* responds to renal perfusion. A drop in renal perfusion stimulates renin release. Renin converts angiotensinogen to angiotensin I, which is subsequently converted to angiotensin II in the lungs by angiotensin-converting enzyme (ACE). Angiotensin II is a potent vasoconstrictor. It also promotes sodium and water retention both directly and by stimulating the adrenal medulla to release aldosterone. Both SVR and CO increase, raising BP.
- *Atrial natriuretic peptide* is released from atrial cells in response to stretching by excess blood volume. It promotes vasodilation and sodium and water excretion, lowering BP.
- *Adrenomedullin* is a peptide synthesized and released by endothelial and smooth muscle cells in blood vessels. It is a potent vasodilator.

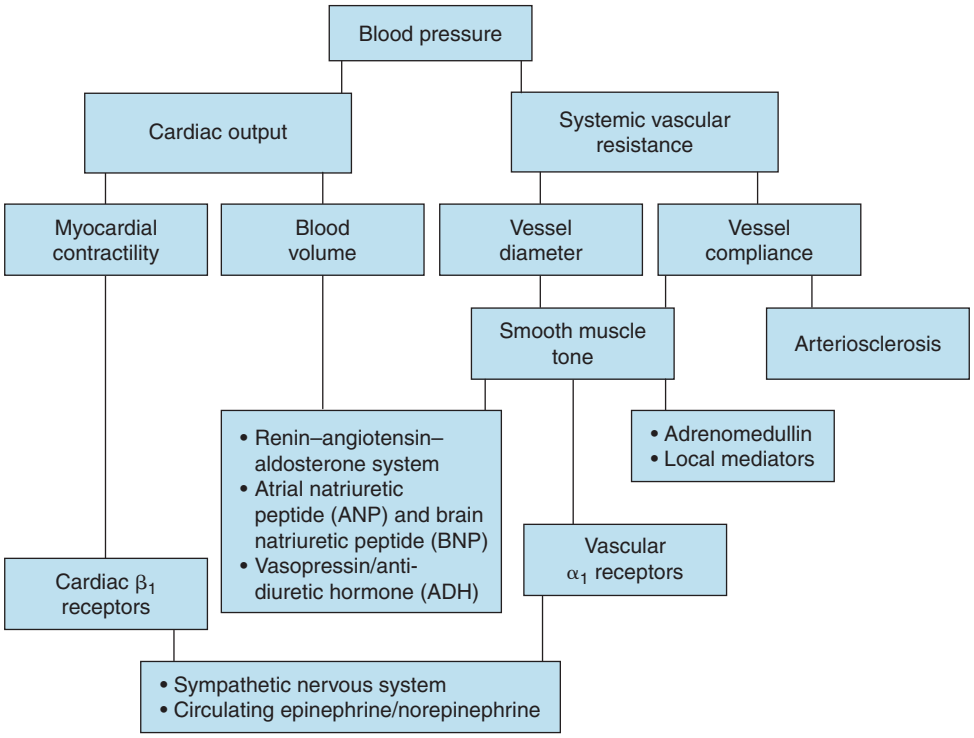

Figure 32–1 ■ Factors affecting blood pressure.

- *Vasopressin* or *antidiuretic hormone* (from the posterior pituitary gland) promotes water retention and vasoconstriction, raising BP.
- *Local factors* such as inflammatory mediators and various metabolites can promote vasodilation, affecting BP.

In addition to the preceding stimuli, the primary factor affecting vessel compliance is the extent of arteriosclerosis (hardening of the arteries) and atherosclerosis (plaque accumulation). Figure 32–1 ■ summarizes the interrelationships of major factors regulating blood pressure.

FAST FACTS

- Sympathetic nervous system stimulation, epinephrine and norepinephrine, and the hormones angiotensin II and vasopressin (antidiuretic hormone or ADH) are *vasoconstrictors*, increasing the blood pressure.
- Parasympathetic nervous system stimulation and the hormones atrial natriuretic peptide and adrenomedullin are *vasodilators*, decreasing the blood pressure.
- The hormones aldosterone and ADH promote sodium and water retention, increasing the blood pressure.

THE PATIENT WITH PRIMARY HYPERTENSION

Primary hypertension, also known as *essential hypertension*, is a persistently elevated systemic blood pressure. One in three, or 73 million, individuals in the United States have hypertension (American Heart Association [AHA], 2013). More than 90% of these have primary hypertension, which has no identified cause.

Hypertension is defined as systolic blood pressure of 140 mmHg or higher, or diastolic pressure of 90 mmHg or higher, based on the average of three or more readings taken on separate occasions. Exceptions include patients being treated for hypertension and an initial reading of a systolic pressure of 210 mmHg or higher and/or a diastolic blood pressure of 120 mmHg or higher. Table 32–1 identifies classifications of blood pressure for adults ages 18 and older as defined by the Joint National Committee.

Hypertension is an important public health issue: Although it rarely causes symptoms or noticeably limits the patient's functional health, hypertension is a major risk factor for coronary heart disease, heart failure, stroke, and renal failure. Hypertension and its consequences are not unique to the United States. The World Health Organization identifies blood pressure above optimal levels (a systolic BP $>$ 115 mmHg) as responsible for 62% of cerebrovascular disease and 49% of ischemic heart disease worldwide.

The identification and treatment of hypertension in the United States has improved significantly in the past 25 years. It is estimated that about 33% of U.S. adults older than 20 years of age have hypertension. About 82% of adults with hypertension are aware that they have it. There is a gap between knowledge of diagnosis and adequate

TABLE 32–1 Classification of Blood Pressure for Adults*

Category	Systolic (mmHg)		Diastolic (mmHg)
Normal	< 120	and	< 80
Prehypertension	120–139	or	80–89
Hypertension‡			
Stage 1	140–159	or	90–99
Stage 2	≥ 160	or	≥ 100

*When systolic and diastolic blood pressures fall into different categories, the higher category is used to classify blood pressure status.

‡Based on the average of two or more readings taken at each of two or more visits after an initial screening.

management; 75% of people with known hypertension are under current treatment, but only 53% of those have effective blood pressure control (AHA, 2013).

Pathophysiology

Primary hypertension is thought to develop from complex interactions among factors that regulate cardiac output and systemic vascular resistance. These interactions may include the following:

- Excess sympathetic nervous system with overstimulation of α- and β-adrenergic receptors, resulting in vasoconstriction and increased cardiac output.
- Altered function of the renin–angiotensin–aldosterone system (RAAS) and its responsiveness to factors such as sodium intake and overall fluid volume. The RAAS affects vasomotor tone and salt and water excretion. Chronically high levels of angiotensin II lead to arteriolar remodeling, which permanently increases SVR. In approximately 20% of people with primary hypertension, renin levels are lower than normal. Increased sodium intake increases the blood pressure in these patients. Low plasma renin levels are more commonly seen in African Americans than in Whites. Another 15% of patients with hypertension have higher than normal plasma renin levels. For these patients, salt intake has less of an effect on blood pressure (Huether & McCance, 2011). Most people with hypertension have normal levels of renin activity.
- Other chemical mediators of vasomotor tone and blood volume such as atrial natriuretic peptide (factor) play a role by affecting vasomotor tone and sodium and water excretion. Vascular endothelium itself produces hormones (*endothelins*) that also affect vasomotor tone. Endothelin-1 is a potent vasoconstrictor (Huether & McCance, 2011).
- The interaction between insulin resistance, hyperinsulinemia, and endothelial function may be a primary cause of hypertension. Excess insulin has several effects that potentially contribute to hypertension: (1) sodium retention by the kidneys, (2) increased sympathetic nervous system activity, (3) hypertrophy of vascular smooth muscle, and (4) changes in ion transport across cell membranes (Huether & McCance, 2011).

The result is sustained increases in blood volume and peripheral resistance. The cardiovascular system adapts to increased blood volume by increasing cardiac output. Autoregulatory mechanisms in the systemic arteries react to the increased volume, causing vasoconstriction. The increased systemic vascular resistance causes hypertension.

It appears unlikely that one single cause and pathologic process will be found to account for essential hypertension. Increasingly, evidence points to hypertension as a diverse group of pathophysiologic mechanisms resulting in the common manifestation of elevated blood pressure.

Manifestations

The early stages of primary hypertension typically are asymptomatic, marked only by elevated blood pressure. Blood pressure elevations are initially transient but eventually become permanent. When symptoms do appear, they are usually vague. Headache, usually in the back of the head and neck, may be present on awakening, subsiding during the day. Other symptoms result from target organ damage, and may include nocturia, confusion, nausea and vomiting, and visual disturbances. Examination of the retina of the eye may reveal narrowed arterioles, hemorrhages, exudates, and *papilledema* (swelling of the optic nerve).

Complications

Sustained hypertension affects the cardiovascular, neurologic, and renal systems. The rate of atherosclerosis accelerates, increasing the risk for coronary heart disease and stroke. The workload of the left ventricle increases, leading to ventricular hypertrophy, which then increases the risk for coronary heart disease, dysrhythmias, and heart failure. The diastolic blood pressure is a significant cardiovascular risk factor until age 50; the systolic pressure then becomes the more important factor contributing to cardiovascular risk. Most deaths due to hypertension result from coronary heart disease and acute myocardial infarction or heart failure.

Accelerated atherosclerosis associated with hypertension increases the risk for cerebral infarction (stroke). Increased pressure in the cerebral vessels can lead to development of microaneurysms and an increased risk for cerebral hemorrhage. *Hypertensive encephalopathy* may develop. This syndrome is characterized by extremely high blood pressure, altered level of consciousness, increased intracranial pressure, papilledema, and seizures. Its etiology is unclear.

Hypertension can lead to nephrosclerosis and renal insufficiency. Proteinuria and microscopic hematuria develop, as well as signs of chronic renal failure. African Americans experience hypertensive kidney disease more frequently than Whites.

Incidence and Risk Factors

Hypertension primarily affects middle-age and older adults: More than 50% of people ages 60 to 74 and about 75% of those ages 75 and older are hypertensive (AHA, 2013). An age-related increase in the systolic blood pressure is the primary factor leading to the high incidence of hypertension in older adults. Unlike the diastolic blood pressure, which tends to rise until approximately age 50, then level off, the systolic blood pressure continues to rise with aging.

The prevalence of hypertension is significantly higher in Blacks than in Whites and Hispanics. Nearly 44% of Black adults are hypertensive, with Black women having a higher incidence than Black men. Less than 34% of adult White and Hispanic people are affected. In Whites and Hispanics, more males than females are hypertensive; in Blacks, more women than men are affected (AHA, 2013).

FAST FACTS

- About one-third of the adult population in the United States has hypertension.
- The prevalence of hypertension is highest in African American females and lowest in people of Asian ancestry.
- The prevalence of hypertension is higher among people who live in the southeastern United States.
- Up until age 45, more men than women are affected by hypertension. The gender distribution then becomes similar between ages 45 and 64; after that, it affects more women than men.
- Hypertension increases the risk of stroke to about four times that of people with normal blood pressure, and the risk for heart failure by two to three times that of people with normal blood pressure.

Source: (AHA, 2013).

BOX 32–1 Factors Contributing to Hypertension

MODIFIABLE FACTORS
- High sodium intake
- Low potassium, calcium, and magnesium intake
- Obesity
- Excess alcohol consumption
- Insulin resistance

NONMODIFIABLE FACTORS
- Genetic factors
- Family history
- Age
- Race

A number of risk factors have been identified for primary hypertension (Box 32–1). Genetics plays a role, as do environmental factors.

- *Family history.* Studies show a genetic link in up to 40% of people with primary hypertension (Huether & McCance, 2011). Genes involved in the RAAS and others that affect vascular tone, salt and water transportation in the kidney, obesity, and insulin resistance are likely involved in the development of hypertension, although no consistent genetic linkages have been found.
- *Age.* The incidence of hypertension rises with increasing age. Aging affects baroreceptors involved in blood pressure regulation as well as arterial compliance. As the arteries become less compliant, pressure within the vessels increases. This is often most apparent as a gradual increase in the systolic pressure with aging. See the Nursing Care of the Older Adult feature on this page.
- *Race.* Primary hypertension is more common and more severe in Blacks than in people of other ethnic backgrounds (see the accompanying Focus on Cultural Diversity box). It also tends to develop at an earlier age, and is associated with more cardiovascular and renal damage. More African Americans with hypertension have low renin levels and altered renal excretion of sodium at normal blood pressure levels than other ethnicities. This genetic tendency to conserve salt may have developed as an adaptation to working in a warm environment, when salt and water conservation are beneficial (Huether & McCance, 2011).
- *Mineral intake.* High sodium intake often is associated with fluid retention. Hypertension related to sodium intake involves a number of different physiologic mechanisms, including the RAAS, nitric oxide, catecholamines, endothelin, and atrial natriuretic peptide. Low potassium, calcium, and magnesium intakes contribute to hypertension by unknown mechanisms. The ratio of sodium to potassium intake appears to play a role, possibly through the effects of increased potassium intake on sodium excretion. Potassium promotes vasodilation by reducing responses to catecholamines and angiotensin II. Calcium also has a vasodilator effect. Although magnesium has been shown to reduce the blood pressure, its mechanism of action is unclear (Huether & McCance, 2011).
- *Obesity.* Central obesity (fat cell deposits in the abdomen), determined by an increased waist-to-hip ratio, has a stronger correlation with hypertension than body mass index or skinfold thickness. Although a clear correlation exists between obesity and hypertension, the relationship may be one common cause: Genetic factors appear to play a role in the common triad of obesity, hypertension, and insulin resistance.

FOCUS ON CULTURAL DIVERSITY

Hypertension in African Americans

- The prevalence of hypertension among Blacks living in the United States is among the highest in the world: In Black adults, 41.8% of males and 45.4% of females are hypertensive.
- African Americans with the highest risk for hypertension tend to be the following:
  - Middle age or older
  - Less educated
  - Overweight or obese
  - Physically inactive
  - Affected by diabetes.

Source: (AHA, 2013).

- *Insulin resistance.* Insulin resistance with resulting hyperinsulinemia is linked with hypertension by its effects on the sympathetic nervous system, vascular smooth muscle, renal regulation of sodium and water, and changes in ion transport across cell membranes. Insulin resistance may be a genetic or an acquired trait. Although more commonly seen in obese individuals, insulin resistance also has been found in people of normal weight.
- *Excess alcohol consumption.* Regular consumption of three or more drinks a day increases the risk of hypertension. Decreasing or discontinuing alcohol consumption reduces the blood pressure, particularly systolic readings. Lifestyle factors associated with excessive alcohol intake (obesity and lack of exercise) may contribute to hypertension as well.
- *Stress.* Physical and emotional stress cause transient elevations of blood pressure, but the role of stress in primary hypertension is less clear. Blood pressure normally fluctuates throughout the day,

NURSING CARE OF THE OLDER ADULT

Hypertension

Controlling high blood pressure is as important in the older adult as in younger adults. In the United States, the lifetime risk of hypertension is about 90% in men and women who live to age 80 to 85 (AHA, 2013). Systolic hypertension is common, as is an elevated pulse pressure (systolic BP minus diastolic BP), indicating decreased compliance of large arteries.

The Framingham Heart Study shows that cardiovascular deaths are two to five times more common in older adults with isolated systolic hypertension than in people with normal blood pressures. Stroke is more common in older adults with systolic hypertension. These findings appear to relate to changes in blood vessels associated with aging: decreased compliance and decreased baroreceptor sensitivity. Decreased compliance impairs the ability of the vessels to expand and contract with varying amounts of blood, increasing peripheral vascular resistance and decreasing renal blood flow.

To obtain accurate blood pressure readings for older patients, slightly different procedures may be required. Palpation of the artery during cuff inflation is recommended to prevent inaccurate systolic readings due to an auscultatory gap, present in many older adults. The reflexes that maintain blood pressure during position changes diminish with aging. Allow the older patient to sit upright or stand for 2 to 5 minutes before evaluating the blood pressure for true orthostatic readings.

Reference: Framingham Heart Study. (2014). Home Page. Retrieved from http://www.framinghamheartstudy.org/.

increasing with activity, discomfort, or emotional responses such as anger. Frequent or continued stress may cause vascular smooth muscle hypertrophy or affect central integrative pathways of the brain.

●○● INTERPROFESSIONAL CARE

Hypertension management focuses on reducing the blood pressure to less than 140 mmHg systolic and 90 mmHg diastolic. The ultimate goal of hypertension management is to reduce cardiovascular and renal morbidity and mortality. The risk of cardiovascular complications (coronary heart disease, heart failure, stroke) decreases when the average blood pressure is less than 140/90 mmHg; when the patient also has diabetes or renal disease, the treatment goal is a blood pressure less than 130/80 mmHg. It now is recognized that most people with hypertension will require a combination of two or more drugs along with lifestyle changes to achieve recommended blood pressure levels (James et al., 2014). Although there is no cure for hypertension, it can be controlled. Figure 32–2 ■ shows the updated 2014 recommended algorithm for hypertension management.

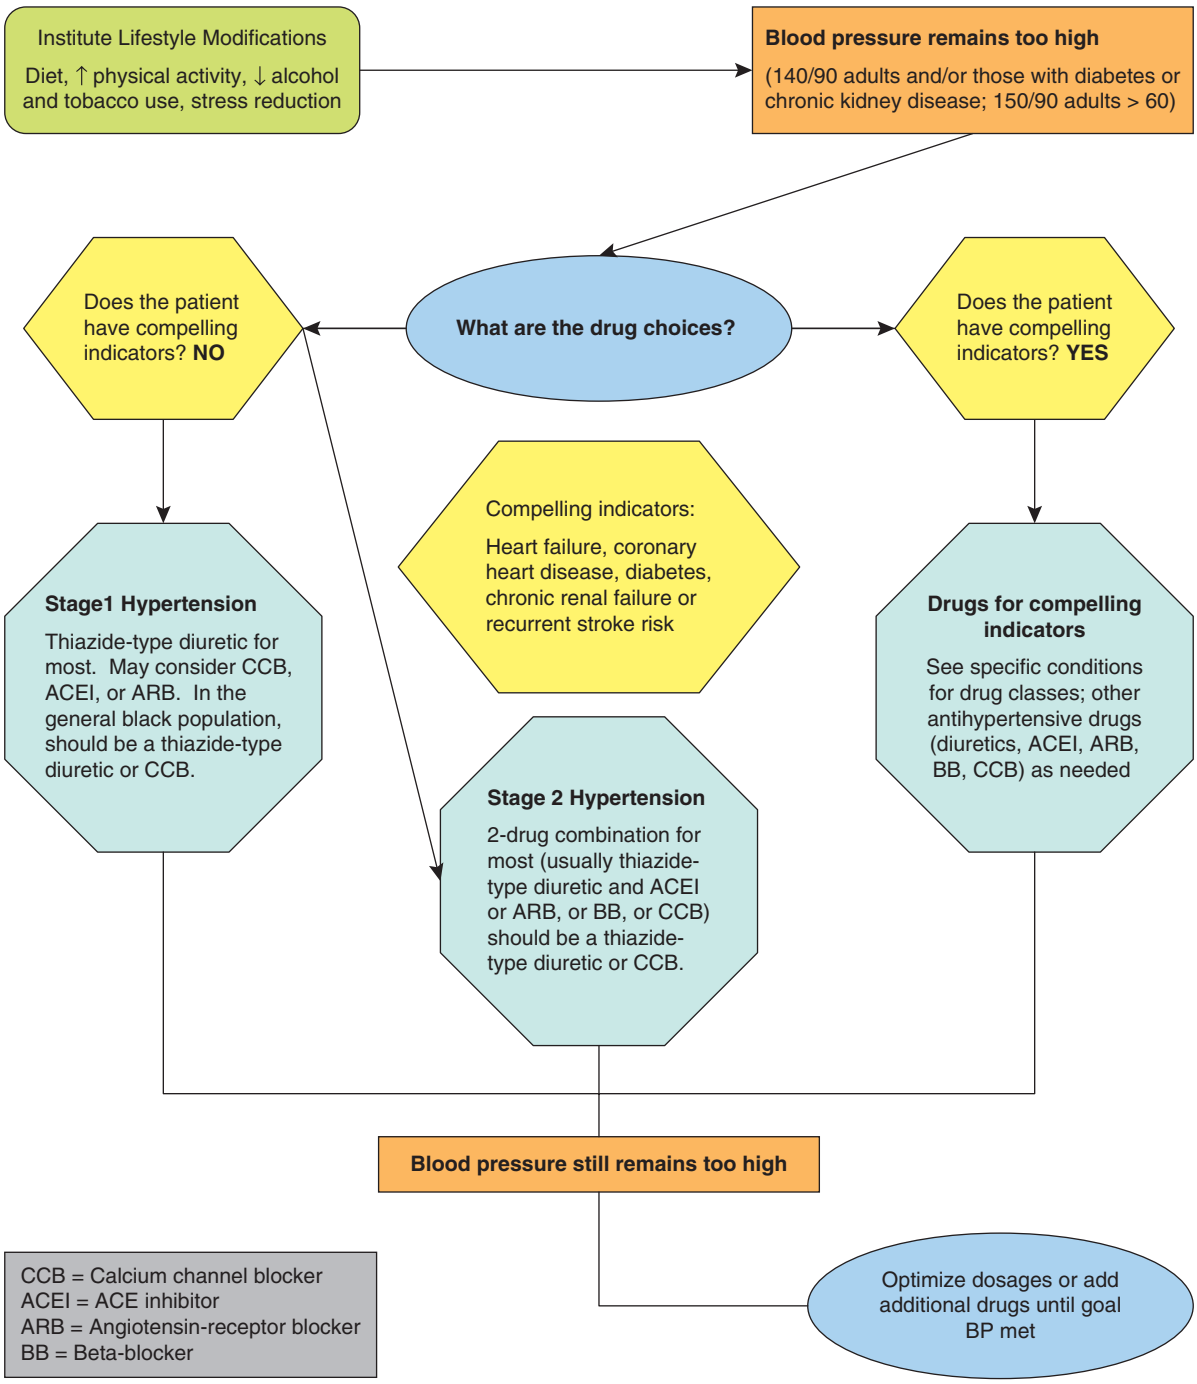

Figure 32–2 ■ Algorithm for treating hypertension.
Source: Adapted from James et al. (2014).

DIAGNOSIS

The patient with hypertension is evaluated for the presence of identifiable causes of hypertension, cardiovascular risk factors, and the presence or absence of target organ damage (heart, brain, kidneys, peripheral vascular systems, and retina of the eye). Before treatment is started, the following diagnostic tests are performed:

- Electrocardiogram (ECG)
- Urinalysis
- Blood glucose
- Hematocrit
- Serum potassium, creatinine, and calcium
- Cholesterol and lipoprotein profile, including high-density lipoprotein (HDL), low-density lipoprotein (LDL), and triglycerides.

Additional tests that may be done include urinary albumin excretion, evaluation of the glomerular filtration rate (such as the creatinine clearance), and tests for emerging cardiovascular risk factors such as C-reactive protein and homocystine levels.

LIFESTYLE MODIFICATIONS

Lifestyle modifications are recommended for all patients whose blood pressure falls within the prehypertension range (120–139/80–89 mmHg) and everyone with intermittent or sustained hypertension. These modifications include weight loss, dietary changes, restricted alcohol use and cigarette smoking, increased physical activity, and stress reduction (Box 32–2).

DIET Dietary approaches to managing hypertension focus on reducing sodium intake, maintaining adequate potassium and calcium intakes, and reducing total and saturated fat intake. A mild to moderate sodium restriction (no added salt) lowers blood pressure and potentiates the effect of antihypertensive drugs for most hypertensive patients. The DASH (Dietary Approaches to Stop Hypertension) diet has proven beneficial effects in lowering blood pressure. This diet (Box 32–3) focuses on whole foods rather than individual nutrients. It is rich in fruits and vegetables (up to 10 servings per day), and low in total and saturated fats.

Weight loss is recommended for patients who are obese. Loss of as little as 4.5 kg (10 lb) reduces blood pressure in many people. A balanced diet such as the DASH diet is recommended for weight loss.

PHYSICAL ACTIVITY Regular exercise (such as walking, cycling, jogging, or swimming) reduces blood pressure and contributes to weight loss, stress reduction, and feelings of overall well-being. Previously sedentary patients are encouraged to engage in aerobic exercise for 30 to 45 minutes per day most days of the week (5 to 6 days). Isometric exercise (such as weight training) may not be appropriate, because it can raise the systolic blood pressure.

BOX 32–2 Lifestyle Modifications for Hypertension

- Maintain normal body weight; lose weight if overweight.
- Make dietary modifications:
  - Eat a diet rich in fruits, vegetables, and low-fat dairy products.
  - Reduce sodium intake.
  - Reduce intake of cholesterol, total and saturated fat.
- Limit alcohol intake to no more than 1 oz of ethanol (1/2 oz for women and lighter weight people) per day.
- Engage in aerobic exercise for 30 minutes most days of the week (5 to 6).
- Stop smoking.
- Use stress management techniques such as relaxation therapy.

BOX 32–3 DASH Diet Recommendations

- Grains—seven to eight servings per day
- Vegetables—four to five servings per day
- Fruits—four to five servings per day
- Nonfat/low-fat dairy products—two to three servings per day
- Meats, poultry, and fish—two or fewer 3-oz servings per day
- Nuts, seeds, and dry beans—four to five servings per week
- Fats and oils—two to three servings per day
- Sweets—five servings per week (should be low in fat)

ALCOHOL AND TOBACCO USE The recommended alcohol intake for patients with hypertension is no more than 1 oz of ethanol or two drinks per day. A drink is 12 oz of beer, 5 oz of wine, or 1.5 oz of 80-proof whiskey. Women and lighter-weight people should reduce this limit by half. Although alcohol withdrawal may increase blood pressure, this is usually temporary and diminishes as abstinence or restricted intake continues.

Although nicotine is a vasoconstrictor, substantial data linking smoking to hypertension are lacking. A definitive link exists between smoking and heart disease, however. Patients who smoke are strongly urged to quit. Smoking reduces the effect of some antihypertensive medications such as propranolol (Inderal). Smoking cessation aids such as nicotine patches and gum contain lower amounts of nicotine and usually do not raise blood pressure.

STRESS REDUCTION Stress stimulates the sympathetic nervous system, increasing vasoconstriction, systemic vascular resistance, cardiac output, and the blood pressure. Regular, moderate exercise is the treatment of choice for reducing stress in hypertensive patients. Relaxation techniques such as biofeedback, therapeutic touch, yoga, and meditation to relax both mind and body may also lower blood pressure, although their effect has not been proven in hypertension management.

MEDICATIONS

Current pharmacologic treatment of hypertension involves using one or more of the following drug classes: diuretics, beta-adrenergic blockers, centrally acting sympatholytics, vasodilators, angiotensin-converting enzyme (ACE) inhibitors, angiotensin II receptor blockers (ARBs), and calcium channel blockers. For most patients, two or more antihypertensive drugs selected from different drug classes are necessary to achieve effective control. These drug classes have different sites of action (Figure 32–3 ■). Nursing implications for administration of antihypertensive drugs (other than diuretics) are outlined in the Medication Administration feature on page 974.

DRUG CLASSES Diuretics are the preferred treatment for systolic hypertension in older adults. Diuretics are relatively safe and well-tolerated drugs; in addition, most are relatively inexpensive. Thiazide diuretics, such as hydrochlorothiazide (HydroDIURIL), are widely used. In major clinical studies, treatment with a single diuretic

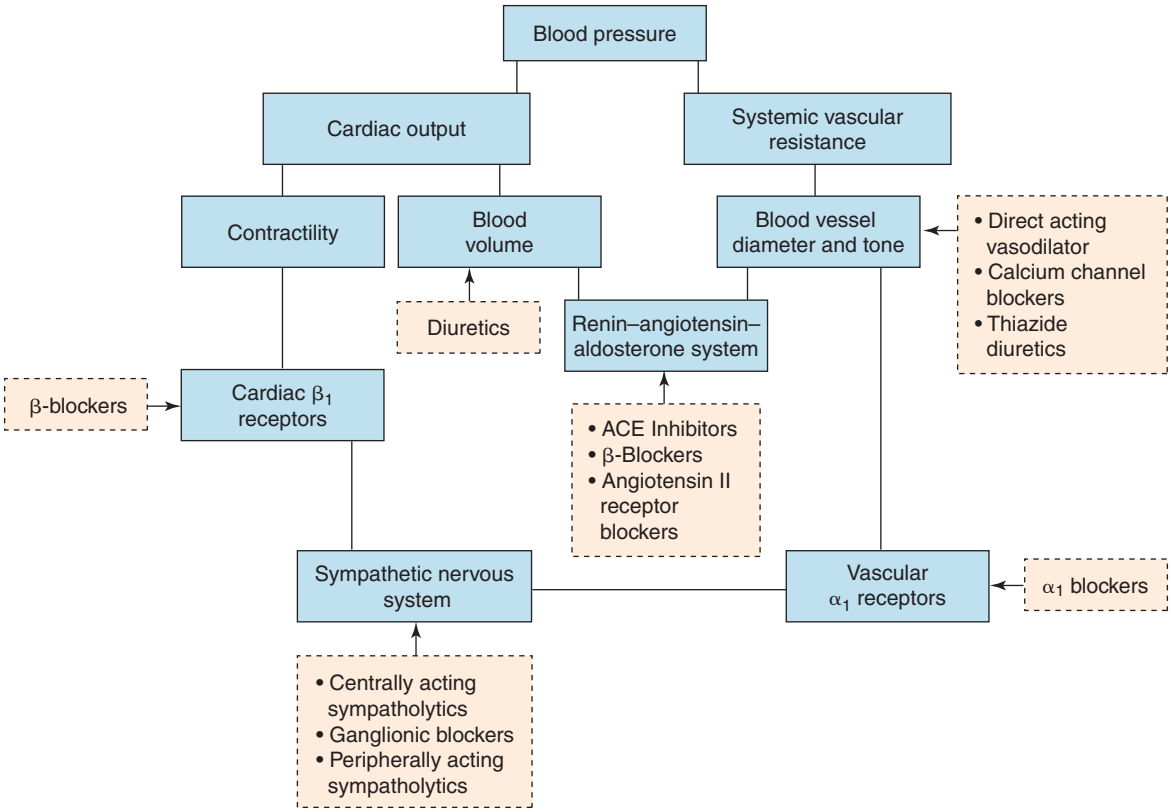

Figure 32–3 ■ Sites of antihypertensive drug action.

controlled blood pressure in about 50% of the patients and reduced hypertension-linked morbidity and mortality related to coronary heart disease. Diuretics control hypertension primarily by preventing tubular reabsorption of sodium, thus promoting sodium and water excretion and reducing blood volume. Thiazide diuretics reduce systemic vascular resistance through an unknown mechanism. Diuretics are particularly effective in Blacks and in patients who are obese, older, or who have increased plasma volume or low renin activity. The adverse effects of diuretics generally are dose related. In addition to hypokalemia, diuretics may affect serum levels of glucose, triglycerides, uric acid, LDLs, and insulin.

Patients with heart failure, coronary heart disease, or diabetes may initially be treated with a beta-blocker. These drugs lower blood pressure, apparently by reducing peripheral vascular resistance. They may reduce the amount of renin released by the kidneys by blocking $beta_1$ receptors in the kidney. Beta-blockers reduce the risk of complications such as heart failure and stroke. They are, however, relatively contraindicated for patients with asthma or chronic obstructive pulmonary disease, because they promote bronchial constriction.

ACE inhibitors and ARBs are commonly used in initial treatment of hypertension, particularly for patients who are diabetic or who have heart failure, a history of MI, or chronic kidney disease. ACE inhibitors block formation of angiotensin II by inhibiting the action of angiotensin-converting enzyme. Angiotensin II is a potent vasoconstrictor that stimulates aldosterone release from the adrenal gland; blocking its action prevents vasoconstriction and sodium and water retention resulting from aldosterone release. ARBs have a very similar effect, although their action is to block angiotensin II receptors, thus preventing their vasoconstrictive and volume expansion effects.

Several drug classes work through their ability to promote vasodilation and reduce peripheral vascular resistance. Alpha-blockers such as prazosin and terazosin block stimulation of $alpha_1$-receptors on arterioles and veins, preventing vasoconstriction. Because of their ability to dilate both arterioles and veins, alpha-blockers can cause significant orthostatic hypotension, particularly following the initial dose.

Calcium channel blockers promote dilation of arterioles, the primary regulators of peripheral vascular resistance. These drugs can cause reflex tachycardia. Some calcium channel blockers, verapamil and diltiazem in particular, also suppress heart function, reducing stroke volume and cardiac output. Reflex tachycardia is minimal with these calcium channel blockers. Direct-acting vasodilators such as hydralazine and minoxidil directly affect the arterioles, reducing peripheral vascular resistance. These drugs have little effect on veins, so the risk of orthostatic hypotension is minimal. They are, however, associated with reflex tachycardia and fluid retention, so rarely are they administered as in single-drug treatment regimens.

Other factors considered in selecting drugs for treating hypertension include demographic characteristics of the patient, concurrent conditions, quality of life, cost, and possible interactions among prescribed drugs. In general, diuretics and calcium channel blockers are more effective for treating hypertension in Blacks than beta-blockers or ACE inhibitors. Beta-blockers are preferred to treat hypertension with concurrent coronary heart disease and angina, but are contraindicated for patients who have asthma or depression. Beta-blockers reduce exercise tolerance and may adversely affect lifestyle for some patients.

DRUG REGIMENS Treatment usually is initiated using a single antihypertensive drug at a low dose. Unless otherwise indicated,

MEDICATION ADMINISTRATION

Antihypertensive Drugs

ALPHA-ADRENERGIC BLOCKERS

doxazosin (Cardura)
prazosin (Minipress)
terazosin (Hytrin)

Alpha-adrenergic blocking agents block alpha-receptors in vascular smooth muscle, decreasing vasomotor tone and vasoconstriction. They also reduce serum levels of LDLs and very low-density lipoproteins (VLDLs). However, vasodilation may cause orthostatic hypotension and reflex stimulation of the heart, resulting in tachycardia and palpitations. A beta-blocker may be ordered to minimize this effect.

Nursing Responsibilities

- Give the first dose at bedtime to minimize risk of fainting (called *first-dose syncope*). If the first dose is given in the daytime (or if the dose is increased), instruct to remain in bed for 3 to 4 hours.
- Assess blood pressure and apical pulse before each dose and as indicated thereafter.

Health Education for the Patient and Family

- There is a risk of fainting after taking the first dose of this drug. Take the drug at bedtime to reduce this risk, and do not drive or engage in other hazardous activities for 12 to 24 hours after the first dose.
- This drug may cause dizziness or light-headedness. Change positions slowly, and sit down if you become dizzy or light-headed.
- Notify your primary care provider if you develop nasal congestion or impotence while taking this drug.
- Notify your primary care provider before discontinuing this medication.

ANGIOTENSIN-CONVERTING ENZYME (ACE) INHIBITORS

Benazepril (Lotensin)
Moexipril (Univasc)
Captopril (Capoten)
Perindopril (Aceon)
Enalapril (Vasotec)
Quinapril (Accupril)
Fosinopril (Monopril)
Ramipril (Altace)
Lisinopril (Prinivil, Zestril)
Trandolapril (Mavik)

Angiotensin II Receptor Blockers (ARBs)

Azilsartan (Edarbi)
Losartan (Cozaar)
Candesartan (Atacand)
Olmesartan (Benicar)
Eprosartan (Teveten)
Telmisartan (Micardis)
Irbesartan (Avapro)
Valsartan (Diovan)

The ACE inhibitors lower blood pressure by preventing conversion of angiotensin I to angiotensin II. This in turn prevents vasoconstriction and sodium and water retention. ARBs have the same effect, but they act by blocking the effect of angiotensin II on receptors. Both ACE inhibitors and ARBs are less effective in Black patients and are contraindicated in pregnancy (Vallerand & Sanoski, 2012). Their primary adverse effects are persistent cough, first-dose hypotension, and hyperkalemia.

Nursing Responsibilities

- Assess blood pressure and WBC before giving the first dose. Monitor blood pressure for 2 hours after the first dose and regularly thereafter.
- Administer PO 1 hour before meals; tablets may be crushed.
- Report changes in WBC or differential, hyperkalemia, or changes in BUN or serum creatinine to the primary care provider.
- Do not administer to patients with renal artery stenosis or who are pregnant.
- Immediately report and treat manifestations of angioedema (giant wheals and edema of the tongue, glottis, and pharynx). Initiate resuscitation measures as needed. Discontinue drug immediately and do not use in the future.

Health Education for the Patient and Family

- Report peripheral edema, signs of infection, or difficulty breathing to your primary care provider.
- Change position (lying to sitting and sitting to standing) slowly to prevent dizziness; sit down if dizziness or light-headedness develops.
- Do not take a potassium supplement or use a potassium-based salt substitute while taking this drug unless prescribed by your healthcare provider.
- Notify your healthcare provider if you become pregnant while taking this drug. Although it is safe early in pregnancy, taking the drug during the second and third trimesters may harm the fetus.

CALCIUM CHANNEL BLOCKERS

Amlodipine (Norvasc)
Nicardipine (Cardene)
Clevidipine (Cleviprex) (IV)
Nifedipine (Procardia)
Diltiazem (Cardizem)
Nisoldipine (Sular)
Felodipine (Plendil)
Verapamil (Isoptin)
Isradipine (DynaCirc)

Calcium channel blockers inhibit the flow of calcium ions across the cell membrane of vascular tissue and cardiac cells. In doing so, they relax arterial smooth muscle, lowering peripheral resistance through vasodilation. Calcium channel blockers can cause reflex tachycardia, and some (e.g., verapamil and diltiazem) may impair cardiac function, worsening heart failure.

Nursing Responsibilities

- Assess blood pressure, apical pulse, and liver and renal function tests prior to giving these drugs.
- Calcium channel blockers may be given orally or intravenously.
- Do not administer verapamil or diltiazem to patients with severe hypotension, sinus, or atrioventricular blocks. Administer with caution to patients also taking digoxin or a beta-blocker.
- Periodically monitor blood pressure and apical pulse during therapy. Promptly report signs of bradycardia, AV block, or heart failure to the healthcare provider.

Health Education for the Patient and Family

- Take blood pressure and pulse daily as taught. Notify your healthcare provider if your pulse is less than 60 bpm or your blood pressure is not within the specified range.
- This drug may cause constipation. Drink six to eight glasses of water each day, and increase fiber in diet.
- Report shortness of breath, weight gain, or swelling in feet or ankles to your primary care provider.

BETA-ADRENERGIC BLOCKING AGENTS

Acebutolol (Sectral)
Nadolol (Corgard)
Atenolol (Tenormin)
Nebivolol (Bystolic)
Betaxolol (Kerlone)
Penbutolol (Levatol)
Bisoprolol (Zebeta)
Pindolol (Visken)
Carteolol (Cartrol)
Propranolol (Inderal)
Esmolol (Brevibloc)
Sotalol (Betapace)
metoprolol tartrate (Lopressor)
Timolol (Blocadren)

MEDICATION ADMINISTRATION (*continued*)

Combined with an alpha-blocker:
carvedilol (Coreg)
labetalol (Normodyne)

Beta-adrenergic blockers are less commonly used as initial therapy to control hypertension (Mann, 2012). Beta-blockers reduce blood pressure by preventing beta-receptor stimulation in the heart, thereby decreasing heart rate and cardiac output. Beta-blockers also interfere with renin release by the kidneys, decreasing the effects of angiotensin and aldosterone. Potential adverse effects of beta-blockers include bronchospasm, fatigue, sleep disturbances, nightmares, bradycardia, heart block, worsening of heart failure, gastrointestinal disturbances, impotence, and increased triglyceride levels.

Nursing Responsibilities
- Before giving initial dose, assess for contraindications to beta-blockers such as asthma, chronic lung disease, bradycardia, or heart block.
- Assess blood pressure and apical pulse before giving dosage; notify primary care provider if vital signs are outside established parameters.
- Report adverse effects such as bradycardia, decreased cardiac output (fatigue, dyspnea with exertion, hypotension, decreased level of consciousness), heart failure, heart block, bronchoconstriction (wheezing, dyspnea), or altered blood glucose levels (in patients with diabetes).
- Carefully monitor responses of the older patient.

Health Education for the Patient and Family
- Monitor blood pressure and pulse daily as instructed.
- Change position (lying to sitting and sitting to standing) slowly to prevent dizziness and possible falls.
- Report effects such as fatigue, lethargy, and impotence to your primary care provider.
- Notify your healthcare provider if you become short of breath or develop a cough or swelling of your extremities.
- If you have diabetes, check blood glucose levels more frequently because hypoglycemia may develop with few symptoms.
- Talk to your primary care provider before taking any over-the-counter medications.
- Carry an adequate supply of the drug when traveling. Do not stop taking this drug without notifying your primary care provider.

CENTRALLY ACTING SYMPATHOLYTICS

clonidine (Catapres)	methyldopa (generic only)
guanfacine (Tenex)	reserpine (generic only)

The centrally acting sympatholytics stimulate the alpha$_2$-receptors in the CNS to suppress sympathetic outflow to the heart and blood vessels. A fall in cardiac output and vasodilation results, reducing blood pressure. Dry mouth and sedation are common adverse effects. Severe reflex hypertension may occur if abruptly discontinued. Clonidine is contraindicated during pregnancy; methyldopa is contraindicated for patients with active liver disease.

Nursing Responsibilities
- Assess for contraindications to therapy. Obtain baseline blood pressure, CBC, Coombs' test, and liver function studies.
- Administer oral doses at bedtime to minimize effects of sedation.
- Methyldopa may be given intravenously for hypertensive emergencies.
- Apply transdermal clonidine patch to dry, hairless area of intact skin on the chest or upper arm. Assess for rash, which indicates allergy, at area of application.
- Promptly report changes in laboratory values to the healthcare provider. Discontinue methyldopa if manifestations of liver dysfunction develop.

Health Education for the Patient and Family
- Relieve dry mouth by sipping water or chewing sugarless gum.
- Take with meals if gastric upset or nausea develops.
- Change position (lying to sitting and sitting to standing) slowly to prevent dizziness and possible falls.
- Do not suddenly discontinue medication or skip doses; this could cause serious hypertension.
- Report mental depression or decreased mental acuity to your healthcare provider.
- Side effects (such as dry mouth, nausea, and dizziness) tend to diminish over time.
- Do not drive a car if the medications cause drowsiness.

VASODILATORS
hydralazine (Apresoline)

Vasodilators reduce blood pressure by relaxing vascular smooth muscle (especially in the arterioles), and decreasing peripheral vascular resistance. These drugs are often prescribed in combination with a diuretic or beta-blocker, because they can cause reflex tachycardia and fluid retention. Because these drugs can have significant toxic effects, they are not routinely used to manage chronic hypertension.

Nursing Responsibilities
- Hydralazine may be given orally or intravenously; minoxidil is given orally.
- Assess blood pressure and pulse before giving the drug and monitor during therapy as indicated. Report tachycardia or hypotension to the healthcare provider.
- Report peripheral edema and manifestations of volume overload and heart failure.
- Immediately report muffled heart sounds or paradoxical pulse as pericardial effusion and possible cardiac tamponade may develop during minoxidil therapy.
- Discontinue hydralazine and report manifestations of a systemic lupus erythematosus–like syndrome: muscle or joint pain, fever, or symptoms of nephritis or pericarditis.

Health Education for the Patient and Family
- Change position (lying to sitting and sitting to standing) slowly to prevent dizziness and possible falls.
- Report muscle, joint aches, and fever to your healthcare provider.
- Headache, palpitations, and rapid pulse may develop but should abate in about 10 days.
- Do not discontinue the medication without talking to your healthcare provider.
- Minoxidil may cause excessive hair growth. Contact your healthcare provider if this becomes troublesome.

Note: Drugs identified in *italics* are among the 200 most commonly prescribed medications in the U.S.

a diuretic is recommended as the initial drug of choice. The dose is slowly increased until optimal blood pressure control is achieved. If the drug does not effectively lower the blood pressure or has troubling side effects, a different drug from another class of antihypertensive medications is substituted. On the other hand, if the drug is tolerated well but has not lowered blood pressure to the desired level, a second drug from another class may be added to the treatment regimen.

Treatment of patients with stage 2 hypertension generally is more aggressive to minimize the risk of myocardial infarction (MI),

heart failure, or stroke. When the average blood pressure is greater than 200/120 mmHg, immediate therapy, and possible hospitalization, is vital.

After a year of effective hypertension control, an effort may be made to reduce the dosage and number of drugs. This is known as *step-down therapy*. It is more successful in patients who have made lifestyle modifications. Careful blood pressure monitoring is necessary during and after step-down therapy, because the blood pressure often rises again to hypertensive levels.

COMPLEMENTARY THERAPIES

Behavioral and mind–body therapies may be helpful for some patients in lowering blood pressure (see the Moving Evidence into Action box). The blood pressure increases in response to physiologic and psychologic stress and anxiety. Mind–body therapies such as yoga and tai chi, meditation, and guided imagery are designed to modify both physiologic and cognitive aspects of the stress response. In a study of older African American men and women with moderate hypertension, transcendental meditation was shown to reduce the blood pressure. Eastern exercises such as yoga and tai chi, which often combine imagery, meditation, and physical exercise, have been shown to reduce SNS activity, blood pressure, and heart and respiratory rates (Okonta, 2012).

●○● NURSING CARE

Health Promotion

Health promotion teaching and activities focus on the modifiable risk factors for hypertension. Advise all patients (as well as children and adolescents) to stop or never start smoking. Discuss the risks of obesity, excess alcohol intake, and a sedentary lifestyle with patients. Encourage all patients to eat a diet rich in fruits and vegetables and low in total and saturated fat. Discuss the potential benefits of following the DASH diet or a similar eating plan. Advise all patients to remain active and engage in aerobic exercise 5 or more days a week. Discuss the stress-reducing benefits of exercise.

Offer blood pressure screening, and refer patients for follow-up as indicated (Table 32–2).

Assessment

See the Manifestations and Interprofessional Care sections for the assessment of the patient with hypertension.

Focused assessment of the patient with hypertension includes the following:

- *Health history:* complaints of morning headache, cervical pain; cardiovascular or central nervous system (CNS) manifestations; history of hypertension, renal disease, diabetes; family history of high blood pressure, heart failure, or kidney disease; current medications
- *Physical assessment:* vital signs including blood pressure in both arms, apical and peripheral pulses; ophthalmologic exam of retinal fundus as appropriate
- *Laboratory data:* serum electrolytes, glucose, and creatinine; cholesterol and lipoprotein profile; urinalysis.

Moving Evidence into Action

The Patient with Primary Hypertension

Standard therapies for hypertension include lifestyle changes and medications. Patients often are advised to reduce stress levels in their lives, but rarely are provided with the tools to do so. Okonta (2012) conducted an integrative review to validate yoga therapy as an effective complementary treatment in the management of hypertension. As part of the systematic assessment for published research, 10 studies were found to meet the criteria of randomized control trials, quasiexperimental studies, and pilot studies that focused on yoga as a complementary intervention in the treatment of hypertension. The review revealed that yoga is a multifunctional exercise modality with numerous benefits including reductions in BP, blood glucose level, cholesterol levels, and body weight. Ongoing nursing and allied medicine research continues with several National Institute of Health–funded studies under way.

Implications for Nursing

Addressing the mind–body interactions related to chronic diseases like hypertension is the role of the nurse practicing in a holistic manner. Yoga has been shown to reduce BP through its ability to modulate the heart rate. Through its meditative component, it is believed to reduce stress. Yoga is gentle for deconditioned patients and for those more acclimated to exercise. Additionally, nurses are in a position to identify patients with prehypertension through blood pressure screening. It is appropriate to suggest mind–body therapies such as yoga to these patients, most of whom do not require medication.

Moving Knowledge into Action

1. This integrative review found that patients with diagnosed hypertension had reductions in BP due to the reduction in heart rate during yoga. Why do you think more benefit was seen in heart rate vs. other physiologic changes?
2. While you are discussing lifestyle modifications and the use of mind–body therapies with a patient with prehypertension, he tells you that he thinks all this is nonsense. How would you respond?

Priorities of Care

Collaborating with the interprofessional team to ensure adequate treatment of the underlying process while providing care that supports the physical and psychologic responses to the disorder is a priority of nursing care.

TABLE 32–2 Recommended Blood Pressure Follow-Up

Category	Blood Pressure (mmHg)	Recommended Follow-Up
Normal	< 120/80	Recheck in 2 years
Prehypertension	120–139/80–89	Recheck in 1 year
Stage 1 hypertension	140–159/90–99	Confirm within 2 months
Stage 2 hypertension	≥ 160/100	Evaluate or refer to care provider within 1 month; for higher pressures (e.g., ≥ 180/110), evaluate or refer to care provider immediately or within 1 week as indicated

Diagnoses, Outcomes, and Interventions

All patients with primary hypertension and their families need significant teaching to manage this chronic condition. Health maintenance is a high-priority problem. Depending on the stage of hypertension and concurrent illnesses, other appropriate nursing diagnoses may include *Imbalanced Nutrition*, *Fluid Volume Excess*, and *Risk for Noncompliance*.

Ineffective Health Maintenance

An unhealthy lifestyle and behaviors can contribute to health problems such as hypertension. When hypertension has been identified, knowledge of the disease and its management is vital for the patient. Willingness to take responsibility for hypertension management is central to effective blood pressure control. Adopting healthy lifestyle changes enhances drug therapy; in some cases, the need for medications may be eliminated or reduced. Because hypertension is often an asymptomatic disease and many antihypertensive drugs have unpleasant side effects, it is vital that the patient understand the chronic progressive nature of the disease and its long-term consequences.

Expected Outcome: Patient will be knowledgeable about management of hypertension as evidenced by being able to describe the components and rationale for the treatment plan.

- Assist with identifying current behaviors that contribute to hypertension. *The patient must first identify contributory behaviors before he or she can change them. Using knowledge of hypertension risk factors, the nurse can help identify behaviors and factors contributing to hypertension that can be changed. Including the family in this process is important to reduce potential sabotage of the patient's efforts to adopt healthier behaviors.*
- Assist in developing a realistic health maintenance plan. *Preparing a health maintenance plan for the patient does little to encourage personal responsibility for health. However, nurses can guide patients in developing realistic goals and expectations for the treatment plan and modifying risk factors such as smoking, exercise, diet, and stress.*
- Help the patient and family identify strengths and weaknesses in maintaining health. *Discussing areas of the health maintenance plan that are working well and those that present difficulties can help to identify necessary changes in the plan and additional strategies for implementing it.*

Risk for Noncompliance

Noncompliance, or failure to follow the identified treatment plan, is a continuing risk for any patient with a chronic disease. Recommended lifestyle changes such as diet, exercise, restricted alcohol intake, stress reduction, and smoking cessation often are difficult to maintain on a continuing basis. In addition, prescribed medications may have undesirable effects, whereas hypertension itself often has no symptoms or noticeable effects.

Expected Outcome: Patient will be in compliance as evidenced by the following treatment plan.

- Inquire about reasons for noncompliance with the recommended treatment plan. Listen openly and without judging. *Nonthreatening discussion of factors contributing to noncompliance validates the patient's self-esteem and partnership in the treatment plan.*
- Assess factors contributing to noncompliance, such as adverse drug effects. Suggest measures to manage adverse effects or, if indicated, contact the primary care provider about possible alternative drugs. *Some adverse effects of antihypertensive drugs, such as gastric upset, light-headedness, or nocturia, may be easily managed by changing the timing of the drug dose. Others, such as fatigue, decreased exercise tolerance, or impotence, may interfere with lifestyle and life roles to the extent that the patient finds them intolerable.*
- Evaluate knowledge of hypertension, its long-term effects, and treatment. Provide additional information and reinforce teaching as needed. *Knowledge increases the sense of control, which increases the likelihood of compliance with treatment.*
- Assist to develop realistic short-term goals for lifestyle changes. *Attempting to lose weight, exercise daily, stop smoking, and dramatically change the diet all at the same time may be overwhelming, leading to a sense of failure. Smaller, gradual changes are more easily incorporated into lifestyle and daily activities, improving compliance.*
- Work with the patient to develop mutual outcomes for the treatment plan. Discuss measures to improve compliance. The patient has absolute control over compliance with the treatment plan. *Demonstrating respect and involving the patient in decision making and planning can improve compliance.*
- Help the patient identify cues and develop reminders (e.g., written notes, a medication box filled weekly) to assist with maintaining a schedule for exercise and medications. *Cues and other devices provide helpful reminders of activities and schedules until they are incorporated into habits.*
- Reassure the patient that relapse into old habits and behaviors is common. Encourage avoiding feelings of guilt associated with relapse, and use the circumstance to renew efforts to comply with treatment. *Guilt and feelings of failure can lead to further noncompliance unless the event is used to identify reasons for noncompliance and ways to prevent it from recurring in the future.*

Imbalanced Nutrition: More Than Body Requirements

The relationship between obesity, excess alcohol intake, and hypertension is well documented. Hypertension is particularly associated with central obesity, identified by waist circumference greater than hip circumference. Although achieving weight loss is difficult and takes a commitment to changing eating and exercise habits, it is possible for most patients to achieve.

Expected Outcomes: If obese, patient will practice weight loss behaviors as evidenced by use of food diaries, selection of a healthy target weight, and following of a consistent exercise program.

- Assess usual daily food intake, and discuss possible contributing factors to excess weight, such as sedentary lifestyle, or using food as a reward or stress reliever. Inquire about diversional activities, exercise patterns, and previous weight reduction efforts (e.g., participation in weight reduction programs or using fad or crash diets). *Assessment data provides clues about contributing factors to obesity, the patient's knowledge base about the relationship between eating and exercise habits and weight, and safe weight loss strategies. This provides direction for further teaching and for developing a realistic weight reduction plan.*
- Mutually determine with the patient a realistic target weight (e.g., loss of 10% of current body weight over a 6-month period). Regularly monitor weight. Encourage a system of nonfood

rewards for achieving small, incremental goals. *Setting weight loss goals helps formalize the process and provides motivation for continued progress. Developing realistic goals may be difficult; unrealistic goals, however, set the patient up for failure. Continuous incremental weight loss provides reassurance that it can be achieved and promotes permanent weight reduction.*

- Refer to a dietitian for information about low-fat, low-calorie foods and eating plans. Focus on changing eating habits as opposed to "following a diet." *Focusing on changing eating habits promotes the sense that low-fat, low-calorie eating patterns should become a part of lifestyle rather than a short-term measure to be endured until the weight loss goal is achieved.*
- Recommend participating in an approved weight loss program such as Weight Watchers, Overeaters Anonymous, or Take Off Pounds Sensibly (TOPS). *Organized weight loss programs provide structure for a balanced weight reduction program, as well as mutual support from others trying to lose weight.*

Excess Fluid Volume

Excess fluid volume often contributes to hypertension by increasing the cardiac output. A number of factors associated with hypertension can cause excess fluid volume, including sodium retention and disruption of the renin-angiotensin-aldosterone system. In addition, some antihypertensive drugs, such as calcium channel blockers and vasodilators, can contribute to excess fluid in the interstitial spaces and peripheral edema.

Expected Outcome: Patient's fluid volume will be normal as evidenced by weight loss and decreases in edema, jugular venous distention, and abdominal distention.

- Monitor blood pressure and other vital signs as indicated: every 1 to 2 hours or more frequently during acute hypertensive states; or once a week or more frequently during initial treatment outside of the hospital setting. *Vital signs are an indicator of fluid balance and the effectiveness of treatment. An elevated blood pressure, pulse, and respiratory rate may indicate fluid retention, whereas orthostatic hypotension and tachycardia may indicate fluid volume deficit.*
- Monitor intake and output, and weigh daily (if in an acute or long-term care facility) or weekly (in the community). *Rapid weight changes (over days) more accurately reflect fluid balance than intake and output records. One liter of fluid weighs 1 kg (2.2 lb). Weight changes and intake and output records help monitor the effects of therapy.*
- Monitor for peripheral edema (sacral edema in the bedridden patient). *Drugs such as vasodilators can cause fluid accumulation in interstitial tissues, leading to peripheral or dependent edema. Adding a diuretic to the treatment plan may be necessary.*
- Refer to a dietitian for teaching about a restricted sodium diet. Discuss the relationship between sodium intake and fluid retention. Provide opportunities to choose low-sodium foods from simulated menus. Support efforts, and reassure that lifestyle changes such as consuming less sodium take time. *Knowledge provides the power to take control of sodium intake. Patience and perseverance are needed to succeed; positive reinforcement of efforts to change long-standing dietary patterns is important.*
- Monitor laboratory values, such as blood urea nitrogen (BUN), urine specific gravity, creatinine, electrolytes, and hematocrit and hemoglobin. Hypertension can alter renal perfusion and function, leading to fluid retention and altered laboratory values. *Changes in BUN and creatinine indicate impaired renal function, whereas changes in hematocrit and hemoglobin often reflect changes in fluid volume.*
- Discuss the importance of adhering to treatment plans such as dietary restrictions and medication schedules. *Understanding the rationale for treatment measures promotes the patient's sense of control and encourages compliance with the treatment regimen.*

Continuity of Care

Effective control of hypertension requires the patient to not only participate in the plan of care, but also to take an active role in managing the disease. Treatment is managed in community settings, with regular visits to a clinic or office to monitor blood pressure and effects of treatment measures. Include the following topics when teaching the patient and family about hypertension:

- Specific lifestyle changes recommended for the patient and suggestions for implementing them. For example, consider the following:
  - Increase activity gradually. Develop a realistic exercise program that is enjoyable and fits into lifestyle. Identify an exercise buddy for additional motivation. Activity and exercise, through a gradual conditioning of muscles and blood vessels, lower blood pressure by reducing peripheral vascular resistance. As the heart becomes conditioned and pumps more efficiently, kidney perfusion improves and intravascular volume falls, further reducing blood pressure. Exercise reduces stress and contributes to weight loss and maintenance. Aerobic exercises, such as walking, jogging, swimming, and cycling, are appropriate; isometric activities (such as weight lifting) should be avoided without healthcare provider approval.
  - Adopt healthy eating patterns, following a low-fat, low-cholesterol, moderate sodium diet that is rich in fruits and vegetables and includes at least two servings of low-fat milk or milk products daily. Do not give up if you slip into old eating habits on occasion; use such occasions to identify ways to avoid future lapses.
  - Stop smoking. Participating in organized smoking cessation programs or using aids such as nicotine patches can help.
  - Use alcohol in moderation if at all, consuming no more than 1.5 oz of hard liquor, 5 to 10 oz of wine, or 12 to 20 oz of beer per day.
  - Use stress-reducing techniques such as meditation, relaxation, deep breathing, and exercise to manage stress. Anger and hostility intensify vasoconstriction; channeling these emotions into more positive responses such as using a change process to modify factors that provoke these emotions can reduce their harmful effects on blood pressure.
- Prescribed medications, their intended effect, dose and timing, interactions, and possible adverse effects. Discuss effects that should be reported to the healthcare provider, and those that can be managed by the patient or that will diminish over time.
- The importance of monitoring blood pressure and regular visits to the primary care provider or hypertension clinic to monitor treatment. During follow-up visits, assess the blood pressure and specific laboratory work (such as serum creatinine, BUN, and/or serum electrolytes) to evaluate the disease and the effects of antihypertensive medications.

Refer the patient to community blood pressure clinics, and to home health services as needed for regular follow-up and reinforcement

CASE STUDY & NURSING CARE PLAN A Patient with Hypertension

Margaret Spezia is a married, 49-year-old Italian American with eight children whose ages range from 3 to 18 years. For the past 2 months, Mrs. Spezia has had frequent morning headaches, and occasional dizziness and blurred vision. At her annual physical examination 1 month ago, her blood pressure was 168/104 and 156/94 mmHg. She was instructed to reduce her fat and cholesterol intake, to avoid using salt at the table, and to start walking for 30 to 45 minutes daily. Mrs. Spezia returns to the clinic for a follow-up.

ASSESSMENT

While escorting Mrs. Spezia to the exam room and obtaining her weight, blood pressure, and history, Lisa Christos, RN, notices that Mrs. Spezia seems restless and upset. Ms. Christos says, "You look upset about something. Is everything OK?" Mrs. Spezia responds, "Well, my head is throbbing, and I'm sort of dizzy. I think I'm just overdoing it and not getting enough rest. You know, raising eight children is a lot of work and expense. I just started working part time so we wouldn't get behind in our bills. I thought the extra money might relieve some of my stress, but I'm not so sure that's really happening. I'm not getting any better and I'm worried that I'll lose my job or become disabled and that my husband won't be able to manage the children by himself. I really need to go home, but first, I want to get rid of this awful headache. Would you please get me a couple of aspirin or something?"

Mrs. Spezia's history shows a steady weight gain during the past 18 years. She has no known family history of hypertension. Physical findings include height 160 cm (63 in.), weight 102 kg (225 lb), T 37.2°C (99°F), P 100 bpm and regular, R 16/min, BP 180/115 (lying), 170/110 (sitting), 165/105 mmHg (standing), average 10-point difference in readings between right and left arm (lower on left). Skin cool and dry, capillary refill 4 seconds right hand, 3 seconds left hand. Mrs. Spezia's total serum cholesterol is 245 mg/dL (normal < 200 mg/dL). All other blood and urine studies are within normal limits. Based on analysis of the data, Mrs. Spezia is started on enalapril 5 mg and hydrochlorothiazide 12.5 mg in a combination drug (Vaseretic), and placed on a low-fat, low-cholesterol, no-added-salt diet.

DIAGNOSES

- *Fatigue* related to effects of hypertension and stresses of daily life
- *Imbalanced Nutrition: More Than Body Requirements* related to excessive food intake
- *Ineffective Health Maintenance* related to inability to modify lifestyle
- *Deficient Knowledge* related to effects of prescribed treatment

EXPECTED OUTCOMES

- Patient will reduce blood pressure readings to less than 150 systolic and 90 diastolic by return visit next week.
- Patient will incorporate low-sodium and low-fat foods from a list provided into her diet.
- Patient will develop a plan for regular exercise.
- Patient will verbalize understanding of the effects of prescribed drug, dietary restrictions, exercise, and follow-up visits to help control hypertension.

PLANNING AND IMPLEMENTATION

- Teach to take own blood pressure daily and record it, bringing the record to scheduled clinic visits.
- Teach name, dose, action, and side effects of her antihypertensive medication.
- Instruct to walk for 15 minutes each day this week, and to investigate swimming classes at the local pool.
- Discuss strategies for achieving a realistic weight loss goal.
- Refer patient to a dietary consultation for further teaching about fat and sodium restrictions.
- Discuss stress-reducing techniques, helping identify possible choices.

EVALUATION

Mrs. Spezia returns to the clinic 1 week later. Her average blood pressure is now 148/88 mmHg. She has lost 1.5 lb, and states that her oldest daughter has suggested that they join a weight reduction program together. Mrs. Spezia is walking for an average of 20 minutes at a local mall each day. She verbalizes an understanding of her medication, and is taking it in the morning and before dinner each day. She met with the dietitian and discussed ways to reduce the sodium and fat in her diet. The dietitian provided a list of low-fat, low-sodium foods and recommended cookbooks to help Mrs. Spezia modify her cooking. Mrs. Spezia tells Ms. Christos, "I just can't believe how much better I feel already. My headaches are gone, I've actually lost some weight, and I feel motivated to keep going. If I had only known how much better I could feel! I don't expect I'll ever go back to my old habits again; it's just not worth it!"

Clinical Reasoning in Patient Care

1. Identify the factors that contributed to Mrs. Spezia's hypertension. Which were modifiable and which were not?
2. What is the rationale for reducing sodium and fat in Mrs. Spezia's diet?
3. Suppose your hypertensive patient is homeless and has no source of income. How could you help ensure your patient would follow the treatment plan? What would you do if the patient did not follow it?
4. Discuss the role of stress in hypertension. What factors in Mrs. Spezia's life contribute to her stress level?
5. Develop a plan of care for the nursing diagnosis *Situational Low Self-Esteem* related to obesity.

See Evaluating Your Response in Appendix B.

of teaching. Refer to a dietitian or to an organized weight loss program as indicated for further teaching and weight loss support. The accompanying Case Study & Nursing Care Plan provides additional information about community-based care for the patient with high blood pressure.

THE PATIENT WITH SECONDARY HYPERTENSION

Secondary hypertension is elevated blood pressure resulting from an identifiable underlying process. It accounts for only 5% to 10% of identified cases of hypertension. Kidney disease is the most common identifiable cause of high blood pressure in both adults and children (Huether & McCance, 2011). Other common identifiable causes of hypertension in adults include renovascular disease (reduced blood flow to the kidneys), disorders of the adrenal cortex, pheochromocytoma, coarctation of the aorta, and sleep apnea. The pathophysiology of selected causes of high blood pressure are summarized as follows:

- *Kidney disease.* Any disease that affects renal blood flow (e.g., renal artery stenosis) or renal function (e.g., glomerulonephritis, renal failure) can lead to hypertension. Disruption of the blood supply stimulates the RAAS, with resulting vasoconstriction and sodium and water retention. Altered kidney function affects the elimination of water and electrolytes, leading to hypertension.
- *Coarctation of the aorta.* Coarctation of the aorta is narrowing of the aorta, usually just distal to the subclavian arteries. Reduced renal and peripheral blood flow stimulates the RAAS and local vasoconstrictive responses, raising the blood pressure. A marked difference

between pressures in the upper and lower extremities is common, with weak pulses and poor capillary refill in the lower extremities.

- *Endocrine disorders.* Adrenal gland disorders such as Cushing's syndrome and primary aldosteronism can cause hypertension. A rare tumor of the adrenal medulla, *pheochromocytoma*, causes persistent or intermittent hypertension. Other endocrine disorders such as hyperthyroidism and pituitary disorders also can lead to hypertension.
- *Neurologic disorders.* Increased intracranial pressure causes an elevated blood pressure as the body attempts to maintain cerebral blood flow. Disorders that interfere with autonomic nervous system regulation (such as high spinal cord injury) may allow the sympathetic nervous system to predominate, increasing systemic vascular resistance and blood pressure.
- *Drug use.* Estrogen and oral contraceptive use may lead to hypertension, possibly by prompting sodium and water retention and affecting the RAAS. Stimulant drugs, such as cocaine and methamphetamines, increase systemic vascular resistance and cardiac output, resulting in hypertension.
- *Pregnancy.* About 10% of all pregnant women are hypertensive. Hypertension may predate pregnancy or occur as a direct response to the pregnancy. The mechanism of pregnancy-induced hypertension (PIH) is unclear. It is a significant cause of maternal and fetal morbidity and mortality and requires careful perinatal management.

The pattern of secondary hypertension varies, depending on its cause. Pheochromocytoma may cause attacks of hypertension that last for minutes to hours, accompanied by anxiety, palpitations, diaphoresis, pallor, and nausea and vomiting. Primary aldosteronism may cause hypertension, weakness, paresthesias, polyuria, and nocturia (see Chapter 19). Symptoms of kidney disease accompany hypertension when a renal disorder is the cause.

The following diagnostic tests may be ordered to differentiate primary from secondary hypertension.

- *Renal function studies* and *urinalysis* identify renal causes of hypertension. Elevated serum creatinine and BUN, reduced creatinine clearance, and hematuria, proteinuria, and casts often indicate kidney disease.
- *Serum potassium* is decreased in hyperaldosteronism.
- *Blood chemistries*, including serum electrolytes, glucose, and lipid studies, are done to detect abnormalities indicative of endocrine or cardiovascular disease.
- *Intravenous pyelography (IVP)*, *renal ultrasonography*, *renal arteriography*, and *CT* or *MRI* may be done when secondary hypertension is suspected.

Interprofessional and nursing care for the patient with secondary hypertension is the same as that for primary hypertension, discussed in the previous section. In addition, the underlying process is treated. See chapters covering specific disorders for more information about treatment measures.

THE PATIENT WITH HYPERTENSIVE CRISIS

Some patients with hypertension may, for reasons not clearly understood, develop rapid, significant elevations in systolic and/or diastolic pressures. In a *hypertensive emergency* (or *malignant hypertension*) the systolic pressure is greater than 180 mmHg and the diastolic pressure is higher than 120 mmHg. Immediate treatment (within 1 hour) is vital to prevent cardiac, renal, and vascular damage, and reduce morbidity and mortality. Intense cerebral artery spasms help protect the brain from excess pressure; however, cerebral edema often develops. Prolonged severe hypertension damages walls of the arterioles and renal blood vessels, and may lead to intravascular coagulation and acute renal failure.

Patients presenting with a hypertensive emergency may have manifestations such as headache, confusion, swelling of the optic nerve (papilledema), blurred vision, restlessness, and motor and sensory deficits. Manifestations of hypertensive emergencies are listed in the accompanying box.

Most hypertensive emergencies occur when patients suddenly stop taking their medications or their hypertension is poorly controlled. Younger patients (30 to 50 years old), African American men, pregnant women with preeclampsia, and people with collagen and/or renal disease also are at higher risk for a hypertensive emergency (Huether & McCance, 2011).

The goal of care in hypertensive emergencies is to reduce the blood pressure by no more than 25% within minutes to 1 hour, then toward 160/100 within 2 to 6 hours. It is important to avoid rapid or excessive blood pressure decreases that may lead to renal, cerebral, or cardiac ischemia. Blood pressure is monitored frequently (every 5 to 30 minutes) during a hypertensive emergency. The BUN, serum creatinine, calcium, and total protein levels are carefully monitored to help determine the prognosis for recovery. Drug treatment for malignant hypertension includes parenteral administration of a rapidly acting antihypertensive, such as the potent vasodilator sodium nitroprusside (Nipride). Other medications that may be used are outlined in Table 32–3. Management also focuses on treating any underlying or coexisting heart, kidney, and CNS disorders.

Nursing care for the patient with a hypertensive emergency focuses on continuous monitoring of the blood pressure and titrating drugs (administered by intravenous bolus or infusion) as ordered to achieve desired blood pressure. Avoiding excessive or very rapid blood pressure reductions is as important as achieving the desired blood pressure readings. Reassure the patient and family of the rapid effect of prescribed drugs. Provide psychologic and emotional support as needed. Maintain an attitude of confidence that the treatment will achieve the desired effect. Following resolution of the hypertensive crisis, review causes of the crisis. Teach the patient and family measures to effectively manage hypertension and prevent future hypertensive emergencies.

Disorders of the Aorta and Its Branches

The aorta and its branches may be affected by occlusions, aneurysms, and inflammations. These disorders may be chronic or acute and life threatening (e.g., a thoracic dissection). This section focuses on aneurysms of the aorta and its branches.

THE PATIENT WITH AN ANEURYSM

An **aneurysm** is an abnormal dilation of a blood vessel, commonly at a site of a weakness or a tear in the vessel wall. Aneurysms commonly affect the aorta and peripheral arteries because of the high

TABLE 32–3 Intravenous Drugs Used to Treat Hypertensive Emergencies

Class/Drug	Onset	Duration	Nursing Implications
VASODILATORS			
Sodium nitroprusside (Nipride)	Seconds	1–2 min	• Is effective, easy to titrate. • May cause nausea, vomiting, muscle twitching, sweating. • Use with caution in increased intracranial pressure.
Nitroglycerin	2–5 min	5–10 min	• Used when coronary ischemia accompanies hypertension. • May cause headache, vomiting. • Tolerance may develop with prolonged use.
Diazoxide (Hyperstat)	1–2 min	4–24 h	• Avoided in patients with coronary artery disease. • Used with beta-blockers and diuretics. • Painful if it enters tissues.
Fenoldopam (Corlopam)	< 5 min	30 min	• Use with caution in patients with glaucoma. • May cause tachycardia, headache, nausea, flushing. • Do not use concurrently with beta-blockers. • Monitor for heart failure, ischemic heart disease.
Hydralazine (Apresoline)	10–30 min	2–6 h	• May be used for hypertension associated with eclampsia. • Avoided in patients with coronary heart disease. • May cause tachycardia, flushing, headache, vomiting, angina.
CALCIUM CHANNEL BLOCKERS			
Nicardipine (Cardene)	5–10 min	15–30 min; up to 4 h	• Use with caution in coronary heart disease. • Avoid in patients with heart failure. • May cause tachycardia, headache, flushing, local phlebitis.
ACE INHIBITORS			
Enalaprilat (Vasotec)	15–30 min	6–12 h	• Monitor for hypotension. • Used in acute left heart failure. • Avoid in acute myocardial infarction.
ADRENERGIC BLOCKERS			
Labetalol (Trandate)	5–10 min	3–6 h	• Avoid in patients with acute heart failure and asthma. • May cause nausea, vomiting, dizziness. • Monitor for dyspnea, wheezing, heart block, orthostatic hypotension.
Esmolol (Brevibloc)	1–2 min	10–30 min	• Avoided in patients with heart failure and asthma. • May cause nausea. • Monitor for hypotension, dyspnea, wheezing, heart failure, first degree heart block.
Phentolamine (Regitine)	1–2 min	10–30 min	• May cause tachycardia, flushing, headache.

MANIFESTATIONS OF HYPERTENSIVE EMERGENCIES

- Rapid onset
- Blurred vision, papilledema
- Systolic pressure > 180 mmHg
- Diastolic pressure > 120 mmHg
- Headache
- Confusion
- Motor and sensory deficits

pressure in these vessels. An aneurysm may develop in the ventricular wall, usually affecting the left ventricle. Most arterial aneurysms are caused by arteriosclerosis or atherosclerosis; trauma also may lead to aneurysm formation.

Arterial aneurysms are most common in men over age 65, with a history of ever smoking (> 100 cigarettes in lifetime), most of whom are asymptomatic at the time of diagnosis. Hypertension is a major contributing factor in the development of some types of aortic aneurysms.

FAST FACTS

- The incidence of aortic aneurysm is an estimated 5.9 per 100,000 people per year.
- Aortic dissection affects an estimated 5 to 30 per 1 million people per year.
- Although aortic aneurysm and aortic dissection can occur concurrently, this is rare.

Pathophysiology and Manifestations

Aneurysms form due to weakness of the arterial wall. The major structural proteins of the aorta are collagen and elastin. Collagen provides tensile strength of the vessel, preventing excessive dilation. Elastin allows vessel recoil, during which the vessel returns to its original size following systole. This recoil provides continued propulsion of the bolus of blood expelled from the ventricle. Elastin is a primary component of internal elastic lamina, which separates the intimal and medial layers of the aorta, and of the media, the smooth muscle layer of the aorta. Destruction of elastin can lead to abnormal dilation of the vessel; collagen destruction can allow the vessel to rupture.

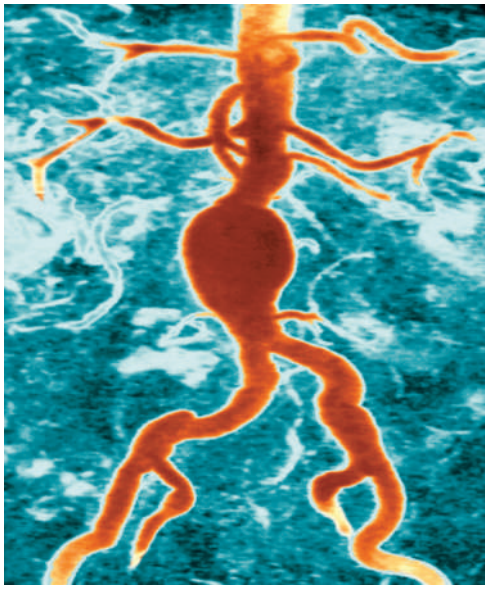

Figure 32–4 ■ A magnetic resonance angiogram (MRA) showing a circumferential aneurysm of the lower abdominal aorta.

True aneurysms are caused by the slow weakening of the arterial wall due to the long-term, eroding effects of atherosclerosis and hypertension. True aneurysms affect all three layers of the vessel wall, and most are fusiform and circumferential. Fusiform aneurysms are spindle shaped and taper at both ends. Circumferential aneurysms involve the entire diameter of the vessel (Figure 32–4 ■). They generally grow slowly but progressively. Their length and diameter vary considerably among patients. A large fusiform aneurysm may affect most of the ascending aorta as well as a large portion of the abdominal aorta.

False aneurysms, also known as traumatic aneurysms, are caused by a traumatic break in the vessel wall rather than weakening of the vessel. They often are saccular, shaped like small outpouchings (sacs) on a portion of the vessel wall (Figure 32–5 ■). A berry aneurysm is a type of saccular aneurysm. They are often small (less than 2 cm in diameter) and are caused by congenital weakness in the tunica media of the artery. Berry aneurysms are commonly found in the circle of Willis in the brain.

Dissecting aneurysms are unique, developing when a break or tear in the tunica intima and media allows blood to invade or *dissect* the layers of the vessel wall. The blood usually is contained by the adventitia, forming a saccular or longitudinal aneurysm (Figure 32–6 ■).

Aneurysms affect different segments of the aorta and its branches. Their manifestations generally are due to pressure of the aneurysm on adjacent structures. Table 32–4 summarizes the manifestations and complications of various types of aortic aneurysms.

THORACIC AORTIC ANEURYSMS

Thoracic aortic aneurysms account for about 10% of aortic aneurysms, with an annual incidence of about 6 per 100,000 people. They usually result from weakening of the aortic wall by arteriosclerosis and hypertension. Other causes include trauma, coarctation of the aorta, tertiary syphilis, fungal infections, and Marfan syndrome. The syphilis spirochete can invade and weaken aortic smooth muscle, causing an aneurysm to develop as long as 20 years after the primary infection. Marfan syndrome fragments elastic fibers of the aortic media, weakening the vessel wall. The accompanying box discusses genetic links associated with thoracic aortic aneurysms.

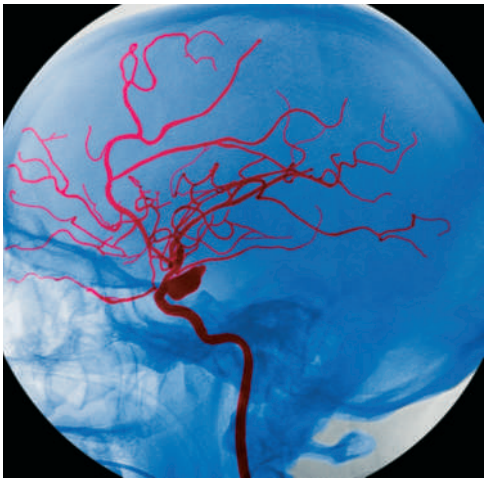

Figure 32–5 ■ An angiogram showing a saccular (berry) aneurysm in the carotid artery of a 50-year-old man.

Thoracic aneurysms frequently are asymptomatic. When present, manifestations are caused by the effects of the aneurysm on blood flow (e.g., to the coronary arteries and great vessels of the head and upper body) and pressure placed by the distended aorta on surrounding structures. Consequently, manifestations vary by the location, size, and growth rate of the aneurysm. Substernal, neck, or back pain may occur. Pressure on the trachea, esophagus, laryngeal nerve, or superior vena cava may cause dyspnea, stridor, cough, difficult or painful swallowing, hoarseness, edema of the face and neck, and distended neck veins.

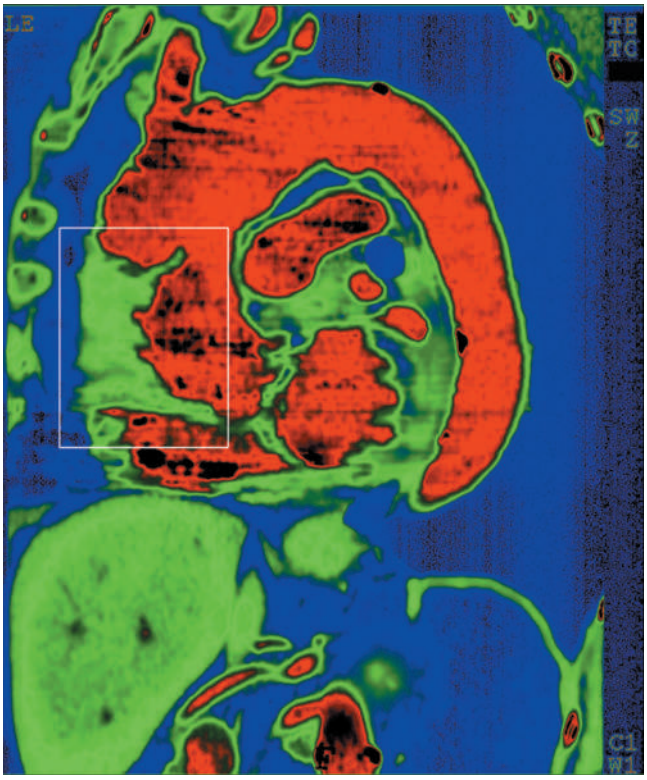

Figure 32–6 ■ In an aortic dissection, a tear in the intima and media of the artery allows blood to invade and dissect the wall of the aorta.
Source: Custom Medical Stock Photos, Inc.

TABLE 32–4 Manifestations and Complications of Aortic Aneurysms

Type or Location	Manifestations	Complications
Thoracic	• May be asymptomatic • Back, neck, or substernal pain • Dyspnea, stridor, or brassy cough if pressing on trachea • Hoarseness and dysphagia if pressing on esophagus or laryngeal nerve • Edema of the face and neck • Distended neck veins	• Rupture and hemorrhage
Abdominal	• Pulsating abdominal mass • Aortic calcification noted on x-ray • Mild to severe midabdominal or lumbar back pain • Cool, cyanotic extremities if iliac arteries are involved • Claudication (ischemic pain with exercise, relieved by rest)	• Peripheral emboli to lower extremities • Rupture and hemorrhage
Aortic dissection	• Abrupt, severe, ripping or tearing pain in area of aneurysm • Mild or marked hypertension early • Weak or absent pulses and blood pressure in upper extremities • Syncope	• Hemorrhage • Renal failure • MI, heart failure, cardiac tamponade • Sepsis • Weakness or paralysis of lower extremities

Aneurysms of the ascending aorta typically cause angina due to disruption of blood flow into the coronary arteries. Heart failure may develop as a result of disruption of the aortic valve and regurgitation of blood back into the left ventricle. Aneurysms of the aortic arch often cause dysphagia, dyspnea, hoarseness, confusion, and dizziness (due to disrupted cerebral blood flow). Thrombi that form within a thoracic aneurysm can embolize, causing a stroke, renal or mesenteric ischemia, or ischemia of the lower extremities. Aneurysms of the thoracic aorta tend to enlarge progressively and may rupture, causing death (Ramanath et al., 2009).

ABDOMINAL AORTIC ANEURYSMS

Abdominal aortic aneurysms are associated with arteriosclerosis and hypertension. Increasing age and smoking are believed to contribute as well. Most abdominal aortic aneurysms are found in adults over age 65. The vast majority (over 90%) develop below the renal arteries, usually where the abdominal aorta branches to form the iliac arteries (refer to Figure 32–4).

Most abdominal aneurysms are asymptomatic, but a pulsating mass in the mid and upper abdomen and a bruit over the mass are found on exam. When pain is present, it may be constant or intermittent, usually felt in the midabdominal region or lower back. Its intensity may range from mild discomfort to severe pain. Pain intensity often correlates with the size and severity of the aneurysm. Severe pain may indicate impending rupture.

Sluggish blood flow within the aneurysm may cause thrombi (blood clots) to form. These can become emboli (circulating clots), traveling to the lower extremities and occluding peripheral arteries. The aneurysm may rupture, with hemorrhage and hypovolemic shock. The risk of rupture increases as the size of the aneurysm increases; 20% to 40% of aneurysms more than 5 cm in diameter rupture. After acute rupture, the mortality rate is greater than 50%, even when emergency surgery is performed.

POPLITEAL AND FEMORAL ANEURYSMS

Most popliteal and femoral aneurysms are due to arteriosclerosis. They are often bilateral and usually affect men.

Popliteal aneurysms may be asymptomatic (Figure 32–7 ■). Manifestations, if any, are due to decreased blood flow to the lower

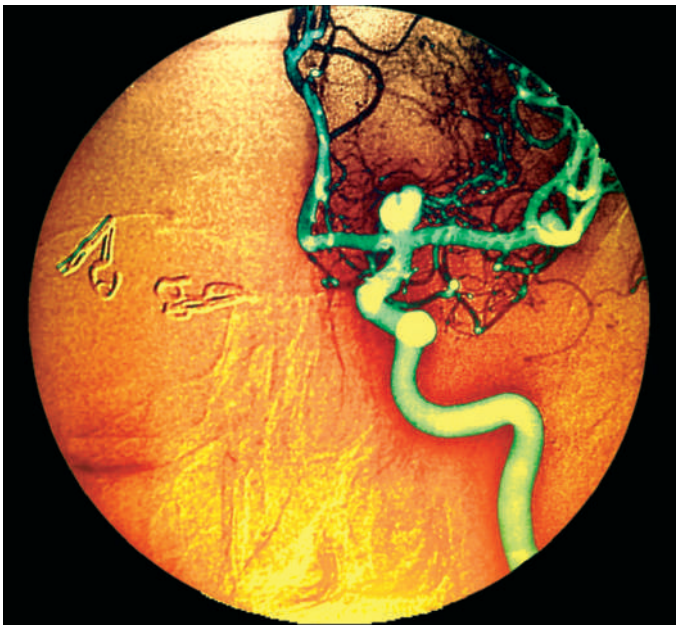

Figure 32–7 ■ An angiogram showing several popliteal aneurysms.

GENETIC CONSIDERATIONS

Thoracic Aortic Aneurysms

About 20% of patients with aortic aneurysms have a family history of the disorder.

A condition known as *cystic medial necrosis* is prevalent in patients with Marfan syndrome and Ehlers-Danlos syndrome, inherited disorders involving connective tissues. In cystic medial necrosis, collagen and elastic fibers of the tunica media of the aorta degenerate. This loss of collagen and elastic tissues weakens the wall of the proximal aorta, leading to circumferential dilation of the ascending aorta and development of a fusiform aneurysm. In many other patients with thoracic aortic aneurysm (up to 20%), genetic syndromes affecting collagen and elastin are not recognized, but a strong family history of the disorder is present.

extremity and include **intermittent claudication** (cramping or pain in the leg muscles brought on by exercise and relieved by rest), rest pain, and numbness. A pulsating mass may be palpable in the popliteal fossa (behind the knee). Thrombosis and embolism are complications; gangrene may result, often necessitating amputation.

A *femoral aneurysm* usually is detected as a pulsating mass in the femoral area. The manifestations are similar to those of popliteal aneurysms, resulting from impaired blood flow. Femoral aneurysms may rupture.

AORTIC DISSECTIONS

Dissection is a life-threatening emergency caused by a tear in the intima of the aorta with hemorrhage into the media. The hemorrhage dissects or splits the vessel wall, forming a blood-filled channel between its layers. Dissection can occur anywhere along the aorta. *Type A dissection* (*proximal dissection*) affects the ascending aorta; *type B dissection* (*distal dissection*) is limited to the descending aorta (refer to Figure 32–6).

Hypertension is a major predisposing factor for aortic dissection, accounting for 70% of aortic dissections. Cystic medial necrosis (see the Genetic Considerations box) is a major risk factor. Other risk factors include male gender, advancing age, pregnancy, congenital defects of the aortic valve, coarctation of the aorta, and inflammatory aortitis (Huether & McCance, 2011).

Dissection of the thoracic aortic walls progresses along the length of the vessel, moving both proximally and distally. As the aneurysm expands, pressure may prevent the aortic valve from closing or may occlude the branches of the aorta. Descending aortic dissection may extend into the renal, iliac, or femoral arteries.

The primary symptom of an aortic dissection is sudden, excruciating pain. The pain, often described as a ripping or tearing sensation, is usually over the area of dissection. Thoracic dissections cause chest or back pain. Other symptoms may include syncope, dyspnea, and weakness. The blood pressure may initially be increased, but rapidly falls and is often inaudible as the dissection occludes blood flow. Peripheral pulses are absent for the same reason.

Complications develop if major arteries are affected. Obstruction of the carotid artery causes neurologic symptoms such as weakness or paralysis. The myocardium, kidneys, or bowel may become ischemic or infarct if blood flow to the coronary arteries, renal arteries, or mesenteric artery is affected. Acute aortic regurgitation may develop with dissection of the ascending aorta. With treatment, the long-term prognosis is generally good, although the in-hospital mortality rate following surgery is 15% to 20%.

●○● INTERPROFESSIONAL CARE

Most aneurysms are asymptomatic, detected through a routine physical examination. Treatment depends on the size of the aneurysm. Small, asymptomatic aneurysms may not be treated or are medically managed; large aneurysms ($>$ 5 cm) at risk for rupture require surgery. In 2010 the American Heart Association updated the guidelines for management of thoracic aortic diseases (Hiratzka et al., 2010).

DIAGNOSIS

Diagnostic studies done to establish the diagnosis and determine the size and location of the aneurysm may include the following:

- *Chest x-ray* to visualize thoracic aortic aneurysms.
- *Abdominal ultrasonography* to diagnose abdominal aortic aneurysms. One-time screening of men ages 65 to 75 who have ever smoked is recommended (U.S. Preventative Services Task Force, 2005).
- *Transesophageal echocardiography* to identify the specific location and extent of a thoracic aneurysm and to visualize a dissecting aneurysm.
- *Contrast-enhanced CT* or *MRI* allows precise measurements of aneurysm size.
- *Angiography* uses contrast solution injected into the aorta or involved vessel to visualize the precise size and location of the aneurysm.

MEDICATIONS

Thoracic aortic aneurysms may be treated with long-term beta-blocker therapy and additional antihypertensive drugs as needed to control heart rate and blood pressure.

Patients with aortic dissection are initially treated with intravenous beta-blockers such as propranolol (Inderal), metoprolol (Lopressor), or esmolol (Brevibloc) to reduce the heart rate to about 60 bpm. Sodium nitroprusside (Nipride) infusion is started concurrently to reduce the systolic pressure to 120 mmHg or less. Calcium channel blockers (verapamil and diltiazem) also may be used. Direct vasodilators such as diazoxide (Hyperstat) and hydralazine (Apresoline) are avoided because they may actually worsen the dissection. Constant monitoring of vital signs, hemodynamic pressures (via Swan-Ganz catheter; refer to Chapter 30 for more information about hemodynamic pressure monitoring), and urine output are vital to ensure adequate perfusion of vital organs.

Following surgical correction of an aneurysm, anticoagulant therapy may be initiated. Heparin therapy is used initially, with conversion to oral anticoagulation prior to discharge. Many patients are maintained indefinitely on anticoagulant therapy; others may use lifelong, low-dose aspirin therapy to reduce the risk of clot formation.

SURGERY

Operative repair of aortic aneurysms is indicated when the aneurysm is symptomatic or expanding rapidly. Thoracic aneurysms of more than 6 cm in diameter are surgically repaired; asymptomatic abdominal aneurysms greater than 5 cm in diameter may be repaired, depending on the patient's operative risk factors. Type A dissections are repaired as soon as feasible; type B dissections may be surgically repaired, depending on the extent of involvement and risk for rupture.

Endovascular stent grafts (EVSGs) are increasingly being used to treat abdominal and thoracic aortic aneurysms. The use of EVSGs to treat aortic dissections is in investigational stages. The stent, which consists of a metal sheath covered with polyester fabric or a woven polyester tube, usually is placed percutaneously via the femoral artery. Fluoroscopy is used to guide its placement. Both straight and bifurcated grafts are available. Endovascular stent placement results in a shorter hospital stay and lower treatment cost. EVSG is associated with fewer pulmonary, renal, and cardiovascular complications than open surgical aneurysm repair (Huether & McCance, 2011). This option generally is preferred for patients who have a high surgical risk. The most common complication of endovascular aneurysm repair is persistent perfusion of the aneurysm (endoleak) caused by an ineffective seal at the proximal or distal end of the graft. Regular follow-up with abdominal CT scans is necessary to detect this complication,

which can develop at any time postoperatively. Because stent grafts are handcrafted to fit the individual, repeated CT scans with contrast media are required preoperatively, increasing the risk for kidney damage and renal failure. On rare occasions, the graft may be malpositioned or may migrate from the desired location.

An open surgical procedure in which the aneurysm is excised and replaced with a synthetic fabric graft is the standard treatment for expanding abdominal aortic aneurysms (Figure 32–8 ■). Although the aneurysm walls may be excised, they usually are left intact and used to cover the graft. Surgical repair of thoracic aneurysms is similar but more complex due to major vessels exiting at the aortic arch. Cardiopulmonary bypass is required if the ascending aorta is involved. The aortic valve also may be replaced during surgery. See Nursing Care of the Patient having Surgery of the Aorta.

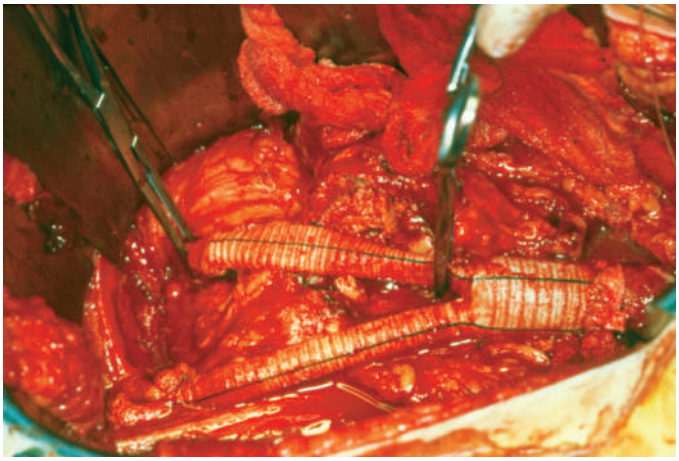

Figure 32–8 ■ Repair of an abdominal aortic aneurysm. The aorta is exposed and clamped between the renal and iliac arteries. Atherosclerotic plaque and thrombotic materials are removed. A synthetic graft is used to replace the aneurysm. The aneurysm walls are then sutured around the graft.

PRACTICE ALERT!

Monitor for and report manifestations of graft leakage:

- Ecchymoses of the scrotum, perineum, or penis; a new or expanding hematoma
- Increased abdominal girth
- Weak or absent peripheral pulses; tachycardia; hypotension
- Decreased motor function or sensation in the extremities
- Fall in hemoglobin and hematocrit
- Increasing abdominal, pelvic, back, or groin pain
- Decreasing urinary output (less than 30 mL/h)
- Decreasing CVP, pulmonary artery pressure, or pulmonary artery wedge pressure

These manifestations may signal graft leakage and possible hemorrhage. Pain may be due to pressure from an expanding hematoma or bowel ischemia. Decreased renal perfusion causes the glomerular filtration rate and urine output to fall.

●○● NURSING CARE

Assessment

See the Manifestations and Interprofessional Care sections for the assessment of the patient with an aneurysm.

NURSING CARE OF THE PATIENT

Having Surgery of the Aorta

PREOPERATIVE CARE

- As time permits, provide routine preoperative care and teaching, as outlined in Chapter 4. *Patients having vascular surgery have similar preoperative nursing care needs to other patients having major abdominal or thoracic surgery. If emergent surgery is required, time for preoperative care and teaching may be limited.*
- Implement measures to reduce fear and anxiety:
  a. Orient to the intensive care unit, if appropriate.
  b. Describe and explain the reason for all equipment and tubes, such as cardiac monitors, ventilators, nasogastric tubes, urinary catheters, intravenous lines and fluids, and intra-arterial lines.
  c. Explain what to expect following surgery (sights, sounds, frequency of taking vital signs, dressings, pain relief measures, communication strategies).
  d. Allow time for questions and expression of fears and concerns.

  These explanations provide a sense of control for the patient and family.
- Monitor for and implement care to reduce the risk of aneurysm rupture (see the following Diagnoses, Outcomes, and Interventions section). *Patients with a rapidly expanding or symptomatic aneurysm are at risk for rupture prior to surgical repair.*

POSTOPERATIVE CARE

- Provide routine postoperative care and specific measures as ordered by the healthcare provider. *Patients undergoing aneurysm repair require nursing care similar to that provided to all patients with major thoracic or abdominal surgery, in addition to specific measures related to vascular surgery.*
- Maintain fluid replacement and blood or volume expanders as ordered. Promptly report changes in vital signs, level of consciousness, and urine output. *Hypovolemic shock may develop due to blood loss during surgery, third spacing, inadequate fluid replacement, and/or hemorrhage if graft separation or leakage occurs.*
- Report manifestations of lower extremity embolism: pain and numbness in lower extremities, decreasing pulses, and pale, cool, or cyanotic skin. *Pulses may be absent for 4 to 12 hours postoperatively due to vasospasm; however, absent pulses with pain, changes in sensation, and a pale, cool extremity are indicative of arterial occlusion.*
- Report manifestations of bowel ischemia or gangrene: abdominal pain and distention, occult or fresh blood in stools, and diarrhea. *Bowel ischemia may result from an embolism or occur as a complication of surgery.*
- Report manifestations of impaired renal function: urine output less than 30 mL/h, fixed specific gravity, and increasing BUN and serum creatinine levels. *Hypovolemia or clamping of the aorta during surgery may impair renal perfusion, leading to acute renal failure.*
- Report manifestations of spinal cord ischemia: lower extremity weakness or paraplegia. *Impaired spinal cord perfusion may lead to ischemia and impaired function*.

Focused assessment for the patient with a suspected aortic aneurysm includes the following:

- *Health history:* complaints of chest, back, or abdominal pain; extremity weakness; shortness of breath, cough, difficult or painful swallowing, hoarseness; history of hypertension, coronary heart disease, heart failure, or peripheral vascular disease
- *Physical assessment:* vital signs including blood pressure in upper and lower extremities; peripheral pulses; skin color and temperature; neck veins; abdominal exam including gentle palpation for masses and auscultation for bruits; neurologic exam including level of consciousness, sensation, and movement of extremities.

Priorities of Care

Collaborating with the interprofessional team to ensure adequate treatment of the underlying process while providing care that supports the physical and psychologic responses to the disorder is a priority of nursing care.

Diagnoses, Outcomes, and Interventions

Nursing care for patients with an aneurysm of the aorta or its branches focuses on monitoring and maintaining tissue perfusion, relieving pain, and reducing anxiety. Nursing care usually is acute, precipitated by a complication or surgical repair of the aneurysm.

Risk for Ineffective Tissue Perfusion

Patients with aortic aneurysms are at risk for impaired tissue perfusion due to aneurysm rupture with resulting hemorrhage and lack of blood flow to tissues distal to the rupture. In addition, thrombi often form within the aneurysm and may become emboli, obstructing distal arterial blood flow.

Expected Outcome: Patient's tissue perfusion will be adequate as evidenced by adequate arterial flow (i.e., strong peripheral pulses).

PRACTICE ALERT!

Immediately report manifestations of impending rupture, expansion, or dissection of the aneurysm: increased pain, discrepancy between upper and lower extremity blood pressures and peripheral pulses, increased mass size, change in LOC or motor or sensory function, and laboratory results. Rapid expansion may indicate increased risk for rupture, with resulting hemorrhage, shock, and possible death. Elective or planned surgery may rapidly become emergency surgery to prevent complications.

- Implement interventions to reduce the risk of aneurysm rupture:
  a. Maintain bed rest with legs flat.
  b. Maintain a calm environment, implementing measures to reduce psychologic stress.
  c. Prevent straining during defecation and instruct to avoid holding the breath while moving.
  d. Administer beta-blockers and antihypertensives as prescribed.

Activity, stress, and the Valsalva maneuver increase blood pressure, increasing the risk of rupture. Elevating or crossing the legs restricts peripheral blood flow and increases pressure in the aorta or iliac arteries. Beta-blockers and antihypertensives often are ordered to reduce pressure in the dilated vessel.

- Report manifestations of arterial thrombosis or embolism: absent peripheral pulses; a pale or cyanotic, cool extremity; severe, diffuse abdominal pain with guarding; or increased groin, lumbar, or lower extremity pain. Sluggish blood flow within the aneurysm often causes thrombi to form. These thrombi can break loose, becoming emboli that can occlude peripheral arteries or arteries to the kidneys or mesentery. *Arterial occlusion may necessitate emergency surgery to restore blood flow and prevent tissue infarct or gangrene.*
- Continuously monitor cardiac rhythm. Report complaints of chest pain or changes in ECG tracing. Administer oxygen as indicated. *Aortic dissection and repair place the patient at significant risk for MI, a major cause of postoperative mortality and morbidity. Rapid identification and treatment of this complication can reduce the risk of death or the long-term adverse effects of MI.*
  - Immediately report changes in mental status or symptoms of peripheral neurologic impairment (weakness, paresthesias, paralysis). The expanding aneurysm or dissection can affect carotid and cerebral blood flow or spinal cord perfusion, leading to neurologic symptoms. *Immediate restoration of blood flow is vital to prevent permanent neurologic deficits.*

Risk for Injury

Potent antihypertensive drugs often are given intravenously to reduce the pressure on an expanding or dissecting aneurysm. Continuous monitoring of infusions and hemodynamic parameters such as arterial pressure, pulmonary pressures, and cardiac output is vital to ensure that adequate tissue perfusion is maintained during infusions of these potent drugs.

Expected Outcome: Patient will experience effective risk control through use of close and careful drug monitoring.

- Use an infusion control device for all drug infusions. *These devices prevent accidental or inadvertent changes in the rate of the infusion and dose of the drug.*
- Continuously monitor arterial pressure and hemodynamic parameters as indicated. Promptly report results outside the specified parameters to the healthcare provider. *Many of the drugs used are effective within minutes. Responses vary among individuals, particularly in the older adult, necessitating continuous monitoring.*
- Monitor urine output hourly. Report output less than 30 mL/h. *The kidneys are very sensitive to reduced perfusion pressure; inadequate renal blood flow can lead to acute renal failure.*

Anxiety

Patients with aortic aneurysms often are highly anxious because of the urgent nature of the disorder. The nurse manages the anxiety levels of both the patient and family members to effectively address

Evidence for Nursing Care

The Patient with Aortic Aneurysm

A selected resource that nurses may find helpful when planning evidence-based nursing care follows.

- Harger, B. (2012, May 1). Abdominal aortic aneurysms: This deadly condition often goes undetected. *Advances for NPs and PAs.* Retrieved from http://nurse-practitioners-and-physician-assistants.advanceweb.com/Features/Articles/Abdominal-Aortic-Aneurysms.aspx.

physiologic care needs. Stress reduction is necessary to help maintain the blood pressure within desired limits.

Expected Outcome: Patient's anxiety will be controlled as evidenced by verbalized decrease in subjective distress.

- Explain all procedures and treatments, using simple and understandable terms. *Simplified explanations are necessary when anxiety levels interfere with learning and understanding.*
- Respond to all questions honestly, using a calm, empathetic, but matter-of-fact manner. *Honesty with the patient and family promotes trust and provides reassurance that the true nature of the situation is not being "hidden" from them.*
- Provide care in a calm, efficient manner. *Using a calm manner even during preparations for emergency surgery reassures the patient and family that although the situation is critical, the staff is prepared to handle things effectively.*
- Spend as much time as possible with the patient. Allow supportive family members to remain with the patient when possible. *The presence of a health professional and supportive family member reassures the patient that he or she is not alone in facing this crisis.*

Continuity of Care

Topics to discuss when preparing patients and their families for home care or care in a community-based setting depend on the treatment plan. Discuss the following topics when surgical repair is not immediately planned and the aneurysm will be monitored:

- Measures to control hypertension, including lifestyle and prescribed drugs
- The benefits of smoking cessation
- Manifestations of increasing aneurysm size or complications to report to the healthcare provider.

Following surgery, discuss the following topics to prepare the patient and family for home care:

- Wound care and preventing infection; manifestations of impaired healing or infection to be reported
- Prescribed antihypertensive and anticoagulant medications and their expected and unintended effects
- The importance of adequate rest and nutrition for healing
- Measures to prevent constipation and straining at stool (such as increasing fluid and fiber in the diet)
- The importance of avoiding prolonged sitting, lifting heavy objects, engaging in strenuous exercise, and having sexual intercourse until approved by the healthcare provider (usually 6 to 12 weeks)
- Signs and symptoms of complications to report to the healthcare provider.

Provide referrals to a home health agency or community health service as necessary. Referrals are especially important for older adults and their caregivers, who may require additional assistance with complex care needs.

Disorders of the Peripheral Arteries

Disorders that impair peripheral arterial blood flow may be *acute* (e.g., arterial thrombosis) or *chronic* (e.g., peripheral arteriosclerosis). Chronic occlusive disorders may be due to structural defects of the arterial walls or spasm of affected arteries. Impaired peripheral arterial circulation limits the availability of oxygen and nutrients to the tissues, and can have significant adverse effects. This section focuses on acute and chronic disorders affecting peripheral arteries. The nurse's role in caring for patients with peripheral arterial disorders focuses on maintaining tissue perfusion and educating the patient and family about the disorder and its management.

Physiology Review

Peripheral arteries are the part of the systemic circulation that delivers oxygen and nutrients to the skin and the extremities. Arterial walls have three layers: the intima, which includes the endothelium and a layer of connective tissue and the basement membrane; the media, composed of smooth muscle and elastic fibers; and the adventitia, a thin layer of connective tissue that contains collagen and elastic fibers. The smooth muscle of peripheral arteries controls blood flow as it contracts and relaxes. Contraction narrows the vessel lumen (**vasoconstriction**), whereas smooth muscle relaxation expands the vessel (**vasodilation**). Peripheral arteries become progressively smaller; arterioles are less than 0.5 mm in diameter and are composed primarily of smooth muscle. The arterioles control blood flow through the capillary beds where gas, nutrient, and waste product exchange occurs. Capillary walls are very thin, consisting of a single layer of endothelial cells surrounded by a thin basement membrane.

Blood flows from an area of higher pressure to an area of lower pressure. *Resistance* opposes blood flow. Resistance is created by friction of the blood itself, although the primary determinants of vascular resistance are the diameter and length of the blood vessel. See the Physiology Review section under the Disorders of Blood Pressure Regulation section earlier in this chapter for more information about factors that determine vessel resistance.

THE PATIENT WITH PERIPHERAL VASCULAR DISEASE

Arteriosclerosis is the most common chronic arterial disorder, characterized by thickening, loss of elasticity, and calcification of arterial walls. **Atherosclerosis** is a form of arteriosclerosis in which deposits of fat and fibrin obstruct and harden the arteries. In the peripheral circulation, these pathologic changes impair the blood supply to peripheral tissues, particularly the lower extremities. This is known as **peripheral vascular disease (PVD)**.

Pathophysiology

The pathophysiology of atherosclerosis is detailed in Chapter 30. Atherosclerotic lesions involve both the intima and the media of the involved arteries. There are three types of PVD: type 1 (10% to 15% of patients), involving the aorta and iliac arteries; type 2 (~25% of patients), involving the aorta and the common and external iliac arteries; and type 3 (~60% to 70% of patients), in which the aorta and the iliac, femoral, popliteal, and tibial arteries are involved.

Arteriosclerosis in the abdominal aorta leads to the development of aneurysms as plaque erodes the vessel wall.

Plaque tends to form at arterial bifurcations. The vessel lumen is progressively obstructed, decreasing blood flow to the lower extremities. Tissue hypoxia or anoxia results. With gradual obstruction of the vessel, collateral circulation often develops. However, it is usually not adequate to supply tissue needs, especially when metabolic demand increases (e.g., during exercise). Manifestations typically develop only when the vessel is occluded by 60% or more.

Manifestations and Complications

Pain is the primary symptom of peripheral atherosclerosis. Intermittent claudication, a cramping or aching pain in the calves of the legs, the thighs, and the buttocks that occurs with a predictable level of activity, is characteristic of PVD. The pain is often accompanied by weakness and is relieved by rest.

Rest pain, in contrast, occurs during periods of inactivity. It is often described as a burning sensation in the lower legs. Rest pain increases when the legs are elevated and decreases when the legs are dependent (e.g., hanging over the side of the bed). The legs may feel cold or numb along with the pain. Sensation is diminished and the muscles may atrophy.

Peripheral pulses may be decreased or absent. A bruit may be heard over large affected arteries, such as the femoral artery and the abdominal aorta. The legs are pale when elevated, but often are dark red (*dependent rubor*) when dependent. The skin often is thin, shiny, and hairless, with discolored areas. Toenails may be thickened. Areas of skin breakdown and ulceration may be evident. Edema may develop with severe PVD. See the Manifestations of Peripheral Atherosclerosis box.

Complications of peripheral atherosclerosis include gangrene and extremity amputation, rupture of abdominal aortic aneurysms, and possible infection and sepsis.

Incidence and Risk Factors

PVD usually affects people in their 60s and 70s; men are more often affected than women. Deaths attributed to peripheral arterial disease are about the same for Black and White males, but are higher among Black women than White women (AHA, 2013).

Risk factors for PVD are similar to those for atherosclerosis and coronary heart disease (refer to Chapter 30). Diabetes mellitus, hypercholesterolemia, hypertension, cigarette smoking, and high homocystine levels are risk factors for PVD (AHA, 2013).

FAST FACTS

- PVD is a common manifestation of atherosclerosis, particularly in older men.
- PVD interferes with arterial blood flow to the lower extremities, increasing the risk for neuropathy and paresthesias, ulcers that do not heal, necrosis, gangrene, and amputation.
- Regular daily exercise is a primary intervention for all types of peripheral arterial disease to promote development of collateral circulation and maintain tissue perfusion.

●○● INTERPROFESSIONAL CARE

Management of peripheral vascular disease focuses on slowing the atherosclerotic process and maintaining tissue perfusion.

MANIFESTATIONS OF PERIPHERAL ATHEROSCLEROSIS

- Intermittent claudication
- Rest pain
- Paresthesias (numbness, decreased sensation)
- Diminished or absent peripheral pulses
- Pallor with extremity elevation, dependent rubor when dependent
- Thin, shiny, hairless skin; thickened toenails
- Areas of discoloration or skin breakdown

DIAGNOSIS

Although PVD often can be diagnosed by the history and physical examination, diagnostic tests may be ordered to evaluate its extent. Noninvasive studies often are sufficient.

- *Segmental pressure measurements* use sphygmomanometer cuffs and a Doppler device to compare blood pressures between the upper and lower extremities (normally similar) and within different segments of the affected extremity. In PVD, the BP may be lower in the legs than in the arms.
- *Stress testing* using a treadmill provides functional assessment of limitations. In PVD, pressure at the ankle may decline even further with exercise, confirming the diagnosis. Evaluation for coronary heart disease may be done simultaneously during exercise testing.
- *Doppler ultrasound* uses sound waves reflected off moving red blood cells within a vessel to evaluate blood flow. The impulses may be translated into an audible signal or a graphic waveform. With significant PVD, the waveform becomes progressively flatter as the transducer is moved distally along the affected vessel. Segmental pressures may be used to locate the site of obstruction.
- *Duplex Doppler ultrasound* combines the audible or graphic Doppler ultrasound with ultrasound imaging to identify arterial or venous abnormalities. Ultrasonic imaging provides views of the affected vessel while Doppler ultrasound evaluates blood flow. *Color-flow Doppler ultrasound (CDU)* provides color images of the vessel and blood flow.
- *Transcutaneous oximetry* evaluates oxygenation of tissues.
- *Angiography* or *magnetic resonance angiography* is done before revascularization procedures to locate and evaluate the extent of arterial obstruction. For angiography, a contrast medium is injected and vessels are visualized using fluoroscopy and x-rays. Magnetic resonance angiography does not require injection of a contrast medium and may replace angiography.

MEDICATIONS

Drug treatment of peripheral atherosclerosis is less effective than with coronary heart disease. Medications to inhibit platelet aggregation, such as aspirin or clopidogrel (Plavix) are ordered to reduce the risk of arterial thrombosis. Cilostazol (Pletal), a platelet inhibitor with vasodilator properties, improves claudication. Pentoxifylline (Trental) decreases blood viscosity and increases red blood cell flexibility, increasing blood flow to the microcirculation and tissues of the extremities. Parenteral vasodilator prostaglandins may be given on a long-term basis to decrease pain and facilitate healing in patients with severe limb ischemia (Vallerand & Sanoski, 2012).

BOX 32–4 Foot Care for the Patient with Peripheral Atherosclerosis

1. Keep legs and feet clean, dry, and comfortable.
   - Wash legs and feet daily in warm water, using mild soap.
   - Pat dry using a soft towel; be sure to dry between the toes.
   - Apply moisturizing cream to prevent drying, but avoid lotion between toes.
   - Use powder on the feet and between the toes.
   - Buy shoes in the afternoon (when feet are largest); never buy shoes that are uncomfortable. Be sure toes have adequate room.
   - Wear a clean pair of cotton socks each day. Be sure sock seams are on the outside to reduce pressure.
2. Prevent accidents and injuries to the feet.
   - Always wear shoes or slippers when getting out of bed.
   - Walk on level ground and avoid crowds, if possible.
   - Do not go barefoot.
   - Inspect legs and feet daily; use a mirror to examine backs of legs and bottoms of feet.
   - Have a professional foot care provider trim toenails and care for corns, calluses, ingrown toenails, or athlete's foot.
   - Always check the temperature of the water before stepping into a tub.
   - Do not get the legs or tops of the feet sunburned.
   - Report leg or foot problems (increased pain, cuts, bruises, blistering, redness, or open areas) to your healthcare provider.
3. Improve blood supply to the legs and feet.
   - Do not cross legs.
   - Do not wear garters, girdles, or knee stockings.
   - Do not swim or wade in cold water.

TREATMENTS

Smoking cessation is vital. Nicotine not only promotes atherosclerosis, but also causes vasospasm, further reducing blood flow to the extremities.

Meticulous foot care is vital to prevent ulceration and infection (Box 32–4). Elastic support hose, which reduce circulation to the skin, are avoided. Elevating the head of the bed on blocks may help relieve rest pain. Regular, progressively strenuous exercise, such as 30 to 45 minutes of walking daily, is important. The patient is taught to rest at the onset of claudication, resuming activity when the pain resolves.

Other measures to slow the process of atherosclerosis, such as controlling diabetes and hypertension, lowering cholesterol levels, and weight loss, also are recommended (refer to Chapter 30). See the Nursing Care of the Older Adult feature on this page.

REVASCULARIZATION

Revascularization may be performed if symptoms are progressive, severe, or disabling. Other indications for surgery include symptoms that significantly interfere with activities of daily living, rest pain, and pregangrenous or gangrenous lesions. Either nonsurgical revascularization procedures or surgery may be performed.

Nonsurgical procedures include percutaneous transluminal angioplasty (PTA), stent placement, or atherectomy. Techniques may include balloon angioplasty to dilate the narrowed lumen, mechanical atherectomy to remove plaque, or laser or thermal angioplasty to vaporize the occluding material. In either case, a stent typically is placed at the time of PTA to maintain vessel patency. Iliac and femoral-popliteal PTA initially reestablish good blood flow and relieve symptoms in more than 80% of patients. Although its 3-year success rate is lower, stent placement improves the duration of symptom relief. Refer to Chapter 30 for more information about revascularization procedures.

Surgical options include endarterectomy to remove occlusive plaque from the artery and bypass grafts. Knitted Dacron bypass grafts are commonly used. Both immediate and long-term graft patency is better with bypass grafting than with nonsurgical revascularization procedures, but the risk for operative complications such as myocardial infarction, stoke, infection, and peripheral embolization is higher. Nursing care for the patient having revascularization surgery is similar to that provided for patients having surgery of the aorta (refer to the Nursing Care of the Patient Having Surgery of the Aorta box on page 985).

COMPLEMENTARY THERAPIES

Complementary therapies for peripheral vascular disease include interventions to improve circulation and to reduce stress. A number of complementary therapies may improve peripheral circulation, including aromatherapy with rosemary or vetiver; biofeedback; healing or therapeutic touch and massage; herbs such as ginkgo, garlic, cayenne, hawthorn, and bilberry; and exercise including yoga. Aromatherapy and yoga may reduce stress, as can breathing exercises, meditation, and counseling. In addition, complementary therapies to reduce atherosclerosis and lower cholesterol levels may slow the progress of PVD. Measures such as a very low-fat or vegetarian diet, including antioxidant nutrients or using vitamin C, vitamin E, or garlic supplements, may be useful.

●○● NURSING CARE

Health Promotion

Discuss healthy lifestyle habits with community and religious groups, schoolchildren (grades K through 12), and through the print media to reduce the incidence and slow the progression of atherosclerosis.

NURSING CARE OF THE OLDER ADULT

Peripheral Vascular Disease

With aging, blood vessels thicken and become less compliant. These changes reduce oxygen delivery to the tissues and impair carbon dioxide and waste product removal from the tissues. When normal effects of aging combine with an increased risk of atherosclerosis, the risk of peripheral vascular disease is high.

The older adult with peripheral vascular disease requires the same care and teaching as other patients. However, visual deficits and osteoarthritis may make foot care more difficult. Long-standing smoking habits are difficult to break. Mobility may be impaired by arthritis or the effects of neurologic disorders. The patient who lives alone may resist walking. Periodic visits by a community or home health nurse may be helpful, as may be encouraging the patient to join a support group for stopping smoking, changing eating habits, and taking part in regular activity.

Strongly encourage all patients to avoid smoking in the first place, and to stop all forms of tobacco use. Discuss the adverse effects of smoking and the benefits of quitting. Provide information about dietary recommendations to maintain a healthy weight and optimal cholesterol levels. Discuss the benefits and importance of regular exercise. Finally, encourage patients with cardiovascular risk factors to undergo regular screening for hypertension, diabetes, and hyperlipidemia.

Assessment

See the Manifestations and Interprofessional Care sections for the assessment of the patient with peripheral vascular disease.

Focused assessment related to peripheral atherosclerosis includes the following:

- *Health history:* complaints of pain, its relationship to exercise or rest, timing, associated symptoms, and relief measures; history of coronary heart disease, peripheral vascular disease, hyperlipidemia, hypertension, or diabetes; current medications; smoking history; usual diet and activity patterns.
- *Physical assessment:* vital signs; strength and equality of peripheral pulses of all extremities; capillary refill; skin color, temperature, hair distribution, presence of any discolorations or lesions; movement and sensation of lower extremities.

Priorities of Care

Collaborating with the interprofessional team to ensure adequate treatment of the underlying process while providing care that supports the physical and psychologic responses to the disorder is a priority of nursing care.

Diagnoses, Outcomes, and Interventions

Impaired tissue perfusion is an obvious problem in peripheral atherosclerosis. Acute and chronic pain may interfere with activities of daily living, and ambulation may be limited. The possibility of losing a lower extremity is frightening.

Ineffective Tissue Perfusion: Peripheral

Impaired blood flow to the lower extremities affects gas, nutrient, and waste product exchange between the capillaries and cells. Oxygen and nutrient deprivation impairs cell function and tissue integrity, causing pain and impaired healing. Pain develops with exercise and when extremities are elevated.

Expected Outcome: Patient's tissue perfusion will be adequate as evidenced by adequate arterial flow (i.e., strong peripheral pulses).

- Assess peripheral pulses, pain, color, temperature, and capillary refill every 4 hours and as needed. Use a Doppler device if pulses are not palpable. Mark pulse locations with an indelible marker. *Assessment data provide a baseline for evaluating the effectiveness of interventions and identifying changes in arterial blood flow.*
- Position with extremities dependent. *Gravity promotes arterial flow to the dependent extremity, increasing tissue perfusion and relieving pain.*
- Instruct to avoid smoking. If necessary, obtain an order for a nicotine patch or gum from the healthcare provider. Nicotine is a potent vasoconstrictor that further impairs arterial blood flow. Nicotine patches and gum contain less nicotine than cigarettes, and can help reduce the stress of smoking cessation. *Smoking cessation is a vital component of care.*
- Discuss the benefits of regular exercise. *Exercise promotes development of collateral circulation to ischemic tissues and slows the process of atherosclerosis.*
- Use a foot cradle and lightweight blankets, socks, and slippers to keep extremities warm. Avoid electric heating pads or hot water bottles. *Keeping extremities warm conserves heat, prevents vasospasm, and promotes arterial flow. External heating devices are avoided to reduce the risk of burns in the patient with impaired sensation. The foot cradle protects tissues from compression by linens.*
- Encourage frequent position changes. Instruct to avoid crossing legs or using a pillow under the knees. *Position changes promote blood flow and reduce damage caused by pressure. Leg crossing and excessive flexion of the hip or knee joints can compress partially obstructed arteries and impair blood flow to distal tissues.*

Pain

Impaired blood flow results in tissue ischemia. Metabolism shifts from an efficient aerobic process to an anaerobic process. Lactic acid and metabolic waste products accumulate in tissues, causing pain. Severe and cramping pain generally occurs with exercise early in the disease. Rest initially produces relief, similar to the process of angina (refer to Chapter 30). As the disease progresses, pain develops with less exercise and often occurs even at rest. Rest pain disrupts sleep, the sense of well-being, and has significant disruptive effects on life roles.

Expected Outcome: Patient's pain control will be adequate as evidenced by physical well-being.

- Assess pain at least every 4 hours using a standard pain scale; assess more often as needed. *Pain is a subjective experience. Using a standard pain scale allows evaluation of treatment measures in relieving pain and restoring blood flow.*
- Keep extremities warm. *Cooling leads to vasoconstriction, increasing pain. Warming the extremities promotes vasodilation and improves arterial flow, reducing pain.*
- Teach pain relief and stress reduction techniques such as relaxation, meditation, and guided imagery. *Pain increases stress. The stress response leads to vasoconstriction, increasing pain. Stress reduction techniques, when combined with other measures to promote blood flow, can help reduce pain.*

Impaired Skin Integrity

Patients with PVD are at risk for impaired skin integrity as a result of oxygen and nutrient deprivation. Chronic tissue ischemia leads to dry, scaly, and atrophied skin. Pruritus can lead to scratching; minor injuries may go unnoticed due to impaired sensation. Impaired tissue healing can lead to ulceration, infection, and potential gangrene.

Expected Outcome: Patient will demonstrate understanding of plan to heal skin and prevent reinjury.

- Assess and document skin condition at least every 8 hours and with each home visit, more frequently as indicated. Tissue ischemia increases the risk for damage, even with minor trauma such as pressure from poorly fitting shoes or bed linens. *Frequent inspection and documentation of skin condition is vital to identify early indicators of impaired skin integrity and reduce the risk of complications such as infection.*

CASE STUDY & NURSING CARE PLAN A Patient with Peripheral Vascular Disease

William Duffy, age 69, is retired. His wife convinces him to see his primary care provider for increasing leg pain with walking and other exercise.

ASSESSMENT

Katie Kotson, RN, obtains Mr. Duffy's history before he sees his healthcare provider. He states that he can only walk about a block before the pain in his calves gets so bad that he has to stop and rest. As a result, he has been less and less active, spending most of his time the past few months watching sports on television. He denies rest pain. He was diagnosed with type 2 diabetes about 15 years ago, which he manages with daily glyburide (DiaBeta), an oral hypoglycemic. He has stable angina, for which he takes atenolol (Tenormin) and an occasional nitroglycerin tablet. His alcohol intake is moderate, averaging 1 to 2 beers per day, and he smokes about a pack of cigarettes per day. He states he tried to quit smoking after developing angina, but "after nearly 50 years of smoking, I think that's impossible!"

Physical exam findings include height 173 cm (68 in.), weight 107 kg (235 lb), BP 168/78 mmHg, P 66 bpm, R 16/min, T 36.5°C (97.6°F); upper extremities warm and pink, normal hair distribution, pulses strong and equal; lower extremities below knees cool and ruddy when dependent, pale to pink when elevated, skin shiny, scant hair; posterior tibial pulses weak bilaterally; weak pedal pulse on R, unable to palpate on L; 1+ to 2+ edema both feet and ankles.

The healthcare provider finds that Mr. Duffy's systolic blood pressure in his legs is an average of 28 mmHg lower than in his arms. He makes the diagnosis of peripheral atherosclerosis, and schedules Mr. Duffy for an exercise stress test with ankle pressure measurements before and after exercise and a color-flow Doppler ultrasound. Mr. Duffy is to return in 3 weeks after these studies have been completed.

DIAGNOSES

- *Activity Intolerance* related to poor blood flow to lower extremities
- *Ineffective Health Maintenance* related to smoking and lack of information about disease management
- *Risk for Impaired Skin Integrity* related to ischemic tissues of legs and feet
- *Risk for Peripheral Neurovascular Dysfunction* related to impaired peripheral blood flow to lower extremities

EXPECTED OUTCOMES

- Patient will walk for at least 15 minutes three to four times per day, gradually increasing his pace and duration of exercise.
- Patient will relate the benefits of smoking cessation.
- Patient will identify strategies to improve chances for success in stopping smoking.
- Patient will meet with dietitian before next visit to discuss dietary measures to promote weight loss and slow atherosclerosis.
- Patient will verbalize an understanding of appropriate foot care measures.
- Patient will identify measures to prevent inadvertent injury of feet and legs.

PLANNING AND IMPLEMENTATION

- Teach about peripheral atherosclerosis and its relationship to Mr. Duffy's symptoms.
- With Mr. and Mrs. Duffy, plan strategies to start and maintain a program of regular exercise.
- Instruct to warm up slowly, and to stop exercise and rest for 3 minutes (or until pain is relieved) when claudication develops, then resume exercising.
- Discuss the effects of smoking on blood vessels.
- Help Mr. Duffy identify smoking cessation strategies such as support groups, clinics, and nicotine patches.
- Schedule an appointment with the dietitian to develop a low-calorie, low-fat, and low-cholesterol American Diabetes Association (ADA) diet that includes preferred foods and considers usual eating patterns.
- Reinforce and supplement previous foot care teaching.
- Discuss effects of impaired circulation on sensation in feet and legs and measures to prevent injury.

EVALUATION

When Mr. Duffy returns to the office 3 weeks later, his diagnosis has been confirmed by the diagnostic studies. The healthcare provider decides to continue conservative therapy, now prescribing atorvastatin (Lipitor) to lower Mr. Duffy's serum cholesterol level, and cilostazol (Pletal) to reduce the risk of thrombosis and improve symptoms of claudication. Mr. Duffy asks his healthcare provider for a prescription for nicotine patches, saying he is ready to quit smoking, but thinks he needs help to be successful. Mr. and Mrs. Duffy tell Miss Kotson that they are walking before every meal and really enjoying being outside more. They plan to walk in the local shopping mall when the weather gets worse. Mrs. Duffy has bought an American Heart Association cookbook, and is carefully planning their meals. Both Mr. and Mrs. Duffy have lost 2.3 kg (5 lb) since the previous visit. Mr. Duffy's skin on his legs and feet remains intact, and he identifies the measures he is using to protect his lower extremities from injury.

Clinical Reasoning in Patient Care

1. What additional lifestyle changes related to peripheral atherosclerosis might be appropriate to suggest to Mr. Duffy at this time? Why?
2. Explain the relationship between physical exercise and pain in the patient with peripheral atherosclerosis. Compare this relationship to that between exercise and angina.
3. Mr. Duffy uses a beta-blocker, atenolol, to prevent angina. Why is this drug not effective in preventing claudication?
4. Develop a nursing care plan for the diagnosis *Imbalanced Nutrition: More Than Body Requirements.*

See Evaluating Your Response in Appendix B.

- Provide meticulous daily skin care, keeping the skin clean and dry. Apply a moisturizing cream to dry or scaly areas. *Intact skin is the body's first defense against bacterial invasion. Ischemic tissues of the injured extremity provide an excellent medium for microorganism growth. Clean, dry, supple skin decreases the risk of breakdown.*
- Apply a bed cradle. *The bed cradle suspends bed linens over the legs, preventing them from placing pressure on extremities and injured tissues. Minimizing pressure on the tissues promotes capillary blood flow.*
- Provide an egg-crate mattress, flotation pad, sheepskin, or heel protectors. *Ischemic tissues may be damaged by minor trauma such as that created by the shearing forces of skin against bed linens.*

Activity Intolerance

Pain and impaired perfusion of peripheral tissues may limit the patient's ability to engage in desired activities, even impairing self-care.

Expected Outcome: Patient will participate in activity program without suffering any complications.

- Assist with care activities as needed. *Severe claudication or rest pain may limit activities. Muscle atrophy of affected extremities is common, leading to fatigue and weakness.*
- Unless contraindicated, encourage gradual increases in duration and intensity of exercise. Teach to rest with extremities dependent

when claudication develops, resuming activity after pain has abated. *Gradual increases in the duration and intensity of exercise promote development of collateral circulation, improve exercise tolerance, provide a sense of well-being, and support self-esteem.*

- Provide diversional activities during periods of prescribed bed rest. Encourage relaxation techniques to reduce muscle tension. *Diversional activities help prevent boredom and stress associated with enforced rest. Relaxation techniques reduce vasoconstriction induced by stress, improving peripheral circulation.*
- Encourage frequent position changes and active range-of-motion exercises. Encourage self-care to the extent possible. *Position changes relieve pressure on tissues, improving capillary circulation and reducing tissue ischemia. Range-of-motion exercises help prevent muscle atrophy and joint contractures. Self-care supports self-esteem.*

Continuity of Care

Discuss the following topics when preparing the patient and family for home and community-based care. See the accompanying Case Study & Nursing Care Plan for additional community-based nursing interventions.

- Smoking cessation strategies and ways to avoid secondhand smoke
- Prescribed medications and anticoagulants, their purpose, doses, desired and adverse effects
- Signs of excess bleeding to report to the healthcare provider
- Skin surveillance and foot care (refer to Box 32–4)
- Recommended diet and exercise.

If revascularization or surgery has been performed, include the following topics as appropriate:

- Incision care
- Manifestations of complications (e.g., infection, graft leakage, or thrombosis) to be reported to the healthcare provider
- Activity limitations.

Provide referrals to home health services, physical or occupational therapy, and home maintenance assistance services as indicated. Consider resources such as Meals-on-Wheels for patients who are severely limited by their disease.

THE PATIENT WITH THROMBOANGIITIS OBLITERANS

Thromboangiitis obliterans (also called *Buerger's disease*) is an occlusive vascular disease in which small and midsize peripheral arteries become inflamed and spastic, causing clots to form. This disease may affect either the upper or lower extremities; it often affects a leg or foot. Its exact etiology is unknown, but there is evidence of significant T-cell activation, autoimmunity, and inflammation (Huether & McCance, 2011).

Pathophysiology and Course

Inflammatory cells infiltrate the wall of small and midsize arteries in the feet and possibly the hands. This inflammatory process is accompanied by thrombus formation and vasospasms of arterial segments that impair blood flow. Adjacent veins and nerves may be affected. As the disease progresses, affected vessels become scarred and fibrotic.

The course of the disease is intermittent with dramatic exacerbations and marked remissions. The disease may remain dormant for periods of weeks, months, or years. As the disease progresses, collateral vessels are more extensively involved. Consequently, subsequent episodes are more intense and prolonged. Prolonged periods of tissue hypoxia increase the risk for tissue ulceration and gangrene.

Manifestations and Complications

Pain in the affected extremities is the primary manifestation of thromboangiitis obliterans. Both claudication, cramping pain in the calves and feet or the forearms and hands, and rest pain in the fingers and toes may occur. Sensation is diminished. Eventually, the skin becomes thin and shiny and the nails are thickened and malformed. On examination, the involved digits and/or extremities are pale, cyanotic, or ruddy, and cool or cold to touch. Distal pulses (e.g., the dorsalis pedis, posterior tibial, ulnar, or radial) are either difficult to locate or absent, even with a Doppler device.

Painful ulcers and gangrene may develop in the fingers and toes, as a result of severely impaired blood flow. Amputation may be necessary to remove necrotic tissue.

Incidence and Risk Factors

Thromboangiitis obliterans primarily affects men under age 40 who smoke. Cigarette smoking is the single most significant cause of the disease. The disease is more prevalent in Asians and people of eastern European descent. The incidence of HLA-B5 and 2A9 antigens is higher in people with thromboangiitis obliterans, suggesting a genetic link.

●○● INTERPROFESSIONAL CARE

Thromboangiitis obliterans usually is diagnosed by the history and physical examination. Doppler studies may be used to locate and determine the extent of the disease. Angiography and magnetic resonance imaging may be used to evaluate the extent of the disease, but usually are unnecessary.

The one most important component in managing this disease is smoking cessation. While stopping smoking does not cure the disease, it may slow its extension to other vessels. With continued smoking, attacks become increasingly intense and last much longer, significantly increasing the risk for ulcerations and gangrene.

Additional conservative measures are used to prevent vasoconstriction, improve peripheral blood flow, and prevent complications of chronic ischemia. These measures include keeping extremities warm, managing stress, keeping affected extremities in a dependent position, preventing injury to affected tissues, and regular exercise. Walking for 20 or more minutes several times a day is recommended.

There are no specific drugs for thromboangiitis obliterans. A calcium channel blocker such as diltiazem (Cardizem) or verapamil (Isoptin), or pentoxifylline (Trental), which decreases blood viscosity and increases red blood cell flexibility to improve peripheral blood flow, may provide some symptom relief.

Surgical approaches for thromboangiitis obliterans include sympathectomy or arterial bypass graft. Sympathectomy interrupts sympathetic nervous system input to affected vessels, reducing vasoconstriction and spasm. Arterial bypass grafts may be useful when larger vessels are affected by the disease. Amputation of an affected

digit or extremity may be necessary if gangrene develops. (See Chapter 39 for more information about amputation.) Only portions of digits or of limbs (e.g., below the knee) may be amputated, to preserve as much healthy tissue as possible.

The prognosis for thromboangiitis obliterans depends significantly on the patient's ability and willingness to stop smoking. With smoking cessation and good foot care, the prognosis for saving the extremities is good, even though no cure is available.

●○● NURSING CARE

Health promotion activities to prevent thromboangiitis obliterans focus on preventing smoking, especially in high-risk populations. Nursing assessment and care for patients with this disease is similar to that provided for patients with other arterial occlusive diseases. Nursing care focuses on promoting arterial circulation and preventing prolonged tissue hypoxia. Because inflammatory, spastic episodes may be unpredictable, care focuses on smoking cessation and relieving acute manifestations. In addition, postsurgical care is necessary if surgery has been performed. Refer to the Nursing Care section for peripheral atherosclerosis earlier in this chapter, as well as nursing care of the postsurgical patient (Chapter 4) and following amputation (Chapter 39).

Continuity of Care

Discuss the following topics when preparing patients with thromboangiitis obliterans and their families for home or community-based care:

- Absolute necessity of smoking cessation
- Foot care
- Protecting affected extremities from injury
- Purpose, dose, desired and adverse effects, interactions, and any precautions associated with prescribed medications
- Signs and symptoms to report to the healthcare provider.

THE PATIENT WITH RAYNAUD'S DISEASE

Raynaud's disease and **phenomenon** are characterized by episodes of intense vasospasm in the small arteries and arterioles of the fingers and sometimes the toes. Raynaud's disease and phenomenon differ only in terms of cause. Raynaud's disease has no identifiable cause; Raynaud's phenomenon occurs secondarily to another disease (such as collagen vascular diseases like scleroderma and rheumatoid arthritis), other known causes of vasospasm, or long-term exposure to cold or machinery (Huether & McCance, 2011).

Raynaud's disease primarily affects young women between the ages of 20 and 40. Genetic predisposition may play a role in its development, although the actual cause is unknown. Table 32–5 compares thromboangiitis obliterans and Raynaud's disease.

Pathophysiology and Manifestations

Raynaud's disease and phenomenon are characterized by spasms of the small arteries in the digits. The arterial spasms limit arterial blood flow to the fingers and possibly the toes. Initial attacks may involve only the tips of one or two fingers; with disease progression, the entire finger and all fingers may be affected.

The manifestations of Raynaud's occur intermittently when spasms develop. Raynaud's disease has been called "the blue-white-red disease," because affected digits initially turn blue as blood flow is reduced due to vasospasm, then white as circulation is more severely limited, and finally very red as the fingers are warmed and the spasm

TABLE 32–5 Comparison of Raynaud's Disease and Thromboangiitis Obliterans

Topic	Raynaud's Disease	Thromboangiitis Obliterans
Etiology	• Unknown • Possible genetic predisposition	• Cigarette smoking most probable single cause • Possible autoimmune response
Incidence/course of the disease	• Onset commonly between 15 and 45 years of age • Usually affects young women • Becomes progressively worse over time	• Occurs predominantly in men under 40 • More common in Asians and people of European heritage • Intermittent course with exacerbations and remissions • Increased severity and duration of attacks over time
Triggering stimuli	• Emotional stress • Exposure to cold	• Cigarette smoking
Assessment findings	• Usually affects hands, sometimes toes • Pain becomes more severe and prolonged as disease progresses • "Blue-white-red" changes in color of hands with accompanying changes in skin temperature	• Claudication and pain • Numbness or diminished sensation • Cool, pale, or cyanotic skin • Shiny, thin skin and white, malformed nails in affected extremities • Distal pulses difficult to find or absent • Trophic changes to nail beds • Ulceration and gangrene in later stages • Small, red, tender vascular cords in affected extremities
Management	• Avoid unnecessary cold exposure • Emphasize smoking cessation • Medications such as calcium channel or alpha-adrenergic blockers as indicated • Teach stress management	• Stop smoking (crucial) • Regular exercise • Protect extremities from cold injury • Teach stress management

Figure 32–9 ■ Fingers of a patient with Raynaud's phenomenon. Note the extreme pallor of the fifth digit in response to exposure to cold.
Source: Custom Medical Stock Photo, Inc.

resolves (Figure 32–9 ■). Sensory changes may occur during attacks, including numbness, stiffness, decreased sensation, and aching pain.

The attacks tend to become more frequent and prolonged over time. With repeated attacks (and resultant decrease in oxygenation), the fingertips thicken and the nails become brittle. Ulceration and gangrene are serious complications that rarely occur.

●○● INTERPROFESSIONAL CARE

Raynaud's disease and phenomenon are primarily diagnosed by the history and physical examination. There are no specific diagnostic tests for these disorders.

Vasodilators may be prescribed to provide symptomatic relief. Low doses of a sustained-release calcium channel blocker such as nifedipine (Procardia) or diltiazem (Cardizem) may be prescribed. The alpha-adrenergic blocker prazosin (Minipress) also may reduce the frequency and severity of attacks. Transdermal nitroglycerine (or longer-acting oral nitrates) helps some patients by decreasing the amount of time necessary for the hands to return to normal following an attack.

Conservative measures are a mainstay of treatment. Patients are instructed to keep their hands warm, wearing gloves when outside in cold weather and kitchen gloves when handling cold items (for instance, when preparing and serving cold foods and cleaning the refrigerator). Measures to avoid injury to the hands are taught. Sometimes attacks can be stopped by swinging the arms back and forth, increasing perfusion pressure in the small arteries by centrifugal force.

Smoking cessation is important. Stress reduction measures such as exercise, relaxation techniques, massage therapy, hobbies, aroma therapy, and counseling are taught or suggested. Additional lifestyle habits that contribute to vascular health are encouraged, such as reducing dietary fat, increasing activity level, and maintaining normal body weight.

●○● NURSING CARE

Nursing care for the patient with Raynaud's disease or phenomenon is primarily educative and supportive. Protecting the hands and feet from exposure to cold and trauma is the major teaching topic. The diagnoses, outcomes, and interventions previously outlined for peripheral atherosclerosis also are appropriate for patients with Raynaud's.

Continuity of Care

Reassure patients with Raynaud's phenomenon that most people with the disorder experience only mild, infrequent episodes. Discuss the following topics in preparing the patient for managing the disorder:

- Dress warmly, keeping the trunk and hands warm.
- Avoid unnecessary exposure to cold.
- Stop smoking or do not start.
- Discuss the use, purpose, and desired and potential adverse effects of prescribed medications, if any.

THE PATIENT WITH ACUTE ARTERIAL OCCLUSION

A peripheral artery may be acutely occluded by development of a thrombus (blood clot) or by an embolism. Blood flow to tissues supplied by the artery is impaired, resulting in acute tissue ischemia and a risk for necrosis and gangrene.

Pathophysiology

ARTERIAL THROMBOSIS

A **thrombus** is a blood clot that adheres to the vessel wall. Thrombi tend to develop in areas where intravascular factors stimulate coagulation (e.g., where a vessel lumen is partially obstructed and its wall is damaged and roughened by atherosclerosis). Other disorders, such as infection or inflammation of the vessel wall or pooling of blood (e.g., in an aneurysm), also can prompt coagulation and thrombus formation (Huether & McCance, 2011). A developing thrombus can occlude arterial blood flow through the vessel, leading to ischemia of tissues supplied by that artery. The extent of ischemia depends on the size of the affected artery and the degree of collateral circulation. In gradual processes of arterial occlusion such as atherosclerosis, collateral vessels often develop to compensate for impaired arterial flow. The extent of collateral circulation affects the degree of tissue ischemia distal to the thrombus.

ARTERIAL EMBOLISM

An **embolism** is sudden obstruction of a blood vessel by debris. A thrombus can break loose from the arterial wall to become a **thromboembolus**. Other substances can become emboli: atherosclerotic plaque, masses of bacteria, cancer cells, amniotic fluid, bone marrow fat, and foreign objects such as air bubbles or broken intravenous catheters. Regardless of cause, an embolus eventually lodges in a vessel that is too small to allow it to pass.

Arterial emboli often originate in the left side of the heart. They are associated with myocardial infarction, valvular heart disease, left-sided heart failure, atrial fibrillation, or infectious heart diseases. Emboli from the left heart often enter the carotid arteries and become trapped in the cerebral circulation, causing neurologic deficits (see Chapter 42). Thromboemboli that develop in the aorta or peripheral arterial circulation tend to lodge in areas where the arterial lumen is narrowed by atherosclerotic plaque and at arterial bifurcations.

Manifestations

The manifestations of arterial thrombosis and embolism are those of tissue ischemia. Ischemic tissues are painful, pale, and cool or cold. Distal pulses are absent. Paresthesias (numbness and tingling) develop in the extremity. Cyanosis and mottling are common. Paralysis and muscle spasms may develop in the affected extremity. A line of demarcation between normal and ischemic tissue may be seen, particularly with embolism. Tissue below the line is cool or cold, and pale, cyanotic, or mottled. See the Manifestations box.

Arterial occlusion can result in permanent vessel and limb damage. Complete arterial occlusion leads to tissue necrosis and gangrene unless blood flow is promptly restored.

●○● INTERPROFESSIONAL CARE

Acute arterial occlusions may require emergency treatment to preserve the limb if the obstructed vessel is large or collateral circulation is minimal. If the limb is not in jeopardy, more conservative management may be initiated.

DIAGNOSIS

The diagnosis of acute arterial occlusion often is apparent by the signs and symptoms. *Arteriography* is used to confirm the diagnosis, locate the occlusion, and determine its extent.

MEDICATIONS

Anticoagulation with intravenous heparin is initiated to prevent further clot propagation and recurrent embolism. Anticoagulation is continued with oral anticoagulants after discharge. See the section on venous thrombosis later in this chapter for more information about anticoagulant therapy.

Arterial thrombosis may be treated with intra-arterial thrombolytic therapy using streptokinase, urokinase, or tissue plasminogen activator (tPA) (refer to Chapter 30). Lysis of the thrombus or embolus is achieved in 50% to 80% of the cases. Local intra-arterial injection of the thrombolytic drug allows use of lower doses and reduces the bleeding risk associated with thrombolytic drugs.

SURGERY

Immediate *embolectomy* (within 4 to 6 hours) is the treatment of choice for acute arterial occlusion by an embolus to prevent tissue necrosis and gangrene. When the involved vessel is in an extremity, local anesthesia and a special balloon-tipped catheter known as a Fogarty catheter may be used for high surgical risk patients. An embolus in the mesenteric circulation necessitates emergency laparotomy. The risk of complications and limb loss increases significantly if surgery is delayed by 12 or more hours. Potential major complications include compartment syndrome (Chapter 39), acute respiratory distress syndrome (Chapter 37), or acute renal failure (Chapter 28).

Arterial thrombosis may be treated surgically, although the required surgery may be more extensive due to the length of the vessel involved. *Thromboendarterectomy* is done to remove the thrombus and plaque in the artery. An arterial graft may be required. Nursing care for patients who have undergone embolectomy or thrombus removal is discussed in the nursing care section that follows.

MANIFESTATIONS OF ACUTE ARTERIAL OCCLUSION

- Pain
- Pallor or mottling
- Paresthesias (numbness and tingling)
- Cool or cold skin
- Pulselessness distal to the blockage
- Possible paralysis, weakness, or muscle spasms
- Possible line of demarcation; with pallor, cyanosis, and cooler skin distal to the blockage (especially with arterial embolism)

●○● NURSING CARE

Assessment

See the Manifestations and Interprofessional Care sections for the assessment of the patient with acute arterial occlusion.

Nursing assessment for the patient with an acute arterial occlusion is highly focused due to the emergency nature of the problem.

- *Health history:* complaints of pain, numbness, tingling, or weakness in the involved extremity; history of atherosclerotic vessel disease, heart disease, or recent invasive procedure (e.g., angiography, percutaneous revascularization procedure)
- *Physical assessment:* vital signs; peripheral pulses in both extremities; color, temperature, sensation, and movement of involved extremity; skin condition; presence of a line of demarcation.

Priorities of Care

Collaborating with the interprofessional team to ensure adequate treatment of the underlying process while providing care that supports the physical and psychologic responses to the disorder is a priority of nursing care.

Diagnoses, Outcomes, and Interventions

Nursing care related to acute arterial occlusion focuses on protecting the affected extremity, managing anxiety, and reducing the risk of complications related to anticoagulant therapy.

Ineffective Tissue Perfusion: Peripheral

Protecting ischemic tissue from injury prior to surgery or medical thrombolysis is vital. Following surgery, there is a risk for thrombosis at the graft site or impaired perfusion due to edema of the surgical site.

Expected Outcome: Patient's tissue perfusion will be adequate as evidenced by adequate arterial flow (i.e., strong peripheral pulses).

- Monitor extremity perfusion, comparing affected and unaffected extremities. Assess peripheral pulses (using the Doppler stethoscope as needed), skin temperature and color, capillary refill, movement, and sensation every 1 to 4 hours. Promptly report changes or complaints of increased or unrelieved pain. Propagation of a thrombus can further obstruct arterial flow, increasing tissue ischemia. Following surgery, arterial spasms may cause a cyanotic, pulseless extremity; normal color and pulses should return within 12 hours. *A thrombus may form at the surgical site or within a graft, causing tissue ischemia with pain and other manifestations of arterial occlusion. Further measures to restore circulation may be necessary.*
- Maintain intravenous fluids as ordered. *Adequate circulating blood volume is necessary to maintain cardiac output and tissue perfusion.*

- Protect the extremity, keeping it horizontal or lower than the heart. Use a cradle to keep bedclothes off the extremity and a sheepskin or foam pad to protect it from hard or abrasive surfaces. Do not apply heat or cold. *Keeping the extremity lower than the heart promotes collateral blood flow. Ischemic tissue is easily damaged by minimal trauma such as shearing by bed linens, or heat or cold application.*
- Following surgery, avoid raising the knee, placing pillows under the knees, or sitting with 90-degree hip flexion. *These activities may impair blood flow through the affected vessel.*

Anxiety

Patients with an acute arterial occlusion often are very anxious. The rapid and intense nature of preoperative activities can be overwhelming, increasing anxiety about the disorder and its outcome. Manifestations of anxiety may include trembling, palpitations, restlessness, dry mouth, helplessness, inability to relax, irritability, forgetfulness, and lack of awareness of surroundings. Nursing measures focus on establishing trust and minimizing the effects of anxiety to decrease surgical risk and improve recovery.

Expected Outcome: Patient will be able to control anxiety as evidenced by verbalized decrease in subjective distress.

- Spend as much time as possible with the patient. Provide opportunities to verbalize anxiety; offer reassurance and support. Support adaptive coping mechanisms. *The presence of a caring nurse provides a safe environment for expressing fears and anxieties. Coping mechanisms reduce the immediate perceived threat and increase the ability to deal with the situational crisis.*
- Perform required measures in an expedient but calm manner. *Calm, confident performance of treatment measures reassures the patient and family that appropriate care is being given to treat the problem at hand.*
- Assess anxiety level at least every 8 hours, and more often as needed. Intervene as indicated to reduce anxiety. *Assessment helps determine the intensity of anxiety and the patient's ability to control it, and directs interventions to reduce it.*
- Decrease sensory stimuli as much as possible. *Reducing environmental stimuli provides the patient a degree of control over anxiety.*
- Speak slowly and clearly and avoid unnecessary interruptions when listening. Give concise directions, focusing on the present. Involve the patient in simple tasks and decisions to the extent possible. *High levels of anxiety interfere with learning. Keeping interactions focused on the present situation directs the patient's focus and provides reassurance that it is the most important focus of the nurse as well. Providing opportunities for self-care and decision making reinforces the patient's importance and power to control the situation.*

Altered Protection

Thrombolytic and/or anticoagulant therapy used to dissolve existing clots and prevent further clot formation increases the risk for bleeding. Close monitoring of physical status and laboratory data is vital, as are measures to reduce the risk for injury and bleeding.

Expected Outcome: Patient will remain free of any evidence of new bleeding and take precautions to prevent bleeding.

PRACTICE ALERT!

Assess for and report manifestations of impaired clotting, including excessive incisional bleeding; prolonged oozing from injection sites; bleeding gums, nose bleed, or hematuria; petechiae, bruising, or purpura. Anticoagulants and thrombolytics interfere with the clotting cascade and may cause abnormal bleeding.

- Monitor activated partial thromboplastin time (aPTT) during heparin therapy and prothrombin time (PT) or International Normalized Ratio (INR) during oral anticoagulant therapy. Report values outside desired range. *The aPTT, PT, and INR are prolonged by anticoagulant therapy. Values higher than the desired range may indicate an increased risk for bleeding; values below the target may indicate inadequate anticoagulation.*
- Protect from injury: Use side rails or other measures as needed to prevent falls; avoid parenteral injections and other invasive procedures as much as possible; hold firm pressure over injection and intravenous sites for 5 minutes and over arterial punctures for 20 minutes; use a soft toothbrush or sponge for oral care; use an electric razor for shaving. *Minor trauma can lead to extensive bleeding, particularly in the patient who has received a thrombolytic drug.*

Continuity of Care

When preparing the patient and family for home or community-based care related to an acute arterial occlusion, discuss the following topics as indicated:

- Care of the incision
- Manifestations of complications to be reported, including symptoms of infection or occlusion of the graft or artery
- Long-term anticoagulant therapy, including the reason, prescribed dose, follow-up laboratory testing and appointments, interactions with other drugs, and manifestations of excessive bleeding
- Any activity restrictions or dietary modifications
- Lifestyle modifications to slow atherosclerosis and control hypertension
- Measures to promote peripheral circulation and maintain tissue integrity (see the discussion of venous peripheral atherosclerosis that follows).

Refer for home care services (nursing care, physical therapy, housekeeping services) as indicated.

Disorders of Venous Circulation

The two primary categories of venous system disorders are occlusive disorders and those related to ineffective venous blood flow. Impaired venous blood flow can lead to stasis and clotting, as well as tissue changes associated with venous congestion.

Physiology Review

The venous system is a low-pressure system in comparison with the arterial circulation. Veins and venules are thin-walled, distensible vessels. Although they contain smooth muscle that allows

them to contract or expand, the media (muscle layer) of veins is significantly thinner than that of arteries. The low pressures in the venous system allow it to serve as a reservoir for blood. Stimulation by the sympathetic nervous system causes veins to contract, helping maintain vascular volume. The low-pressure venous system relies on skeletal muscle contractions and pressure changes in the abdomen and thorax to facilitate blood return to the heart. Unlike arteries, veins of the extremities contain valves to prevent retrograde blood flow.

THE PATIENT WITH VENOUS THROMBOSIS

Venous thrombosis (*thrombophlebitis*) is a condition in which a blood clot (thrombus) forms on the wall of a vein, accompanied by inflammation of the vein wall and some degree of obstructed venous blood flow.

Venous thrombi are more common than arterial thrombi because of lower pressures and flow within the venous system (Huether & McCance, 2011). Thrombi can form in either superficial or deep veins. **Deep venous thrombosis (DVT)** is a common complication of hospitalization, surgery, and immobilization. Obstetric and orthopedic procedures carry a higher risk for venous thrombosis; it may develop in more than 50% of patients having orthopedic surgery, particularly surgeries involving the hip or knee. Other significant risk factors for venous thrombosis include abdominal or thoracic surgery, certain cancers, trauma, pregnancy, and use of oral contraceptives or hormone replacement therapy. See Box 32–5.

Pathophysiology

Three pathologic factors, called *Virchow's triad*, are associated with thrombophlebitis: stasis of blood, vessel damage, and increased blood coagulability. Vessel trauma stimulates the clotting cascade. Platelets aggregate at the site, particularly when venous stasis is present. Platelets and fibrin form the initial clot. Red blood cells are trapped in the fibrin meshwork, and the thrombus propagates (grows) in the direction of blood flow. The inflammatory response is triggered, causing tenderness, swelling, and erythema in the area of the thrombus. Initially the thrombus floats within the vein. Pieces of the thrombus may break loose and travel through the circulation as emboli. Fibroblasts eventually invade the thrombus, scarring the vein wall and destroying venous valves. Although patency of the vein may be restored, valve damage is permanent, affecting directional flow.

BOX 32–5 Factors Associated with Venous Thrombosis

- Immobilization: myocardial infarction, heart failure, stroke, postoperative
- Surgery: orthopedic, thoracic, abdominal, genitourinary
- Cancer: pancreatic, lung, ovary, testes, urinary tract, breast, stomach
- Trauma: fractures of the spine, pelvis, femur, tibia; spinal cord injury
- Pregnancy and delivery
- Hormone therapy: oral contraceptives, hormone replacement therapy
- Coagulation disorders

DEEP VENOUS THROMBOSIS

The deep veins of the legs, primarily in the calf, and the pelvis provide the most hospitable environment for venous thrombosis. Approximately 80% of DVTs begin in the deep veins of the calf, often propagating into the popliteal and femoral veins (Figure 32–10 ■). DVT usually is asymptomatic; in some patients, a pulmonary embolism may be the first indication.

MANIFESTATIONS When present, the manifestations of DVT are primarily due to the inflammatory process accompanying the thrombus. Calf pain, which may be described as tightness or a dull, aching pain in the affected extremity, particularly upon walking, is the most common symptom. Tenderness, swelling, warmth, and erythema may be noted along the course of involved veins. The affected extremity may be cyanotic and often is edematous. Rarely, a cord may be palpated over the affected vein. A positive Homans' sign (pain in the calf when the foot is dorsiflexed) is an unreliable indicator of DVT. See the Manifestations box for a summary of the manifestations of deep and superficial venous thrombosis.

COMPLICATIONS The major complications of deep venous thrombosis are chronic venous insufficiency and pulmonary embolism. Pulmonary embolism occurs when the clot fragments or breaks loose from the vein wall. As the clot travels, it moves through progressively larger veins and into the right side of the heart. From there it enters the pulmonary circulation, where it eventually occludes arterial flow to a portion of the lungs. The result is a mismatch between ventilation (air flow) and perfusion (blood flow) in a portion of the lungs. The effect on gas exchange depends on the size of the embolism and the vessel it occludes. See Chapter 37 for more information about pulmonary emboli.

FAST FACTS

- DVT is a common complication of surgery and immobility. It usually develops in the deep veins of the calf (80%).
- Venous stasis (sluggish blood flow), altered blood coagulation, and damage (e.g., inflammation) to blood vessels are precipitating factors for DVT.
- A thrombus or a portion of a thrombus may break loose, traveling through the venous system to the right side of the heart and into the pulmonary circulation, where it ultimately becomes lodged (pulmonary embolus).

MANIFESTATIONS OF VENOUS THROMBOSIS

DEEP VENOUS THROMBOSIS

- Usually asymptomatic
- Dull, aching pain in affected extremity, especially when walking
- Possible tenderness, warmth, erythema along affected vein
- Cyanosis of affected extremity
- Edema of affected extremity

SUPERFICIAL VENOUS THROMBOSIS

- Localized pain and tenderness over the affected vein
- Redness and warmth along the course of the vein
- Palpable cordlike structure along the affected vein
- Swelling and redness of surrounding tissue

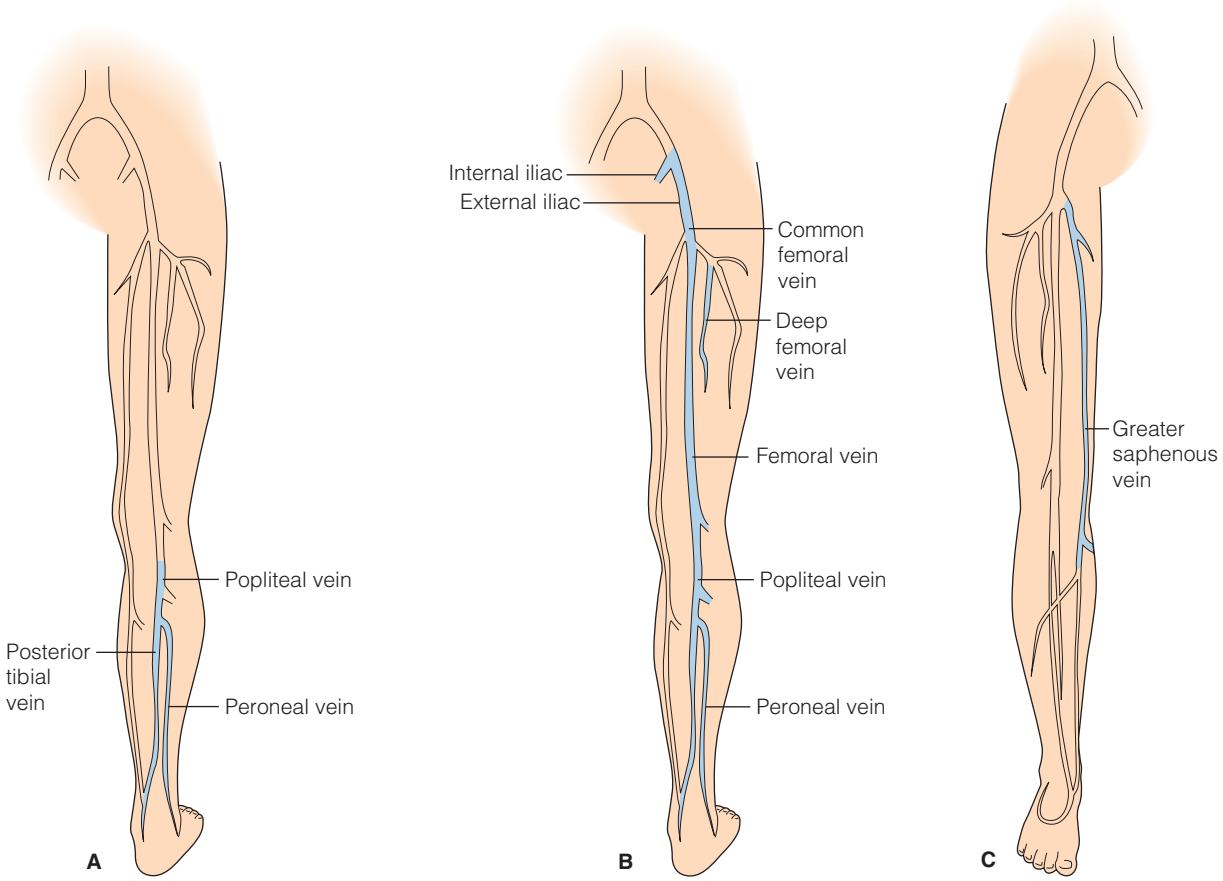

Figure 32–10 ■ Common locations of venous thrombosis. A, The most common sites of deep venous thrombosis. B, DVT extending from the calf to the iliac veins. C, Superficial venous thrombosis.

SUPERFICIAL VENOUS THROMBOSIS

Venous catheters and infusions are the primary risk factors for superficial venous thrombosis. Superficial venous thrombosis may develop in conjunction with thromboangiitis obliterans, varicose veins, or deep venous thrombosis. It may develop spontaneously in pregnant women or following delivery. In some cases, superficial venous thrombosis of the long saphenous vein is the earliest sign of an abdominal cancer such as pancreatic cancer.

Superficial venous thrombosis is marked by pain and tenderness at the site of the thrombus. A reddened, warm, tender cord extending along the affected vein can be palpated. The area surrounding the vein may be swollen and red (see the Manifestations box).

●○● INTERPROFESSIONAL CARE

It is important to differentiate venous thrombosis from other causes of extremity pain, such as cellulitis, muscle strain, contusion, and lymphedema. The history, physical examination, and diagnostic tests are used to establish the diagnosis. Treatment focuses on preventing further clotting or extension of the clot and addressing underlying causes.

DIAGNOSIS

- *Duplex venous ultrasonography* is a noninvasive test used to visualize the vein and measure the velocity of blood flow in the veins. Although the clot often cannot be visualized directly, its presence can be inferred by an inability to compress the vein during the examination.
- *Plethysmography* is a noninvasive test that measures changes in blood flow through the veins. It is often used in conjunction with Doppler ultrasonography. Plethysmography is most valuable in diagnosing thromboses of larger or more superficial veins.
- *Magnetic resonance imaging (MRI)* is another noninvasive means of detecting deep venous thrombosis. It is particularly useful when thrombosis of the vena cavae or pelvic veins is suspected.
- *Ascending contrast venography* uses an injected contrast medium to assess the location and extent of venous thrombosis. Although invasive, expensive, and uncomfortable, contrast venography is the most accurate diagnostic tool for venous thrombosis. It is used when the results of less invasive tests leave the diagnosis unclear.

PROPHYLAXIS

Medications and other measures are used to prevent venous thrombosis when the risk is high. Low-molecular-weight heparins (see the following section) prevent deep venous thrombosis in patients who are undergoing general or orthopedic surgery, experiencing acute medical illness, or are on prolonged bed rest. Oral anticoagulation may be used as a prophylactic measure in patients with fractures or who are undergoing orthopedic surgery.

Elevating the foot of the bed with the knees slightly flexed promotes venous return. Early mobilization and leg exercises such as ankle flexion and extension assist venous flow by muscle compression. Intermittent pneumatic compression devices applied to the legs are effective to prevent DVT. They also are used when anticoagulation is

contraindicated due to the increased risk for bleeding. Elastic stockings are used to prevent venous thrombosis as well in patients at risk.

MEDICATIONS

Anticoagulants to prevent clot propagation and enable the body's own lytic system to dissolve the clot are the mainstay of treatment for venous thrombosis. Thrombolytic drugs such as streptokinase or tissue plasminogen activator (tPA) may accelerate the process of clot lysis and prevent damage to venous valves. There is, however, no evidence that thrombolytic therapy is more effective in preventing pulmonary embolism in patients with existing DVT than anticoagulants. It also significantly increases the risk for bleeding and hemorrhage.

Nonsteroidal anti-inflammatory agents such as indomethacin (Indocin) or naproxen (Naprosyn) may be ordered to reduce inflammation in the veins and provide symptomatic relief, particularly for patients with superficial venous thrombosis.

ANTICOAGULANTS Anticoagulants are given to prevent clot extension and reduce the risk of subsequent pulmonary embolism. Anticoagulation is initiated with unfractionated heparin or low-molecular-weight (LMW) heparin. Following an initial intravenous bolus of 7,500 to 10,000 units of unfractionated heparin, a continuous heparin infusion of 1000 to 1500 International Units per hour is started. The dosage is calculated to maintain the activated partial thromboplastin time (aPTT) at approximately twice the control or normal value. An infusion pump is used to deliver the prescribed dosage. Frequent monitoring of the infusion is an important nursing responsibility. Subcutaneous heparin injections may be used as an alternate to intravenous infusion in some instances.

LMW heparins are increasingly used to prevent and treat venous thrombosis. They do not require the close laboratory monitoring of unfractionated heparins. LMW heparin is administered subcutaneously in fixed doses once or twice daily, allowing the option of outpatient treatment. LMW heparins have additional advantages, in that they are more effective and carry lower risks for bleeding and thrombocytopenia than conventional, unfractionated heparins.

Oral anticoagulation with warfarin may be initiated concurrently with heparin therapy. Overlapping heparin and warfarin therapy for 4 to 5 days is important because the full anticoagulant effect of warfarin is delayed, and it may actually promote clotting during the first few days of therapy. Warfarin doses are adjusted to maintain the INR at 2.0 to 3.0 (Vallerand & Sanoski, 2012).

Once this level is achieved, the heparin is discontinued and a maintenance dose of warfarin is prescribed to prevent recurrent thrombosis. Anticoagulation generally is continued for at least 3 months. When DVT is recurrent or risk factors such as altered coagulability or cancer are present, anticoagulant therapy may be prolonged. Regular follow-up is necessary to be sure prothrombin times (INR) remain within the desirable range for anticoagulation. See the Medication Administration box for the nursing implications for anticoagulant therapy.

TREATMENTS

Treatment of venous thrombosis includes measures to relieve symptoms and reduce inflammation. With superficial venous thrombosis, applying warm, moist compresses over the affected vein, extremity rest, and anti-inflammatory agents usually provide relief of symptoms.

Bed rest may be ordered for deep venous thrombosis. The duration of bed rest typically is determined by the extent of leg edema. The legs are elevated 15 to 20 degrees, with the knees slightly flexed, above the level of the heart to promote venous return and discourage venous pooling. Elastic antiembolism stockings (TEDS) or pneumatic compression devices are frequently ordered to stimulate the muscle-pumping mechanism that promotes the return of blood to the heart. When permitted, walking is encouraged while avoiding prolonged standing or sitting. Crossing the legs is avoided, as are tight-fitting garments or stockings that bind.

SURGERY

Venous thrombosis usually is effectively treated with conservative measures and anticoagulation. In some cases, however, surgery is required to remove the thrombus, prevent its extension into deep veins, or prevent the effects of embolization.

Venous thrombectomy is done when thrombi lodge in the femoral vein and their removal is necessary to prevent pulmonary embolism or gangrene. Successful thrombus removal rapidly improves venous circulation. The duration of this effect varies.

When venous thrombosis is recurrent and anticoagulant therapy is contraindicated, a filter may be inserted into the vena cava to capture emboli from the pelvis and lower extremities, preventing pulmonary embolism. Several different filters are available (Figure 32–11 ■). The Greenfield filter is widely used for its ability to trap emboli within its apex while maintaining patency of the vena cava. The filter can be inserted under fluoroscopy with local anesthesia. Mortality and morbidity associated with the filter are very low.

Extensive thrombosis of the saphenous vein may necessitate ligation and division of the saphenous vein where it joins the femoral vein to prevent clot extension into the deep venous system. A vein affected by septic venous thrombosis is excised to control the infection. Antibiotic therapy also is initiated.

●○● NURSING CARE

Health Promotion

Prevention of venous thrombosis is an important component of nursing care for all at-risk patients. Position patients to promote venous blood flow from the lower extremities, with the feet elevated and the knees slightly bent. Avoid placing pillows under the knees

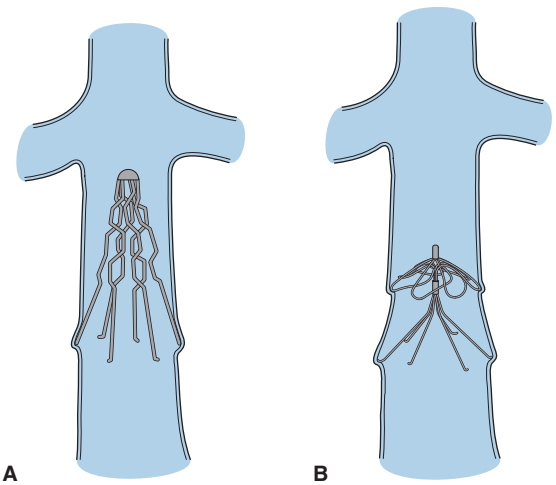

Figure 32–11 ■ Venal caval filters. A, Greenfield filter. B, Nitinol filter.

MEDICATION ADMINISTRATION

Anticoagulant Therapy

HEPARIN

Heparin interferes with the clotting cascade by inhibiting the effects of thrombin and preventing the conversion of fibrinogen to fibrin. This prevents the formation of a stable fibrin clot. At therapeutic levels, heparin prolongs the thrombin time, clotting time, and aPTT. When given intravenously, its effect is immediate. Given subcutaneously, its onset of action is within 1 hour. When heparin is discontinued, clotting times return to normal within 2 to 6 hours (Karch, 2012; Vallerand & Sanoski, 2012). *Heparin-induced thrombocytopenia (HIT)* is a potential complication of therapy with unfractionated heparin. See Chapter 33 for more information about HIT and nursing responsibilities in monitoring for this dangerous potential complication.

Nursing Responsibilities

- Assess for history of unexplained or active bleeding. Assess laboratory results for abnormal clotting profile or evidence of active bleeding.
- Give a test dose as indicated to patients with a history of multiple allergies or a history of asthma.
- Administer by deep subcutaneous injection; abdominal sites are preferred. Avoid injecting within 2 inches of the umbilicus. Rotate sites. Do not aspirate prior to injecting or massage after the injection.
- Intravenous solutions may be diluted with dextrose, normal saline, or Ringer's solution. Use an infusion pump.
- Keep protamine sulfate, a heparin antagonist, available to treat excessive bleeding.
- Monitor and report abnormal laboratory results and aPTT values outside the desired range.
- Promptly report evidence of bleeding such as hematemesis, hematuria, bleeding gums, or unexplained abdominal or back pain.

Health Education for the Patient and Family

- Report unusual bleeding or excessive menstrual flow.
- Use an electric razor and a soft-bristle toothbrush; prevent injury by clearing pathways, using a night-light, and other measures. Do not consume alcohol.
- Avoid contact sports while on anticoagulant therapy.
- Do not consume large amounts of food rich in vitamin K (yellow and dark green vegetables).
- Do not use aspirin or NSAIDs while on heparin therapy unless advised to do so by your healthcare provider.
- Wear a medical alert tag and advise all healthcare providers (including dentists and podiatrists) of therapy.

LOW-MOLECULAR-WEIGHT HEPARINS

dalteparin (Fragmin)

enoxaparin (Lovenox)

LMW heparins are the most bioavailable fraction of heparin. They provide a more precise and predictable anticoagulant effect than unfractionated heparins. Like unfractionated heparin, LMW heparin prevents conversion of prothrombin to thrombin, liberation of thromboplastin from platelets, and formation of a stable clot. LMW heparins cannot be used interchangeably with each other or with unfractionated heparin. Although the risk of heparin-induced thrombocytopenia is significantly lower with LMW heparin, patients who were previously treated with unfractionated heparin may develop HIT when treated with LMW heparin.

Other Injectable Anticoagulants

antithrombin III (Thrombate III)

ardeparin (Normiflo)

argatroban (Acova)

bivalirudin (Angiomax)

desirudin (Iprivask)

fondaparinux (Arixtra)

tinzaparin (Innohep)

Nursing Responsibilities

- Assess for evidence of active bleeding, a history of bleeding disorders or thrombocytopenia, or sensitivity to heparin, sulfites, or pork products.
- Monitor for unusual or masked bleeding. PT and aPTT levels may be within normal levels even in the presence of hemorrhage.
- Administer by deep subcutaneous injection into abdominal wall, thigh, or buttocks. Rotate sites. Do not aspirate or massage.

Health Education for the Patient and Family

- Subcutaneous self-administration technique, timing of doses, and site rotation. Do not rub site after administering to minimize bruising.
- Do not take aspirin, NSAIDs, or other over-the-counter drugs unless recommended by your healthcare provider.
- Promptly report excessive bruising or bleeding, chest pain, difficulty breathing, itching, rash, or swelling to your healthcare provider.
- Keep follow-up appointments as scheduled.

ORAL ANTICOAGULANT

warfarin (Coumadin)

Warfarin interferes with synthesis of vitamin K–dependent clotting factors by the liver, leading to depletion of these factors. It has no effect on already circulating clotting factors or on existing clots. Warfarin inhibits extension of existing thrombi and the formation of new clots. Its action is cumulative and more prolonged than that of heparin.

Other Oral Anticoagulants

dabigatran (Pradaxa)

rivaroxaban (Xarelto)

Dabigatran is a direct thrombin inhibitor that helps to stop clots from forming by working directly on thrombin. Rivaroxaban acts as a selective factor X inhibitor, inactivating the cascade of coagulation. Neither requires monitoring like warfarin does, however, there is no reversal agent available for these drugs. Costs are also significantly higher for these drugs when compared to warfarin.

Nursing Responsibilities

- Assess laboratory results and history for evidence of abnormal bleeding.
- Multiple drugs affect the metabolism and protein binding of warfarin; note all medications and assess for interactions with warfarin.
- Do not give during pregnancy because warfarin may cause congenital malformations.
- Oral tablets may be crushed and given without regard to meals.
- Dilute intravenous warfarin with supplied diluent; administer within 4 hours by direct intravenous injection at a rate of 25 mg/min.
- Keep vitamin K available to reverse effects of warfarin in the event of excessive bleeding or hemorrhage.
- Monitor PT or INR; report values outside the desired range (warfarin only).

Health Education for the Patient and Family

- Do not take your prescribed dose and notify your healthcare provider immediately if bleeding occurs (hematemesis, bright red or black, tarry feces, hematuria, bleeding gums, excessive bruising, etc.). Report rash or manifestations of hepatitis (dark urine, malaise, yellow skin or sclera).
- Take your warfarin at the same time every day; do not change brands as their effects may differ.
- Menstrual bleeding may be slightly increased; contact your healthcare provider if it increases significantly. Use reliable birth control to prevent pregnancy while taking warfarin. Immediately

MEDICATION ADMINISTRATION (*continued*)

contact your healthcare provider if you think you may be pregnant.
- Take precautions to prevent injury and bleeding: Use a soft toothbrush and electric razor, wear shoes, and use a night-light. Avoid participating in contact sports.
- Do not smoke, use alcohol, or take any over-the-counter drugs unless specifically recommended by your healthcare provider. Notify all healthcare providers, including dentists and podiatrists, of therapy. Wear a medical alert tag.
- Obtain lab tests as scheduled and keep all scheduled follow-up appointments.

Note: Drugs identified in *italics* are among the 200 most commonly prescribed medications in the U.S.

and positions in which the hips and knees are sharply flexed. Use a recliner chair or footstool when sitting. Ambulate patients as soon as possible, and maintain a regular schedule of ambulation throughout the day. Teach ankle flexion and extension exercises, and frequently remind patients to perform them. Apply elastic hose and pneumatic compression devices when appropriate. Instruct patients to avoid crossing legs when in bed or sitting. Inquire about possible prophylactic heparin or warfarin therapy for patients undergoing orthopedic surgery or other high-risk procedures. Frequently assess intravenous sites. Change the site and catheter as dictated by agency protocol and if evidence of local inflammation is noted.

Assessment

See the Manifestations and Interprofessional Care sections for the assessment of the patient with venous thrombosis.

Assess patients at risk for venous thrombosis for manifestations and risk factors.

- *Health history:* Ask about complaints of leg or calf pain, its duration and characteristics, and the effect of walking on the pain; history of venous thrombosis or other clotting disorders; current medications.
- *Physical assessment:* Inspect affected extremity for redness, edema; palpate for tenderness, warmth, cordlike structures; body temperature.
- *Laboratory data:* Tests include clotting studies (APTT, pro time, INR).

See the accompanying Case Study & Nursing Care Plan for an example of an assessment of a patient with deep venous thrombosis.

Priorities of Care

Collaborating with the interprofessional team to ensure adequate treatment of the underlying process while providing care that supports the physical and psychologic responses to the disorder is a priority of nursing care.

Diagnoses, Outcomes, and Interventions

In addition to the preventive measures identified earlier, priority nursing diagnoses for the patient with venous thrombosis relate to pain, maintenance of tissue perfusion and integrity, and the potential adverse effects of prescribed treatments.

Pain

The pain associated with venous thrombosis results from inflammation of the involved vein. It may be aggravated by use of the involved extremity. Associated edema and swelling may contribute to discomfort. Measures to reduce the inflammation often help relieve the pain.

Expected Outcome: Patient will exhibit adequate pain control as evidenced by physical well-being.

- Regularly assess pain location, characteristics, and level using a standardized pain scale. Report increasing pain or changes in its location or characteristics. *Tissue substances released during the inflammatory process can stimulate pain receptors. In addition, localized swelling presses on pain-sensitive structures in the area of the inflammation, contributing to discomfort. As inflammation and swelling are reduced, pain should abate. Continued or increasing pain may indicate extension of the thrombosis. Sudden chest pain may indicate a pulmonary embolism, necessitating immediate intervention.*
- Measure calf and thigh diameter of the affected extremity on admission and daily thereafter. Report increases promptly. *The inflammatory process causes vasodilation and increases vessel permeability, causing edema of the affected extremity. Baseline and subsequent measurements provide a measure of treatment effectiveness.*
- Apply warm, moist heat to affected extremity at least four times daily, using warm, moist compresses or an aqua-K pad. *Moist heat penetrates tissues to a greater depth than dry heat. Warmth promotes vasodilation, allowing reabsorption of excess fluid into the circulation. Vasodilation also reduces resistance within the affected vessel, reducing pain. As edema subsides, pressure on surrounding tissues is relieved, thereby reducing pain.*
- Maintain bed rest as ordered. *Using leg muscles during walking exacerbates the inflammatory process and increases edema. This, in turn, increases venous compression and pain.*

Ineffective Tissue Perfusion: Peripheral

As thrombi develop, they occlude the lumen of the vein and obstruct blood flow. In addition, the accompanying inflammatory response may precipitate vessel spasms, further impairing arterial and venous blood flow and tissue perfusion. Impaired tissue perfusion, in turn,

Evidence for Nursing Care

The Patient with Deep Venous Thrombosis

Selected resources that nurses may find helpful when planning evidence-based nursing care follow.

CASE STUDY & NURSING CARE PLAN A Patient with Deep Venous Thrombosis

Mrs. Opal Hipps, age 75, lives alone with her dog, Chester, in her family home in the suburbs. She retired from her job as a postal clerk 10 years ago and now spends a lot of time reading and watching television. During the past week she developed a vague aching pain in her right leg. She ignored the pain until last night when it developed into a much more severe pain in her right calf. She noticed that her right lower leg seemed larger than the left, and it was very tender to the touch. After seeing her healthcare provider and undergoing Doppler ultrasound studies, Mrs. Hipps is admitted to the hospital with the diagnosis of deep venous thrombosis in the right leg. She is placed on bed rest and intravenous heparin. Michael Cookson, RN, is assigned to admit and care for Mrs. Hipps.

ASSESSMENT

Mr. Cookson notices that Mrs. Hipps was admitted 14 months ago for repair of a fractured femur. Mrs. Hipps says, "This business about a blood clot really has me worried." She also tells Mr. Cookson that she is worried about who will care for her dog while she is in the hospital. Physical findings include height 157 cm (62 in.), weight 68 kg (149 lb), T 37.3°C (99.2°F); vital signs within normal limits otherwise. Her left leg is warm and pink, with strong peripheral pulses and good capillary refill. Her right calf is dark red, very warm, and dry to touch. It is tender to palpation. The right femoral and popliteal pulses are strong, but the pedal and posterior tibial pulses are difficult to locate. The right calf diameter is 1.27 cm (0.5 in.) larger than the left.

DIAGNOSES

- *Pain* related to inflammatory response in affected vein
- *Anxiety* related to unexpected hospitalization and uncertainty about the seriousness of her illness
- *Ineffective Tissue Perfusion: Peripheral* related to decreased venous circulation in the right leg
- *Risk for Impaired Skin Integrity* related to pooling of venous blood in the right leg

EXPECTED OUTCOMES

- Patient will verbalize relief of right leg pain by day of discharge.
- Patient will verbalize reduced anxiety by the second day of her hospitalization.
- Patient will demonstrate reduced right leg diameter by 0.64 cm (0.25 in.) by the fifth day of hospitalization.
- Patient will maintain intact skin on the right foot throughout the hospital stay.

PLANNING AND IMPLEMENTATION

- Elevate legs, maintaining slight knee flexion, while in bed.
- Apply warm, moist compresses to right leg using a 2-hour-on, 2-hour-off schedule around the clock.
- Administer prescribed analgesics and evaluate effectiveness.
- Spend time with Mrs. Hipps to explain venous thrombosis and its treatment.
- Arrange for a friend or neighbor to care for Mrs. Hipps's dog.
- Apply antiembolism stockings as ordered; remove for 30 minutes every 8 hours.
- Monitor laboratory values to assess effect of anticoagulant therapy; report values outside desired range.
- Assist with progressive ambulation when allowed.
- Inspect legs and feet and record findings every 8 hours.

EVALUATION

Seven days after admission, the pain in Mrs. Hipps's right leg has subsided and the diameter of her right calf is equal to that of her left calf. Mrs. Hipps admits to Mr. Cookson that her fears really relate to a cousin who was hospitalized for a similar problem and had his leg amputated. After talking about her condition and the steps she can take to prevent its recurrence, she is much less anxious. Before discharge, Mr. Cookson reviews instructions for use of antiembolism stockings, daily walking, warfarin schedule, and scheduled follow-up appointment. Her neighbor, Kate, came to pick her up. As Mr. Cookson was helping Mrs. Hipps into the car, Kate handed her a small brown dog and said, "I took good care of Chester for you, but he's missed you." Mrs. Hipps smiled, and assured Mr. Cookson that she would call the number he provided if she had any questions.

Clinical Reasoning in Patient Care

1. Describe the pathophysiologic reasons for the pain in Mrs. Hipps's right leg.
2. How would you respond if Mrs. Hipps tells you she does not have the money to buy the prescribed anticoagulant when she goes home?
3. How would you change your teaching and discharge planning if Mrs. Hipps had difficulty caring for herself?
4. Design a plan of care for Mrs. Hipps for the diagnosis of *Activity Intolerance.*

See Evaluating Your Response in Appendix B.

deprives tissues of nutrients and oxygen. As a result, distal tissues of the affected extremity are at risk for ulceration and infection.

Expected Outcome: Patient's tissue perfusion will be adequate as evidenced by adequate arterial flow (i.e., strong peripheral pulses).

- Assess peripheral pulses, skin integrity, capillary refill times, and color of extremities at least every 8 hours. Report changes promptly. Assessment of both extremities allows comparison of the affected and unaffected limbs. *Weak or absent pulses, impaired capillary refill, or significant color changes in the affected extremity may indicate extension of the thrombus or a possible complication.*
- Assess the skin of the affected lower leg and foot at least every 8 hours, and more often as indicated. *Frequent assessment is important to rapidly detect early signs of tissue breakdown and implementation of measures to protect vulnerable tissues. Early intervention allows healing and restoration of tissue integrity; allowed to continue, the process can lead to necrosis and potential gangrene.*
- Elevate extremities at all times, keeping knees slightly flexed and legs above the level of the heart. *Elevation of the extremities promotes venous return and reduces peripheral edema. Knee flexion promotes muscle relaxation.*

PRACTICE ALERT!

Remove antiembolic stockings or pneumatic compression device for 30 to 60 minutes during daily hygiene. Antiembolic stockings (e.g., TED hose) and pneumatic compression devices exert pressure on the extremity and promote venous return. They can, however, impair perfusion of the dermis. Removing them periodically allows for assessment of the underlying tissue and restores perfusion of the dermis, reducing the risk for skin breakdown. Their use may be continued following discharge to reduce the risk of recurrent venous thrombosis.

- Use mild soaps, solutions, and lotions to clean the affected leg and foot daily. Pat dry after washing, and apply a nonalcohol-based lotion or moisturizing cream. *Daily hygiene with nondrying soaps*

and solutions removes potential pathogens from the skin surface, and maintains skin integrity and the first line of defense against infection. Caustic or harsh soaps or solutions can dry and crack the skin. Dry, cracked skin permits bacteria and other microorganisms to enter and infect the tissue, potentially leading to ulceration and venous gangrene.

- Use a weight-dispersion appliance such as an egg-crate mattress or sheepskin on the bed as needed. *Egg-crate mattresses and sheepskins distribute weight more evenly, preventing excess pressure on affected tissues.*
- Encourage frequent position changes at least every 2 hours while awake. *Frequent position changes reduce pressure on bony prominences and edematous tissue, reducing the risk of tissue breakdown.*

Ineffective Protection

Anticoagulant therapy interferes with the body's normal clotting mechanisms, increasing the risk for bleeding and hemorrhage.

Expected Outcome: Patient will remain free of any evidence of new bleeding and take precautions to prevent bleeding.

SAFETY ALERT

Assess for and promptly report evidence of bleeding, such as petechiae; bruising; bleeding gums; obvious or occult blood in vomitus, stool, or urine; or unexplained back or abdominal pain. Anticoagulants interfere with the ability to form a stable clot and prevent excessive bleeding. Even minor trauma such as tooth brushing or bumping into furniture can result in bleeding.

- Monitor laboratory results, including the INR (prothrombin time), aPTT, hemoglobin, and hematocrit as indicated. Report values outside the normal or desired range. *Coagulation studies are used to monitor the effect of anticoagulant medications. Values within the desired range prevent further clot development while carrying a low risk for bleeding and hemorrhage. A fall in the hemoglobin and hematocrit levels may indicate undetected bleeding.*

Impaired Bed Mobility

Although prolonged bed rest rarely is required, when it is required, it is associated with many problems, including constipation, joint contractures, muscle atrophy, and boredom. Nursing care goals include maintaining joint range of motion, minimizing muscle atrophy, and reducing boredom.

Expected Outcome: Patient will demonstrate optimal independence in positioning, exercising, and performing functional activities in bed.

- Encourage active range-of-motion (ROM) exercises at least every 8 hours. Provide passive ROM as needed. *ROM exercises maintain joint mobility and prevent contractures. Active ROM (performed by the patient) also helps prevent muscle atrophy and preserve function. While passive ROM exercises do not prevent muscle atrophy, they do maintain joint mobility.*
- Encourage frequent position changes, deep breathing, and coughing. *Prolonged immobility can lead to impaired airway clearance and respiratory complications, such as atelectasis or pneumonia. Turning, coughing, and deep breathing facilitate expulsion of secretions from the respiratory tract, airway clearance, and alveolar ventilation.*
- Encourage increased fluid and dietary fiber intake. *Constipation is a frequent complication of immobility due to decreased gastrointestinal motility and loss of abdominal muscle strength. Increasing fluid and fiber intake helps maintain soft, easily expelled stools.*
- Assist with and encourage ambulation as allowed. *Ambulation promotes venous blood flow, helps maintain muscle tone and joint mobility, and increases the sense of well-being.*
- Encourage diversional activities such as reading, handiwork or other hobbies, television or video games, and socializing. *Boredom may lead to dozing and inertia, with little physical movement or mental stimulation, increasing the risk for complications of immobility.*

Risk for Ineffective Tissue Perfusion: Cardiopulmonary

A thrombus that forms in the deep veins of the legs or pelvis may break loose or fragment, becoming an embolism. Emboli that originate in the venous system usually become trapped in the pulmonary circulation (pulmonary embolism). Gas exchange in the affected area is impaired as blood flow ceases or is reduced to an area of the lungs that is well ventilated (see Chapter 37).

Expected Outcome: Patient's tissue perfusion will be adequate as evidenced by adequate arterial flow (i.e., strong peripheral pulses) and freedom from dyspnea.

- Frequently assess respiratory status, including rate, depth, ease, and oxygen saturation levels. *A mismatch of ventilation and perfusion can significantly affect gas exchange, leading to rapid, shallow respirations, dyspnea and air hunger, and a fall in oxygen saturation levels.*

PRACTICE ALERT!

Immediately report complaints of chest pain and shortness of breath, anxiety, or a sense of impending doom. The manifestations of pulmonary embolism are similar to those of myocardial infarction. Prompt intervention to restore pulmonary blood flow can reduce the risk of significant adverse effects.

- Initiate oxygen therapy, elevate the head of the bed, and reassure the patient who is experiencing manifestations of pulmonary embolism. *Oxygen therapy and elevating the head of the bed promote ventilation and gas exchange in those alveoli that are well perfused, helping maintain tissue oxygenation. Reassurance helps reduce anxiety and slow the respiratory rate, promoting greater respiratory depth and alveolar ventilation.*

Continuity of Care

Treatment measures for venous thrombosis may be initiated and carried out on an outpatient basis or continued for an extended period of time following hospital discharge. Include the following topics when teaching for home care:

- Explanation of the disease process
- Treatment measures, including laboratory tests and their purposes, medications, and adverse effects that should be reported
- Appropriate methods of heat application
- Prescribed activity restrictions
- Measures to prevent future episodes of venous thrombosis
- The importance of follow-up visits and laboratory tests as scheduled.

Refer patients for community nursing services for continued assessment and reinforcement of teaching. Provide referrals for

assistance with ADLs and home maintenance services as indicated. Consider referral for physical therapy if needed.

THE PATIENT WITH CHRONIC VENOUS INSUFFICIENCY

Chronic venous insufficiency is a disorder of inadequate venous return over a prolonged period. Deep venous thrombosis is the most frequent cause of chronic venous insufficiency. Other conditions, such as varicose veins or leg trauma, may contribute; in some instances, it develops without an identified precipitating cause (Huether & McCance, 2011).

Pathophysiology

Following DVT, large veins may remain occluded, increasing the pressure in other veins of the extremity. This increased pressure distends the veins, separating valve leaflets and impairing their ability to close. DVT also damages valve leaflets, causing them to thicken and contract. The result is impaired unidirectional blood flow and deep vein emptying (Huether & McCance, 2011).

When venous valves are incompetent, the muscle-pumping action produced during activity cannot propel blood back to the heart. Venous blood collects and stagnates in the lower leg (*venous stasis*). Venous pressures in the calf and lower leg increase, particularly during ambulation. This increased pressure impairs arterial circulation to the lower extremities as well. The body's ability to provide sufficient oxygen and nutrients to the cells and remove metabolic waste products diminishes. Eventually, there is so little oxygen and nutrients that cells begin to die. The skin atrophies, and subcutaneous fat deposits necrose. Breakdown of red blood cells in the congested tissues causes brown skin pigmentation. Venous stasis ulcers develop. Congested tissues impair the body's ability to increase the supply of oxygen, nutrients, and metabolic energy to heal the ulcer. As a result, the condition worsens and, over time, the ulcers enlarge. The congested venous circulation also prevents the blood from mounting effective inflammatory and immune responses, significantly increasing the risk for infection in the ulcerated tissue (Huether & McCance, 2011).

Figure 32–12 ■ Chronic venous insufficiency. Note the discoloration of the ankle and the stasis ulcer.

Manifestations

Manifestations of chronic venous insufficiency include lower leg edema, itching, and discomfort of the affected extremity that increases with prolonged standing. The extremity is cyanotic. Recurrent stasis ulcers develop (Figure 32–12 ■), usually forming just above the ankle, on the medial or anterior aspect of the leg. They heal poorly, forming scar tissue that breaks down easily. Tissue surrounding the ulcer is shiny, atrophic, and cyanotic, and there is a brownish pigmentation to the skin. Other skin changes may develop as well, such as eczema or stasis dermatitis. Necrosis and fibrosis of subcutaneous tissue cause the affected area of the leg to feel hard and somewhat leathery to the touch, but even the slightest trauma to the area can produce serious tissue breakdown. See the accompanying Manifestations box. Table 32–6 compares venous and arterial ulcers.

●○● INTERPROFESSIONAL CARE

Collaborative care for the patient with venous insufficiency focuses on relieving symptoms, promoting adequate circulation, and healing and preventing tissue damage.

TABLE 32–6 Comparison of Arterial and Venous Leg Ulcers

Factor	Arterial Ulcers	Venous Ulcers
Location	Toes, feet, shin	Over medial or anterior ankle
Ulcer appearance	Deep, pale	Superficial, pink
Skin appearance	Normal to atrophic Pallor on elevation Rubor on dependency	Brown discoloration Stasis dermatitis Cyanosis on dependency
Skin temperature	Cool	Normal
Edema	Absent or mild	May be significant
Pain	Usually severe Intermittent claudication Rest pain	Usually mild Aching pain
Gangrene	May occur	Does not occur
Pulses	Decreased or absent	Normal

MANIFESTATIONS OF CHRONIC VENOUS INSUFFICIENCY

- Lower extremity edema that worsens with standing
- Itching, dull leg discomfort or pain that increases with standing
- Thin, shiny, atrophic skin
- Cyanosis and brown skin pigmentation of lower leg and foot
- Possible weeping dermatitis
- Thick, fibrous (hard) subcutaneous tissue
- Recurrent ulcerations of medial or anterior ankle

The history and physical examination often establish the diagnosis of chronic venous insufficiency. Because a history of deep venous thrombosis is a major risk factor, careful evaluation of the past medical history and questioning of the patient are important. There are no specific diagnostic tests to confirm the diagnosis of chronic venous insufficiency.

Conservative management of venous insufficiency focuses on reducing edema and treating ulcerations. Prolonged standing or sitting is discouraged. Graduated compression hosiery is ordered for daytime use, and frequent elevation of the legs and feet during the day is recommended. At night, the legs and feet should be elevated above the level of the heart by raising the foot of the mattress.

Treatment of associated stasis dermatitis varies, based on the duration of the condition. Wet compresses of boric acid, buffered aluminum acetate (Burrow's solution), or isotonic saline solution are applied to acute weeping dermatitis four times a day for 1-hour periods. Following the compress, a topical corticosteroid (such as 0.5% hydrocortisone cream) is applied. Bed rest is prescribed during the acute period. Stasis dermatitis that is subsiding or chronic may be treated with a topical corticosteroid, zinc oxide ointment, or a topical broad-spectrum antifungal cream such as clotrimazole (Lotrimin) cream or miconazole (Monistat) cream.

Isotonic saline compresses or wet-to-dry dressings are applied to stasis ulcers to promote healing. A dilute topical antibiotic solution and an occlusive hydroactive or polyurethane foam also may be used. The ulcer may be treated by using a semirigid boot applied to the foot and lower leg. This device may be made of Unna's paste or Gauzetex bandage. Bony prominences must be well padded and the boot changed weekly. This device often allows ambulatory treatment.

A very large, chronic ulcer may require surgery. In this case, the incompetent veins are ligated, the ulcer is excised, and the area is covered with a skin graft (refer to Chapter 16).

●○● NURSING CARE

Nursing care for the patient with chronic venous insufficiency is primarily educative and supportive. Patient teaching includes the following recommendations:

- Elevate the legs while resting and during sleep. See the Moving Evidence into Action box for a nursing research study that provides evidence supporting the supine position for resting.
- Walk as much as possible, but avoid sitting or standing for long periods of time.
- When sitting, do not cross your legs or allow pressure on the back of the knees (such as sitting on the side of the bed).
- Do not wear anything that pinches your legs (such as knee-high hose, garters, or girdles).

Moving Evidence into Action

The Patient with Venous Leg Ulcers

Chronic leg ulcers due to venous insufficiency are a challenge to treat and heal. The use of preventive activities to reduce recurrence has not been previously well described. Finlayson and colleagues (2011) conducted a prospective longitudinal study to identify relationships between preventive activities, psychosocial factors (depression and self-efficacy or general self-confidence to handle the health problem), and leg ulcer recurrence. Of the 80 participants who completed self-report questionnaires on physical activity, nutrition, preventive activities, and psychosocial measures with follow-up data collected every 3 months for a full year, 35 leg ulcer recurrences were reported. A Cox proportional hazard regression model found the following variables were significantly associated with lower recurrence of leg ulcers: leg elevation > 1 hour/day for 6 or more days/week while wearing Class 2 or Class 3 compression hosiery; higher social support and higher general self-efficacy. Variables found to be statistically significant for recurrence were male gender and history of deep venous thrombosis.

Implications for Nursing

The results of this study support the implementation of a holistic long-term management program that improves self-efficacy and facilitates preventive self-care activities.

Moving Knowledge into Action

1. What is the mechanism of compression stockings that helps to prevent leg ulcer recurrence?
2. What is required for tissue healing? What measures can the nurse take to promote tissue healing in a patient with impaired peripheral tissue perfusion?
3. How do higher levels of social support and self-efficacy add to the prevention of recurring leg ulcers?

- Wear elastic hose as prescribed. The elastic hose should be tighter over the feet than at the top of the leg. Be sure the tops of the elastic hose do not cut into your legs. Put on the hose after you have had your legs elevated.
- Keep the skin on your feet and legs clean, soft, and dry.
- Refer to the guidelines in Box 32–4 for care of the legs and feet.

The following nursing diagnoses may apply to the patient with chronic venous insufficiency:

- *Disturbed Body Image* related to edema and stasis ulcers on lower leg
- *Ineffective Health Maintenance* related to lack of knowledge about disorder and prescribed treatments
- *Risk for Infection* related to ulcerations
- *Impaired Physical Mobility* related to pain and edema in lower legs
- *Impaired Skin Integrity* related to presence of stasis ulcers
- *Ineffective Tissue Perfusion: Peripheral* related to incompetent venous valves

See other sections of this chapter for specific nursing interventions related to many of these diagnoses. See also the Nursing Care of the Older Adult with Chronic Venous Stasis box.

THE PATIENT WITH VARICOSE VEINS

Varicose veins are irregular, tortuous veins with incompetent valves. Varicosities may develop in any veins, and may be called by other names, such as hemorrhoids in the rectum and varices in the esophagus. Varicosities usually affect the veins of the lower extremities; the

NURSING CARE OF THE OLDER ADULT

Chronic Venous Stasis

Disorders of venous stasis are common after the fifth decade of life. Aging affects vessels and tissues, increasing the risk for venous insufficiency and varicose veins. In addition, mobility frequently declines with aging, reducing the effect of the muscle pump in promoting venous return.

Regular exercise, walking in particular, is an important part of the treatment plan. Safety when walking is an important issue for older patients. Assess the patient's mobility and stability during ambulation. If appropriate, suggest using a walker and quad-cane as needed. Assist older patients holding jobs that require prolonged standing to identify strategies to minimize standing and incorporate periods of activity into their work.

Following surgery or during treatment for stasis ulcers, older patients may need additional assistance with home care and maintenance. Initiate referral to social services as needed to arrange for home nursing care, meals, assistance with ADLs, and home maintenance services as indicated. In some instances, temporary placement in an extended care facility is necessary until the patient and family can assume care.

long saphenous vein is often affected, and they also may develop in the short saphenous vein.

Pathophysiology

Varicose veins are classified as primary (with no involvement of deep veins) or secondary (caused by the obstruction of deep veins). In both cases, long-standing increased venous pressure stretches the vessel wall. This sustained stretching impairs the ability of the venous valves to close, causing them to become incompetent.

The erect position produces a twofold negative effect on the veins. When standing, the leg veins resemble vertical columns and must withstand the full force of venous blood pressure. Prolonged standing, the force of gravity, lack of leg exercise, and incompetent venous valves all weaken the muscle-pumping mechanism, reducing venous blood return to the heart. As standing continues, the amount of blood pooled in the veins increases, further stretching the vessel wall. The venous valves become increasingly incompetent.

Manifestations

Although varicose veins may be asymptomatic, most cause manifestations such as severe aching leg pain, leg fatigue, leg heaviness, itching, or feelings of heat in the legs. The degree of valvular incompetence does not seem to correlate well with the extent of symptoms. The menstrual cycle tends to worsen symptoms, suggesting a possible correlation with hormonal factors in women. Assessment reveals obvious dilated, tortuous veins beneath the skin of the upper and lower leg. If varicose veins are long-standing, the skin above the ankles may be thin and discolored, with a brown pigmentation. See the Manifestations box.

MANIFESTATIONS OF VARICOSE VEINS

- Severe, aching pain in the leg
- Leg fatigue, heaviness
- Itching of the affected leg (stasis dermatitis)
- Feelings of warmth in the leg
- Visibly dilated veins
- Thin, discolored skin above the ankles
- Stasis ulcers

Complications

Complications of varicose veins include venous insufficiency and stasis ulcers. Chronic stasis dermatitis may also develop. Superficial venous thrombosis may develop in varicose veins, especially during and after pregnancy, following surgery, and in patients on estrogen therapy (oral contraceptives or hormone replacement therapy).

Incidence and Risk Factors

Varicose veins affect about 15% of adults. They are more common in women over age 35 with an increased risk related to venous stasis during pregnancy. Aging is a risk factor, possibly related to decreased exercise and other factors that contribute to venous stasis. People in occupations that involve prolonged standing (such as beauticians, salespeople, and nurses) also have an increased incidence of varicose veins. Race is a risk factor: Whites are more frequently affected than Blacks. The majority of people with primary varicose veins (those affecting superficial veins) have a family history of the disorder, suggesting a genetic link (Huether & McCance, 2011).

Most varicosities occur in the deep veins of the legs. Contributing causes include obesity, venous thrombosis, congenital arteriovenous malformations, or sustained pressure on abdominal veins (as in pregnancy and/or the presence of abdominal tumors). The effects of gravity, produced by long periods of standing, are a major causative factor.

●○● INTERPROFESSIONAL CARE

Varicose veins usually can be managed using conservative measures, although surgery may be required if symptoms are severe, when complications develop, or for cosmetic reasons.

DIAGNOSIS

Although varicose veins often are diagnosed by the history and physical examination, diagnostic tests may be ordered.

- *Doppler ultrasonography* or *duplex Doppler ultrasound* may be performed to identify specific locations of incompetent valves. This test is particularly useful before surgery to identify valves that allow reflux of blood from the femoral, popliteal, or peripheral deep veins into the superficial veins.
- A *Trendelenburg test* may be performed to determine the underlying cause of superficial venous insufficiency. The leg is elevated, then an elastic tourniquet is placed around the distal thigh. The varicosities then are observed as the patient stands. When valves of the deep veins are incompetent, the veins remain flat on standing; they rapidly distend when the superficial venous valves are the underlying cause.

TREATMENTS

Although there is no real cure, conservative measures are the core of treatment for most patients with uncomplicated varicose veins. These measures often relieve symptoms and prevent complications by improving venous circulation and relieving pressure on venous tissues. Properly fitted graduated compression stockings are commonly prescribed. They compress the veins, propelling blood back to the heart. Compression stockings augment the muscle pumping action of the legs. When worn during times of prolonged standing and in combination with frequent leg elevation, compression stockings often prevent progression of the condition and development of complications.

Regular, daily walking also is important. Prolonged sitting and standing are discouraged, although elevating the legs for specified periods during the day is beneficial. Leg elevation promotes venous return, prevents venous stasis, and decreases leg heaviness and fatigue.

COMPRESSION SCLEROTHERAPY

In compression sclerotherapy, a sclerosing solution is injected into the varicose vein and a compression bandage is applied for a period of time. This obliterates the vein. Venous blood is rerouted through healthy vessels whose valves are not compromised. Compression sclerotherapy may be used to treat small, symptomatic varicosities. It may be the primary treatment, or it may be used in conjunction with varicose vein surgery. While compression sclerotherapy may be done for cosmetic reasons, complications such as phlebitis, tissue necrosis, or infection may occur and need to be considered prior to the procedures.

SURGERY

Surgical treatment of varicose veins generally is reserved for patients who are very symptomatic, experience recurrent superficial venous thrombosis, and/or develop stasis ulcers. The objective of surgery is to remove the diseased veins. It may be considered for cosmetic reasons.

Surgery usually involves extensive ligation and stripping of the greater and lesser saphenous veins. The evening before surgery, the surgeon marks all incompetent superficial and perforating varicose veins with a permanent ink marker. Under either regional or general anesthesia, the greater saphenous vein is removed and the connected smaller tributaries that have not naturally clotted off are tied off. Multiple small incisions may be made over the varicosities, allowing removal of the affected segments of the vein. Incompetent tributaries that communicate with larger vessels also are ligated. For patients with less extensive disease or patients seeking cosmetic improvement, surgery may involve only the removal of the lesser saphenous vein through an incision in the popliteal fossa.

Postoperative care includes applying pressure bandages for a minimum of 6 weeks, elevating the extremities to minimize postoperative edema, and gradually increasing amounts of ambulation. Sitting and standing are prohibited during the initial recovery period, and are gradually reintroduced as deemed appropriate by the surgeon.

●○● NURSING CARE

Health Promotion

Health promotion activities to reduce the incidence of varicose veins include teaching all patients, particularly young women, the benefits of regular exercise continued over the lifetime. Discuss the effect of prolonged sitting or standing on the legs, and encourage the patient whose occupation involves these activities to periodically get up and move or to sit with the legs elevated. Encourage all patients to maintain normal weight for their height.

Assessment

See the Manifestations and Interprofessional Care sections for the assessment of the patient with varicose veins.

Focused assessment of the patient with varicose veins includes the following:

- *Health history:* complaints of leg pain, aching, heaviness, or fatigue; ankle swelling; history of venous thrombosis
- *Physical assessment:* visible, dilated, tortuous superficial veins in lower extremities.

Priorities of Care

Collaborating with the interprofessional team to ensure adequate treatment of the underlying process while providing care that supports the physical and psychologic responses to the disorder is a priority of nursing care.

Diagnoses, Outcomes, and Interventions

In planning and providing nursing care for patients with varicose veins, emphasis is placed on the importance of health teaching to manage the symptoms of varicose veins, particularly because there is no cure for the disease. Nursing care for patients who have undergone surgical treatment for varicose veins focuses on assessing and promoting wound healing and preventing infection. Nursing diagnoses may include those related to pain, impaired tissue perfusion and skin integrity, and a risk for impaired neurovascular function.

Chronic Pain

Varicose veins can lead to pooling of venous blood in the lower extremities. Venous congestion can cause a dull ache or feeling of pressure in the legs, particularly after prolonged standing. As venous pressure rises, arterial circulation and delivery of oxygen and nutrients to tissues is impaired. Tissue ischemia contributes to the pain. The pain associated with varicose veins tends to be chronic, developing and progressing gradually over a long period of time.

Expected Outcome: Patient will exhibit adequate pain control as evidenced by physical well-being.

- Assess pain, including its intensity, duration, and aggravating and relieving factors. *Pain assessment allows collaborative planning with the patient to identify appropriate interventions.*
- Inquire about current measures being used by the patient to manage pain and its effects. Ask about the effectiveness of current management strategies and the desire to change. *Chronic pain management ultimately falls to the patient. Strategies to address the pain must meet the patient's needs.*
- Suggest keeping a diary of pain intensity, timing, precipitating events, and effectiveness of relief measures. *Systematic tracking of pain is an important measure in improving its management.*
- Teach and reinforce nonpharmacologic pain management strategies such as progressive relaxation, imagery, deep breathing, distraction, and meditation.*The effectiveness of such strategies is well documented. Nonpharmacologic measures provide a variety of options for controlling pain while maintaining independence. These measures also can reduce reliance on analgesics.*
- *Collaborate with the patient to establish a pain control plan. Collaborative planning for pain management increases the patient's sense of control and reduces powerlessness. This, in turn, enhances the ability to cope with pain and its effects.*
- Regularly evaluate the effectiveness of planned interventions and pain management strategies. *Regular evaluation allows modification of the care plan as needed, as well as providing a measure of disease progression. Increasing or poorly controlled pain may necessitate additional collaborative interventions to manage the disorder.*

Ineffective Tissue Perfusion: Peripheral

Varicose veins and venous stasis impair delivery of nutrients and oxygen to peripheral tissues as elevated venous pressures interfere with blood flow through the capillary beds. Improving venous blood flow reduces venous pressures and promotes arterial flow to peripheral tissues.

Expected Outcome: Patient's tissue perfusion will be adequate as evidenced by adequate arterial flow (i.e., strong peripheral pulses).

- Assess peripheral pulses, capillary refill, skin color and temperature, and extent of edema. *Assessment of arterial flow and tissue perfusion provides baseline and continuing data for evaluating the effectiveness of interventions.*
- Teach application and use of properly fitted elastic graduated compression stockings. *Elastic compression stockings compress the veins, promoting venous return from the lower extremities. During ambulation, the stockings enhance the blood-pumping action of the muscles. Because elastic stockings inhibit blood flow through small superficial vessels, they should be removed at least once each day for at least 30 minutes.*
- Instruct to maintain a program of regular exercise, such as walking for 20 to 30 minutes several times a day. When ambulation is restricted, active ROM exercises help maintain muscle tone, joint mobility, and venous return. *Exercise stimulates circulation and promotes blood flow through the vascular system.*
- Advise to elevate the legs for 15 to 20 minutes several times a day and to sleep with the legs elevated above the level of the heart. *Elevating the legs promotes venous return, reducing tissue congestion and improving arterial circulation. Improved venous return also increases the cardiac output and renal perfusion, promoting elimination of excess fluid and decreasing peripheral edema.*

Risk for Impaired Skin Integrity

Ineffective venous valve function impairs venous return and increases venous pressures. *These increased pressures oppose arterial blood flow and the delivery of oxygen and nutrients to the cells. As a result, tissues are vulnerable to any additional insult, and may break down.*

Expected Outcome: Patient will demonstrate an understanding of plan to heal skin and prevent reinjury.

- Assess lower extremity color, temperature, moisture, and for evidence of pressure or breakdown on admission and at each visit. *Initial and continuing assessment allows timely detection of early signs of skin and tissue breakdown. This, in turn, allows early institution of measures to prevent further tissue damage and promote healing.*
- Teach foot and skin care measures such as daily cleansing with nondrying soap, gentle drying, and lotions to prevent skin dryness and cracking. *Cleansing removes potentially harmful microorganisms and stimulates circulation. Care is taken to keep the skin moist and supple, promoting its function as the first line of defense against infection.*
- Discuss the importance of adequate nutrition and fluid intake. *Adequate nutrients are necessary to maintain tissue integrity and promote healing. A diet high in protein, carbohydrates, and vitamins and minerals promotes growth and maintenance of skin cells, provides energy, and helps prevent skin breakdown. Adequate hydration helps maintain the moisture and turgor of skin, reducing the risk of drying and breakdown.*

Risk for Peripheral Neurovascular Dysfunction

Severe varicose veins can lead to chronic venous insufficiency, impaired arterial circulation, and ultimately, disrupted sensation in the affected extremity. Impaired neurologic function increases the patient's risk for injury and infection of the extremity, as minor trauma may go unnoticed.

Expected Outcome: Patient will experience optimal peripheral neurovascular function as evidenced by freedom from pain, baseline peripheral sensation, and intact skin of the extremity.

- Assess circulation, sensation, and movement of the lower extremities. *Disrupted circulation and venous congestion may interfere with sensory and motor function of the affected extremity. The potential for nerve and muscle involvement is especially high in patients with venous stasis ulcers.*
- Instruct to report signs of neurovascular dysfunction, such as numbness, coldness, pain, or tingling of an extremity. Early recognition of neurovascular dysfunction facilitates institution of interventions to prevent complications. Because the postoperative hospital stay following varicose vein surgery or venous stasis ulcer repair is brief, manifestations of neurovascular dysfunction may initially be detected by the patient. *Careful assessment and prompt reporting helps prevent potential complications such as skin breakdown, infection, and nerve damage.*
- Teach measures to protect the extremities from injury, such as always wearing shoes or firm slippers, wearing cotton socks to absorb moisture, and testing the temperature of bath water with a thermometer or the upper extremities before stepping in. *Sensation in the lower extremities may be affected by poor circulation, necessitating additional measures to protect the legs and feet from injury.*

Continuity of Care

Most patients with varicose veins provide self-care at home. Include the following topics when preparing the patient and family for home care:

- Leg elevation and exercise program
- Application and use of graduated elastic compression stockings
- Foot and leg care (refer to Box 32–4)
- Measures to avoid injury and skin breakdown
- Symptoms or potential complications to report to the healthcare provider.

Provide information about suppliers for elastic stockings and any other required supplies. If venous stasis ulcers have developed, consider referral to home health services for regular assessment of healing and additional teaching.

Disorders of the Lymphatic System

The lymphatic system, which includes the lymphatic vessels and the lymph nodes, is a unique part of the circulatory system. The lymphatic system returns plasma and plasma proteins filtered out of the capillaries from interstitial tissues to the bloodstream. This fluid is called *lymph*. The lymphatic system consists of closed capillaries leading to larger lymphatic venules and lymphatic veins. These vessels contain smooth muscle and one-way valves that help move fluid toward the heart. Lymphatic vessels share the same sheath as arteries and veins; arterial pulsations and skeletal muscle contractions compress the lymphatic vessels to assist in maintaining lymph flow. As lymph moves through the lymphatic system, it is filtered through thousands of bean-shaped lymph nodes clustered along the vessels.

Within these nodes, phagocytes remove foreign material from the lymph, preventing it from entering the bloodstream.

THE PATIENT WITH LYMPHADENOPATHY

Lymphadenopathy, enlarged lymph nodes, may be localized or generalized. Localized lymphadenopathy usually results from an inflammatory process (e.g., streptococcal pharyngitis or an infected wound). The node enlarges as lymphocytes and monocytes proliferate within the node to destroy infectious material. Palpable lymph nodes often develop in response to minor trauma or a localized infection. Generalized lymphadenopathy usually is associated with malignancy or disease. Malignant cells or other abnormal cells invade the node, causing it to enlarge.

Lymphangitis, inflammation of the lymph vessels draining an infected area of the body, is characterized by a red streak along the inflamed vessels, pain, heat, and swelling. Fever and chills also may be present. Local lymph nodes are swollen and tender.

Treatment for lymphadenopathy and lymphangitis focuses on identifying and treating the underlying condition. Elevating the body part and applying heat to inflamed lymphatic vessels help reduce swelling and promote blood flow to the affected area.

THE PATIENT WITH LYMPHEDEMA

Lymphedema may be a primary or a secondary disorder, resulting from inflammation, obstruction, or removal of lymphatic vessels. It is characterized by extremity edema due to accumulation of lymph. *Primary lymphedema* is uncommon, affecting about 1 in 10,000 people. It affects females more frequently than males, and may be associated with a genetic disorder such as Turner syndrome or Klinefelter syndrome. See the accompanying Genetic Considerations box.

Secondary lymphedema is an acquired condition, resulting from damage, obstruction, or removal of lymphatic vessels. The most common worldwide cause of secondary lymphedema is *filariasis*, infestation of the lymphatic vessels by filaria, a nematode worm. Other important causes of secondary lymphedema include recurrent episodes of bacterial lymphangitis, obstruction of lymph vessels by tumors, and surgical or radiation treatment for breast cancer.

Pathophysiology and Manifestations

Obstruction of lymph drainage prevents fluid and protein molecules from interstitial tissues from returning to the circulation. The protein molecules increase the osmotic pressure in interstitial tissues, drawing in additional fluid that causes edema in the soft tissues. One or both extremities may be affected.

The edema begins distally, progressing up the limb to involve the entire extremity. Initial edema is soft and pitting; with chronic congestion, subcutaneous tissues become fibrotic, causing thick, rough skin and a woody texture of the limb (*brawny edema*). In contrast, the edema associated with venous disorders is softer, and the skin often is hyperpigmented with evidence of stasis dermatitis. Lymphedema generally is painless, although the limb may feel heavy.

GENETIC CONSIDERATIONS

Primary Lymphedema

Primary lymphedema develops as a result of agenesis, hypoplasia, or obstruction of lymphatic vessels.

- *Congenital lymphedema* appears shortly after birth; two other forms of lymphedema develop later, one at the time of puberty (*lymphedema praecox*), the other usually after age 35 (*lymphedema tarda*).
- Congenital lymphedema and lymphedema praecox may be inherited as an autosomal dominant trait with variable penetrance.
- Lymphedema also may be inherited (although less commonly) as an autosomal or sex-linked recessive disorder.

●○● INTERPROFESSIONAL CARE

Interprofessional care for the patient with lymphedema focuses on relieving edema and preventing or treating infection. The disorder may be difficult to treat effectively, and can lead to progressive disability due to the weight and awkwardness of the affected extremity.

DIAGNOSIS

Abdominal or pelvic ultrasound and computed tomography (CT) scans are used to detect obstructing lesions. Magnetic resonance imaging (MRI) can show edema and identify lymph nodes and enlarged lymphatic vessels. More invasive procedures such as lymphangiography and radioactive isotope studies may occasionally be necessary to identify the lymphatic defect causing lymphedema.

- *Lymphangiography* uses injected contrast media to illustrate lymphatic vessels on x-rays. Organic dyes are used to identify a distal lymphatic vessel, and then a contrast medium is injected into the vessel for visualization of the lymphatic system of the limb. In primary lymphedema, lymph vessels are absent or hypoplastic (underdeveloped). In secondary lymphedema, lymph channels often are dilated; it may be possible to determine the level of obstruction.
- *Lymphoscintigraphy* involves injecting a radioactively tagged substance into distal subcutaneous tissues of the extremity, then mapping its flow through the lymphatic system. The pattern of lymph fluid distribution and transport is abnormal in patients with lymphedema.

TREATMENTS

Meticulous skin and foot care is vital to prevent infection in the affected extremity. Shoes should always be worn to reduce the risk of injury. Careful cleansing and use of emollient lotions are recommended to prevent drying of the skin. Exercise is encouraged, as are frequent periods of leg elevation. The foot of the bed is raised by 15 to 20 degrees at night to promote lymph flow. Elastic graduated compression stockings may be ordered for use during the day. In some cases, an intermittent pneumatic compression device to reduce edema may be prescribed for home use.

Antibiotics are given to prevent and treat infection, which can be recurrent and difficult to eradicate. Diuretic therapy may be used intermittently, particularly when primary lymphedema is exacerbated by the menstrual cycle or seasonal variability.

Patients who do not respond to conservative treatment measures or who experience recurrent episodes of cellulitis and lymphangitis may require surgical treatment. Microvascular techniques may be used to create anastomoses between obstructed lymphatic vessels and adjacent veins, providing channels to redirect lymph into

the venous system. Successful surgery may improve both extremity function and its cosmetic appearance.

●○● NURSING CARE

Nursing care for patients with lymphatic disorders focuses on reducing edema, preventing tissue damage related to the edema, and promoting effective coping with the effect of the disorder on body image and function.

Assessment

See the Manifestations and Interprofessional Care sections for the assessment of the patient with lymphatic disorders.

Priorities of Care

Collaborating with the interprofessional team to ensure adequate treatment of the underlying process while providing care that supports the physical and psychologic responses to the disorder is a priority of nursing care.

Diagnoses, Outcomes, and Interventions

Nursing diagnoses for the patient with lymphedema may include *Impaired Tissue Integrity*, *Excess Fluid Volume*, and *Disturbed Body Image*.

Impaired Tissue Integrity

Obstructed lymphatic flow leads to fluid congestion of the interstitial spaces of subcutaneous tissue. The resulting edema compresses and damages tissues of the affected extremity. Subcutaneous tissues become fibrotic, reducing their protective functions of shock absorption and insulation. In addition, obstructed lymphatic flow reduces the effectiveness of lymph nodes in filtering and removing foreign material and pathogens from the body. This increases the risk for local tissue infection such as *cellulitis*, a diffuse bacterial infection of the skin. Cellulitis increases the risk for skin and tissue breakdown and, if not effectively treated, can lead to sepsis.

Expected Outcome: Patient will be able to describe measures to protect healthy tissue and prevent injury.

- Frequently inspect the skin of the affected extremity, documenting the condition with each assessment. Promptly report areas of pallor, redness, or apparent inflammation. Breaks in the skin surface allow microbial invasion, and increase the risk for infection. *Prompt identification and treatment of any lesions is vital to prevent further tissue breakdown and infection.*
- Apply well-fitting elastic graduated compression stockings or intermittent pneumatic pressure devices as ordered. *Elastic stockings and/or pneumatic pressure devices oppose the movement of fluid out of capillaries and improve its reabsorption into vascular spaces for transportation back to the heart.*
- Remove elastic stockings and intermittent pressure devices every 8 hours or at each home visit to inspect the underlying skin for evidence of redness, irritation, dryness, or breakdown. *Elastic graduated compression stockings, antiembolic stockings, and pneumatic compression devices compress small vessels nourishing the skin and subcutaneous tissue. Periodic removal not only allows inspection of the underlying skin, but also allows restoration of blood flow to these small vessels and the tissues.*
- Instruct to elevate the extremities while seated and during sleep. *Elevation of the extremities diminishes venous congestion, promotes venous return, facilitates arterial circulation and tissue perfusion, and helps reduce the accumulation of excess fluids in interstitial spaces of the affected extremity.*
- Use preventive skin care devices as indicated. Collected fluid in the affected extremity increases its weight and interferes with regular movement. The increased weight places greater pressure on surfaces of the limb that come in contact with furniture. *Protective devices such as egg-crate foam, sheepskin, pillows, or padding help prevent tissue compression, promoting circulation and reducing the risk of skin and tissue breakdown.*
- Keep skin clean and dry, especially in interdigital spaces. Teach skin and foot care to the patient and family. *Clean, dry skin provides the first line of defense against infection. Significant limb edema can interfere with reaching the distal extremity and cleaning interdigital spaces. The dark, moist spaces between the toes are an excellent environment for bacterial growth. Teaching fosters self-care and independence, as well as preparing the patient and family to manage this often chronic condition.*
- Discuss the importance of adhering to the therapeutic regimen. *Lymphedema generally is a chronic condition; effective management requires active patient participation in planning and implementing care to reduce edema and maintain tissue integrity.*

Excess Fluid Volume

In lymphedema, obstruction, destruction, or congenital malformation of lymphatic vessels interferes with the normal circulation of lymphatic fluid. As a result, lymph collects in the subcutaneous tissues of the affected extremity, causing excess fluid volume of that extremity. Some patients may benefit from intermittent diuretic therapy and dietary sodium restriction.

Expected Outcome: Patient's fluid volume will be normal as evidenced by weight loss and decreases in edema, jugular venous distention, and abdominal distention.

- Monitor intake and output and/or weight (daily or weekly). Use consistent scales, timing, and clothing for accurate weight measurements. *Intake and output records and short-term changes in weight reflect fluid balance. Measures of fluid balance permit evaluation of the effectiveness of interventions such as restricted sodium intake and diuretic therapy.*
- Discuss the rationale for restricted sodium intake if ordered. Teach ways to maintain the recommended sodium restriction, and assist to choose foods that are low in sodium. *Sodium causes retention of extracellular water; restricting dietary sodium may help prevent additional fluid accumulation in interstitial spaces.*
- During acute periods, assess the affected extremity daily for increased edema; measure girth of the extremity using consistent technique. *The size of the affected extremity provides a measure of the effectiveness of ordered interventions and progression of the disorder.*

Disturbed Body Image

The disproportionate size of an extremity or extremities due to lymphedema can profoundly affect body image. During early stages of the disease, conservative measures may effectively reduce the edema and size of the affected limb. However, as the disease

progresses, conservative measures may become less effective, leading to more permanent disfigurement. Mobility may be impaired, and the patient may develop an increasingly negative self-perception.

Expected Outcome: Patient will verbalize realistic expectations of lymphedema therapy impact on edema.

- Encourage discussions about usual coping patterns and perception of self. *Knowledge of existing coping patterns and behaviors helps the nurse assess the patient's ability to cope with the current situation. This knowledge is then used to reinforce effective coping mechanisms and help develop more effective coping strategies. This exchange allows the patient to voice feelings related to actual or perceived changes in body image.*
- Accept the patient's perception of self and of the impact of the changes in appearance. *Nonjudgmental acceptance of the patient's view of self and of the effects of changes in appearance builds trust and promotes rapport. A trusting relationship promotes the patient's ability to take an active role in managing the disorder, participate in healthcare decisions, and adhere to the plan of care. Nonjudgmental listening also promotes mutual respect and demonstrates caring and compassion.*
- Encourage active participation in self-care. Assist with identifying alternative self-care strategies when the extent of edema interferes with performing some aspects of self-care such as trimming toenails or washing feet. *The patient initially may have difficulty viewing or touching the affected body part. Gentle encouragement and support from the nurse helps the patient assume self-care and accept the affected body part. Brainstorming to identify alternative care strategies promotes the patient's independence even when total self-care is not feasible.*

Continuity of Care

When preparing the patient with chronic lymphedema and family to manage the disorder, include the following teaching topics:

- Recommended program of exercise and elevation of the extremity
- Foot and skin care
- Use of elastic graduated compression stockings and/or intermittent pressure devices
- Importance of wearing elastic stockings during the majority of waking hours, removing them once during the daytime and while sleeping
- Measures to prevent infection in the affected extremity, such as wearing gloves while gardening
- Signs and symptoms to report to the healthcare provider (e.g., manifestations of tissue breakdown or infection, increasing edema, or evidence of compromised circulation)
- Use and precautions associated with any prescribed medications
- Sodium-restricted diet if ordered.

Provide information about contacts for questions, and make referrals as needed. Evaluate the need for home health, home maintenance assistance, and other services such as physical or occupational therapy.

CHAPTER HIGHLIGHTS

- **Essential hypertension, blood pressure of 140/90 mmHg or higher with no clearly identified cause, rarely causes symptoms but is a major risk factor for coronary heart disease, heart failure, stroke, and renal insufficiency.**
- Prehypertension, a newly identified category, is an average blood pressure of 120–139/80–89 mmHg. Patients with prehypertension are advised to make lifestyle changes indicated for hypertension (weight loss, exercise, dietary changes, limited alcohol intake, and stress reduction), but generally are not treated with medications unless other risk factors such as diabetes or kidney disease are present.
- Systolic hypertension, an elevated systolic blood pressure without elevation of the diastolic pressure, is common in older adults and contributes to complications such as coronary heart disease and stroke.
- Medications to treat hypertension include diuretics, alpha- and beta-adrenergic blockers, ACE inhibitors and angiotensin II blockers, calcium channel blockers, and vasodilators. A combination of two or more drugs often is required for effective blood pressure control.
- **Aneurysms, abnormal dilation of a blood vessel, commonly affect the aorta and the iliac arteries, particularly in older men. A slowly expending abdominal aortic aneurysm that does not produce symptoms or impair flow through the renal arteries may not be repaired, particularly in an older patient. Percutaneously inserted endovascular splints provide an alternative to surgery for abdominal aortic aneurysms.**
- **Peripheral vascular disease, obstruction or occlusion of peripheral arteries by atherosclerotic plaque, is common and a leading cause of disability and amputation.**
- Smoking cessation and regular daily exercise are key components of treatment for peripheral vascular disorders such as atherosclerosis, thromboangiitis obliterans, and Raynaud's disease.
- **Venous thrombosis, particularly of the deep veins of the legs and pelvis, develops as a result of venous stasis, blood vessel damage, and increased coagulability of the blood. The developing clot may fragment or break loose, becoming an embolus that typically lodges in the pulmonary circulation (pulmonary embolus). Chronic venous insufficiency and venous stasis may develop as a result of deep venous thrombosis.**

- Prophylactic anticoagulation and mobilization of the patient are the primary preventive measures for venous thrombosis. Monitoring coagulation studies and assessing for evidence of bleeding (overt or covert) are important nursing measures for the patient on anticoagulant therapy.
- **Lymphadenopathy (enlarged lymph nodes), lymphangitis (inflammation of the lymph vessels), and lymphedema are the most common disorders affecting the lymph system.**

TEST YOURSELF NCLEX-RN® REVIEW

1. A patient whose blood pressure averages 180/106 mmHg on two different readings says to the nurse, "I don't understand how it could be so high—I feel just fine." What response should the nurse make to this patient?
1. "This is probably just a false reading due to 'white coat syndrome.' Don't worry about it."
2. "High blood pressure often has few or no symptoms; that's why it is called the 'silent killer.'"
3. "It is unusual that you are not having some symptoms such as severe headaches and nosebleeds."
4. "You probably should have your blood pressure rechecked in 3 months or so and then follow up with your primary care provider if it is still high."

2. The nurse instructs a patient about the DASH diet for blood pressure control. Which patient statement indicates that additional teaching is necessary?
1. "I will enjoy having frozen yogurt as my bedtime snack on occasion."
2. "Having a handful of nuts when the predinner 'munchies' hit is a good idea."
3. "It will be a challenge to incorporate all those servings of fruits and vegetables into my diet."
4. "I'm glad I can still eat as much pasta as usual; I was afraid I would have to give up my weekly lasagna."

3. A patient is prescribed valsartan (Diovan) for treatment of hypertension. What should the nurse include when teaching the patient about this medication? (Select all that apply.)
1. Report a persistent disruptive cough to your healthcare provider.
2. Use caution when rising from bed or a chair to prevent dizziness.
3. Take the drug at bedtime to reduce the risk of falling due to light-headedness.
4. Use a potassium-based salt substitute to prevent hypokalemia while taking this drug.
5. You may stop taking this drug once your blood pressure is within the normal range for at least 2 months.

4. A patient is complaining of new-onset calf and foot pain. The nurse notes that the leg below the knee is cool and pale and that dorsalis pedis and posterior tibial pulses are absent. What should the nurse do first to help this patient?
1. Notify the healthcare provider.
2. Prepare to initiate heparin therapy.
3. Position the leg flat, supported in anatomic position.
4. Place a cradle over the leg to prevent pressure from bedding.

5. The nurse is caring for an 86-year-old patient with a newly diagnosed abdominal aortic aneurysm. What information should the nurse use to plan care for this patient?
1. Surgery is indicated for type A aneurysms.
2. The risk of surgical repair is lower than the risk that the aneurysm will rupture.
3. Opening the abdomen for the surgical procedure greatly increases the risk of rupture.
4. A percutaneously inserted endovascular stent may be considered because of the patient's age.

6. A patient is diagnosed with peripheral atherosclerosis. What should the nurse expect to assess in this patient?
1. pallor of the legs and feet when dependent
2. impaired sensation in the affected extremity
3. increased hair growth on the affected extremity
4. higher blood pressure readings in the affected extremity

7. The nurse is planning care for a patient being discharged with peripheral vascular disease. In which order should the nurse provide teaching to this patient?
1. foot and leg care
2. smoking cessation
3. weight loss strategies
4. regular daily exercise
5. daily inspection of feet and legs

8. The nurse provides discharge instructions to a patient with a deep venous thrombosis. Which patient statement indicates that teaching has been effective?
1. "I'll use a hard-backed, upright chair when sitting instead of my recliner."
2. "I understand why I am not allowed to exercise for the next six weeks and will take it easy."
3. "I'll get my blood drawn as scheduled and notify the doctor if I have any unusual bleeding or bruising."
4. "I'll have my wife buy a low-cholesterol cookbook and we'll make an appointment with the dietitian to learn about a low-fat, low-cholesterol diet."

9. A patient with visible varicose veins wants to have surgery to remove them because of leg pain. What would be the most appropriate response for the nurse to make to this patient?
1. "Surgery will have a good cosmetic effect, but will not relieve the discomfort associated with varicose veins."
2. "All varicose veins should be surgically removed to restore adequate blood flow to your legs and prevent gangrene."
3. "Often measures such as elevating your legs and elastic stockings can relieve the discomfort associated with varicose veins."
4. "Surgery is never indicated unless the varicose veins are interfering with circulation. Have you tried cosmetic measures to cover them up?"

10. The nurse is caring for a patient with lymphedema. Which nursing intervention is the highest priority for this patient?
1. Elevate affected extremities at night.
2. Reinforce the importance of taking prescribed diuretics.
3. Assist to apply elastic compression stockings during the day.
4. Carefully dry and apply emollient lotion to affected extremities after bathing.

See Test Yourself answers in Appendix B.

33 Nursing Care of Patients with Hematologic Disorders

LEARNING OUTCOMES

1. Relate the physiology and assessment of the hematologic system and related systems to commonly occurring hematologic disorders.
2. Describe the pathophysiology of common hematologic disorders.
3. Explain nursing implications for medications and other treatments prescribed for hematologic disorders.
4. Discuss indications for and complications of bone marrow or stem cell transplantation, as well as related nursing care.
5. Compare and contrast the pathophysiology, manifestations, and management of bleeding disorders.
6. Describe the major types of leukemia and the most common treatment modalities and nursing interventions.
7. Differentiate Hodgkin's disease from non-Hodgkin's lymphomas.

CLINICAL COMPETENCIES

1. Assess the effects of hematologic disorders and prescribed treatments on patients' functional health status.
2. Monitor and document continuing assessment data, including laboratory test results, subjective and objective information, and reporting data outside the normal or expected range.
3. Based on knowledge of pathophysiology, prescribed treatment, and assessed data, identify and prioritize nursing diagnoses for patients with hematologic disorders.
4. Use nursing research and evidence-based practice to identify and implement individualized nursing interventions for the patient with a hematologic disorder.
5. Safely administer prescribed medications and treatments for patients with hematologic disorders.
6. Collaborate with the interprofessional care team to plan and provide coordinated, effective care for patients with hematologic disorders.
7. Provide appropriate teaching for patients with hematologic disorders, evaluating learning and the need for continued reinforcement of information.
8. Use continuing assessment data to revise the plan of care as needed to restore, maintain, or promote functional health in the patient with a hematologic disorder

MAJOR CHAPTER CONCEPTS

- Anemia is the most common disorder of the red blood cells; nutritional deficiencies are the most common causes of anemia.
- Nursing care related to anemia is primarily educational to prepare the patient for effective self-care, including diet, prescribed medications, and measures to prevent sickling episodes (for patients with sickle cell disease).
- Four major subgroups of leukemia are identified: acute and chronic myeloid leukemias, and acute and chronic lymphocytic (or lymphoblastic) leukemias.
- Nursing care for patients with leukemia and lymphoma focuses on reducing the risk for infection and bleeding, managing the effects of chemotherapy and radiation therapy, and, in some cases, caring for patients before and after bone marrow or stem cell transplant.
- Multiple myeloma is a malignancy of plasma cells, B lymphocytes that produce antibodies.
- Bleeding and clotting disorders can result from either inadequate platelets (thrombocytopenia) or disruption of the clotting mechanisms (hemophilia, disseminated intravascular coagulation).

thalassemia, *1020*
thrombocytopenia, *1050*

Disorders affecting the blood and blood-forming organs have effects that range from minor disruptions in daily activities to major life-threatening crises. Patients with hematologic disorders need holistic nursing care, including emotional support and care for problems involving major body systems. This chapter focuses on health changes resulting from changes in red cells, white cells, platelets, and clotting factors.

Red Blood Cell Disorders

Red blood cells (RBCs) transport oxygen to body tissues and help return carbon dioxide to the lungs for excretion. Alterations in the number, size, shape, or composition of RBCs affect their ability to effectively carry out these functions. Anemia, the most common RBC disorder, is an abnormally low RBC count or reduced hemoglobin content. Polycythemia is an abnormally high RBC count.

THE PATIENT WITH ANEMIA

Anemia is an abnormally low number of circulating RBCs, low hemoglobin concentration, or both. A decrease in the number of circulating RBCs is the usual cause of anemia. This may result from blood loss, inadequate RBC production, or increased RBC destruction. Insufficient or defective hemoglobin within RBCs contributes to anemia. Depending on its severity, anemia may affect all major organ systems.

FAST FACTS

- Iron-deficiency anemia, a nutritional anemia, is the most common type of anemia.
- Blood loss anemia may be either acute, resulting from hemorrhage, or chronic, resulting from chronic blood loss (e.g., menstrual flow, slow gastrointestinal bleeding).
- Risk for anemia increases with age. Persons older than 85 years are two to three times more likely to have anemia compared to other older adults.

Physiology Review

As blood flows through the pulmonary vascular system, oxygen diffuses from alveoli into capillary blood. The majority of the oxygen binds reversibly with the hemoglobin in RBCs; only about 3% of the oxygen remains in solution in the blood. When the blood reaches the capillaries serving body tissues, oxygen is released from the hemoglobin molecule and diffuses out of the capillary to reach the cells. The amount of oxygen that reaches the tissues depends on a number of factors, including the following:

- Available oxygen in the alveoli
- The diffusing surface and capacity of the lungs
- The number of RBCs and the amount and type of hemoglobin they contain
- The ability of the cardiovascular system to transport blood and oxygen to the tissues.

For more information about red blood cells (RBCs), hemoglobin, and their production and function, refer to Chapter 29.

Physiology and Manifestations

A number of different pathologic mechanisms can lead to anemia (Box 33–1). Regardless of the cause, every type of anemia reduces the oxygen-carrying capacity of the blood due to a deficiency of RBCs or hemoglobin, leading to tissue hypoxia. The resulting manifestations depend on the severity of the anemia, how quickly it develops, and other factors such as age and health status.

BOX 33–1 Pathophysiologic Mechanisms of Anemia

DECREASED RBC PRODUCTION

- Altered hemoglobin synthesis
  - Iron deficiency
  - Thalassemias
  - Chronic inflammation
- Altered DNA synthesis
  - Vitamin B_{12} or folic acid malabsorption or deficiency
- Bone marrow failure
  - Aplastic anemia (stem cell dysfunction)
  - Red cell aplasia
  - Myeloproliferative leukemias
  - Cancer metastasis, lymphoma
  - Chronic infection or inflammation, physical and emotional fatigue

INCREASED RBC LOSS OR DESTRUCTION

- Acute or chronic blood loss
  - Hemorrhage or trauma
  - Chronic gastrointestinal bleeding, menorrhagia
- Increased hemolysis
  - Hereditary cell membrane disorders
  - Defective hemoglobin—sickle cell disease or trait
  - Pyruvate kinase (PK) or glucose-6-phosphate dehydrogenase (G6PD) deficiency affecting glycolysis or cell oxidation
  - Immune mechanisms and disorders (e.g., blood reaction, hypersensitivity responses, autoimmune disorders)
  - Splenomegaly and hypersplenism
  - Infection
  - Erythrocyte trauma (e.g., due to cardiopulmonary bypass, hemolytic uremic syndrome)

When anemia develops gradually and the RBC reduction is moderate, successful compensatory mechanisms may result in few symptoms except when the oxygen needs of the body increase due to exercise or infection. Symptoms develop as RBCs and hemoglobin levels are further reduced. Pallor of the skin, mucous membranes, conjunctiva, and nail beds develops as a result of blood redistribution to vital organs and lack of hemoglobin (Figure 33–1 ■). As tissue oxygenation decreases, the heart and respiratory rates rise in an attempt to increase cardiac output and tissue perfusion. Tissue hypoxia may cause angina, fatigue, dyspnea on exertion, and night cramps. It also stimulates erythropoietin release; increased erythropoietin activity stimulates RBC production in the bone marrow, and may lead to bone pain. Cerebral hypoxia can lead to headache, dizziness, and dim vision. Heart failure may develop in severe anemia.

With rapid blood loss, blood volume is decreased, as is the oxygen-carrying capacity of the blood. Initial manifestations include tachycardia and tachypnea; the skin may be pale, cool, and clammy

Figure 33–1 ■ The skin of the patient with anemia appears pale beside that of an individual with a normal hemoglobin and hematocrit.

as peripheral vessels constrict to maintain blood flow to the heart and brain. With significant blood loss, signs of circulatory shock may occur, including hypotension, tachycardia, decreased level of consciousness, and oliguria. With chronic bleeding, fluid shifts from the interstitial spaces into the vessels, maintaining blood volume. Blood viscosity is reduced, which may result in a systolic heart murmur. See the Multisystem Effects of Anemia feature on page 1017.

Anemia is categorized by cause: blood loss, nutritional, hemolytic, and bone marrow suppression (aplastic). Genetics also plays a role in some anemias. Discussions of the pathophysiology and specific manifestations of these types of anemias follow.

BLOOD LOSS ANEMIA

When anemia results from acute or chronic bleeding, RBCs and other blood components (such as iron) are lost from the body. With acute blood loss, circulating volume decreases. As a result, the cardiac output falls. Compensatory mechanisms are activated to maintain the cardiac output: The heart rate increases, and peripheral blood vessels constrict. Vessels in the liver, a blood storage organ, also constrict, increasing circulating volume. Fluid shifts from the interstitial spaces into the vascular compartment to maintain blood volume, diluting the cellular components of the blood and reducing its viscosity. If hemorrhage continues, compensatory mechanisms become less effective, increasing the risk for shock and circulatory failure (refer to Chapter 11).

In acute blood loss, circulating RBCs are of normal size and shape (*normocytic*). Early in the hemorrhage, the RBC count, hemoglobin, and hematocrit may be normal; as fluid shifts from the interstitial space into the vascular space to maintain circulating volume, the RBC count, hemoglobin, and hematocrit fall. If sufficient iron is available, the number of circulating RBCs and hemoglobin levels return to normal within 3 to 4 weeks after the bleeding episode. Chronic blood loss, on the other hand, depletes iron stores as RBC production attempts to maintain the RBC supply. The resulting RBCs are *microcytic* (small) and *hypochromic* (pale).

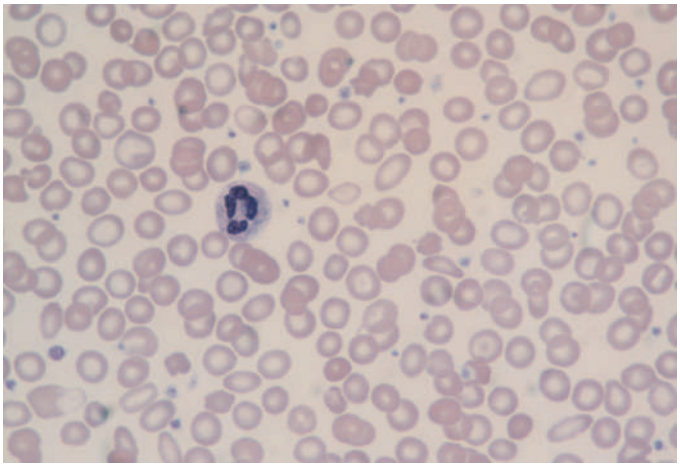
NUTRITIONAL ANEMIAS

A number of different nutrients are required for normal RBC development (erythropoiesis). Iron is a key nutrient necessary for hemoglobin synthesis. In addition, adequate supplies of protein (and its building blocks, amino acids), vitamins, and other minerals are required. The B vitamins, particularly B_{12} (cobalamin) and folate, play a key role in RBC development. Vitamins C and E also are necessary. Nutritional anemias result from nutrient deficits that affect RBC formation or hemoglobin synthesis. The nutrient deficit may be caused by inadequate diet, malabsorption of the nutrient, or an increased need for the nutrient. The most common types of nutritional anemias are iron-deficiency anemia, vitamin B_{12} anemia, and folic acid deficiency anemia. Vitamin B_{12} and folic acid anemias are sometimes called *megaloblastic* anemias, because enlarged nucleated RBCs called megaloblasts are seen in these anemias.

IRON-DEFICIENCY ANEMIA **Iron-deficiency anemia** is the most common type of anemia. It develops when the supply of iron is inadequate for optimal RBC formation. The body cannot synthesize hemoglobin without iron. Normally, the body efficiently recycles and stores iron, reusing much of the iron contained in RBCs that are removed from circulation due to age or damage. However, small amounts of iron continually are lost in the feces; therefore, adequate iron intake is necessary for normal hemoglobin synthesis and RBC production. Iron-deficiency anemia results in fewer numbers of RBCs, microcytic and hypochromic RBCs, and malformed RBCs (*poikilocytosis*) (Figure 33–2 ■).

Excessive iron loss due to chronic bleeding is the usual cause of iron-deficiency anemia in adults. Menstrual blood loss is the most common cause in adult females. Iron-deficiency anemia also may result from inadequate dietary iron intake (less than 1 mg/day), malabsorption syndromes, or the increased iron requirements associated with pregnancy and lactation. Box 33–2 summarizes common causes of iron-deficiency anemia.

Iron-deficiency anemia is particularly common in older adults. Chronic, occult (hidden) blood loss may occur from slowly bleeding peptic ulcers, GI inflammation, hemorrhoids, and cancer. Inadequate dietary iron intake also contributes to anemia in the older adult. Access to transportation may limit fresh food consumption, a factor contributing to poor iron intake among all adults, especially people with limited or fixed incomes. See the Nursing Care of the Older Adult box.



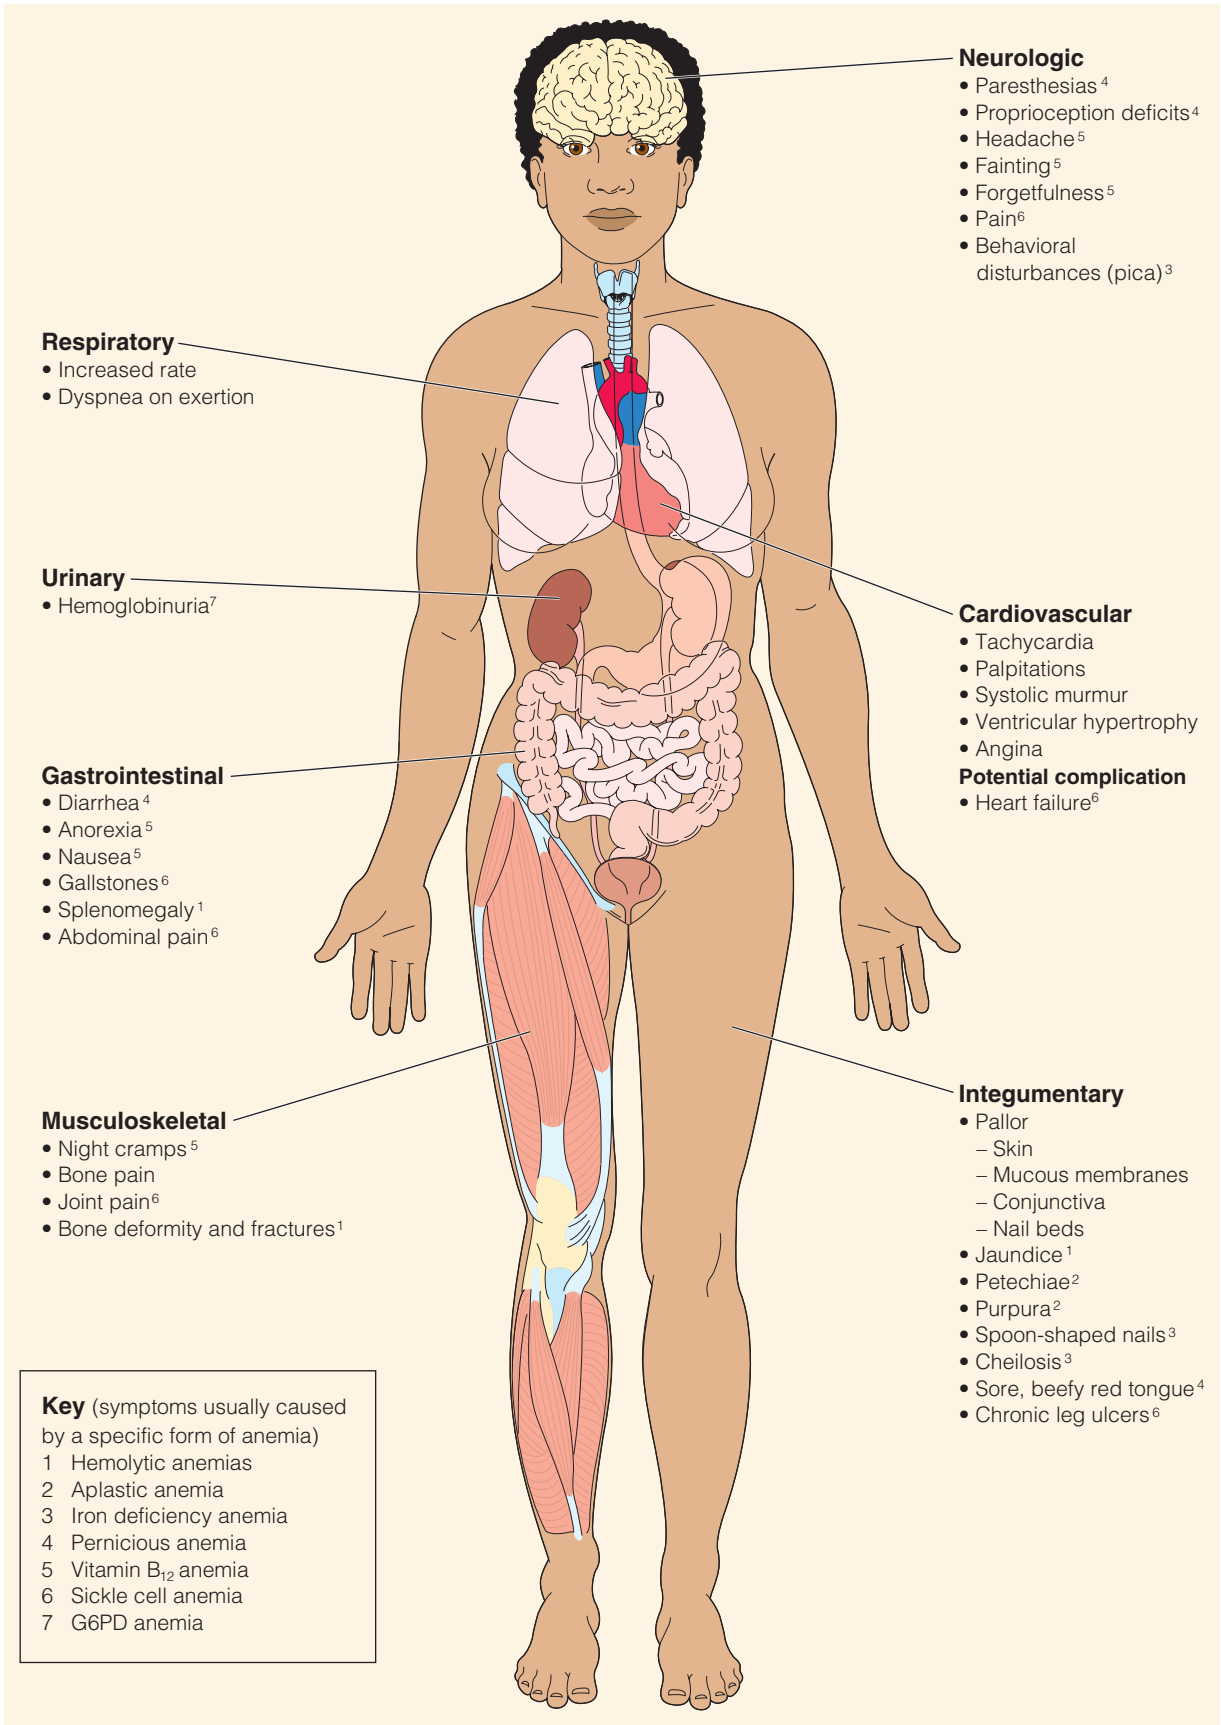


Figure 33–2 ■ A blood smear showing RBCs characteristically seen in iron-deficiency anemia. Note the pale color of the RBCs (hypochromic). Many of the cells also are smaller than normal (microcytic) and misshapen, reducing their oxygen-carrying capacity.

MULTISYSTEM EFFECTS OF
Anemia

BOX 33–2 Causes of Iron-Deficiency Anemia

- Dietary deficiencies
  a. Vegetarian diet
  b. Inadequate protein intake
- Decreased absorption
  a. Partial or total gastrectomy
  b. Chronic diarrhea
  c. Malabsorption syndromes
- Increased metabolic requirements
  a. Pregnancy
  b. Lactation
- Blood loss
  a. Gastrointestinal bleeding (especially due to ulcers or chronic aspirin use)
  b. Menstrual losses
- Chronic hemoglobinuria

NURSING CARE OF THE OLDER ADULT

Anemia

Anemia is a significant problem in older adults. When the data from the National Health and Nutrition Examination Survey III (NHANES III) 1988–1994 was compared to data from other large-scale epidemiologic studies, Pang and Schrier (2012) reported differences in findings based on the geographic location of older adults. Unexplained anemia was found in 30% to 46% of older adults with anemia. Iron deficiency is noted to be caused by blood loss in the United States and western Europe, whereas in the developing world, other nutritional deficiencies contribute to the etiology. Also noted was the 4% prevalence of myelodysplastic syndromes among older adults.

MANIFESTATIONS In addition to the general manifestations of anemia described earlier, chronic iron deficiency may lead to brittle, spoon-shaped nails; cheilosis (cracks at the corners of the mouth); a smooth, sore tongue; and *pica* (a craving for unusual substances, such as clay or starch).

VITAMIN B_{12} DEFICIENCY ANEMIA Vitamin B_{12} is necessary for DNA synthesis and is found almost exclusively in foods derived from animals. Vitamin B_{12} deficiency occurs when inadequate vitamin B_{12} is consumed, or, more commonly, when it is poorly absorbed from the GI tract. Deficiency of this vitamin impairs cell division and maturation of the cell nucleus, especially in rapidly proliferating RBCs. As a result, macrocytic (large), misshapen (oval rather than concave) RBCs with thin membranes are produced. Great numbers of these large, immature RBCs enter the circulation. These cells are fragile, incapable of carrying adequate amounts of oxygen, and have a shortened life span.

Failure to absorb dietary vitamin B_{12} is called **pernicious anemia**. It develops due to lack of intrinsic factor, a substance secreted by the gastric mucosa. Intrinsic factor binds with vitamin B_{12} and travels with it to the ileum, where the vitamin is absorbed. In the absence of intrinsic factor, vitamin B_{12} cannot be absorbed into the body.

Vitamin B_{12} deficiency may also result from other malabsorption disorders and dietary factors. Resection of the stomach or ileum, loss of pancreatic secretions, and chronic gastritis can affect vitamin B_{12} absorption. Dietary deficiencies of vitamin B_{12} are rare, usually occurring only among strict vegetarians.

MANIFESTATIONS Manifestations of vitamin B_{12} deficiency anemia develop gradually as bodily stores of the vitamin are depleted. Pallor or slight jaundice and weakness develop. In pernicious anemia, a smooth, sore, beefy red tongue and diarrhea may occur. Because vitamin B_{12} is important for neurologic function, *paresthesias* (altered sensations, such as numbness or tingling) in the extremities and problems with *proprioception* (the sense of one's position in space) develop. These manifestations may progress to difficulty maintaining balance due to spinal cord damage. Central nervous system (CNS) manifestations of relatively short duration (6 months or less) are reversible with treatment, but may be permanent if treatment is delayed.

FOLIC ACID DEFICIENCY ANEMIA Like vitamin B_{12}, folic acid is required for DNA synthesis and normal maturation of RBCs. Folic acid deficiency anemia is characterized by fragile, megaloblastic (large and immature) cells. Folic acid is found in green leafy vegetables, fruits, cereals, and meats, and is absorbed from the intestines.

Folic acid deficiency anemia due to inadequate intake is more common among people who are chronically undernourished. This includes older adults and people with alcoholism or drug addictions. People with alcoholism are especially at risk because alcohol suppresses folate metabolism, which forms folic acid. Increased folic acid requirements also may lead to anemia. Pregnant women are at the greatest risk. Infants and teenagers can develop temporary folic acid deficiencies during periods of rapid growth. Impaired folic acid absorption and metabolism can cause folic acid deficiency anemia. Malabsorption disorders such as celiac sprue (a hereditary GI disorder characterized by inability to metabolize amino acids found in gluten) and certain medications, such as methotrexate and some chemotherapeutic agents, may be implicated. Causes of folic acid deficiency anemia are summarized in Box 33–3.

MANIFESTATIONS The manifestations develop gradually as folic acid stores are depleted. Signs and symptoms may include pallor, progressive weakness and fatigue, shortness of breath, and heart palpitations. Manifestations similar to those associated with vitamin B_{12} anemia, such as glossitis, cheilosis, and diarrhea, are common. No neurologic symptoms occur with folic acid deficiency anemia, helping differentiate it from vitamin B_{12} deficiency anemia. These two nutritional anemias do, however, sometimes coexist.

Folic acid deficiency is strongly associated with neural tube defects such as meningomyelocele. The neural tube develops early in the process of fetal development, often before pregnancy is recognized.

BOX 33–3 Causes of Folic Acid Deficiency Anemia

- Inadequate dietary intake
  At risk:
  a. Older adults
  b. People with alcoholism
  c. Patients receiving total parenteral nutrition
- Increased metabolic requirements
  At risk:
  a. Pregnant women
  b. Infants and teenagers
  c. Patients undergoing hemodialysis
  d. Patients with forms of hemolytic anemia
- Folic acid malabsorption and impaired metabolism
  a. Celiac sprue
  b. Chemotherapeutic agents, folate antagonists (methotrexate, pentamidine), or anticonvulsants
  c. Alcoholism

HEMOLYTIC ANEMIAS

Hemolytic anemias are characterized by premature destruction (*lysis*) of RBCs. When RBCs break down, iron and other by-products of their destruction remain in the plasma. RBC lysis (hemolysis) may occur within the circulatory system or due to phagocytosis by WBCs such as circulating monocytes and macrophages in the spleen. In response to hemolysis, the hematopoietic activity of bone marrow increases, leading to increased reticulocytes (immature RBCs) in circulating blood. Most types of hemolytic anemia are characterized by normocytic and normochromic RBCs.

Hemolytic anemias have many different causes (Box 33–4). The cause may be *intrinsic*, arising from disorders within the RBC itself, or *extrinsic*, originating outside the RBC. Intrinsic disorders include cell membrane defects, defects in hemoglobin structure and function, and inherited enzyme deficiencies. See the accompanying Focus on Cultural Diversity box for more information about inherited intrinsic RBC disorders associated with hemolytic anemia. Extrinsic causes of hemolytic anemia include drugs, bacterial and other toxins, and trauma. This section discusses sickle cell disease, thalassemia, acquired hemolytic anemia, and glucose-6-phosphate dehydrogenase anemia.

SICKLE CELL DISEASE **Sickle cell disease** is a hereditary, chronic hemolytic anemia. It is characterized by episodes of *sickling*, during which RBCs become abnormally crescent shaped. The disorder is transmitted as an autosomal recessive genetic defect (Figure 33–3 ■). This defect causes synthesis of an abnormal form of hemoglobin (HbS) within RBCs. Sickle cell disease can significantly shorten the life span, with most deaths occurring due to infection (Huether & McCance, 2011).

The disease is most common among people of African descent (refer to the Focus on Cultural Diversity feature). In the United States, 7% to 13% of Blacks carry the defective gene, having inherited it from one parent (Huether & McCance, 2011). These people have *sickle cell trait*. About 40% of their hemoglobin is HbS. They are likely to remain asymptomatic unless stressed by severe hypoxia. Less than 1% of African Americans are homozygous for the disorder; that is, they have inherited a defective gene from both parents. These people have *sickle cell disease*; nearly all their hemoglobin is HbS. They are at risk for **sickle cell crisis**, severe episodes of fever and intense pain that are the hallmark of this disorder.

BOX 33–4 Causes of Hemolytic Anemia

INTRINSIC
- RBC cell membrane defects
- Hemoglobin structure defects (e.g., sickle cell disease, thalassemia)
- Inherited enzyme defects (e.g., G6PD deficiency)

EXTRINSIC
- Drugs, chemicals
- Toxins and venoms
- Bacterial and other infections
- Trauma, burns
- Mechanical damage (prosthetic heart valves)

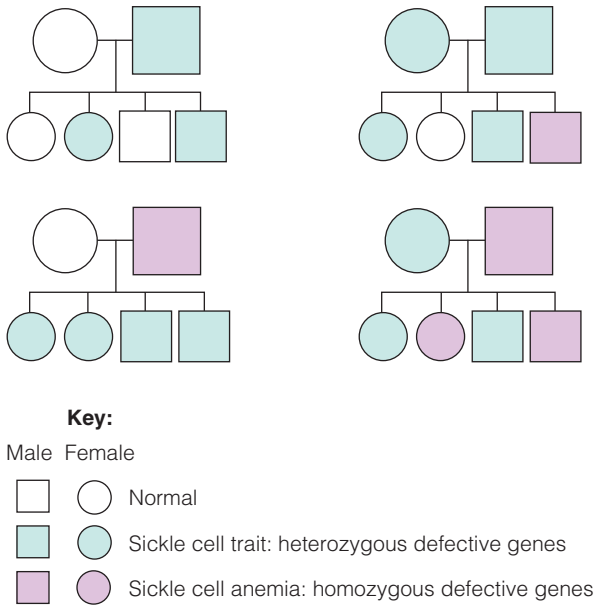

Figure 33–3 ■ Inheritance pattern for sickle cell disease.

FOCUS ON CULTURAL DIVERSITY

Inherited Hemolytic Anemias

- Sickle cell disease affects about 70,000 to 100,000 people in the United States (National Heart, Lung, and Blood Institute, 2012).
  - In African Americans, sickle cell disease occurs in 1 out of every 500 births.
  - People from Central and South America, Cuba, Saudi Arabia, India, and Mediterranean countries such as Turkey, Greece, and Italy also may be at risk; sickle cell disease occurs in 1 of every 1000 to 1400 Hispanic American births.
- Thalassemia is less common than sickle cell disease.
  - Alpha-thalassemia primarily affects people of Southeast Asian, Indian, Chinese, and Filipino ancestry.
  - Beta-thalassemia is seen primarily in people of Mediterranean, Asian, and African origin.
- G6PD anemia primarily affects people of African or Mediterranean descent.
  - This hereditary defect is carried on the X chromosome and affects more men than women.

FOCUS ON CULTURAL DIVERSITY

Sickle Cell Disease

Sickle cell disease tends to affect people whose origins are in equatorial countries, particularly those in central Africa, the Near East, the Mediterranean region, and parts of India. Hispanics from the Caribbean and Central and South America also may have the HbS gene. This gene may protect against lethal forms of malaria, an endemic disease in many equatorial regions.

The gene for HbS is transmitted in an autosomal recessive pattern from parent to offspring. A parent with one HbS gene (heterozygous) has a 50% risk of transmitting the gene to each child (refer to Figure 33–3). If both parents carry the gene, each child has a 25% risk of inheriting the gene from both parents. An individual who carries both HbS genes (homozygous) is likely to develop sickle cell disease.

Sickle cell disease is a serious chronic and recurrent disease. The stress of the disease is compounded by the risk for its transmission to offspring. Recommend that all patients with sickle cell trait or disease obtain genetic counseling as part of their family planning process.

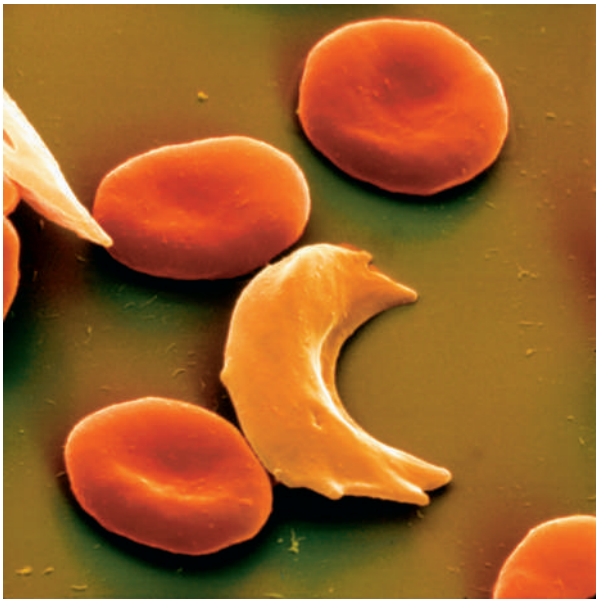

Figure 33–4 ■ Blood smear containing normal red blood cells and sickled cells.

The HbS gene changes the structure of the beta chain of the hemoglobin molecule. When hypoxemia develops and HbS is deoxygenated, it crystallizes into rodlike structures. Clusters of these rods form long chains that deform the erythrocyte into a crescent or sickle shape (Figure 33–4 ■). The sickled cells tend to clump together and obstruct capillary blood flow, causing ischemia and possible infarction of surrounding tissue. See the Pathophysiology Illustrated feature on page 1021.

When normal oxygen tension is restored, the sickled RBCs resume their normal shape; that is, they "unsickle." Repeated episodes of sickling and unsickling weaken RBC cell membranes. The weakened RBCs are hemolyzed and removed. Consequently, the normal life span of RBCs is greatly reduced in sickle cell disease, increasing the demand for RBC production. Conditions likely to trigger sickling include hypoxia, low environmental or body temperature, excessive exercise, anesthesia, dehydration, infections, or acidosis.

MANIFESTATIONS AND COMPLICATIONS The acute and chronic manifestations of sickle cell disease arise from episodes of RBC sickling. Sickling causes general manifestations of hemolytic anemia, including pallor, fatigue, jaundice, and irritability. Extensive sickling can precipitate a crisis due to occluded circulation, impaired erythropoiesis, or sequestration of large amounts of blood in the liver or spleen.

A vasoocclusive or thrombotic crisis occurs when sickling develops in the microcirculation. Obstruction of blood flow triggers vasospasm that halts all blood flow in the vessel. Lack of blood flow leads to tissue ischemia and infarction. Vasoocclusive crises are painful and last an average of 4 to 6 days. Infarction of small vessels in the extremities causes painful swelling of the hands and feet; large joints also may be affected. Priapism (persistent, painful erection of the penis) may develop. Abdominal pain may signal infarction of abdominal organs and structures. Infarction may affect bone marrow or lead to aseptic necrosis of affected bones. Stroke may result from cerebral vessel occlusion (Huether & McCance, 2011). Skin ulcers may develop as a result of occluded vessels supplying the dermis. Repeated infarcts associated with sickling can affect the structure and function of nearly every organ system. People with sickle cell disease may develop an enlarged spleen and liver, renal insufficiency, gallstones, and other manifestations of organ dysfunction. *Acute chest syndrome*, a symptom complex that includes fever, chest pain, an increasing WBC count, and pulmonary infiltrates, may develop, as well as other pulmonary complications like pneumonia, pulmonary infarction, and pulmonary embolism.

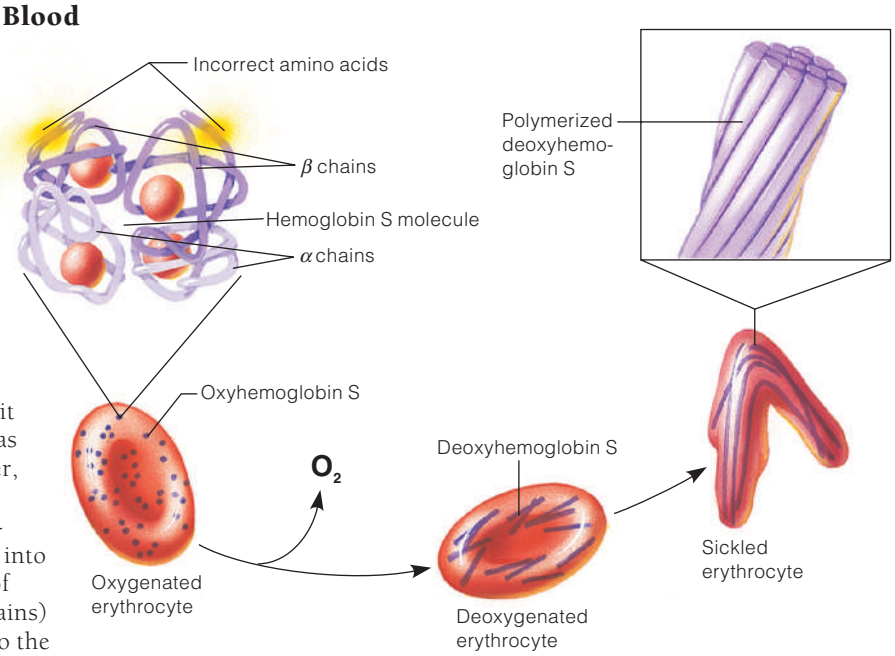
The shortened RBC life span and compromised erythropoiesis can lead to profound *aplastic anemia* in sickle cell disease. *Sequestration crises* are marked by pooling of large amounts of blood in the liver and spleen. This sickle cell crisis only occurs in children, but is thought to be the cause of sickle cell disease–related deaths in early childhood (Huether & McCance, 2011).

THALASSEMIA The **thalassemias** are inherited disorders of hemoglobin synthesis in which either the alpha or beta chains of the hemoglobin molecule are missing or defective. This leads to deficient hemoglobin production and fragile hypochromic, microcytic RBCs called *target cells* because of their distinctive bull's-eye appearance.

Thalassemia usually affects certain populations. People of Mediterranean descent (southern Italy and Greece) are more likely to have beta-defect thalassemias (often called *Cooley's anemia* or Mediterranean anemia). People of Asian ancestry, especially from Thailand, the Philippines, and China, more often have alpha-defect thalassemia. Africans and African Americans may have both alpha- and beta-defect thalassemia. As with sickle cell disease, only one defective beta chain–forming gene may be present (*beta-thalassemia minor*), causing mild symptoms, or both may be defective (*beta-thalassemia major*), leading to more severe symptoms. Children with thalassemia major rarely reach adulthood, although repeated blood transfusions may extend their life span (Huether & McCance, 2011). Four genes are responsible for alpha chain formation; one, two, three, or all four may be defective. In the latter case (*alpha-thalassemia major*), death is inevitable and usually occurs in utero. Genetic studies and counseling are recommended for people at risk for this illness.

MANIFESTATIONS AND COMPLICATIONS People with thalassemia minor often are asymptomatic. When manifestations do occur, they include mild to moderate anemia, mild splenomegaly, bronze skin coloring, and bone marrow hyperplasia. The major form of the disease causes severe anemia, heart failure, and liver and spleen enlargement from increased red cell destruction. Fractures of the long bones, ribs, and vertebrae may result from bone marrow expansion and thinning due to increased hematopoiesis. Jaundice may develop due to hemolysis, as well as hepatomegaly and splenomegaly. Accumulation of iron in the heart, liver, and pancreas following repeated transfusions for treatment may eventually cause failure of these organs.

ACQUIRED HEMOLYTIC ANEMIA *Acquired hemolytic anemia* results from hemolysis due to factors outside of the RBC. Causes of acquired hemolytic anemias include the following:

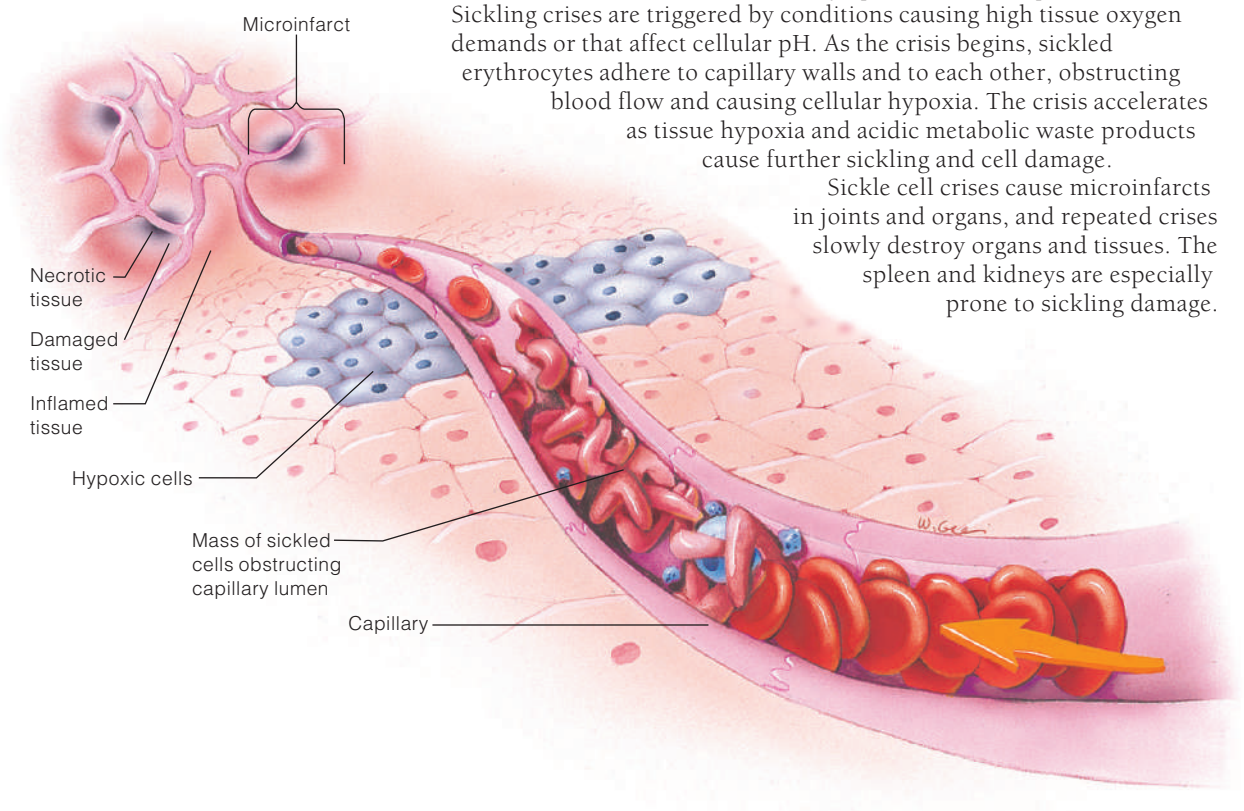


- Mechanical trauma to RBCs produced by prosthetic heart valves, severe burns, hemodialysis, or radiation
- Autoimmune disorders
- Bacterial or protozoal infection
- Immune-system-mediated responses, such as transfusion reactions
- Drugs, toxins, chemical agents, or venoms.

PATHOPHYSIOLOGY ILLUSTRATED
Sickle Cell Disease

Hemoglobin S and Red Blood Cell Sickling

Sickle cell anemia is caused by an inherited autosomal recessive defect in Hb synthesis. Sickle cell hemoglobin (HbS) differs from normal hemoglobin only in the substitution of the amino acid valine for glutamine in both beta chains of the hemoglobin molecule.



When HbS is oxygenated, it has the same globular shape as normal hemoglobin. However, when HbS off-loads oxygen, it becomes insoluble in intracellular fluid and crystallizes into rodlike structures. Clusters of rods form polymers (long chains) that bend the erythrocyte into the characteristic crescent shape of the sickle cell.

The Sickle Cell Disease Process

Sickle cell disease is characterized by episodes of acute painful crises. Sickling crises are triggered by conditions causing high tissue oxygen demands or that affect cellular pH. As the crisis begins, sickled erythrocytes adhere to capillary walls and to each other, obstructing blood flow and causing cellular hypoxia. The crisis accelerates as tissue hypoxia and acidic metabolic waste products cause further sickling and cell damage.

Sickle cell crises cause microinfarcts in joints and organs, and repeated crises slowly destroy organs and tissues. The spleen and kidneys are especially prone to sickling damage.

The manifestations of acquired hemolytic anemia depend on the extent of hemolysis and the body's ability to replace destroyed RBCs. The anemia itself often is mild to moderate as erythropoiesis increases to replace the destroyed RBCs. The spleen enlarges as it removes damaged or destroyed RBCs. If the breakdown of heme units exceeds the liver's ability to conjugate and excrete bilirubin, jaundice develops. When the condition is severe, bone marrow expands, and bones may be deformed or may develop pathologic fractures. The severity of generalized manifestations of anemia (tachycardia, pallor, etc.) depends on the degree of anemia and deficiency of tissue oxygenation.

GLUCOSE-6-PHOSPHATE DEHYDROGENASE (G6PD) ANEMIA

Glucose-6-phosphate dehydrogenase (G6PD) anemia is caused by a hereditary defect in RBC metabolism. It is relatively common in people of African and Mediterranean descent. The defective gene is located on the X chromosome and therefore affects more males than females. There are many variations of this genetic defect.

G6PD is an enzyme that catalyzes glycolysis, the process in which an RBC derives cellular energy. A defect in G6PD action causes direct oxidation of hemoglobin, damaging the RBC. Hemolysis usually occurs only when the affected person is exposed to stressors (e.g., drugs such as aspirin, sulfonamides, or vitamin K derivatives) that increase the metabolic demands on RBCs. The G6PD deficiency impairs the necessary compensatory increase in glucose metabolism and causes cellular damage. Damaged RBCs are destroyed over a period of 7 to 12 days.

When exposed to a stressor triggering G6PD anemia, symptoms develop within several days. These may include pallor, jaundice, hemoglobinuria (hemoglobin in the urine), and an elevated reticulocyte count. As new RBCs develop, counts return to normal.

APLASTIC ANEMIA

In **aplastic anemia**, the bone marrow fails to produce all three types of blood cells, leading to *pancytopenia.* Normal bone marrow is replaced by fat. Fortunately, aplastic anemia is rare. *Fanconi anemia* is a rare aplastic anemia caused by defects of DNA repair. The underlying cause of about 50% of acquired aplastic anemia is unknown (*idiopathic aplastic anemia*). Other cases follow stem cell damage caused by exposure to radiation or certain chemical substances such as benzene, arsenic, nitrogen mustard, certain antibiotics (especially chloramphenicol), and chemotherapeutic drugs (Huether & McCance, 2011). Aplastic anemia also may occur with viral infections such as mononucleosis, hepatitis C, and HIV disease.

In aplastic anemia, the number of stem cells in the bone marrow is significantly reduced. The stem cell pool may be less than 1% of normal when the disease is recognized. Anemia develops as the bone marrow fails to replace RBCs that have reached the end of their life span. Remaining RBCs may be normochromic and normocytic or may be large with increased mean corpuscular volume.

MANIFESTATIONS Manifestations of aplastic anemia vary with the severity of the pancytopenia. Its onset usually is insidious, but may be sudden. Manifestations include fatigue, pallor, progressive weakness, exertional dyspnea, headache, and ultimately tachycardia and heart failure. Platelet deficiency leads to bleeding problems; bleeding gums, excessive bruising, and nosebleeds may be the initial symptoms. A deficiency of WBCs increases the risk of infection, causing manifestations such as sore throat and fever.

●○● INTERPROFESSIONAL CARE

Ensuring adequate tissue oxygenation is the priority of care in treating anemia. Specific therapy is determined by the underlying cause of the disorder. Usual treatments include medications, dietary modifications, blood replacement, or supportive interventions. Table 33–1 outlines interprofessional care measures for selected types of anemia.

TABLE 33–1 Interprofessional Care Focus for Major Anemias

Type of Anemia	Interprofessional Care
Iron-deficiency anemia	• Increased dietary intake of iron-rich foods • Oral or parenteral iron supplements
Vitamin B_{12} deficiency anemia	• Increased dietary intake of foods containing vitamin B_{12} (e.g., meats, eggs, and dairy products) • Oral or parenteral vitamin B_{12} supplements • Parenteral vitamin B_{12} for deficiency due to malabsorption or lack of intrinsic factor
Folic acid deficiency anemia	• Increased dietary intake of foods rich in folic acid (folate) • Oral folic acid supplements • Folic acid supplements recommended for women who are pregnant or may become pregnant to prevent neural tube defects
Sickle cell disease	• Treatment is primarily supportive • Hydroxyurea 10–30 mg/kg per day • Sickle cell crisis: • Rest • Oxygen therapy to maintain SaO_2 • Narcotic analgesia • Vigorous hydration • Treatment of precipitating factors • Acute chest syndrome: • Careful hydration; hemodynamic monitoring • Oxygen therapy • Transfusion • Folic acid supplements • Blood transfusions during surgery or pregnancy as necessary • Genetic counseling recommended
Thalassemia	• Regular blood transfusions • Folic acid supplements • Possible splenectomy • Genetic counseling
Aplastic anemia	• Withdrawal of the causative agent, if known • Blood transfusions • Bone marrow transplant as indicated

DIAGNOSIS

When anemia is suspected, the following laboratory and diagnostic tests may be ordered:

- *Complete blood count (CBC)* is done to determine blood cell counts, hemoglobin, hematocrit, and RBC indices (refer to Table 33–1 for care details). The severity of the anemia, shape, volume, and iron content of the RBCs can help determine the cause of anemia.
- *Iron level* and *total iron-binding capacity* tests are performed to detect iron-deficiency anemia. A low serum iron concentration and elevated total iron-binding capacity are indicative of iron-deficiency anemia.
- *Serum ferritin* is low due to depletion of the total iron reserves available for hemoglobin synthesis. Ferritin is an iron-storage protein produced by the liver, spleen, and bone marrow. Ferritin mobilizes stored iron when metabolic needs are higher than dietary intake.
- *Sickle cell test* is a screening test to evaluate hemolytic anemia and detect HbS.
- *Hemoglobin electrophoresis* separates normal hemoglobin from abnormal forms. It is used to evaluate hemolytic anemia, diagnose thalassemia, and differentiate sickle cell trait from sickle cell disease.
- *Schilling test* measures vitamin B_{12} absorption before and after intrinsic factor administration to differentiate between pernicious anemia and intestinal malabsorption of the vitamin. A 24-hour urine sample is collected following administration of radioactive vitamin B_{12}. Lower-than-normal levels of the tagged B_{12} when intrinsic factor is given concurrently indicate malabsorption rather than pernicious anemia.
- *Bone marrow examination* is done to diagnose aplastic anemia. In aplastic anemia, normal marrow elements are significantly decreased as they are replaced by fat cells. Nursing implications for bone marrow collection are described on page 1040.
- *Quantitative assay of G6PD* may be performed to confirm a diagnosis of G6PD deficiency.

MEDICATIONS

Medications used to treat anemia depend on its cause. Iron replacement therapy is ordered for iron-deficiency anemia. Supplemental iron may be given by mouth or parenterally. Intravenous administration of iron is becoming more common, particularly in patients with an acute deficiency and in anemia associated with chronic GI blood loss, chronic renal failure, and other chronic conditions that increase the need for blood cell production (e.g., cancers). The risk of anaphylaxis is a major concern when iron dextran is given intravenously. Other parenteral iron solutions, including intravenous sodium ferric gluconate (Ferrlecit) and iron sucrose (Venofer), carry a much lower risk of adverse and allergic reactions.

Parenteral vitamin B_{12} is given when malabsorption or lack of intrinsic factor leads to vitamin B_{12} deficiency anemia. Folic acid is ordered for women of childbearing age, pregnant women, and patients with folic acid deficiency or sickle cell disease to meet the increased demands of the bone marrow. Hydroxyurea, a drug that promotes fetal hemoglobin production, may be prescribed for patients with sickle cell disease, particularly those with frequent crises or severe disease. Resulting increased levels of fetal hemoglobin interfere with the sickling process and reduce the incidence of painful crises. Nursing implications for patients receiving iron, vitamin B_{12}, and folic acid are found in the accompanying Medication Administration box.

Erythropoietin may be ordered for patients with low erythropoietin levels (e.g., patients with chronic renal failure) and people with anemia associated with other chronic diseases. Erythropoietin is given subcutaneously, and may be given as often as three times a week in chronic renal failure. Because erythropoietin stimulates RBC production, adequate iron must be present. Patients receiving erythropoietin may require regular intravenous iron therapy as well (Vallerand & Sanoski, 2012).

Immunosuppressive therapy with antithymocyte globulin (ATG), corticosteroids, and cyclosporine may be used to treat aplastic anemia. Androgens may stimulate blood cell production in some patients with aplastic anemia. See Chapter 12 for more information about immunosuppression.

NUTRITION

Dietary modifications are recommended for nutritional deficiency anemias, such as iron-deficiency anemia, vitamin B_{12} deficiency anemia, or folic acid deficiency anemia. Box 33–5 identifies good sources of dietary iron, folic acid, and vitamin B_{12}.

BLOOD TRANSFUSION

Blood transfusions may be indicated to treat anemias resulting from major blood loss, such as from trauma or major surgery, and severe anemia regardless of cause. In acute hemorrhage, whole blood may

BOX 33–5 Dietary Sources of Iron, Folic Acid, and Vitamin B_{12}

IRON

Iron in the diet comes from two sources. *Heme iron* makes up about one-half of the iron from animal sources. *Nonheme iron* includes the remaining iron from animal sources and all the iron from plants, legumes, and nuts. Heme iron promotes absorption of nonheme iron from other foods when both forms are consumed at the same time. Absorption of nonheme iron is also enhanced by vitamin C and inhibited by tea and coffee.

SOURCES OF HEME IRON

- Beef
- Chicken
- Egg yolk
- Clams, oysters
- Pork loin
- Turkey
- Veal

SOURCES OF NONHEME IRON

- Bran flakes
- Brown rice
- Whole-grain breads
- Dried beans
- Dried fruits
- Leafy greens
- Oatmeal

SOURCES OF FOLIC ACID

- Green leafy vegetables
- Broccoli
- Organ meats
- Eggs
- Wheat germ
- Asparagus
- Liver
- Milk
- Yeast
- Kidney beans

SOURCES OF VITAMIN B_{12}

- Liver
- Fresh shrimp and oysters
- Eggs
- Milk
- Kidney
- Meats (muscle)
- Cheese

MEDICATION ADMINISTRATION

Drugs to Treat Anemia

IRON SOURCES

ferrous sulfate (Feosol, Fer-in-sol)

ferrous gluconate (Fergon, Ferralet, Fertinic)

iron dextran injection (Imferon)

iron polysaccharide

iron sucrose (Venofer)

sodium ferric gluconate (Ferrlecit)

Iron preparations are normally taken by mouth and are absorbed from the GI tract. They are given to treat anemias resulting from iron deficiency or blood loss. When absorbed, iron combines with transferrin. This complex then is transported to the bone marrow and incorporated into hemoglobin.

Nursing Responsibilities

- Prior to giving the drug, assess for use of drugs that might interact with iron (e.g., antacids, allopurinol, chloramphenicol, tetracyclines, vitamin E), GI bleeding, and manifestations of anemia.
- Administer iron preparations with orange juice to enhance absorption.
- If using an elixir, give it through a straw to prevent staining the teeth.
- Monitor for manifestations of iron toxicity: nausea, diarrhea, or constipation; symptoms of anaphylactic shock (extreme cases).
- Monitor hemoglobin and reticulocyte counts.
- If the patient is also taking tetracyclines, schedule the dose of iron 2 hours before tetracycline (iron reduces the absorption of tetracycline).
- When administering IM or IV, monitor closely for anaphylaxis.

Health Education for the Patient and Family

- GI side effects may be reduced by taking iron with food (but not milk, which decreases absorption).
- Stools may be dark green or black; this is harmless.
- Increase fluids and fiber in diet to decrease constipation.

VITAMIN B_{12} SOURCES

cyanocobalamin (Kaybovite [oral], Anacobin [parenteral], Bedoz)

Cyanocobalamin is used to treat vitamin B_{12} deficiencies or malabsorption and pernicious anemia. It is rapidly absorbed when administered orally or by injection, and it is stored in the liver. Intrinsic factor is necessary for absorption from the GI tract.

Nursing Responsibilities

- Do not expose crystalline injection to light.
- Assess for other drugs that might interfere with the therapeutic response: Chloramphenicol, cimetidine, colchicine, and timed-release potassium decrease its effectiveness.
- Do not mix cyanocobalamin in a syringe with other medications.
- Administer parenteral doses intramuscularly or deep subcutaneously to decrease local irritation.
- Monitor hemoglobin, RBC counts, reticulocyte counts, and potassium levels.

Health Education for the Patient and Family

- A burning sensation with injection is temporary.
- Avoid alcohol, which interferes with absorption.
- If used to treat pernicious anemia, the medication must be taken for life.

FOLIC ACID SOURCES

folic acid (Folvite, Novo-Folacid)

Synthetic folic acid is used to treat folic acid deficiency and megaloblastic or macrocytic anemia. It is absorbed from the GI tract and stored in the liver.

Nursing Responsibilities

- Prior to giving the medication, assess for use of drugs that alter its effect: corticosteroids, methotrexate, oral contraceptives, phenytoin, sulfonamides.
- Do not mix folic acid with other medications in the same syringe.
- Monitor for possible hypersensitivity response of skin rash.

Health Education for the Patient and Family

- Large doses of folic acid may cause the urine to become darker yellow.
- Excess alcohol intake increases folic acid requirements.

be given to replace both blood cells and volume. A unit of packed RBCs may be given when anemia is severe and the patient demonstrates cardiovascular instability or compromise. Blood transfusions are fully discussed in Chapter 11.

COMPLEMENTARY THERAPIES

Complementary healthcare practitioners may recommend specific plant enzymes to treat nutritional anemias. Plant enzymes are believed to aid digestion of proteins, fats, and carbohydrates, facilitating absorption of their nutrients. Therapy is determined by the specific type of anemia. Plant enzymes should not be used alone to treat anemia, and it is important to check for possible interactions with prescribed medications before starting therapy.

●○● NURSING CARE

For nursing care specific to the patient with a nutritional anemia, see the accompanying Case Study & Nursing Care Plan.

Health Promotion

Nursing measures to prevent anemia focus on teaching good dietary habits to all patients, regardless of age. Stress the importance of consuming adequate amounts of iron, folate, and the B vitamins. Provide a list of dietary sources of these nutrients. Discuss alternate iron sources with vegetarian patients, and teach them that foods high in vitamin C enhance the absorption of iron from grains, legumes, and other sources. Emphasize the importance of adequate iron intake in women of childbearing age and older adults. Stress the increased need for these nutrients during pregnancy, and discuss strategies to ensure an adequate intake.

Assessment

See the Manifestations and Interprofessional Care sections for the assessment of the patient with anemia.

Assessment data to collect for patients with suspected anemia includes the following:

- *Health history:* complaints of shortness of breath with activity, fatigue, weakness, dizziness or fainting, palpitations; history of previous anemia, bleeding episodes; menstrual history (if appropriate); medications; chronic diseases; usual diet and patterns of alcohol intake or cigarette smoking
- *Physical assessment:* general appearance, skin color; vital signs including temperature; heart and lung sounds; peripheral pulses,

capillary refill; abdominal tenderness; obvious bleeding or bruising
- *Laboratory data:* CBC, hemoglobin and hematocrit; bone marrow studies; specialized tests (e.g., hemoglobin electrophoresis, Schilling test).

Priorities of Care

Collaborating with the interprofessional team to ensure adequate treatment of the underlying process while providing care that supports the physical and psychologic responses to the disorder is a priority of nursing care.

Diagnoses, Outcomes, and Interventions

Anemia affects circulating oxygen levels and tissue oxygenation. Priority nursing diagnoses include *Activity Intolerance*, *Altered Oral Mucous Membranes*, and *Self-Care Deficits*. With acute blood-loss anemia, risk for insufficient cardiac output also is a priority. Patients with sickle cell disease have specific needs related to the effects of the disease on tissue perfusion; see the section on disseminated intravascular coagulation (DIC) later in this chapter for nursing interventions appropriate to ineffective tissue perfusion, associated pain, and maintaining oxygenation.

Activity Intolerance

Anemia causes weakness and shortness of breath on exertion. These symptoms are due to decreased circulating oxygen levels secondary to low hemoglobin levels. Weakness, fatigue, and/or vertigo may occur even during activities of daily living (ADLs), including those associated with self-care, home life, job performance, and social roles.

Expected Outcome: Patient will participate in activity program without suffering any complications.

- Help identify ways to conserve energy when performing necessary or desired activities. *Modifying the approach to a particular activity may reduce cardiorespiratory symptoms and activity-related fatigue. Alternative ways of performing tasks (e.g., sitting when performing hygiene care and kitchen tasks) may reduce oxygen demands. In some cases, assistance from others is necessary to conserve energy and reduce symptoms.*
- Help the patient and family establish priorities for tasks and activities. *Because family members may need to assume responsibility for additional tasks, the plan's success depends on mutually established goals.*
- Assist to develop a schedule of alternating activity and rest periods throughout the day. *Rest periods decrease oxygen needs, reducing strain on the heart and lungs, and allowing restoration of homeostasis before further activities.*

Evidence for Nursing Care

The Patient with Iron-Deficiency Anemia

Selected resources that nurses may find helpful when planning evidence-based nursing care follow.

- Milman, N. (2012). Postpartum anemia II: Prevention and treatment. *Annals of Hematology, 91*(2), 143–154.
- Sabol, V. K., Resnick, B., Galik, E., Gruber-Baldini, A., Morton, P. G., & Hicks, G. E. (2010). Anemia and its impact on function in nursing home residents: What do we know? *Journal of the American Academy of Nurse Practitioners, 22*(1), 3–16.

- Encourage 8 to 10 hours of sleep at night. *Rest decreases oxygen demands and increases available energy for morning activities.*
- Monitor vital signs before and after activity. *Vital signs provide a measure of activity tolerance. Increased heart and respiratory rates or a change in blood pressure may indicate intolerance of the activity.*
- Discontinue activity if any of the following occurs:
  - Complaints of chest pain, breathlessness, or vertigo
  - Palpitations or tachycardia that does not return to normal within 4 minutes of resting
  - Bradycardia
  - Tachypnea or dyspnea
  - Decreased systolic blood pressure.*These changes may signify cardiac decompensation due to insufficient oxygenation. The intensity, duration, or frequency of the activity needs to be reduced.*
- Instruct the patient not to smoke. *Smoking causes vasoconstriction and increases carbon monoxide levels in the blood, interfering with tissue oxygenation.*

Impaired Oral Mucous Membrane

Glossitis and cheilosis may occur with nutritional deficiencies of iron, folate, and vitamin B_{12}. The tongue and lips become very red, and fissures or cracks may form at the corners of the mouth.

Expected Outcome: Patient will maintain intact, moist oral mucous membranes through use of measures to promote oral membrane health.

- Monitor condition of lips and tongue daily. *Glossitis and cheilosis increase the risk for bleeding and infection and may require medical treatment. Pain and discomfort may interfere with oral intake, further worsening the nutritional deficiency.*
- Use a mouthwash of saline, saltwater, or half-strength peroxide and water to rinse the mouth every 2 to 4 hours. Avoid alcohol-based mouthwashes. *This cleanses and soothes oral mucous membranes. Alcohol-based mouthwashes further irritate and dry oral tissues.*
- Provide frequent oral hygiene (after each meal and at bedtime) with a soft bristle toothbrush or sponge. *Removing food debris from painful fissures promotes comfort. A soft toothbrush reduces irritation or bleeding of oral mucosa. Keeping the oral cavity clean also reduces the risk of infection.*
- Apply a petroleum-based lubricating jelly or ointment to the lips after oral care. *Lubricating ointment helps to retain moisture, facilitate healing, and protect the lips from other drying agents.*
- Instruct to avoid hot, spicy, or acidic foods. *Such foods may further irritate and dry mucous membranes.*
- Encourage soft, cool, bland foods. *Foods that are soothing to the mucous membranes promote comfort and help maintain adequate food and fluid intake. Minimizing oral pain may also promote compliance with oral care routines.*
- Encourage eating four to six small meals daily with high protein and vitamin content. *Small, frequent meals may be better tolerated, increasing intake. Nutrient-rich meals promote healing of the mucous membranes.*

Risk for Decreased Cardiac Output

Cardiac output may be affected by acute bleeding and volume loss or by heart failure resulting from severe anemia. In addition, impaired tissue oxygenation leads to an increased respiratory rate and dyspnea.

Expected Outcome: Patient will demonstrate adequate cardiac output as evidenced by blood pressure and pulse rate being within normal parameters.

- Monitor vital signs, breath sounds, and apical pulse. *Increased cardiac workload can affect the blood pressure, heart, and respiratory rates. Increased blood flow can lead to heart murmur or abnormal heart sounds such as S_3 or S_4. Tachypnea and dyspnea may affect the depth of respirations, alveolar ventilation, and blood and tissue oxygenation.*
- Assess for pallor, cyanosis, and dependent edema. *Blood is shunted to the vital organs, causing vasoconstriction of skin vessels. This, in addition to lower levels of hemoglobin, causes pallor. Cyanosis, especially of the lips and nail beds, indicates inadequate oxygenation of blood. Dependent edema occurs in response to right ventricular failure.*

SAFETY ALERT

Report signs of decreased cardiac output to the healthcare provider. Severe anemia can lead to heart failure, necessitating additional treatment.

- Closely monitor for manifestations of anaphylaxis (urticaria, erythema or flushing, edema, wheezing, dyspnea, nausea and vomiting, anxiety) when administering parenteral iron preparations, particularly iron dextran. Immediately notify the healthcare provider, and prepare to administer prescribed drugs such as diphenhydramine (Benadryl) or epinephrine as ordered. Institute cardiopulmonary resuscitation measures as necessary. *Anaphylaxis, a systemic type I hypersensitivity (allergic) reaction, is a risk when administering parenteral iron preparations, iron dextran in particular. Anaphylaxis can lead to severe cardiopulmonary compromise, necessitating emergency measures to preserve life.*

Self-Care Deficit

Energy expenditures for ADLs may cause oxygen demands to exceed supply in the patient with severe anemia.

Expected Outcome: Patient will perform self-care activities to optimal potential.

- Assist with ADLs, such as bathing, grooming, and eating, as needed. *Assistance decreases energy expenditures and tissue requirements for oxygen, reducing cardiac workload.*
- Discuss the importance of rest periods prior to such activities as dressing. *Rest reduces oxygen demand and cardiac workload. The person who is able to perform self-care in ADLs maintains independence, self-esteem, and morale.*

Continuity of Care

With the exception of anemia resulting from acute hemorrhage, most patients with anemia are treated in the home and community setting. Include the following topics when preparing the patient and family for home care:

- Nutritional strategies to address deficiencies
- Prescribed medications, vitamins, or mineral supplements and their appropriate use, intended effect, possible adverse effects, and interactions with food or other medications
- Energy conservation strategies
- Other recommended treatment measures and follow-up
- If the anemia is genetically transmitted, such as sickle cell disease, include inheritance patterns of the disorder, symptoms of crisis, and manifestations to report to the healthcare provider.

Provide referrals for counseling to facilitate decisions about pregnancy as indicated. Also refer for nutritional assistance and teaching, home healthcare, or assistance with self-care and home maintenance activities as indicated. Older adults with nutritional anemias may benefit from community services such as senior meals or Meals-on-Wheels.

THE PATIENT WITH MYELODYSPLASTIC SYNDROME

Myelodysplastic syndrome (MDS) is a group of blood disorders characterized by abnormal-appearing bone marrow and cytopenia (low numbers of circulating blood cells). MDS is not a single disease; at least five variations of the disorder have been identified. Anemia that does not respond to treatment (*refractory anemia*) is a characteristic of most forms of myelodysplasia.

Idiopathic MDS primarily affects older adults; men have a slightly higher incidence of the disorder than women. Risk factors for secondary MDS include exposure to environmental toxins such as cigarette smoke, benzene and radiation, radiation therapy or chemotherapy for cancer treatment, and other anemias such as aplastic anemia or Fanconi's anemia (National Comprehensive Cancer Network [NCCN], 2013).

FAST FACTS

- Idiopathic or primary MDS accounts for 70% to 80% of all identified cases.
- MDS as a secondary condition related to factors such as smoking or exposure to environmental toxins, radiation, chemotherapy, or other risk factors accounts for 20% to 30% of cases.

Pathophysiology

MDS is a stem cell disorder in which stem cells fail to reproduce and differentiate into the various types of blood cells. The genetic components of stem cells (nuclear DNA and/or mitochondrial DNA) are altered. The bone marrow loses its ability to produce normal blood cells, instead producing abnormal (*dysplastic*) cells. With significant alterations, leukemia (proliferation of abnormal WBCs) may develop in people with MDS.

Manifestations

Anemia is the predominant early manifestation of MDS. The patient may develop symptoms of the anemia with increasing fatigue, weakness, dyspnea, and pallor. In many cases, the disorder is asymptomatic, identified when a routine blood count shows anemia. Splenomegaly may develop, leading to discomfort and a feeling of fullness in the LUQ of the abdomen. Hepatomegaly also may develop, leading to RUQ discomfort. Thrombocytopenia can lead to abnormal bleeding tendencies, and neutropenia increases the risk for infection (NCCN, 2013).

CASE STUDY & NURSING CARE PLAN A Patient with Folic Acid Deficiency Anemia

Sheri Matthews is a 76-year-old widow who lives alone. She tells Lisa Apana, RN, the nurse in her care provider's office, that she liked to cook when her husband was alive, but preparing an entire meal just for herself seems senseless. She relates that her typical day's menu includes coffee for breakfast; a bologna sandwich and coffee for lunch; and a hot dog or two, a few cookies, and a glass of milk for dinner.

ASSESSMENT

Mrs. Matthews's nursing history includes a 9-kg (20-lb) weight loss since her husband died 8 months ago. She states that she sometimes has heart palpitations and always feels weak. Physical assessment: T 37.1°C (98.8°F), P 110 bpm, R 22/min, and BP 90/52 mmHg. Skin warm, pale, and dry. Diagnostic tests indicate folic acid deficiency anemia, and Mrs. Matthews is started on an oral folic acid supplement and instructed about foods containing folic acid.

DIAGNOSES

- *Activity Intolerance* related to weakness secondary to decreased tissue oxygenation
- *Imbalanced Nutrition: Less Than Body Requirements* related to lack of motivation to cook and understanding of nutritional needs, as manifested by weight loss of 9 kg, and folic acid deficiency
- *Deficient Knowledge* related to lack of information about a well-balanced diet and foods containing folic acid

EXPECTED OUTCOMES

- Patient will verbalize the importance of taking folic acid supplements and eating a balanced diet.
- Patient will gain at least 0.45 kg (1 lb) per week.
- Patient will return to previous level of physical energy.
- Patient will consume a balanced diet, including foods containing folic acid.

PLANNING AND IMPLEMENTATION

- Discuss foods required for a well-balanced diet, as well as dietary sources of folic acid.
- Develop a dietary plan with Mrs. Matthews that includes food preferences and foods that are easy and quick to prepare.
- Discuss the importance of taking the folic acid supplement. Advise to continue taking it even after she begins to feel better.
- Help Mrs. Matthews develop a schedule of activities that provides adequate rest and energy for cooking.

EVALUATION

Mrs. Matthews gained 0.45 kg (1 lb) during the first week of treatment. She has met with a nutritionist and has a better understanding of nutritional needs. She states that she can prepare hot meals when she schedules a rest period before and after lunch. Ms. Apana has provided written and verbal information about the folic acid supplement and diet. Mrs. Matthews verbalizes understanding, stating, "I will continue to take the folic acid until the doctor tells me to stop. I'm beginning to enjoy cooking again, now that I have a reason to cook!" Ms. Apana contacts the local senior services representative to determine if Mrs. Matthews is able to participate in the local Meals-on-Wheels program.

Clinical Reasoning in Patient Care

1. What is the pathophysiologic basis for Mrs. Matthews's abnormal vital signs during her initial assessment?
2. Design a week's menu that includes foods high in folic acid.
3. Why was Mrs. Matthews placed on a folic acid supplement in addition to dietary modifications?
4. Why is the older adult at increased risk for developing folic acid deficiency anemia? Consider physiologic, economic, and social factors.

See Evaluating Your Response in Appendix B.

●○● INTERPROFESSIONAL CARE

Patients with MDS require long-term supportive care and therapy to maintain their quality of life. Stem cell transplant offers the only real hope for cure of MDS. See the leukemia section later in this chapter for more information about stem cell transplant and associated nursing care.

DIAGNOSIS

- The *CBC* reveals anemia. Although anemia may be the only abnormality of the blood count, the WBC count and the platelet count also may be low. Abnormalities of size and shape may be noted in all blood cells.
- The *bone marrow* often appears normal, although precursor cells may have an abnormal appearance. Increased numbers of myeloblasts (granulocyte precursor cells) may be present in the bone marrow.
- *Serum erythropoietin, vitamin B_{12}, serum iron, total iron-binding capacity, ferritin levels*, and *RBC folate levels* are drawn to help guide supportive therapy.

TREATMENT

Management of MDS is based on the severity of the disease. Several classification systems are available, including the French-American-British (FAB) classification system, the International Prognostic Scoring System (IPSS), and the World Health Organization (WHO) classification system (NCCN, 2013). These systems are used to guide therapy for the patient with MDS.

All patients with MDS require monitoring, with regular healthcare provider visits and laboratory evaluations. Psychosocial support is provided to assist the patient and family dealing with a chronic, progressive, and ultimately fatal disease.

Patients with MDS may require frequent RBC transfusions to treat the predominant anemia. Each unit of packed RBCs contains 250 to 300 mg of iron. The body is unable to excrete this excess iron, so it accumulates, leading to problems such as endocrine dysfunction, cirrhosis, pericarditis, and heart failure. *Iron chelation therapy* is used to remove excess iron from the body. Deferoxamine (Desferal) is administered by slow intravenous infusion or continuous subcutaneous infusion using an infusion pump to maintain a normal or negative iron balance. This drug is relatively safe, although local skin reactions such as rash and urticaria may develop. An oral form of the drug, deferasirox, is available, but not widely used.

Blood cell growth factors may be administered to stimulate stem cell development in MDS, although the response rate is low. Platelet transfusions are given when bleeding occurs due to low platelet levels. Antibiotic therapy is initiated for bacterial infections (NCCN, 2013). Chemotherapy regimens similar to those employed to treat leukemia may be used, but rarely are effective in treating MDS. Azacitidine (Vidaza), an antileukemic agent that acts on abnormal blood-forming cells in the bone marrow, may be more effective in treating MDS than

standard chemotherapy regimens. As previously noted, stem cell transplant offers the only hope for cure. This high-risk therapy, however, is reserved for higher-risk patients. Factors such as age, functional ability, and other existing disease conditions help guide the decision to undergo stem cell transplant (NCCN, 2013).

●○● NURSING CARE

See the Manifestations and Interprofessional Care sections for the assessment of the patient with myelodysplastic syndrome.

Priorities of Care

Collaborating with the interprofessional team to ensure adequate treatment of the underlying process while providing care that supports the physical and psychologic responses to the disorder is a priority of nursing care.

Diagnoses, Outcomes, and Interventions

Activity intolerance and the need for education about this disorder are the priorities of nursing care for the patient with MDS being managed in a community-based setting. Although neutropenia and thrombocytopenia may accompany the anemia of MDS, these problems are less common. See the section of this chapter on leukemia for additional potential nursing diagnoses and interventions for the patient with MDS.

Activity Intolerance

The patient with MDS experiences fatigue, weakness, and shortness of breath on exertion related to the lack of RBCs and ineffective oxygen transport. These symptoms may affect the patient's ability to maintain self-care, home life, job performance, and social roles.

Expected Outcome: Patient will participate in activity program without suffering any complications.

- Monitor vital signs, breath sounds, and apical pulse. *Increased cardiac workload due to anemia and impaired oxygen transport can affect the blood pressure, heart, and respiratory rates. Increased blood flow can lead to heart murmur or abnormal heart sounds such as S_3 or S_4. Accumulated iron can lead to pericarditis and a pericardial friction rub.*
- Help identify energy-conserving ways of performing necessary or desired activities. *Alternative ways of performing tasks (e.g., sitting while performing hygiene measures) may reduce oxygen demands and fatigue.*
- Help the patient and family establish priorities for tasks and activities. *Because family members may need to assume responsibility for additional tasks, the plan's success depends on mutually established goals.*
- Suggest planning recreational activities following a transfusion and adjusting activity level between transfusions to match energy and minimize fatigue. *The patient with MDS will have more energy and activity tolerance following a transfusion when RBC counts, hemoglobin, and hematocrit approach normal levels and oxygen transport is optimal.*
- Encourage 8 to 10 hours of sleep at night. *Rest decreases oxygen demands and increases available energy for morning activities.*
- Discontinue activity if any of the following occurs:
  - Complaints of chest pain, breathlessness, or vertigo
  - Palpitations or tachycardia that does not return to normal within 4 minutes of resting
  - Bradycardia
  - Tachypnea or dyspnea
  - Decreased systolic blood pressure.

  These changes may signify cardiac decompensation due to insufficient oxygenation. The intensity, duration, or frequency of the activity needs to be reduced.
- Instruct the patient not to smoke. *Smoking causes vasoconstriction and increases carbon monoxide levels in the blood, interfering with tissue oxygenation.*

Risk for Ineffective Health Maintenance

MDS is a chronic, usually progressive disorder, requiring active management to maintain functional status and quality of life. Regular visits to the healthcare provider or clinic may be necessary. In addition, the patient or family members may need to learn to administer iron chelation therapy or chemotherapy drugs and measures to prevent complications (NCCN, 2013). The chronic nature of the disorder and the often advanced age of the patient and family caregivers may interfere with effective management of the disorder.

Expected Outcome: Patient will be knowledgeable about management of MDS as evidenced by being able to describe the components and rationale for the treatment plan.

- Assess knowledge of disorder and the related treatments. *Assessment allows identification of knowledge gaps and provides a basis on which to provide additional information. Impaired disease management may be due to lack of knowledge or an inability to learn and perform psychomotor skills, for example, administration of parenteral drug therapy.*
- Provide information about the disorder, its effects, and prescribed medications and treatments. *Individualized instruction is more effective than general, possibly irrelevant information. The patient and caregivers need to be able to identify and manage possible adverse effects of drug therapy and to recognize potential complications to be reported to the healthcare provider.*
- Provide emotional support, expressing confidence in the patient's and caregivers' abilities to manage care. *Emotional support helps the patient and family caregivers incorporate the care regimen into their lifestyle.*
- Provide supervised learning and practice opportunities for administering parenteral medications if ordered. *Successful practice sessions instill confidence in the ability to manage care and provide an opportunity for questions and exploring alternatives.*

Continuity of Care

The patient with myelodysplastic syndrome needs information about this chronic and ultimately fatal disease. Provide information about treatment options, including management of the infusion pump if ordered. Discuss the timing of and options for stem cell transplant, and assist the patient to evaluate the potential benefits and risks of this treatment option.

THE PATIENT WITH POLYCYTHEMIA

Polycythemia, or *erythrocytosis*, is an excess of RBCs characterized by a hematocrit higher than 55%. The two major types of polycythemia are primary and secondary. A third type of polycythemia, relative polycythemia, results from a fluid volume deficit, not excess RBCs.

FAST FACTS

- *Primary polycythemia* (*polycythemia vera*) is uncommon.
  - In primary polycythemia, RBC production is increased.
  - Primary polycythemia more commonly affects men of European Jewish ancestry between the ages 40 and 70.
- *Secondary polycythemia* (*erythrocytosis*) is the most common form of polycythemia.
  - Secondary polycythemia occurs when erythropoietin levels are elevated.
  - It may affect patients of any age or origin.
  - It usually develops in response to hypoxia (living at a high altitude, smoking, or chronic lung disease).
- *Relative polycythemia* occurs due to fluid deficit, not excess RBCs.
  - In relative polycythemia the total RBC count is normal.
  - The hematocrit is elevated because of increased cell concentration.
  - It is corrected by rehydration.

Pathophysiology

PRIMARY POLYCYTHEMIA

Primary polycythemia, or polycythemia vera (PV), is a neoplastic stem cell disorder characterized by overproduction of RBCs and, to a lesser extent, WBCs and platelets. It is classified as a myeloproliferative disorder. Its cause is unknown. In PV, colonies of endogenous erythroid stem cells develop. These colonies produce RBCs in the absence of erythropoietin, leading to excess RBC production.

MANIFESTATIONS Initially, PV is asymptomatic, and the diagnosis may be made during routine blood tests. Its manifestations are caused by increased blood volume and viscosity. Hypertension is common, and may lead to complaints of headaches, dizziness, and vision and hearing disruptions. Venous stasis causes *plethora*, a ruddy, red color of the face, hands, feet, and mucous membranes. This often is accompanied by severe, painful itching of the fingers and toes. Retinal and cerebral vessels may be engorged. Hypermetabolism develops, causing weight loss and night sweats. Mental status may be altered, leading to drowsiness or delirium.

Thrombosis and hemorrhage are potential complications of PV. Thrombosis may cause transient ischemic attacks, angina, or manifestations of peripheral vascular disease. GI bleeding may occur, and portal hypertension may develop.

SECONDARY POLYCYTHEMIA

Secondary polycythemia, or erythrocytosis, is increased numbers of RBCs in response to excess erythropoietin secretion or prolonged hypoxia. Secondary polycythemia is the most common form of polycythemia.

Abnormally high erythropoietin levels can result from kidney disease or erythropoietin-secreting tumors (e.g., renal cell carcinoma). Chronic hypoxia that stimulates erythropoietin release is a more common cause of secondary polycythemia. People living at high altitudes where the atmospheric oxygen pressure is lower develop a degree of polycythemia, as do people with chronic heart or lung disease and smokers. Abnormal hemoglobin that forms tighter bonds with oxygen also may lead to secondary polycythemia.

MANIFESTATIONS The manifestations of secondary polycythemia are similar to those of primary polycythemia. Splenomegaly, however, does not develop. Early symptoms often are overshadowed by the manifestations of the underlying disorder. For the manifestations of polycythemia see the accompanying box.

MANIFESTATIONS OF POLYCYTHEMIA

- Hypertension
- Headache, tinnitus, blurred vision
- Plethora: dark redness of the lips, feet, ears, fingernails, and mucous membranes
- Splenomegaly (polycythemia vera)
- Severe pruritus, extremity pain
- Weight loss, night sweats
- GI bleeding
- Intermittent claudication
- Symptoms from thrombosis within various organs

●○● INTERPROFESSIONAL CARE

DIAGNOSIS

In PV, serum erythropoietin levels are low. Bone marrow studies show hyperplasia of all hematopoietic elements. With secondary polycythemia, serum erythropoietin levels usually are high, and bone marrow studies show only red stem cell hyperplasia.

TREATMENTS

For secondary polycythemia, treatment focuses on the underlying cause of the disorder. It is a physiologic response in people living at high altitudes, and unless the hematocrit is too high or oxygen saturation levels are low, no treatment is usually necessary. Smokers are urged to quit. Measures to raise oxygen saturation levels and reduce tissue hypoxia often will relieve the polycythemia. Patients with both primary and secondary polycythemia benefit from periodic phlebotomy (removing 300 to 500 mL of blood) to keep blood volume and viscosity within normal levels. For PV, chemotherapeutic agents such as hydroxyurea may be used to suppress marrow function but may increase the risk of developing leukemia (discussed later in this chapter). Pruritus may be relieved by antihistamines, or may require more aggressive treatment with interferon-α or other treatments. One 325-mg aspirin tablet daily may be ordered to control thrombosis without increasing the risk of bleeding.

●○● NURSING CARE

Preventing polycythemia begins with educating children and adults about the dangers of smoking. Measures to reduce risk factors for cardiovascular disease may be beneficial.

This chronic condition is managed in community-based settings unless a complication develops. Teach the patient and family the importance of maintaining adequate hydration, increasing fluid intake during hot weather and when exercising. Discuss measures to prevent blood stasis: elevating legs and feet when sitting, using support stockings, and continuing treatment measures. Instruct to report manifestations of thrombosis (leg or calf pain, chest pain, neurologic symptoms) or bleeding (black, tarry stools; vomiting blood or coffee-grounds emesis) immediately. Monitor the hematocrit and cell counts throughout treatment.

Examples of nursing diagnoses appropriate for the patient with polycythemia follow:

- *Decisional Conflict Regarding Smoking Cessation* related to addictive effects
- *Pain* related to effects of altered blood flow in distal extremities
- *Risk for Ineffective Tissue Perfusion* related to sluggish blood flow and increased risk for thrombosis

White Blood Cell and Lymphoid Tissue Disorders

Disorders of the WBCs and lymphoid tissue include the leukemias, malignant lymphomas (Hodgkin's disease and non-Hodgkin's lymphoma), multiple myeloma, neutropenia, and infectious mononucleosis. Review the physiology of white blood cells (WBCs) and their function in Chapter 12.

THE PATIENT WITH LEUKEMIA

Leukemia (literally, *white blood*) is a group of chronic malignant disorders of WBCs and WBC precursors. In leukemia, the usual ratio of red to white blood cells is reversed. Leukemias are characterized by replacement of bone marrow by malignant immature WBCs, abnormal immature circulating WBCs, and infiltration of these cells into the liver, spleen, and lymph nodes throughout the body.

Physiology Review

WBCs are the most diverse of the cellular components of the blood. They arise from three different precursor cells: myeloblasts, which further differentiate into the granular leukocytes (granulocytes), neutrophils, eosinophils, and basophils; monoblasts, which mature into circulating monocytes, and ultimately into macrophages; and lymphoblasts, which become lymphocytes and mature in lymphoid tissue to B cells and T cells.

As a whole, the primary function of WBCs is to help maintain the body's immune defenses. Neutrophils, the most numerous WBCs in circulation, are active phagocytes, the first cells to arrive at injured tissue. Monocytes and macrophages also are phagocytic cells that dispose of foreign and waste material from tissues. Eosinophils and basophils are more specialized. Eosinophils are primarily involved in allergic responses and parasitic infections. Basophils are actively involved in the inflammatory response, releasing substances such as histamine and heparin into inflamed tissues. Lymphocytes, the smallest of the WBCs, are an integral part of the immune system. B cells are part of the humoral immune response, producing antibodies to specific antigens. T cells are part of the cell-mediated immune response. For more information about the inflammatory and immune responses, refer to Chapter 13. The normal WBC count and differential are presented in Table 33–2.

TABLE 33–2 Normal White Blood Cell Count and Differential

Laboratory Test	Value
WBC count	5000–10,000/mm^3
Differential WBC count	
Neutrophils	60–70% or 3000–7000/mm^3
Eosinophils	1–3% or 50–400/mm^3
Basophils	0.3–0.5% or 25–200/mm^3
Lymphocytes	20–30% or 1000–4000/mm^3
Monocytes	3–8% or 100–600/mm^3

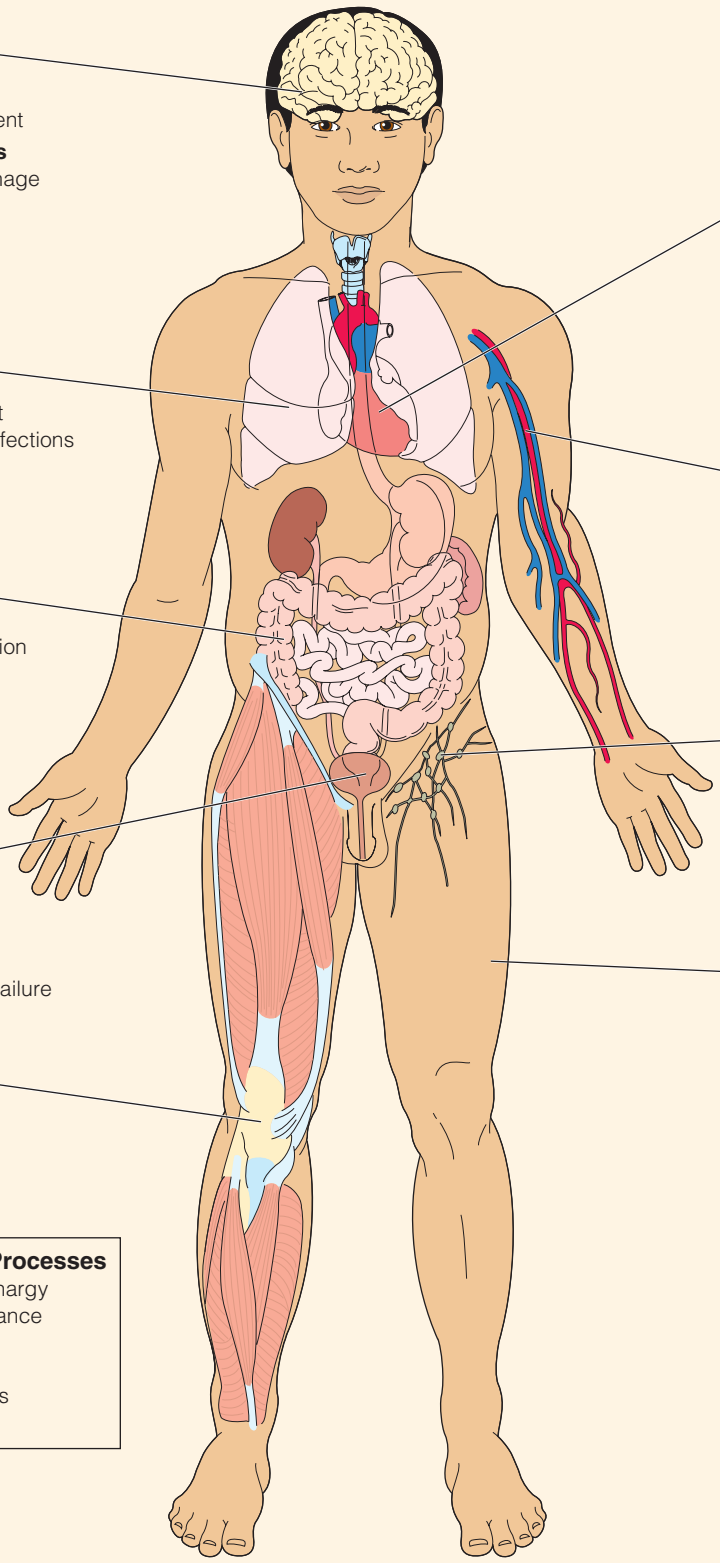
Pathophysiology

Leukemia begins with malignant transformation of a single stem cell. Leukemic cells proliferate slowly, but do not differentiate normally. They have a prolonged life span and accumulate in the bone marrow. As they accumulate, they compete with the proliferation of normal cells. Leukemic cells do not function as mature WBCs, and are ineffective in the inflammatory and immune processes. Leukemic cells replace normal hematopoietic elements in the marrow. Because erythrocyte- and platelet-producing cells are crowded out, severe anemia, splenomegaly, and bleeding difficulties result.

Leukemic cells leave the bone marrow and travel through the circulatory system, infiltrating other body tissues such as the CNS, testes, skin, GI tract, and the lymph nodes, liver, and spleen. Death usually is due to internal hemorrhage and infections.

Manifestations

The general manifestations of leukemia (regardless of type) result from anemia, infection, and bleeding. These include pallor, fatigue, tachycardia, malaise, lethargy, and dyspnea on exertion. Infection may cause fever, night sweats, oral ulcerations, and frequent or recurrent respiratory, urinary, integumentary, or other infections. Increased bleeding due to thrombocytopenia leads to bruising, petechiae, bleeding gums, and bleeding within specific organs and tissues. See the Multisystem Effects of Leukemia feature on page 1031.



Other manifestations result from leukemic cell infiltration, increased metabolism, and increased leukocyte destruction. Infiltration of the liver, spleen, lymph nodes, and bone marrow causes pain and tissue swelling in the involved areas. Meningeal infiltration may cause manifestations of increased intracranial pressure, such as headache, altered level of consciousness, cranial nerve impairment, and nausea and vomiting. Infiltration of the kidneys may affect renal function, wi th decreased urine output and increased blood urea nitrogen and creatinine. Increased metabolism causes heat intolerance, weight loss, dyspnea on exertion, and tachycardia. Destruction of large numbers of WBCs releases substantial amounts of uric acid into the circulation; uric acid crystals may obstruct renal tubules, causing renal insufficiency.

Without treatment, leukemia is invariably fatal, usually due to complications of leukemic cell infiltration of bone marrow or vital organs. With treatment, prognosis varies. The overall 5-year survival rate is just over 50%. Survival rates differ by type of leukemia: People with acute myeloid leukemia have a 25% 3-year survival rate, whereas the rate is 76% for people with chronic lymphocytic leukemia (American Cancer Society [ACS], 2012; National Cancer Institute, 2012). The types, pathology, manifestations, and treatment for the major leukemias are outlined in Table 33–3.

Incidence and Risk Factors

Although leukemia is often thought of as a childhood disease, it is diagnosed 10 times more often in adults than in children. An estimated

MULTISYSTEM EFFECTS OF Leukemia

Neurologic
- Headache
- Altered LOC
- Cranial nerve impairment

Potential complications
- Subarachnoid hemorrhage
- Retinal hemorrhage
- Seizures, coma

Respiratory
- Dyspnea on exertion
- Pharyngitis, sore throat
- Frequent respiratory infections

Potential complication
- Pulmonary bleeding

Gastrointestinal
- Anorexia, nausea
- Oral ulcerations, infection
- Bleeding gums
- Gingival hyperplasia (gum overgrowth)
- Abdominal pain
- Hepatomegaly
- Occult GI bleeding

Urinary
- Urinary tract infection
- Hematuria

Potential complication
- Renal insufficiency or failure

Musculoskeletal
- Weakness
- Bone tenderness, pain
- Joint pain

Metabolic Processes
- Malaise, lethargy
- Heat intolerance
- Diaphoresis
- Chills, fever
- Night sweats
- Weight loss

Cardiovascular
- Tachycardia, palpitations
- Orthostatic hypotension
- Heart murmurs
- Hematomas
- Edema

Potential complications
- Hemorrhage
- Thrombophlebitis

Hematologic
- Anemia
- Thrombocytopenia
- Leukopenia
- Bleeding (epistaxis)
- Splenomegaly

Potential complication
- DIC

Immunologic
- Frequent or recurrent infections
- Lymphadenopathy

Potential complications
- Abscesses
- Septicemia

Integumentary
- Skin and mucous membrane pallor
- Petechiae
- Bruising, purpura
- Ulcerations
- *Chloromas* (skin infiltrations near bony prominences)

TABLE 33–3 Major Types of Leukemia

Classification	Characteristics	Manifestations	Treatment
Acute lymphoblastic leukemia (ALL)	Primarily affects children and young adults; leukemic cells may infiltrate CNS	Recurrent infections; bleeding; pallor, bone pain, weight loss, sore throat, fatigue, night sweats, weakness	Chemotherapy; bone marrow transplant (BMT), or stem cell transplant (SCT)
Chronic lymphocytic leukemia (CLL)	Primarily affects older adults; insidious onset and slow, chronic course	Fatigue; exercise intolerance; lymphadenopathy and splenomegaly; recurrent infections, pallor, edema, thrombophlebitis	Often requires no treatment; chemotherapy; BMT
Acute myeloid leukemia (AML)	Common in older adults, may affect children and young adults. Strongly associated with toxins, genetic disorders, and treatment of other cancers	Fatigue, weakness, fever; anemia; headache; bone and joint pain; abnormal bleeding and bruising; recurrent infection; lymphadenopathy, splenomegaly, and hepatomegaly	Chemotherapy; SCT
Chronic myeloid leukemia (CML)	Primarily affects adults; early course slow and stable, progressing to aggressive phase in 3–4 years	Early: weakness, fatigue, dyspnea on exertion; possible splenomegaly Later: fever, weight loss, night sweats	Interferon-α; chemotherapy with imatinib mesylate (Gleevec), SCT

48,000 new cases of leukemia occur annually; slightly more than half are acute leukemia and less than half are chronic leukemia. In 2008, the American Cancer Society (2012) estimated that 47,150 people were diagnosed with leukemia and 23,540 people died of leukemia. The highest incidence of leukemia is found in the United States, Canada, Sweden, and New Zealand (Huether & McCance, 2011).

Although the cause of most leukemias is unknown, certain risk factors have been identified. Men are affected more frequently than are women. People with certain genetic disorders such as Down syndrome have a higher incidence of leukemia. Environmental risk factors play a role as well. Risk factors for myeloid leukemia include cigarette smoking and chemicals such as benzene (present in cigarette smoke and gasoline). Exposure to ionizing radiation increases the risk for several types of leukemia. Patients who have undergone treatment for cancer have an increased risk. The human T-cell leukemia/lymphoma virus-1, a retrovirus, is known to cause certain leukemias and lymphomas (ACS, 2012).

Classifications

Leukemias are classified by their acuity and by the predominant cell type involved. The *acute* leukemias are characterized by an acute onset, rapid disease progression, and immature or undifferentiated blast cells. *Chronic* leukemias, on the other hand, have a gradual onset, prolonged course, and abnormal mature-appearing cells. *Lymphocytic* (or *lymphoblastic*) leukemias involve immature lymphocytes and their precursor cells in the bone marrow. Lymphocytic leukemias infiltrate the spleen, lymph nodes, CNS, and other tissues. *Myeloid* (also called *myelogenous*,*myelocytic*, or *myeloblastic*) leukemias involve myeloid stem cells in the bone marrow, interfering with the maturation of all types of blood cells, including granulocytes, RBCs, and thrombocytes (Huether & McCance, 2011). Acute lymphoblastic leukemia is the most common type of leukemia in children. In adults, acute myeloid leukemia and chronic lymphocytic leukemia are the most common types (Huether & McCance, 2011). In summary, the general types of leukemia are as follows:

- Acute lymphocytic (lymphoblastic) leukemia (ALL)
- Chronic lymphocytic leukemia (CLL)
- Acute myeloid (myeloblastic) leukemia (AML)
- Chronic myeloid (myelogenous) leukemia (CML).

This general system of classifying leukemias does not differentiate subtypes of acute leukemias. The FAB system for classifying acute leukemias further differentiates acute leukemias by the predominant cell involved and the degree of cell differentiation (Table 33–4).

TABLE 33–4 FAB Classification of Acute Leukemia

Type	Class	Predominant Cells	Prognosis
Acute lymphocytic leukemia (ALL)	L_1	Immature lymphoblasts	> 90% remission rate in children
	L_2	Mature lymphoblasts	Relapse common after 2 or more years of remission
Acute myeloid leukemia	M_0	Undifferentiated cells	Poor
	M_1	Immature myeloblasts	Good; complete response in 65% or more
	M_2	Mature myeloblasts	Good for 2 or more years of remission
	M_3	Promyelocytes	Good in adults
	M_4	Myelocytes and monocytes	Poorest in adults
	M_5	Poorly or well-differentiated monocytes	Poor
	M_6	Predominant erythroblasts	Variable
	M_7	Megakaryocytes	

ACUTE MYELOID LEUKEMIA

Acute myeloid leukemia (AML) is characterized by uncontrolled proliferation of myeloblasts (the precursors of granulocytes) and hyperplasia of the bone marrow and spleen (Figure 33–5 ■). AML accounts for 80% of acute leukemia cases in adults. Treatment induces complete remission in 66% of patients, although only about 30% to 40% achieve cure or long-term remission (ACS, 2012; Huether & McCance, 2011).

The manifestations of AML result from neutropenia and thrombocytopenia. Decreased neutrophils lead to recurrent severe infections, such as pneumonia, septicemia, abscesses, and mucous membrane ulceration. The manifestations of thrombocytopenia include petechiae, purpura, ecchymoses (bruising), epistaxis (nosebleeds), hematomas, hematuria, and GI bleeding. Bone infarctions or subperiosteal infiltrates of leukemic cells may cause bone pain. Anemia is a late manifestation, causing fatigue, headaches, pallor, and dyspnea on exertion. Death usually results from infection or hemorrhage.

Bone marrow aspiration shows a proliferation of immature WBCs. The CBC shows thrombocytopenia and normocytic, normochromic anemia.

CHRONIC MYELOID LEUKEMIA

Chronic myeloid leukemia (CML) is characterized by abnormal proliferation of all bone marrow elements. This type of leukemia constitutes approximately 15% of adult leukemias. It affects men more frequently than women. The onset of CML typically is between ages 30 or 40 and 50, although it is seen in children and adolescents as well (Huether & McCance, 2011).

CML is usually associated with a chromosome abnormality called the Philadelphia chromosome, a balanced translocation of chromosome 22 to chromosome 9 (Figure 33–6 ■). The fusion gene produced by this translocation, known as *bcr/abl*, is an *oncogene* capable of initiating a malignancy. Very large doses of ionizing radiation also may induce CML in some patients.

People with CML are often asymptomatic in the early stages and, in fact, are often diagnosed when a routine blood test reveals abnormal cell counts. Anemia causes weakness, fatigue, and dyspnea on exertion. The spleen often is enlarged, causing abdominal discomfort. Within 3 to 4 years, disease progresses to a more aggressive phase. Rapid cell proliferation and hypermetabolism cause fatigue, weight loss, sweating, and heat intolerance. The spleen enlarges, leading to a sensation of abdominal fullness and discomfort. Platelet function is affected in this stage, leading to bleeding and increased bruising. Finally, the disease evolves to acute leukemia, with blast cell proliferation. This stage, known as the *terminal blast crisis phase*, is characterized by significant constitutional manifestations, splenomegaly, and infiltration of leukemic cells into the skin, lymph nodes, bones, and CNS (Huether & McCance, 2011). Survival following the onset of this final stage averages only 2 to 4 months.

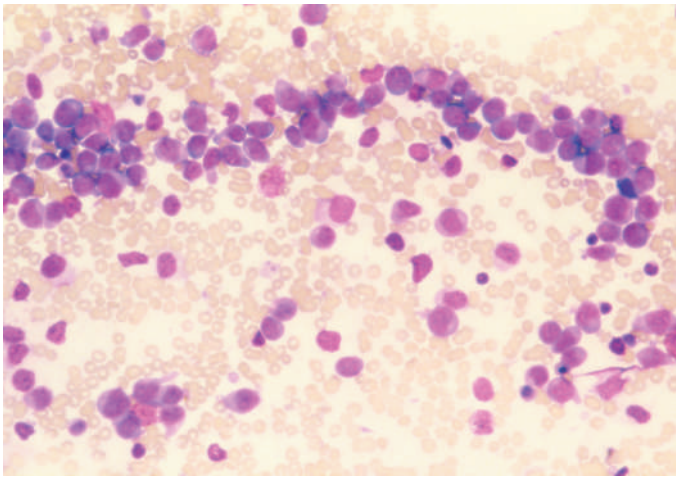


Figure 33–5 ■ A blood smear from the bone marrow of a patient with acute myeloid leukemia. Note the abnormally large number of myelocyte WBCs (stained purple) among the small RBCs.

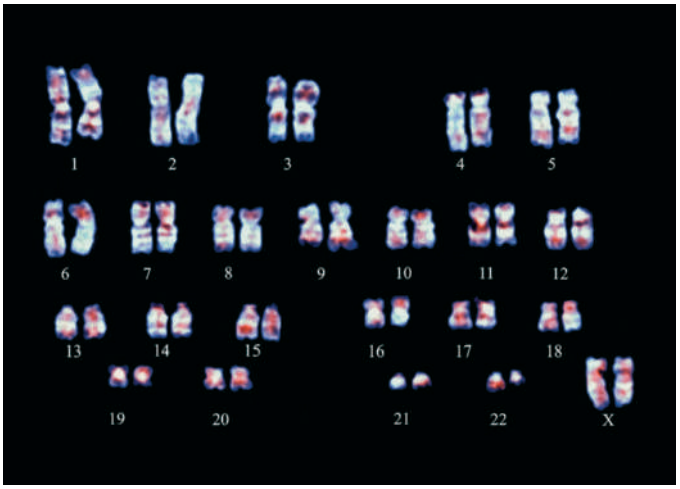

Figure 33–6 ■ The Philadelphia chromosome. Note the chromosomes of pairs 9 and 22. In each instance, the left-hand chromosome of the pair is normal, whereas an exchange of material between chromosomes has made the right-hand chromosome 9 larger and the right-hand chromosome 22 smaller. In stem cells within the bone marrow, the chromosome 22 defect leads to chronic myeloid leukemia.

ACUTE LYMPHOCYTIC LEUKEMIA

Acute lymphocytic leukemia (ALL) is the most common type of leukemia in children and young adults. In adults, ALL is rarely seen until late middle age, and then its incidence increases with aging. Genetic factors may play a role in its development, particularly the *bcr/abl* translocation also implicated in CML.

Most (80%) cases of ALL result from malignant transformation of B cells, with the remaining 20% arising from T cells. The malignant cells resemble immature lymphocytes (*lymphoblasts*); however, they do not mature or function effectively to maintain immunity. These lymphoblasts accumulate in the bone marrow, lymph nodes, and spleen, as well as in circulating blood. Some types of lymphoma are thought to represent a later stage of the same disease.

The onset of ALL is usually rapid. Lymphoblasts proliferating in bone marrow and peripheral tissues crowd the growth of normal cells (Figure 33–7 ■). Normal hematopoiesis is suppressed, leading to thrombocytopenia, leukopenia, and anemia. Manifestations of infections, bleeding, and anemia develop. Bone pain resulting from rapid generation of marrow elements, lymphadenopathy, and liver enlargement are also common. Infiltration of the CNS causes headaches, visual disturbances, vomiting, and seizures.

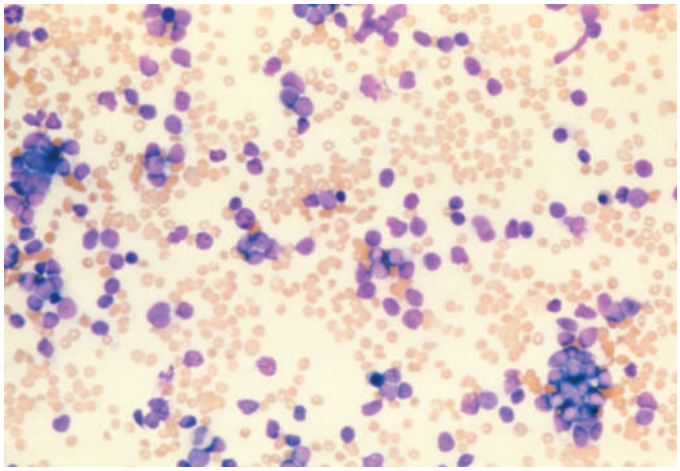

Figure 33–7 ■ A blood smear from the bone marrow of a patient with acute lymphocytic leukemia. Note the abnormally large number of lymphocytes (stained purple) crowding the bone marrow. As a result, normal production of RBCs, functional WBCs, and platelets is suppressed.

The CBC shows an elevated WBC count with increased lymphocytes on the differential. RBC and platelet counts are decreased. Bone marrow studies reveal a hypercellular marrow with growth of lymphoblasts. Combination chemotherapy produces complete remission in 80% to 90% of adults with ALL.

CHRONIC LYMPHOCYTIC LEUKEMIA

Chronic lymphocytic leukemia (CLL) is characterized by proliferation and accumulation of small, abnormal, mature lymphocytes in the bone marrow, peripheral blood, and body tissues. The abnormal cells are usually B lymphocytes that are unable to produce adequate antibodies to maintain normal immune function. Only about 5% of CLL involves T cells. CLL occurs more commonly in adults, especially in older adults (median age 65). CLL is the least common type of the major leukemias.

CLL has a slow onset and is often diagnosed during a routine physical examination. If symptoms are present, they usually include vague complaints of weakness or malaise. Possible clinical findings include anemia, infection, and enlarged lymph nodes, spleen, and liver. As in other leukemias, bone marrow hyperplasia is present. Erythrocyte and platelet counts are reduced. Leukocyte counts may either be elevated or reduced, but abnormal cells are always present. In CLL, years may elapse before treatment is required. Survival of this disease averages approximately 7 years.

●○● INTERPROFESSIONAL CARE

Treatment for leukemia focuses on achieving remission or cure and relieving symptoms. The methods of treatment may include chemotherapy, radiation therapy, and bone marrow or stem cell transplantation. Cure is more often achieved in children with acute leukemia than in adults, although long-term remissions (disease-free periods with no signs or symptoms) often can be achieved.

DIAGNOSIS

The following diagnostic tests are ordered when leukemia is suspected:

- *CBC* with differential is done to evaluate cell counts, hemoglobin and hematocrit levels, and the number, distribution, and morphology (size and shape) of WBCs.
- Platelets are measured to identify possible thrombocytopenia secondary to the leukemia and the risk of bleeding.
- Bone marrow examination provides information about cells within the marrow, the type of erythropoiesis, and the maturity of erythropoietic and leukopoietic cells.

Table 33–5 outlines usual diagnostic test results in the various forms of leukemia.

CHEMOTHERAPY

Single agent or combination chemotherapy is the treatment of choice for most types of leukemia, with the goal of eradicating leukemic cells

TABLE 33–5 Diagnostic Findings by Type of Leukemia

Test	AML	CML	ALL	CLL
RBC count	Low	Low	Low	Low
Hemoglobin	Low	Low	Low	Low
Hematocrit	Low	Low	Low	Low
Platelet count	Very low	High early, low late	Low	Low
WBC count	Varies	Increased	Varies	Increased
Myeloblasts	Present			
Neutrophils	Decreased	Increased	Decreased	
Lymphocytes		Normal		Normal
Monocytes		Normal/low		Increased
Blasts	Present	Present (crisis)	Present	
Bone marrow	Hypercellular		Hypercellular	
Myeloblasts	Present			
Lymphoblasts			Present	
Lymphocytes				Present

TABLE 33–6 Chemotherapeutic Regimens Used to Treat Leukemia

Acute myeloid leukemia	• Cytarabine (Cytoxan, an alkylating agent), *with* daunorubicin (Cerubidine, an antitumor antibiotic) or idarubicin (Idamycin, an antitumor antibiotic) • All-*trans* retinoic acid (ATRA) added for patients with promyelocytic leukemia
Chronic myeloid leukemia	• Imatinib mesylate (Gleevec), a *bcr/abl* tyrosine kinase (enzyme) inhibitor • Hydroxyurea (a DNA inhibitor) *or* homoharringtonine (HHT, a plant alkaloid) if imatinib not tolerated
Acute lymphocytic leukemia	• Daunorubicin (Cerubidine, an antitumor antibiotic) *with* vincristine (Oncovin, a plant alkaloid) *with* prednisone with asparaginase (Elspar)
Chronic lymphocytic leukemia	• Fludarabine (Fludara, an antimetabolite) *or* chlorambucil (Chloromycetin, an antitumor antibiotic) • Cyclophosphamide (Cytoxan, an alkylating agent), vincristine, and prednisone • Cyclophosphamide, doxorubicin (Adriamycin, an antitumor antibiotic), vincristine, and prednisone

and producing remission. Table 33–6 outlines typical chemotherapy regimens for different types of leukemia. Combination chemotherapy reduces drug resistance and toxicity, and interrupts cell growth at various stages of the cell cycle, producing a complementary effect of the drugs used. Cancer treatment with chemotherapy is discussed in detail in Chapter 14.

Chemotherapy for leukemia generally is divided into the induction phase and postremission therapy. During induction, drug doses are high to eradicate leukemic cells from the bone marrow. These high doses often also damage stem cells and interfere with production of normal blood cells. Circulating mature blood cells are not affected because they are no longer dividing. The degree of bone marrow suppression is influenced by a number of factors, including age, nutritional status, concurrent chronic diseases such as impaired liver or renal function, the drug and drug dose, and prior treatment.

Colony-stimulating factors (CSFs), also called hematopoietic growth factors, often are administered to "rescue" the bone marrow following induction chemotherapy. CSFs are cytokines that regulate the growth and differentiation of blood cells. Factors that support neutrophil maturation, *granulocyte-macrophage CSF (GM-CSF)* and *granulocyte CSF (G-CSF)*, are commonly used. Bone pain is a common side effect of therapy with these agents. Patients also may experience fevers, chills, anorexia, muscle aches, and lethargy (Vallerand & Sanoski, 2012).

Once remission has been achieved, postremission chemotherapy is continued to eradicate any additional leukemic cells, prevent relapse, and prolong survival. A single chemotherapeutic agent, combination therapy, or bone marrow transplant may be used for postremission treatment.

RADIATION THERAPY

Radiation therapy damages cellular DNA. While the cell continues to function, it cannot divide and multiply. Cells that divide rapidly, such as bone marrow and cancer cells (radiosensitive cells), respond quickly to radiation therapy. Although normal cells are affected, they are better able to recover from the damage caused by the radiation than are cancer cells. The types of delivery, effects, and toxicities of radiation are discussed in greater detail in Chapter 14.

BONE MARROW TRANSPLANT

Bone marrow transplant (BMT) is the treatment of choice for some types of leukemia. BMT often is used in conjunction with or following chemotherapy or radiation. There are two major categories of BMT: In allogeneic BMT, the bone marrow of a healthy donor is infused into the patient with the illness; in autologous BMT, the patient is infused with his or her own bone marrow.

ALLOGENEIC BMT *Allogeneic BMT* uses bone marrow cells from a donor (often from a sibling with closely matched tissue antigens; closely matched unrelated donors also may be used). Prior to allogeneic BMT, high doses of chemotherapy and/or total body irradiation are used to destroy leukemic cells in the bone marrow. The donor's bone marrow is aspirated (Figure 33–8 ■) and infused through a central venous line into the recipient. Prior to BMT and reestablishment of bone marrow function, the patient is critically ill and at significant risk for infection and bleeding due to depletion of WBCs and platelets.

AUTOLOGOUS BMT *Autologous BMT* uses the patient's own bone marrow to restore bone marrow function after chemotherapy or radiation. This procedure is often called *bone marrow rescue*. In autologous BMT, about 1 L of bone marrow is aspirated (usually from the iliac crests) during a period of disease remission. The bone marrow is then frozen and stored for use after treatment. If relapse occurs, lethal doses of chemotherapy or radiation are given to destroy the immune system and malignant cells, and to prepare space in

Figure 33–8 ■ Allogeneic bone marrow transplant. Bone marrow from the donor is aspirated, then filtered and infused into the recipient.

the bone marrow for new cells. The filtered bone marrow is then thawed and infused intravenously through a central line. The infused marrow cells slowly become a part of the patient's bone marrow, the neutrophil count increases, and normal hematopoiesis takes place.

As in allogeneic BMT, the patient is critically ill during the period of bone marrow destruction and immunosuppression. The patient is hospitalized in a private room for 6 to 8 weeks or more. Potential complications include malnutrition, infection, and bleeding.

STEM CELL TRANSPLANT

Allogeneic **stem cell transplant (SCT)** is an alternative to bone marrow transplant. SCT results in complete and sustained replacement of the recipient's blood cell lines (WBCs, RBCs, and platelets) with cells derived from the donor stem cells.

Donors must have tissue that is closely matched with that of the recipient. Prior to harvesting, hematopoietic growth factors, including G-CSF and GM-CSF, are administered to the donor for 4 to 5 days. This increases the concentration of stem cells in peripheral blood, allowing it to be used for the transplant instead of bone marrow. Peripheral blood is removed and white cells are separated from the plasma, then administered via a large central venous catheter. Large concentrations of stem cells also are present in umbilical cord blood. This may be stored and used in some cases.

The recipient undergoes similar treatment prior to SCT as for BMT. The risks for infection and other complications, as well as graft-versus-host disease, are similar.

GRAFT-VERSUS-HOST DISEASE Allogeneic BMT or SCT may precipitate *graft-versus-host disease (GVHD)*, which develops in up to 60% of all patients receiving an allogeneic BMT or SCT. In GVHD, immune cells of the donated bone marrow identify the recipient's body tissue as foreign. Consequently, T lymphocytes in the donated marrow attack the liver, skin, and GI tract, causing skin rashes progressing to desquamation (loss of skin), diarrhea, GI bleeding, and liver damage. *Acute GVHD* develops within days or weeks of the transplant and is usually marked by a pruritic, maculopapular rash that begins on the palms and soles of the feet, and may extend over the entire body. Vaso-occlusive disease of the liver affects up to 25% of allogeneic bone marrow transplant recipients, with jaundice and elevated liver function tests (Huether & McCance, 2011). *Chronic GVHD* develops later, 100 or more days after the transplant, affecting 20% to 50% of patients who survive 6 months or more following allogeneic BMT or SCT. It may follow acute GVHD or develop in patients with no prior symptoms. GVHD is treated with antibiotics and steroids; immunosuppressant drugs such as thalidomide and immunotoxin (XomaZyme) may be used if necessary.

BIOLOGIC THERAPY

Cytokines such as interferons and interleukins are biologic agents that may be used to treat some leukemias. These agents modify the body's response to cancer cells; in some cases they are cytotoxic as well. Interferons are a complex group of messenger proteins normally produced in response to antigens such as viruses (refer to Chapter 12). They have multiple effects, including moderating immune function and inhibiting abnormal cell proliferation and growth. Interferon-α may be used to treat some leukemias, particularly CML. Side effects commonly associated with interferon therapy include flu-like symptoms, persistent fatigue and lethargy, weight loss, and muscle and joint pain.

COMPLEMENTARY THERAPIES

Although many complementary and alternative medicine therapies have been purported to treat cancer in general, at this time none have been shown to provide sustained benefit in treating leukemia. Clinical trials have demonstrated the efficacy of both coping skills training (relaxation and imagery) and hypnosis to significantly reduce the oral discomfort associated with leukemia and its treatment.

●○● NURSING CARE

For nursing care specific to the patient undergoing diagnostic testing for leukemia, see the accompanying Case Study & Nursing Care Plan.

Health Promotion

Health promotion activities related to leukemia include teaching about leukemia risk factors, particularly those that can be controlled. Discuss the potential dangers of exposure to ionizing radiation and certain chemicals such as benzene. Encourage all patients to avoid smoking cigarettes. Discuss genetic counseling with patients at high risk for having a child with Down syndrome (over age 35).

Assessment

See the Manifestations and Interprofessional Care sections for the assessment of the patient with leukemia.

Focused assessment data related to leukemia includes the following:

- *Health history:* complaints of fatigue, weakness, dyspnea on exertion, frequent infections, sore throat, night sweats, bleeding gums, or nosebleeds; recent weight loss; exposure to ionizing radiation (multiple x-rays, residence near a site of radiation or atomic testing) or chemicals (occupational); prior treatment for cancer; history of an immune disorder
- *Physical assessment:* skin and mucous membranes for bruising, purpura, petechiae, ulcers or lesions; pallor; vital signs including orthostatic vitals; heart and lung sounds; abdominal examination; stool for occult blood
- *Laboratory data:* blood count with differential; bone marrow studies.

Priorities of Care

Collaborating with the interprofessional team to ensure adequate treatment of the underlying process while providing care that supports the physical and psychologic responses to the disorder is a priority of nursing care.

Diagnoses, Outcomes, and Interventions

When caring for the patient with leukemia, the nurse considers the chronic and life-threatening nature of the disease as well as the effects of treatment. See the accompanying Moving Evidence into Action box. Priority nursing problems may include *Risk for Infection*, *Imbalanced Nutrition*, *Impaired Oral Mucous Membranes*, *Impaired Protection (Bleeding)*, and *Grieving*.

Risk for Infection

Changes in WBC function impair the immune and inflammatory responses in leukemia, increasing the risk for infection. WBCs may be

Moving Evidence into Action

Patients with Acute or Chronic Leukemia: Outpatient Management with Clofarabine

Patients with acute or chronic leukemia are more frequently being managed in the outpatient setting for subsequent administration of chemotherapy. One such drug is clofarabine, a second-generation purine nucleoside analog. Although most patients receive the first dose while hospitalized, many receive subsequent courses in the outpatient setting provided adequate monitoring and support are available. According to Dressel and colleagues (2011), proactive nursing and collaborative care can reduce side effects such as GI-related symptoms, myelosuppression, hepatotoxicity, renal dysfunction or anorexia. An evidence table of Phase II clinical trials of clofarabine monotherapy or combination therapy provides the external evidence supporting the chemotherapeutic agent's use. The authors go on to describe general warnings and precautions for clofarabine administration as well as recommended actions with specific toxicities.

Implications for Nursing

This clinical review article describes the evidence basis for the use of clofarabine, taking the information a step further to provide specific information for the oncology nurse who may encounter use of this novel chemotherapy for leukemia in the outpatient setting. Nurses are often the first line of defense in the early detection and management of symptoms and drug side effects.

Moving Knowledge into Action

1. Describe the evidence supporting the use of clofarabine in adults with hematologic malignancies.
2. Patients undergoing treatment for leukemia, malignant lymphoma, and other cancers may have few outward manifestations of their disease or responses to treatment. Discuss how this apparent well-being may affect nurses' perception of care needs.
3. Develop a nursing care plan for a patient with acute leukemia to address the nursing diagnosis of *Ineffective Sexuality Pattern* related to fatigue and lack of energy.

Evidence for Nursing Care

The Patient with Bone Marrow Transplant

Selected resources that nurses may find helpful when planning evidence-based nursing care follow.

- Chow, K., & Coyle, N. (2011). Providing palliative care to family caregivers throughout the bone marrow transplantation trajectory. *Journal of Hospice & Palliative Nursing, 13*(1), 7–15.
- Cooke, L. D., Gemmill, R., & Grant, M. L. (2011). Creating a palliative educational session for hematopoietic stem cell transplant recipients at relapse. *Clinical Journal of Oncology Nursing, 15*(4), 411–417.
- Lindberg, D. (2012). What ongoing surveillance do you provide for patients post-transplant? *ONS Connect, 27*(11), 15.

immature and ineffective or, in some cases, deficient. Chemotherapy or radiation therapy further depresses bone marrow function and increases the risk for infection.

Expected Outcome: Patient will describe measures to protect healthy tissue and prevent infection.

- Promptly report manifestations of infection: fever, chills, throat pain, cough, chest pain, burning on urination, purulent drainage, and itching and burning in vaginal or rectal areas. *Prompt reporting allows timely intervention to prevent overwhelming infection and sepsis.*
- Institute infection protection measures.
  - Maintain protective isolation as indicated.
  - Ensure meticulous hand hygiene among all people in contact with the patient.
  - Assist as needed with appropriate hygiene measures.
  - Restrict visitors with colds, flu, or infections.
  - Provide oral hygiene after every meal.
  - Avoid invasive procedures when possible, including injections, intravenous catheters, catheterizations, and rectal and vaginal procedures. When necessary, use strict aseptic technique for all invasive procedures and monitor carefully for infection.

  These precautions minimize exposure to bacterial, viral, and fungal pathogens. Infection is the major cause of death in patients with leukemia. Mucous membranes are especially susceptible to breakdown and infection as a result of tissue damage from chemotherapy or radiation.
- Monitor vital signs including temperature and oxygen saturation every 4 hours. Report temperature spikes with chilling, tachypnea, tachycardia, restlessness, change in PaO_2, and hypotension. *The inflammatory response may be impaired in leukemia, masking signs of infection until sepsis develops, indicated by manifestations such as those listed.*
- Monitor neutrophil levels (measured in cubic millimeters) for relative risk for infection:
  2000 to 2500: no risk
  1000 to 2000: minimal risk
  500 to 1000: moderate risk
  Below 500: severe risk.
  Neutrophils are the first line of defense against infection. As levels decrease, the risk for infection increases.
- Explain infection precautions and restrictions and their rationale; explain that these measures are usually temporary. *Patient and family understanding increases compliance and lowers the risk of infection.*

Imbalanced Nutrition: Less Than Body Requirements

The patient with leukemia may have difficulty meeting nutritional needs due to increased metabolism, fatigue, loss of appetite from radiation, nausea and vomiting from chemotherapy, or painful oral mucous membranes that make chewing and swallowing difficult and/or painful.

Expected Outcome: Patient will consume adequate nourishment to promote weight within normal range.

- Weigh regularly and evaluate weight loss over time to determine degree of malnutrition. A weight loss of 10% to 20% may indicate malnutrition. *A minimum intake of nutrients is necessary for health and tissue repair; cancer increases metabolic needs over this basal requirement. Weight loss occurs when metabolic requirements are not met. Both the disease process and its treatment can interfere with nutrient intake.*

- Address causative or contributing factors to inadequate food and fluid intake.
  - Provide mouth care before and after meals; use a soft toothbrush or sponges as necessary.
  - Provide liquids with different textures and tastes.
  - Increase liquid intake with meals.
  - Reduce intake of milk and milk products, which make mucus more tenacious.
  - Assist to a sitting position for eating.
  - Ensure that the environment is clean and odor free.
  - Provide medications for pain or nausea 30 minutes before meals, if prescribed.
  - Provide rest periods before meals.
  - Offer small, frequent meals including low-fat, high-kilocalorie foods throughout the day.
  - Provide commercial supplements, such as Ensure.
  - Avoid painful or unpleasant procedures immediately before or after meals.
  - Suggest measures to improve food tolerance, such as eating dry foods when arising, consuming salty foods if allowed, and avoiding very sweet, rich, or greasy foods.

  Anorexia, nausea and vomiting, diarrhea, stomatitis, taste changes, and dysphagia often make eating difficult during cancer treatment when good nutrition is most important. Maintaining nutritional status decreases morbidity and mortality by preventing weight loss, improving the response to treatment, minimizing adverse effects, and improving quality of life. Small, frequent meals are often better tolerated, especially high-protein, high-kilocalorie foods.

Impaired Oral Mucous Membrane

Stomatitis, inflammation and ulceration of the oral mucous membrane, is common in leukemia. Chemotherapy can further impair the integrity of constantly dividing oral tissues.

Expected Outcome: Patient will maintain intact, moist oral mucous membranes through use of measures to promote oral membrane health.

- Inspect the buccal region, gums, sublingual area, and the throat daily for swelling or lesions. Ask about oral pain or burning. *Breakdown of the oral mucous membrane increases the risk of infection and bleeding, causes pain and discomfort with eating and swallowing, and may cause swelling that interferes with the airway.*
- Culture any oral lesions. *Herpes simplex virus and* Candida *(yeast) are more common in patients with neutropenia. Herpes lesions are usually red, raised, fluid-filled blisters;* Candida *causes a white coating and patches of white plaque.*
- Assist with mouth care and oral rinses with saline or a solution of hydrogen peroxide and water (1:1 or 1:3 hydrogen peroxide and water) every 2 to 4 hours. Apply petroleum jelly to the lips to prevent dryness and cracking. *These measures help prevent infection and increase comfort.*
- Encourage use of soft-bristle toothbrush or sponge to clean teeth and gums. *Toothbrushes with hard bristles may abrade inflamed mucosa, causing bleeding and increasing the risk of infection.*
- Administer medications as ordered to treat infection or relieve pain. *Topical antifungal agents such as nystatin may be prescribed to treat* Candida *infections. Topical anesthetics such as lidocaine may be prescribed to relieve comfort and facilitate good oral care.*
- Instruct to avoid alcohol-based mouthwashes, citrus fruit juices, spicy foods, very hot or very cold foods, alcohol, and crusty foods. Suggest bland, cool foods and cool liquids at least every 2 hours. *Avoiding mucosa-traumatizing foods and liquids increases comfort; bland, cool foods and liquids cause the least pain. Intake of adequate fluids is necessary to prevent dehydration.*

Ineffective Protection

Bleeding is the second most common cause of leukemia deaths. As platelet counts decrease, the risk of bleeding increases (see the section later in this chapter on thrombocytopenia). Tumor lysis syndrome also is a risk in patients with leukemia who are undergoing their initial treatment with chemotherapy. Tumor lysis syndrome develops when a large number of malignant cells are destroyed by treatment with chemotherapy or radiation. The resultant by-products of cell lysis can overwhelm the body's ability to effectively eliminate them, leading to hyperkalemia, hyperphosphatemia with secondary hypocalcemia, and hyperuricemia.

Expected Outcome: Patient will remain free of any evidence of new bleeding and take precautions to prevent bleeding and to identify early onset of tumor lysis syndrome.

- Assess vital signs every 4 hours and body systems every shift for bleeding:
  - Skin and mucous membranes for petechiae, ecchymoses, and purpura
  - Gums, nasal membranes, and conjunctiva for bleeding
  - Vomitus, stool, and urine for visible or occult blood
  - Vaginal bleeding
  - Prolonged bleeding from puncture sites
  - Neurologic changes such as headache, visual changes, altered mentation, decreased level of consciousness, seizures
  - Abdomen for complaints of epigastric pain, diminished bowel sounds, increasing abdominal girth, rigidity, or guarding.

  Early identification of bleeding helps prevent significant blood loss and potential shock. Internal hemorrhage may lead to tachycardia, hypotension, pallor, and diaphoresis. Bleeding into the lungs may cause dyspnea; bleeding into the abdomen causes increased girth, pain, and guarding. Intracranial bleeding affects mental status and level of consciousness.
- Avoid invasive procedures such as rectal temperatures and suppositories, vaginal douches, suppositories, tampons, urinary catheterization, and parenteral injections if possible. Diagnostic procedures such as biopsy or lumbar puncture should not be done if the platelet count is less than 50,000. *Invasive procedures can cause tissue trauma and bleeding. Procedures that use large-bore needles should be delayed until the platelet count is increased.*
- Apply pressure to injection sites for 3 to 5 minutes, and to arterial punctures for 15 to 20 minutes. *Pressure prevents prolonged bleeding by prompting hemostasis and clot formation.*
- Instruct to avoid forcefully blowing or picking the nose, forceful coughing or sneezing, and straining to have a bowel movement. *These activities can damage mucous membranes, increasing the risk for bleeding.*
- Monitor and promptly report abnormal blood levels of electrolytes, uric acid, urea nitrogen, and creatinine, or manifestations of tumor lysis syndrome. *Significant alterations in electrolyte levels can lead to complications such as cardiac dysrhythmias, muscle*

weakness or tetany, paresthesias, and mental status changes. Excess uric acid can compromise renal function and lead to metabolic acidosis and gout.

- Maintain adequate hydration and administer prescribed medications such as allopurinol and diuretics as ordered. *Hydration is vital to maintain renal function and promote elimination of tumor lysis byproducts. Allopurinol reduces the risk of uric acid crystallization in the kidneys and other tissues* (*Vallerand & Sanoski, 2012*).

Anticipatory Grieving

The diagnosis of cancer and a potentially life-threatening illness causes actual or perceived losses, such as loss of function, independence, normal appearance, friends, self-esteem, and self. Grieving is the emotional response to those losses. The adaptive process of mourning a loss and resolving grief is called grief work; grief work cannot begin until a loss is acknowledged. Refer to Chapter 5 for a detailed discussion of grief and loss.

Expected Outcome: Patient and family will discuss the meaning of losses (actual or perceived) to the patient and family's life.

- Discuss roles of the patient and family and ways in which they have managed stressful situations in the past. Assess coping strategies and their effectiveness. Help identify sources of strength and support. Discuss changing roles resulting from a leukemia diagnosis and its effect on spiritual, social, and economic status, and usual lifestyle. Evaluate cultural or ethnic factors that affect grief reactions. *Grieving is a normal response to a real or potential loss that begins at the time of diagnosis. The timing, duration, and intensity of grief and responses to grief may differ among family members. Share information on diagnosis, role change, and physical loss among all family members to build the foundation for mutual understanding and trust.*
- Use therapeutic communication skills to facilitate open discussion of losses and provide permission to grieve. *Encouraging discussion of the meaning of the loss helps decrease some of the anxiety associated with loss. This in turn allows the patient and family to examine the current situation and compare it with past situations with which they have coped successfully.*
- Provide information about agencies that may help in resolving grief, and make referrals as indicated. Consider self-help groups, cancer support groups, and bereavement groups. *Participating in support groups with others who are anticipating or experiencing a similar loss can decrease feelings of isolation.*

Continuity of Care

Patient and family teaching for home care after treatment for leukemia focuses on encouraging self-care, providing information about the disease and the treatment, preventing infection and injury, and promoting nutrition. Teaching topics for each of these areas are as follows.

Encouraging Self-Care

- Hygiene measures and energy conservation during self-care activities
- Oral hygiene including using a soft-bristle toothbrush several times daily; avoid flossing
- Reporting lesions, bleeding, or signs of infection promptly
- Maintaining a balance of rest and activity

Information about Leukemia and Treatment

- Bone marrow function, the pathophysiology of leukemia, and potential complications of leukemia
- Prognosis for the specific type of leukemia
- Treatment measures such as chemotherapy, radiation, bone marrow or stem cell transplant, their purpose and effects, where treatment is available, and potential adverse effects or risks
- Community, regional, and national resources for people with leukemia

Preventing Infection and Injury

- Hand hygiene and other measures to reduce exposure to pathogens such as avoiding people who are ill and avoiding crowds
- Avoiding foodborne illnesses by washing fruits and vegetables, proper food storage
- Dental hygiene measures
- Avoiding immunizations
- Manifestations to report: fever, chills, burning on urination, foul-smelling urine, vaginal or rectal discharge, skin lesions
- Avoiding contact sports or strenuous exercise if platelet count is low
- Using an electric razor for shaving, avoiding rectal or vaginal suppositories, vaginal tampons, or enemas
- Increasing dietary fiber and using a bulk-forming laxative as needed to prevent straining
- Avoiding over-the-counter or prescription drugs that interfere with platelet function (see Box 33–7 on page 1053)
- The importance of reporting any bleeding (nosebleeds, rectal bleeding, vomiting blood, excessive menstrual periods, blood in the urine, bleeding gums, bruises, or collections of blood under the skin) or changes in behavior to the healthcare provider

Promoting Nutrition

- Eating several small, low-fat, high-calorie meals and drinking five to eight glasses of water daily
- Reporting continued weight loss, loss of appetite, or inability to eat for 24 hours
- Discussing dietary needs with the dietitian.

Assistance with physical care, finances, and transportation may be required following discharge. As needed, refer the patient and family to social services, support groups, home care services, and other agencies that can provide needed services (such as local chapters of the American Cancer Society, which can provide hospital beds and transportation for outpatient cancer treatment).

THE PATIENT WITH MALIGNANT LYMPHOMA

Lymphomas are malignancies of lymphoid tissue. They are characterized by the proliferation of lymphocytes, histiocytes (resident monocytes or macrophages), and their precursors or derivatives. Lymphomas are closely related to lymphocytic leukemias. Some experts consider them to be different forms or stages of the same disease processes.

Although there are many types of malignant lymphoid cells, at this time lymphomas commonly are identified as Hodgkin's disease or non-Hodgkin's lymphoma.

CASE STUDY & NURSING CARE PLAN A Patient with Acute Myelocytic Leukemia

Catherine Cole is a 37-year-old secretary who lives with her husband, Ray, and teenage daughter, Amy, in an apartment in a large metropolitan area. About 2 months ago, Mrs. Cole began to tire easily and experience night sweats several times a week. She noted that she was pale, bruised easily, and was having heavier menstrual periods. Blood tests ordered by her primary care provider are abnormal. She is admitted for a bone marrow biopsy.

ASSESSMENT

Mary Losapio, RN, obtains a nursing history and physical assessment for Mrs. Cole. Mrs. Cole tells her, "I'm so tired, and I have these bruises all over me. I'm so afraid of the results of the bone marrow examination. I don't know what we will do if I have cancer." Mrs. Cole clutches her husband's hand and then begins to cry. Physical assessment data include height 156 cm (64 in.), weight 48.1 kg (106 lb); vital signs T 37.8°C (100°F), P 102 bpm, R 22/min, BP 130/82 mmHg. Numerous petechiae scattered over trunk and arms; ecchymoses noted on lower right arm and right calf. Oral mucosa is red, with several small ulcerations in buccal areas.

Blood count shows reduced RBCs, hemoglobin, and hematocrit levels. The WBC is high, with myeloblasts seen on differential. The platelet count is very low. A tentative diagnosis of acute myelogenous leukemia is made.

DIAGNOSES

- *Risk for Infection* related to altered WBC production and immune function
- *Ineffective Protection* related to reduced platelet count and risk for bleeding
- *Impaired Oral Mucous Membrane* secondary to anemia and reduced platelets
- *Fatigue* related to anemia
- *Anxiety* related to fear of leukemia diagnosis

EXPECTED OUTCOMES

- Patient will remain free of infection.
- Patient will experience no significant bleeding.
- Patient will have intact oral mucous membranes.
- Patient will manage self-care activities despite fatigue.
- Patient will verbalize decreased anxiety.

PLANNING AND IMPLEMENTATION

- Place in a private room.
- Limit visitors to immediate family for the present.
- Instruct all staff, the family, and patient to carefully perform hand hygiene. Post a sign over the washbasin in the room as a reminder for hand washing.
- Record vital signs every 4 hours.
- Avoid invasive procedures unless absolutely necessary.
- Monitor for bleeding every 4 hours, including skin, oral mucosa, abdominal assessment, body fluids, and menstrual pad count.
- Instruct to perform oral hygiene every 2 to 4 hours, using a soft-bristle toothbrush.
- Ask the dietitian to work with Mrs. Cole to identify preferred foods. Instruct to avoid foods that may damage oral mucosa, such as very hot, very cold, or highly acidic or spicy foods.
- Provide for periods of rest alternating with activity.
- Teach about the bone marrow biopsy. Allow time for questions and to verbalize fears.
- Refer to the oncology nurse specialist for further teaching and support.

EVALUATION

The bone marrow biopsy confirms the diagnosis of acute myelogenous leukemia. Mrs. Cole is very upset, but calms as the healthcare provider and the oncology nurse discuss treatment plans and the possibility of remission. She decides to have outpatient chemotherapy. During her hospital stay, Mrs. Cole remained free of infection or further bleeding. She tells Ms. Losapio that her mouth feels better, although it is still painful. During routine assessment, Mrs. Cole remarks, "You know, I was so scared when I came here, but I think I am a little less so now. Sometimes not knowing what is wrong is worse than knowing."

Clinical Reasoning in Patient Care

1. Describe how alterations in WBCs can increase a person's susceptibility to infection.
2. List sources of potential infection for the hospitalized patient.
3. What is the rationale for having the patient do her own oral and physical hygiene?
4. Outline a teaching plan for this patient and her family for home care to prevent infection.
5. Develop a care plan for Mrs. Cole for the nursing diagnosis *Activity Intolerance*.

See Evaluating Your Response in Appendix B.

Pathophysiology

HODGKIN'S DISEASE

Hodgkin's disease is a lymphatic cancer, occurring most often in people between the ages of 15 and 35 or over age 50. It is somewhat more common in men than women. Approximately 9060 new cases of Hodgkin's disease were diagnosed in 2012 (ACS, 2012). The exact cause of Hodgkin's disease is unknown, but both Epstein-Barr virus (EBV) infection and genetic factors appear to play a role in its development. Hodgkin's disease is one of the most curable cancers. While as many as 60% to 90% of people with localized disease achieve cure with a normal life span, there may be an increased risk for a second cancer occurrence throughout life.

Hodgkin's disease develops in a single lymph node or chain of nodes, spreading to adjoining nodes. Involved lymph nodes contain *Reed-Sternberg cells* (malignant cells) surrounded by host inflammatory cells. These malignant cells secrete inflammatory mediator substances, attracting inflammatory cells to the tumor site. They may invade almost any tissue in the body. The spleen often is involved; as the disease progresses, the liver, lungs, digestive tract, and CNS may be affected (Huether & McCance, 2011). Rapid proliferation of abnormal lymphocytes impairs the immune response, especially cell-mediated immune responses. Infections are common.

Hodgkin's disease is classified as classic Hodgkin's disease or as nodular lymphocyte-predominant Hodgkin's disease. The classic form of the disease accounts for 95% of all cases; nodular lymphocyte-predominant Hodgkin's is rare. Classic Hodgkin's can be further divided into four subtypes by cells identified within the tumor, but the subtype does not affect the prognosis.

MANIFESTATIONS The most common symptom of Hodgkin's disease is one or more painlessly enlarged lymph nodes, usually in the cervical or subclavicular region. Systemic manifestations such as persistent fever, night sweats, fatigue, and weight loss are associated with a poorer prognosis for the disease. Late symptoms such as malaise, pruritus, and anemia indicate spread of the disease (Huether & McCance, 2011). The spleen may be enlarged, and

other organ systems such as the lungs and GI tract are occasionally involved.

NON-HODGKIN'S LYMPHOMA

Non-Hodgkin's lymphoma (NHL) is a diverse group of lymphoid tissue malignancies that do not contain Reed-Sternberg cells. Non-Hodgkin's lymphomas tend to arise in peripheral lymph nodes and spread early to tissues throughout the body. Non-Hodgkin's lymphoma is more common than Hodgkin's disease, affecting an estimated 70,130 people annually and causing about 18,940 deaths in 2012 (ACS, 2012). Older adults are more often affected, and it occurs more frequently in men than in women. Like Hodgkin's disease, its cause is unknown, although both genetic and environmental factors (e.g., viral infections such as EBV, HTLV-1 and HTLV-2, and HIV) are thought to play a role.

As in most malignancies, non-Hodgkin's lymphoma begins as a single transformed cell; it may arise from T cells, B cells, or tissue macrophages (histocytes). The primary types of non-Hodgkin's lymphoma are identified in Table 33–7. Although non-Hodgkin's lymphoma usually arises in a lymph node, it can originate in any lymphoid tissue. It tends to spread early and unpredictably to other lymphoid tissues and organs. Extranodal spread may involve the nasopharynx, GI tract, bone, CNS, thyroid, testes, and soft tissue.

The prognosis for non-Hodgkin's lymphoma ranges from excellent to poor, depending on the identified cell type and grade of differentiation. Low-grade tumors (better differentiated) tend to be less aggressive and more curable. Higher-grade tumors often are disseminated at the time of diagnosis and have a poorer prognosis.

MANIFESTATIONS The early manifestations of non-Hodgkin's lymphoma are similar to those for Hodgkin's disease. Painless lymphadenopathy may be localized or widespread (Figure 33–9 ■). Systemic manifestations such as fever, night sweats, fatigue, and weight loss may be present, but are less common in non-Hodgkin's lymphoma. Organ system involvement may cause symptoms such as abdominal pain, nausea, and vomiting. Headaches, peripheral or cranial nerve symptoms, altered mental status, or seizures may signal CNS involvement.

Figure 33–9 ■ Cervical lymphadenopathy in a patient with lymphoma of the neck.

TABLE 33–7 Subtypes of Non-Hodgkin's Lymphoma

Subtype	Incidence	Course and Prognosis
B-CELL LYMPHOMAS		
Diffuse large B-cell lymphomas	Most common adult type (40%–50% of adult lymphomas) More common in males Incidence increases with aging	Aggressive tumor 45%–50% cure rate
Follicular lymphoma	Accounts for 40% of adult lymphomas, rare in children Incidence increases with aging	Bone marrow frequently involved Course slow, indolent; 72% 5-year survival
Extranodal marginal zone lymphoma (MALT lymphoma)	Accounts for about 5% of adult lymphomas, rare in children Incidence increases with aging More common in Italy	Presents with tumors outside lymphatic system: GI tract, lung, thyroid, urinary tract, skin, CNS Slow, indolent course; 74% 5-year survival
Mantle cell lymphoma	Accounts for 3% to 4% of adult lymphomas, rare in children Predominantly affects older men (74%)	Aggressive, difficult to cure 27% 5-year survival
Burkitt lymphoma	Rare in adults (< 1% of lymphomas), more common in children (~30% NHL)	Rapidly progressive but responds well to therapy 45% 5-year survival
T-CELL LYMPHOMAS		
Precursor T-cell lymphoblastic leukemia/lymphoma	More common in children and young adults More common in males than females	Can present either as ALL or lymphoma Aggressive disease; 26% 5-year survival
Peripheral T-cell lymphoma	Most common T-cell lymphoma in adults	Often presents as disseminated disease 25% 5-year survival
Mycosis fungoides/ cutaneous T-cell lymphoma	Onset typically during mid-50s; more common in African Americans	Cutaneous lymphoma Slow course, progressing from patchy skin lesions to plaque to cutaneous tumors

TABLE 33–8 Features and Manifestations of Hodgkin's Disease and Non-Hodgkin's Lymphoma

Feature or Manifestation	Hodgkin's Disease	Non-Hodgkin's Lymphoma
Lymphadenopathy	Localized to a single node or chain, often cervical, subclavicular, or mediastinal	Multiple peripheral nodes, nodes of the mesentery often involved
Spread	Orderly and continuous	Diffuse and unpredictable
Extranodal involvement	Rare	Early and common
Bone marrow involvement	Uncommon	Common
Fever, night sweats, weight loss	Common	Uncommon until disease is extensive
Other manifestations	Fatigue, pruritus, splenomegaly; anemia, neutrophilia	Abdominal pain, nausea, vomiting; dyspnea, cough; CNS symptoms; lymphocytopenia

The manifestations and clinical features of Hodgkin's disease and non-Hodgkin's lymphoma are compared in Table 33–8.

Course

In both Hodgkin's disease and non-Hodgkin's lymphoma, the stage of the disease, the presence of systemic manifestations, and factors such as age help determine the prognosis. The prognosis is good when the disease is localized to one or two node regions. Factors such as anemia, thrombocytopenia, and older age reduce the likelihood of disease cure.

Incidence and Risk Factors

Malignant lymphomas are the seventh leading cause of cancer deaths in the United States. Approximately 79,190 new cases of lymphoma were diagnosed in 2012, and 20,130 deaths were attributed to the disease. The incidence of non-Hodgkin's lymphoma has nearly doubled since 1970, but currently has stabilized, primarily due to a fall in its incidence related to HIV infection and AIDS. The incidence of Hodgkin's disease has significantly declined since 1990 (ACS, 2012).

While the cause of lymphoma is unknown, some risk factors have been identified. See the accompanying Genetic Considerations box for information about identified genetic links for lymphoma development. Immunosuppression due to drug therapy following organ transplant or to HIV disease increases the risk for non-Hodgkin's lymphoma. Infectious agents such as human T-cell leukemia/lymphoma virus-1 (HTLV-1) and the Epstein-Barr virus (EBV) also have been identified as risk factors. Others may include occupational herbicide or chemical exposure.

GENETIC CONSIDERATIONS

Focus on Lymphoma

Although specific genetic alterations have not been identified for all types of lymphoma, recurring genetic abnormalities associated with lymphomas point to a genetic link in disease development. Three distinct genetic abnormalities have been identified in non-Hodgkin's lymphomas: gross chromosomal changes such as translocations; rearrangements of specific genes; and altered expression of specific oncogenes (overexpression, underexpression, or mutation). Consistent genetic changes are associated with some lymphomas; in other cases, several genetic abnormalities may be seen. Hodgkin's disease is unique from other lymphomas in that no specific genetic abnormalities have been identified. For more information about genetics and disease, refer to Chapter 8.

●○● INTERPROFESSIONAL CARE

Chemotherapy and radiation therapy, either alone or in combination, are the primary treatments for Hodgkin's disease and non-Hodgkin's lymphoma. Use of monoclonal antibodies to target lymphoma cells, and bone marrow and peripheral stem cell transplants are under investigation for treating lymphomas as well. See the previous section on treatment of leukemia for more information about these transplants.

DIAGNOSIS

The following diagnostic tests may be ordered for lymphomas:

- *CBC* results often show a mild normochromic, normocytic anemia in Hodgkin's disease; other findings in Hodgkin's disease may include leukocytosis with high neutrophil and eosinophil counts, and an elevated sed rate. In non-Hodgkin's lymphoma, the CBC typically remains normal until late in the disease, when pancytopenia may develop.
- An *erythrocyte sedimentation rate (ESR)* test is done to identify possible inflammatory causes of lymph node enlargement.
- *Chemistry studies of major organ function* (including liver function tests and renal function studies) are performed to identify possible organ involvement. *Serum LDH levels* and *protein electrophoresis* also may be done when Hodgkin's disease is suspected.
- *Chest x-ray* is done to identify possible enlarged mediastinal lymph nodes and pulmonary involvement.
- *CT scans* of the chest, abdomen, and pelvis are performed to identify abnormal or enlarged nodes.
- *PET* or *gallium scans* may be performed in diagnosing the disease, as well as to evaluate the effectiveness of treatment.
- *Biopsy* of the largest, most central enlarged lymph node and of the bone marrow is done to establish the diagnosis for both Hodgkin's disease and non-Hodgkin's lymphoma. The presence of Reed-Sternberg cells confirms the diagnosis of Hodgkin's disease.

STAGING

Staging is used to determine the extent of the disease and appropriate treatment. The Ann Arbor Staging System is used to assess the extent and severity of lymphomas. The stages are as follows:

Stage I: involvement of a single lymph node region or lymphoid structure (e.g., spleen, thymus, lymphoid tonsillar tissue)

Stage II: involvement of two or more lymph node regions on the same side of the diaphragm

Stage III: involvement of lymph node regions or structures on both sides of the diaphragm:

III_1: limited to upper abdomen (spleen, splenic, celiac, or portal nodes)

III_2: involvement of lower abdominal nodes (para-aortic, iliac, or mesenteric)

Stage IV: involvement of an extranodal site (not proximal or contiguous with an involved node) such as the liver, lung or pleura, bone or bone marrow, or skin.

The presence or absence of systemic symptoms is indicated by either an A (no systemic symptoms) or B (systemic symptoms of fever, night sweats, weight loss).

CHEMOTHERAPY

Combination chemotherapy is used to treat both Hodgkin's disease and non-Hodgkin's lymphoma. In both cases, chemotherapy often is followed by radiation therapy to involved lymph node regions. The choice of drug combination depends on the stage of the disease as well as the patient's age and general condition. Combination regimens used in the United States include CHOP (cyclophosphamide, doxorubicin, vincristine, and prednisone), ABVD (doxorubicin, bleomycin, vinblastine, and dacarbazine), MOPP (nitrogen mustard, vincristine, procarbazine, and prednisone), and ChlVPP (chlorambucil, vinblastine, procarbazine, and prednisone). These regimens also may be combined in alternating months to reduce the adverse effects and improve tumor cell kill. More than 75% of patients with Hodgkin's disease who do not have systemic symptoms achieve complete remission with treatment. The prognosis for patients with non-Hodgkin's lymphoma varies by the type and stage of the disease. For more information about nursing care of the patient receiving combination chemotherapy, refer to Chapter 14.

IMMUNOTHERAPY

Rituximab (Rituxan) is a monoclonal antibody used to destroy the CD20 antigen in B lymphocytes. This destruction results in cellular death of the lymphoma cell. It can be used alone or with cyclophosphamide, vincristine, and prednisone (CVP). The patient should be closely monitored for tumor lysis syndrome. It is recommended that patients be premedicated with diphenhydramine and acetaminophen. Rituximab should be used cautiously in patients with known cardiac disorders (Vallerand & Sanoski, 2012).

RADIATION THERAPY

Radiation therapy may be the primary treatment for early-stage Hodgkin's disease, although early chemotherapy is becoming more common. In later stages and in non-Hodgkin's lymphoma, it usually is combined with chemotherapy. Many lymphomas are highly responsive to radiation. The involved lymph node region is treated, with careful shielding to protect unaffected areas and minimize the extent of radiation burn and normal cell destruction (Figure 33–10 ■). If the disease is advanced, total nodal irradiation may be done. Refer to Chapter 14 for nursing care of the patient receiving radiation therapy.

STEM CELL TRANSPLANT

Autologous peripheral blood stem cell transplant (PBSCT) is a treatment option for patients who experience remission of malignant lymphoma. Autologous PBSCT uses the patient's own stem cells to restore bone marrow function after chemotherapy or radiation. In autologous PBSCT, stem cells are obtained from peripheral blood following chemotherapy and treatment with colony-stimulating factors to promote development of normal blood cells. The blood containing these normal stem cells is then frozen and stored for use after treatment. If relapse occurs, lethal doses of chemotherapy or radiation are given to destroy the immune system and malignant cells. The blood is then thawed and infused intravenously through a peripheral line. The infused stem cells become a part of the patient's bone marrow and normal hematopoiesis takes place.

The patient is critically ill during the period of bone marrow destruction and immunosuppression. He or she is hospitalized in a private room for 6 to 8 weeks or more. See the accompanying Moving Evidence into Action box for discussion of the meaning of nurses' work related to BMT.

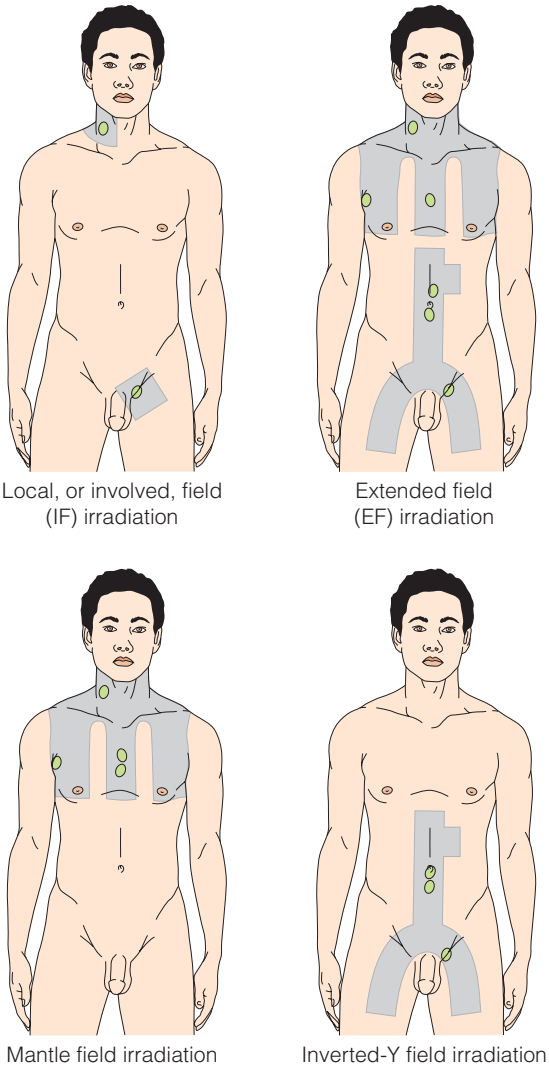

Figure 33–10 ■ Patterns of radiation therapy used to treat lymphoma based on the location and extent of the disease.

COMPLICATIONS OF TREATMENT

Both chemotherapy and radiation therapy may have long-term effects. Permanent sterility is common, especially in older adults. Bone marrow depression can lead to immunosuppression, anemia, and bleeding. Secondary cancers and cardiac injury are the most serious late adverse effects of treatment. Chemotherapy regimens using the MOPP or a related protocol carry a risk of acute leukemia. Cancers such as breast or lung cancer may develop 10 or more years after

Moving Evidence into Action

Meaning in Bone Marrow Transplant Nurse's Work

Bone marrow transplant (BMT) is a clinical culture that emphasizes cure. However, this culture leads to enormous stress on the nursing staff when a patient is suffering or dying. In light of the strong culture of cure, Leung and colleagues (2012) conducted a qualitative study using interpretive phenomenology to guide data analysis. They conducted the study to explore BMT nurses' experiences of meaning and hope and the effects of a meaning-centered intervention on these experiences. The meaning-centered intervention was delivered over five sessions. To evaluate the impact of the intervention, interviews were conducted with the nurses one month before and after the intervention. The intervention appeared to inspire the nurses to engage more with patients and their suffering. Subthemes included awareness of boundaries between their personal and professional involvement; enhanced empathy based on awareness of shared mortality and increased hope when the nurses linked their patient's suffering with meaning. The study concluded that patient suffering constitutes nurses' search for meaning and hope in their work.

Implications for Nursing

Nurses are the professional caregivers that patients interact with more than any other health profession. In the face of a "cure culture" this study supports that nurses can learn to be more responsive to patients' suffering beyond limits of cure. "A minimal intervention, such as the MCI, supports BMT nurses in finding positive personal meaning and purpose in their otherwise highly stressful work culture" (Leung et al., 2012).

Moving Knowledge into Action

1. Nursing in a bone marrow transplant unit is often focused on acutely ill patients requiring high-acuity care. Do you think these findings could also apply to nurses who work with BMT patients in other settings (i.e., home care)?
2. In this study, the researchers focused on patient suffering in the context of the meaning of the nurses' work. How might you expect the results to differ had the patients been having a different course (i.e., all doing very well or all responding poorly to the bone marrow transplant)?
3. Can the results of this study be applied when caring for patients undergoing BMT at other centers or SCT? Why or why not?

thoracic radiation. Thoracic radiation also increases the risk for coronary heart disease and hypothyroidism.

●○● NURSING CARE

In addition to the following discussion, also see the Case Study & Nursing Care Plan at the end of this section for application of nursing care strategies for a specific patient with Hodgkin's disease.

Assessment

See the Manifestations and Interprofessional Care sections for the assessment of the patient with lymphoma.

Focused assessment of the patient with Hodgkin's disease or non-Hodgkin's lymphoma includes the following:

- *Health history:* complaints of enlarged lymph node(s), fever, night sweats, weight loss, fatigue or general malaise, abdominal pain, respiratory symptoms, numbness or tingling of extremities, visual changes, or changes in mentation; history of infectious mononucleosis, HIV disease, or other immunosuppressive disorders
- *Physical assessment:* mental status exam; inspection and palpation of lymph nodes (cervical, subclavicular, axillary, and inguinal) for enlargement, tenderness; heart and lung sounds; abdominal examination for tenderness, masses, liver or spleen enlargement
- *Laboratory data:* CBC, hemoglobin and hematocrit, ESR; serum chemistry results; x-ray, scan, and biopsy results.

Priorities of Care

Collaborating with the interprofessional team to ensure adequate treatment of the underlying process while providing care that supports the physical and psychologic responses to the disorder is a priority of nursing care.

Diagnoses, Outcomes, and Interventions

Nursing care of the patient with malignant lymphoma involves both physical and emotional support during diagnosis and treatment. Common nursing care problems include impaired protection due to bone marrow suppression, fatigue, nausea, and altered body image. See the earlier Nursing Care section for leukemia for specific nursing interventions for *Ineffective Protection*.

Fatigue

General malaise and fatigue may accompany malignant lymphoma and are side effects of chemotherapy. In addition, the physical and psychologic stress of dealing with a chronic, debilitating disease and its treatment may cause fatigue.

Expected Outcome: Patient will track patterns of fatigue and describe use of energy conservation techniques to offset fatigue.

- Inquire about feelings of malaise (a vague feeling of body weakness or discomfort) and fatigue (a pervasive, drained feeling that cannot be eliminated). *Both malaise and fatigue are subjective experiences with physiologic, situational, and psychologic components.*
- Encourage verbalization of feelings about the impact of the disease and fatigue on lifestyle. *Discussion of feelings helps the patient clarify values and may assist in identifying priorities.*
- Encourage enjoyable but quiet activities, such as reading, listening to music, or hobbies. *Enjoyable activities help decrease feelings of fatigue. Quiet activities conserve energy while yielding a sense of accomplishment.*
- Encourage to establish priorities and include rest periods or naps when scheduling daily activities. *This provides a sense of control over activities and helps maintain self-esteem. Scheduled rest periods help restore energy and decrease fatigue.*
- Encourage delegation of some responsibilities to family members. *Delegation helps maintain the patient's involvement and role in family decisions and responsibilities, while conserving energy for those activities identified as high priority by the patient.*
- Identify and encourage the patient to use energy-saving equipment. *Performing tasks with less exertion and in less time helps conserve energy.*

- Encourage a diet high in carbohydrates and fluids. *A high-carbohydrate diet helps maintain muscle glycogen stores. A liberal fluid intake promotes excretion of metabolic by-products that may contribute to malaise and fatigue.*

Nausea

The effects of malignant lymphoma and its treatment with chemotherapy and/or radiation therapy can contribute to nausea and interfere with nutritional status. Nausea, a sensation of abdominal fullness, and fear of vomiting often limit food intake. See the nursing diagnosis *Imbalanced Nutrition* in the earlier section on leukemia for additional interventions.

Expected Outcome: Patient will report relief from nausea and methods to decrease onset of nausea.

- Assess precipitating factors for nausea and/or vomiting, the frequency of vomiting, and relief measures used by the patient. *Careful assessment allows development of interventions tailored to the patient's situation and needs.*

PRACTICE ALERT!

Provide ordered antiemetics before chemotherapy is started. Administering prescribed antiemetics before chemotherapy helps prevent nausea and the psychologic association of nausea with chemotherapy.

- Teach measures to prevent or relieve nausea and vomiting.
  - Eat soda crackers and suck on hard candy.
  - Eat soft, bland foods that are cold or at room temperature.
  - Avoid unpleasant odors, and get fresh air.
  - Eat prior to but not immediately before chemotherapy.
  - Use distraction or progressive muscle relaxation when nauseated.
  - If vomiting occurs, gradually resume oral intake with frequent sips of clear liquids or ice, progressing to bland foods.

  Crackers and hard candy often relieve queasiness, whereas hot, spicy, sweet, or strong smelling foods may increase nausea. Alternative nausea relief measures may be effective.
- Provide small feedings of high-kilocalorie, high-protein foods and fluids. *This increases nutritional intake.*
- Assist with oral care, general hygiene, and environmental control of temperature, appearance, and odors. *These measures enhance appetite.*
- Identify and provide preferred foods. *This promotes nutritional intake.*
- Assist to a sitting position during and immediately after meals. *The sitting position helps decrease early feelings of fullness.*

Disturbed Body Image

The diagnosis of cancer is often devastating to the sense of trust in and the perception of one's body. Radiation and chemotherapy lead to changes in appearance and body function (e.g., hair loss, reduced libido, and infertility), further altering body image. Reactions to this diagnosis vary and may include refusal to look in a mirror, refusal to discuss the effects of the disease or treatment, unwillingness to participate in rehabilitation, inappropriate treatment decisions, increasing dependence on others or refusal to provide self-care, hostility, withdrawal, and signs of grieving.

Expected Outcome: Patient will verbalize realistic expectations of therapy impact on body appearance and function.

- Assess perception of body image through subjective information such as
  - What the patient likes most and least about his or her body
  - Preillness perception of people who are sick or have a disability
  - Current understanding of health and limitations imposed by illness or treatment
  - Feelings about the illness and its effect on perception of self and others.

  Body image is one's mental idea or picture of the body. It is based on past and present experiences and includes components of one's actual body and emotional responses to that body. Body image changes constantly. There is often a time lag between an actual body change and the changed body image; during this time, the diagnosis, teaching, and treatment may be rejected.
- Discuss the risk for and measures to cope with alopecia. Suggest wearing wigs, scarves, hats, or caps. Teach proper scalp care using baby shampoo or mild soap, a soft brush, sunscreen, and mineral oil to reduce itching. If eyelashes and eyebrows are lost, teach eye protection, such as wearing eyeglasses and caps with wide brims. *Chemotherapeutic agents attack rapidly dividing cells such as those responsible for hair growth. Hair loss usually begins 1 to 2 weeks after initiation of chemotherapy, with maximum loss 1 to 2 months later. Alopecia may range from thinning to total hair loss. Regrowth depends on the treatment schedule and doses; however, it usually begins 2 to 3 months after treatment ends. New hair may be softer, more curly, and slightly different in color. Teaching and emotional support help the patient anticipate hair loss, discuss its potential effect on body image, and learn self-care techniques.*
- Discuss available resources for financial assistance with purchase of wigs, including local American Cancer Society chapters and insurance plans. *A well-matched wig (or one the color the patient has always wished for!) can help maintain a positive body image.*

Sexual Dysfunction

Sexual dysfunction may result from the malignancy and the effects of radiation and chemotherapy. Reproductive tissues are made of rapidly dividing cells, and cancer treatment may cause temporary or permanent sterility, changes in menstruation, and changes in libido.

Expected Outcome: Patient will identify underlying cause of sexual dysfunction and discuss alternative satisfying and acceptable sexual practices for self and partner.

- Encourage discussion of actual or potential sexual dysfunction or sterility with the patient and significant other. *Patients may be reluctant to discuss this unintended effect of treatment unless encouraged.*
- Assess knowledge, provide information, and clarify misconceptions. Discuss realistic measures for coping (e.g., sperm banking prior to chemotherapy or radiation therapy). *Patients and their partners may be unclear about expected effects on sexuality, reproduction, and the permanency of these effects.*
- Refer for counseling as indicated. *Sexual counseling can help the patient and partner develop alternative strategies for expressing their sexuality.*

Risk for Impaired Skin Integrity

Malignant lymphomas may cause significant pruritus and drenching night sweats. As a result, skin integrity may be impaired. In addition, radiation therapy can cause superficial burns, which also may affect skin integrity.

Expected Outcome: Patient will demonstrate understanding of plan to heal skin and prevent reinjury.

- Frequently assess skin, especially in areas undergoing radiation. Instruct to report any blistering. *Early identification of lesions allows timely treatment and can prevent further disruption of this important line of defense against infection.*
- Provide and teach measures to promote comfort and relieve itching: Use cool water and a mild soap to bathe; blot (rather than rub) dry skin; apply plain cornstarch or nonperfumed lotion or powder to the skin unless contraindicated; use lightweight blankets and clothing; maintain adequate humidity and a cool room temperature; wash bedding and clothes in mild detergent, and put them through second rinse cycle. Also teach to avoid sunbathing and tanning beds, and to protect the area from the sun. *Pruritus is aggravated by excessive warmth, excessive dryness, rough fabrics, fatigue, and stress. Lotions and some powders may be contraindicated during radiation therapy.*

Continuity of Care

When teaching the patient and family about home care, include the following topics in addition to those previously identified for specific nursing diagnoses:

- Information about the illness, planned treatment, and anticipated side effects of treatment
- Skin care and measures to relieve itching and protect areas of radiation
- Symptoms to report to the healthcare provider, including those of vertebral compression (decreased sensation or strength in lower extremities)
- Use of analgesics and alternative relief strategies for abdominal pain and peripheral neuropathies
- Respiratory care if mediastinal nodes are enlarged or lungs or pleurae are involved
- Planning ADLs to ensure adequate rest and exercise
- Measures to relieve nausea and maintain adequate nutrition.

Refer patients and family members to the local chapter of the American Cancer Society for information, assistance, and counseling. A list of state and local agencies that offer information about malignant lymphoma and financial assistance can be obtained from the Leukemia Society of America.

CASE STUDY & NURSING CARE PLAN A Patient with Hodgkin's Disease

Albin Quito, age 28, is the nurse manager of a thoracic intensive care unit in a large teaching hospital. Lately he has been more tired than usual, often wakes up at night covered with sweat, and just does not feel well. He had thought that his symptoms were due to a viral illness and his busy work schedule. However, yesterday morning Mr. Quito noticed a large swollen area on the right side of his neck. He made an appointment with his primary healthcare provider who found a large cervical lymph node. A biopsy of the node and a CT scan of the chest were scheduled.

ASSESSMENT

David Herzog, the nurse in charge of the outpatient clinic, obtains a nursing history and assessment on Mr. Quito. His physical examination is essentially normal, with the exception of the enlarged node, which is not tender to palpation. When Mr. Quito is weighed, he tells Mr. Herzog that he has lost 3.2 kg (7 lb) in the past 2 months. In reviewing the results of the blood studies, Mr. Herzog notes mild anemia and an increased neutrophil count. The lymph node biopsy shows Reed-Sternberg cells. The clinic healthcare provider and Mr. Herzog tell Mr. Quito that the findings indicate stage I-B Hodgkin's disease but that the prognosis is very good. The healthcare provider recommends a short course of combination chemotherapy followed by radiation therapy to involved sites.

DIAGNOSES

- *Anxiety* related to the diagnosis of Hodgkin's disease and effects of treatment on job performance
- *Risk for Infection* related to potential bone marrow depression due to chemotherapy
- *Fatigue* related to effects of cancer, chemotherapy, and radiation therapy

EXPECTED OUTCOMES

- Patient will verbalize reduced anxiety.
- Patient will remain free of infection.
- Patient will identify and use methods to preserve energy.

PLANNING AND IMPLEMENTATION

- Encourage to consider a leave of absence from work during course of treatment.
- Discuss joining a support group for people with cancer.
- Provide information about the illness, combination chemotherapy, and radiation therapy.
- Reinforce knowledge of actions to decrease the risk of infection.
- Discuss ways to decrease fatigue and maintain energy:
  - Take a 1- to 2-hour nap once or twice a day.
  - Avoid overexertion during weekends and time-off.
  - Maintain a well-balanced diet.

EVALUATION

When Mr. Quito returns the following week to begin chemotherapy, he brings his friend Nancy to meet Mr. Herzog and asks him to discuss his treatment with her. Mr. Quito says, "I am still really scared, but being able to talk about this with Nancy will help a lot." Mr. Quito has made arrangements to take a 4-month leave from work, with the understanding that his job will be held for him. He states that he will have some problems with money but is working them out. He also says he feels that taking a nap is silly but that he will rest to maintain his energy level. Mr. Quito and Nancy express confidence that he will be cured and say they plan to be active members of the cancer support group—even after recovery.

Clinical Reasoning in Patient Care

1. Discuss the rationale for treating Hodgkin's disease with chemotherapy and radiation.
2. Design a teaching plan to help Mr. Quito prevent infection while he is at home.
3. What effect does the diagnosis of cancer have on the developmental tasks of a young adult?
4. Develop a care plan for Mr. Quito for the nursing diagnosis of *Ineffective Role Performance*.

See Evaluating Your Response in Appendix B.

THE PATIENT WITH MULTIPLE MYELOMA

Multiple myeloma is a malignancy in which plasma cells multiply uncontrollably and infiltrate the bone marrow, lymph nodes, spleen, and other tissues. *Plasma cells* are B-cell lymphocytes that develop to produce antibodies (immunoglobins).

Pathophysiology

Malignant plasma cells arise from one clone (*monoclonal*) of B cells that produces abnormally large amounts of a particular immunoglobin called the *M protein*. This abnormal protein interferes with normal antibody production and impairs the humoral immune response. It also increases blood viscosity and may damage kidney tubules. As myeloma cells proliferate, they replace the bone marrow and infiltrate the bone itself. Cortical bone is progressively destroyed by tumor growth and enzymes produced by myeloma cells. These enzymes facilitate bone destruction, its infiltration by tumor cells, development of new blood vessels to sustain the tumor, and growth of myeloma cells (Huether & McCance, 2011). Affected bones (primarily the vertebrae, ribs, skull, pelvis, femur, clavicle, and scapula) are weakened and may break without trauma (pathologic fracture). With disease progression, malignant cells spread via the bloodstream to invade other organs (Figure 33–11 ■).

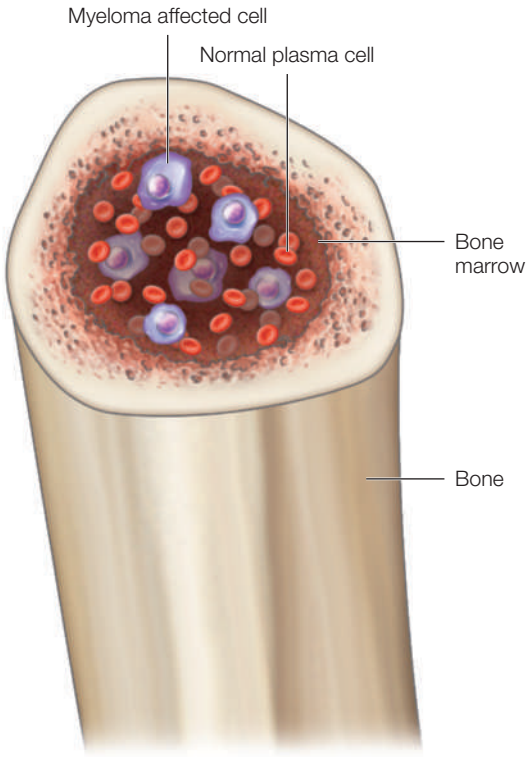

Figure 33–11 ■ An illustration of the progress of multiple myeloma in an African American male. Abnormal plasma cells proliferate uncontrollably, gradually replacing bone marrow and infiltrating bone itself. As the disease progresses, these cells spread to other organs via the bloodstream.

Manifestations

The disease develops slowly, with up to 30% of patients diagnosed during evaluation for unrelated problems, and is known for being difficult to diagnose. Manifestations of multiple myeloma are due to its effects on the bone and the impaired immune response due to M protein production. Bone pain is the most common presenting symptom. With progression of the disease, the pain may increase in severity and become more localized. Rapid bone destruction releases calcium from the bone, leading to hypercalcemia and manifestations of neurologic dysfunction, such as lethargy, confusion, and weakness.

As functional antibody formation decreases and the humoral immune response is suppressed, recurrent infections develop. Cell-mediated immunity remains intact. *Bence Jones proteins* are found in the urine in multiple myeloma. These proteins are toxic to the renal tubules, and may lead to renal failure with azotemia and uremia (refer to Chapter 28 for more information about renal failure).

About 15% of patients with multiple myeloma die within 3 months of the diagnosis. More frequently, the disease course is chronic, progressing more rapidly with each relapse after remission. The acute terminal stage of the disease is marked by pancytopenia and widespread organ infiltration by myeloma cells (Huether & McCance, 2011).

Incidence and Risk Factors

The incidence of multiple myeloma is increasing slightly, with an estimated 21,700 cases diagnosed and 10,710 deaths due to the disease in 2012 (ACS, 2012). It affects Blacks nearly twice as often as Whites, and men slightly more frequently than women. The incidence of multiple myeloma increases with age, rarely occurring before age 40 (Huether & McCance, 2011). Its cause is unknown. Possible contributing factors include genetic alterations, radiation exposure, oncogenic virus, inflammatory stimuli, and chronic antigenic stimulation. The risk for developing multiple myeloma is higher in people of lower socioeconomic status. This increased risk may relate to environmental factors such as poor housing, occupational hazards, poor nutritional status, and other physical and psychosocial stressors such as exposure to infectious agents.

●○● INTERPROFESSIONAL CARE

DIAGNOSIS AND STAGING

Diagnostic tests for multiple myeloma include the following:

- *X-rays* and other radiologic studies of the bone may reveal multiple punched-out lesions.
- *Bone marrow examination* shows an abnormal number of immature plasma cells.
- *CBC* shows moderate to severe anemia, and the *ESR* usually is elevated.
- *Protein electrophoresis* shows a spike of one type of antibody, usually IgG.
- *Serum calcium, creatinine, uric acid*, and *BUN levels* often are elevated.
- *Urinalysis* shows Bence Jones proteins in the urine.
- *Biopsy* of myeloma lesions confirms the diagnosis of multiple myeloma.

Staging of multiple myeloma is based on the hemoglobin and serum calcium levels, the amount of abnormal protein present, and the degree of bone involvement.

TREATMENT

There is no cure for multiple myeloma. In some patients, active observation is indicated, as the disease may continue with a slow, indolent (sluggish, not developing or progressing) course for many years. When indicated by disease stage or progression, standard treatment includes induction chemotherapy followed by stem cell transplant and maintenance chemotherapy to control progression of the disease. Supportive care is provided to reduce complications of the disease and their effects.

Combination chemotherapy with an alkylating agent (melphalan [Alkeran], cyclophosphamide [Cytoxan], or chlorambucil [Chloromycetin]) and prednisone administered for 4 to 7 days every 4 to 6 weeks is commonly used. Chemotherapy typically reduces bone pain, hypercalcemia, anemia, and the number of infections. Novel therapies that include immunomodulatory drugs lenalidomide (Revlimid) and thalidomide (Thalomid) and the proteasome inhibitor bortezomib (Velcade) contribute to improved survival rates and better response rates when compared to conventional chemotherapy. Localized radiation therapy may be used to treat painful bone lesions. High-dose chemotherapy followed by peripheral allogeneic stem cell transplant may be more effective in achieving cure, but is associated with a high mortality rate. When autologous SCT is used, G-CSF is administered prior to harvesting and preserving peripheral stem cells for collection, preservation, and transplant.

Supportive care may include treatment of hypercalcemia with hydration, possible bisphosphonate therapy to reduce bone loss (see Chapter 40), and calcium, vitamin D, and fluoride supplements to support bone structure. Plasma exchange therapy (plasmapheresis) to remove circulating M proteins is used as needed to treat acute renal failure. Infections are treated promptly when they develop.

●○● NURSING CARE

Assessment

See the Manifestations and Interprofessional Care sections for the assessment of the patient with multiple myeloma.

Focused assessment data for the patient with multiple myeloma includes the following:

- *Health history:* complaints of back or bone pain, onset, duration, and intensity; complaints of weakness, fatigue, anorexia; history of frequent or recurrent infections; neurologic symptoms such as numbness and tingling or clumsiness
- *Physical assessment:* level of consciousness and mental status; mobility, gait; localized tenderness or pain, bony crepitus with movement or palpation; movement and sensation in extremities.

Priorities of Care

Collaborating with the interprofessional team to ensure adequate treatment of the underlying process while providing care that supports the physical and psychologic responses to the disorder is a priority of nursing care.

Diagnoses, Outcomes, and Interventions

Nursing care of the patient with multiple myeloma focuses on problems of chronic pain, impaired mobility, and the risk for injury. Risk for infection is a major nursing care focus; see the previous section on leukemia for specific interventions to reduce this risk. Other nursing care needs are similar to those of patients with other cancers and chronic pain. Refer to Chapters 9 and 14 for additional specific nursing interventions for these problems.

Chronic Pain

Patients with multiple myeloma typically experience chronic back pain and deep bone pain as myeloma cells saturate the bone marrow and invade the bone structure. Pathologic fractures are a common and reoccurring problem.

Expected Outcome: Patient will experience adequate pain control as evidenced by physical well-being.

- Assess pain, including intensity (use a standard pain scale), onset, duration, precipitating factors, and effective relief measures. *Identifying the intensity, causes, and precipitating factors of pain helps determine and evaluate effective pain relief measures.*
- Determine position of greatest comfort, and assist as needed into this position. *The patient is best able to identify positions that minimize pain, but may need assistance with repositioning.*
- Support position with pillows. *Bony prominences may be painful due to infiltrates. Pillows can help relieve pressure on these prominences, thus reducing pain.*
- Provide uninterrupted rest periods. *Adequate rest facilitates pain relief and improves pain tolerance.*
- Teach adjunctive pain relief strategies such as relaxation or guided imagery. *A combination of pharmacologic and nonpharmacologic methods provides better management of chronic pain, especially bone pain.*
- Teach effective analgesic use, including the family in instruction. *Analgesics are most effective when taken before pain becomes severe. Patients and their families may be reluctant to use prescription analgesics on a regular basis.*
- Report unrelieved pain to the healthcare provider. *A different analgesic or addition of an adjunctive medication such as a nonsteroidal anti-inflammatory drug (NSAID) may be needed to effectively control pain.*

Impaired Physical Mobility

Painful bony infiltrates and pathologic fractures may limit mobility. A brace or splint may be used to protect extremities or support the back. In addition, persistent weakness associated with the cancer and anemia may limit the patient's ability to participate in usual activities.

Expected Outcome: Patient will demonstrate optimal independence in positioning, exercising, and performing functional activities.

- Assist to change position at least every 2 hours. *Assistance with repositioning is necessary due to weakness. Frequent repositioning improves comfort and reduces the risk for impaired skin and tissue integrity.*

PRACTICE ALERT!

Gently support extremities during repositioning. Weakened extremities due to infiltration of bone by myeloma cells and muscle atrophy from lack of use increase the risk for pathologic fractures.

- Provide a trapeze to assist in repositioning. *A trapeze provides better leverage, allowing the patient to assist with repositioning and providing a degree of independence. The ability to participate in self-care improves self-esteem.*

Risk for Injury

The bone involvement of multiple myeloma places the patient at high risk for pathologic and traumatic fractures. Pathologic fractures can occur with simple activities such as turning or reaching for an item. The spine usually is affected; the ribs and bones of the extremities also may be at risk for fracture.

Expected Outcome: Patient will effectively control risk through use of close and careful positioning and activity monitoring.

- Place needed items close at hand. *Straining to reach objects increases the risk of falling or sustaining other injury.*
- Provide safety measures to prevent falls from bed: Place the bed in a low position, use side rails as indicated, and place the call bell within reach. *Safety measures help prevent accidental injury. A secure environment minimizes risk and helps prevent falls.*
- Provide shoes with nonskid soles, a clear pathway, adequate lighting, and a level surface free of scatter rugs or other hazards when ambulating. Provide a walker as needed for support and security. *Weight-bearing exercise promotes bone repair. Safety measures, such as an unobstructed pathway and a firm walking surface, help prevent falls.*

Continuity of Care

When teaching patients and their families for home care, include the following topics:

- Strategies for home maintenance management
- Signs and symptoms of complications to be reported to the healthcare provider (e.g., symptoms of vertebral and extremity fractures)
- Manifestations of infection to report: fever and chills; increased malaise, fatigue, or weakness; cough with or without sputum; sore throat; dysuria, nocturia, frequency, urgency, or malodorous urine

Provide referrals for home health and home maintenance services, physical or occupational therapy, social services, and hospice care as appropriate.

THE PATIENT WITH NEUTROPENIA

Leukopenia is a decrease in the total circulating WBC count. Although any type of WBC may be affected, neutrophils, which make up the majority of WBCs, are affected most often. *Neutropenia* is a decrease in circulating neutrophils, usually less than 1500 cells/μm. Neutropenia may be either congenital or acquired, developing secondarily to prolonged infection, hematologic disorders, starvation, or autoimmune disorders (such as rheumatoid arthritis). Chemotherapy and other drugs can suppress the bone marrow. Neutropenia develops in approximately half of patients undergoing chemotherapy to treat cancer. *Agranulocytosis* is severe neutropenia, with less than 200 cells/μm. Numbers of other granulocytes also are reduced. It is usually a result of impaired leukocyte formation in the bone marrow or increased cell destruction in circulating blood. Agranulocytosis significantly increases the risk for infection. *Aplastic anemia* affects production of all blood cells, resulting in anemia, thrombocytopenia, and agranulocytosis.

Pathophysiology and Manifestations

Neutrophils are an integral component of the immune response. They are phagocytes, drawn to and activated by infection and inflammation to engulf and degrade invading microorganisms. Their life span in peripheral blood is short, less than 1 day. When *granulopoiesis* (the development and maturation of granulocytes) in the bone marrow is suppressed, the number of circulating neutrophils falls rapidly. As a result, the body's ability to defend itself against infection is significantly reduced.

The manifestations of neutropenia reflect the resulting impaired immunity and inflammatory response. Opportunistic bacterial, fungal, and protozoal infections develop, commonly affecting the respiratory tract and mucosa of the mouth, GI tract, and vagina. Malaise, chills, and fever with extreme weakness and fatigue are common manifestations.

●○● INTERPROFESSIONAL CARE

The diagnosis of neutropenia is made based on the patient's manifestations, risk factors, and the CBC. The total WBC is low, often less than $1000/mm^3$.

Hematopoietic growth factors such as GM-CSF are administered to stimulate granulocyte maturation and differentiation. Infections are treated with antibiotic therapy. Protective isolation procedures may be initiated to prevent exposure to pathogens. When neutropenia is related to chemotherapy, cancer treatment often must be halted, at least temporarily, to allow the bone marrow to recover.

●○● NURSING CARE

The primary nursing care focus is early identification of neutropenia and protecting the patient from infection. The WBC count is monitored on a regular basis, and any decline reported to the healthcare provider. Protective isolation may be indicated, including restricting the number of visitors and people with apparent illness. See the Risk for Infection entry in the earlier section on leukemia for specific nursing interventions for the patient with neutropenia.

THE PATIENT WITH INFECTIOUS MONONUCLEOSIS

Infectious mononucleosis is characterized by invasion of B cells in the oropharyngeal lymphoid tissues by the Epstein-Barr virus (EBV). This disease is usually benign and self-limiting. It often affects young adults between the ages of 15 and 30. Although many children are infected with EBV, symptomatic infectious mononucleosis is uncommon in early childhood. The virus is present in saliva, which appears to be the primary mode of transmission. As a result, infectious mononucleosis is sometimes called the "kissing disease."

EBV also is associated with some cancers, including Burkitt's lymphoma and Hodgkin's disease, B-cell lymphoma, and nasopharyngeal carcinoma.

Pathophysiology and Manifestations

When the virus enters the body, unaffected B cells produce antibodies against the virus, and T cells directly attack the virus. Infected B cells are destroyed as the virus replicates. The proliferation of B and T cells, as well as the removal of dead and damaged leukocytes, is responsible for the swelling of lymphoid tissues.

The incubation period for infectious mononucleosis is 4 to 8 weeks. Its onset is insidious, with headache, malaise, and fatigue. Fever, sore throat, and cervical lymphadenopathy (lymph node enlargement and pain) lasting 1 to 3 weeks are common. Symptom severity varies from person to person. Lymph node involvement may

be generalized; about 50% of people with infectious mononucleosis develop an enlarged spleen (splenomegaly).

●○● INTERPROFESSIONAL CARE

Laboratory findings include increased lymphocytes and monocytes, with about 20% of the cells atypical in form. Early in the infection, the WBC count usually is normal or low, but by the second week it increases and remains elevated for 4 to 8 weeks. Platelet counts are often low during the illness.

Recovery occurs in 2 to 3 weeks; however, debility and lethargy may last for up to 3 months. The treatment includes bed rest and analgesic agents to alleviate the symptoms. Nursing care is primarily educational to prevent further spread of the disease.

Platelet and Coagulation Disorders

Platelet and coagulation disorders affect **hemostasis**, control of bleeding. Hemostasis maintains a relatively steady state of blood volume, blood pressure, and blood flow through injured vessels. Bleeding disorders result from deficient platelets, disruption of the clotting cascade, or a combination of factors.

THE PATIENT WITH THROMBOCYTOPENIA

Thrombocytopenia is a platelet count of less than 100,000 per milliliter of blood. It can lead to abnormal bleeding. A continuing decline in circulating platelets to less than 20,000/mL can lead to spontaneous bleeding and hemorrhage from minor trauma (Figure 33–12 ■). Bleeding due to platelet deficiency usually occurs in small vessels, causing manifestations such as *petechiae* and *purpura*. The mucous membranes of the nose, mouth, GI tract, and vagina often bleed. Serious and potentially fatal bleeding occurs when the platelet count is less than 10,000/mL.

Thrombocytopenia results from one of three mechanisms: decreased production, increased sequestration in the spleen, or accelerated destruction. Primary thrombocytopenia that leads to increased platelet destruction is discussed next. Secondary thrombocytopenia may be caused by aplastic anemia, bone marrow malignancy, infection, radiation therapy, or drug therapy (Box 33–6). Heparin therapy is the most common drug-induced thrombocytopenia; it is included in the discussion that follows. Platelet sequestration usually is due to an enlarged spleen. Up to 80% of platelets may be removed from circulation with significant splenomegaly (Huether & McCance, 2011). Finally, thrombocytopenia may result from premature platelet destruction associated with disseminated intravascular coagulation (DIC).

Figure 33–12 ■ Significant ecchymosis of the eyelid associated with minor trauma in a patient with thrombocytopenia.

BOX 33–6 Selected Causes of Secondary Thrombocytopenia

DISEASES
- Vitamin B_{12} anemia
- Folic acid anemia
- Aplastic anemia
- Leukemia
- Alcoholism
- DIC
- Infectious mononucleosis
- Viral infections
- HIV disease

DRUGS
- Thiazide diuretics
- Aspirin
- Ibuprofen
- Indomethacin
- Naproxen
- Sulfonamides
- Phenytoin
- Cimetidine
- Digoxin
- Furosemide
- Heparin
- Morphine

TREATMENTS
- Radiation therapy
- Chemotherapy
- Massive transfusion of stored blood

Physiology Review

Effective control of bleeding requires a series of complex interactions between the damaged tissue and blood vessel, platelets, clotting factors, and processes to dissolve clots once bleeding has been controlled. Platelets are formed in the bone marrow under control of thrombopoietin, a protein produced by the liver, kidney, smooth muscle, and bone marrow. Platelets are attracted to the damaged vessel wall, where they aggregate and release mediators that activate the clotting process. Refer to Chapter 29 for a more complete discussion about platelets, clotting, and hemostasis.

Pathophysiology

The two types of primary thrombocytopenia are immune thrombocytopenic purpura and thrombotic thrombocytopenic purpura.

IMMUNE THROMBOCYTOPENIC PURPURA

Immune thrombocytopenic purpura (ITP), also known as *idiopathic thrombocytopenic purpura*, is an autoimmune disorder in which platelet destruction is accelerated. In ITP, proteins on the platelet cell membrane stimulate autoantibody production, usually IgG antibodies. These autoantibodies adhere to the platelet membrane. Although the platelets function normally, the spleen reacts to them as being foreign and destroys the altered platelets after only 1 to 3 days of circulation.

MANIFESTATIONS The manifestations of ITP are due to bleeding from small vessels and mucous membranes. Petechiae and purpura develop, often on the anterior chest, arms, neck, and oral mucous membranes. Bruising also may be apparent. As bleeding progresses, epistaxis (nosebleed), hematuria, excess menstrual bleeding, and bleeding gums occur. Spontaneous intracranial bleeding is rare but does occur. Associated symptoms include weight loss, fever, and headache.

INCIDENCE AND COURSE Acute ITP affects people of any age following a viral illness. Acute ITP typically lasts only 1 to 2 months, resolving without long-term consequences. In its chronic form, ITP typically affects adults between the ages of 20 and 50; women are affected more often than men. Its onset is insidious. Chronic (or adult) ITP often occurs in people with other immune-associated disorders such as systemic lupus erythematosus or HIV disease.

THROMBOTIC THROMBOCYTOPENIC PURPURA

Thrombotic thrombocytopenic purpura (TTP) is a rare disorder in which thrombi occlude arterioles and capillaries of the microcirculation. Many organs are affected, including the heart, kidneys, and brain. The incidence of TTP is increasing (Huether & McCance, 2011). Its cause is unknown. Platelet aggregation is a key feature of the disorder. As RBCs circulate through partially occluded vessels, they fragment, leading to hemolytic anemia.

MANIFESTATIONS TTP may be acute, the more common and severe form, or chronic. Acute idiopathic TTP may be fatal within months if untreated. The manifestations of TTP include purpura and petechiae, and neurologic symptoms such as headache, seizures, and altered consciousness.

HEPARIN-INDUCED THROMBOCYTOPENIA

Heparin-induced thrombocytopenia (HIT) develops as a result of an abnormal response to heparin therapy. Unfractionated heparin carries a greater potential to precipitate HIT; it can, however, develop in patients receiving low-molecular-weight heparin who have previously been treated with unfractionated heparin. Refer to Chapter 32 for further discussion of heparin therapy and the forms of heparin.

Heparin is a protein that occurs naturally in human tissues and inflammatory cells. It can react directly with platelets, causing them to agglutinate (clump), and be removed from circulation by phagocytosis. This form of HIT, called type I HIT, typically causes mild thrombocytopenia. The more severe form, type II HIT, results from an immune reaction to heparin. In type II HIT, heparin forms an immune complex with a platelet protein known as platelet factor 4 (PF4). This complex acts as a foreign antigen in some patients, stimulating antibody production. The antibody binds with the heparin–PF4 complex, and these antibody–heparin–PF4 complexes subsequently bind with circulating platelets, causing them to aggregate. As affected platelets aggregate, they are removed from circulation, leading to thrombocytopenia. In addition, small pieces of platelets can break loose, stimulating the clotting cascade and the development of thrombosis (clotting). The thrombocytopenia and the thrombosis can be reversed by prompt withdrawal of heparin therapy.

MANIFESTATIONS Despite thrombocytopenia, bleeding is usually a manifestation of HIT, probably because of the increased tendency to form clots. The patient may develop manifestations of an arterial thrombosis (severe pain, paresthesias, pallor and cool skin temperature, and pulselessness distal to the arterial occlusion) or of venous thrombosis (edema, redness, and warmth of the affected area). On rare occasions, an intravenous bolus of unfractionated heparin can precipitate an acute inflammatory response with manifestations that may mimic an acute pulmonary embolism—fever, chills, hypertension, tachycardia, dyspnea, chest pain, and cardiopulmonary arrest.

●○● INTERPROFESSIONAL CARE

The diagnosis of thrombocytopenia is based on history, manifestations, and diagnostic test results. Management focuses on treating or removing any causative factors and treating the platelet deficiency.

DIAGNOSIS

The following diagnostic tests are used to identify thrombocytopenia:

- *CBC with platelet count* is done to evaluate blood cell counts, hemoglobin, and hematocrit.
- *Antinuclear antibodies (ANA)* are measured to assess for autoantibodies and identify possible contributing disorders such as systemic lupus erythematosus.
- *Serologic studies* for hepatitis viruses, cytomegalovirus (CMV), EBV, toxoplasma, and HIV may be done. Serologic testing also may be performed when HIT is suspected.
- *Bone marrow examination* evaluates for aplastic anemia and megakaryocyte production.

MEDICATIONS

Oral glucocorticoids, such as prednisone, are prescribed to suppress the autoimmune response. Many patients who respond to glucocorticoid treatment relapse when the drug is withdrawn, however. Immunosuppressive drugs such as azathioprine, cyclophosphamide, and cyclosporine may be used.

Prompt withdrawal of heparin therapy is vital when HIT is the cause of thrombocytopenia. All sources of heparin are removed, including heparin used to flush intravenous or other catheters and heparin-coated catheters. A nonheparin anticoagulant such as lepirudin (Refludan) or argatroban may be substituted. Lepirudin is a thrombin inhibitor. It is a recombinant form of hirudin, originally isolated from the salivary glands of leeches. Its primary adverse effect is bleeding; as a protein, it also can stimulate antibody development, resulting in rare instances of anaphylaxis. Argatroban is a synthetic direct thrombin inhibitor with a short half-life. It clears quickly when the infusion is discontinued, an advantage if excessive bleeding develops or invasive procedures must be performed (Vallerand & Sanoski, 2012).

TREATMENTS

Platelet transfusions may be required to treat acute bleeding due to thrombocytopenia. Platelets are prepared from fresh whole blood; one unit contains 30 to 60 mL of platelet concentrate. The expected increase in platelets after one unit is infused is 10,000/mL. *Plasmapheresis*, or *plasma exchange therapy*, is the primary treatment for acute thrombotic thrombocytopenic purpura. The patient's plasma is removed and replaced with fresh frozen plasma to remove autoantibodies, immune complexes, and toxins.

SURGERY

A *splenectomy* (surgical removal of the spleen) is the treatment of choice if the patient with ITP relapses when glucocorticoids are discontinued. The spleen is the site of platelet destruction and antibody

production. This surgery often cures the disorder, although relapse may occur years after splenectomy.

●○● NURSING CARE

Assessment

See the Manifestations and Interprofessional Care sections for the assessment of the patient with thrombocytopenia.

- *Health history:* complaints of bruising with minor or no trauma, bleeding gums, nosebleed, heavy or prolonged menstrual periods; black, tarry, or bloody stools; hematemesis, headache, fever, or neurologic symptoms; recent weight loss; recent viral or other illness; current and recent medications; exposure to toxins; previous exposure to heparin
- *Physical assessment:* skin and mucous membranes for color, temperature, petechiae, purpura, or bruises; vital signs; weight; mental status and level of consciousness; heart and breath sounds; abdominal exam; body fluids for occult blood
- *Laboratory data:* CBC, hemoglobin and hematocrit, platelet count; serologic and ANA test results; bone marrow examination results.

Priorities of Care

Collaborating with the interprofessional team to ensure adequate treatment of the underlying process while providing care that supports the physical and psychologic responses to the disorder is a priority of nursing care.

Diagnoses, Outcomes, and Interventions

Inadequate platelets impair hemostasis, placing the patient at risk for bleeding. Bleeding gums, an early sign of the disorder, affect oral mucous membrane integrity as well.

Ineffective Protection

Bleeding is a serious complication associated with thrombocytopenia. As platelet counts (measured in cubic millimeters) decrease, the risk of bleeding increases: The risk is minimal with counts greater than 50,000 mm^3; moderate when the count is between 20,000 and 50,000 mm^3; and significant when the count falls below 20,000 mm^3.

Expected Outcome: Patient will remain free of any evidence of new bleeding and take precautions to prevent bleeding.

- Monitor vital signs, heart, and breath sounds every 4 hours. Frequently assess for other manifestations of bleeding:
  - Skin and mucous membranes for petechiae, ecchymoses, and hematoma formation
  - Gums, nasal membranes, and conjunctiva for bleeding
  - Overt or occult blood in emesis, urine, or stool
  - Vaginal bleeding
  - Prolonged bleeding from puncture sites
  - Neurologic changes: headache, visual changes, altered mental status, decreasing level of consciousness, seizures
  - Abdominal: epigastric pain, absence of bowel sounds, increasing abdominal girth, abdominal guarding or rigidity.

  Early identification of bleeding is important to prevent serious blood loss and shock.

SAFETY ALERT

Avoid invasive procedures such as rectal temperatures, urinary catheterization, and parenteral injections to the extent possible. Diagnostic procedures such as biopsy or lumbar puncture should be avoided if the platelet count is less than 50,000 mm^3. Invasive procedures can cause tissue trauma and bleeding. Procedures that use large-bore needles should be delayed until the platelet count is increased.

- Apply pressure to puncture sites for 3 to 5 minutes; apply pressure to arterial blood gas sites for 15 to 20 minutes. *Pressure promotes hemostasis and clot formation.*
- Instruct to avoid forcefully blowing the nose or picking crusts from the nose, straining to have a bowel movement, and forceful coughing or sneezing. *These activities increase the risk of external and internal bleeding.*

Impaired Oral Mucous Membranes

Thrombocytopenia frequently leads to bleeding of the gums and oral mucosa. As a result, risk for infection and impaired nutrition increases.

Expected Outcome: Patient will maintain intact, moist oral mucous membranes through use of measures to promote oral membrane health.

- Frequently assess the mouth for bleeding. Inquire about oral pain or tenderness. *Breakdown of oral mucous membranes increases the risk of infection and bleeding, and causes discomfort with eating.*
- Encourage use of a soft-bristle toothbrush or sponge to clean teeth and gums. *Hard bristles may abrade oral mucosa, causing bleeding and increasing the risk of infection.*
- Instruct to rinse the mouth with saline every 2 to 4 hours. Apply petroleum jelly to lips as needed to prevent dryness and cracking. *Saline mouth rinses and petroleum jelly help maintain oral tissue integrity and promote cleansing and healing.*
- Instruct to avoid alcohol-based mouthwashes, very hot foods, alcohol, and crusty foods. Teach to drink cool liquids at least every 2 hours. *Avoiding foods and liquids that traumatize oral mucosa increases comfort; fluid intake prevents dehydration and helps maintain mucous membrane integrity.*

Continuity of Care

In the adult, ITP often is a chronic disorder that the patient and family must learn to manage. Secondary thrombocytopenia may be either acute or chronic. Discuss the following topics when preparing the patient and family for home care:

- Nature of the disorder, its usual course, and the treatment plan
- Use and desired and potential adverse effects of prescribed medications
- Risks and benefits of surgery or treatments such as plasma replacement therapy
- The importance of follow-up tests and visits for care
- Measures to reduce the risk of bleeding: safety measures such as use of a soft-bristle toothbrush and electric razor, avoidance of contact sports and hazardous activities, and avoidance of medications that further interfere with platelet function (Box 33–7)

Refer for home health or other community services (e.g., housekeeping, shopping) as indicated.

BOX 33–7 Medications That May Interfere with Platelet Function

OVER-THE-COUNTER MEDICATIONS

- Aspirin and salicylates, including the following:
  - Alka-Seltzer
  - Bufferin
  - Doan's Pills
  - Ecotrin
  - Excedrin
  - Midol
  - Pepto-Bismol
  - Vanquish
- NSAIDs such as the following:
  - Advil
  - Aleve
  - Nuprin
  - Pamprin IB

PRESCRIPTION MEDICATIONS

- Aspirin-containing analgesics
- Chemotherapy drugs
- Antibiotics such as penicillin
- Carbamazepine (Tegretol)
- Colchicine
- Dipyridamole (Persantine)
- Gold salts
- Heparin
- Quinine derivatives
- Sulfonamides
- Thiazide diuretics

THE PATIENT WITH HEMOPHILIA

Hemophilia is a group of hereditary clotting factor disorders that lead to persistent and sometimes severe bleeding (see the accompanying Genetic Considerations box). Although often considered a disease of children, hemophilia may be diagnosed in adults. Deficiencies of three clotting factors, VIII, IX, and XI, account for 90% to 95% of the bleeding disorders collectively called hemophilia (Huether & McCance, 2011).

Physiology Review

When tissue injury occurs, platelets collect at the site, adhering to the damaged vessel wall (the platelet plug). Activation of the clotting cascade, a sequential process of interactive reactions of clotting factors, is vital to form a stable clot. Clotting factors are plasma proteins primarily produced by the liver. A number of these factors require the presence of vitamin K for synthesis and activation. Once the clot has been formed and stabilized, it begins to retract, pulling together the edges of the damaged blood vessel to initiate the healing process.

GENETIC CONSIDERATIONS

Focus on Hemophilia

The incidence and pattern of inheritance for the forms of hemophilia differ:

- Hemophilia A occurs in about 1 in 10,000 male births, transmitted on the X chromosome: Each male offspring has a 50% risk of inheriting the defective gene; each female offspring has a 50% risk of becoming a carrier.
- Hemophilia B occurs in about 1 in 100,000 male births, transmitted on the X chromosome.
- Von Willebrand's disease affects about 1 in 100 to 500 people, usually inherited as an autosomal dominant trait: Offspring of an affected person have a 50% risk of inheriting the trait and the disorder.
- Factor XI deficiency is inherited as an autosomal recessive trait: Each offspring of a carrier and an unaffected individual has a 50% risk of inheriting the trait; each offspring of two carriers has a 50% risk of being a carrier and a 25% risk of having the disorder. This deficiency is common in Ashkenazi Jews.

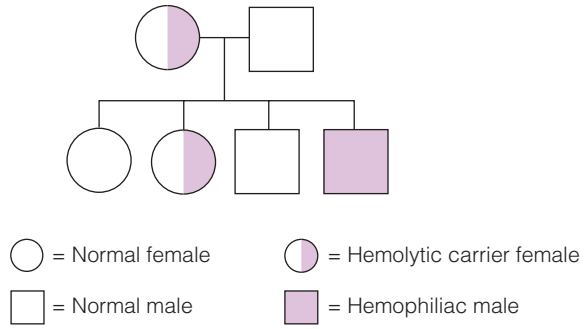

Figure 33–13 ■ The inheritance pattern of hemophilia A and B. Both are transmitted as X-linked recessive disorders. Females may be carriers, but only males develop these disorders.

Pathophysiology

Hemophilia A (or *classic hemophilia*) is the most common type of hemophilia, caused by deficiency or dysfunction of clotting factor VIII. It is transmitted as an X-linked recessive disorder from mothers to sons (Figure 33–13 ■). The genetic defect of hemophilia A on the X chromosome may cause deficient Factor VIII production or a defective form of the protein. When the concentration of the clotting factor is 5% to 35% of normal, the disease is mild. Bleeding is infrequent, and usually associated with trauma. Concentrations of 1% to 5% of normal result in moderate disease. Again, bleeding usually occurs secondarily to trauma. Severe hemophilia occurs when concentrations are less than 1% of normal. Bleeding is frequent, often occurring without trauma (Huether & McCance, 2011).

Hemophilia B (also called *Christmas disease*) accounts for about 15% of cases, and is caused by a deficiency in Factor IX. Despite the difference in clotting factor deficits, hemophilia A and B are clinically identical.

Von Willebrand's disease, often considered as a type of hemophilia, is the most common hereditary bleeding disorder (Huether & McCance, 2011). It is caused by a deficit of or defective von Willebrand (vW) factor, a protein that mediates platelet adhesion. Reduced levels of Factor VIII often also are present, because vW factor carries Factor VIII. This clotting disorder affects men and women equally. Bleeding associated with von Willebrand's disease rarely is severe. It often is diagnosed when prolonged bleeding follows surgery or a dental extraction.

Factor XI deficiency (or *hemophilia C*) is usually a mild disorder, identified when postoperative bleeding is prolonged. A comparison of the types of hemophilia is found in Table 33–9.

People with hemophilia form a platelet plug at the site of bleeding, but the clotting factor deficit impairs formation of a stable fibrin clot. The effect of vW factor deficiency is somewhat different, in that platelet aggregation at the site of injury is impaired. In either case, prolonged or extensive bleeding may result. Often bleeding occurs in response to injury or as a result of surgery. However, a severe clotting factor deficit can lead to spontaneous bleeding into the joints (*hemarthrosis*), deep tissues, and CNS. Hemarthrosis often causes joint deformity and disability, usually of the elbows, hips, knees, and ankles.

Manifestations

The following are manifestations of hemophilia:

- Hemarthrosis
- Easy bruising and cutaneous hematoma formation with minor trauma (e.g., an injection)

TABLE 33–9 Types of Hemophilia

Type/Name	Deficiency	Characteristics	Treatment
Hemophilia A (classic hemophilia)	Factor VIII	Transmitted by females; occurs primarily in males; bleeding time normal; coagulation time prolonged.	Factor VIII concentrate or cryoprecipitate
Hemophilia B	Factor IX	Transmitted by females; occurs primarily in males; bleeding time normal; coagulation time prolonged.	Factor IX (Christmas disease concentrate)
Von Willebrand's disease	vW Factor VIII	Occurs in both females and males; bleeding time and coagulation time are both prolonged.	Cryoprecipitate and DDAVP
Factor XI deficiency	Factor XI	Occurs in both males and females; the activated partial thromboplastin time (aPTT) is prolonged.	Fresh-frozen plasma

- Bleeding from the gums and prolonged bleeding following minor injuries or cuts
- GI bleeding, with hematemesis (vomiting blood), occult blood in the stools, gastric pain, or abdominal pain
- Spontaneous hematuria or epistaxis (nosebleed)
- Pain or paralysis due to the pressure of hematomas on nerves

Intracranial hemorrhage is a potentially life-threatening manifestation of hemophilia.

●○● INTERPROFESSIONAL CARE

Treatment of hemophilia focuses on preventing and/or treating bleeding, primarily by replacing deficient clotting factors. Specific treatment depends on the severity of the disorder and the specific factor deficiency. Care may be complicated by hepatitis or HIV disease in people with hemophilia treated with clotting factor concentrates prepared from multiple units of donated blood. Today, routine testing of all blood, improved blood donor screening, and current methods of treating hemophilia have significantly reduced the risk for these bloodborne diseases.

DIAGNOSIS

The following laboratory tests may be ordered:

- *Serum platelet levels* are measured and are usually normal.
- *Coagulation studies* such as aPTT, bleeding time, and prothrombin time are used to screen for hemophilia when abnormal bleeding occurs. The activated PTT is increased in all types of hemophilia. Prothrombin time is unaffected in these disorders but may be measured to rule out other disorders. Bleeding time is prolonged in von Willebrand's disease but normal in hemophilia A and B.
- *Factor assays* are performed; Factor VIII is decreased in hemophilia A and often in von Willebrand's disease, Factor IX is decreased in hemophilia B, and Factor XI in hemophilia C.
- Amniocentesis or chorionic villus sampling is used to identify the genetic defect of hemophilia when there is a known family history of the disease.

MEDICATIONS

Deficient clotting factors are replaced regularly, as a prophylactic measure before surgery and dental procedures and to control bleeding. Clotting factors may be given as fresh-frozen plasma, cryoprecipitates, or concentrates. Factor levels are measured on a regular basis to determine whether the treatment is adequate. Clotting factors are often self-administered and may be taken on either a regular or intermittent schedule.

Fresh-frozen plasma replaces all clotting factors (including both Factor VIII and Factor IX) except platelets. When the cause of bleeding is not yet determined, fresh-frozen plasma may be administered intravenously until a definitive diagnosis is made.

Hemophilia A is usually treated with either heat-treated Factor VIII concentrate (heat treating reduces the risk of transmitting disease) or recombinant Factor VIII. Although recombinant Factor VIII, produced using recombinant DNA technology, eliminates the risk of viral disease transmission, its use is limited by cost. The dose of Factor VIII is determined by the severity of the deficit and the presence or prospect of active bleeding (e.g., planned surgery).

Desmopressin acetate (DDAVP, Stimate) may be given to people with mild hemophilia A or von Willebrand's disease prior to minor surgeries. This drug causes release of Factor VIII and will raise blood levels by two- or threefold for several hours, reducing the risk of bleeding and the need for clotting factor concentrate (Vallerand & Sanoski, 2012).

Factor IX concentrate (administered intravenously) is used to treat hemophilia B. Because Factor IX concentrates also contain a number of other proteins, there is risk of thrombosis with recurrent use. They are used judiciously, only when needed. Products produced by recombinant technology or that are monoclonally purified carry a lower risk of stimulating thrombus formation (Vallerand & Sanoski, 2012). Fresh-frozen plasma replaces Factor XI and is used when necessary. It may be given daily until the risk for bleeding decreases.

Factor VIII concentrates contain functional vW factor, and may be used to treat von Willebrand's disease. Aspirin is avoided in all types of hemophilia.

●○● NURSING CARE

Although primary responsibility for care falls to the patient and family, nursing care presents challenges. For additional assessment and nursing care strategies, see the accompanying Case Study & Nursing Care Plan.

Health Promotion

Encourage patients with a family history of hemophilia or bleeding disorders to seek genetic counseling during their family planning process. Although tests are available for the hemophilia gene, the technology to correct the disorder in utero does not yet exist. Refer to Chapter 8.

Assessment

Whereas severe hemophilia usually is diagnosed in childhood, milder cases may not be identified until surgery, invasive dental work, or a traumatic injury causes extensive or prolonged bleeding.

See the Manifestations and Interprofessional Care sections for the assessment of the patient with hemophilia.

Focused assessment related to hemophilia includes the following:

- *Health history:* previous bleeding episodes with or without trauma; history of easy bruising, hematomas, epistaxis, bleeding gums, hematuria, vomiting blood, or joint pain; aspirin use; family history of hemophilia or bleeding disorders
- *Physical assessment:* vital signs; bruising or bleeding of skin or mucous membranes; mental status; abdominal assessment; presence of joint deformity, decreased range of motion
- *Laboratory data:* CBC including hemoglobin, hematocrit, and platelet count; clotting factor assays; tests for occult blood (urine, stool, emesis); x-ray and scan results for evidence of bleeding.

Priorities of Care

Collaborating with the interprofessional team to ensure adequate treatment of the underlying process while providing care that supports the physical and psychologic responses to the disorder is a priority of nursing care.

Diagnoses, Outcomes, and Interventions

Impaired blood clotting, the need for continuing care and disease management, and the risk for genetic transmission of hemophilia are priority problems for the patient with hemophilia.

Ineffective Protection

The inability to form stable clots and stem bleeding from injured blood vessels creates a significant risk for the patient with hemophilia. Nursing care measures focus on preventing injury and protecting the skin from damage.

Expected Outcome: Patient will remain free of any evidence of new bleeding and take precautions to prevent bleeding.

- Monitor for signs of bleeding, including hematomas, ecchymoses, and purpura, as well as surface oozing or bleeding. Check emesis and stool for occult blood. *Bleeding may occur in cutaneous tissues as well as internal organs. Bleeding in the upper GI tract may not be readily apparent in the stool.*
- Notify the healthcare provider of any apparent bleeding. *Prompt intervention with administration of clotting factor concentrate decreases the risk of hemorrhage and subsequent hypovolemia.*
- Avoid intramuscular injections, rectal temperatures, and enemas. *These can pose a risk of tissue and vascular trauma, which can precipitate bleeding.*
- Use safety measures in personal care. For example, use an electric razor rather than a razor blade to shave. *Use of an electric razor minimizes the opportunity to develop superficial cuts that may result in bleeding.*
- If bleeding occurs, control blood loss using gentle pressure, ice, or a topical hemostatic agent, such as an absorbable gelatin sponge, microfibrillar collagen hemostat, or topical thrombin. *Direct pressure occludes bleeding vessels. Ice, a vasoconstrictor, may facilitate bleeding control, as do topical hemostatic agents.*
- Instruct to avoid activities that increase the risk of trauma, including contact sports, physical exertion associated with job performance, and to eliminate safety hazards in the home. *Depending on the severity of the clotting factor deficit, even minor trauma can lead to serious bleeding episodes. Safer activities such as noncontact sports (e.g., swimming, golf) and occupations that do not require physical labor may be substituted.*

Risk for Ineffective Health Maintenance

Hemophilia is a chronic disorder, requiring active management to prevent and control bleeding and complications. Frequent visits to the healthcare provider or clinic may be necessary. In addition, the patient may need to learn to self-administer clotting factors and measures to prevent complications. The lifelong nature of the disorder may interfere with compliance, especially during early adulthood.

Expected Outcome: Patient will be knowledgeable about management of hemophilia as evidenced by being able to describe the components and rationale for the treatment plan.

- Assess knowledge of disorder and the related treatments. *Assessment allows identification of knowledge gaps and provides a basis on which to provide additional information. Impaired disease management may be due to lack of knowledge or a conscious decision not to follow the recommendations of the healthcare provider.*
- Provide information about the bleeding disorder and prescribed medications and treatments. *Individualized instruction is more effective than general, possibly irrelevant information.*
- Provide emotional support, expressing confidence in the patient's self-care abilities. *Emotional support helps the patient incorporate the care regimen into his or her lifestyle.*
- Provide supervised learning and practice opportunities for administering clotting factors and topical hemostatic agents. *Successful practice sessions instill confidence in the ability to manage care and provide an opportunity for questions and exploring alternatives.*

Continuity of Care

Discuss the following topics when preparing the patient with a bleeding disorder and the family for home care:

- Recognizing the manifestations of internal bleeding: pallor, weakness, restlessness, headache, disorientation, pain, swelling. These

Evidence for Nursing Care

The Patient with Hemophilia

Selected resources that nurses may find helpful when planning evidence-based nursing care follow.

CASE STUDY & NURSING CARE PLAN A Patient with Hemophilia

Jermiel Cruise is a 20-year-old student at the community college. He is admitted to the emergency department with a nosebleed that began when he fell during a touch football game. It has continued to bleed for over an hour.

ASSESSMENT

Mr. Cruise states that he has hemophilia and realizes that playing contact sports "is probably a dumb thing to do." He adds that he has not had any recent bleeding episodes. An ice bag and manual pressure are applied in the emergency department. The healthcare provider orders Factor VIII concentrate to be administered. Physical assessment findings are T 36.2°C (97.2°F), BP 118/64 mmHg, P 78 BPM, R 18/min. Skin pale but warm. Laboratory tests reveal a prolonged aPTT and a normal bleeding time and PT. Following treatment, Mr. Cruise's bleeding subsides.

DIAGNOSES

- *Risk for Aspiration* related to uncontrolled nosebleed
- *Noncompliance* with activity recommendations
- *Ineffective Protection* related to lack of clotting factor VIII

EXPECTED OUTCOMES

- Patient will exhibit no further signs of bleeding.
- Patient will maintain vital signs within his usual range.
- Patient will maintain an open airway.
- Patient will identify sports and recreation activities in which he can safely participate.
- Patient will verbalize self-care measures to control bleeding.

PLANNING AND IMPLEMENTATION

- Monitor vital signs and for further signs of bleeding.
- Assess airway and auscultate breath sounds.
- Review emergency measures to help stop bleeding.
- Reiterate the importance of seeking prompt medical attention if bleeding should occur.
- Advise regarding the importance of wearing a medical alert bracelet identifying him as a hemophiliac.
- Discuss alternative noncontact sports and recreational activities.

EVALUATION

On discharge, Mr. Cruise has no further signs of bleeding, shock, or aspiration. He is able to verbalize methods to help stop local bleeding and the importance of seeking medical attention promptly when bleeding continues. Mr. Cruise agrees to stop at a local drugstore on the way home to order a medical alert bracelet. In addition, Mr. Cruise verbalizes an understanding of the importance of avoiding contact sports and has identified swimming and golf as alternative leisure activities that he might enjoy.

Clinical Reasoning in Patient Care

1. What is the pathophysiologic basis for the bleeding that occurs in hemophilia A and B?
2. What was Mr. Cruise's priority nursing diagnosis? Why?
3. Why is family planning a special consideration with a patient who has hemophilia?
4. Outline a plan to teach the family of a patient diagnosed with hemophilia how to administer an intravenous infusion.
5. Develop a care plan for Mr. Cruise for the nursing diagnosis *Impaired Social Interaction.* Consider Mr. Cruise's age and developmental level in creating the plan.

See Evaluating Your Response in Appendix B.

manifestations require emergency medical care and should be reported immediately.
- Applying cold packs and immobilizing the joint for 24 to 48 hours if hemarthrosis occurs.
- Using analgesics for pain; avoiding prescription and over-the-counter drugs containing aspirin.
- Ensuring a safe home environment (e.g., padding sharp edges of furniture, using transition lighting or a night-light; avoiding scatter rugs, and wearing protective gloves when working in the house or yard).
- Using safe grooming practices such as electric razors.
- Wearing a medical alert bracelet in case of accident.
- Practicing good dental hygiene to decrease potential tooth decay and extractions. If dental procedures are necessary, discuss the need for prophylactic factor administration with the dentist and healthcare provider.
- Following safer-sex practices.
- Preparing and administering intravenous medications.

Refer the patient and family to a local hemophilia or bleeding disorders support group. Provide contact information for national organizations and information clearinghouses, such as the National Hemophilia Foundation.

THE PATIENT WITH DISSEMINATED INTRAVASCULAR COAGULATION

Disseminated intravascular coagulation (DIC) is a disruption of hemostasis characterized by widespread intravascular clotting and bleeding. It may be acute and life threatening or relatively mild.

BOX 33–8 Conditions That May Precipitate Disseminated Intravascular Coagulation

TISSUE DAMAGE
- Trauma: burns, gunshot wounds, frostbite, head injury
- Obstetric complications: septic abortion, abruptio placentae, amniotic fluid embolus, retained dead fetus
- Neoplasms: acute leukemia, adenocarcinomas
- Hemolysis
- Fat embolism

VESSEL DAMAGE
- Aortic aneurysm
- Acute glomerulonephritis
- Hemolytic uremic syndrome

INFECTIONS
- Bacterial infection or sepsis
- Viral or mycotic infections
- Parasitic or rickettsial infection

DIC is a clinical syndrome that develops as a complication of a wide variety of other disorders (Box 33–8). Sepsis is the most common cause of DIC. Gram-negative and gram-positive bacteria as well as viruses, fungi, and protozoal infections may lead to DIC (Huether & McCance, 2011).

Pathophysiology

DIC is triggered by endothelial damage, release of tissue factors into the circulation, or inappropriate activation of the clotting cascade by an endotoxin. Both the intrinsic and the extrinsic clotting

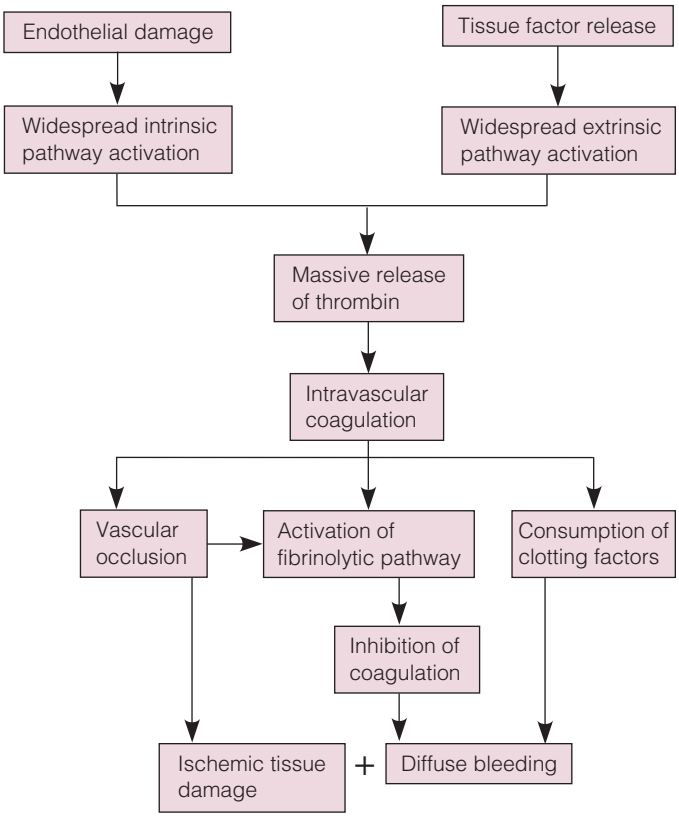

Figure 33–14 ■ Disseminated intravascular coagulation (DIC). Endothelial cell injury or release of tissue factors activates the intrinsic or extrinsic clotting pathway (or both). As a result, numerous microthrombi form throughout the vasculature, causing ischemic tissue damage. Simultaneously, rapid consumption of clotting factors and activation of fibrinolytic mechanisms trigger widespread bleeding.

cascade may be activated, although the extrinsic cascade usually is the one activated. Extensive thrombin entering the systemic circulation overwhelms natural anticoagulants, leading to unrestricted clot formation (Huether & McCance, 2011). Clotting may be localized to an individual organ, or widespread with deposition of small thrombi and emboli throughout the microvasculature. The widespread clotting consumes clotting factors (prothrombin, platelets, Factor V, and Factor VIII in particular) and activates fibrinolytic processes with anticoagulant production. As a result, hemorrhage occurs (Figure 33–14 ■).

The sequence of DIC follows:

1. Endothelial damage, tissue factors, or toxins stimulate the clotting cascade.
2. Excess thrombin within the circulation overwhelms naturally occurring anticoagulants.
3. Widespread clotting occurs within the microvasculature.
4. Thrombi and emboli impair tissue perfusion, leading to ischemia, infarction, and necrosis.
5. Clotting factors and platelets are consumed faster than they can be replaced.
6. Clotting activates fibrinolytic processes that begin to break down clots.
7. Fibrin degradation products (FDPs, potent anticoagulants) are released, contributing to bleeding.
8. Clotting factors are depleted, the ability to form clots is lost, and hemorrhage occurs.

MANIFESTATIONS OF DIC

- Frank hemorrhage from incisions
- Oozing of blood from punctures, intravenous catheter sites
- Purpura, petechiae, bruising
- Cyanosis of extremities
- GI bleeding or hemorrhage
- Dyspnea, tachypnea, bloody sputum
- Tachycardia, hypotension
- Hematuria, oliguria, acute renal failure
- Manifestations of increased intracranial pressure: decreased level of consciousness, papillary, motor, and sensory changes
- Mental status changes

Manifestations

The manifestations of DIC result from both clotting and bleeding, although bleeding is more obvious, especially in acute DIC. Bleeding ranges from oozing blood following an injection to frank hemorrhage from every body orifice (see the Manifestations box). Chronic DIC may be asymptomatic, or may present with peripheral cyanosis, thrombosis, and pregangrenous changes in the fingers and toes, nose, and genitalia.

●○● INTERPROFESSIONAL CARE

Treatment of DIC is directed toward treating the underlying disorder and preventing further bleeding or massive thrombosis. Treatment stabilizes the patient, reduces complications, and allows recovery to occur; it does not cure DIC.

DIAGNOSIS

Diagnostic tests are used to confirm the diagnosis of DIC and evaluate the risk for hemorrhage:

- *CBC* and *platelet count* are used to evaluate the hemoglobin, hematocrit, and number of circulating platelets. *Schistocytes*, fragmented RBCs, may be noted due to cell trapping and damage within fibrin thrombi. The platelet count is decreased.
- Coagulation studies show prolonged *prothrombin time (PT)*, *partial thromboplastin time (PTT)*, and *thrombin time*, and a low *fibrinogen level* due to depletion of clotting factors. The fibrinogen level helps predict bleeding in DIC: As it falls, the risk of bleeding increases.
- *Fibrin degradation products (FDPs)* or *fibrin split products (FSPs)* are increased due to the fibrinolysis that occurs with DIC.

TREATMENTS

When bleeding is the major manifestation of DIC, fresh-frozen plasma and platelet concentrates are given to restore clotting factors and platelets. Heparin, although controversial, may be administered. Heparin interferes with the clotting cascade and may prevent further clotting factor consumption due to uncontrolled thrombosis. It

is used when bleeding is not controlled by plasma and platelets, as well as when the patient has manifestations of thrombotic problems such as acrocyanosis and possible gangrene. Long-term heparin therapy (administered by injection or continuous infusion using a portable pump) may be necessary for patients with chronic DIC.

●○● NURSING CARE

Assessment

Nurses can be instrumental in identifying early manifestations of DIC, facilitating timely intervention. See the Manifestations and Interprofessional Care sections for the assessment of the patient with myelodysplastic syndrome.

Focused nursing assessment for DIC includes the following:

- *Health history:* recent abortion (spontaneous or therapeutic) or current pregnancy; presence of a known malignant tumor; history of abnormal bleeding episodes or a hematologic disorder
- *Physical assessment:* bleeding from puncture wounds (e.g., injections), IV sites, incisions; hematuria, obvious or occult blood in emesis or stool, epistaxis, other abnormal bleeding; vital signs; heart and breath sounds; abdominal assessment including girth, contour, bowel sounds, tenderness or guarding to palpation; color, temperature, skin condition of hands, feet, and digits; petechiae or purpura of skin, mucous membranes
- *Laboratory data:* CBC with hemoglobin, hematocrit; platelet count; coagulation studies; evaluations of organ system function (e.g., liver and renal function tests); CT scans of the head and abdomen.

Priorities of Care

Collaborating with the interprofessional team to ensure adequate treatment of the underlying process while providing care that supports the physical and psychologic responses to the disorder is a priority of nursing care.

Diagnoses, Outcomes, and Interventions

Patients with acute DIC often are critically ill, with multiple nursing care needs. Priority nursing diagnoses discussed in this section focus on impaired tissue perfusion and gas exchange, pain, and fear. Septic shock may precipitate DIC; hemorrhagic shock may occur as a complication of DIC. Refer to Chapter 11 for nursing diagnoses and interventions related to these problems.

Ineffective Tissue Perfusion

Thrombi and emboli forming throughout the microcirculation affect the perfusion of multiple organs and tissues. Additionally, bleeding due to clotting factor consumption affects cardiac output and blood flow to these tissues.

Expected Outcome: Patient will achieve adequate tissue perfusion as evidenced by adequate arterial flow (i.e., strong peripheral pulses) and absence of symptoms of cardiac, pulmonary, and neurologic ischemia.

- Assess extremity pulses, warmth, and capillary refill. Monitor level of consciousness (LOC) and mental status. *Monitoring central and peripheral tissue perfusion facilitates early treatment of impaired perfusion.*

PRACTICE ALERT!

Promptly report complaints of chest pain, changes in mental status, LOC, tissue perfusion, respirations, GI function, and urinary output. Chest pain or respiratory changes (tachypnea, dyspnea, orthopnea) may be due to angina, pulmonary embolism, or bleeding into lung tissue. Changes in mentation or LOC can indicate cerebral ischemia. A painful, pale, and cold extremity with no or diminished pulses indicates arterial occlusion. Prompt intervention is critical to save the extremity. Acute abdominal pain, decreased bowel sounds, and GI bleeding may indicate mesenteric occlusion, a surgical emergency. Decreased urine output may signify renal artery thrombosis; renal failure may develop.

- Carefully reposition at least every 2 hours. *Position changes facilitate circulation and tissue perfusion and provide an opportunity to assess for purpura, pallor, and bleeding.*
- Discourage crossing the legs, and do not elevate the knees on the bed or with a pillow. *These positions may impair arterial and venous flow to the lower legs and feet, increasing vascular stasis and the risk for thrombosis.*
- Minimize use of tape on the skin, using binders, nonadhesive dressings, and other devices as needed. *Preventing skin trauma reduces the risk for bleeding and potential infection.*

Impaired Gas Exchange

Microclots in the pulmonary vasculature are likely to interfere with gas exchange in the patient with DIC.

Expected Outcome: Patient will achieve adequate tissue perfusion as evidenced by adequate arterial flow as evidenced by absence of symptoms of cardiac, pulmonary and neurologic ischemia.

- Monitor oxygen saturation continuously. Administer oxygen as ordered. *Oxygen saturation levels are a noninvasive means of assessing gas exchange. Supplemental oxygen promotes gas exchange and reduces cardiac work, relieving dyspnea.*

SAFETY ALERT

Monitor arterial blood gas results; report abnormal results to the healthcare provider. Low PaO_2 and rising $PaCO_2$ levels indicate impaired gas exchange and may signify the need for additional treatment.

- Place in Fowler's or high-Fowler's position as tolerated. *Elevating the head of the bed improves diaphragmatic excursion and alveolar ventilation.*
- Maintain bed rest. *Bed rest reduces oxygen demands and cardiac work.*
- Encourage deep breathing and effective coughing. *Increased respiratory depth and clearance of secretions from airways improve alveolar ventilation and oxygenation.*
- Cautious nasotracheal suctioning may be instituted if cough is ineffective or an endotracheal tube is in place. *Removal of secretions facilitates ventilation and oxygenation. However, care must be used to minimize suction-induced hypoxia and airway trauma.*
- Administer analgesics and antianxiety drugs as needed to control pain and anxiety. Provide reassurance and comfort measures. *Pain and anxiety increase the respiratory rate and decrease the depth of respirations, reducing effective ventilation and gas exchange.*

Pain

Both the underlying cause of DIC and tissue ischemia from microvascular clots can cause pain. Identifying the etiology of pain is important to identify potential complications or harmful effects of DIC and to institute effective treatment.

Expected Outcome: Patient will exhibit adequate pain control as evidenced by physical well-being.

- Use a standard pain scale chart to evaluate and monitor pain and analgesic effectiveness. *Monitoring pain and the response to medication facilitates development of an appropriate and effective treatment plan.*

SAFETY ALERT

Notify the healthcare provider promptly of new or a sudden increase in pain, especially when accompanied by changes in assessment findings. New or increased complaints of pain may signify increased circulatory impairment and ischemic changes in tissues such as the heart, bowel, or extremities. Circulation to a painful, pale or cyanotic, or cold extremity may be occluded by an arterial clot. Prompt intervention is necessary to save the extremity. Acute abdominal pain may signify mesenteric occlusion, a surgical emergency. Anginal pain may indicate occlusion of coronary arteries.

- Handle extremities gently. *Gentle handling reduces the risk of further injury to and pain in ischemic tissues.*
- Apply cool compresses to painful joints. *Application of cold decreases pain through the gate-control mechanism, inhibiting the dorsal horn of the spinal cord and reducing the sensation of pain.*

SAFETY ALERT

Continuously monitor effects of analgesics and mental and respiratory status. Analgesics may mask manifestations of neurologic impairment due to thromboembolism, and may depress the respiratory center, further impairing gas exchange. Judicious analgesic administration with careful monitoring is vital to safely provide effective pain relief.

Fear

The underlying serious illness and a complication such as DIC result in an uncertain prognosis, often accompanied by fear.

Expected Outcome: Patient will express fears about uncertain prognosis.

- Encourage the patient and family to verbalize concerns. *This helps the patient and family identify their concerns and frame questions.*
- Answer questions truthfully. *Providing honest answers is vital to developing a therapeutic nurse–patient relationship. Accurate responses allow the patient and family to set priorities as they plan for an uncertain future.*
- Help the patient and family identify coping strategies to manage this significant situational stressor. *Implementing past effective coping methods may provide the skills to manage the current crisis.*
- Provide emotional support. *The presence of a caring nurse helps reduce the fear and anxiety associated with a crisis.*
- Maintain a calm environment. *A calm environment provides reassurance that the situation is in control, reduces anxiety, and promotes rest.*
- Respond promptly when the patient calls for help. *Prompt responses to expressed needs help develop a trusting relationship and a sense of security that assistance is readily available.*
- Teach relaxation techniques. *Relaxation techniques can reduce muscle tension and other signs of anxiety. Gaining control over physical responses can help the patient gain a sense of control over the situation.*

Continuity of Care

Although the immediate crisis of acute DIC is resolved prior to discharge, the patient may have some continuing effects of the disorder, such as impaired tissue integrity of distal extremities. Teach the patient and family about specific care needs, such as foot care or dressing changes. Provide instruction about any continuing medications and follow-up care.

Patients with chronic DIC may require continuing heparin therapy, using either intermittent subcutaneous injections or a portable infusion pump. Teach the patient and family members how to administer the injection or manage the infusion pump. Provide a referral to home healthcare or a home intravenous management service for assistance. Discuss the manifestations of excessive bleeding or recurrent clotting that need to be reported to the healthcare provider.

CHAPTER HIGHLIGHTS

- **Anemia is the most common disorder of the red blood cells; nutritional deficiencies are the most common causes of anemia. Its manifestations relate to the function of RBCs and hemoglobin, transporting oxygen to the cells: fatigue, increased respiratory and heart rates, shortness of breath with activity, and pallor.**
- Genetically transmitted disorders such as sickle cell disease and thalassemia can cause significant anemia and associated problems in affected populations. These patients require teaching and episodic acute care for crises such as vaso-occlusive crisis in sickle cell disease.
- **Nursing care related to anemia is primarily educational to prepare the patient for effective self-care, including diet, prescribed medications, and measures to prevent sickling episodes (for patients with sickle cell disease).**
- Leukemia and lymphomas are the primary disorders of white blood cells and lymphoid tissues.

- Manifestations of the leukemias reflect the altered ability of abnormal WBCs to perform effective immune surveillance and crowding of the bone marrow and other organs by rapidly proliferating cells. Frequent sore throats, increased risk for infection, and manifestations of anemia and thrombocytopenia are seen, as well as an enlarged spleen and abdominal pain.
- **Four major subgroups of leukemia are identified: acute and chronic myeloid leukemias, and acute and chronic lymphocytic (or lymphoblastic) leukemias. The primary population affected differs for each of these leukemias, as does their course.**
- Genetic alterations and certain viruses are linked to the development of leukemia, as are exposure to chemotherapy drugs, environmental toxins, and ionizing radiation.
- Lymphocytic leukemias and lymphomas are closely related disorders.
- **Nursing care for patients with leukemia and lymphoma focuses on reducing the risk for infection and bleeding, managing the effects of chemotherapy and radiation therapy, and, in some cases, caring for patients before and after bone marrow or stem cell transplant.**
- The major risks associated with bone marrow and stem cell transplant are infection prior to and immediately following the transplant and graft-versus-host disease, a potentially fatal condition. A pruritic rash and desquamation of the palms and soles; abdominal pain, nausea, and diarrhea; and jaundice and elevated liver enzymes are common early manifestations of GVHD.
- The treatment of and nursing care for patients with lymphomas (including Hodgkin's disease and non-Hodgkin's lymphoma) is similar to that provided for patients with leukemia.
- **Multiple myeloma is a malignancy of plasma cells, B lymphocytes that produce antibodies.**
- Circulating M proteins and Bence Jones proteins in the urine are seen in multiple myeloma. The usual presenting manifestation is bone pain. Pathologic fractures and hypercalcemia are common complications of multiple myeloma as bone is destroyed.
- **Bleeding and clotting disorders can result from either inadequate platelets (thrombocytopenia) or disruption of the clotting mechanisms (hemophilia, disseminated intravascular coagulation). Petechiae and purpura are common manifestations of bleeding/clotting disorders.**
- Hemophilias are genetically transmitted disorders. Hemophilia A and B are transmitted on the X chromosome (sex-linked) from mother to son. Von Willebrand's disease, the most common bleeding disorder, is transmitted as an autosomal dominant disorder and affects men and women equally.
- Hemophilias are treated by replacement of the missing clotting factor and measures to prevent injury and bleeding.
- Disseminated intravascular coagulation is a disorder of widespread microvascular clotting. It commonly is precipitated by sepsis, but also may occur with conditions such as major trauma, malignancy, or as an obstetric emergency.
- In DIC, platelets and clotting factors are consumed by the abnormal clotting processes, leading the manifestations of bleeding, including frank hemorrhage, hematuria, oozing blood from parenteral and intravenous injection sites, and GI bleeding. Blood flow to organs and tissues is compromised by clot formation, leading to manifestations such as cyanosis of extremities, abdominal pain, renal failure, and changes in mental status and level of consciousness. Nursing care is supportive, focusing on administering prescribed treatments and monitoring and supporting cardiovascular, respiratory, and renal function.

TEST YOURSELF NCLEX-RN® REVIEW

1. The nurse is beginning an assessment of a patient with moderate anemia. Which manifestation should the nurse expect to assess in this patient?
   1. pulse rate 140 bpm
   2. hematocrit 45%
   3. WBC 14,000/μL
   4. complaints of shortness of breath with exercise
2. The nurse is concerned that a patient recovering from gastric resection may develop nutritional deficiency anemia related to malabsorption. For which manifestation should the nurse assess this patient?
   1. bone pain
   2. steatorrhea
   3. dark yellow or bronze skin color
   4. numbness and tingling of extremities
3. The nurse is identifying diagnoses appropriate for a patient receiving a bone marrow transplant for treatment of acute myelocytic anemia. Which diagnoses would be the highest priority for this patient? (Select all that apply.)
   1. *Anxiety*
   2. *Risk for Infection*
   3. *Ineffective Protection*
   4. *Disturbed Body Image*
   5. *Imbalanced Nutrition: Less Than Body Requirements*
4. The nurse is planning care for a patient with acute myeloid leukemia. Which interventions are priorities for this patient? (Select all that apply.)
   1. Place in a private room.
   2. Request soft, bland diet.
   3. Monitor rectal temperature q4h.
   4. Assist with oral hygiene after meals.
   5. "Implement airborne infection control precautions."
5. A patient with non-Hodgkin's lymphoma tells the nurse, "I might as well give up on dating. No woman will want me now." What is the most appropriate response for the nurse to make?
   1. "Lots of women find bald men attractive; besides, your hair may grow back soft and curly."
   2. "It sounds like you are concerned about the effects of this disease and the proposed treatment plan."
   3. "Don't worry. Malignant lymphomas are very treatable when caught in an early state of the disease."
   4. "Well, you may never be able to have children all right, but there are other ways to have a satisfying relationship with a woman."

6. A patient with lymphoma is prescribed the CHOP chemotherapy regimen. What should the nurse explain about the purpose of combining these medications as treatment for the disorder?
   1. Targets different phases of the cell cycle.
   2. Targets malignant cells in different organs.
   3. Prevents the development of adverse effects.
   4. Supports growth and development of normal cells.
7. A patient with multiple myeloma calls the home health nurse complaining of a new onset of severe back pain. What should the nurse respond to this patient?
   1. Suggest use of a back brace to reduce pain.
   2. Notify the healthcare provider of the onset of new pain.
   3. Reassure the patient that bone pain is expected with this disease.
   4. Inquire about the patient's use of NSAIDs and analgesics to manage pain.
8. During an assessment the nurse observes reddish-purple spots and areas of purple bruising on a patient's arms and legs. Which laboratory result would be consistent with this assessment finding?
   1. INR 4.0
   2. hematocrit 28%.
   3. WBC 4,500/mm^3
   4. Platelets 60 × 103/mm^3
9. A patient whose husband has hemophilia asks if her newborn baby girl could have the disease. What information should the nurse use when responding to this patient?
   1. Hemophilia is an autosomal dominant disorder; therefore, her daughter has a 50% chance of having the disorder.
   2. The most common forms of hemophilia are transmitted as sex-linked recessive disorders; her daughter is at risk for carrying the defective gene.
   3. Although hemophilia is genetically transmitted, its pattern of inheritance is unknown, and her daughter will need to be tested for the defective gene.
   4. Because hemophilia is a sex-linked recessive disorder carried on the Y chromosome, her daughter has no risk of having or carrying the disease.
10. The nurse is administering platelets to a patient with disseminated intravascular coagulation (DIC). What is the intended effect of this treatment?
    1. Replace depleted platelets.
    2. Restore tissue oxygenation.
    3. Promote intravascular clotting.
    4. Replace specific clotting factors.

See Test Yourself answers in Appendix B.

UNIT

8 Building Clinical Competencies

Responses to Altered Cardiovascular Function

CLINICAL SCENARIO

Directions: *Read the following clinical scenarios and answer the questions that follow. To complete this exercise successfully, you will not only use knowledge of the content in this unit, but also principles related to priority setting and maintaining patient safety.*

You have been assigned to work with the following four patients for the 0700 shift on a cardiac telemetry unit. Significant data obtained during report is as follows:

- Betty Williams, age 62, was admitted with an anterior MI and had successful fibrinolytic therapy 3 days ago. Significant history includes type 2 diabetes, angina, hypertension, and a history of smoking (1.5 to 2 packs per day for 45 years). Her CCU course was uneventful. Current vital signs are T 37.2°C (98.9°F), P 76 bpm, R 16/min, BP 148/88 mmHg. Cardiac monitor shows normal sinus rhythm with no ectopy. She has been pain free since her nitroglycerin drip was titrated off in the CCU 2 days ago. Lung sounds are clear.
- Arnold Markus, age 71, was admitted with acute heart failure 2 days ago, treated and stabilized in the CCU, and transferred to the cardiac telemetry unit. Current vital signs are T 36.9°C (98.4°F), P 88 bpm, R 18/min, BP 112/74 mmHg. Cardiac monitor shows normal sinus rhythm with new isolated premature ventricular contractions (PVCs). Lung sounds are clear in upper lobes with crackles in the left base, and he was able to sleep intermittently during the night using two pillows.
- Theresa Cartwright, a 34-year-old mother of four young children, was admitted for anticoagulant therapy after developing a deep venous thrombosis after a fall down the steps and hitting her calf. She was started on a continuous heparin infusion yesterday and needs blood drawn for a partial thromboplastin time (PTT) to determine if the results are within therapeutic range.
- Scott Jacoby, a 25-year-old with Down syndrome, was admitted yesterday with an upper respiratory infection. Upon assessment he was pale, had a temperature of 38.3°C (101°F), a heart rate of 100 bpm, respiratory rate of 30/min with dyspnea on exertion, blood pressure of 118/86 mmHg, and multiple bruises and petechiae on his arms and legs. He is scheduled for a bone marrow examination this morning.

CLINICAL REASONING

1. What did you do to help your patients manage their activity needs without increasing their cardiac workload? What safety measures did you take to protect your patients with peripheral vascular or hematologic disorders?

Priority Setting

2. In what order would you visit these patients after report?
   A. _____
   B. _____
   C. _____
   D. _____

Health Promotion

3. What health promotion topics should be included in discharge teaching for Mrs. Williams?

Nursing Process

4. You are completing a beginning-of-shift assessment with Mr. Markus. Which of the following items takes priority?
   A. rhythm strip analysis
   B. lung sounds
   C. oxygen saturation
   D. heart sounds

5. Mrs. Williams rings the call bell and tells you that she is having pressure in her chest. On assessment, she rates it as a 5. Which of the following nursing actions should take priority?
   A. Obtain a full symptom assessment.
   B. Administer a prn nitroglycerine tablet SL.
   C. Call for an electrocardiogram.
   D. Notify the physician.

6. Which is the most important for you to report when caring for Mr. Jacoby?
   A. constipation and straining with bowel movements
   B. fever and burning on urination
   C. weight loss and decreased appetite
   D. dyspnea and shortness of breath with exercising

7. When Mrs. Cartwright is placed on warfarin (Coumadin) therapy, which laboratory studies would you expect to draw? (Select all that apply.)
   A. prothrombin time (PT)
   B. white blood cell (WBC) count
   C. partial thromboplastin time (PTT)
   D. complete blood cell (CBC) count
   E. International Normalized Ratio (INR)

Communication

8. Mrs. Cartwright needs further teaching regarding anticoagulant therapy when she makes which statement?
   A. "It takes four to five days of heparin and Coumadin to reach a good effect from the drugs."
   B. "I need to continue to have blood drawn to watch my drug levels as long as I am taking these drugs."
   C. "I cannot continue to take birth control pills while I am taking these drugs."
   D. "I need to take the medication at the same time every day for the drug to be effective."

9. Mrs. Williams asks how this heart attack will affect her active life. How will you answer?

Delegation

10. For each patient, what care-related activities can be delegated to the unlicensed assistive personnel (UAP)? What responsibility does the nurse have for delegated nursing care activities?

Interprofessional Care

11. The nurse collaborates with the healthcare provider regarding the pharmacologic management of Mr. Markus's heart failure. Which of the following medications should the nurse anticipate being ordered as part of standard care for heart failure management?
   A. aspirin 325 mg daily
   B. enalapril (Vasotec) 5 mg twice daily
   C. alprazolam (Xanax) 0.25 mg twice daily
   D. warfarin (Coumadin) 2.5 mg daily at 5:00 p.m.

Continuity of Care

12. When should cardiac rehabilitation begin for Mrs. Williams?
   A. immediately upon discharge from the healthcare facility
   B. on admission to the healthcare facility
   C. one week after discharge from the healthcare facility
   D. after the first visit to the cardiologist after discharge from the healthcare facility

Safety

13. Which of the following activities by the nurse ensures safe infusion of continuous heparin therapy for Mrs. Cartwright?
   A. Calculates the drops per minute for the infusion using 60-drop intravenous tubing.
   B. Maintains the infusion on an intravenous "smart" pump.
   C. Monitors the patient's PT to determine the effectiveness of the heparin.
   D. Calculates the heparin infusion into the intake and output.

Quality Improvement

14. The nurse manager of the cardiac telemetry unit has noted an increase in repeat admissions for heart failure. Which data should the manager collect to attempt to identify possible causation?

Informatics

15. When caring for a patient with a cardiac disorder, telemetry monitoring is common. Where in the electronic medical record would you expect to find related vital signs collected via monitoring?
   A. progress note
   B. laboratory results
   C. flow sheet
   D. diagnostic tests

UNIT

9

Responses to Altered Respiratory Function

34 Assessing the Respiratory System 1065

35 Nursing Care of Patients with Upper Respiratory Disorders 1080

36 Nursing Care of Patients with Ventilation Disorders 1114

37 Nursing Care of Patients with Gas Exchange Disorders 1165

Activity–Exercise Pattern

The respiratory system provides the cells of the body with the oxygen necessary for metabolism and energy production to carry out activities of daily living.

34 Assessing the Respiratory System

LEARNING OUTCOMES

1. Describe the anatomy, physiology, and functions of the respiratory system.
2. Compare and contrast factors affecting respiration.
3. Identify specific topics for consideration during a health history interview of the patient with health problems involving the respiratory system.
4. Give examples of genetic disorders of the respiratory system.
5. Describe normal variations in assessment findings for the older adult.
6. Identify abnormal findings that may indicate alterations in respiratory function.

CLINICAL COMPETENCIES

1. Complete a health history of the respiratory system incorporating appraisal of physiologic and psychosocial issues.
2. Conduct and document a health history for patients having or at risk for alterations in the respiratory system.
3. Conduct and document a physical assessment of respiratory structures and functions demonstrating sensitivity and respect for the diversity of the human experience.
4. Monitor the results of diagnostic tests and communicate abnormal findings within the interprofessional team.

MAJOR CHAPTER CONCEPTS

- Correct structure and function of the respiratory system is vital to ventilation, resulting in oxygenation of all body tissues.
- Manifestations of dysfunction, injury, and disorders affecting the respiratory system may be detected during a general health assessment as well as during a focused respiratory system assessment.

KEY TERMS

apnea, *1076*
atelectasis, *1076*
bradypnea, *1076*
crackles, *1078*
friction rub, *1078*
lung compliance, *1071*
oxyhemoglobin, *1071*
surfactant, *1071*
tachypnea, *1076*

vital capacity (VC), *1069*
wheezes, *1078*

EQUIPMENT NEEDED

- Tongue blade
- Penlight
- Nasal speculum
- Metric ruler
- Marking pen
- Stethoscope with diaphragm

The respiratory system provides oxygen to cells and eliminates carbon dioxide, formed as a waste product of cellular metabolism. The events in this process, called *respiration*, are ventilation (the movement of air into and out of the lungs), perfusion (the flow of blood through the capillary system surrounding the lungs), and diffusion (the process of gas exchange between the blood and the alveoli of the lungs). The movement of respiratory muscles is controlled by the nervous system and respiratory rate is adjusted to match body requirements during various activities.

Anatomy, Physiology, and Functions of the Respiratory System

The respiratory system functions as a whole but for discussion purposes is divided in this chapter into the upper respiratory system and the lower respiratory system.

The Upper Respiratory System

The upper respiratory system, composed of the conducting airways (nose, mouth and pharynx, larynx, and trachea), serves as a passageway for air moving into the lungs and for carbon dioxide moving out to the external environment (Figure 34–1 ■). As air moves through these structures, it is cleaned, filtered, humidified, and warmed.

THE NOSE AND SINUSES

The nose, the external opening of the respiratory system, is given structure by the nasal, frontal, and maxillary bones as well as plates of hyaline cartilage. The nostrils (also called the *external nares*) are two cavities within the nose, separated by the nasal septum. Nasal hairs filter the air as it enters the nares, and secreted mucus not only traps dust and bacteria but also contains lysozyme, an enzyme that destroys bacteria as they enter the nose. As mucus and debris accumulate, mucosal ciliated cells move it toward the pharynx, where it is swallowed. The mucosa is highly vascular, warming air that moves across its surface. The nasal cavity is surrounded by paranasal sinuses (Figure 34–2 ■), located in the frontal, sphenoid, ethmoid, and maxillary bones. Sinuses lighten the skull, assist in speech, and produce mucus that drains into the nasal cavities to help trap debris. The mouth is an alternate airway, used if the nasal passages are plugged or a large intake of air is needed (for example, during strenuous exercise).

THE PHARYNX

The pharynx, a funnel-shaped passageway about 13 cm (5 in.) long, extends from the base of the skull to the level of the C_6 vertebra. The pharynx serves as a passageway for both air and food. It is divided into three regions: the nasopharynx, the oropharynx, and the laryngopharynx.

The nasopharynx serves only as a passageway for air. Masses of lymphoid tissue (the tonsils and adenoids), located in the mucosa high in the posterior wall, trap and destroy infectious agents entering with the air. The eustachian tubes open into the nasopharynx, connecting it with the middle ear. The oropharynx lies behind the oral cavity and extends from the soft palate to the level of the hyoid bone. It serves as a passageway for both air and food. An upward rise of the soft palate prevents food from entering the nasopharynx during swallowing. The laryngopharynx, extending from the hyoid bone to the larynx, serves as a passageway for both food and air.

THE LARYNX

The larynx is about 5 cm (2 in.) long. It provides an airway, routes air and food into the proper passageway, and contains the vocal cords. As long as air is moving through the larynx, its inlet is open; however, the inlet closes during swallowing. The larynx is framed by the thyroid, the cricoid, and the epiglottis cartilages. The thyroid cartilage is formed by the fusion of two cartilages; the fusion point is visible as the Adam's apple. The cricoid cartilage lies below the thyroid cartilage. The epiglottis normally projects upward to the base of the tongue; however, during swallowing, the larynx moves upward and the epiglottis tips to cover the opening to the larynx. If anything other than air enters the larynx, a cough reflex expels the foreign substance before it can enter the lungs. This protective reflex does not work if the person is unconscious.

THE TRACHEA

The trachea begins at the inferior larynx and descends anteriorly to the esophagus to enter the mediastinum, where it divides to become the right and left primary bronchi of the lungs. The trachea is about 12 to 15 cm (4 to 5 in.) long and 2.5 cm (1 in.) in diameter.

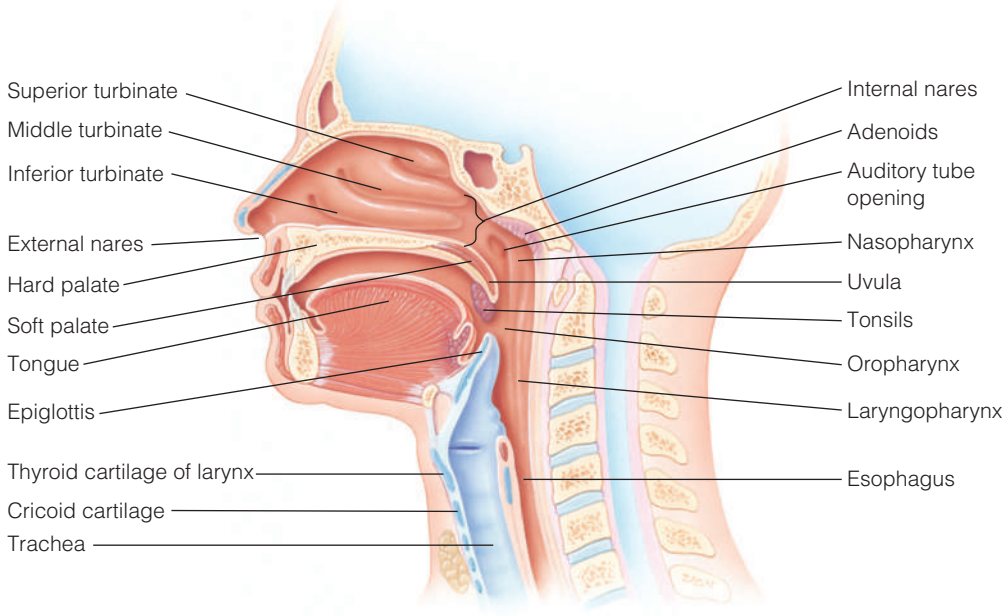

Figure 34–1 ■ The upper respiratory system.

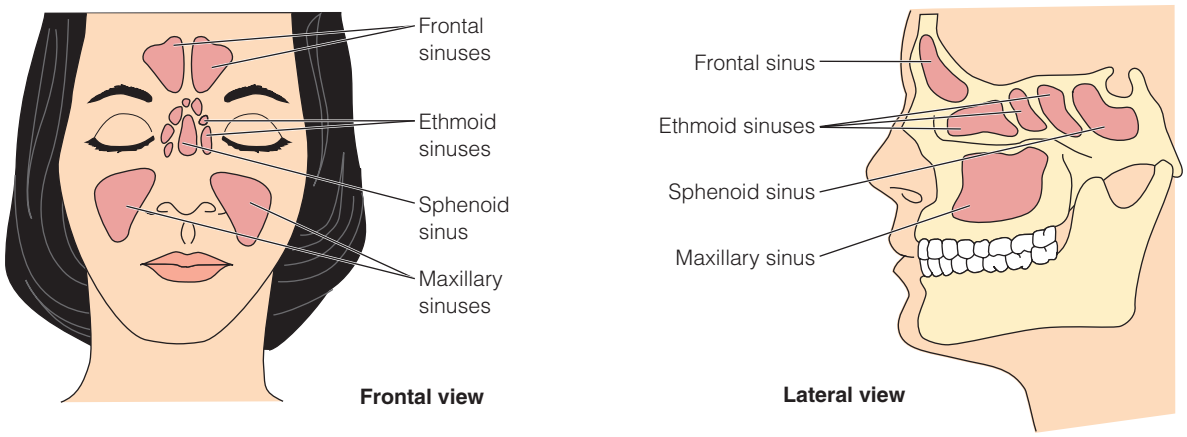

Figure 34–2 ■ Sinuses, frontal and lateral views.

The mucosal lining of the trachea includes seromucous glands that produce thick mucus. Dust and debris in inspired air are trapped in this mucus, moved toward the throat by the cilia, and then either swallowed or coughed out through the mouth.

The Lower Respiratory System

The lower respiratory system includes the lungs, the bronchi, and the bronchioles (Figure 34–3 ■ and Figure 34–4 ■).

THE LUNGS

The center of the thoracic cavity is filled by the mediastinum, which contains the heart, great blood vessels, bronchi, trachea, and esophagus. The mediastinum is flanked on either side by the lungs. Each lung is suspended in its own pleural cavity, with the anterior, lateral, and posterior lung surfaces lying close to the ribs. The hilus, on the mediastinal surface of each lung, is where blood vessels of the pulmonary and circulatory systems and the primary bronchus enter and exit the lungs. The apex of each lung lies just below the clavicle and the base of each lung rests on the diaphragm. The lungs are elastic connective tissue, called *stroma*, and are soft and spongy. The two lungs differ in size and shape. The left lung is smaller and has two lobes, whereas the right lung has three lobes.

The vascular system of the lungs consists of the pulmonary arteries, which deliver blood to the lungs for oxygenation, and the pulmonary veins, which deliver oxygenated blood to the heart. Within the lungs, the pulmonary arteries branch into a pulmonary

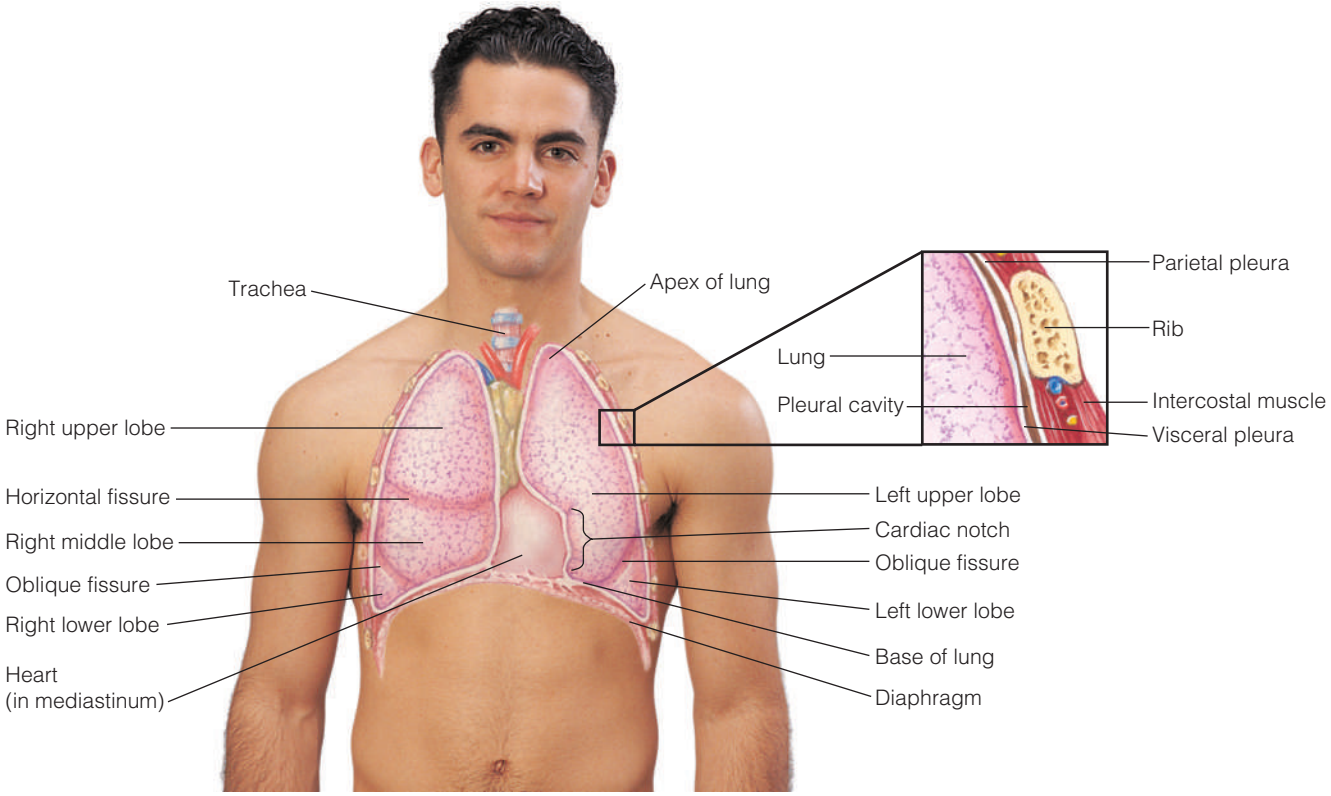

Figure 34–3 ■ The lower respiratory system, showing the location of the lungs, the mediastinum, and layers of visceral and parietal pleura.

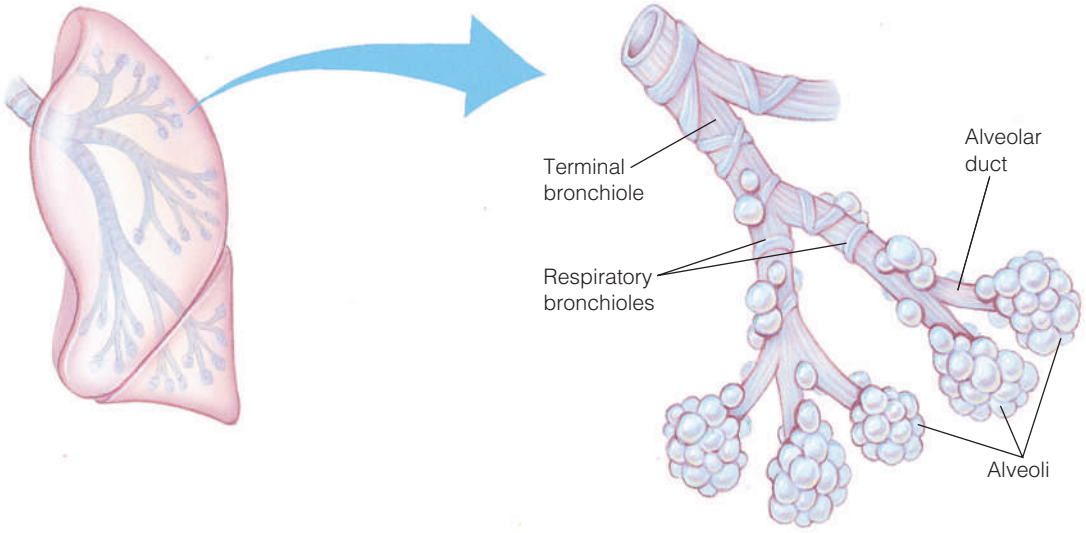

Figure 34–4 ■ Respiratory bronchi, bronchioles, alveolar ducts, and alveoli.

capillary network that surrounds the alveoli. Lung tissue receives its blood supply from the bronchial arteries and drains by the bronchial and pulmonary veins.

THE PLEURA

The pleura is a double-layered membrane that covers the lungs and the inside of the thoracic cavities (refer to Figure 34–3). The parietal pleura lines the thoracic wall and mediastinum. It is continuous with the visceral pleura, which covers the external lung surfaces. The pleura produces pleural fluid, a lubricating, serous fluid that allows the lungs to move easily over the thoracic wall during breathing. The structure of the pleura creates a slightly negative pressure in the pleural space (which is actually a potential rather than an actual space), necessary for lung function.

THE BRONCHI AND ALVEOLI

The trachea divides into right and left primary bronchi; the right primary bronchus is shorter, wider, and situated more vertically (making aspiration of foreign bodies into the right primary bronchus more likely). The point where the trachea divides is innervated with sensory neurons; coughing and bronchospasm may be induced by stimulation of these neurons through activities such as tracheal suctioning, The bronchi subdivide into smaller bronchi, and then into smaller bronchioles, ending in the terminal bronchioles, which are extremely small (refer to Figure 34–4). These branching passageways collectively are called the *bronchial tree*. From the terminal bronchioles, air moves into air sacs, which further branch into alveolar ducts that lead to alveolar sacs and then to the tiny alveoli. During inspiration, air enters the lungs through the primary bronchus and then moves through the increasingly smaller passageways of the lungs to the alveoli, where oxygen and carbon dioxide exchange occurs.

Alveoli cluster around the alveolar sacs, which open into a common chamber called the *atrium*. The adult lung has approximately 300 million alveoli, providing an enormous surface for gas exchange. The walls of alveoli are a single layer of squamous epithelial cells over a very thin basement membrane. The external surface of the alveoli are covered with pulmonary capillaries. The alveolar and capillary walls form the respiratory membrane. Gas exchange across the respiratory membrane occurs by simple diffusion. The alveolar walls also contain cells that secrete a surfactant-containing fluid, necessary for maintaining a moist surface and reducing the surface tension of the alveolar fluid to help prevent collapse of the lungs.

THE RIB CAGE AND INTERCOSTAL MUSCLES

The lungs are protected by the bones of the rib cage and the intercostal muscles. The 12 pairs of ribs articulate with the thoracic vertebrae (Figure 34–5 ■). The sternum has three parts: the manubrium, the body, and the xiphoid process. The spaces between the ribs are called the *intercostal spaces*. Each intercostal space is named for the rib immediately above it (e.g., the space between the third and fourth ribs is designated as the third intercostal space). The intercostal muscles between the ribs, along with the diaphragm, are called the *inspiratory muscles*.

FACTORS AFFECTING RESPIRATION

Many factors affect respiration. Those discussed here include changes in volume and capacity; air pressures; oxygen, carbon dioxide, and hydrogen ion concentrations in the blood; airway resistance, lung compliance, and elasticity; and alveolar surface tension.

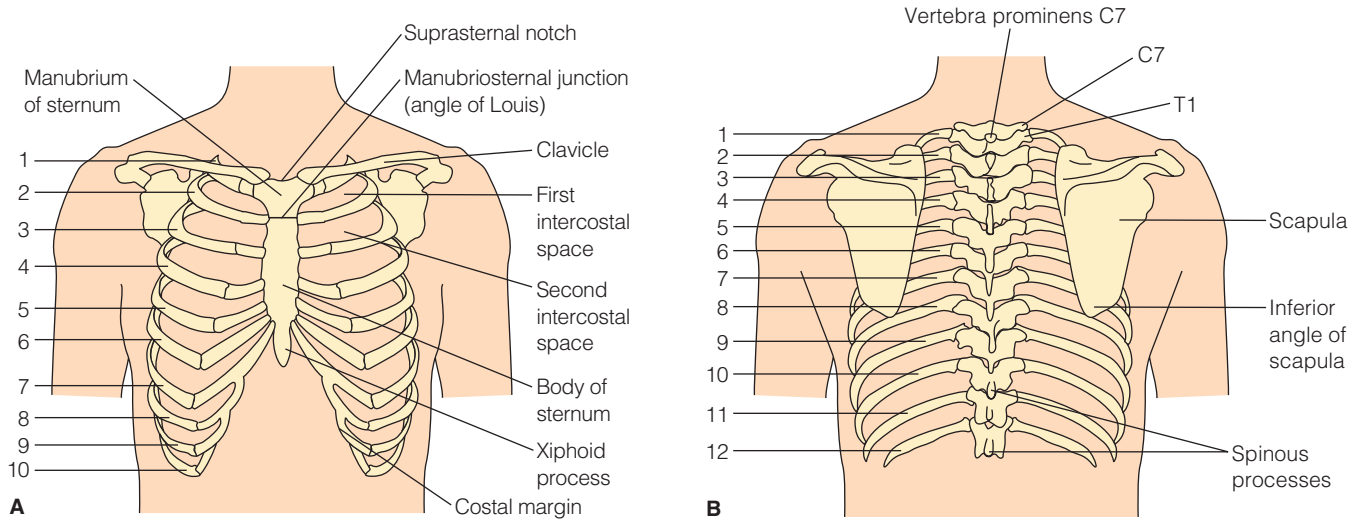
Respiratory Volume and Capacity

Pulmonary function tests measure respiratory volumes and capacities, and are described and illustrated in Box 34–1.

Air Pressures

Ventilation has two phases: inspiration, during which air flows into the lungs; and expiration, during which gases flow out of the lungs. The two phases make up a single breath, and normally occur from 12 to 20 times each minute. A single inspiration lasts for about 1 to 1.5 seconds, whereas expiration lasts for about 2 to 3 seconds.

During inspiration, the diaphragm contracts and flattens to increase the vertical diameter of the thoracic cavity (Figure 34–6 ■).



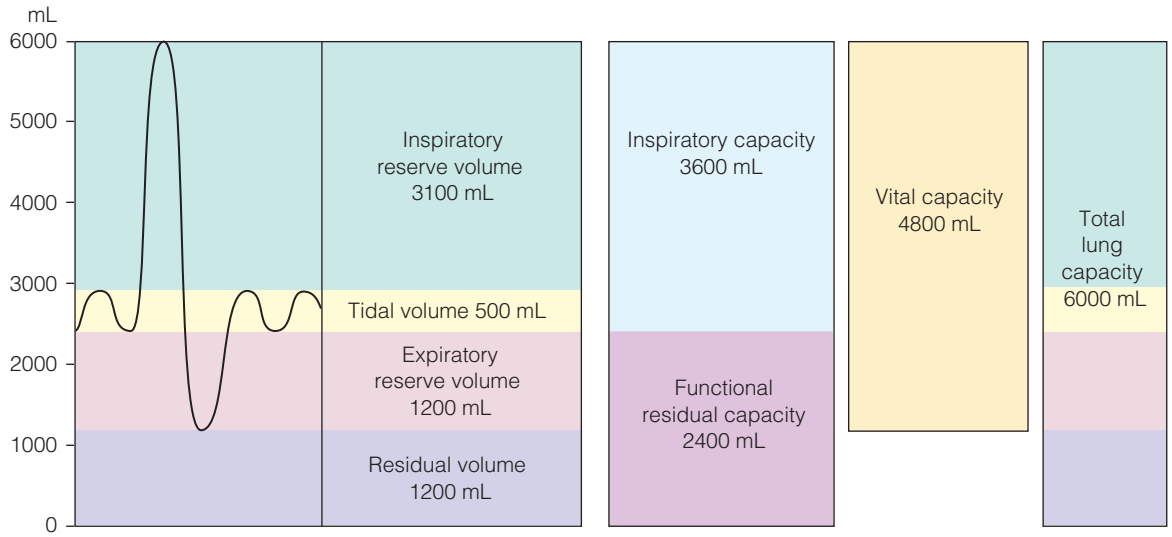


Figure 34–5 ■ A, Anterior rib cage, showing intercostal spaces. B, Posterior rib cage.

BOX 34–1 Pulmonary Function Tests

Pulmonary function tests (PFTs) are performed in a pulmonary function laboratory. After preparing the patient, a nose clip is applied and the patient breathes into a spirometer or body plethysmograph, a device for measuring and recording lung volume in liters versus time in seconds. The patient is instructed on how to breathe for specific tests; for example, to inhale as deeply as possible and then exhale to the maximal extent possible. Using measured lung volumes, respiratory capacities are calculated to assess pulmonary status. The specific values determined by PFT and illustrated in the accompanying figure include the following:

- *Total lung capacity (TLC)* is the total volume of the lungs at their maximum inflation. Four values are used to calculate TLC, with normal values for a healthy adult shown in parentheses:
  a. **Tidal volume (TV)**, the volume inhaled and exhaled with normal quiet breathing (500 mL)
  b. *Inspiratory reserve volume (IRV)*, the maximum amount that can be inhaled over and above a normal inspiration (2000 to 3100 mL)
  c. *Expiratory reserve volume (ERV)*, the maximum amount that can be exhaled following a normal exhalation (1000 mL)
  d. *Residual volume (RV)*, the amount of air remaining in the lungs after maximal exhalation (1100 mL)
- **Vital capacity (VC)** is the total amount of air that can be exhaled after a maximal inspiration. It is calculated by adding together the IRV, TV, and the ERV (4500 mL).
- *Inspiratory capacity* is the total amount of air that can be inhaled following a normal quiet exhalation. It is calculated by adding the TV and IRV.
- *Functional residual capacity (FRC)* is the volume of air left in the lungs after a normal exhalation. The ERV and RV are added to determine the FRC.
- *Forced expiratory volume (FEV_1)* is the amount of air that can be exhaled in 1 second.
- *Forced vital capacity (FVC)* is the amount of air that can be exhaled forcefully and rapidly after maximum air intake.
- *Minute volume (MV)* is the total amount or volume of air breathed in 1 minute.

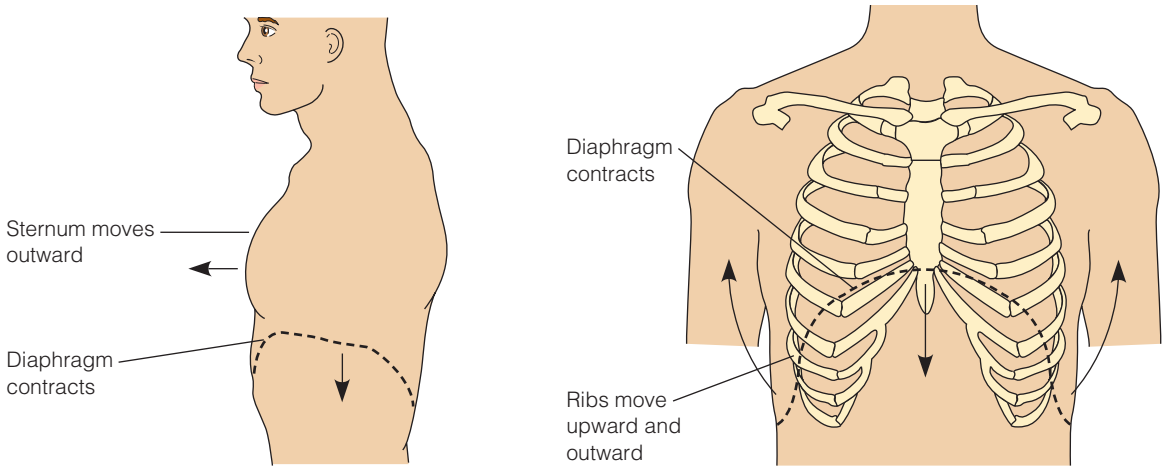

Figure 34–6 ■ Respiratory inspiration: lateral and anterior views. Note the volume expansion of the thorax as the diaphragm flattens.

The external intercostal muscles contract, elevating the rib cage and moving the sternum forward to expand the lateral and anteroposterior diameter of the thoracic cavity, decreasing intrapleural pressure. The lungs stretch and the intrapulmonary volume increases, decreasing intrapulmonary pressure slightly below atmospheric pressure. Air rushes into the lungs as a result of this pressure gradient until the intrapulmonary and atmospheric pressures equalize. In contrast, expiration is primarily a passive process that occurs as a result of the elasticity of the lungs (Figure 34–7 ■). The inspiratory muscles relax, the diaphragm rises, the ribs descend, and the lungs recoil. Both the thoracic and intrapulmonary pressures increase, compressing the alveoli.

Ventilation depends on volume changes within the thoracic cavity. A change in the volume of air in the thoracic cavity leads to a change in the air pressure within the cavity. Because gases always flow along their pressure gradients, a change in pressure results in gases flowing into or out of the lungs to equalize the pressure. The pressures normally present in the thoracic cavity are the intrapulmonary pressure and the intrapleural pressure. The intrapulmonary pressure, within the alveoli of the lungs, rises and falls constantly as a result of inhalation and exhalation. The intrapleural pressure, within the pleural space, also rises and falls with inhalation and exhalation, but it is always less than (or negative to) the intrapulmonary pressure. Intrapulmonary and intrapleural pressures are necessary not only to expand and contract the lungs, but also to prevent their collapse. The intrapulmonary pressure rises to a level greater than atmospheric pressure, and gases flow out of the lungs.

Oxygen, Carbon Dioxide, and Hydrogen Ion Concentrations

The rate and depth of respirations are controlled by respiratory centers in the medulla oblongata and pons of the brain and by chemoreceptors located in the medulla and in the carotid and aortic bodies. The centers and chemoreceptors respond to changes in the concentration of oxygen, carbon dioxide, and hydrogen ions in arterial blood. For example, when carbon dioxide concentration increases or the pH decreases, the respiratory rate increases. This process is further described in Chapter 10.

Airway Resistance, Lung Compliance, and Elasticity

Respiratory passageway resistance, lung compliance, and lung elasticity also affect respiration. Respiratory passageway resistance is created by the friction encountered as gases move along

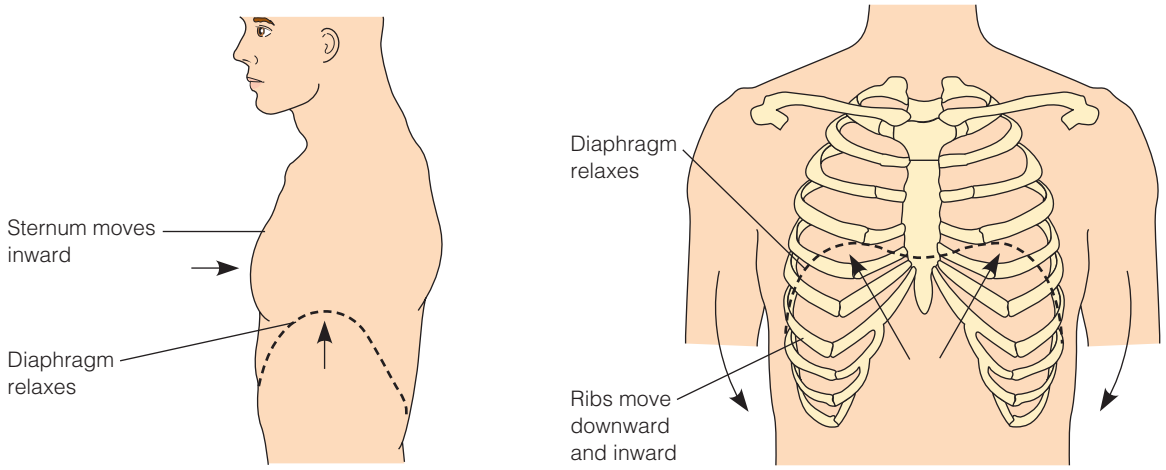

Figure 34–7 ■ Respiratory expiration: lateral and anterior views.

the respiratory passageways, by constriction of the passageways (especially the larger bronchioles), by accumulations of mucus or infectious material, and by tumors. As resistance increases, gas flow decreases. **Lung compliance** is the distensibility of the lungs. It depends on the elasticity of the lung tissue and the flexibility of the rib cage. Compliance is decreased by factors that decrease the elasticity of the lungs, block the respiratory passageways, or interfere with movement of the rib cage. Lung elasticity is essential for lung distention during inspiration and lung recoil during expiration. Decreased elasticity from disease such as emphysema impairs respiration.

Alveolar Surface Tension

A liquid film, primarily composed of water, covers the alveolar walls. At any gas–liquid boundary, the molecules of liquid are more strongly attracted to each other than to gas molecules. This produces a state of tension, called *surface tension*, that draws the liquid molecules even more closely together. The water content of the alveolar film compacts the alveoli and aids in the lungs' recoil during expiration. **Surfactant**, a lipoprotein produced by the alveolar cells, interferes with this adhesiveness of the water molecules, reducing surface tension and helping expand the lungs.

OXYGEN AND CARBON DIOXIDE TRANSPORT

The alveolar and capillary structures of the lungs allow oxygen to be restored to the arterial blood and carbon dioxide to be removed from the venous blood. The blood carries both oxygen and carbon dioxide as dissolved gases and in chemical combination with hemoglobin. In addition, carbon dioxide is changed to and transported as bicarbonate. When arterial blood gases are measured in the practice setting, they are given values that reflect the partial pressure of the gas in the alveoli (PO_2 = partial pressure of oxygen, PCO_2 = partial pressure of carbon dioxide). Arterial blood gases are used for clinical measurement as they reflect the gas exchange function of the alveoli (venous blood reflects the metabolic demands of the tissues). Normally, the PO_2 of arterial blood is greater than 80 mmHg and the PCO_2 of arterial blood ranges from 35 to 45 mmHg. The arterial blood gases reflect the partial pressure of the gas in the alveoli, increasing and decreasing as the alveolar pressure increases and decreases.

Oxygen Transport and Unloading

In the alveoli, oxygen moves to the pulmonary capillaries as a dissolved gas, moving down a concentration gradient. Oxygen is carried in the blood either dissolved or bound to hemoglobin. Because oxygen is relatively insoluble in solution, its ability to bind with hemoglobin is essential. Approximately 98% to 99% of oxygen is transported in the blood combined with hemoglobin as **oxyhemoglobin**; the remaining 1% to 2% is carried in the dissolved state.

Each hemoglobin molecule is made of four polypeptide chains, with each chain bound to an iron-containing heme group. The iron groups are the binding sites for oxygen; each hemoglobin molecule can form a loose and reversible bond with four molecules of oxygen. Oxygen binding is rapid and its affinity to hemoglobin is affected by temperature, blood pH, PO_2, PCO_2, and serum concentration of 2,3-DPG. These factors interact to ensure adequate delivery of oxygen to the cells.

- Under normal conditions, the hemoglobin in arterial blood is almost fully saturated at a PO_2 of 70 mmHg. As arterial blood flows through the capillaries, oxygen is unloaded, so that the oxygen saturation of hemoglobin in venous blood is 75%.
- The affinity of oxygen and hemoglobin decreases as the temperature of body tissues increases above normal. As a result, less oxygen binds with hemoglobin, and oxygen unloading increases. Conversely, as the body is chilled, oxygen unloading decreases.
- The oxygen–hemoglobin bond is weakened by increased hydrogen ion concentrations. As blood becomes more acidotic, oxygen unloading to the tissues increases. The same process occurs when the partial pressure of carbon dioxide increases because this decreases the pH (acid–base balance is discussed in Chapter 10).
- The organic chemical 2,3-DPG is formed in red blood cells and increases the release of oxygen from hemoglobin by binding to it during times of increased metabolism (as when body temperature increases). This binding alters the structure of hemoglobin to facilitate oxygen unloading.

When the blood reaches the capillary level, it is critical that oxygen be able to dissociate from hemoglobin because only dissolved oxygen that is not bound to hemoglobin is able to pass through the capillary wall, diffuse through the cell membrane, and be available for use in cell metabolism. The relation between the oxygen carried in combination with hemoglobin and the PO_2 of the blood can be illustrated by an oxygen–hemoglobin dissociation curve, which demonstrates the release of oxygen from hemoglobin at the tissue capillaries (see Figure 34–8 ■).

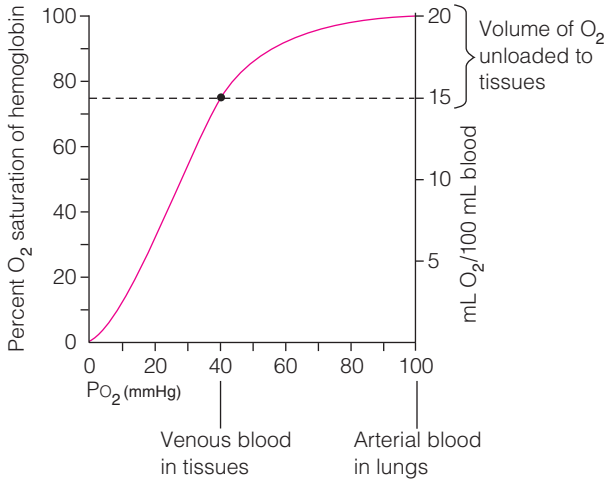

Figure 34–8 ■ Oxygen–hemoglobin dissociation curve. The percent O_2 saturation of hemoglobin and total blood oxygen volume are shown for different oxygen partial pressures (PO_2). Arterial blood in the lungs is almost completely saturated. During one pass through the body, about 25% of hemoglobin-bound oxygen is unloaded to the tissues. Thus, venous blood is still about 75% saturated with oxygen. The steep portion of the curve shows that hemoglobin readily off-loads or on-loads oxygen at PO_2 levels below about 50 mmHg.

Carbon Dioxide Transport

Active cells produce about 200 mL of carbon dioxide each minute; this amount is exactly the same as that excreted by the lungs each minute. Excretion of carbon dioxide from the body requires transport by the blood from the cells to the lungs. Carbon dioxide is transported in three forms: as bicarbonate ions in the plasma (the largest amount is in this form), dissolved in plasma, and bound to hemoglobin.

The amount of carbon dioxide transported in the blood is strongly influenced by the oxygenation of the blood. When the PO_2 decreases, with a corresponding decrease in oxygen saturation, increased amounts of carbon dioxide can be carried in the blood. Carbon dioxide entering the systemic circulation from the cells causes more oxygen to dissociate from hemoglobin, in turn allowing more carbon dioxide to combine with hemoglobin and more bicarbonate ions to be generated. This situation is reversed in the pulmonary circulation, where the uptake of oxygen facilitates the release of carbon dioxide.

ASSESSING RESPIRATORY FUNCTION

Function of the respiratory system is assessed by findings from diagnostic tests, genetic considerations, a health assessment interview to collect subjective data, and a physical assessment to collect objective data.

Diagnostic Tests

The results of diagnostic tests of respiratory function are used to support the diagnosis of a specific disease, to provide information to identify or modify the appropriate medications or therapy used to treat the disease, and to help nurses monitor the patient's responses to treatment and nursing care interventions. Diagnostic tests to assess the structures and functions of the respiratory system are described in the Diagnostic Tests table. More information is included in the discussion of specific disorders in Chapters 35, 36, and 37.

Regardless of the type of diagnostic test, the nurse is responsible for explaining the procedure and any special preparation needed, assessing for medication use that may affect the outcome of the tests, supporting the patient during the examination as necessary, ensuring the consent form is signed (if necessary), documenting the procedures as appropriate, and monitoring the results of the tests.

Genetic Considerations

When conducting a health assessment interview and a physical assessment, the nurse should consider genetic influences on the health of the adult. During the health assessment interview, ask about family members with health problems affecting respiratory function. In addition, ask about a family history of emphysema, asthma, cystic fibrosis, or lung cancer. During the physical assessment, assess for any manifestations that might indicate a genetic disorder (see the Genetic Considerations box). If data are found to indicate genetic risk factors or alterations, ask about genetic testing and refer for appropriate genetic counseling and evaluation. Chapter 8 provides further information about genetics in medical-surgical nursing.

GENETIC CONSIDERATIONS

Examples of Respiratory Disorders

- Deficiency of alpha$_1$-antitrypsin (a protein that protects the body from damage by its immune cells) is caused by a mutation of a gene located on chromosome 14. Deficiency of this protein leaves the lung susceptible to emphysema.
- Asthma, a disease that affects more than 5% of the population, is an inheritable disease with a number of responsible genes. (There are other causes of asthma.)
- Cystic fibrosis is the most common fatal genetic disease in the United States today. All gene defects result in defective transport of chloride and sodium by epithelial cells. As a result, the amount of sodium chloride is increased in body secretions. Thick mucus is produced that clogs the lungs, leads to infection, and blocks pancreatic enzymes from reaching the intestines to digest food.
- A familial history of lung cancer increases the risk of developing lung cancer, and small-cell lung cancer has a definite genetic component. In addition, researchers have found that patients with lung cancer who never smoked are more likely than smokers to have one of two genetic mutations linked to the disease.

Health Assessment Interview

A health assessment interview to determine problems with respiratory structure and function may be conducted during a health screening, may focus on a chief complaint (such as shortness of breath), or may be part of a total health assessment. If the patient has a problem with respiratory function, analyze its onset, characteristics, course, severity, precipitating and relieving factors, and any associated symptoms, noting the timing and circumstances. For example, ask the patient the following:

- Describe the problems you are having with your breathing. Is your breathing more difficult if you lie flat? Is it painful to breathe in or out?
- When did you first notice that your cough was becoming a problem? Do you cough up mucus? What color is the mucus?
- Have you had nosebleeds in the past?

During the interview, carefully observe the patient for difficulty in breathing, pausing to breathe in the middle of a sentence, hoarseness, changes in voice quality, and cough. Ask about present health status, medical history, family health history, and risk factors for illness. To determine present health status, ask about pain in the nose, throat, or chest. Information about cough includes what type of cough (for example: dry, constant, worse at night, painful), when it occurs, and how it is relieved. The patient should describe any sputum associated with the cough. Is the patient experiencing any dyspnea (difficult or labored breathing)? How is the dyspnea associated with activity levels and time of day? Is the patient having chest pain? How is this related to activity and time of day? Note the severity, type, and location of the pain. Explore problems with swallowing, smelling, or taste. Ask about nosebleeds and nasal or sinus stuffiness or pain, and about current medication use, aerosols or inhalants, and oxygen use.

Document past medical history by asking questions about a history of allergies, asthma, bronchitis, emphysema, pneumonia, tuberculosis, or congestive heart failure. Other questions include a history of surgery or trauma to the respiratory structures and a history of other chronic illnesses such as cancer, kidney disease, and heart disease. If the patient has a health problem involving the respiratory system, ask about medications used to relieve nasal congestion,

DIAGNOSTIC TESTS of the Respiratory System

Name of Test	Purpose and Description	Related Nursing Interventions
Arterial blood gases (ABGs)	This test of arterial blood is done to assess alterations in acid–base balance caused by a respiratory disorder, a metabolic disorder, or both. A pH of less than 7.35 indicates acidosis and a pH of more than 7.45 indicates alkalosis (see Chapter 10). To determine a respiratory cause, assess the $PaCO_2$: If pH is decreased and $PaCO_2$ is increased, respiratory acidosis is indicated. Normal values: pH: 7.35–7.45 $PaCO_2$: 35–45 mmHg PaO_2: 75–100 mmHg HCO_3: 22–26 mEq/L BE: ± 2 meq/L	Arterial blood is collected in a heparinized needle and syringe. Notify the person collecting the blood sample if the patient is taking anticoagulants or aspirin, or has a clotting problem. The sample is placed on an ice-water bag and taken immediately to the lab. If patient is receiving oxygen, indicate the type, flow rate, administration device, and patient's temperature on lab slip. Apply pressure to puncture site for 5 minutes or longer if needed (for example, taking anticoagulants or streptokinase). Do not collect blood from the same arm used for an IV infusion.
Biopsy of the lung	A biopsy of the lung is done to obtain tissue to differentiate benign from malignant tumors of the lungs. The biopsy may be done during a bronchoscopy, or by surgical procedure.	Same as bronchoscopy or the same as a thoracotomy (incision through the chest wall) if a surgical biopsy is performed.
Bronchoscopy	A bronchoscopy is the direct visualization of the larynx, trachea, and bronchi through a bronchoscope to identify lesions, remove foreign bodies and secretions, obtain tissue for biopsy, and improve tracheobronchial drainage (Figure 34–9 ■). The bronchoscope (in most cases, a fiberoptic scope) is passed through the nose or mouth and into the trachea. During the test, a catheter brush or biopsy forceps can be passed to obtain secretions or tissue for examination for cancer. The test is done in the hospital, and may be done at the bedside, in a special procedure room, or in the surgical suite.	Assess for pregnancy and hypersensitivity to anesthetics, antibiotics, iodine, or contrast dyes; if present, notify the physician. Tell the patient not to eat or drink fluids for 8–12 h before the test. Remove dentures, contact lenses, and jewelry. Assess and record vital signs. Administer ordered premedications. After the procedure, assess for complications (laryngeal edema, bronchospasm, pneumothorax, cardiac dysrhythmias, and bleeding). Monitor for manifestations of respiratory difficulty (dyspnea, decreased breath sounds, decreased O_2 saturation) and hemoptysis (bloody sputum). Assess if the gag reflex is present before beginning food or fluids. Instruct the patient not to smoke for 6–8 h after the procedure because smoking may cause coughing and bleeding. Tell the patient it is normal to have some blood-tinged sputum, hoarseness, and/or a sore throat, but to notify the physician of any bleeding, pain, or respiratory difficulty.
Chest x-ray	Chest x-rays are used to identify abnormalities in chest structure and lung tissue, for diagnosis of diseases and injuries of the lungs, and to monitor treatment.	No special preparation is needed.

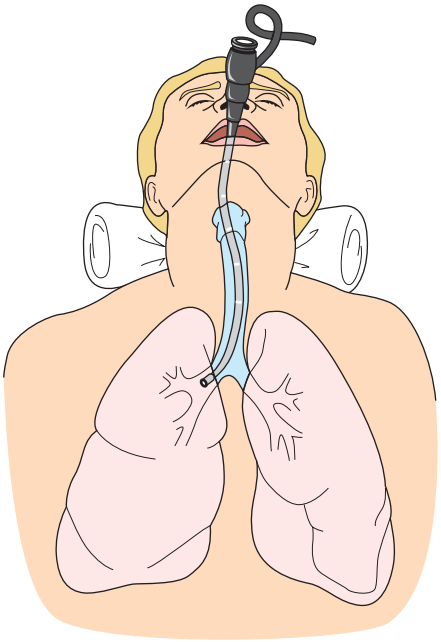

Figure 34–9 ■ Fiberoptic bronchoscopy.

(*continued*)

DIAGNOSTIC TESTS of the Respiratory System (*continued*)

Name of Test	Purpose and Description	Related Nursing Interventions
CT scan of the thorax	CT of the thorax may be performed when x-rays do not show some areas well, such as the pleura and mediastinum. It is also done to differentiate pathologic conditions (such as tumors, abscesses, and aortic aneurysms), to identify pleural effusion and enlarged lymph nodes, and to monitor treatment. Images are shown in cross section.	If contrast dye is used, inform patient to not take oral food or fluids for 4 h before the test; if dye is not used, there are no food or fluid restrictions. Assess for allergies to iodine (for example, to shellfish or previous procedures) and, if present, notify the physician; medications such as diphenhydramine (Benadryl) and ranitidine (Zantac) may be given 1 h before the procedure. Assess medications: Oral hypoglycemic agents (including metformin) are contraindicated for use with iodinated contrast. Instruct the patient to increase oral fluid intake after the examination.
Magnetic resonance imaging (MRI) of the thorax	An MRI of the thorax is used to diagnose alterations in lung tissue that are more difficult to visualize by CT scan and to identify abnormal masses and fluid accumulation.	Inform patient of need to lie still during the examination. Assess for any metallic implants (such as pacemakers, clips on brain aneurysms, body piercing, tattoos, shrapnel). If present, notify imaging physician. Remove transdermal medication patches (both over-the-counter and prescribed) unless otherwise ordered (U.S. Food and Drug Administration, 2009). Replace the patch following the procedure. Tell the patient to inform the staff about the patch when making the appointment and when completing the admission information. Ask if patient is pregnant; if so, the test is not performed. Ask about claustrophobia; if it is a problem, request the patient to ask for a relaxing medication to take prior to the MRI.
Pulmonary angiography (angiogram)	This test, conducted in the hospital setting, is done to identify pulmonary emboli, tumors, aneurysms, vascular changes associated with emphysema, and pulmonary circulation. A catheter is inserted into the brachial or femoral artery, threaded into the pulmonary artery, and then dye is injected. ECG leads are applied to the chest for cardiac monitoring. Images of the lungs are taken.	Assess for hypersensitivity to iodine, seafood, or previous procedures using contrast dye. Take and record baseline vital signs. After the procedure, apply pressure to the injection site for 5–10 min (or until bleeding has stopped). Enforce bed rest for 12–24 h as ordered. Monitor vital signs, injection site, and peripheral pulses distal to the site after the test. Tell patient that coughing is a common occurrence after this test.
Pulmonary ventilation scan (V/Q scan)	This test is performed with two nuclear scans to measure breathing (ventilation) and circulation (perfusion) in all parts of the lungs. A ventilation scan is performed by scanning the lungs as the patient inhales radioactive gas. A perfusion scan is performed by injecting radioactive albumin into a vein and scanning the lungs. A decreased uptake of radioisotope during the perfusion scan indicates a blood flow problem, such as from a pulmonary embolus or pneumonitis. A decreased uptake of gas during the ventilation scan may indicate airway obstruction, pneumonia, or chronic pulmonary obstructive disease (COPD).	Tell the patient to remove all jewelry from the neck and chest.
Pulse oximetry	This noninvasive test is used to evaluate or monitor oxygen saturation of the blood. A device that uses infrared light is attached to an extremity (most commonly the finger, but can be used on the toe, earlobe, or nose) and light is passed through the tissues or reflected off bony structures. Normal value: 90%–100%	Assess for factors that may alter findings, including faulty placement, movement, dark skin color, and acrylic nails. Light may affect the readings; the area of application should be shielded from external light sources.
Positron emission tomography (PET)	This relatively noninvasive test, when used to examine the lungs, is performed to identify lung nodules (cancers). The patient is given a radioactive substance and cross-sectional images are displayed on a computer.	Tell the patient that no alcohol, coffee, or tobacco is allowed for 24 h prior to the test. Encourage increased fluid intake post-test to help eliminate the radioactive material.

DIAGNOSTIC TESTS of the Respiratory System (*continued*)

Name of Test	Purpose and Description	Related Nursing Interventions
Sputum studies: • Culture and sensitivity • Acid-fast smear and culture • Cytology	Culture and sensitivity of a single sputum specimen is done to diagnose bacterial infections, identify the most effective antibiotic, and evaluate treatment. Sputum is examined for presence of acid-fast bacillus, specifically tuberculosis. A series of three early-morning sputum specimens is used. Sputum is examined for presence of abnormal (malignant) cells. A single sputum specimen is collected in a special container of fixative solution.	Instruct the patient to collect the specimen early in the morning. Explain that the sputum should come from deep in the lungs; take two or three deep breaths, and then cough the specimen into a sterile container. Sputum specimens may be obtained by a respiratory therapist or during bronchoscopy (described earlier) if the patient is unable to provide a specimen.
Thoracentesis	A thoracentesis is done to obtain a specimen of pleural fluid for diagnosis (and used as a procedure to remove pleural fluid or instill medication). A large-bore needle is inserted through the chest wall and into the pleural space. Following the procedure, a chest x-ray is taken to check for a pneumothorax.	Nursing care of the patient having a thoracentesis is provided in Chapter 36.

cough, dyspnea, or chest pain. Document a family history of allergies, tuberculosis, emphysema, and cancer.

The patient's personal lifestyle, environment, and occupation may provide clues to risk factors for actual or potential health problems. Question the patient about a history of smoking and/or exposure to environmental chemicals (including smog), dust, vapors, animals, coal dust, asbestos, fumes, or pollens. Other risk factors include a sedentary lifestyle and obesity. Ask the patient about use of alcohol and substances that are injected (such as heroin) or inhaled (such as cocaine or marijuana).

Physical Assessment

Physical assessment of the respiratory system may be performed either as part of a total assessment, or alone for a patient with known or suspected problems. The techniques used to assess the respiratory system are inspection, palpation, percussion, and auscultation. In addition, note the patient's level of consciousness, restlessness, and anxiety level, and assess the color of the lips and nail beds. Normal age-related findings for the older adult are summarized in the Nursing Care of the Older Adult box.

The room should be warm and well lighted. Ask the patient to remove all clothing above the waist; give women a gown to wear during the examination. Conduct the examination with the patient in the sitting position. Prior to the examination, collect all necessary equipment and explain the techniques to the patient to decrease anxiety.

NURSING CARE OF THE OLDER ADULT

Age-Related Changes in the Respiratory System

Age-Related Change	Significance
• ↓ elastic recoil of lungs during expiration because of less elastic collagen and elastin. • Calcification of the costal cartilage and weakening of the intercostal muscles. • Loss of skeletal muscle strength in the thorax and diaphragm. Flattening of the diaphragm. • Alveoli are less elastic, more fibrotic, and have fewer functional capillaries. • Cough is less effective. • PO_2 reduces as much as 15% by age 80.	The older adult often has an increased anterior-posterior chest diameter, with kyphosis and barrel chest. There is a reduction in vital capacity and an increase in residual volume, with decreased effectiveness in coughing up phlegm or sputum. All of these changes greatly increase the risk of respiratory infections (such as pneumonia), especially if the person becomes immobile. They also mean that respiratory infections are more difficult to treat.

Respiratory Assessments

Technique/Normal Findings	Abnormal Findings
Nasal Assessment	
Inspect the nose for changes in size, shape, or color. *The nose should be midline in the face, of the same color as the face, and the nares should be symmetric.*	• The nose may be asymmetrical as a result of previous surgery or trauma. • The skin around the nostrils may be red and swollen in allergies or upper respiratory infections.
Inspect the nasal cavity. Use an otoscope with a broad, short speculum. Gently insert the speculum into each of the nares and assess the condition of the mucous membranes and the turbinates. *The septum should be midline with pink mucosa and without drainage.*	• The septum may be deviated. • Perforation of the septum may occur with chronic cocaine abuse. • Red mucosa indicates infection. • Purulent drainage indicates nasal or sinus infection. • Watery nasal drainage, pale turbinates, and polyps on the turbinates may indicate allergies.

(*continued*)

Respiratory Assessments (*continued*)

Technique/Normal Findings	Abnormal Findings
Assess ability to smell (cranial nerve I, olfactory). Ask the patient to breathe through one nostril while pressing the other one closed. Ask the patient to close his or her eyes. Place a substance with an aromatic odor under the patient's nose (use ground coffee or alcohol) and ask the patient to identify the odor. Test each nostril separately. *This test is usually done only if the patient has problems with the sense of smell, but the patient should be able to distinguish different odors.*	• Changes in the ability to smell may be the result of damage to the olfactory nerve or to chronic inflammation of the nose. • Zinc deficiency may cause a loss of the sense of smell.
Sinus Assessment	
Palpate the frontal and maxillary sinuses. *The sinuses should not be tender to palpation.*	• Frontal and maxillary sinuses are tender to palpation with allergies or sinus infections.
Thoracic Assessment	
Assess respiratory rate. *The normal respiratory rate is 12 to 20 breaths per minute.*	• **Tachypnea** (rapid respiratory rate) is seen in **atelectasis** (collapse of lung tissue following obstruction of the bronchus or bronchioles), pneumonia, asthma, pleural effusion, pneumothorax, congestive heart failure, anxiety, and in response to pain. • Damage to the brainstem from a stroke or head injury may result in either tachypnea or **bradypnea** (low respiratory rate). • Bradypnea is seen with some circulatory disorders, lung disorders, and as a side effect of some medications. • **Apnea**, cessation of breathing lasting from a few seconds to a few minutes, may occur following a stroke or head trauma, as a side effect of some medications, or following airway obstruction.
Inspect the anteroposterior diameter of the chest. The anteroposterior diameter of the chest should be less than the transverse diameter. *Normal ratio is 1:2.*	• The anteroposterior diameter is equal to the transverse diameter in barrel chest, which typically occurs with emphysema.
Inspect for intercostal retraction or bulging. *There should be no retraction or bulging.*	• Retraction of intercostal spaces may be seen in asthma. • Bulging of intercostal spaces may be seen in pneumothorax.
Inspect and palpate for chest expansion. Place your hands with the fingers spread apart palm down on the patient's posterolateral chest. Gently press the skin between your thumbs (Figure 34–10 ■). Ask the patient to breathe deeply. As the patient inhales, watch your hands for symmetry of movement. *Chest expansion should be bilaterally symmetric, with the examiner's hands moving 5 to 10 cm (2 to 4 in.) apart.*	• Thoracic expansion is decreased on the affected side in atelectasis, pneumonia, pneumothorax, and pleural effusion. • Bilateral chest expansion is decreased in emphysema.
Gently palpate the location and position of the trachea. *The trachea should be midline.*	• The trachea shifts to the unaffected side in pleural effusion and pneumothorax; it shifts to the affected side in atelectasis.

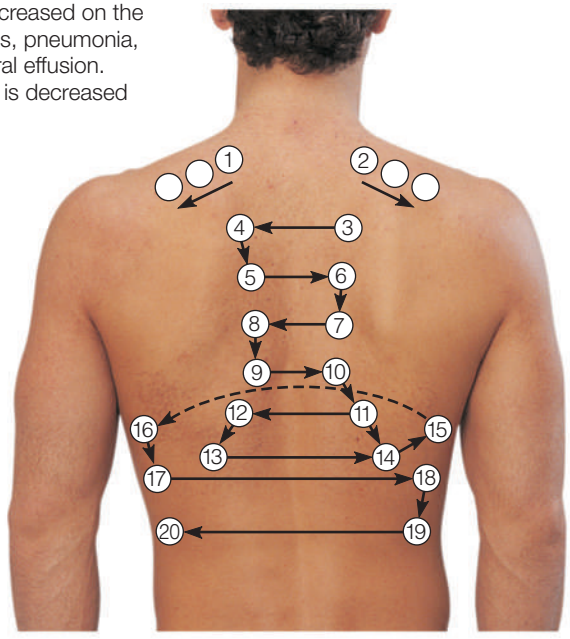

Figure 34–10 ■ Palpating for chest expansion.

Respiratory Assessments (*continued*)

Technique/Normal Findings	Abnormal Findings
Percuss the lungs for dullness over shoulder apices and over anterior, posterior, and lateral intercostal spaces (Figure 34–11 ■). *The normal percussion tone over normal lung tissue is resonance.*	• Dullness is heard in patients with atelectasis, lobar pneumonia, and pleural effusion. • Hyperresonance is heard in those with chronic asthma, emphysema, and pneumothorax.

Figure 34–11 ■ Sequence for lung percussion.

Percuss the posterior chest for diaphragmatic excursion. Systematic percussion of the posterior chest from a level of lung resonance to the level of diaphragmatic dullness reveals diaphragmatic excursion, a measurement of the level of the diaphragm. First percuss downward over the posterior thorax while the patient exhales fully and holds the breath. Mark the spot at which the sound changes from resonant to dull. Then ask the patient to inhale and hold the breath while you percuss downward again to note the descent of the diaphragm. Again mark the spot where the sound changes. Measure the difference. *Diaphragmatic excursion normally varies from about 3 to 5 cm (about 1 to 2 in.) (Figure 34–12 ■).*	• Diaphragmatic excursion is decreased in emphysema, ascites, on the affected side in pleural effusion, and in pneumothorax. • A high level of dullness or a lack of excursion may indicate atelectasis or pleural effusion.

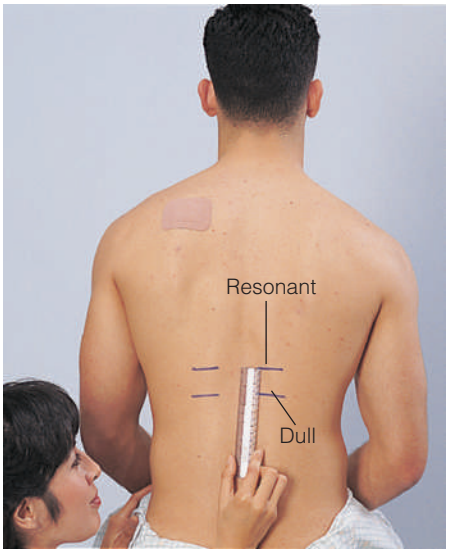

Figure 34–12 ■ Measuring diaphragmatic excursion.

(*continued*)

Respiratory Assessments (*continued*)

Technique/Normal Findings	Abnormal Findings

Breath Sound Assessment

Auscultate the lungs for breath sounds with the diaphragm of the stethoscope by having the patient take slow deep breaths through the mouth. Listen over anterior, posterior, and lateral intercostal spaces (Figure 34–13 ■). *The three different types of normal breath sounds are vesicular, bronchovesicular, and bronchial (Table 34–1).*

- Bronchial breath sounds (expiration > inspiration) and bronchovesicular breath sounds (inspiration = expiration) are heard over lungs filled with fluid or solid tissue.
- Breath sounds are decreased or diminished over atelectasis, emphysema, asthma, pleural effusion, and pneumothorax.
- Breath sounds are increased over lobar pneumonia.
- Breath sounds are absent over collapsed lung, surgical removal of lung, pleural effusion, and primary bronchus obstruction.

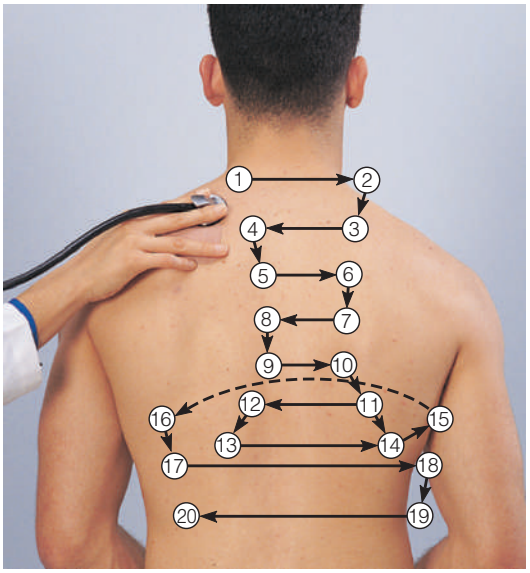

Figure 34–13 ■ Sequence for lung auscultation.

Auscultate for crackles, wheezes, and friction rubs. If crackles or wheezes are heard, ask the patient to cough and note if adventitious sound is cleared. *Normally, crackles, wheezes, and friction rubs are not present.*

- **Crackles** (short, discrete, crackling or bubbling sounds) may be noted in pneumonia, bronchitis, and congestive heart failure.
- **Wheezes** (continuous, musical sounds) may be heard in patients with bronchitis, emphysema, and asthma.
- A **friction rub** is a loud, dry, creaking sound that indicates pleural inflammation.

TABLE 34–1 Normal Breath Sounds

Type of Breath Sound	Characteristics
Vesicular	• Soft, low-pitched, gentle sounds • Heard over all areas of the lungs except the major bronchi • Have a 3:1 ratio for inspiration and expiration, with inspiration lasting longer than expiration
Bronchovesicular	• Medium pitch and intensity of sounds • Have a 1:1 ratio, with inspiration and expiration being equal in duration • Heard anteriorly over the primary bronchus on each side of the sternum, and posteriorly between the scapulae
Bronchial	• Loud, high-pitched sounds • Gap between inspiration and expiration • Have a 2:3 ratio for inspiration and expiration, with expiration longer than inspiration • Heard over the manubrium

SAMPLE DOCUMENTATION

Assessment of the Lungs

57-year-old male, history of smoking 2 packs cigarettes/day for 37 years; continues to smoke despite previous discussions. Works as a dry-wall installer. No family history of cancer or TB. States he has trouble breathing, especially at night. Often sleeps on a recliner "to breathe better." Complains of a cough, but denies sputum production. Diagnosed 3 years ago with emphysema. Color of face is dusky red. Fingernails pink. Respirations 30/min, unlabored, regular (R varies from 26 to 32 on visits to the clinic). Thoracic assessment = intercostal bulging, barrel chest, diminished lung sounds bilaterally in lower lobes. Crackles present in upper lobes, not cleared by coughing. Discussed possible use of low-flow nasal oxygen at night to help with breathing; will check with primary provider.

CHAPTER HIGHLIGHTS

- **Correct structure and function of the respiratory system is vital to ventilation, resulting in oxygenation of all body tissues.**
- **Manifestations of dysfunction, injury, and disorders affecting the respiratory system may be detected during a general health assessment as well as during a focused respiratory system assessment.**
- Normal anatomy, physiology, and functions of the upper and lower respiratory systems are the basis for assessment.
- Both general health and focused pulmonary system assessments can detect dysfunction, injury, and disorders.
- Assessment of the pulmonary system includes diagnostic tests, genetic considerations, a health interview, and a physical assessment.

TEST YOURSELF NCLEX-RN® REVIEW

1. The nurse is assessing breath sounds. Where should the nurse place the diaphragm of the stethoscope to listen to the apex of the left lungs?
1. in the mediastinum
2. just below the clavicle
3. within the parietal pleura
4. resting on the diaphragm

2. The nurse is concerned that a patient is at risk for developing lung cancer. What risk factor did the nurse most likely assess in this patient?
1. childhood obesity
2. family history of asthma
3. family history of lung cancer
4. frequent upper respiratory infections

3. Prior to providing care to a patient, the nurse reviews the previous day's vital sign assessments and notes that bronchovesicular breath sounds were documented. What should the nurse do next?
1. Notify the physician.
2. Measure and record vital signs as usual.
3. Request a respiratory therapy treatment.
4. Document the inability to hear breath sounds.

4. The nurse notes that a patient has an elevated body temperature. What process is initiated between oxygen and hemoglobin as the temperature of body tissues increases?
1. Respiratory rate decreases.
2. Lung compliance increases.
3. Oxygen unloading is inhibited.
4. Oxygen unloading is enhanced.

5. The nurse is teaching a patient about a thoracentesis. What should the nurse include in this teaching? (Select all that apply.)
1. Fluid is removed from around the lung.
2. A chest x-ray is done after the procedure.
3. A needle is inserted through the chest wall.
4. General anesthesia is used for the procedure.
5. Strict bed rest is required for 2 hours afterwards.

6. The nurse is completing a respiratory assessment with a patient. Which question should be included to identify health problems?
1. "Tell me how much you exercise each day."
2. "Do your children have trouble breathing at night?"
3. "What did the doctor recommend for your emphysema?"
4. "Has anyone in your family had a stroke or heart attack?"

7. While auscultating a patient's breath sounds, the nurse notes continuous musical sounds. How should the nurse document this finding?
1. crackles
2. wheezes
3. murmurs
4. friction rub

8. While reviewing a patient's assessments, the nurse notes an absence of right-sided breath sounds. Which information in the health history would explain this assessment finding?
1. right lung removed
2. history of tuberculosis
3. pneumonia 10 years ago
4. diagnosed with childhood asthma

9. The nurse is preparing to auscultate a patient's lung sounds. What direction should the nurse provide when making this assessment? (Select all that apply.)
1. "Hold your breath."
2. "Take slow deep breaths."
3. "Breathe through your nose."
4. "Breathe through an opened mouth."
5. "Repeat the number 99 several times."

10. While assessing a patient with a left pneumothorax, the nurse notes decreased diaphragmatic excursion on the left. What should the nurse do next?
1. Document the assessment.
2. Notify the physician immediately.
3. Repeat the assessment several times.
4. Tell the patient to hold his or her breath.

See Test Yourself answers in Appendix B.

35 Nursing Care of Patients with Upper Respiratory Disorders

LEARNING OUTCOMES

1. Relate the anatomy and physiology of the upper respiratory tract to commonly occurring disorders and risk factors for these disorders.
2. Describe the pathophysiology of common upper respiratory tract disorders, relating their manifestations to the pathophysiologic process.
3. Discuss nursing implications for medications and other interprofessional care measures to treat upper respiratory disorders.
4. Describe surgical procedures used to treat upper respiratory disorders and their implications for patient care and recovery.
5. Identify health promotion activities related to reducing the incidence of upper respiratory disorders, describing the appropriate population and setting for implementing identified measures.
6. Discuss treatment options for oral and laryngeal cancers with their implications for the patient's body image and functional health.

CLINICAL COMPETENCIES

1. Assess functional health status of patients with upper respiratory disorders, using data to identify and prioritize holistic nursing care needs.
2. Use nursing research and evidence-based practice to plan and implement nursing care for patients with upper respiratory disorders.
3. Provide safe and effective nursing care for patients having surgery involving the upper respiratory system and/or with a tracheostomy.
4. Safely administer medications and prescribed treatments for patients with disorders of the upper respiratory tract.
5. Provide appropriate teaching for the patient and family affected by upper respiratory tract disorders.
6. Evaluate the effectiveness of care, reassessing and modifying the plan of care as needed to achieve desired patient outcomes.

MAJOR CHAPTER CONCEPTS

- Influenza is differentiated from an upper respiratory infection primarily by the presence of systemic manifestations, the duration and degree of fever, and the presence of persistent cough.
- The incidence of pertussis, a highly contagious reportable disease, is increasing due to waning immunity, decreased rates of childhood pertussis immunizations, and improved identification of the infection among adults.
- Epistaxis (nosebleed) and nasal fracture are relatively common, and pose a risk only when airway clearance is impaired.
- Persistent voice hoarseness is the primary manifestation of laryngeal cancer.
- Following total laryngectomy, a permanent tracheostomy is created and the upper trachea and esophagus are separated, preventing aspiration when feedings are resumed.

Upper respiratory disorders may affect the nose, paranasal sinuses, tonsils, adenoids, larynx, and pharynx, including nasopharynx and oropharynx. A patent (open and clear) upper airway is necessary for effective breathing. Upper respiratory disorders, such as the common cold, may be minor. However, acute and even life-threatening problems develop when upper airway patency is affected (e.g., by laryngeal edema). Upper respiratory disorders can affect breathing, communication, eating, swallowing, and body image. When breathing is compromised because of swelling, bleeding, or accumulation of secretions, fear and anxiety develop.

Nursing care focuses on maintaining the airway, managing pain and symptoms, promoting effective communication, and providing psychologic support for the patient and family.

Infectious or Inflammatory Disorders

Constant exposure of the upper respiratory tract to the environment makes it vulnerable to a variety of infectious and inflammatory conditions. Although most upper respiratory infections and inflammations are minor, complications may result. In the frail older adult, the risk of serious problems following an upper respiratory infection can be significant.

Rhinitis, inflammation of the nasal cavities, is the most common upper respiratory disorder. Rhinitis may be either acute or chronic. *Acute viral rhinitis*, or the common cold, is discussed next. Chronic rhinitis includes allergic, vasomotor, and atrophic rhinitis. *Allergic rhinitis*, or hay fever, results from a sensitivity reaction to allergens such as plant pollens. It tends to occur seasonally but can be perennial. The etiology of *vasomotor rhinitis* is unknown. Although its manifestations are similar to those of allergic rhinitis, it is not linked to allergens. *Atrophic rhinitis* is characterized by changes in the mucous membrane of the nasal cavities.

THE PATIENT WITH VIRAL UPPER RESPIRATORY INFECTION

Viral upper respiratory infections (URIs or the common cold) are the most common respiratory tract infections and are among the most common human diseases. URIs are highly contagious and are prevalent in schools and work environments. The incidence of acute URI peaks during September and late January, coinciding with the opening of schools, as well as toward the end of April. Most adults experience two to four colds each year (Huether & McCance, 2011).

FAST FACTS

- Rhinoviruses are the most common cause of viral URIs.
- Colds due to rhinovirus are more common in early fall and late spring.
- More than 100 different serotypes of rhinovirus have been identified.
- Parainfluenza viruses, respiratory syncytial viruses (RSVs), coronaviruses, and adenoviruses also can cause URIs.
- Colds due to RSVs, coronaviruses, and adenoviruses peak in winter and spring

(Huether & McCance, 2011).

Pathophysiology

More than 200 strains of virus cause URIs, including rhinoviruses, adenoviruses, parainfluenza viruses, coronaviruses, and respiratory syncytial viruses. Occasionally, more than one virus may be present. Viruses causing acute URIs spread by aerosolized droplet nuclei during sneezing or coughing or by direct contact. The virus usually spreads when the hands and fingers pick it up from contaminated surfaces and carry it to the eyes and mucous membranes of the susceptible host. Infected patients are highly contagious, shedding virus for a few days prior to and after the appearance of symptoms. Although immunity is produced to the individual virus strain, the number of viruses causing URIs ensures that most people will experience colds throughout their lifetime.

Viscous mucus secretions in the upper respiratory tract trap invading organisms, preventing contamination of more vulnerable areas. Cells of the upper respiratory tract are infected when the virus attaches to receptors on the cell. Local immunologic defenses, such as secretory IgA antibodies in respiratory secretions, then attempt to inactivate the antigen, producing a local inflammatory response. The mucous membranes of the nasal passages swell and become hyperemic and engorged. Mucus-secreting glands become hyperactive. These responses to the virus produce the typical manifestations of viral URIs.

Manifestations and Complications

Acute viral upper respiratory infection often presents as the common cold. Nasal mucous membranes appear red (*erythematous*) and *boggy* (swollen). Swollen mucous membranes, local vasodilation, and secretions cause nasal congestion. Clear, watery secretions lead to **coryza** (nasal inflammation and profuse nasal discharge). Sneezing and coughing are common. Sore throat is common, and may be the initial symptom. Systemic manifestations of acute viral URIs infrequently include low-grade fever, headache, malaise, and muscle aches. Symptoms generally last for a few days up to 2 weeks. Although acute viral URI is typically mild and self-limited, its effects on the immune defenses of the upper respiratory tract can increase the risk for more serious bacterial infections, such as sinusitis or otitis media.

●○● INTERPROFESSIONAL CARE

Because most acute viral URIs are self-limiting, self-care is appropriate and encouraged. Medical treatment is usually required only when complications such as sinusitis or otitis media develop.

Diagnosis of acute viral URI is usually based on the history and physical examination. Diagnostic testing may be indicated if a complication such as bacterial infection is suspected. A white blood count (WBC) is generally not needed but may be ordered to assess for leukocytosis (an elevated WBC) if there are complications. Cultures of purulent discharge may also be obtained.

Treatment is symptomatic. Adequate rest, maintaining fluid intake, and avoiding chilling help relieve systemic symptoms such as fever, malaise, and muscle ache. Instruct patients to cover the mouth and nose with tissue when coughing or sneezing, and to dispose of soiled tissues properly. Additionally, avoiding crowds helps prevent spread of the infection to others.

MEDICATIONS

Medications may be recommended to shorten the duration of the illness and relieve symptoms. Mild decongestants or over-the-counter antihistamines may help relieve coryza and nasal congestion. Nasal sprays such as phenylephrine (Neo-Synephrine) rapidly relieve nasal congestion, but may lead to dependence and rebound congestion if used for more than a few days at a time. Warm saltwater gargles, throat lozenges, or mild analgesics may be used for sore throat. Although no specific antiviral therapy has been shown to be effective in shortening the duration of a URI, experimental vaccines to prevent acute viral URI are in developmental stages. For the nursing implications of decongestants and common antihistamines, see the accompanying Medication Administration box.

MEDICATION ADMINISTRATION

Decongestants and Antihistamines

DECONGESTANTS

phenylephrine (Neo-Synephrine, others)

phenylpropanolamine (Comtrex, Ornade, Triaminic, others)

pseudoephedrine (Sudafed, Actifed, others)

Decongestants promote vasoconstriction, reducing the inflammation and edema of nasal mucosa and relieving nasal congestion. They are very effective when applied topically (by nasal spray) because of their rapid onset of action. However, the duration of effect is short, followed by vasodilation and rebound congestion. Because of their rapid effect and short duration, these preparations are habit forming. Chronic use may lead to *rhinitis medicamentosa*, a rebound phenomenon of drug-induced nasal irritation and inflammation.

Nursing Responsibilities

- Assess for contraindications, such as hypertension or chronic heart disease. These drugs stimulate the sympathetic nervous system, increasing peripheral vascular resistance, blood pressure, and heart rate.
- Evaluate medication regimen for potential interactions such as antihypertensive medications and monoamine oxidase (MAO) inhibitors.

Health Education for the Patient and Family

- Do not use more than the recommended dose.
- Check with the healthcare provider before taking decongestants if you are taking any prescription medications or are being treated for high blood pressure or heart disease.
- Use nasal sprays for no more than 3 to 5 days.
- Increase fluid intake to relieve mouth dryness.
- These drugs may cause nervousness, shakiness, or difficulty sleeping. Stop the drug if these effects occur.
- In some states, drugs containing pseudoephedrine may require a prescription or be kept behind the counter to reduce its use in preparing methamphetamine.

ANTIHISTAMINES

brompheniramine (Dimetane, others)

chlorpheniramine (Chlor-Trimeton, others)

clemastine (Tavist)

dexchlorpheniramine (Dexchlor, others)

diphenhydramine (Benadryl, others)

triprolidine (Actidil, Myidil)

Nonsedating

cetirizine (Zyrtec)

fexofenadine (Allegra)

loratadine (Claritin)

Antihistamines are widely available with and without a prescription. They are frequently combined with decongestants in over-the-counter (OTC) cold and allergy preparations. Antihistamines relieve the systemic effects of histamine and dry respiratory secretions through an anticholinergic effect. Most antihistamines cause drowsiness; nonsedating forms are less likely to interfere with alertness. Diphenhydramine is used in numerous OTC sleep aids as well as in cold and allergy preparations.

Nursing Responsibilities

- Before administering or recommending these drugs, assess for possible contraindications, including the following:
  - Acute asthma or lower respiratory disease that may be aggravated by drying of secretions
  - Hypersensitivity to antihistamines
  - Glaucoma (increased intraocular pressure)
  - Impaired gastrointestinal motility or obstruction
  - Prostatic hypertrophy or other urinary tract obstruction
  - Heart disease.
- For patients who must remain alert while on antihistamine therapy, recommend nonsedating forms.

Health Education for the Patient and Family

- Do not drive or operate machinery while taking OTC or prescription forms of antihistamines known to be sedating.
- Stop the drug and notify your doctor immediately if you develop confusion, excessive sedation, chest tightness, wheezing, bleeding, or easy bruising while taking antihistamines.
- Do not use alcohol or other CNS depressants while taking antihistamines.
- Hard candy, gum, ice chips, and liquids help relieve mouth dryness caused by antihistamines.

COMPLEMENTARY THERAPIES

Complementary therapies are appropriate for treating most acute viral URIs. Herbal remedies such as echinacea and garlic may have antiviral and antibiotic effects. Echinacea also is thought to stimulate the immune system, improving the body's response to infection. Taken at the first sign of infection, echinacea may reduce the duration and symptoms, although clinical trials have shown no consistent benefit. The recommended dose of echinacea varies, depending on the part of the plant used in the preparation. It should not be used for longer than 2 weeks. It is contraindicated for use during pregnancy and lactation, and in people who have an autoimmune disease such as rheumatoid arthritis (National Library of Medicine, 2012).

Dietary supplements such as vitamin C and zinc also are promoted as measures to reduce the severity and duration of URI. Again, however, no consistent benefit is demonstrated in clinical trials (National Center for Complementary and Alternative Medicine [NCCAM], 2012). Although selected studies have shown a beneficial effect of zinc gluconate lozenges to reduce the duration of an induced URI, no such benefit was found when zinc was compared with placebo to treat naturally occurring URIs (NCCAM, 2012).

Aromatherapy with essential oils such as basil, cedarwood, eucalyptus, frankincense, lavender, marjoram, peppermint, or rosemary can reduce congestion, and promote comfort and recovery. Teach patients that these essential oils are to be used only for inhalation, not for internal consumption. Acupuncture and acupressure have been shown to be effective in treating URIs in adults, particularly when combined with the use of Chinese herbs. Their beneficial effect is most likely related to stimulation of the immune response by acupuncture and acupressure.

●○● NURSING CARE

Health Promotion

Patients can limit their incidence of acute viral URI by frequent hand washing and avoiding exposure to crowds. Maintaining good general health and participating in stress-reducing activities support the immune system and help prevent acute viral URIs. Teach the patient

that becoming chilled or going out in the rain does not cause colds and that URIs are more likely to occur during periods of physical or psychologic stress.

Continuity of Care

The primary nursing role in caring for patients with acute viral URI is educational. Self-care is appropriate for most patients unless the problem is recurrent or a complication occurs. Acute viral URI may interfere with work and recreational activities. Unless limited by symptoms, normal daily activities and roles usually can be maintained. Additional rest during the acute phase of illness is recommended. Additional fluid intake and a well-balanced diet help support the immune response, hastening recovery.

Include the following topics in teaching for home care:

- Use disposable tissues to cover the mouth and nose while coughing or sneezing to reduce airborne spread of the virus.
- Blow the nose with both nostrils open to prevent infected matter from being forced into the eustachian tubes.
- Wash hands frequently, especially after coughing or sneezing, to limit viral transmission.
- Use OTC preparations for symptomatic relief; understand precautions related to the sedating effects of antihistamines.
- Limit use of nasal decongestants to every 4 hours for only a few days at a time to prevent rebound effect.

THE PATIENT WITH RESPIRATORY SYNCYTIAL VIRUS (RSV)

Respiratory syncytial virus (RSV) is a common virus that is the primary cause of respiratory illnesses in young children and the majority of lower respiratory disease in infants. Older children and adults also are commonly, and repetitively, infected by RSV, but the disease is milder, usually presenting as a common cold. However, older adults and people who are immunocompromised may develop severe pneumonitis when exposed to RSV. RSV is transmitted in much the same way as other URIs: via contaminated hands or objects and by coarse droplets spread by coughing and sneezing. The incubation period is 4 to 6 days.

In adults, the manifestations of RSV are those of other common URIs, including rhinorrhea, sore throat, and cough. Headache, malaise, and low-grade fever may occur. In older adults, RSV may present as lower respiratory infection with fever or pneumonia (Huether & McCance, 2011). While the illness also presents as URI in infants, it is more likely to progress to pneumonia, bronchiolitis, and tracheobronchiolitis in this population.

Treatment for adults with upper respiratory RSV is symptomatic (see the section on URIs). When the lower respiratory tract is involved, hydration and other measures to mobilize respiratory secretions are important. Intubation and mechanical ventilation may be necessary if hypoxia develops. Aerosolized ribavirin (Virazole, and antiviral drug) may be prescribed for older adults and immunocompromised patients with RSV pneumonia.

Nursing care is supportive. The focus of nursing care for the adult with URI manifestations of RSV is on teaching for self-care and on identification of complications such as pneumonia, sinusitis, and prevention of viral spread. When lower respiratory symptoms are present, nursing care is similar to that provided for patients with pneumonia (see Chapter 37).

THE PATIENT WITH INFLUENZA

Influenza, or *flu*, is a highly contagious viral respiratory disease characterized by coryza, fever, cough, and systemic symptoms such as headache and malaise. Influenza usually occurs in epidemics or pandemics, although sporadic cases do occur. Localized outbreaks of influenza usually occur about every 1 to 3 years. Global epidemics (pandemics) are less frequent, developing every 10 to 15 years until the past two decades. A recently identified strain of avian (bird) influenza has raised concerns about a potential future pandemic. This strain of influenza virus has not yet demonstrated the ability to spread between humans; however, concerns are that it will mutate to allow person-to-person spread. This viral strain has a mortality rate of greater than 50% in people who have been infected due to close association with infected birds. See Box 35–1 for more information about avian influenza.

Although influenza tends to be mild and self-limited in healthy adults, older adults and people with chronic heart or pulmonary disease have a high incidence of complications (such as pneumonia) and a higher risk for mortality related to the disease and its complications (National Institute of Allergy and Infectious Diseases [NIAID], 2014c). See the accompanying Nursing Care of the Older Adult box.

Pathophysiology

Influenza virus is transmitted by airborne droplet and direct contact. Three major strains of the virus have been identified: influenza A virus, influenza B virus, and influenza C virus. Influenza A virus is responsible for most infections and the most severe outbreaks of influenza. This is primarily due to its ability to alter its surface antigens, bypassing previously developed immune defenses to the virus. New strains of influenza virus are named according to the strain, geographic origin, and year the strain was identified (e.g., A/Taiwan/89). Surface antigens of the specific virus may be used to further differentiate influenza A viruses. Outbreaks of influenza B virus are generally less extensive and less severe than those caused by influenza A virus. Illness associated with influenza C virus is mild and often goes unrecognized.

In 2009, the emergence of a novel influenza A virus, (H1N1) influenza, led to the World Health Organization (WHO) to classify its spread as a pandemic (phase 6) in June 2009. Isolated cases in Europe were found to be resistant to oseltamivir (Tamiflu), but most in the United States were sensitive to Tamiflu. In 2010, the WHO announced

NURSING CARE OF THE OLDER ADULT

Seasonal Influenza

Seasonal influenza is a significant problem in older adults, leading to increased morbidity and mortality compared to other age groups. The Centers for Disease Control and Prevention (CDC) recommends that older adults receive their yearly influenza vaccine in October before influenza activity in the community begins. The optimal time to vaccinate is not precise because influenza seasons vary in their timing and duration, and because more than one outbreak can occur in a community within any flu season. In the United States, outbreaks can occur as early as October; however, since 1976 more than 80% of peak influenza activity (the midpoint of flu season) has not occurred until January or later.

Source: (CDC, 2010).

BOX 35–1 Focus on Avian Influenza

Influenza viruses are common in nature, found in wild birds such as ducks and shore birds. Although these birds carry the virus, they usually are not harmed by it. Movement of the virus into domesticated flocks of ducks and chickens can not only devastate populations of these birds, but can also spread the virus to other domestic animals such as pigs.

Avian influenza is caused by a type A influenza virus identified as *H5N1*. Type A influenza viruses are subclassified by two proteins, hemagglutinin (HA) and neuraminidase (NA), found on the surface of the virus. HA allows the virus to attach to a cell and initiate an infection, whereas NA allows the virus to exit the host cell after replicating. Currently, there are only three known subtypes of influenza A circulating among humans: H1N1, H1N2, and H3N2. The H5N1 virus, which is particularly virulent and spread by migratory birds, raises fears of a potential human pandemic should it evolve to become transmissible from human to human.

Influenza viruses are very changeable, undergoing small, continuous changes as well as occasional large and abrupt changes. *Antigenic drift* is the term for small changes that occur continuously as a virus makes copies of itself. These changes help the virus elude the immune system, and necessitate the production of new vaccines every year. Sudden, dramatic changes occur when two different strains of influenza virus (for example, avian influenza and human influenza) infect the same cell and exchange genetic material. These changes, called *antigenic shift*, create a new subtype of the virus to which people have little or no immunity. Most reported cases of avian influenza A have occurred in previously healthy children and young adults often with an underlying chronic illness.

Symptoms of avian influenza include typical flu-like manifestations such as fever, cough, sore throat, and myalgias. In addition, affected people may develop eye infections, pneumonia, and respiratory distress, including acute respiratory distress syndrome (ARDS) (see Chapter 37 for more information about ARDS and its manifestations).

No vaccine to protect against the H5N1 virus has yet been developed for commercial use. Thailand has begun a phase 1 clinical trial to test an H5N1 avian, or bird, influenza vaccine in a needle-free, nasal spray form. This trial is a result of international collaboration with health agencies around the world, including the U.S. Department of Health and Human Services' Biomedical Advanced Research and Development Authority (BARDA). This is the first step in testing the new vaccine in humans (NIAID, 2014d). Some currently available antiviral medications may effectively treat avian influenza; however, the virus implicated in deaths in Southeast Asia was found to be resistant to amantadine and rimantadine, two commonly used drugs to treat influenza (USDHHS, 2014).

A severe pandemic of H5N1 or avian influenza could disrupt all aspects of life, not only causing severe illness and death, but also overwhelming the healthcare system, impacting social services, and causing significant economic loss. Advance preparations such as those currently being undertaken by the World Health Organization and the United States and other countries can reduce the impact of a pandemic.

that the world is in a postpandemic period. H1N1 is now considered a human seasonal flu virus that also circulates in pigs (U.S. Department of Health and Human Services [USDHHS], 2014). The avian H7N9 influenza virus that emerged early in 2013 is unlikely to cause a pandemic due to its inability to be transmitted between humans (NIAID, 2014b).

FAST FACTS

- Type A influenza viruses are found in birds, pigs, whales, and humans.
- Type A influenza is believed to have caused three pandemics in 1918, 1957, and 1968.
- Type B influenza viruses are commonly found among humans, and often are responsible for influenza outbreaks but not pandemics.
- Type C influenza viruses, found in humans, pigs, and dogs, typically cause mild respiratory infections (NIAID, 2014a).

The incubation period for influenza is short, only 18 to 72 hours. The virus infects the respiratory epithelium. It rapidly replicates in infected cells and is released to infect neighboring cells. Inflammation leads to necrosis and shedding of serous and ciliated cells of the respiratory tract. This allows extracellular fluid to escape, producing rhinorrhea. With recovery, serous cells are replaced more rapidly than ciliated cells, leading to continued cough and coryza. Systemic manifestations of influenza likely are caused by release of inflammatory mediators such as tumor necrosis factor alpha, interleukin alpha, and interleukin 6 (Huether & McCance, 2011). The humoral and cell-mediated immune responses are activated by influenza infection, and are supplemented by other local and systemic responses (such as interferons).

Manifestations

Infection with influenza virus produces one of three syndromes: uncomplicated nasopharyngeal inflammation, viral upper respiratory infection followed by bacterial infection, or viral pneumonia. The onset is rapid; profound malaise may develop in a matter of minutes.

Manifestations of influenza include abrupt onset of chills and fever, malaise, muscle aches, and headache. Respiratory manifestations include dry, nonproductive cough, sore throat, substernal burning, and coryza (see the accompanying box). Acute symptoms subside within 2 to 3 days, although fever may last as long as a week. The cough may be severe and productive. Along with fatigue and weakness, the cough can persist for days or several weeks.

Complications

The respiratory epithelial necrosis caused by influenza increases the risk for secondary bacterial infections. Sinusitis and otitis media are frequent complications of influenza. Tracheobronchitis,

MANIFESTATIONS OF INFLUENZA

RESPIRATORY MANIFESTATIONS

- Coryza
- Cough, initially dry
- Substernal burning
- Sore throat becoming productive

SYSTEMIC MANIFESTATIONS

- Fever and chills
- Malaise
- Muscle aches
- Fatigue

inflammation of the trachea and bronchi, may develop. Although tracheobronchitis is not a serious health risk, its manifestations may persist for up to 3 weeks.

Influenza is clearly linked to an increased risk for pneumonia, particularly in older adults. Changes in respiratory function associated with aging, including decreased effectiveness of cough and increased residual lung volume, pose little risk in the healthy older adult but greatly increase the risk for pneumonia associated with influenza. Primary influenza viral pneumonia, although uncommon, is a serious complication that may be fatal. It typically develops within 48 hours of the onset of influenza, often in patients with preexisting heart valve or pulmonary disease. Influenza pneumonia progresses rapidly and can cause hypoxemia and death within a few days. Secondary bacterial pneumonia is more likely to occur in older at-risk adults but also may affect otherwise healthy adults. It usually presents as a relapse of influenza, with a productive cough and evidence of pneumonia on the chest x-ray. See Chapter 37 for more information about pneumonia.

Other respiratory complications of influenza include exacerbation of chronic obstructive pulmonary disease (COPD), chronic bronchitis, or asthma. Sinusitis (discussed later in this chapter) also may develop.

Reye's syndrome is a rare but potentially fatal complication of influenza. Although it is more likely to affect children, it also has been identified in older adults. Most often associated with influenza B virus, Reye's syndrome develops within 2 to 3 weeks after the onset of influenza. It has a 30% mortality rate. Hepatic failure and encephalopathy develop rapidly in patients with Reye's syndrome.

While uncommon, other potential complications of influenza include myositis (inflammation of skeletal muscles), myocarditis (inflammation of the heart muscle), and CNS disorders such as encephalitis and Guillain-Barré syndrome.

●○● INTERPROFESSIONAL CARE

Preventing community outbreaks and protecting vulnerable populations (e.g., older adults and people with chronic diseases) are the primary focus for interprofessional care related to influenza. Medical treatment of influenza focuses on establishing the diagnosis, providing symptomatic relief, and preventing complications.

PREVENTION

Preventing influenza by immunizing at-risk populations is an important aspect of care. Immunization with polyvalent (containing antigens of several viral strains) influenza virus vaccine is about 85% effective in preventing influenza infection for several months to a year (NIAID, 2014). Annual immunization is recommended for all children (6 months to 18 years) and all adults who want it; at-risk patients, including people over the age of 50; residents of nursing homes; adults and children with chronic cardiopulmonary disorders (e.g., asthma) or chronic metabolic diseases such as diabetes; and healthcare workers who have frequent contact with high-risk patients. Additionally, family members of at-risk patients should be vaccinated to reduce the patient's risk of exposure. The vaccine is given in the fall, prior to the annual winter outbreak. Live attenuated vaccine, administered by internasal spray, is available for healthy people under age 50 (CDC, 2012c).

DIAGNOSIS

The diagnosis of influenza is based on history, clinical findings, and knowledge of an influenza outbreak in the community. A chest x-ray and WBC count may be done to rule out complications such as pneumonia. The WBC is commonly decreased in viral infections such as influenza; bacterial infections usually cause increased WBCs.

MEDICATIONS

Yearly immunization with influenza vaccine is the single most important measure to prevent or minimize symptoms of influenza. Although the vaccine is readily available and inexpensive, only about 30% of at-risk patients are vaccinated each year. Many may fear a reaction from the vaccine, although the vaccines are highly purified and reactions are rare. About 5% of people experience mild symptoms of low-grade fever, malaise, or myalgia for up to 24 hours after vaccination. Because the vaccine is produced in eggs, it should not be given to people who are allergic to egg protein. Serious adverse reactions to influenza vaccine are rare. Guillain-Barré syndrome, an acute neurologic disorder characterized by muscle weakness and distal sensory loss, has been associated with certain batches of vaccine.

Amantadine (Symmetrel) or rimantadine (Flumadine) may be used for prophylaxis in unvaccinated people who are exposed to the virus. If the drug is given before or within 48 hours of exposure, it inhibits viral shedding and prevents or decreases the symptoms of influenza. If possible, unvaccinated people should receive the vaccine along with the antiviral drug. The drug is continued for several weeks or for the duration of the influenza outbreak. Some strains of type A influenza virus have been found to be resistant to amantadine and rimantadine, potentially limiting their effectiveness in preventing or treating an influenza outbreak.

Amantadine, rimantadine, and the antiviral drugs zanamivir (Relenza), oseltamivir (Tamiflu), and ribavirin (Virazole) also may be used to reduce the duration and severity of flu symptoms. Both zanamivir and ribavirin are administered by inhalation; the other drugs are given orally. Zanamivir can precipitate bronchospasm in patients with a history of asthma or chronic obstructive pulmonary disease (COPD), and is not recommended for use in these patients. Specifically, for the 2011–2012 season: 98.6% of the tested 2009 H1N1 viruses were susceptible to oseltamivir (Tamiflu), and 100% of the 2009 H1N1 viruses tested were susceptible to zanamivir (Relenza). Both influenza A and influenza B viruses were also found to be susceptible to both oseltamivir and zanamivir. However, the 2009 H1N1 and the H3N2 viruses showed high levels of resistance to amantadine and rimantadine. Because there were no dramatic changes in antiviral resistance patterns during 2011–2012, the 2012–2013 guidance on the use of influenza antiviral drugs remained the same (CDC, 2012a).

Over-the-counter analgesics such as aspirin, acetaminophen, or NSAIDs provide symptomatic relief of fever and muscle ache. Antitussives and mucolytics may decrease cough, promoting rest. Antibiotics are not indicated unless secondary bacterial infection occurs.

●○● NURSING CARE

Health Promotion

Stress the importance of yearly influenza vaccination for everyone, unless contraindicated, especially patients in the high-risk groups and their families. Teach about spread of the disease, including not going to work or school if sick and measures to reduce the risk of

contracting influenza, such as hand washing, avoiding crowds, and avoiding people who are ill.

Assessment

Unless there is a known outbreak of influenza in the community, it can be difficult to differentiate the manifestations of influenza from those of other URI.

See the Manifestations and Interprofessional Care sections for the assessment of the patient with influenza.

- *Health history:* known exposure to virus; current symptoms, their onset and duration; presence of dyspnea, chest pain, productive cough, facial pain, or pressure in sinus areas; current medications, history of influenza vaccine; chronic diseases such as heart disease, COPD, or diabetes; smoking or alcohol abuse; institutionalized, communal living such as college dormitories; known medication allergies
- *Physical assessment:* general appearance; vital signs including temperature; skin color; lung sounds; abdominal exam; ear, nose, and throat examination.
- *Laboratory data:* influenza tests (nasal swabs, nasal aspirates), but usually not WBC, throat and sputum cultures, and chest x-ray unless suspect for evidence of bacterial infection or pneumonia.

Priorities of Care

Collaborating with the interprofessional team to ensure adequate treatment of the underlying process while providing care that supports the physical and psychologic responses to the disorder is a priority of nursing care.

Diagnoses, Outcomes, and Interventions

Although the symptoms of influenza are distressing, most people with the illness provide self-care and do not contact a healthcare provider. Recommendations to rest in bed during the acute phase of the illness and limit activities until recovery are appropriate for influenza.

Severe disease or complications of influenza may necessitate hospitalization for respiratory support and management. For these patients, nursing care focuses on maintaining breathing patterns, airway clearance, and adequate rest.

Ineffective Breathing Pattern

Muscle aches, malaise, and elevated temperature may increase the respiratory rate and alter the depth of respirations, decreasing effective alveolar ventilation. Shallow respirations also increase the risk of *atelectasis*, lack of ventilation in an area of lung.

Expected Outcome: Patient will utilize techniques to promote adequate ventilation such as deep breathing and incentive spirometry.

- Monitor respiratory rate and pattern. *Tachypnea and/or rapid, shallow respirations may impair effective alveolar ventilation and gas exchange.*
- Pace activities to provide for periods of rest. *Tachypnea increases the work of breathing, causing fatigue; fatigue, in turn, can further impair ventilation and reduce the effectiveness of coughing.*
- Elevate the head of the bed. *The upright position promotes drainage of nasal secretions, improves lung excursion, and reduces the work of breathing by lowering the diaphragm, which moves abdominal contents downward, creating less resistance to diaphragmatic excursion and slightly decreasing venous return.*

Ineffective Airway Clearance

Swelling and congestion of mucous membranes, extracellular fluid exudate, and impaired ciliary action due to cell damage increase the risk of impaired airway clearance in influenza. The older adult is at particular risk because of normally reduced ciliary activity and increased lung compliance.

Expected Outcome: Patient will use techniques to promote airway clearance such as coughing and deep breathing.

- Monitor the effectiveness of cough and ability to remove airway secretions. *Fatigue and general malaise may impair the ability to cough effectively and mobilize secretions.*
- Maintain adequate hydration. Assess mucous membranes and skin turgor for evidence of dehydration. *Fever, increased mucous membrane secretions, and decreased oral fluid intake may lead to dehydration and increased viscosity of secretions. Thick, viscous secretions are more difficult to expectorate.*
- Increase the humidity of inspired air with a bedside humidifier. *Increasing the water content of inhaled air helps loosen thick secretions and soothe mucous membranes.*
- Teach effective cough techniques. Administer analgesics as ordered. *The huff cough is effective to maintain open airways and spares energy (see Chapter 37 for patient teaching of this technique). Relieving muscle ache increases the ability to cough effectively.*

Disturbed Sleep Pattern

Airway congestion, fever, malaise, muscle aches, and persistent cough may interfere with the ability to rest, increasing fatigue and prolonging recovery.

Expected Outcome: Patient will verbalize techniques to reduce impact of upper respiratory symptoms on sleep patterns.

- Assess sleep patterns using subjective and objective information. *The patient may appear to be sleeping but not achieving normal sleep patterns because of influenza symptoms. Both subjective and objective data are important to accurately assess sleep.*
- Provide antipyretic and analgesic medications at or shortly before bedtime. *These drugs promote comfort by reducing fever and relieving muscle aches.*

Risk for Infection

Infection control measures are recommended to prevent person-to-person transmission of influenza and control influenza outbreaks in healthcare facilities.

Expected Outcome: Patient will describe measures to protect healthy tissue and prevent infection.

- Use standard precautions and encourage all staff and visitors to frequently wash hands. *Hand hygiene is a primary infection control measure for infections transmitted via respiratory secretions.*
- Instruct patients and visitors to control respiratory secretions by using tissues, and to maintain a distance of at least 3 feet from others when coughing or sneezing. Provide masks for patients and visitors who are coughing or sneezing. *Limiting the spread of aerosolized secretions by covering the nose and mouth and maintaining*

Evidence for Nursing Care

The Patient with Influenza

Selected resources that nurses may find helpful when planning evidence-based nursing care follow.

- Brownfield, E., Marsden, J. E., Iverson, P. J., Zhao, Y., Mauldin, P. D., & Moran, W. P. (2012). Point of care experience with pneumococcal and influenza vaccine documentation among persons ≥ 65 years: High refusal rates and missing information. *American Journal of Infection Control, 40*(7), 672–674.
- Finkelstein, S., Prakash, S., Nigmatulina, K., McDevitt, J., & Larson, R. (2011). A home toolkit for primary prevention of influenza by individuals and families. *Disaster Medicine & Public Health Preparedness, 5*(4), 266–271.
- Gould, D. (2011). The challenges of caring for patients with influenza. *Nursing Older People, 23*(10), 28–35.
- Rhudy, L. M., Tucker, S. J., Ofstead, C. L., & Poland, G. A. (2010). Personal choice or evidence-based nursing intervention: Nurses' decision-making about influenza vaccination. *Worldviews on Evidence-Based Nursing, 7*(2), 111–120.

distance from other people can reduce the spread of the disease to vulnerable populations.

- Use droplet precautions for patients with suspected or confirmed influenza: private room, masks for caregivers and visitors, and mask the patient when transporting within the facility. *These measures limit the spread of respiratory secretions.*

Continuity of Care

Encourage appropriate self-care for patients with influenza. Discuss the following topics related to home care:

- Increase rest during the acute, febrile phase of the illness.
- Increase fluid intake (to greater than normal level) even if anorexic.
- Use OTC medications at safe and effective dose and frequency for symptom relief.
- Employ hygiene measures such as using disposable tissues and frequent hand hygiene to reduce spread of the disease.
- Know manifestations of potential complications of influenza to report to the primary care provider.

THE PATIENT WITH SINUSITIS

Sinusitis is inflammation of the mucous membranes of one or more of the sinuses. Sinusitis is a common condition that usually follows an upper respiratory infection such as acute viral upper respiratory infection or influenza. Common causative organisms include viruses, streptococci, *S. pneumoniae*, *Haemophilus influenzae*, and staphylococci. The risk of sinusitis is higher when the immune system is suppressed by immunosuppressive drugs or HIV infection. Sinusitis is common and difficult to treat in people who have AIDS.

Physiology Review

The sinuses (or *paranasal sinuses*) are air-filled cavities in the facial bones that open into the turbinates of the nasal cavity. They are lined with ciliated mucous membranes that help move fluid and microorganisms out of the sinuses into the nasal cavity. The sinuses normally are sterile. Air within the sinuses has a lower oxygen content than inspired air.

Pathophysiology

Sinusitis develops when nasal mucous membranes swell or other disorders (such as polyps or tumors) obstruct sinus openings, impairing drainage. Mucus secretions collect in the sinus cavity, serving as a medium for viral or bacterial growth. The nasal and sinus mucous membranes are continuous; therefore, pathogens generally spread to the sinuses via the opening into the nasal turbinates. The inflammatory response provoked by pathogen invasion draws serum and leukocytes to the area to combat the infection, increasing swelling and pressure.

Any process that impairs drainage from the sinuses may precipitate sinusitis. These include nasal polyps, deviated septum, rhinitis, tooth abscess, or swimming or diving trauma. In hospitalized patients, sinusitis may develop following prolonged nasotracheal intubation. Usually more than one sinus is infected. The frontal and maxillary sinuses are usually involved in adults.

Sinusitis may be acute or chronic. Chronic sinusitis results when acute sinusitis is untreated, inadequately treated, or there are recurrent episodes or other factors that prevent sinus drainage. With continued infection, bacteria can become isolated, producing chronic inflammation. Over time, mucous membranes become thickened. Fungal infections may cause chronic infections, especially in immunosuppressed patients. Other factors that may contribute to chronic sinusitis are smoking, allergies, and habitual use of nasal sprays or inhalants.

Manifestations and Complications

The patient with acute sinusitis often looks sick. Manifestations of sinusitis include pain and tenderness across the infected sinuses, headache, fever, and malaise. The pain usually increases with leaning forward. When the maxillary sinuses are involved, pain and pressure are felt over the cheek. The pain may be referred to the upper teeth. Frontal sinusitis causes pain and tenderness across the lower forehead. Infection of the ethmoid sinus produces retro-orbital pain and pain over the high lateral aspect of the nose. Sphenoid sinusitis, the rarest form, may cause pain in the occiput, vertex, or middle of the head. Symptoms often worsen for 3 to 4 hours after awakening and then become less severe in the afternoon and evening as secretions drain. The intensity and location of headache pain may change as sinuses drain. In acute sinusitis, the pain is usually constant and severe. In chronic sinusitis, the pain is described as dull and may be constant or intermittent.

Other symptoms include nasal congestion, purulent nasal discharge, and bad breath. The nasal mucous membrane is red and swollen. Purulent drainage may be noted at the opening to the middle turbinate. This may be the only sign of chronic sinusitis. Swallowed secretions from postnasal drip irritate and inflame the throat, and may cause nausea or vomiting.

Complications develop when the infection spreads to surrounding structures (Box 35–2). These include periorbital abscess, or cellulitis, cavernous sinus thrombosis, meningitis, brain abscess, or sepsis. Eustachian tube edema may lead to temporary hearing loss.

BOX 35–2 Potential Complications of Sinusitis

LOCAL COMPLICATIONS
- Orbital cellulitis
- Subperiosteal abscess
- Orbital abscess
- Cavernous sinus thrombosis
- Mucocele
- Osteomyelitis

INTRACRANIAL COMPLICATIONS
- Meningitis
- Epidural abscess
- Subdural abscess
- Brain abscess
- Venous sinus thrombosis

●○● INTERPROFESSIONAL CARE

Treatment of sinusitis focuses on restoring drainage of obstructed sinuses, controlling infection, relieving pain, and preventing complications.

DIAGNOSIS

The diagnosis of acute sinusitis usually can be made using the history and physical exam. Diagnostic studies such as CT scan or, less frequently, sinus x-rays generally are done only when sinusitis is persistent, chronic, or recurrent. Refer to Chapter 34 for more information about diagnostic studies and their nursing implications.

- *Sinus x-rays* are used infrequently. Sinuses are normally translucent because they are filled with air; affected sinuses appear cloudy or opaque. A visible air-fluid level or thickening of the sinus mucosa may be seen in infected sinuses.
- *CT scan* is a more sensitive indicator of acute and chronic sinusitis and often is performed without preceding x-rays.
- *Magnetic resonance imaging (MRI)* may be ordered if malignancy of the sinus is suspected.

MEDICATIONS

Antibiotic therapy directed at the usual organisms causing sinusitis typically is prescribed if the symptoms have lasted for more than 7 days. Amoxicillin (possibly combined with clavulanate [Augmentin]), trimethoprim-sulfamethoxazole (Bactrim, Septra), cefuroxime (Ceftin), cefaclor (Ceclor), ciprofloxacin (Cipro), or clarithromycin (Biaxin) are commonly used antibiotics for sinusitis. Antibiotic therapy is continued for 10 to 14 days; occasionally a longer course is prescribed to prevent relapse. If the sinusitis does not respond to treatment with oral antibiotics, hospitalization and intravenous antibiotic therapy may be required. Refer to Chapter 12 for nursing care related to antibiotic therapy.

Topical steroids (such as fluticasone) and decongestants (in the form of nasal sprays) or oral decongestants such as pseudoephedrine or phenylephrine are also prescribed to reduce mucosal edema and promote sinus drainage. Antihistamines may decrease nasal congestion and facilitate sinus drainage, but they also tend to increase the viscosity of secretions and hinder drainage. For this reason, they may not be as effective as decongestants. Saline nose drops or sprays promote sinus drainage, as does inhalation of warm steam.

To administer topical drugs, the patient's head is tilted backward and to the side on which the drops are to be instilled. The patient may need to remain in position for 5 minutes to allow the drops to reach the posterior nares.

Systemic mucolytic agents such as guaifenesin may be useful to liquefy secretions, promoting sinus drainage. Aerobic exercise also promotes mucous flow and may be recommended.

SURGERY

Patients who do not respond to pharmacologic measures and who experience persistent facial pain, headache, or nasal congestion may require endoscopic sinus surgery. Detailed evaluation of the sinuses by CT scan is done prior to surgery. Under local or general anesthesia, a fiberoptic nasal endoscope is inserted to visualize the sinus opening. If obstruction is present, it can be removed, restoring patency and drainage. This surgery is most effective for local disease, for recurrent acute sinusitis, and for removing anatomic obstructions. Patients who have endoscopic sinus surgery usually do not require nasal packing postoperatively. Instead, frequent nasal cleaning and irrigation with normal saline are performed. The patient is instructed to sneeze with the mouth open and avoid blowing the nose, lifting, or straining for a week following surgery.

Antral irrigation can be done in the healthcare provider's office under local anesthesia. A 16-gauge needle is inserted under the inferior turbinate of the nose into the maxillary sinus on the affected side. Saline solution is instilled to irrigate the area and wash out the sinus of purulent exudate. The patient is seated with the head forward and mouth open to allow drainage of the solution through the nose and mouth. A culture of the exudate may be obtained to determine appropriate antibiotic therapy.

The *Caldwell-Luc procedure* may be necessary if endoscopic sinus surgery is unsuccessful. It is performed under local or general anesthesia. An incision is made under the upper lip into the maxillary sinus, and diseased mucous membrane and periosteum are removed. An opening between the maxillary sinus and lateral nasal wall, a "nasal antral window," is created to increase aeration of the sinus and promote drainage into the nasal cavity. The area is packed with gauze for 24 to 48 hours postoperatively. The gauze packing obstructs nasal breathing while it is in place. As the maxillary sinus heals, exposed bone is covered by mucosa. The upper lip and teeth may be numb for several months after the procedure because of nerve trauma. Chewing may be impaired on the affected side. Only liquids are given for the first 24 hours, followed by a soft diet. The patient is instructed to avoid wearing dentures and the Valsalva maneuver (no blowing the nose, coughing, or straining at stool) for about 2 weeks after the packing has been removed to prevent bleeding.

In *external sphenoethmoidectomy*, an incision along the side of the nose from the middle of the eyebrow is used to open and remove diseased tissue from the sphenoid or ethmoid sinuses (Figure 35–1 ■). Nasal polyps may also be removed using this approach. Nasal packing is inserted, and an eye pressure patch is applied to decrease periorbital edema. Care is similar to that following the Caldwell-Luc procedure.

COMPLEMENTARY THERAPIES

Complementary therapies may help relieve symptoms of sinusitis and promote comfort. The use of high-volume, low-pressure nasal irrigation has expanded beyond postoperative management. It has been shown to be more effective in managing sinusitis symptoms than nasal sprays (Suh & Kennedy, 2011). Nasal irrigation systems such as neti pots are widely available over the counter. Aromatherapy

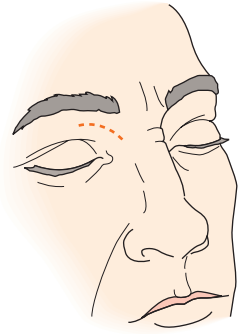

Figure 35–1 ■ Incision to access ethmoid and frontal sinuses. Resulting scar is nearly invisible in folds of the eye.

using herbs such as basil, marjoram, or eucalyptus in a vaporizer or on a handkerchief; herbal teas made from goldenseal, yarrow, or coltsfoot; hot or cold compresses or steam inhalation; and acupressure may be employed.

●○● NURSING CARE

Health Promotion

Measures to prevent sinusitis are those that promote nasal drainage: encouraging increased fluid intake, judicious use of nasal decongestants as needed, and treating any obstructive process (e.g., with nasal steroid spray). Encourage patients with URI to blow their nose with both nares open. Advise patients that use of saline nasal sprays can help maintain patency of the opening to the sinuses, promoting drainage and reducing the risk of obstruction and infection.

Assessment

See the Manifestations and Interprofessional Care sections for the assessment of the patient with sinusitis.

Focused assessment of the patient with suspected sinusitis includes the following:

- *Health history:* complaints of frontal or periorbital headache, cheek, teeth, or ear pain; timing of pain and changes in intensity over course of the day; nasal discharge or postnasal drip; other symptoms like tenderness over the cheeks; previous sinus infections or trauma; current medications, known medication and environmental allergies (allergic rhinitis)
- *Physical assessment:* general appearance, vital signs including temperature; inspection of nasal and pharyngeal mucous membranes; percussion of sinuses for tenderness
- *Laboratory data:* CT of the sinuses, and infrequently sinus x-rays, WBC and differential, cultures of sinus drainage.

Priorities of Care

Collaborating with the interprofessional team to ensure adequate treatment of the underlying process while providing care that supports the physical and psychologic responses to the disorder is a priority of nursing care.

Diagnoses, Outcomes, and Interventions

The patient with sinusitis is often acutely uncomfortable. Obstructed and congested sinuses cause pain and pressure that increase with position changes and leaning forward. Treatment usually is community based, making education the key nursing role. When the patient is hospitalized for intravenous antibiotic therapy or sinus surgery, *Pain* and *Imbalanced Nutrition* are priority nursing diagnoses.

Pain

Although sinus surgery is relatively minor, both the incision and postoperative swelling can cause discomfort. Nasal packing, if used, contributes to the discomfort.

Expected Outcome: Patient will experience adequate pain control as evidenced by physical well-being.

- Assess pain using a standardized pain scale. Administer analgesics as ordered. *Relief of pain promotes a feeling of well-being and enhances recovery.*
- Apply ice packs to the nose. *Cold compresses reduce swelling, control bleeding, and provide local analgesia.*
- Elevate the head of the bed to Fowler's or high-Fowler's position for 24 to 48 hours after surgery. *Elevating the operative site minimizes tissue swelling and promotes comfort.*

Imbalanced Nutrition: Less Than Body Requirements

Postoperatively, the sense of smell, an appetite stimulus, is diminished by nasal packing. Mouth discomfort from the incision and numbness of the upper teeth also may impact appetite and eating.

Expected Outcome: Patient will consume adequate nourishment to promote weight within normal range.

- Provide clear liquid diet progressing to soft foods as tolerated. High-calorie dietary supplements may be used. *A progressive diet is used to assess the ability to swallow without choking and allay fears. Foods high in calories and nutritional value provide for metabolic and healing requirements.*
- Monitor intake, output, and weight. *This information allows assessment of overall fluid balance and the adequacy of dietary intake.*
- Elevate the head of the bed during meals. *The upright position facilitates swallowing and minimizes risk of aspiration.*

Continuity of Care

Teaching for patients with sinusitis and their families focuses on following through with appropriate treatment and promoting comfort. Discuss the following topics when preparing for home care:

- Understand the importance of completing the entire course of prescribed antibiotics to achieve cure and prevent the development of antibiotic-resistant bacteria. Assist in developing a schedule that helps ensure all doses are taken.
- Use measures to prevent superinfections (such as vaginitis or oral thrush) during the prolonged course of treatment (e.g., consume 8 oz of yogurt containing live bacterial cultures daily while on antibiotics).
- Use systemic or topical decongestants to promote sinus drainage.
- Maintain a liberal fluid intake to reduce the viscosity of mucous drainage.
- Use a humidifier or steam inhalation to promote sinus drainage.
- Sleep with the head of the bed elevated to a 45-degree angle and on the unaffected side to promote drainage of affected sinuses.
- Apply a warm, moist pack to the area of pain and tenderness to promote comfort.

- Notify the healthcare provider if symptoms do not improve with treatment or if signs of a complication develop, such as increased pain, and redness and swelling on the side of the nose or around the eyes.
- Understand postoperative instructions to prevent bleeding, such as avoiding blowing the nose for 7 to 10 days and avoiding strenuous activity such as heavy lifting for about 2 weeks.
- Use saline nasal sprays or nasal irrigation postoperatively to keep the nasal mucosa moist.

THE PATIENT WITH PHARYNGITIS OR TONSILLITIS

Pharyngitis, acute inflammation of the pharynx, is one of the most commonly identified clinical problems. Although it is usually viral in origin, pharyngitis may also be caused by bacterial infection. *Group A beta-hemolytic streptococcus (GABHS)* (strep throat) is the most common cause of bacterial pharyngitis. Other bacteria that may cause pharyngitis include *Neisseria gonorrhoeae*, a gram-negative diplococcus that is sexually transmitted, *Mycoplasma*, and *Chlamydia trachomatis*. Pharyngitis may also be a result of postnasal drip from allergic rhinitis or as a result of gastroesophageal reflux into the throat.

Tonsillitis is acute inflammation of the palatine tonsils. Although it is sometimes viral in origin, tonsillitis is usually due to streptococcal infection. The incidence of streptococcal infections is greatest between late fall and spring, especially in cold climates. Viral tonsillitis may occur in epidemics in people living in crowded conditions, such as military recruits.

Pathophysiology and Manifestations

Pharyngitis and tonsillitis are contagious and spread by droplet nuclei. Incubation varies from a few hours to several days, depending on the organism. Viral infections are communicable for 2 to 3 days. Symptoms usually resolve within 3 to 10 days after onset.

Viral pharyngitis may be attributed to the same viruses causing the common cold: rhinovirus, coronavirus, or parainfluenza virus. Pharyngitis caused by adenovirus, influenza virus, or Epstein-Barr virus (associated with infectious mononucleosis) may be particularly severe.

Acute pharyngitis causes pain and fever. The pain may vary from a scratchy sore throat to one so painful that swallowing is difficult. Streptococcal pharyngitis is usually marked by an abrupt onset, with fever of 38.3°C (101°F) or higher, severe sore throat with dysphagia, headache, malaise, and often arthralgias and myalgias and the absence of a cough. Anterior lymph nodes are often enlarged and tender. Exudate (pus) may be seen on the pharynx and tonsils (Figure 35–2 ■). In contrast, the onset of viral pharyngitis is often gradual, with manifestations of low-grade fever, sore throat, mild hoarseness, headache, and rhinorrhea. The pharyngeal membranes appear mildly red with vascular congestion. Infectious mononucleosis, caused by the Epstein-Barr virus, often presents as acute pharyngitis, with visible patches of exudate on the pharynx or tonsils. The cervical lymph nodes are enlarged and tender as well. See the accompanying box for the manifestations of pharyngitis and tonsillitis.

In tonsillitis, the tonsils appear bright red and edematous. White exudate may be present on the tonsils; pressing on a tonsil may produce purulent drainage. The uvula may also be reddened and swollen. The tonsillar lymph nodes are usually tender and enlarged.

Figure 35–2 ■ The appearance of the oral pharynx and tonsils in acute pharyngitis and tonsillitis.

The patient with tonsillitis complains of a sore throat, difficulty swallowing, general malaise, fever, and otalgia (pain referred to the ear). Manifestations are often more severe in adolescents and adults than in children. Infection may extend via the eustachian tubes to cause acute otitis media. This may lead to further damage such as spontaneous rupture of the eardrums and mastoiditis. See Chapter 46 for more information about otitis media.

Complications

Although GABHS pharyngitis may be mild and indistinguishable from viral pharyngitis by its signs and symptoms, it can lead to significant complications such as abscess, scarlet fever, toxic shock syndrome, rheumatic fever, or acute poststreptococcal glomerulonephritis. GABHS is treated with antibiotics to prevent these sequelae. *Peritonsillar abscess*, or *quinsy*, is a potential complication of tonsillitis. It usually results from GABHS infection extending from the tonsils to the surrounding tissue. The abscess causes pus formation behind the tonsil with marked swelling and asymmetric deviation of the uvula. The degree of swelling may make it difficult to swallow anything other than liquids. The patient may exhibit thickening of the voice, drooling, and a tonic contraction of the muscles of mastication, called *trismus*.

Rare (1% to 3%) but serious complications of GABHS pharyngitis and tonsillitis include acute glomerulonephritis and rheumatic fever, abnormal immune responses to the infection. Acute glomerulonephritis generally presents with sudden onset of hematuria, proteinuria, and, less commonly, hypertension and edema within

MANIFESTATIONS OF PHARYNGITIS AND TONSILLITIS

LOCAL
- Sore throat
- Possible dysphagia and otalgia
- Tender, swollen anterior cervical lymph nodes
- Hoarse voice
- Red, swollen pharyngeal mucous membranes and/or tonsils
- Possible visible exudate on pharyngeal membranes and/or tonsils

GENERAL
- Fever
- General malaise
- Arthralgia, myalgia

7 to 10 days after the acute infection. Rheumatic fever typically presents 3 to 5 weeks after acute infection with fever, painful or swollen joints, rash, and heart murmur. Other complications of bacterial infection include sinusitis, otitis media, mastoiditis, and cervical adenitis.

●○● INTERPROFESSIONAL CARE

Both viral and bacterial pharyngitis are usually self-limited diseases. However, because of the risk for serious complications associated with GABHS sore throat, an effort is usually made to identify this pathogen and treat only this pharyngitis with antibiotics.

- *Throat swab* is obtained and examined for streptococcus antigen using the latex agglutination (LA) antigen test or enzyme immunoassay (ELISA) testing. These tests allow rapid identification of the antigen (in as little as 10 minutes for the LA test) but are not highly sensitive. When the test is positive, treatment for strep throat is initiated. If the test is negative, the swab is cultured to ensure that streptococcus organisms are not present. Even throat cultures are not always accurate, with approximately 10% false-negative and 20% false-positive results.
- *Complete blood count (CBC)* may be done on severely ill patients or to rule out other causes of pharyngitis. The WBC count is usually normal or low in viral infections and elevated in bacterial infections.

MEDICATIONS

Antipyretics and mild analgesics such as aspirin or acetaminophen provide symptomatic relief for throat pain and associated myalgias. Penicillin is the drug of choice for group A streptococci. Erythromycin, amoxicillin, or cefuroxime (Ceftin, Kefurox) may be used if the patient is allergic to penicillin. Antibiotic therapy is continued for at least 10 days. The patient is no longer contagious after 24 hours of antibiotic therapy.

A peritonsillar abscess is drained by needle aspiration or by incision and drainage. The area is first sprayed with a topical anesthetic such as Cetacaine and then injected with a local anesthetic. The sitting position is preferred for the procedure, because it enables expectoration of blood and pus. (See the Case Study & Nursing Care Plan for nursing care of the patient with a peritonsillar abscess.) Tonsillectomy is done either immediately or 6 weeks after incision and drainage of peritonsillar abscess.

Tonsillectomy (surgical removal of the tonsils) is indicated for recurrent or chronic infections that have not responded to antibiotic therapy, hypertrophy of the tonsils with risk of airway obstruction, peritonsillar abscess, repeated attacks of purulent otitis media, and tonsil malignancy. Adenoid tissue usually is removed at the same time. Bleeding is the most significant postoperative complication of tonsillectomy, and may develop up to 2 weeks following the surgery.

●○● NURSING CARE

Because of the risk of significant complications associated with GABHS pharyngitis, encourage all patients with symptoms that persist for several days or that include fever, lymphadenopathy, and myalgias to seek evaluation and treatment.

Home care is appropriate for acute uncomplicated pharyngitis. Treatment focuses on adequate rest and relief of symptoms. A liquid or soft diet is useful when swallowing is difficult. Increased fluid intake is encouraged, especially when febrile. Warm saline gargles, moist inhalations, and application of an ice collar are soothing to the sore throat.

Following tonsillectomy, ensure a patent airway by placing the patient in semi-Fowler's position with the head turned to the side to allow secretions to drain from the mouth and pharynx. Keep the

CASE STUDY & NURSING CARE PLAN A Patient with a Peritonsillar Abscess

Monica Wunderman, age 27, was recently treated for tonsillitis caused by an infection by group A streptococcus. She presents to the emergency department (ED) 10 days later appearing acutely ill. She states that her throat is so sore that she has difficulty swallowing even liquids. Ms. Ironhorse, the ED nurse, completes an assessment of Ms. Wunderman.

ASSESSMENT

Findings include T 38.8°C (102°F). An acutely swollen and reddened area of the soft palate is noted in her mouth, half occluding the orifice from the mouth into the pharynx. Yellow exudate is present. CBC reveals an elevated WBC of 16,000/mm^3. A diagnosis of peritonsillar abscess is made. Needle aspiration of the abscess is performed.

DIAGNOSIS

- *Acute Pain* related to swelling
- *Risk for Ineffective Airway Clearance* related to pain and swelling
- *Deficient Fluid Volume* related to fever and difficulty in swallowing fluids

EXPECTED OUTCOMES

- Patient will have minimal or no pain.
- Patient will maintain a patent airway as demonstrated by normal respiratory rate and rhythm.
- Patient will maintain optimal fluid intake as evidenced by consumption of fluids and semiliquid foods, moist mucous membranes, normal skin turgor, and normal temperature.

PLANNING AND IMPLEMENTATION

- Teach that ice-cold fluids may be easier to swallow than hot or room-temperature beverages and may provide a local analgesic effect.
- Advise to avoid citrus juices, hot or spicy foods, and rough-textured foods for 1 week.
- Teach pain management strategies such as applying an ice collar as desired and gargling with warm saline or mouthwash solution every 1 to 2 hours for the first 24 to 48 hours after aspiration of the abscess.
- Instruct to take medications (antibiotics) as prescribed.

EVALUATION

When Ms. Ironhorse contacts Ms. Wunderman by telephone 2 days after her visit to the ED, she reports complete relief of symptoms. She is afebrile, taking fluids without difficulty, and has had no difficulty breathing. She has not experienced any pain.

Clinical Reasoning in Patient Care

1. Describe common symptoms of infectious or inflammatory diseases of the upper airway and discuss methods of symptom relief.
2. Describe common pharmacologic interventions for these disorders.
3. What themes of nursing diagnoses emerge for these patients?

See Evaluating Your Response in Appendix B.

airway in place until the gag and swallowing reflexes have returned. Apply an ice collar to reduce swelling and pain. Notify the surgeon immediately if excessive bleeding or hemorrhage occurs. If there is no bleeding, allow water and cracked ice as desired. Warm saline mouthwashes are helpful in managing thick oral secretions following tonsillectomy. A liquid or semiliquid diet is recommended for several days.

Continuity of Care

Discuss the following topics when preparing the patient for home care:

- The importance of completing the full 10 days of antibiotic therapy if prescribed
- Using warm saline gargles or throat lozenges for symptomatic relief
- Signs and symptoms of possible complications of GABHS streptococcal infection such as glomerulonephritis or rheumatic fever.
- Monitoring temperature in the morning and evening until well to ensure that the infection has not spread to deeper tissues
- Proper use and disposal of tissues and frequent hand hygiene to prevent spreading the infection to others

For the patient who has had a peritonsillar abscess drainage or tonsillectomy, provide the following instructions:

- Postoperative mouth and throat care
- Avoiding use of aspirin for 2 weeks to reduce the risk of postoperative bleeding
- Manifestations of bleeding to report to the healthcare provider (delayed hemorrhage may occur for up to 1 week postsurgery).

THE PATIENT WITH A LARYNGEAL INFECTION

The larynx, located between the upper airways and the lungs, protects the lower respiratory tract from inhaled substances other than air, and allows speech. The larynx includes the epiglottis, which covers the larynx during swallowing, and the glottis, or vocal cords. Either portion of the larynx may become inflamed.

Epiglottitis

Epiglottitis, inflammation of the epiglottis, is an uncommon disorder that presents as a medical emergency. *H. influenzae* infection is the most common cause of epiglottitis. Epiglottitis is a rapidly progressive cellulitis that begins between the base of the tongue and the epiglottis. The epiglottis itself becomes swollen and inflamed; swelling of adjacent tissues pushes the epiglottis posteriorly. This swelling and edema threaten the airway. Adults usually present with a 1- to 2-day history of sore throat, *odynophagia* (painful swallowing), dyspnea, and possibly drooling and stridor.

Use of a tongue blade to view the oropharynx is avoided; this may precipitate laryngospasm and airway obstruction. The epiglottis is visualized using a flexible fiberoptic laryngoscope to establish the diagnosis. The epiglottis appears red, swollen, and edematous. Nasotracheal intubation may be required to ensure airway patency. The patient is admitted to a critical care unit and intravenous antibiotic therapy is initiated. Ceftriaxone (Rocephin), cefuroxime (Ceftin), or ampicillin/sulbactam (Unasyn) may be prescribed. If allergic to penicillin, a combination of clindamycin (Cleocin) and either trimethoprim-sulfamethoxazole (TMP-SMZ) or ciprofloxacin (Cipro) may be used. Dexamethasone, a systemic corticosteroid, is also given to suppress the inflammatory response and rapidly reduce swelling of the epiglottis.

Nursing care for the patient with acute epiglottitis focuses on monitoring and maintaining airway patency. Monitor oxygen saturation continuously. Observe closely for signs of airway obstruction, including nasal flaring, restlessness, stridor, use of accessory muscles, and decreased oxygen saturation measurements. If the patient is not intubated, supplies for emergency intubation should be kept in the unit. Epiglottitis is frightening for both the patient and the nurse. Maintaining a calm, reassuring manner is an essential nursing role.

Laryngitis

Laryngitis, inflammation of the larynx, is a common disorder that may occur alone or in conjunction with other upper respiratory infections. It is commonly associated with viral URI such as influenza. It may also occur with bronchitis, pneumonia, other respiratory infections, or due to a tumor or polyp on the vocal cord. Excessive use of the voice, sudden changes in temperature or exposure to dust, irritating fumes, smoke, or other pollutants can also cause acute or chronic laryngitis. It is more common in the winter and in colder climates. Persistent laryngitis after URI resolution or removal of the irritant should be evaluated to rule out malignancy.

In laryngitis, the mucous membrane lining the larynx becomes inflamed; the vocal cords also may become edematous. The primary symptom of laryngitis is a change in the voice. Hoarseness or *aphonia*, complete loss of the voice, may occur. The throat is often sore and scratchy, and a dry, harsh cough may be present.

There is no specific treatment for viral laryngitis. Any identified precipitating factors such as overuse of the voice and exposure to irritants should be eliminated. Voice rest is advised, as is abstinence from tobacco and alcohol, which are chemical irritants. Treatment may also include inhaling steam or spraying the throat with antiseptic solutions. Identifying and eliminating irritants is helpful to prevent future attacks.

Impaired verbal communication is the priority nursing problem for patients with laryngitis. The meaning of messages is conveyed not only by the words used, but also by the tone and loudness of voice. Instruct to rest the voice as much as possible. Encourage speaking in short sentences or using alternate methods of communication, such as writing. Resting the voice hastens recovery and decreases throat discomfort. Advise to use soothing throat lozenges, sprays, or other comfort measures such as gargling with a warm antiseptic solution. Help identify potential irritants, such as fumes, chemicals, or cold temperature, to prevent future bouts of laryngitis.

THE PATIENT WITH DIPHTHERIA

Diphtheria is an acute, contagious disease caused by *Corynebacterium diphtheriae*, a small aerobic pathogen. This disease, which primarily affects adults, is uncommon in the United States. Waning immunity due to lack of periodic booster immunizations is the primary risk factor for diphtheria in the United States.

The disease is spread through droplet nuclei and by contamination of articles such as eating utensils. Asymptomatic carriers can be a factor in spreading this infection. People who have recovered from diphtheria can harbor bacteria in their throats for up to 4 weeks. Diphtheria is easily spread in areas where sanitation is poor, living conditions are crowded, and access to healthcare is limited. Immunization

is readily available, and infants and children are usually immunized against diphtheria, pertussis, and tetanus concurrently.

Pathophysiology and Manifestations

C. diphtheriae infects the mucous membranes of the respiratory tract and can invade skin lesions. The tonsils and pharynx are common sites of infection. Toxins released by the organism inflame mucosal surfaces of the pharynx. Exudate from inflamed tissues forms a thick, grayish, rubbery pseudomembrane over the posterior pharynx and sometimes into the trachea. This pseudomembrane adheres to inflamed, eroded surfaces and interferes with eating, drinking, and breathing. The airway may be obstructed, necessitating tracheostomy to maintain respirations. The toxins damage the heart and central nervous system (CNS) and may cause myocarditis and paralysis of cranial or peripheral nerves.

Patients with diphtheria develop fever, malaise, sore throat, and malodorous breath. In severe cases, the neck may be warm and swollen because of lymphadenopathy. Isolated patches of gray or white exudate grow and extend to form a gray membrane that becomes progressively thicker. Dislodging the membrane often causes bleeding. Symptoms of airway obstruction, such as stridor and cyanosis, can develop quickly.

●○● INTERPROFESSIONAL CARE

Collaborative care goals for diphtheria are to prevent its transmission, treat the infection, neutralize toxins, and provide respiratory support. The diagnosis is confirmed by a throat culture. Gram-stain or immunofluorescent antibody stains may also be used.

Strict isolation procedures are instituted, and all contacts are screened and immunized. Booster shots are given to people who were immunized 5 or more years previously. Unimmunized contacts are treated with immunization and antibiotics.

Diphtheria antitoxin is given to neutralize free toxin and prevent further toxin production. It is delivered via IV over 1 hour or IM. Diphtheria antitoxin is produced in horses; a skin test for sensitivity to horse serum should precede immunization because about 7% of the population is sensitive to it. Anaphylaxis is a risk during antitoxin therapy; epinephrine must be readily available. Antibiotics such as penicillin or erythromycin are administered to eliminate the organism.

●○● NURSING CARE

Patients with diphtheria require intensive nursing care. The patient is placed on bed rest and monitored closely for airway obstruction, cardiac manifestations, and CNS complications. Nutrition and fluid balance may be affected by difficulty swallowing. Upright positioning can promote fluid intake during the acute phase of the disease. Equipment for suction, emergency intubation, and tracheostomy are kept at the bedside.

SAFETY ALERT

Diphtheria is a reportable disease. Immediately contact the local health department and the Centers for Disease Control and Prevention about all suspected and confirmed cases.

Preventing further cases of diphtheria is a nursing responsibility. Symptomatic patients are isolated and treated until two negative throat cultures are obtained. Nasopharyngeal and throat cultures are also obtained from all close contacts. Asymptomatic disease carriers are confined to home until at least 3 days of antibiotic therapy have been completed. All contacts, including hospital personnel, receive tetanus and diphtheria toxoids (Td). Tetanus, diphtheria, and pertussis (Tdap) vaccine was licensed in 2005. It is the first vaccine for adolescents and adults that protects against pertussis as well as tetanus and diphtheria. It is given only once.

THE PATIENT WITH PERTUSSIS

Pertussis, or *whooping cough*, is a highly contagious acute upper respiratory infection caused by the bacterium *Bordetella pertussis*. Although it is thought to be a childhood disease that has been virtually eliminated by aggressive immunization of infants, pertussis still occurs in North America. Up to 45% of people affected by pertussis are adolescents and adults. Adults are thought to be an important reservoir for this disease (CDC, 2012b).

Pathophysiology

B. pertussis is a gram-negative rod that is spread by respiratory droplets. The bacteria attach to ciliated epithelial cells of the nasopharynx, multiplying and invading respiratory tissues. The damage and effects of pertussis are not due to the infection itself, but to toxins produced by the bacteria. These toxins damage the mucosa and paralyze the cilia. As a result, clearance of respiratory secretions is impaired, increasing the risk for pneumonia. The toxins also prompt an inflammatory response and inhibit immune defenses.

Although immunization does not appear to confer lifetime immunity, the disease tends to be milder in adolescents, adults, and people who have been immunized. These infected individuals can, however, transmit the disease to other susceptible people, including unimmunized or underimmunized infants (Huether & McCance, 2011).

Infants have the highest risk for complications of the disease, such as pneumonia and neurologic complications. Neurologic complications are thought to result from hypoxia due to prolonged paroxysms of coughing. Complications in adolescents and adults may occur as a result of increased intrathoracic pressure during prolonged coughing spells. These may include pneumothorax, weight loss, inguinal hernia, rib fracture, and *cough syncope* (fainting due to hypoxia).

Manifestations

Classic pertussis follows a predictable pattern, with typical URI symptoms (coryza, sneezing, low-grade fever, and mild cough) beginning 7 to 10 days after exposure. After 1 to 2 weeks, the cough becomes more frequent, occurring in paroxysms or bursts of rapid coughs, often ending with an audible whoop caused by rapid inspiration. This whoop is less common in adolescents and adults, often delaying diagnosis. Vomiting commonly follows an episode of coughing. Coughing paroxysms vary in frequency from several per hour to 5 to 10 per day, interfering with eating and sleep. This stage of the disease, called the *paroxysmal stage*, usually lasts no more than 6 weeks, after which coughing becomes less severe and gradually resolves over a period of up to 3 months.

MANIFESTATIONS OF PERTUSSIS

CLASSIC

- Catarrhal phase: coryza, malaise, low-grade fever, sneezing, cough
- Paroxysmal phase: frequent spasms of sometimes violent coughing, worse at night; characteristic whoop on inspiration following cough paroxysm; vomiting, fatigue, weight loss resulting from severe cough
- Convalescent phase: gradually decreasing frequency and severity of coughing episodes

ATYPICAL (OFTEN SEEN IN ADOLESCENTS AND ADULTS)

- Severe, prolonged cough that may not be paroxysmal; whoop uncommon
- Vomiting with cough
- Cough at night

In adolescents and adults, pertussis is suspected when an upper respiratory infection produces a cough that persists longer than 7 days, is accompanied by vomiting, and is worse at night. See the Manifestations box.

●○● INTERPROFESSIONAL CARE

Active immunization with pertussis vaccine is the primary preventive strategy for pertussis. Acellular pertussis vaccines that are effective, but produce fewer adverse reactions than traditional whole-cell vaccines, are available and preferred for immunization.

The diagnosis of pertussis is established by culture of nasopharyngeal secretions. However, nasopharyngeal secretions may remain positive for the organism for only about 3 weeks after the onset of symptoms, so blood tests for antibodies to the organism may be necessary to confirm the diagnosis. Lymphocytosis (elevated lymphocyte count) may be present.

Erythromycin is the antibiotic of choice to eradicate *B. pertussis* infection. TMP-SMZ may be used as an alternate to erythromycin. Hospitalization rarely is required for adults, although children and infants with severe disease often are hospitalized to prevent complications such as the neurologic effects of hypoxia and malnutrition. Respiratory isolation is instituted for 5 days after antibiotic therapy is started. Prophylactic erythromycin or TMP-SMZ is prescribed for all in the household and close contacts of the infected patient.

●○● NURSING CARE

Nurses are instrumental in promoting effective immunization of all infants and young children against pertussis. Education is a key nursing role related to immunization, because significant controversy currently exists about potential long-term adverse consequences of the vaccine. Recommend that all parents request acellular vaccine due to its lower risk of adverse effects.

Recommend nasopharyngeal culture for patients complaining of persistent cough, especially when the cough is accompanied by vomiting or significantly worse at night, or if other members of the household or close contacts have a similar illness.

Evidence for Nursing Care

The Patient with Pertussis

Selected resources that nurses may find helpful when planning evidence-based nursing care follow.

- Plavskin, A., & Nirenberg, A. (2012). Diagnosis and management of adolescents and adults with pertussis. *American Journal for Nurse Practitioners, 16*(1/2), 10–19.

PRACTICE ALERT!

Pertussis is a reportable communicable disease. Report all probable and confirmed cases to the local health department and the Centers for Disease Control and Prevention.

Education is a primary nursing role related to pertussis. Adult patients usually remain in the community for treatment. Teach respiratory isolation measures to be used until the disease is no longer communicable to others. Discuss ways to control respiratory secretions, and the importance of disposing of tissues and secretions personally to prevent exposure of others. Stress the importance of prophylactic treatment for all household and close contacts. Discuss measures to maintain fluid and nutrient intake, and use of a cough suppressant at night to promote rest. Encourage increased fluid intake to promote expectoration of respiratory secretions. Teach about the prescribed antibiotic, including its potential adverse effects and measures to reduce them, such as taking erythromycin with meals to prevent gastric upset. Contact the local county health department for follow-up of contacts and compliance with prescribed treatment. Due to resurgence of pertussis among children, adults are recommended to obtain the Tdap vaccine to boost immunity.

PRACTICE ALERT!

Adults should receive a diphtheria vaccine booster immunization every 10 years (usually given in combination with tetanus vaccine [Td]). However, the Tdap is administered only once and does not require booster injections (CDC, 2012b).

Upper Respiratory Trauma or Obstruction

Obstruction of the upper airway due to trauma (fracture of the nasal septum or the larynx), bleeding (e.g., epistaxis), or a tumor is not only frightening for the patient, but it also may interfere with the ability to breathe.

THE PATIENT WITH EPISTAXIS

The nose has a rich blood supply, receiving major arterial vessels from both the internal and external carotid artery systems. **Epistaxis**, a nosebleed, may be precipitated by a number of factors. Trauma

(picking the nose or blunt trauma) can cause epistaxis, as can drying of nasal mucous membranes, infection, substance abuse (e.g., cocaine), arteriosclerosis, or hypertension. Epistaxis may also indicate a bleeding disorder related to acute leukemia, thrombocytopenia, aplastic anemia, or severe liver disease. Additionally, treatment with an anticoagulant or antiplatelet drug may cause a nosebleed. In adults, men have nosebleeds more frequently than women.

Pathophysiology and Manifestations

Ninety percent of all nosebleeds arise in the anterior nasal septum from Kiesselbach's area, a rich vascular plexus. Because of their location, these vessels are susceptible to trauma from nose picking, drying, and infection. Posterior epistaxis more often develops secondarily to systemic disorders such as blood dyscrasias, hypertension, or diabetes. In posterior epistaxis, bleeding is from the terminal branches of the sphenopalatine and internal maxillary arteries. Posterior epistaxis tends to be more severe and occurs more frequently in the older adult.

Anterior nosebleeds usually produce obvious bleeding from the nares, as well as bleeding into the posterior nasal and oral pharynx. The bleeding from a posterior nosebleed may be less apparent, with most of the blood draining into the posterior nasopharynx and swallowed by the patient. Nausea and vomiting may occur due to swallowed blood.

●○● INTERPROFESSIONAL CARE

The goal of treatment for epistaxis is to identify and control the source of bleeding.

Anterior bleeding can usually be managed by simple first-aid measures, such as applying pressure (pinching the nose toward the septum) for 5 to 10 minutes and applying ice packs to the nose and forehead to cause vasoconstriction. The patient is placed in a sitting position to decrease blood flow to the head and reduce venous pressure. Leaning forward reduces drainage of blood backward into the nasopharynx and decreases swallowing of blood. The patient is instructed to spit out the blood to help estimate the amount of bleeding and to prevent nausea and vomiting as a result of swallowed blood.

If applying pressure does not control the bleeding, medications, nasal packing, or surgery may be necessary.

MEDICATIONS

Topical vasoconstrictors such as cocaine (0.5%), phenylephrine (Neo-Synephrine) (1:1000), or adrenaline (1:1000) may be used to control anterior bleeding. These medications may be applied by nasal spray or on a cotton swab held against the bleeding site. Chemical cauterization of the bleeding vessel may be done using agents such as silver nitrate or Gelfoam. A topical anesthetic such as tetracaine, lidocaine, or cocaine may be used prior to nasal packing. If posterior nasal packing is required, prophylactic antibiotic therapy is initiated to prevent sinusitis or possible toxic shock syndrome.

NASAL PACKING

If bleeding cannot be controlled with pressure and local medications, a nasal tampon (a soft balloon filled with air) may be used to apply direct pressure to the bleeding vessel or the nasal cavity may be packed with 0.25-inch petroleum gauze. For an anterior pack, several feet of packing are placed carefully and systematically along the floor of the nasal cavity and then into the vault of the nose. Anterior nasal packs are usually left in place for 24 to 72 hours. If epistaxis is caused by a bleeding disorder, the packing may be left in place for 4 to 5 days while the disorder is treated.

Posterior nosebleeds are more difficult to control, requiring both anterior and posterior packing (Figure 35–3 ■). Posterior packs are usually left in place for 2 to 5 days. A loose anterior nasal pack may also be inserted. Posterior nasal packing is very uncomfortable, and can cause respiratory and cardiovascular complications. Hypoxemia is common; supplementary oxygen is administered. Endotracheal

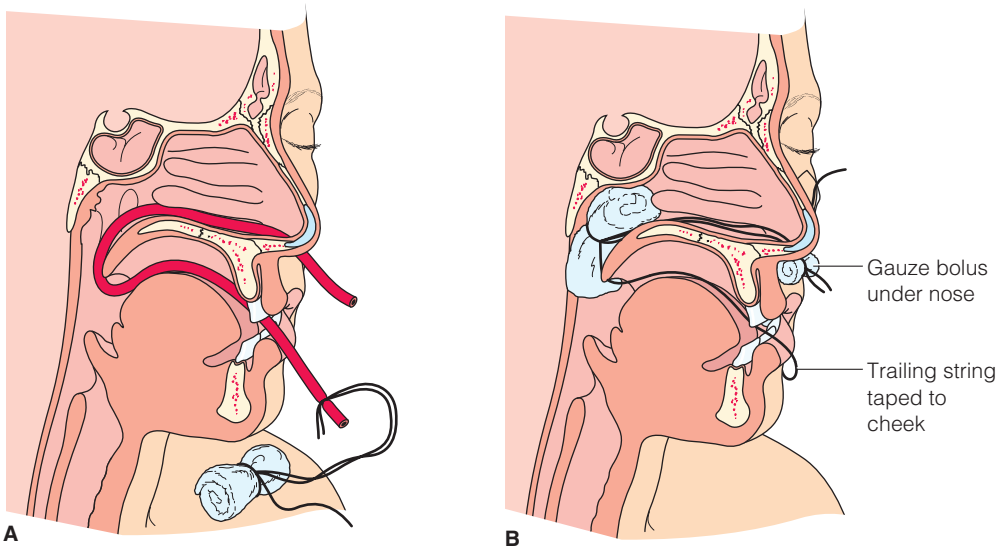

Figure 35–3 ■ Posterior nasal packing. A, A rubber catheter is inserted through the nose and out the mouth and attached to the packing. B, The catheter is withdrawn through the nose to position the packing in the posterior nasopharynx. Ties exiting through the nose and mouth are used to stabilize the packing in position and remove it when it is no longer needed.

intubation may be necessary to maintain adequate ventilation and gas exchange. Narcotic analgesics are prescribed to manage the discomfort. Hypertension, dysrhythmias, and even acute myocardial infarction may occur in patients with severe cardiovascular disease. Toxic shock syndrome is another potential complication of posterior nasal packing. The pack may occlude the eustachian tube and sinus openings, resulting in ear discomfort, possible otitis media, or sinusitis. Oral and nasal dryness can be minimized by use of a high-humidity face tent. Nursing care of the patient with nasal packing is outlined in the accompanying box.

A Foley catheter or inflatable nasal balloons may be used as an alternative to posterior nasal packing for effective tamponade. The catheter or nasal balloon is inserted through the nose into the nasopharynx, inflated, and left in place for 2 to 3 days.

SURGERY

Chemical or surgical cautery procedures may be used to sclerose involved vessels in the anterior aspect of the nose. The resulting scab must be left undisturbed until the mucosa has healed, or further bleeding may occur.

Surgical procedures to control bleeding are often preferred to posterior nasal packing for posterior bleeding. The bleeding vessel may be cauterized using an endoscopic approach. In some cases, surgery is required to occlude the internal maxillary artery by ligation (tying off) or embolization. These procedures may be done under either conscious sedation and local anesthesia or general anesthesia. Facial paralysis, paresthesias, facial pain, and dental injury are potential complications.

●○● NURSING CARE

Assessment

See the Manifestations and Interprofessional Care sections for the assessment of the patient with nosebleed.

Nursing assessment of the patient with a nosebleed focuses on the immediate problem and possible underlying conditions.

- *Health history:* duration of current bleed; any identified precipitating factors such as trauma; history of prior nosebleeds; current medications; chronic conditions such as hypertension, bleeding disorders, and so on.
- *Physical assessment:* estimated amount of bleeding; presence of blood in oropharynx; vital signs; evidence of facial or nasal trauma
- *Laboratory data:* hemoglobin, hematocrit, platelets, and WBC as indicated; oxygen saturation; tests of organ function such as liver function tests (bilirubin, AST, ALT, LDH) or kidney function tests (serum creatinine, BUN).

Priorities of Care

Collaborating with the interprofessional team to ensure adequate treatment of the underlying process while providing care that supports the physical and psychologic responses to the disorder is a priority of nursing care.

Diagnoses, Outcomes, and Interventions

Nosebleeds can be frightening, particularly when they occur without preceding trauma. Nurses provide care for patients with epistaxis in outpatient and emergency settings, and may care for hospitalized patients with nasal packing. Support, reassurance, and education are important nursing roles related to epistaxis. Priority nursing diagnoses include *Anxiety* and *Risk for Aspiration*.

Anxiety

The amount of blood lost in a nosebleed can be frightening. The sensation of blood draining down the throat and inability to breathe through the nose contribute to anxiety. Spontaneous epistaxis may lead to fear of a major health problem such as high blood pressure. This is not a life-threatening event. The nurse should model calmness for the patient and family.

Expected Outcome: Patient will be able to control anxiety as evidenced by verbalized decrease in subjective distress.

- Maintain an attitude of calm reassurance. *By remaining calm and confident, the nurse reassures the patient that the nosebleed is not a life-threatening event.*
- Instruct the patient to pinch the nares together at the bridge of the nose. *Most nosebleeds are anterior in origin; direct pressure usually*

NURSING CARE OF THE PATIENT

With Nasal Packing

- Continuously monitor oxygen saturation. Administer supplementary oxygen as ordered. *Posterior nasal packing causes hypoxemia. Supplemental oxygen is given to maintain tissue oxygenation.*
- Frequently monitor vital signs and respiratory rate or pattern. *Posterior nasal packing increases the risk for respiratory and cardiovascular complications. Tachycardia and tachypnea may be early signs of cardiac or respiratory compromise.*
- Inspect the mouth and oropharynx. Notify the healthcare provider if the packing is seen in the oropharynx. *Misplacement of nasal packing can obstruct the upper airway.*
- Elevate the head of the bed. *Elevating the head of the bed facilitates ventilation.*
- Encourage deep, slow breathing through the mouth. Provide psychologic support, reassurance, and teaching. *Inability to breathe through the nose causes anxiety and fear.*
- Check for blood at the back of the throat and frequent swallowing. *Visible blood or frequent swallowing could indicate posterior bleeding.*
- Report hematemesis. *Bleeding from the posterior portion of the nose often drains down the nasopharynx and is swallowed. Hematemesis may indicate continued bleeding.*
- Apply cold compresses to nose. *An ice or cold compress decreases pain and promotes vasoconstriction, decreasing bleeding and swelling.*
- Provide for rest. *Rest reduces the metabolic demands and oxygen consumption.*
- Ensure adequate oral fluid intake. *Fluid intake helps maintain fluid balance and decreases dryness of oral mucous membranes because of mouth breathing.*
- Provide frequent oral hygiene. Use a bedside humidifier. *These measures reduce drying of oral mucous membranes and promote comfort.*

stops the bleeding. Having the patient place pressure on the nose provides a focus and helps restore a sense of control, reducing anxiety.

- Encourage slow, deep breathing through the mouth. *Controlled mouth breathing maintains lung ventilation and reduces anxiety.*
- Provide a basin and tissues; encourage the patient to expectorate blood, not swallow it. *These measures give the patient greater control and reduce the fear of choking on blood.*

SAFETY ALERT

Assess the patient with nasal packing frequently for adequate oxygenation. Maintain supplemental oxygen as ordered. Cerebral hypoxia produces a sense of apprehension and fear.

Risk for Aspiration

The combination of anxiety and blood draining into the nasopharynx increases the risk for aspiration of blood into the trachea. When nasal packing is in place, the patient is unable to breathe through the nose, increasing the risk of aspiration when food or fluids are consumed.

Expected Outcome: Patient will use vasoconstrictive techniques (i.e., cold compress to face) and head positioning to reduce bloody drainage down the nasopharynx.

- Position upright with the head forward. Provide a basin for expectorating blood. *These measures minimize the amount of blood draining down the nasopharynx and swallowed, reducing the risk of aspiration and minimizing nausea from swallowed blood. Vomiting of swallowed blood increases the risk of aspiration.*
- Apply ice or a cold compress to the nose. *Cold causes vasoconstriction, reducing bleeding.*

Position the patient with nasal packing with the head elevated and on the side when asleep. This position reduces the risk of aspiration of oral secretions.

Continuity of Care

Following an episode of epistaxis, teaching for home care focuses on measures to prevent further bleeding. Include the following teaching topics:

- Avoid strenuous exercise for several days or weeks, depending on the severity of the nosebleed and its treatment.
- Do not blow the nose or engage in activities such as heavy lifting or bending that could increase pressure and dislodge the crust; sneeze with the mouth open to avoid increasing pressure in nasal vessels.
- For an anterior nosebleed, use petroleum jelly, a water-soluble lubricant, or bacitracin ointment to lubricate nasal mucosa and reduce the risk of spontaneous bleeding.
- Use a humidifier or vaporizer to minimize dryness of the mucous membranes.
- Do not forcefully blow the nose or pick the nose.
- For a spontaneous nosebleed, seek medical evaluation for any possible underlying problem, such as hypertension or a bleeding disorder.

THE PATIENT WITH NASAL TRAUMA OR SURGERY

The nose is the most commonly broken bone of the face. A nasal fracture (broken nose) usually is caused by a sports injury or trauma related to violence or motor vehicle crashes. The nasal septum normally divides the nose into two equal parts. Deviation of the septum can result from nasal trauma. Soft tissue trauma commonly accompanies nasal fracture.

Pathophysiology and Manifestations

One or both sides of the nose may be broken. A *unilateral fracture* involves only one side of the nose. It causes little displacement or cosmetic deformity. It is usually not serious, but septal deviation and swelling can obstruct the airway. *Bilateral fractures* are more common, with depression or displacement of both nasal bones to one side. The nose appears flattened or deviated with an S or C configuration. *Complex fractures* may also involve the septum, ascending processes of the maxilla, and frontal bones of the face.

Soft tissue trauma commonly accompanies nasal fracture. Mucous membrane tears cause epistaxis. Soft tissue hematomas (black eyes) are also frequent. Swelling develops rapidly following the injury and may obscure the fracture. Boney crepitus may be felt on gentle palpation. Septal hematoma may develop, increasing the risk for infection. The manifestations of nasal fracture are listed in the Manifestations box.

COMPLICATIONS

Potential complications of nasal fracture include septal hematoma and abscess formation, septal perforation or deviation, and cerebrospinal fluid (CSF) leakage. Septal hematoma can lead to complete and bilateral nasal obstruction. If undrained, hematoma increases the risk of staphylococcal abscess, which can lead to necrosis of septal cartilage and *saddle nose deformity.*

Septal deviation causes varying degrees of nasal obstruction. The septal cartilage bulges or deviates to one side, partially or totally obstructing the nares. Mild deviation is generally asymptomatic. Partial obstruction of airflow through one side may cause noisy breathing while awake and snoring during sleep. Major deviations can cause pain because of sinus obstruction or infection. They may also cause nosebleeds due to dryness of the nasal mucosa. Occasionally, the defect is severe enough to cause cosmetic deformity. Perforations are usually not serious and do not usually require repair unless obstruction or external deformity occurs.

Fractures of other facial bones may accompany a broken nose, particularly when facial trauma is severe. Fractures in the nasoethmoidal or frontal region can disrupt the dura, causing CSF leakage or rhinorrhea. CSF rhinorrhea is suspected when watery nasal drainage tests positive for glucose.

●○● INTERPROFESSIONAL CARE

The major treatment goals for nasal fractures are to maintain a patent airway and prevent deformity. Respirations are closely monitored.

DIAGNOSIS

Head and facial x-rays are done to identify the fracture and assess for other facial fractures. The intranasal cavity is examined using a nasal speculum to rule out septal hematoma. If a CSF leak is suspected,

MANIFESTATIONS OF NASAL FRACTURE

- Epistaxis
- Deformity or displacement to one side
- Crepitus
- Periorbital edema and ecchymosis
- Nasal bridge instability

a CT scan is done. A radiopaque substance or fluorescein dye may be instilled into the intrathecal or lumbar subarachnoid space to identify the site of leakage.

TREATMENTS

Ideally, the fracture is reduced early, before significant edema develops. Nasal fractures heal rapidly. Simple reduction may be done in the emergency department with local anesthesia. An external splint may be applied for 7 to 10 days to maintain proper alignment until healing occurs. The splint is padded to prevent skin breakdown. Ice may be gently applied to the face and nose to control edema and bleeding. Nasal packing may be used to control epistaxis.

SURGERY

Complex nasal fractures, nasal septal deviation, or persistent CSF leakage may require surgical repair or realignment of nasal bones. Rhinoplasty with concurrent septoplasty is the most common procedure used to repair nasal fracture or a deviated nasal septum.

Rhinoplasty is surgical reconstruction of the nose. It is done to relieve airway obstruction and repair visible deformity of the nose following fracture. If edema is excessive after nasal fracture, surgery is delayed for 7 to 10 days to allow swelling to subside. Using an intranasal incision, the nasal skin is lifted and the framework of the nose reshaped by removing, rearranging, or augmenting bone or cartilage. The skin is then repositioned over the reconstructed frame. Prosthetic implants may help reshape the nose. Either local or general anesthesia may be used; hospitalization is often unnecessary. Following surgery, nasal packing is left in place for up to 72 hours to minimize bleeding and provide tissue support. A temporary plastic splint molded to the shape of the nose is removed in 3 to 5 days. The splint protects the reshaped nose and helps to control swelling. Most swelling and bruising subside within 10 to 14 days; normal sensation returns within several months following surgery. Rhinoplasty generally has few complications.

Either a septoplasty or a submucous resection (SMR) may be done under local anesthesia to correct a deviated septum. *Septoplasty* involves incising one side of the septum, elevating the mucous membrane, and removing or straightening the deviated portion of septal cartilage. In a *submucous resection*, bone and cartilage are removed. In both procedures, packing is applied to both sides of the nose to prevent bleeding and to keep the septal mucosa in midline position.

Small defects in the cribriform plate, fovea ethmoidalis, or sphenoid sinus associated with persistent CSF leakage may require endoscopic repair. Either a tissue graft or fibrin glue may be used to repair the defect. The graft or glue is held in place with absorbable packing. Large defects may require craniotomy for repair.

●○● NURSING CARE

Health Promotion

Teach all people, children and adolescents in particular, about the importance of wearing helmets and facial protectors when participating in high-risk sports such as football, hockey, and baseball catching. Promote the use of seat belts with shoulder harness and airbags in vehicles to reduce the risk of facial injury in motor vehicle crashes.

Assessment

See the Manifestations and Interprofessional Care sections for the assessment of the patient with nasal trauma.

Focused nursing assessment for the patient with a suspected nasal fracture includes the following:

- *Health history:* nature and circumstances of the injury; pain; ability to breathe through the nose; complications from prior head injury
- *Physical assessment:* evident trauma, swelling, ecchymosis, or deformity of the nose; vital signs, respiratory rate and ease; gentle palpation of nose and facial bones for crepitus; inspection of oropharynx for drainage; testing of nasal discharge for glucose.

Priorities of Care

Collaborating with the interprofessional team to ensure adequate treatment of the underlying process while providing care that supports the physical and psychologic responses to the disorder is a priority of nursing care.

Diagnoses, Outcomes, and Interventions

Nursing care for patients with nasal fracture focuses on controlling pain, bleeding, and swelling. Airway management is a priority. Most nasal fractures are managed on an outpatient basis, and education is a vital nursing function. See the accompanying Case Study & Nursing Care Plan for additional nursing diagnoses and interventions for the patient with nasal trauma.

Ineffective Airway Clearance

Immediately following nasal trauma and fracture, the airway is at risk for obstruction by bleeding and edema. Deformity resulting from inappropriate fracture position during healing also can impair nasal airway clearance. This is a consideration when inserting nasogastric tubes or suctioning patients with septal deviation.

Expected Outcome: Patient will use techniques to promote airway clearance such as coughing and deep breathing.

- Monitor airway patency. *Edema and bleeding may obstruct the airway, causing signs of respiratory distress such as tachypnea, dyspnea, shortness of breath, tachycardia, and use of accessory muscles.*
- Monitor cough effectiveness and ability to clear airway secretions. *Pain, edema, and nasal bleeding may impair the ability to cough effectively.*

SAFETY ALERT

Have suction equipment available. Airway patency is a priority; oropharyngeal suctioning may be necessary to remove secretions and maintain a clear airway. Suctioning of the nasopharynx is avoided to prevent additional tissue trauma.

- Maintain adequate hydration. Assess mucous membranes and skin turgor for evidence of dehydration. *Decreased oral fluid intake may lead to dehydration and thick, viscous secretions that are more difficult to expectorate.*
- Assess patency of both nares before inserting a nasogastric tube or feeding tube. If airflow is obstructed through one side, insert the tube through the unobstructed nare. Carefully monitor respiratory status following tube insertion. *The nasogastric tube is inserted through the unobstructed nare to avoid mucosal trauma; however, a large gastric tube may interfere with nasal breathing, necessitating close monitoring.*

CASE STUDY & NURSING CARE PLAN A Patient with Nasal Trauma

Clifton Kavanaugh is a 36-year-old mailman who broke his nose when he was hit in the face by a baseball. He is admitted to the emergency department accompanied by a friend.

ASSESSMENT

Mr. Kavanaugh presents with obvious deformity of the nose. It is swollen, bloody, and deviated to one side. The nose is bleeding slightly. Mr. Kavanaugh rates the pain as a 6 on a scale of 1 to 10. Vital signs are BP 132/70 mmHg, P 120 bpm and regular, R 22/min, T 37°C (98.6°F) axillary.

Mr. Kavanaugh is breathing through his mouth and holding an ice compress to his nose. Boney crepitus and edema are felt on palpation. There is no evidence of CSF leak from either nose or ears. X-ray confirms a nasal fracture.

DIAGNOSES

- *Acute Pain* related to nasal fracture
- *Ineffective Breathing Pattern* related to nasal swelling and bleeding
- *Anxiety* related to pain and need for emergency care
- *Disturbed Body Image* related to nasal deformity

EXPECTED OUTCOMES

- Patient will verbalize relief of pain.
- Patient will maintain a patent airway and normalize his breathing pattern.
- Patient will demonstrate reduced anxiety.
- Patient will express concerns about potential body image change.

PLANNING AND IMPLEMENTATION

- Administer analgesics as ordered.
- Apply ice compress to nose.
- Inspect oropharynx for evidence of bleeding.
- Encourage deep, slow breathing through the mouth.
- Provide oral hygiene.
- Discuss concerns regarding injury.
- Assist with nasal splint application.

EVALUATION

Following treatment, Mr. Kavanaugh reports his pain has decreased to a level of 2 on a scale of 1 to 10. He appears more relaxed, has a relaxed posture, and is no longer grimacing. His respirations are easy at 18/min. The nasal splint is intact. Mr. Kavanaugh is able to look in a mirror and state with a laugh, "I look like a raccoon." He is admitted to the hospital for rhinoplasty.

Clinical Reasoning in Patient Care

1. A patient in the emergency department with nasal trauma becomes extremely panicky because of blood draining down his throat. How would you intervene to reduce this patient's anxiety without using nasal suction? Why is it important to avoid suctioning the nasopharynx in the patient with nasal trauma?
2. Develop a plan of care for the patient with a leak of CSF from a nasal fracture.
3. Compare immediate versus delayed rhinoplasty for the patient with nasal fracture.

See Evaluating Your Response in Appendix B.

Risk for Infection

The patient with a nasal fracture is at increased risk for infection. The nasal mucosa is a natural barrier to infection, and trauma increases the risk for invasion by pathogens. Septal hematoma can lead to abscess formation and staphylococcal infection. A CSF leak indicates disruption of the dura, increasing the risk of ascending infection and meningitis.

Expected Outcome: Patient will describe measures to protect healthy tissue and prevent infection.

SAFETY ALERT

Test watery, clear fluid dripping from the ear or nose for glucose. CSF will test positive for glucose on a Dextrostrip.

- Avoid suctioning if possible. *Suctioning catheters could introduce microorganisms and cause additional trauma to tissues.*
- Monitor vital signs every 4 hours. *A rise in temperature may indicate infection.*
- Administer antibiotics as ordered. *Antibiotics may be prescribed to prevent abscess formation, and, if CSF leakage is present, to prevent meningitis.*

Continuity of Care

Provide the following teaching when preparing the patient with a nasal fracture for home care:

- Elevate the head of the bed with blocks and apply ice or cold packs to the nose for 20 minutes four times a day to reduce swelling.
- Swelling usually subsides in several days; bruising may persist for several weeks.
- It is difficult to determine the final cosmetic outcome until swelling has subsided.
- If indicated by delayed fracture reduction or malformation, discuss rhinoplasty and its potential benefits.

If CSF leakage is present, also include the following instructions:

- Rest in bed with the head of the bed elevated to 30 to 45 degrees.
- Restrict fluid intake as ordered and take the prescribed diuretic to reduce intracranial pressure and CSF leakage.
- Distribute allowed fluids throughout the day.
- List name, purpose, effects, and precautions for any prescribed medication.
- Avoid straining, blowing the nose, sneezing, or vigorous coughing until allowed by the healthcare provider.
- Immediately report manifestations of infection, including stiff neck, headache, and fever to the healthcare provider.

Following rhinoplasty or septoplasty, provide the following instructions:

- Apply ice packs to the nose to relieve discomfort and reduce swelling.
- Elevate the head of the bed on blocks to decrease local edema.
- Do not blow the nose for 48 hours after the packing is removed to prevent bleeding.
- Vigorous coughing or straining at stool may cause bleeding and should be avoided.
- Clean teeth and mouth frequently and increase fluid intake to decrease oral dryness due to mouth breathing.
- Bruising around the eyes and nose will last for several days.

THE PATIENT WITH LARYNGEAL OBSTRUCTION OR TRAUMA

The larynx is the narrowest portion of the upper airway. As such, it is at risk for obstruction. Laryngeal obstruction is a life-threatening emergency. Blows to the neck or other traumatic injuries may damage the larynx, interfering with its patency and function.

Pathophysiology and Manifestations

LARYNGEAL OBSTRUCTION

The larynx may be partially or fully obstructed by aspirated food or foreign objects, or by laryngospasm or edema due to inflammation, injury, anaphylaxis, or a tumor. Anything that occludes the larynx can obstruct the airway. The most common cause of obstruction in adults is ingested meat that lodges in the airway (the so-called *café coronary*). Risk factors for food aspiration include ingesting large boluses of food and chewing them insufficiently, consuming excess alcohol, and wearing dentures. A foreign body in the larynx causes pain, laryngospasm, dyspnea, and inspiratory stridor. Aspirated foreign bodies may pass through the larynx into the trachea and lungs, causing pneumonitis.

Laryngospasm occurs due to repeated or traumatic intubation attempts, chemical irritation, or hypocalcemia. An acute type I hypersensitivity response may cause anaphylaxis with release of inflammatory mediators, leading to angioedema of upper airways and severe laryngeal edema.

The most common manifestations of laryngeal obstruction are coughing, choking, gagging, obvious difficulty breathing with use of accessory muscles, and inspiratory stridor. As the airway is obstructed, signs of asphyxia become apparent. Respirations are labored and noisy with wheezing and stridor. Cyanosis may develop. Respiratory arrest and death may result without prompt treatment.

LARYNGEAL TRAUMA

Trauma to the larynx can occur in motor vehicle crashes or assaults (e.g., blows to the neck or attempted strangulation). The larynx also may be traumatized during endotracheal intubation or tracheotomy. Trauma may fracture thyroid and/or cricoid cartilage, resulting in loss of airway patency. Soft tissue injuries can cause swelling that further impairs the airway. Manifestations of laryngeal trauma may include subcutaneous emphysema or crepitus, voice change, dysphagia and pain with swallowing, inspiratory stridor, hemoptysis, and cough.

●○● INTERPROFESSIONAL CARE

The treatment goal is to maintain an open airway. If airway obstruction is partial and the patient is able to cough and move air in and out of the lungs, radiologic and laryngoscopic examination may be done to locate the foreign body. An endotracheal tube may be inserted to maintain airflow through the larynx in spasm or an edematous larynx. For anaphylaxis, epinephrine may be administered to reduce laryngeal edema and relieve obstruction.

When airway obstruction due to a foreign body is complete, the Heimlich maneuver is performed immediately to clear the obstruction. For the conscious person, the rescuer wraps his or her arms around the victim from behind, places one fist between the umbilicus and xiphoid process, covers the fist with the other hand and forcefully thrusts the hands upward (Figure 35–4A ■). For the unconscious victim, the rescuer straddles the victim's thighs and delivers thrusts upward and inward on the upper abdomen (Figure 35–4B). These moves are continued until the obstruction is relieved or more definitive care can be given. Endotracheal intubation may be attempted. If intubation is unsuccessful, an immediate cricothyrotomy or tracheotomy must be performed to open the airway.

CT scan is used to identify laryngeal fractures; however, emergency treatment may be required prior to diagnosis to ensure airway patency and preserve life. Soft tissue injuries may be managed conservatively with a bedside humidifier, intravenous fluids, antibiotics, and corticosteroids to reduce edema. More severe injuries

Figure 35–4 ■ Administering abdominal thrusts (the Heimlich maneuver) to A, a conscious victim, and B, an unconscious victim.

require endotracheal intubation or immediate tracheostomy. Nursing care related to caring for the patient with a tracheostomy is presented later in this chapter. See Chapter 37 for more information about endotracheal intubation and nursing care for the intubated patient.

SAFETY ALERT

The priority of nursing care in laryngeal obstruction or trauma is restoring a patent airway to prevent cerebral anoxia and death. Laryngeal obstruction and trauma are medical emergencies requiring immediate intervention.

●○● NURSING CARE

Closely monitor patients at risk for laryngeal obstruction (e.g., following neck trauma, newly extubated patients, and people receiving medications with a high risk of anaphylaxis, such as intravenous antibiotics or radiologic dyes) for manifestations of obstruction, including dyspnea, nasal flaring, tachypnea, anxiety, wheezing, and stridor. Suction the airway as needed; small aspirated foreign bodies might possibly be removed by suctioning. If obstruction is complete, initiate a cardiopulmonary arrest procedure and perform the Heimlich maneuver until the obstruction is relieved or the emergency response team arrives. Prepare to assist with emergency intubation or tracheotomy as needed. Provide emotional support, reassurance, and teaching for the patient and family to reduce anxiety.

Continuity of Care

Health promotion and teaching for home care focus on preventing laryngeal obstruction and early intervention techniques. Everyone should be aware of the risk factors for adult aspiration. Caution patients who wear dentures to take small bites, chewing each bite carefully before swallowing. Discuss the relationship between excess alcohol intake and food aspiration. Participate in promoting training of the general public in CPR and the Heimlich maneuver. The more people who are adequately trained in emergency procedures, the more likely it is that emergency procedures will be initiated in a timely manner. Patients with a known risk for anaphylaxis, such as people with a previous anaphylactic response and those allergic to bee venom, should wear a medical alert tag and carry a bee-sting kit to allow early intervention to prevent severe laryngeal edema and spasm.

THE PATIENT WITH OBSTRUCTIVE SLEEP APNEA

Sleep apnea, intermittent absence of airflow through the mouth and nose during sleep, is a serious and potentially life-threatening disorder. It affects at least 2% of middle-aged women and 4% of middle-aged men. Sleep apnea is a leading cause of excessive daytime sleepiness, and may contribute to other problems such as poor work performance and motor vehicle crashes (Huether & McCance, 2011; Weaver, 2008a, 2008b,). Recent studies have linked sleep apnea with an increased risk for hypertension, ischemic heart disease, and exacerbation of heart failure (Huether & McCance, 2011).

Types of sleep apnea include obstructive and central. In *obstructive sleep apnea*, the more common type, the respiratory drive remains intact, but airflow ceases due to occlusion of the oropharyngeal airway. *Central sleep apnea* is a rare neurologic disorder that involves transient impairment of the neurologic drive to respiratory muscles.

Pathophysiology

During sleep, skeletal muscle tone decreases (except the diaphragm). The most significant decrease occurs during rapid eye movement (REM) sleep (Huether & McCance, 2011). Loss of normal pharyngeal muscle tone permits the pharynx to collapse during inspiration as pressure within the airways becomes negative in relation to atmospheric pressure. The tongue is also pulled against the posterior pharyngeal wall by gravity during sleep, causing further obstruction. Obesity or skeletal or soft tissue changes that decrease inspiratory tone, such as a relatively large tongue in a relatively small oropharynx, contribute to the problem. Airflow obstruction causes the oxygen saturation, Po_2, and pH to fall, and the Pco_2 to rise. This progressive asphyxia causes brief arousal from sleep, which restores airway patency and airflow. Sleep can be severely fragmented because these episodes may occur hundreds of times each night.

Manifestations

Narrowed upper airways produce loud snoring during sleep, often years before obstructive sleep apnea occurs. Excessive daytime sleepiness, headache, irritability, and restless sleep also are common manifestations. See the accompanying Manifestations box.

Complications

Recurrent episodes of apnea and arousal during sleep have secondary physiologic effects. Sleep fragmentation and loss of slow-wave sleep are thought to contribute to neurologic and behavior problems such as excessive daytime sleepiness, impaired intellect, memory loss, and personality changes. Recurrent nocturnal asphyxia and negative intrathoracic pressure due to airway obstruction increase the workload of the heart. People with coronary heart disease may develop myocardial ischemia and angina. Dysrhythmias, such as significant bradycardia and dangerous tachydysrhythmias, may develop. Left ventricular function may be impaired and heart failure may occur. Systemic blood pressure remains high during sleep and may contribute to systemic hypertension that affects more than 50% of people with obstructive sleep apnea. Pulmonary hypertension also may develop. Sudden cardiac death is believed to be a potential fatal complication of obstructive sleep apnea.

Obstructive sleep apnea is a common condition in people who are morbidly obese. When these patients undergo gastric bypass surgery to treat their obesity, sleep apnea places them at significant risk for postoperative respiratory complications. Not only does the

MANIFESTATIONS OF OBSTRUCTIVE SLEEP APNEA

- Loud, cyclic snoring
- Periods of apnea lasting 15 to 120 seconds during sleep
- Gasping or choking during sleep
- Restlessness, thrashing during sleep
- Daytime fatigue and sleepiness
- Morning headache
- Personality changes, depression
- Intellectual impairment
- Impotence
- Hypertension

obesity interfere with chest movement and ventilation, it increases metabolic demands and carbon monoxide production. Anesthetic and analgesics used during surgery and in the postoperative period can lead to hypoxemia due to muscle relaxation and depression of the respiratory drive.

Risk Factors

In addition to male gender, risk factors for obstructive sleep apnea include increasing age and obesity. Large neck circumference (> 43 cm [17 in.] in men and > 41 cm [16 in.] in women) also is a known risk factor for obstructive sleep apnea (Huether & McCance, 2011). Use of alcohol and other CNS depressants may contribute to sleep apnea.

●○● INTERPROFESSIONAL CARE

The goal of care for obstructive sleep apnea is to restore airflow and prevent the adverse effects of the disorder. Sustained weight loss may cure obstructive sleep apnea.

DIAGNOSIS

The diagnosis of obstructive sleep apnea is based on *polysomnography*, an overnight sleep study. Several variables are recorded during the study:

- Electroencephalogram and measurements of ocular activity and muscle tone
- Recordings of ventilatory activity and airflow
- Continuous arterial oxygen saturation readings
- Heart rate.

Transcutaneous arterial P_{CO_2} readings also may be monitored during the study. Because sleep studies are time consuming and expensive, overnight monitoring of oxygen saturation by pulse oximetry may be used to confirm the diagnosis of sleep apnea when symptoms indicate a high probability of the disorder. See Chapter 41 for more information about electroencephalography.

TREATMENTS

Mild to moderate obstructive sleep apnea may be treated by losing weight, abstaining from alcohol, improving nasal patency, and avoiding the supine position for sleep. Although weight reduction often cures the disorder, maintaining optimal weight is difficult. Oral appliances designed to keep the mandible and tongue forward also may be prescribed.

Nasal continuous positive airway pressure (CPAP) is the treatment of choice for obstructive sleep apnea. Positive pressure generated by an air compressor and administered through a tight-fitting nasal mask (Figure 35–5 ■) splints the pharyngeal airway, preventing collapse and obstruction. With proper training, this device is well tolerated by the patient. Nasal airways can become dry and irritated with CPAP, so an in-line humidifier or room humidifier is recommended. A newer device, the BiPAP ventilator, delivers higher pressures during inhalation and lower pressures during expiration, providing less resistance to exhaling.

SURGERY

Tonsillectomy and adenoidectomy may relieve upper airway obstruction in some patients. Excision of obstructive tissue from the soft palate, uvula, and posterior lateral pharyngeal wall may be accomplished by *uvulopalatopharyngoplasty* (*UPPP*). Although only about 50% of these surgeries are successful in treating sleep apnea, UPPP is useful in selected cases. In severe cases, tracheostomy may also be performed to bypass the area of obstruction.

Figure 35–5 ■ A patient using a nasal mask and CPAP to treat sleep apnea.

●○● NURSING CARE

Obstructive sleep apnea usually is treated in the home. Nursing care focuses on teaching the patient and family about equipment use and strategies to decrease contributing factors such as obesity and alcohol intake. The following nursing diagnoses are appropriate for patients with sleep apnea:

- *Disturbed Sleep Pattern* related to repeated apneic episodes
- *Fatigue* related to interrupted sleep patterns
- *Ineffective Breathing Pattern* related to obstruction of upper airway during sleep
- *Impaired Gas Exchange* related to altered lung ventilation during obstructive episodes
- *Risk for Injury* related to daytime somnolence and altered judgment
- *Risk for Sexual Dysfunction* related to impotence resulting from sleep apnea

Continuity of Care

Effective sleep apnea management depends on the patient's willingness to participate in care. Provide teaching about the following topics:

- Relationship between obesity and sleep apnea
- Plans, resources, and referrals as needed for weight loss (e.g., programs such as Weight Watchers to provide additional support)
- Relationship of alcohol and sedatives to sleep apnea; referral to an alcohol treatment program or Alcoholics Anonymous as indicated
- How to use CPAP if ordered
- The importance of using CPAP continuously at night
- Measures to reduce airway dryness, including supplemental humidity and an adequate fluid intake to maintain moist mucous membranes.

If a support group for people with sleep apnea syndrome is available in the local area, refer the patient and family to the group.

Upper Respiratory Tumors

Although tumors of the upper respiratory tract are relatively uncommon, they have the potential to impair the upper airways and interfere with breathing and ventilation of the lungs. Of the upper respiratory tract structures, the larynx is affected by abnormal growths most often.

THE PATIENT WITH NASAL POLYPS

Nasal polyps are benign grapelike growths of the mucous membrane lining the nose. These benign tumors can interfere with air movement through nasal passages or obstruct sinus openings, leading to sinusitis. They usually affect people who have chronic allergic rhinitis or asthma.

Pathophysiology and Manifestations

Chronic irritation and swelling of the mucous membranes from allergic rhinitis may cause slow polyp formation. Polyps form in areas of dependent mucous membrane, presenting as pale, edematous masses covered with mucous membrane. They are usually bilateral and have a stemlike base, making them fairly movable. Polyps can continue to enlarge, eventually becoming larger than a grape. Polyps may be asymptomatic, although large polyps may cause nasal obstruction, rhinorrhea, and loss of sense of smell. Sinusitis may develop because sinus drainage is obstructed. The voice may have a nasal tone. Asthmatics who have nasal polyps may have an associated aspirin allergy of which they are not aware.

●○● INTERPROFESSIONAL CARE

When polyps occur in conjunction with an acute upper respiratory infection, they may regress spontaneously with resolution of the infection. When symptomatic, polyps may be managed with topical corticosteroid nasal sprays or low-dose oral corticosteroids to shrink the edematous polyps and manage allergic symptoms. However, polyps continue to enlarge when corticosteroid therapy is discontinued.

Surgery may be required to restore normal breathing. Surgical removal of polyps (*polypectomy*) often is done in the healthcare provider's office under local anesthesia. A wire snare is used to clip the polyps from their stemlike base. Nasal packing is inserted to control bleeding after removal. Alternatively, laser surgery may be used to remove polyps. Healing is more rapid following laser intervention, and the risk of bleeding is reduced. Because polyps tend to recur, repeated surgeries may be necessary.

●○● NURSING CARE

Teaching about home care following polypectomy is the primary nursing responsibility for the patient with nasal polyps. Provide postoperative care instructions, and discuss measures to reduce the risk of bleeding.

- Apply ice or cold compresses to the nose to decrease swelling, promote comfort, and prevent bleeding.
- Avoid blowing the nose for 24 to 48 hours after nasal packing is removed.
- Avoid straining at stool, vigorous coughing, and strenuous exercise.

Discuss manifestations of possible bleeding, such as frequent swallowing or visible blood at the back of the throat. Swallowed blood may cause nausea and vomiting. Encourage the patient to rest for 2 to 3 days after surgery to reduce the risk of bleeding. Instruct to increase fluid intake and to clean mouth frequently to reduce oral dryness associated with mouth breathing while nasal packing is in place.

THE PATIENT WITH A LARYNGEAL TUMOR

Laryngeal tumors may be either benign or malignant. Benign tumors of the larynx include papillomas, nodules, and polyps. People who chronically shout, project, or vocalize in an abnormally high or low tone, abusing their voice, are at risk for developing benign laryngeal tumors. In adults, vocal cord nodules are often referred to as "singer's nodules"; cheerleaders and public speakers may also develop them. Voice abuse also contributes to the development of vocal cord polyps, as does cigarette smoking and chronic irritation from industrial pollutants.

FAST FACTS

- Malignancy, or cancer, of the larynx is uncommon and is often curable if detected early.
- An estimated 3650 people died from laryngeal cancer in 2012; and 12,360 new cases were diagnosed (American Cancer Society [ACS], 2012a).

Pathophysiology and Manifestations

BENIGN TUMORS

Papillomas are small, warty growths that are HPV viral in origin. Polyps and nodules may develop on the vocal cords of the larynx as a result of voice abuse (Figure 35–6 ■). Nodules often occur as paired lesions on the free edges of the vocal cords. Hoarseness and a breathy voice quality are manifestations of benign vocal cord tumors.

LARYNGEAL CANCER

Squamous cell carcinoma is the most common malignancy of the larynx. Changes in the laryngeal mucosa occur over time as it is

Figure 35–6 ■ Laryngoscopy showing a polyp on the left vocal cord.
Source: Photo Researchers, Inc.

subjected to noxious irritants such as cigarette smoke. White, patchy, precancerous lesions known as *leukoplakia* appear. Red, velvety patches, called *erythroplakia*, are thought to represent a later stage of carcinoma development. The initial cancerous lesion, carcinoma in situ (CIS), is superficial. Malignant cells replace the lining layer, but do not invade into deeper tissues. Untreated, most CIS lesions develop into squamous cell cancer (ACS, 2012b). Laryngeal cancer spreads by both direct invasion of surrounding tissues and by metastasis. It may metastasize to the lungs; however, metastases of other cancers to the larynx are rare.

Laryngeal cancer may develop in any of the three areas of the larynx: the glottis, supraglottis, or subglottis. Manifestations vary according to the site of the lesion.

Lesions of the true vocal cords or glottis account for nearly 60% of all laryngeal cancers. Fortunately, these cancers tend to be well differentiated and slow growing. Metastasis occurs late in the course of the disease because of a limited lymphatic supply. The usual symptom of glottic cancer is hoarseness, or a change in the voice because the tumor prevents complete closure of the vocal cords during speech.

Approximately 35% of laryngeal cancers develop in the supraglottic area, which includes the epiglottis, aryepiglottic folds, arytenoid muscles and cartilage, and false vocal cords (Figure 35–7 ■).

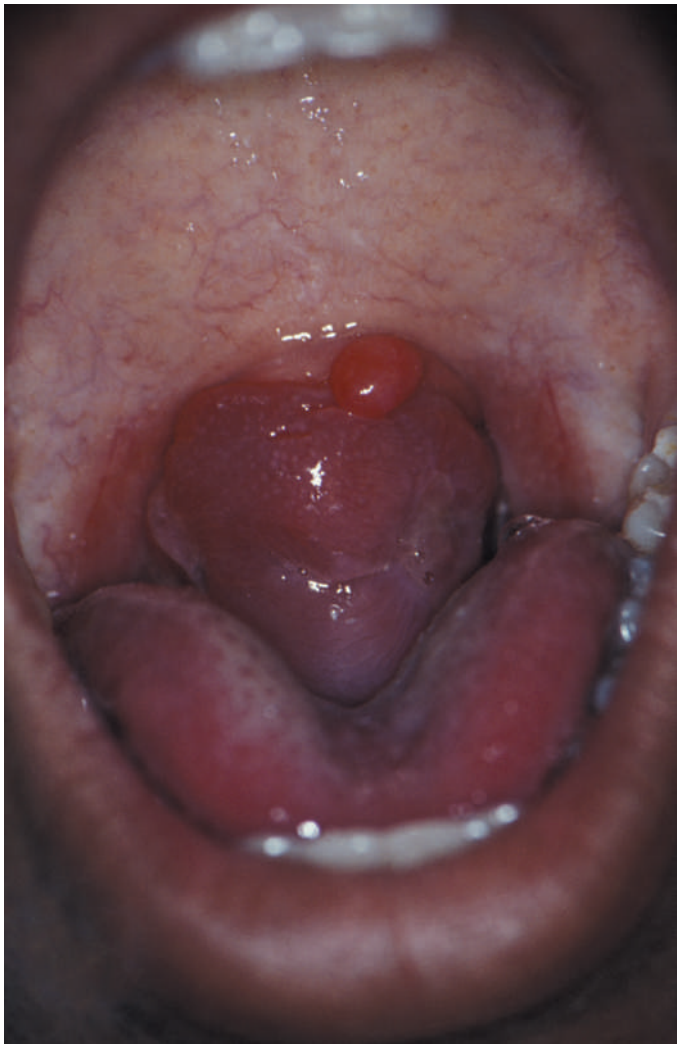

Figure 35–7 ■ Cancer of the larynx and epiglottis.
Source: Photo Researchers, Inc.

Lymphatic supply to this region of the larynx is rich; tumors often invade locally and metastasize early. Symptoms often do not develop until the tumor is relatively large, delaying diagnosis. Manifestations of supraglottic cancer include painful swallowing, sore throat, or a feeling of a lump in the throat. Later manifestations include dyspnea, foul breath, and pain that radiates to the ear.

Subglottic tumors (below the vocal cords) are the least common, accounting for 5% of laryngeal tumors. They often are asymptomatic until the enlarging tumor obstructs the airway. Common manifestations of laryngeal cancer are listed in the accompanying box.

Risk Factors

Men are affected more than four times as often as women. Cancer of the larynx usually develops between ages 50 and 70. Tobacco use is the major risk factor for laryngeal cancer: The risk of developing laryngeal cancer is significantly greater in smokers (cigarette, pipe, or cigar) than in nonsmokers. Alcohol consumption is a significant cofactor in increasing the risk. When combined with smoking, the risk increases synergistically and significantly, perhaps as much as 100 times (ACS, 2012b). Other risk factors include poor nutrition, human papillomavirus (HPV) infection, exposure to asbestos and other occupational pollutants, and race (laryngeal cancer is more common in African Americans than among Whites).

●○● INTERPROFESSIONAL CARE

Benign laryngeal tumors may resolve with correction of the underlying problem, such as voice training with a speech therapist or smoking cessation. Treatment of laryngeal malignancy varies with the extent of the cancer. Early diagnosis and treatment are important: 80% to 95% of early-stage tumors can be cured, whereas 50% to 80% of people with advanced laryngeal cancer die of the disease.

DIAGNOSIS

- *Direct* or *indirect laryngoscopy* is used for initial evaluation when laryngeal cancer is suspected. A fiberoptic laryngoscope is used for direct laryngoscopy; mirrors are used to visualize the larynx in indirect laryngoscopy.
- *Biopsy* is obtained from suspicious lesions to examine the cells. Biopsy is usually obtained under general anesthesia or conscious sedation. Tissue may be obtained via endoscopy or by fine-needle aspiration of the mass.
- *Imaging studies* such as CT scan, MRI, and chest x-ray are obtained to evaluate the size of the mass, possible extension into deeper tissues, involvement of lymph nodes, and possible metastasis to the lungs. A barium swallow may be done to evaluate the effects of the tumor on swallowing. A PET scan also may be done (possibly in conjunction with CT scan) to detect tumor metastasis.

MANIFESTATIONS OF LARYNGEAL CANCER

- Hoarseness
- Change in the voice
- Painful swallowing
- Dyspnea
- Foul breath
- Palpable lump in neck
- Earache

TREATMENTS

An inhaled steroid spray may be used for vocal cord polyps. In some cases, surgical excision of benign nodules or polyps is required. This usually is performed via laryngoscopy, using microforceps or a laser. A biopsy of the tumor is done to rule out malignancy.

Laryngeal cancer treatment is determined by *staging* the cancer. Information such as tumor size and location (T), number of involved lymph nodes (N), and presence or absence of metastases (M) is combined to assign a stage, designated by Roman numerals I to IV. Table 35–1 outlines laryngeal cancer stages.

RADIATION THERAPY Radiation therapy is often the treatment of choice for early laryngeal cancer. Radiation disrupts the DNA of the cell, causing it to die. External radiation commonly is used; brachytherapy, implants of iridium seeds placed into hollow plastic needles that are inserted directly into or near the tumor site during surgery to deliver radiation, is less frequently used for laryngeal or hypopharyngeal cancer. Radiation therapy is extremely effective for treating glottic cancer, with cure rates equal to those achieved by surgery. Radiation therapy preserves the voice, although the tone or timber of the voice may be affected.

Radiation therapy may be used in combination with chemotherapy (*chemoradiotherapy*) to treat more advanced laryngeal cancers. Nearly two-thirds of patients with locally invasive cancers can avoid total laryngectomy when treated with combination radiation and chemotherapy. Survival rates are equal to those achieved with total laryngectomy.

Radiation therapy also may be used in conjunction with surgery to destroy any remaining cancerous cells, or as a palliative treatment for advanced tumors. Refer to Chapter 14 for more information about radiation therapy and its nursing implications.

CHEMOTHERAPY Chemotherapy is used in combination with radiation therapy as the primary treatment for some laryngeal cancers. It also is used to treat distant metastasis and for palliation when the tumor is unresectable. The most commonly used chemotherapy drugs to treat laryngeal cancer are cisplatin (Platinol) and 5-fluorouracil (5-FU). Other drugs that may be used include methotrexate (Mexate), bleomycin sulfate (Blenoxane), and carboplatin (Paraplatin). A multiple-drug treatment regimen may be employed to maximize therapeutic effects. Refer to Chapter 14 for the nursing implications for chemotherapy.

TABLE 35–1 Staging of Laryngeal Tumors

Stage 0	• Carcinoma *in situ* • No lymph node involvement or metastasis
Stage I	• Tumor confined to site of origin with normal vocal cord mobility • No lymph node involvement or metastasis
Stage II	• Tumor involves adjacent tissues • No lymph node involvement or metastasis
Stage III	• Tumor confined to larynx with fixation of vocal cords; immediately surrounding supraglottic tissues may be involved • No lymph node involvement or a single positive node on the side of the tumor • No metastasis
Stage IV	• Massive tumor that extends beyond boundaries of larynx to involve surrounding tissues • Single or multiple lymph nodes may be involved • Distant metastasis may be present

SURGERY

The type of surgery used to treat laryngeal cancer is based on site, size, and invasiveness of the tumor into the larynx and surrounding tissues. The goals of surgery are to remove the malignancy, maintain airway patency, and achieve optimal cosmetic appearance.

Carcinoma in situ, vocal cord polyps, and early vocal cord cancers may be removed by laser during a laryngoscopy procedure. The cure rate for early tumors using this method is excellent. This surgery may be performed on an outpatient basis. The degree of trauma to the vocal cords varies, depending on the size of the lesion. The voice is preserved, but total voice rest with whispering only may be ordered for a week or more following surgery. In some cases, a temporary tracheostomy may be done at the time of surgery to ensure that swelling does not interfere with airway patency. Once the tracheostomy tube is removed and the opening is closed, the patient can eat, speak, and breathe normally.

Laryngectomy, removal of the larynx, may be necessary. A *partial laryngectomy* (hemilaryngectomy, vertical partial laryngectomy) may be used for tumors localized to a portion of the larynx with limited extension beyond the larynx. In a partial laryngectomy, 50% or more of the larynx is removed. The voice generally is well preserved, although it may be changed by the surgery. A tracheostomy tube may be inserted for early postoperative airway management. It is usually removed in 5 to 7 days as postoperative swelling subsides, and the stoma is allowed to close. Normal speaking, breathing, and swallowing are restored. If the epiglottis has been removed, careful monitoring for aspiration is necessary. Enteral tube feedings or parenteral nutrition may be required for several weeks after surgery. Swallowing techniques to prevent aspiration are taught.

A *total laryngectomy* is required for cancers that extend beyond the vocal cords. The entire larynx is removed, along with the epiglottis, thyroid cartilage, several tracheal rings, and the hyoid bone. Because the trachea and the esophagus are permanently separated by this surgery (Figure 35–8 ■), there is no risk of aspiration during swallowing. Normal speech is lost, and a permanent tracheostomy is created in a total laryngectomy. The tracheostomy tube inserted during surgery may be left in place for several weeks and then removed, leaving a natural stoma, or it may be left in place permanently. See the accompanying box for nursing care of the patient having a total laryngectomy.

If cervical lymph nodes are involved but there is no evidence of distal metastasis, *radical* or *modified neck dissection* may be performed along with total laryngectomy. In a radical neck dissection, all soft tissue from the lower edge of the mandible down to the clavicle is removed, including cervical lymph nodes, the sternocleidomastoid muscle, internal jugular vein, cranial nerve XI (spinal accessory), and submaxillary salivary gland. Extensive tissue dissection can result in significant deformity. Skin grafts or flaps may be used to close the wound. Hemovac drains are placed in the wound to prevent hematoma and extensive edema formation. After surgery, the patient may have difficulty lifting and turning the head because of muscle loss. Resection of the spinal accessory nerve causes shoulder drop on the affected side. In a modified neck dissection, neck contents are

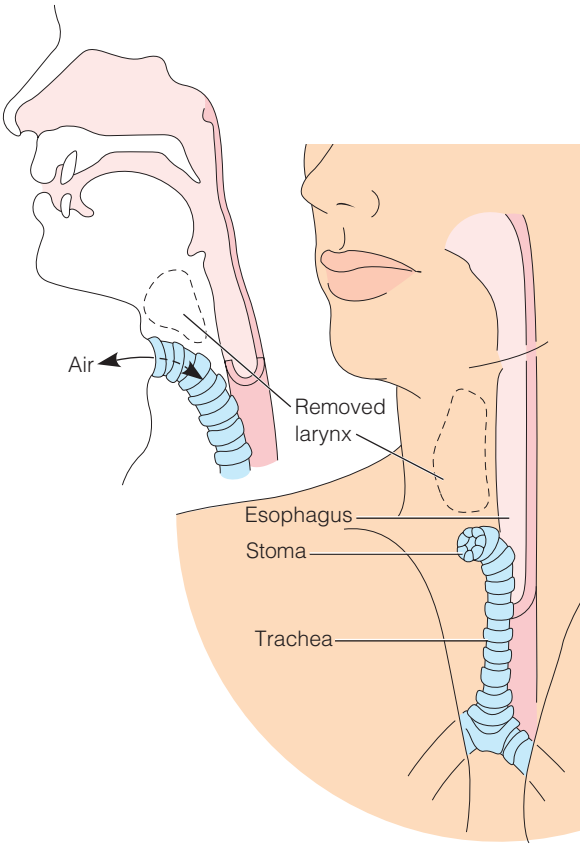

Figure 35–8 ■ Following a total laryngectomy, the patient has a permanent tracheostomy. No connection between the trachea and esophagus remains.

removed, with the exception of the sternocleidomastoid muscle, internal jugular vein, and spinal accessory nerve.

A gastrostomy also may be performed to maintain nutrition in the patient with laryngeal or hypopharyngeal cancer. Refer to Chapter 23 for more information about caring for the patient with a gastrostomy tube.

SPEECH REHABILITATION

Various techniques may be used to restore speech after total laryngectomy. *Tracheoesophageal puncture (TEP)* is the usual method used to restore speech. A small fistula is created between the posterior tracheal wall and the anterior esophagus. A small, one-way shunt valve is fitted into the fistula (Figure 35–9 ■). Occluding the tracheostomy stoma with a finger forces exhaled air through the valve into the esophagus and hypopharynx, creating vibration and sound. The muscles of speech are used to form words. The one-way valve prevents aspiration from the esophagus into the trachea. An external tracheostoma valve may be used to avoid using the hand to occlude the stoma. This device covers the entire tracheal stoma and closes during exhalation, forcing air directly into the voice prosthesis. Not all postlaryngectomy patients are candidates for this device, because its use requires motivation and manual dexterity.

Esophageal speech uses swallowed air to create sound and form words as air is expelled in a controlled belch. The pharyngoesophageal segment vibrates with the belch, creating sound. Muscles of the mouth and tongue are used to control the sound and form words. This form of speech takes practice, and fluent speech may not be restored.

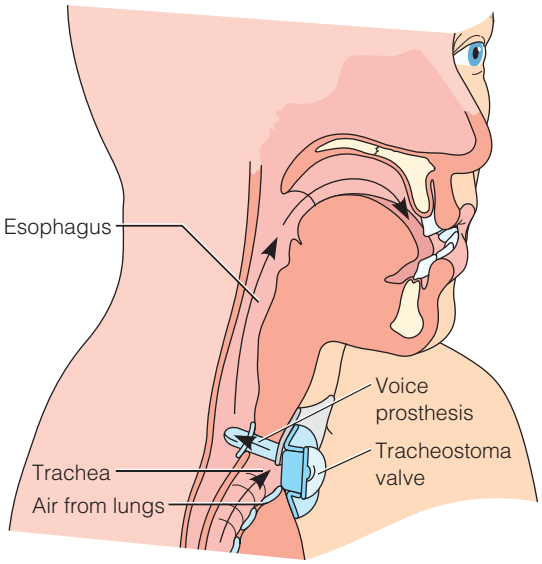

Figure 35–9 ■ The tracheoesophageal prosthesis (TEP) allows diversion of air from the trachea through a one-way valve into the esophagus and oropharynx, producing speech when the tracheostomy stoma is occluded. The one-way valve prevents food from entering the trachea.

Several speech generators (electrolarynx) are available. One type is held to the neck and creates vibrations that are transmitted to the neck and into the mouth (Figure 35–10A ■). The transmitted vibrations are formed into words using the normal muscles of speech. Another device delivers a tone into the mouth via a plastic tube inserted into the corner of the mouth (Figure 35–10B). The lips, tongue, and mouth muscles are used to form the sound into words.

●○● NURSING CARE

Nurses can be instrumental in early identification and treatment of laryngeal disorders by emphasizing the need for patients with new chronic hoarseness to seek treatment.

Health Promotion

Health promotion activities to prevent laryngeal cancer focus on preventing smoking and chewing tobacco among children, adolescents, and young adults, and promoting smoking cessation in people who do smoke. Activities to promote abstinence or moderate alcohol use also are beneficial in reducing a significant risk factor for laryngeal cancer.

Assessment

See the Manifestations and Interprofessional Care sections for the assessment of the patient with laryngeal cancer.

Nurses can be instrumental in identifying early signs of laryngeal cancer, facilitating early diagnosis and treatment.

- *Health history:* current symptoms, including voice change, difficulty swallowing, throat pain, weight loss; risk factors such as voice abuse (e.g., shouting), family history of cancer, occupational exposures (e.g., chemical inhalation); smoking, use of alcohol and amount
- *Physical examination:* voice character; general appearance and apparent state of health, weight loss; swallowing ability; visible or palpable mass in neck.

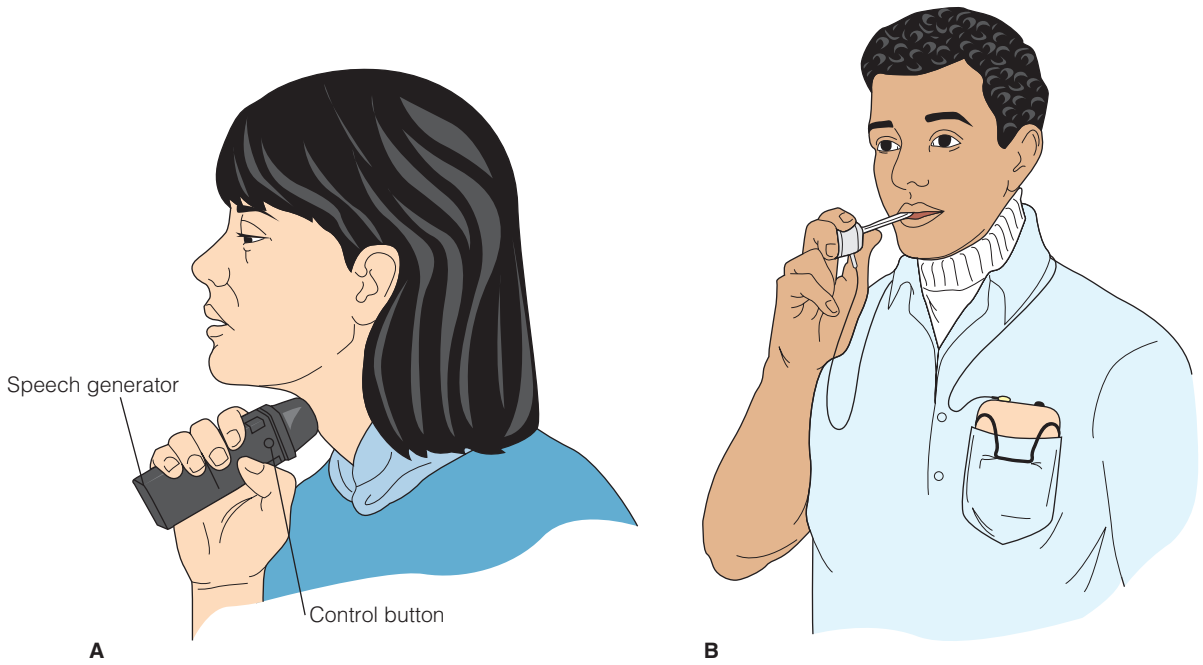

Figure 35–10 ■ Speech generators. A, The patient holds the vibrating tip of the speech generator against the throat, using the mouth to form words. B, A plastic handpiece of the generator is held in the corner of the mouth. The audible tone produced by the generator is formed into words.

Priorities of Care

Collaborating with the interprofessional team to ensure adequate treatment of the underlying process while providing care that supports the physical and psychologic responses to the disorder is a priority of nursing care.

Diagnoses, Outcomes, and Interventions

Nursing care for the patient with a benign tumor of the larynx focuses on maintaining a patent airway and teaching about the disorder and strategies to prevent its recurrence. The patient with laryngeal cancer has multiple nursing care needs. The risk for impaired verbal communication is significant. Dysphagia may interfere with swallowing and nutrition. Nutrition also may be impaired by radiation, chemotherapy, and surgery. Changes in body image may be due to weight loss due to increased metabolic demands of the malignancy. The diagnosis of cancer is frightening for most patients, no matter what the potential for cure is with treatment. See the Case Study & Nursing Care Plan that follows for additional nursing diagnoses and interventions.

Risk for Impaired Airway Clearance

Following resection of a benign or malignant vocal cord nodule, local tissue edema may interfere with airway patency.

Expected Outcome: Patient will use techniques to promote airway clearance as indicated and tolerated in combination with maintenance of patent airway.

SAFETY ALERT

During the immediate postoperative period, closely monitor for signs of airway obstruction, such as labored breathing or inspiratory stridor. The larynx is the narrowest portion of the upper airways. Tissue edema following surgery can further restrict the airway, interfering with lung ventilation and gas exchange.

- Apply cold packs to the neck as ordered or indicated. *Cold application constricts local blood vessels and reduces edema development.*
- Withhold food and fluids until the cough and gag reflexes have returned. *Local anesthesia used during removal of benign tumors and nodules impairs the cough and gag reflexes, increasing the risk for aspiration.*

Impaired Verbal Communication

Treatment of laryngeal cancer often alters the quality of the voice, results in short-term restriction on speaking, or, in the case of total laryngectomy, causes loss of the voice. The patient ultimately determines treatment choices for laryngeal cancer; some choose to forgo laryngectomy to avoid voice loss when the chance for long-term success and cancer cure is minimal.

Expected Outcome: Patient will utilize alternative communication techniques.

- Prior to surgery, assess for additional obstacles to communication. *Communication may be impaired by hearing loss, illiteracy, or weakness associated with the disease process, altering the ability to use alternative communication strategies.*
- Assess the importance of verbal communication to self-concept, occupation, and lifestyle. *Many factors influence adaptation to the loss of normal verbal communication. If the ability to speak is central to an occupation (e.g., elementary school teacher, singer) or self-concept (e.g., a politician or attorney), adapting to a total laryngectomy may be difficult. For these patients, laryngectomy may mean a loss of employment or career.*
- Prior to surgery, introduce nonverbal communication strategies such as pencil and paper, magic slate, or an alphabet board. Encourage the patient to practice using each method and to choose the most acceptable one. *Having the patient determine a means of communication prior to surgery helps to alleviate anxiety and increases the sense of control.*

NURSING CARE OF THE PATIENT

Having a Total Laryngectomy

PREOPERATIVE CARE

- Assess knowledge and understanding of the diagnosis and proposed surgery. Clarify information and reinforce previous teaching as needed. *A clear understanding by the patient and family of the purpose, anticipated benefits, and consequences of total laryngectomy prior to surgery is vital to promote postoperative recovery.*
- Provide routine preoperative care and teaching, as explained in Chapter 4.
- Assess anxiety levels of the patient and family related to the diagnosis and proposed surgery. *High levels of anxiety interfere with learning and the ability to cooperate in care. Interventions to reduce anxiety may be required prior to teaching and providing preoperative instructions.*
- Without increasing fear, emphasize that total laryngectomy results in a loss of speech and that the patient will breathe through a permanent stoma in the neck. *Although patients and family members may verbalize an understanding of the loss of speech following surgery, they may believe that verbal communication will still be possible through the stoma.*
- Establish a means of communicating postoperatively, using a magic slate, alphabet board, eye or hand signals, or other strategies. *Learning techniques for communicating preoperatively decreases the patient's and family's postoperative anxiety. Long-term speech rehabilitation measures, such as a tracheoesophageal puncture, are not appropriate for use in the immediate postoperative period.*
- Point out that surgery will affect the senses of taste and smell and also eating in the initial postoperative period. Reassure that nutritional and fluid needs will be met with intravenous or enteral feedings until eating can be resumed. *The patient may not be prepared for the effect of surgery on taste and smell and, therefore, the enjoyment of food.*
- If possible and desired by the patient and family, arrange a visit by a postlaryngectomy patient who effectively uses an alternate form of verbal communication. *The patient and family may feel more comfortable expressing their fears and asking questions of someone who has gone through the same experience they are facing.*

POSTOPERATIVE CARE

- Provide routine postoperative nursing care and monitoring, as explained in Chapter 4.
- Frequently monitor airway patency and respiratory status, including respiratory rate and pattern, lung sounds, and oxygen saturation. *Excessive or retained respiratory secretions can impair gas exchange, increase the work of breathing, and lead to complications such as pneumonia.*
- Encourage deep breathing and coughing. *Deep breathing helps ensure adequate ventilation of lower airways; coughing helps to move secretions out of airways.*
- Elevate the head of the bed. *The upright position promotes effective ventilation of the lungs, and reduces edema and swelling of the neck.*
- Maintain humidification of inspired gases. *With a tracheostomy, humidification of inspired air in the upper airways is lost. Humidified air helps maintain moist mucous membranes and secretions, promoting secretion removal by coughing or suctioning.*
- Maintain an adequate fluid intake (intravenously, enteral, and oral when allowed). *Adequate hydration keeps secretions liquid and mucous membranes moist.*
- Suction via tracheostomy using sterile technique as needed. *Surgery, impaired nutrition, and the effects of radiation therapy may cause fatigue and a weak cough effort. Suctioning may be necessary to clear secretions and maintain airway patency.*
- Provide tracheostomy care as needed. *Periodic cleaning of the tracheostomy tube is necessary to remove accumulated secretions and maintain airway patency.*
- Teach to protect the stoma from particulate matter in the air with a gauze square or other stoma protector. *Permanent tracheostomy results in loss of the protective mechanisms of the upper airway that prevent foreign material from entering the lungs.*
- Instruct to support the head when moving in bed. *Additional head support reduces the strain on tissues in the operative area.*
- Place the call light within easy reach at all times; answer the call light promptly. *The patient who is unable to speak needs reassurance that help is within reach at all times.*
- Encourage family members to remain present when possible. *Supportive family presence helps reassure the patient that he or she will not be left alone or helpless.*
- Spend as much time as possible with the patient. When leaving the room, specify the time when you will return. *These measures help establish trust and relieve anxiety.*

- Arrange consultation with a speech therapist about alternate forms of oral communication prior to surgery if possible. *Determining a means of communicating on a continuing basis prior to surgery helps to relieve fear of inability to communicate and may guide the choice of a surgical procedure.*

SAFETY ALERT

After surgery, assess frequently. Place the call bell at hand. The presence of a caring nurse helps to decrease anxiety and promotes communication. Knowing that help is readily available enhances feelings of security and decreases anxiety.

- Reinforce teaching about alternative communication strategies. *Anxiety or information overload may impair the ability to retain information; reinforcement facilitates learning.*
- Maintain a positive attitude about postoperative communication, but do not promote unrealistic expectations. *Not all patients are able to use all alternative methods of verbal communication after the laryngectomy. Some patients remain nonverbal.*
- If desired, arrange a visit by a rehabilitated laryngectomy patient who has mastered an alternative form of verbal communication and has a positive attitude about rehabilitation. *Many patients and their families find that they are better able to communicate their fears with someone who has gone through the same experience they are facing.*

See the accompanying Moving Evidence into Action box for more information about assistive devices for use in the early postoperative period.

Impaired Swallowing

Disruption of laryngeal structures by the tumor itself or due to radiation or surgery can impair the swallowing mechanism. Additionally, even when a total laryngectomy has been performed and a

Moving Evidence into Action

The Patient Undergoing Laryngectomy

Communication methods and content among patients who had undergone surgery for head or neck cancer were evaluated in this pilot study of the use of electronic speech-generating devices (SGDs) (Happ et al., 2005). The researchers also looked at the quality (ease and patient satisfaction) of communications among study participants, as well as barriers to SGD use and the effect of patient factors such as age and illness severity on communications. All study participants were alert and able to write legibly; the majority had at least some experience using a computer. While 60% of study participants were found to be able to use SGDs with minimal assistance and instruction, the devices were used in only 17% of observed communications; writing and nonverbal communications were used the majority of the time. The barriers observed that reduce/prevent use of the devices included placement of the device out of the patient's reach, mechanical malfunctions, and impatience of caregivers with the time required for typed communications. Patients expressed frustration with the lack of a standard keyboard and with the impersonality of the computerized voice. Overall, the devices were found to be useful as one of several methods of communication used by the patient.

Implications for Nursing

Speech-generating devices can facilitate communication for selected patients, particularly when the content of the message is complex. Training of patients, caregivers, and family members is necessary for effective use of these devices, however. Preoperatively, patients scheduled for laryngectomy should be instructed in communication methods to use after surgery, including use of gestures, written messages (including predeveloped messages, such as "I am in pain."), and use of any assistive communication devices.

Moving Knowledge into Action

1. In this study, SGDs often were found out of the patient's reach. What planning should the nurse do to help ensure that assistive communication devices are accessible to the patient?
2. Patients in this study were literate and many had at least some experience using computers. Do you think results of the study would differ if the study population had less education, was illiterate, or had minimal English language proficiency? Why or why not?
3. Develop a teaching plan for a preoperative laryngectomy patient using the nursing diagnosis *Deficient Knowledge* related to postoperative communication strategies.

connection between the oropharynx and trachea no longer exists, swallowing may cause fear of choking.

Expected Outcome: Patient will utilize modified food and fluid consistency to promote swallowing while using techniques to avoid choking.

- Maintain intravenous fluids and enteral feedings or parenteral nutrition until adequate food and fluids can be ingested orally. *It is important to maintain nutritional and fluid balance until normal eating can be resumed.*
- Postoperatively, initiate oral intake with soft foods, not liquids. *Soft foods are easier than liquids to handle and swallow initially. As recovery progresses, thickened liquids can be swallowed, progressing to liquids, and, eventually, a normal diet.*
- Following total laryngectomy, reassure that choking is not possible, because there is no connection between the esophagus and trachea. *Patients often fear that swallowing will result in choking and they will be unable to cough effectively.*
- Instruct to initiate a swallow by placing a small amount of food on the back of the tongue, flex the head forward, and then think "swallow." *Swallowing is no longer an automatic function and needs to be relearned.*
- Provide for privacy during initial attempts at eating. *Eating in the presence of others may cause embarrassment until confidence in eating is regained. Privacy also reduces distractions, allowing concentration on swallowing.*

Imbalanced Nutrition: Less Than Body Requirements

Large laryngeal tumors often place pressure on the esophagus and may cause dysphagia (difficulty swallowing) or odynophagia (painful swallowing). In either case, difficulty eating may ultimately impair nutrition. Additionally, cancer often produces a hypermetabolic state, increasing calorie requirements. If surgery is performed, difficulty swallowing and a fear of aspiration in the early postoperative period also interfere with eating. Enteral or parenteral feedings are usually needed initially to meet nutritional status. After a total laryngectomy, the senses of taste and smell are disrupted. Although the sense of taste may be partially recovered, patients may complain that eating no longer is pleasurable.

Expected Outcome: Patient will consume adequate nourishment to promote weight within normal range.

- Assess nutritional status using height and weight charts, reported weight loss, and anthropometric measurements such as skinfolds. *Thorough assessment of nutritional status is important in planning to meet current and anticipated calorie needs.*
- Monitor food and fluid intake and urinary output. *Pain or fatigue, rather than a sensation of fullness, may prompt the decision to stop eating, resulting in inadequate intake.*
- Evaluate current and preferred eating habits and foods, as well as understanding of nutrition. *This evaluation provides additional information about nutrition as well as a basis for future planning.*
- Weigh daily. *Daily weight is an accurate measure of both fluid balance and nutritional status.*
- Refer to a dietitian for further evaluation, planning, and education. *A professional can identify nutritional needs and help plan a diet that will meet them.*
- *Refer to a swallowing therapist (specialized speech therapist) for additional resources to improve nutritional intake.*
- Encourage experimentation with foods of different textures and temperatures. *Very cold foods or foods of a soft texture may be easier to swallow.*
- Encourage frequent, small meals rather than three large meals per day. *Frequent, small quantities of food improve overall intake when dysphagia, odynophagia, or fatigue interfere with nutrition.*
- Recommend liquid supplements such as Ensure when calorie needs are not being met. Provide information about where to

obtain nutritional supplements. *Liquid dietary supplements provide balanced nutrition as well as additional calories and are an effective way of increasing intake. They are available without prescription in major supermarkets.*

- Provide mouth care before meals and supplemental feedings. Provide a topical anesthetic such as viscous lidocaine before eating for stomatitis or esophagitis related to radiation or chemotherapy. *The tumor or its treatment may cause bad breath or a foul taste in the mouth, which suppresses appetite. Inflamed mucosa may make eating uncomfortable. A topical anesthetic may relieve this discomfort and thus promote food intake.*
- Provide an antiemetic 30 minutes before eating as needed to relieve nausea. *Nausea interferes with food intake. An antiemetic can relieve nausea and make eating possible.*
- Suggest enteral (tube) feedings via nasogastric or gastrostomy tube if the patient is unable to consume enough food to maintain weight and nutritional status. *Both cancer and surgery increase calorie needs. Supplemental enteral feedings may be necessary to prevent catabolism and to promote healing and recovery.*

SAFETY ALERT

Following laryngectomy, place in semi-Fowler's or Fowler's position. Elevating the head of the bed facilitates swallowing of oral secretions and helps prevent regurgitation of tube feedings.

- Instruct to perform mouth rinses before initiating feeding postoperatively. *Rinsing helps clean the mouth and also practice in using tongue and cheek muscles to control fluid in the mouth.*
- Refer to a physical or speech therapist for swallowing rehabilitation following laryngectomy. *Because surgery changes the relationship of the trachea, esophagus, and oropharynx, swallowing needs to be relearned before eating.*
- Reinforce swallowing instructions. *Reinforcement promotes learning.*

Anticipatory Grieving

The patient with laryngeal cancer faces not only the diagnosis of cancer, which is often perceived as a death sentence, but also the prospect of mutilating surgery. If laryngectomy is necessary, the patient grieves the loss of both a body part and an important function, speech, a vital aspect of social interaction and interpersonal relationships and often necessary for one's career. It also enables people to express their needs when they cannot meet them alone. The loss of speech, therefore, is a major loss. In addition, the tracheal stoma changes the manner in which the patient breathes. If radical neck dissection is required, loss of neck musculature and function also alters body image and self-concept.

Expected Outcome: Patient and family will discuss the meaning of losses (anticipated or actual) to the patient and family's life.

- Provide opportunities for expressing feelings of grief, anger, or fear about the diagnosis of cancer, the impending surgery, and the anticipated loss of speech. *The patient with laryngeal cancer needs the opportunity (and may need permission) to grieve anticipated losses. A cancer diagnosis may precipitate grieving for unfulfilled plans and expectations, even though a cure may be anticipated. Laryngectomy causes a major change in body image, with loss of a vital body part and creation of a stoma. The patient also grieves the loss of speech. This loss can have a significant impact on occupation and social interaction.*
- Provide a calm, supportive environment with adequate privacy and emotional support for the patient and family members as they work through the grieving process. *It is important for the patient and family to know that their feelings of loss are real and accepted by caregivers.*
- Help the patient and family discuss the potential impact of the loss on family structure and function. *Discussion helps family members understand each other's feelings and support one another.*
- Refer for psychologic or spiritual counseling as appropriate. *Counseling and spiritual guidance can help the patient and family deal with the diagnosis and proposed treatment, and help prevent a sense of defeat and hopelessness.*
- Help identify additional resources, such as coping strategies that have been successfully used in the past to deal with crises. *This exercise helps the patient and family identify strengths they can use to deal with the present situation.*

Continuity of Care

Teaching for the patient with a benign laryngeal tumor emphasizes management of contributing factors. Stress the importance of not yelling or screaming. Refer patients, particularly singers, to a speech therapist for voice training. Emphasize the need to keep the voice within its normal range to reduce vocal cord stress. Encourage smoking cessation, particularly if the patient is also a singer. Discuss the relationship of industrial or occupational pollutants to laryngeal tumors and help explore ways of reducing pollutant exposure.

Teaching the patient and family about laryngeal cancer, treatment options, and home care related to those treatments is an important nursing responsibility. Include the following topics when teaching:

- Clarification of treatment options, including risks and benefits.
- Importance of early intervention to reduce the risk of local spread and metastasis.
- If a total laryngectomy is proposed, options for communication after surgery, including the pros and cons of each:
  a. The tracheoesophageal puncture device requires some manual dexterity to manipulate.
  b. Only about 30% of patients are able to master esophageal speech.
  c. A trial of the speech generator prior to surgery may reduce frustration in learning to use it postoperatively.
- Care related to radiation therapy, including skin and mouth care, and management of secretions. (Refer to Chapter 14 for more information about radiation therapy and its effects.)
- Strategies and resources for smoking cessation and alcohol abstinence.
- Ways to achieve and maintain optimal nutrition.
- Tracheostomy stoma care and preventing respiratory infection. Provide opportunities to practice and redemonstrate techniques. Clean technique (rather than sterile) is used; the tracheostomy tube may not be needed once the stoma is fully healed. Discuss these additional measures:
  a. Using a humidifier or vaporizer to add humidity to inspired air.
  b. Increasing fluid intake to maintain mucosal moisture and loosen secretions.

CASE STUDY & NURSING CARE PLAN A Patient with Total Laryngectomy

David Tom is a 61-year-old accountant who is divorced and has two adult children. He has smoked two packs of cigarettes daily since high school, and usually has three or four cocktails each evening. After several months of a persistent sore throat and hoarseness, Mr. Tom was diagnosed with cancer of the larynx. He has been admitted to the surgical care unit from the ICU 2 days post–total laryngectomy.

ASSESSMENT

Mr. Tom's vital signs are stable: BP 146/84 mmHg, P 92 bpm and regular, R 18/min, T 36.7°C (98°F) axillary. A tracheostomy tube is sutured in place, and he is receiving humidified oxygen at 28% per tracheostomy collar. Pulse oximetry is 94%. He is receiving continuous tube feeding per nasogastric feeding tube. Two Hemovac wound drains are present in the right neck area. A moderate amount of edema is noted in the right facial and submandibular area. Mr. Tom is ambulatory within the room.

DIAGNOSES

- *Risk for Ineffective Airway Clearance* related to postoperative edema
- *Risk for Ineffective Breathing Pattern* related to pain and anxiety
- *Disturbed Body Image* related to total laryngectomy and presence of tracheostomy stoma
- *Impaired Verbal Communication* related to total laryngectomy
- *Pain* related to surgical procedure
- *Risk for Imbalanced Nutrition: Less Than Body Requirements* related to difficulty eating after surgery

EXPECTED OUTCOMES

- Patient will maintain clear airways and lung sounds.
- Patient will maintain oxygen saturation level greater than 92%.
- Patient will demonstrate interest in providing incision and stoma care.
- Patient will accept information about potential communication strategies.
- Patient will communicate effective pain management.
- Patient will maintain appropriate body weight, intake, and output.

PLANNING AND IMPLEMENTATION

- Assess respiratory status including rate, pattern, lung sounds, and cough effectiveness at least every 4 hours.
- Monitor quantity, color, and odor of secretions.
- Assess vital signs and pain at least every 4 hours. Administer analgesics as ordered.
- Schedule time to sit with Mr. Tom and discuss his concerns and feelings at least three times per day.
- Provide written information as requested.
- Monitor intake, output, and daily weight.
- Arrange dietary consultation to determine caloric requirements.

EVALUATION

Mr. Tom reports in writing that his pain is adequately controlled. His respiratory status is stable with clear breath sounds throughout and an oxygen saturation of 94%. He is afebrile. Mr. Tom is tolerating tube feedings well and expresses a desire to begin eating. The dietitian has visited and assisted in planning to begin oral feedings. Intake and output are stable, as is his weight. Mr. Tom has been receptive to receiving information about follow-up care and exploration of various modalities of speech.

Clinical Reasoning in Patient Care

1. Compare and contrast advantages and disadvantages of various methods to allow speech following total laryngectomy.
2. Develop a plan of care for Mr. Tom for the nursing diagnosis *Disturbed Body Image*.
3. Discuss nursing interventions to provide wound care for the patient with laryngectomy and radical neck dissection.
4. List strategies to optimize ventilation.

See Evaluating Your Response in Appendix B.

c. Shielding the stoma with a stoma guard, such as a gauze square on a tie around the neck, to prevent particulate matter from entering the lower respiratory tract.
d. Promptly removing secretions from skin surrounding the stoma to prevent irritation and skin breakdown.
e. Water sports are contraindicated with a permanent tracheostomy; there is no restriction on other activities although lifting may be more difficult because of an inability to hold one's breath (the Valsalva maneuver).
f. Showering and bathing (without submerging the neck or head) are allowed; protect the stoma with a cupped hand or washcloth.

- Manifestations of potential complications of laryngectomy to be reported to the healthcare provider, including loss of hearing or facial expression due to auditory or facial nerve injury, or shoulder drop due to damage to the spinal accessory nerve.

The patient and family need emotional and motivational support through this trying time. Refer to local support groups such as a laryngectomy club or lost cord club. If the patient and family are having difficulty adjusting to the diagnosis of cancer and the effects of treatment, provide referral to counseling.

CHAPTER HIGHLIGHTS

- Upper respiratory infections (the common cold) are caused by a multitude of different viruses. Most are mild, self-limiting infections, appropriate for self-care; some viruses, however, such as RSV can cause serious lower respiratory illness in the very young or very old.
- Three different strains of influenza virus are identified; type A causes most outbreaks of influenza. Because this disease increases the risk of pneumonia in older adults, people with chronic diseases, and people who are immunocompromised, annual immunization is important for these populations and their caregivers.
- **Influenza is differentiated from URI primarily by the presence of systemic manifestations, the duration and degree of fever, and the presence of persistent cough.**
- Pharyngitis (sore throat) may be either viral or bacterial in origin; manifestations are similar. Patients with persistent or severe symptoms that include fever, enlarged lymph nodes, and myalgias should be evaluated to rule out GABHS pharyngitis, which can have significant complications such as rheumatic fever or post-streptococcal glomerulonephritis.
- **The incidence of pertussis, a highly contagious reportable disease, is increasing due to waning immunity, decreased rates of childhood pertussis immunizations, and improved identification of the infection among adults. In adults, it is often recognized by prolonged and persistent coughing spells. Pertussis is treated in community settings with antibiotic therapy (usually erythromycin or TMP-SMZ).**
- **Epistaxis (nosebleed) and nasal fracture are relatively common, and pose a risk only when airway clearance is impaired. Emergency care for epistaxis includes pinching the nares or bridge of the nose, sitting upright leaning forward, and applying ice to the nose. When nasal packing is required to control bleeding, close monitoring of respiratory status (respiratory rate and effort, oxygen saturation) is critical.**
- **Persistent voice hoarseness is the primary manifestation of laryngeal cancer. When identified and treated early, the rate of cure for laryngeal cancer is high. Some laryngeal tumors, however, have few manifestations until advanced. They may be treated by radiation therapy, chemotherapy, or surgery (laryngectomy and neck dissection).**
- **Following total laryngectomy, a permanent tracheostomy is created and the upper trachea and esophagus are separated, preventing aspiration when feedings are resumed. A tracheoesophageal puncture (TEP) may be created to allow verbal communication following total laryngectomy.**

TEST YOURSELF NCLEX-RN® REVIEW

1. A patient with mild hypertension asks the nurse what can be done to relieve the symptoms of an acute URI. What should the nurse recommend to this patient?
   1. Ask his healthcare provider for an antibiotic prescription.
   2. Take 1000 mg of vitamin C and use zinc lozenges on a regular basis.
   3. Discuss the use of an over-the-counter nasal spray with the healthcare provider.
   4. Use an over-the-counter decongestant such as pseudoephedrine to relieve symptoms.

2. The community nurse is planning health promotion activities for a group of community-dwelling senior citizens. Which activity would most likely prevent influenza and pneumonia?
   1. Advising to avoid crowds
   2. Teaching effective hand washing
   3. Providing influenza vaccination clinics at the senior center
   4. Scheduling indoor exercise programs during winter months

3. The nurse is teaching a patient with bacterial sinusitis on care needed when at home. What should the nurse emphasize in this teaching?
   1. Using a humidifier to promote sinus drainage
   2. Completing the antibiotic prescription as ordered
   3. Sleeping with the head of the bed elevated to 45 degrees
   4. Maintaining a liberal fluid intake to help liquefy secretions

4. The nurse is planning care for a patient with posterior nasal packing. Which nursing intervention is of the highest priority for this patient?
   1. Maintain oxygen therapy.
   2. Elevate the head of the bed.
   3. Provide frequent oral hygiene.
   4. Apply cold compresses to the nose.

5. A patient with facial trauma sustained in a motor vehicle crash complains of a "dripping" nose. The drainage appears like watery blood. What would be the most appropriate action for the nurse to take at this time?
   1. Provide a box of tissues.
   2. Suction the nasopharynx.
   3. Obtain a specimen for glucose testing.
   4. Reassure the patient that this is expected with a nasal fracture.

6. The nurse suspects that a patient is experiencing obstructive sleep apnea. What did the nurse most likely assess in this patient? (Select all that apply.)
   1. Loud cyclic snoring
   2. Elevated blood pressure
   3. Complaints of morning headache
   4. Complaints of daytime sleepiness
   5. Decreased oxygen saturation levels while awake

7. The nurse notes that a patient's voice is hoarse. What would be the most appropriate question for the nurse to ask the patient during the assessment?
   1. "Do you smoke?"
   2. "Do you have a sore throat?"
   3. "How long has your voice been hoarse?"
   4. "Would you like a prescription for throat lozenges?"

8. The nurse evaluates teaching provided to a patient with stage I laryngeal cancer. Which patient statement indicates teaching has been effective?
   1. "Thank goodness this type of cancer usually doesn't spread anywhere else."
   2. "I'm glad I don't have to worry about treating this cancer now because it was found so early."
   3. "I'm glad this was diagnosed early, when it can be treated with radiation so I won't lose my voice."
   4. "I hate to think about eventually losing the ability to speak, but I'd rather treat it aggressively than lose my life to cancer."

9. The nurse is caring for a patient recovering from a total laryngectomy and radical neck dissection. Place the interventions in the order in which the nurse should provide them to the patient.
1. Provide small, frequent meals.
2. Suction via tracheostomy as needed.
3. Instruct to support head when moving.
4. Arrange consultation with speech therapist.
5. Encourage to express feelings regarding loss of voice.

10. The nurse is providing tracheostomy care to a patient recovering from a total laryngectomy. Which action should the nurse perform when providing this care?
1. Cut the dressing using sterile scissors.
2. Secure clean ties before removing soiled ones.
3. Use clean technique to cleanse the outer cannula.
4. Cleanse the incision with an iodine-based antiseptic.

36 Nursing Care of Patients with Ventilation Disorders

LEARNING OUTCOMES

1. Relate the pathophysiology and manifestations of lower respiratory infections and inflammation, chest wall disorders, trauma, and lung cancer to the ability to maintain effective ventilation and respiration (gas exchange).
2. Compare and contrast the etiology, risk factors, and vulnerable populations for lower respiratory infections, chest wall disorders, trauma, and lung cancer.
3. Describe interprofessional care and the nursing role in health promotion and caring for patients with lower respiratory infections, chest wall disorders, trauma, and lung cancer.
4. Discuss surgery and other invasive procedures used to treat chest wall disorders, trauma, and lung cancer, and nursing responsibilities in caring for patients undergoing these procedures.
5. Describe the nursing implications for medications used to treat respiratory disorders and oxygen therapy.

CLINICAL COMPETENCIES

1. Assess functional health status and the effects of lower respiratory and chest wall disorders on ventilation and gas exchange.
2. Use assessed data and knowledge of the effects of the disorder and prescribed treatment to identify priority nursing diagnoses and plan care for patients with lower respiratory disorders.
3. Use the nursing process and evidence-based nursing research to plan and implement individualized nursing care, including measures to promote ventilation and gas exchange for patients with lower respiratory disorders.
4. Plan and provide appropriate teaching for health promotion among vulnerable populations and to prepare patients and families for continuity of care
5. Evaluate the effectiveness of nursing interventions and teaching, revising strategies and teaching plans as needed.
6. Knowledgably and safely coordinate interprofessional care and administer prescribed medications and treatments for patients with lower respiratory disorders.

MAJOR CHAPTER CONCEPTS

- Pneumonia, inflammation of the respiratory bronchioles and alveoli, is usually bacterial in origin.
- Tuberculosis affects many people worldwide; in the United States, the primary affected populations are immigrants, people with compromised immunity, and people living in crowded or unsanitary conditions.
- Disorders of the pleura, such as pleural effusion and pneumothorax, can affect lung expansion, ventilation, and gas exchange when significant.
- Trauma may affect the chest wall (rib fracture, flail chest), the surface of the lungs (pulmonary contusion), or the airways and alveoli (smoke inhalation and near-drowning).
- Lung cancer, the leading cause of cancer deaths, typically is advanced when diagnosed.

severe acute respiratory syndrome (SARS), *1124*
thoracentesis, *1143*
tuberculosis (TB), *1128*

Disorders affecting the lower respiratory system (below the larynx), pleural cavity, and chest wall can affect the ability to effectively move air into and out of the lungs (ventilation) and the exchange of oxygen and carbon dioxide across the alveolar-capillary membrane (respiration). The disorders discussed in this chapter—respiratory infections and inflammation, disorders and trauma of the chest wall or pleural cavity, and neoplasms of the lung—all affect the ability to maintain clear and patent airways and ventilate the lungs. While

these disorders can also affect gas exchange, nursing care for patients with these disorders generally focuses on maintaining airway patency and an effective breathing pattern.

The lower respiratory and chest wall disorders discussed in this chapter and Chapter 37 (disorders of gas exchange) have both local and systemic effects. Local effects include cough, excess mucus production, shortness of breath or **dyspnea** (difficult or labored breathing), **hemoptysis** (bloody sputum), and chest pain. Systemic effects may include fever, anorexia and malaise, **cyanosis** (gray to blue or purple skin color caused by deoxygenated hemoglobin), and other manifestations of impaired gas exchange.

Infections and Inflammatory Disorders

Infections and inflammation of the lower respiratory system are common. The respiratory tree is constantly exposed to the environment as air moves into and out of the lower respiratory tract. In addition, the oropharynx is colonized by huge numbers of microorganisms that may be aspirated into the bronchial tree. Both anatomic and physiologic defenses help maintain the sterility of the lower respiratory tract. When these defenses are impaired, the risk for infection increases. For example, drugs, alcohol, or neuromuscular disease may suppress the cough reflex, and the influenza virus can leave the respiratory epithelium vulnerable to bacterial infection. Even in healthy people, microorganisms and other foreign material occasionally enter the bronchial tree and lung parenchyma.

THE PATIENT WITH ACUTE BRONCHITIS

Bronchitis, inflammation of the bronchi, may be either an acute or a chronic condition. Acute bronchitis is relatively common in adults The risk for acute bronchitis is increased by impaired immune defenses and cigarette smoking. In otherwise healthy adults, it typically follows a viral upper respiratory infection. Chronic bronchitis is a component of chronic obstructive pulmonary disease (COPD) and is discussed in Chapter 37.

Pathophysiology and Manifestations

Infectious bronchitis can be caused by either viruses or bacteria that damage the respiratory mucosa. In healthy adults, bacterial bronchitis generally only occurs as a complication of viral infection. Inhalation of toxic gases or chemicals can lead to inflammatory bronchitis.

The inflammatory response to infection or tissue damage from inhaled substances causes capillary dilation and edema of the mucosal lining of the bronchi. Inflammatory cells infiltrate the affected mucosa, leading to exudate formation and increased mucus production. Ciliated epithelium is damaged by the inflammatory response and ciliary function is impaired. The immune response of lymphocytes and tissue macrophages is inhibited by some viruses and mycobacteria, increasing the risk for bacterial infection. Mucosal irritation and increased mucus production initiate the cough reflex. The respiratory tract may become hyperirritable for an extended period of time, leading to paroxysms of coughing and bronchospasm.

Acute bronchitis is typically heralded by a nonproductive cough that later becomes productive. The cough often occurs in paroxysms, and may be aggravated by cold, dry, or dusty air. Chest pain, often substernal, is common. Other manifestations include moderate fever and general malaise.

●○● INTERPROFESSIONAL CARE

The diagnosis of acute bronchitis typically is based on the history and clinical presentation. A chest x-ray may be ordered to rule out pneumonia, because the presenting manifestations can be similar. Other diagnostic testing is rarely indicated. Treatment is symptomatic and includes rest, increased fluid intake, and the use of aspirin or acetaminophen to relieve fever and malaise. Many healthcare providers prescribe a broad-spectrum antibiotic such as erythromycin or penicillin, because approximately 50% of acute bronchitis is bacterial in origin. An expectorant cough medication is recommended for use during the day and a cough suppressant for night to facilitate rest.

●○● NURSING CARE

Nursing interventions for patients with acute bronchitis are primarily educational. Include the following teaching topics:

- Increase fluid intake to keep mucus thin and meet increased needs related to fever.
- Use over-the-counter analgesics and cough preparations containing dextromethorphan for symptom relief.
- Be aware of the use and effects of any prescribed medications.
- Understand the importance of smoking cessation (as appropriate).

THE PATIENT WITH PNEUMONIA

Inflammation of the lung parenchyma (the respiratory bronchioles and alveoli) is known as **pneumonia**. Despite significant advances in antibiotic therapy, pneumonia remains the eighth leading cause of death in the United States, and the leading cause of death from infectious disease (Centers for Disease Control and Prevention [CDC], 2011a). In 2009 more than 53,692 deaths in the United States were attributed to pneumonia and influenza. Its incidence and mortality are highest in older adults and people with debilitating diseases. Pneumonia currently accounts for about 10% of adult hospital admissions in the United States.

FAST FACTS

- The age-adjusted death rate for influenza and pneumonia per 100,000 population declined from 53.7 in 1960 to 17.5 in 2009.
- Overall women now have a higher death rate (18.4/100,000) than men (16.6/100,000) attributed to influenza and pneumonia
- The differences in death rates attributed to influenza and pneumonia among different races and ethnicity are relatively small. Asian/Pacific Islanders have the lowest rate at 10.15 per 100,000, Blacks are at 12.9, and Whites have the highest rate at 18.8 per 100,000 (CDC, 2011a).

TABLE 36–1 Common Organisms Causing Pneumonia in Adults

Community Acquired	Healthcare Associated	Opportunistic
• *Streptococcus pneumoniae*	• *Staphylococcus aureus*	• *Pneumocystis jiroveci*
• *Mycoplasma pneumoniae*	• *Pseudomonas aeruginosa*	• *Mycobacterium tuberculosis*
• *Haemophilus influenzae*	• *Klebsiella pneumoniae*	• Cytomegalovirus (CMV)
• Influenza virus	• *Escherichia coli*	• Atypical mycobacteria
• *Chlamydia pneumoniae*		• Fungi
• *Legionella pneumophila*		

Pneumonia may be either infectious or noninfectious. Bacteria, viruses, fungi, protozoa, and other microbes can lead to infectious pneumonia. Noninfectious causes include aspiration of gastric contents and inhalation of toxic or irritating gases. Infectious pneumonias often are classified as community acquired, nosocomial (healthcare associated), or opportunistic. Different organisms are implicated in each of these classifications (Table 36–1). The most common causative organism for community-acquired pneumonia is *Streptococcus pneumoniae* (also called pneumococcus), a gram-positive bacterium. This organism causes about 66% of cases of community-acquired pneumonia leading to hospital admission. *Mycoplasma pneumoniae*, *Chlamydia pneumoniae*, *Haemophilus influenzae*, and the influenza virus are also leading causes of community-acquired pneumonia. *Staphylococcus aureus* and gram-negative bacteria such as *Klebsiella pneumoniae*, *Pseudomonas aeruginosa*, and enteric bacilli, including *Escherichia coli*, are often implicated as nosocomial causes of pneumonia. Organisms such as *Pneumocystis* generally cause infections only in immunocompromised people (opportunistic infections).

Physiology Review

The lower respiratory tract normally is sterile. A number of defense mechanisms help maintain this sterile environment. Infectious particles trapped by the mucous membranes of the nose are removed by sneezing, whereas those deposited in the nasopharynx usually are swallowed or expectorated. Reflex closure of the epiglottis and the branching bronchial tree present anatomic barriers to entry of microorganisms and other possible contaminants. The cilia and mucus that line the respiratory tract and the cough reflex serve to trap and eliminate foreign matter that enters the lower respiratory tract. Organisms that make it past these barriers usually are rapidly phagocytized in the alveolus by resident macrophages, then attacked by the inflammatory and immune defenses of the body. Aging impairs these immune responses, increasing the risk for pneumonia (see the accompanying box).

Pathophysiology

The most common means of entry of pathogens into the lung is aspiration of oropharyngeal secretions containing microbes. Microorganisms also may be inhaled after having been released when an infected person coughs, sneezes, or talks. Contaminated aerosolized water also may be inhaled, an important means of spread for viral and some other types of pneumonia. Finally, bacteria may spread to the lungs through the bloodstream from infection elsewhere in the body. Host defenses must be overwhelmed either by the number of organisms or their *virulence* (disease-causing ability) in order for an infection to develop.

NURSING CARE OF THE OLDER ADULT

Pneumonia

Several changes associated with aging and disease affect respiratory function and airway clearance. The number of cilia decreases, and the cough weakens. Gag and cough reflexes diminish. The older adult is at greater risk for dehydration, leading to thick, viscous mucus that is difficult to expectorate. Immune function declines with aging. These factors increase the risk of pulmonary infection and reduce the older adult's ability to respond effectively to infectious processes.

Other factors also may increase the risk for and severity of lower respiratory infections in the older adult: immobility, smoking history, surgical procedures, use of multiple medications, malnutrition, and diseases such as COPD and heart disease.

When the invading microorganisms colonize the alveoli, an inflammatory and immune response is initiated. The antigen–antibody response and endotoxins released by some organisms damage bronchial and alveolar mucous membranes, causing inflammation with vascular congestion and edema. Infectious debris and exudate can fill alveoli, interfering with ventilation and gas exchange (Figure 36–1 ■). Pneumonia may develop in four distinct patterns: lobar pneumonia, bronchopneumonia, interstitial pneumonia, and miliary pneumonia (Table 36–2).

The pathologic process, anatomic location, and manifestations of pneumonias vary according to the infective organism.

ACUTE BACTERIAL PNEUMONIA

Of the bacterial pneumonias, the pathogenesis of pneumococcal (*Streptococcus pneumoniae*) pneumonia is best understood (Figure 36–2 ■). These bacteria reside in the upper respiratory tract of up to 70% of adults. They may be spread by direct person-to-person contact via droplets. In many cases, infection results from aspiration of resident bacteria. In the lower respiratory tract, the inflammatory response initiated by these organisms causes alveolar edema and the formation of exudate. As alveoli and respiratory bronchioles fill with serous exudate, blood cells, fibrin, and bacteria, *consolidation* (solidification) of lung tissue occurs. The lower lobes of the lungs are usually affected because of gravity. Consolidation of a large portion of an entire lung lobe is known as *lobar pneumonia*. This is the typical pattern for pneumococcal pneumonia. *Bronchopneumonia* is patchy consolidation involving several lobules. Other bacterial pneumonias often present with the patchy involvement of bronchopneumonia; pneumococcal pneumonia may also follow this pattern. The process resolves when macrophages dominate, digesting and removing inflammatory exudate from the infected lung.

Figure 36–1 ■ In pneumonia, the inflammatory response causes fluid to accumulate in the alveoli and edema to form as alveolar capillaries dilate and allow fluid to leak into interstitial tissues.
Source: Custom Medical Stock Photo, Inc.

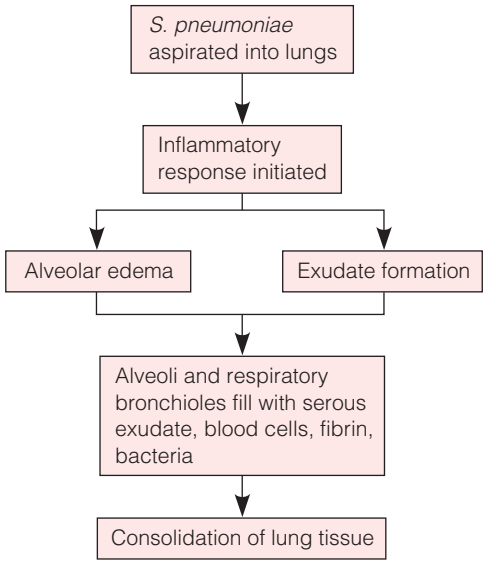

Figure 36–2 ■ The pathogenesis of pneumococcal pneumonia.

MANIFESTATIONS The presentation of bacterial pneumonia is usually acute, with rapid onset of shaking chills (rigors), fever, and cough productive of rust-colored or purulent sputum. Chest aching or *pleuritic pain* (sharp localized chest pain that increases with breathing and coughing) is common. Limited breath sounds and fine crackles or rales are heard over the affected area of lung. A pleural friction rub may be audible. If the involved area is large and gas exchange is impaired, dyspnea and cyanosis may be noted.

A more insidious onset with low-grade fever, cough, and scattered crackles is more typical of bronchopneumonia. Dyspnea is less commonly seen. The older adult or debilitated patient may have atypical manifestations of pneumonia, with little cough, scant sputum, and minimal evidence of respiratory distress. Fever, tachypnea, and altered mentation or agitation may be the primary presenting symptoms.

COMPLICATIONS Pneumococcal pneumonia typically resolves uneventfully; normal lung structure is restored on completion of the process. Local extension of the infection to involve the pleura (*pleuritis*) is the most common complication. Pneumonias caused by *Staphylococcus aureus* and gram-negative bacteria often cause extensive parenchymal damage with necrosis, lung abscess, and

TABLE 36–2 Patterns of Lung Involvement in Pneumonia

Pattern of Involvement	Description
Lobar pneumonia	Typically involves an entire lobe of a lung. Early in the process, when the immune response is minimal, bacteria spread throughout the affected lobe by rapid accumulation of edema fluid. As the immune and inflammatory responses develop, RBCs and neutrophils, damaged epithelial cells, and fibrin accumulate in the alveoli. Purulent exudate containing neutrophils and macrophages forms. As alveoli and respiratory bronchioles fill with exudate, blood cells, fibrin, and bacteria, *consolidation* (solidification) of lung tissue occurs. Finally, the process resolves as enzymes destroy the exudate and residual debris is reabsorbed, phagocytized, or coughed out.
Bronchopneumonia	Usually involves dependent portions of lung tissue, characterized by patchy consolidation. Exudate tends to remain primarily in the bronchi and bronchioles, with less edema and congestion of the alveoli than in lobar pneumonia.
Interstitial pneumonia	The inflammatory process primarily involves the interstitium: the alveolar walls and connective tissue supporting the bronchial tree. Involvement may be patchy or diffuse as lymphocytes, macrophages, and plasma cells infiltrate the alveolar septa. While alveoli typically do not contain significant exudates, protein-rich hyaline membranes may line the alveoli, interfering with gas exchange.
Miliary pneumonia	In miliary pneumonia, numerous discrete inflammatory lesions develop as a result of spread of the pathogen to the lungs via the bloodstream. Miliary pneumonia is primarily seen in people who are severely immunocompromised. As a result, the immune response is poor and damage to pleural tissue may be significant.

empyema or pleural effusion. Progressive destruction of lung tissue and functional impairment is a possible consequence of *Klebsiella* pneumonia.

A *lung abscess* is a local area of necrosis and pus formation within the lung itself. They are relatively uncommon. The manifestations of lung abscess develop slowly, and include weight loss, malaise, night sweats, fever, and a productive cough. Sputum is foul smelling and tasting. Rupture of the abscess into a larger airway is heralded by production of copious amounts of purulent sputum.

Empyema is accumulation of purulent exudate in the pleural cavity, identified by chest x-ray or CT scan. Thoracentesis may be done or a chest tube inserted to remove purulent exudates. Bacteremia can spread the infection to other tissues, leading to meningitis, endocarditis, or peritonitis, and increasing the risk of mortality.

LEGIONNAIRES' DISEASE

Legionnaires' disease is a form of bronchopneumonia caused by *Legionella pneumophila*, a gram-negative bacterium widely found in water, particularly warm standing water. Legionnaires' disease occurs sporadically and in outbreaks, such as that which occurred at an American Legion convention in 1976, when the disease was first recognized. Contaminated water-cooled air-conditioning systems and other water sources have been implicated in its spread.

Smokers, older adults, and people with chronic diseases or impaired immune defenses are most susceptible to Legionnaires' disease. Symptoms develop gradually, beginning 2 to 10 days after exposure. Dry cough, dyspnea, general malaise, chills and fever, headache, confusion, anorexia and diarrhea, myalgias, and arthralgias are common manifestations. Consolidation of lung tissue is patchy or lobar. The mortality rate in Legionnaires' disease is reported to be 5% to 30%; however, this may be low due to lack of reporting of the disease. Mortality with nosocomial infections is about 30% to 33%.

PRIMARY ATYPICAL PNEUMONIA

Pneumonia caused by *Mycoplasma pneumoniae* is generally classified as *primary atypical pneumonia* because its presentation and course differ significantly from those of other bacterial pneumonias. Mycoplasma infection often causes pharyngitis or bronchitis. When pneumonia develops, patchy inflammatory changes in the alveolar septum and interstitial tissue of the lung occur. Alveolar exudate and consolidation of lung tissue are not features of atypical pneumonia.

Young adults—college students and military recruits in particular—are the primary affected population. Primary atypical pneumonia is highly contagious. Its manifestations resemble those of viral pneumonia; systemic manifestations of fever, headache, myalgias, and arthralgias often dominate. The cough associated with atypical pneumonia is dry, hacking, and nonproductive. Because of the typically mild nature and predominant systemic manifestations, mycoplasmal and viral pneumonia are often referred to as *walking pneumonias*.

VIRAL PNEUMONIA

Approximately 10% of pneumonias in adults are viral. Influenza and adenovirus are the most common organisms; however, the incidence of cytomegalovirus (CMV) pneumonia is increasing in immunocompromised people. Other viruses such as herpes viruses and measles virus also may cause viral pneumonia. As in primary atypical pneumonia, lung involvement in viral pneumonia is limited to the alveolar septum and interstitial spaces.

Viral pneumonia is typically a mild disease that often affects older adults and people with chronic conditions. It usually occurs in community epidemics. Flu-like symptoms of headache, fever, fatigue, malaise, and muscle aching are common, along with a dry cough.

PNEUMOCYSTIS PNEUMONIA

People with acquired immunodeficiency syndrome (AIDS) and others with significant immunocompromise are at risk for developing an opportunistic pneumonia caused by *Pneumocystis jiroveci*, a common parasite found worldwide. Immunity to *Pneumocystis* is nearly universal, except in immunocompromised people. Opportunistic infection may develop in people treated with immunosuppressive or cytotoxic drugs for cancer or organ transplant and in people with genetic or acquired immunodeficiency. *Pneumocystis* pneumonia can be seen in up to 80% of patients with AIDS who do not receive prophylaxis.

Infection with *Pneumocystis* produces patchy involvement throughout the lungs, causing affected alveoli to thicken, become edematous, and fill with foamy, protein-rich fluid. Gas exchange is severely impaired as the disease progresses. *Pneumocystis* pneumonia (PCP) has an abrupt onset with fever, tachypnea and shortness of breath, and a dry, nonproductive cough. Respiratory distress can be significant, with intercostal retractions and cyanosis.

Table 36–3 compares the manifestations of infectious pneumonias.

ASPIRATION PNEUMONIA

Aspiration of gastric contents into the lungs results in a chemical and bacterial pneumonia known as *aspiration pneumonia*. Major risk factors for aspiration pneumonia include emergency surgery or obstetric procedures, depressed cough and gag reflexes, and impaired swallowing. Older surgical patients are at significant risk. Enteral nutrition by either nasogastric or gastric tube also increases the risk for aspiration pneumonia. Vomiting is not always apparent; silent regurgitation of gastric contents may occur when the level of consciousness is decreased. Measures to reduce the risk for aspiration pneumonia include minimizing the use of preoperative medications, promoting anesthetic elimination from the body, and preventing nausea and gastric distention.

The low pH of gastric contents causes a severe inflammatory response when aspirated into the respiratory tract. Pulmonary edema and respiratory failure may result. Common complications of aspiration pneumonia include abscesses, bronchiectasis (chronic dilation of the bronchi and bronchioles), and gangrene of pulmonary tissue.

●○● INTERPROFESSIONAL CARE

Prevention is a key component in managing pneumonia. Identifying vulnerable populations and instituting preventive strategies are measures to reduce the mortality and morbidity associated with pneumonia. With early identification of the infecting organism, appropriate treatment, and support of respiratory function, most patients recover uneventfully. However, pneumonia remains a serious disease with significant mortality, especially in aged and debilitated populations.

DIAGNOSIS

The history, physical examination, and diagnostic testing are used to establish the diagnosis, determine the extent of lung involvement, and identify the causative organism.

TABLE 36–3 Manifestations of Infectious Pneumonias

Type	Onset	Respiratory Manifestations	Systemic Manifestations
Pneumococcal or lobar pneumonia	Abrupt	Cough productive of purulent or rust-colored sputum; pleuritic or aching chest pain; decreased breath sounds and crackles over affected area; possible dyspnea and cyanosis	Chills and fever
Bronchopneumonia	Gradual	Cough, scattered crackles; minimal dyspnea and respiratory distress	Low-grade fever
Legionnaires' disease	Gradual	Dry cough; dyspnea	Chills and fever; general malaise; headache; confusion; anorexia and diarrhea; myalgias and arthralgias
Primary atypical pneumonia	Gradual	Dry, hacking, nonproductive cough	Fever, headache, myalgias, and arthralgias dominate
Viral pneumonia	Sudden or gradual	Dry cough	Flu-like symptoms
Pneumocystis pneumonia	Abrupt	Dry cough; tachypnea and shortness of breath; significant respiratory distress	Fever

- *Chest x-ray* is obtained to determine the extent and pattern of lung involvement. Fluid, infiltrates, consolidated lung tissue, and atelectasis (areas of alveolar collapse) appear as densities on the film. The *CT scan* provides a more detailed image of pulmonary tissue and may be used when the chest x-ray is not diagnostic.
- *Sputum gram stain* rapidly identifies the infecting organisms as gram-positive or gram-negative bacteria. Antibiotic therapy can then be directed at the predominant type of organism until culture and sensitivity results are obtained.
- *Sputum culture and sensitivity* is ordered to identify the infecting organism and determine the most effective antibiotic therapy. When obtaining sputum for culture, it is important to obtain secretions from the lower respiratory tract, not the mouth and nasal passages.
- *Complete blood count (CBC) with white blood cell (WBC) differential* shows an elevated WBC (11,000/mm^3 or higher) with increased circulating immature leukocytes (a left shift) in response to the infectious process. WBC changes are minimal in viral and other pneumonias.
- *Serology testing*, blood tests to detect antibodies to respiratory pathogens, may be used to identify the infecting organism when blood and sputum cultures are negative.
- *Pulse oximetry*, a noninvasive method of measuring arterial oxygen saturation, is ordered to continuously monitor gas exchange. The Sao_2 normally is 95% or higher. An Sao_2 of less than 95% may indicate impaired alveolar gas exchange.
- *Arterial blood gases (ABGs)* may be ordered to evaluate gas exchange. Respiratory secretions or pleuritic pain can interfere with alveolar ventilation. Alveolar inflammation can interfere with gas exchange across the alveolar-capillary membrane, especially if exudate or consolidation is present. An arterial oxygen tension (Po_2) of less than 75 to 80 mmHg indicates impaired gas exchange or alveolar ventilation. See Chapters 10 and 34 for more information about gas transport, arterial blood gases, and normal or expected values.
- *Fiberoptic bronchoscopy* may be done to obtain a sputum specimen or remove secretions from the bronchial tree (refer to Figure 34–4 in Chapter 34). Nursing responsibilities related to bronchoscopy are summarized in the Diagnostic Tests table in Chapter 34.

IMMUNIZATION

Vaccines offer some degree of protection against the most common bacterial and viral pneumonias.

Pneumococcal vaccine, made of antigens from 23 types of pneumococcus, usually imparts lifetime immunity with a single dose. The vaccine is recommended for people who have a high risk of adverse outcome from bacterial pneumonias: people over age 65; those with chronic cardiac or respiratory conditions, diabetes mellitus, alcoholism, or other chronic diseases; and immunocompromised people. A one-time revaccination is recommended for selected populations, including people over age 65 who were immunized more than 5 years previously and before age 65, people with chronic renal failure or immunosuppressive conditions (e.g., malignancy), and people receiving chemotherapy with selected agents (CDC, 2012a).

Influenza vaccine is also recommended for high-risk populations. The predominant strain of influenza virus varies from year to year. A new vaccine formulation is prepared yearly, incorporating antigens of the influenza strains predicted to be the most prevalent for the upcoming flu season (typically the winter months). Vulnerable populations for whom yearly vaccine is recommended include those listed earlier as well as healthcare workers and residents of long-term care facilities. The vaccine contains egg protein, and is not recommended for people who have a severe allergy to eggs or who have previously experienced a severe hypersensitivity response to the vaccine.

MEDICATIONS

Medications used to treat pneumonia may include antibiotics to eradicate the infection and bronchodilators to reduce bronchospasm and improve ventilation.

Initial antibiotic therapy is based on the results of sputum Gram stain and the pattern of lung involvement shown on the chest x-ray. Considerations such as the presence of cardiovascular disease or residence in a long-term care facility also are considered in the initial antibiotic choice. Typically, a broad-spectrum antibiotic such as a macrolide (e.g., clarithromycin, azithromycin, or erythromycin), a penicillin or a second- or third-generation cephalosporin, or a fluoroquinolone (e.g., ciprofloxacin) is ordered until the results of sputum culture and sensitivity tests are available. Table 36–4 lists

TABLE 36–4 Antibiotic Therapy for Selected Pneumonias

Causative Organism	Antibiotic of Choice	Alternative Antibiotics
Streptococcus pneumoniae	*Penicillin G; amoxicillin*	Erythromycin, *cephalosporins*, *doxycycline*, fluoroquinolones, clindamycin, vancomycin, *trimethoprim-sulfamethoxazole* (*TMP-SMZ*), linezolid
Haemophilus influenzae	Second- or third-generation cephalosporins, *doxycycline, azithromycin, TMP-SMZ*	Fluoroquinolones, *clarithromycin*
Staphylococcus aureus	Penicillinase-resistant penicillin (e.g., nafcillin); vancomycin for methicillin-resistant organisms	*Cephalosporins*, vancomycin, clindamycin; *ciprofloxacin,* fluoroquinolones, *TMP-SMZ*
Mycoplasma pneumoniae	Erythromycin, *doxycycline*	*Clarithromycin*, *azithromycin*, fluoroquinolones
Klebsiella pneumoniae	Third-generation cephalosporin (with aminoglycoside if severe); metronidazole	Aztreonam, imipenem-cilastatin, fluoroquinolones
Legionella pneumophila	Macrolide + rifampin; fluoroquinolones	*TMP-SMZ, doxycycline* + rifampin
Pneumocystis	*TMP-SMZ,* pentamidine + *prednisone*	Dapsone + *trimethoprim*, *clindamycin* + primaquine, trimetrexate + folinic acid
Chlamydia pneumoniae	*Doxycycline*	Macrolide, fluoroquinolones

Note: Drugs identified in *italics* are among the 200 most commonly prescribed medications in the U.S.

commonly prescribed antibiotics for selected pneumonias; nursing implications for selected antibiotics are summarized on pages 289–91 of Chapter 12.

When an inflammatory response to the infection causes bronchospasm and constriction, bronchodilators may be ordered to improve ventilation and reduce hypoxia. Bronchodilators generally belong to one of two major groups: the sympathomimetic drugs, such as albuterol sulfate (Proventil) and metaproterenol (Alupent); or the methylxanthines, such as theophylline and aminophylline. Use of these drugs and related nursing implications are discussed in detail in the section on asthma.

An agent to break up mucus or reduce its viscosity may be prescribed. Acetylcysteine (Mucomyst), potassium iodide, and guaifenesin (a common ingredient in expectorant cough syrups) help to liquefy mucus, making it easier to expectorate. For many patients, however, increasing fluid intake is an effective means of liquefying mucus.

TREATMENTS

When mucous secretions are thick and viscous, increasing fluid intake to 2500 to 3000 mL/day helps liquefy secretions, making them easier to cough up and expectorate. If the patient is unable to maintain an adequate oral intake, intravenous fluids and nutrition may be required.

Incentive spirometry may be used to promote deep breathing, coughing, and clearance of respiratory secretions. Endotracheal suctioning may be required if the cough is ineffective. This invasive technique is discussed in the section describing nursing care for the patient with acute respiratory failure in Chapter 37. On occasion, bronchoscopy is used to perform pulmonary toilet and remove secretions.

OXYGEN THERAPY Oxygen therapy may be indicated for the patient who is tachypneic or hypoxemic.

Inflammation of the alveolar-capillary membrane interferes with diffusion of gases across the membrane. Diffusion is affected by several other factors, including the partial pressure of gases on each side of the membrane. Increasing the percentage of inspired oxygen above that of room air (21%) increases the partial pressure of oxygen in the alveoli and enhances its diffusion into the capillaries. Supplemental oxygen therefore improves oxygenation of the blood and tissues in patients with pneumonia.

Depending on the degree of hypoxia, oxygen may be administered by either a low-flow or high-flow system. Low-flow systems include the nasal cannula, simple face mask, partial rebreathing mask, and nonrebreathing mask (Figure 36–3 ■). A nasal cannula can deliver 24% to 45% oxygen concentrations with flow rates of 2 to 6 L/min. The nasal cannula is comfortable and does not interfere with eating or talking. A simple face mask delivers 40% to 60% oxygen concentrations with flow rates of 5 to 8 L/min. Up to 100% oxygen can be delivered by the nonrebreather mask, the highest concentration possible without mechanical ventilation. When the amount of oxygen delivered must be precisely regulated, a high-flow system such as a Venturi mask is used (Figure 36–4 ■). The Venturi mask regulates the ratio of oxygen to room air, allowing precise regulation of the oxygen percentage delivered, from 24% to 50%. High-flow oxygen can also be delivered via nasal cannula (Vapotherm). In these methods, oxygen and warmed normal saline are aerosolized. Flow at 15 L/min provides up to 90% FiO_2, whereas 10 L/min provides 65% FiO_2. Severe hypoxia may necessitate intubation and mechanical ventilation. Endotracheal intubation and methods of mechanical ventilation are discussed in Chapter 37.

CHEST PHYSIOTHERAPY Chest physiotherapy, including percussion, vibration, and postural drainage, may be prescribed to reduce lung consolidation and prevent atelectasis. *Percussion* is performed by rhythmically striking or clapping the chest wall with cupped hands, using rapid wrist flexion and extension. Cupping traps air between the palm and the patient's skin, setting up vibrations through the chest wall that loosen respiratory secretions. The trapped air also provides a cushion, preventing injury. When performed correctly, percussion produces a hollow, popping sound. Percussion may also be done using a mechanical percussion cup, vibration modes on certain hospital beds, or via a vest or chest wrap. The breasts, sternum, spinal column, and kidney regions are avoided during percussion.

Vibration facilitates secretion movement into larger airways. It usually is combined with percussion, although it may be used when

Figure 36–3 ■ Low-flow oxygen delivery devices. A, Nasal cannula. B, Simple face mask. C, Nonrebreather mask.

Figure 36–4 ■ Venturi mask, a high-flow oxygen delivery system.

percussion is contraindicated or poorly tolerated. Vibration is performed by repeatedly tensing the arm and hand muscles while maintaining firm but gentle pressure over the affected area with the flat of the hand.

Percussion and vibration are done in conjunction with *postural drainage*, which uses gravity to facilitate removal of secretions from a particular lung segment. The patient is positioned with the segment to be drained superior to or above the trachea or mainstem bronchus. Drainage of all lung segments requires a variety of positions (Figure 36–5 ■); rarely do all segments require drainage. Bronchodilators or nebulizer treatments are administered as ordered prior to postural drainage. It is best to perform postural drainage before meals to avoid nausea and vomiting.

COMPLEMENTARY THERAPIES

Although complementary therapies do not replace conventional treatment for pneumonia, they often promote comfort and speed recovery. The herb echinacea is widely used to stimulate immune function and treat upper respiratory infections (URIs). Because viral URIs often precede pneumonia, it may be helpful in preventing pneumonia. Past research, however, shows mixed results for the effectiveness of echinacea in reducing the duration and severity of URI. Goldenseal, which often is sold in combination with echinacea, is used to treat bacterial, fungal, and protozoal infections of the mucous membranes of the respiratory tract.

Advise patients inquiring about the use of Chinese herbal remedies to reduce pneumonia symptoms to determine if any of the products contain *ma huang* (a form of ephedra) or ephedra. Patients should avoid these products, which are banned in the United States, because ephedra use is linked to significant safety risks.

●○● NURSING CARE

Health Promotion

Health promotion activities focus on pneumonia prevention. Make patients in high-risk groups aware of the benefits of immunizations against influenza and pneumococcal pneumonia. A single dose of pneumococcus vaccine usually produces immunity to most strains of pneumococcal pneumonia, although repeat doses may be needed for older adults and people who are immunosuppressed. (Pneumococcal vaccine is contraindicated for people receiving immunosuppressive therapy.) Annual influenza vaccine helps prevent pneumonia because pneumonia often occurs as a sequela to influenza.

SAFETY ALERT

Inquire about allergic responses to eggs or previous influenza vaccinations prior to administering influenza vaccine. A significant hypersensitivity response may occur in patients who are allergic to egg protein.

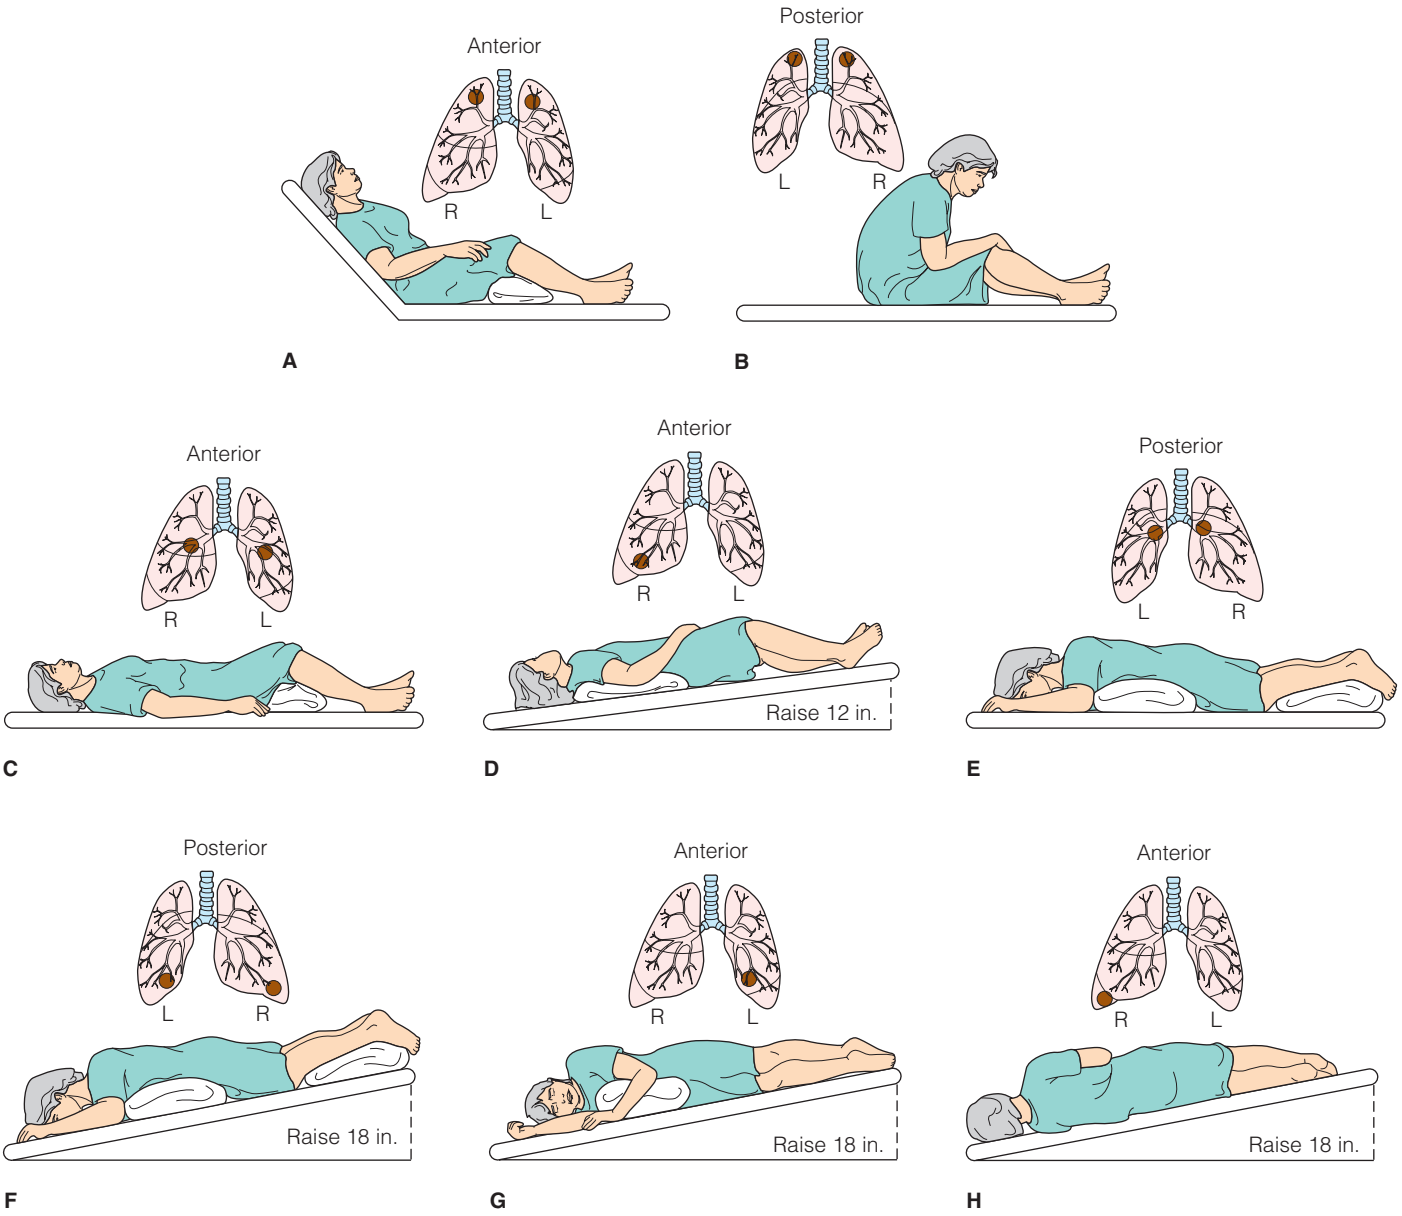

Figure 36–5 ■ Positions for postural drainage. A, Left and right anterior apical. B, Left and right posterior apical. C, Left and right anterior upper. D, Right middle lobe. E, Superior lower lobes. F, Left and right lower posterior. G, Left lower lateral. H, Right lower lateral.

Additional measures to screen for and detect pneumonia in older adults are appropriate. Frequent pulmonary assessment and aggressive interventions help prevent problems. Restoring and maintaining mobility improves ventilation and helps mobilize secretions. Promoting adequate fluid intake liquefies secretions, making them easier to expectorate.

Assessment

See the Manifestations and Interprofessional Care sections for the assessment of the patient with pneumonia.

Focused assessment of the patient with pneumonia includes the following:

- *Health history:* current symptoms and their duration; presence of shortness of breath or difficulty breathing, chest pain and its relationship to breathing; cough, productive or nonproductive, color, consistency of sputum; other symptoms; recent upper respiratory or other acute illness; chronic diseases such as diabetes, chronic lung disease, or heart disease; current medications; medication allergies
- *Physical assessment:* presentation, apparent distress, level of consciousness; vital signs including temperature; skin color, temperature; respiratory excursion, use of accessory muscles of respiration; lung sounds
- *Laboratory data:* WBC with differential, sputum gram stain, culture and sensitivity, chest x-ray or CT scan.

Priorities of Care

Collaborating with the interprofessional team to ensure adequate treatment of the pneumonia infectious process while providing care that

supports the physical and psychologic responses to the disorder throughout the acute and rehabilitative phases of care is a priority of nursing care.

Diagnoses, Outcomes, and Interventions

Patients with lower respiratory disorders such as pneumonia may have multiple nursing care needs, depending on the severity of the illness. Alveolar ventilation and the process of alveolar respiration can be affected by inflammation and secretions. **Hypoxemia**, low levels of oxygen in the blood, and tissue hypoxia may result. Nursing care focuses on supporting optimal respiratory function and promoting rest to reduce metabolic and oxygen needs. Priority nursing diagnoses include *Ineffective Airway Clearance*,*Ineffective Breathing Pattern*, and *Activity Intolerance.*

Ineffective Airway Clearance

The inflammatory response to infection causes tissue edema and exudate formation. In the lungs, the inflammatory response can narrow and potentially obstruct bronchial passages and alveoli. Assessment findings supporting this nursing diagnosis include adventitious breath sounds such as crackles (rales), rhonchi, and wheezes; dyspnea and tachypnea; coughing; and indicators of hypoxia such as cyanosis, reduced SaO_2 levels, anxiety, and apprehension.

Expected Outcome: Patient will use techniques to promote airway clearance such as coughing and deep breathing.

- Assess respiratory status, including vital signs, breath sounds, SaO_2, and skin color at least every 4 hours. *Early identification of respiratory compromise allows intervention before tissue hypoxia is significant.*
- Assess cough and sputum (amount, color, consistency, and possible odor). *Assessment of the cough and nature of sputum produced allows evaluation of the effectiveness of respiratory clearance and the response to therapy.*
- Monitor arterial blood gas results; report increasing hypoxemia and other abnormal results to the healthcare provider. *Blood gas changes may be an early indicator of impaired gas exchange due to airway narrowing or obstruction.*
- Place in Fowler's or high-Fowler's position. Encourage frequent position changes and ambulation as allowed. *The upright position promotes lung expansion; position changes and ambulation facilitate the movement of secretions.*
- Assist to cough, deep breathe, and use assistive devices. Provide endotracheal suctioning using aseptic technique as ordered. *Coughing, deep breathing, and suctioning help clear airways.*
- Provide a fluid intake of at least 2500 to 3000 mL/day. *A liberal fluid intake helps liquefy secretions, facilitating their clearance.*
- Work with the healthcare provider and respiratory therapist to provide pulmonary hygiene measures, such as incentive spirometry, postural drainage, percussion, and vibration. *These techniques help mobilize and clear secretions.*
- Administer prescribed medications as ordered, and monitor their effects. *If the infecting organism is resistant to the prescribed antibiotic, little improvement may be seen with treatment. Bronchodilators help maintain open airways but may have adverse effects such as anxiety and restlessness.*

Ineffective Breathing Pattern

Pleural inflammation often accompanies pneumonia, causing sharp localized pain that increases with deep breathing, coughing, and movement, which can lead to rapid and shallow breathing. Distal airways and alveoli may not expand optimally with each breath, increasing the risk for atelectasis and decreasing gas exchange. Fatigue from the increased work of breathing is an additional problem in pneumonia. This, too, can lead to decreased lung inflation and an ineffective breathing pattern.

Expected Outcome: Patient will utilize techniques to promote adequate ventilation such as deep breathing and incentive spirometry.

- Assess respiratory rate, depth, and lung sounds at least every 4 hours. *Tachypnea and diminished or adventitious breath sounds may be early indicators of respiratory compromise.*
- Provide for rest periods. *Rest reduces metabolic demands, fatigue, and the work of breathing, promoting a more effective breathing pattern.*
- Assess for pleuritic discomfort. Provide analgesics as ordered. *Adequate pain relief minimizes splinting and promotes adequate ventilation.*
- Provide reassurance during periods of respiratory distress. *Hypoxia and respiratory distress produce high levels of anxiety, which tends to further increase tachypnea and fatigue and decrease ventilation.*
- Administer oxygen as ordered. *Oxygen therapy increases the alveolar oxygen concentration and facilitates its diffusion across the alveolar-capillary membrane, reducing hypoxia and anxiety.*
- Teach slow abdominal breathing. *This breathing pattern promotes lung expansion.*
- Teach use of relaxation techniques, such as visualization and meditation. *These techniques help reduce anxiety and slow the breathing pattern.*

Activity Intolerance

Impaired airway clearance and gas exchange interfere with oxygen delivery to body cells and tissues. At the same time, the infectious process and the body's response to it increase metabolic demands on the cells. The net result of this imbalance between oxygen delivery and oxygen demand is a lack of physiologic energy to maintain normal daily activities.

Expected Outcome: Patient will participate in physical activity as tolerated.

- Assess activity tolerance, noting any increase in pulse, respirations, dyspnea, diaphoresis, or cyanosis. *These assessment findings may indicate limited or impaired activity tolerance.*

SAFETY ALERT

Activity intolerance may be an early sign of cardiorespiratory compromise, particularly in the older adult or patient with preexisting heart disease. New or worsening manifestations of activity intolerance should be reported to the healthcare provider.

- Assist with self-care activities, such as bathing. *Assistance with ADLs reduces energy demands.*
- Schedule activities, planning for rest periods. *Rest periods minimize fatigue and improve activity tolerance.*
- Provide assistive devices, such as an overhead trapeze. *These assistive devices facilitate movement and reduce energy demands.*
- Enlist the family's help to minimize stress and anxiety levels. *Stress and anxiety increase metabolic demands and can decrease activity tolerance.*

- Perform active or passive ROM exercises. *Exercises help maintain muscle tone and joint mobility, and prevent contractures if bed rest is prolonged.*
- Provide emotional support and reassurance that strength and energy will return to normal when the infectious process has resolved and the balance of oxygen supply and demand is restored. *The patient may be concerned that activity intolerance will continue to be a problem after the acute infection is resolved.*

Continuity of Care

Patients with pneumonia usually are treated in the community, unless their respiratory status is significantly compromised (e.g., altered mental status, tachypnea, tachycardia, hypotension, hypo- or hyperthermia, and altered blood gases) or risk factors such as advanced age and/or coexisting heart, kidney, or liver disease are present.

Discuss the following topics when preparing the patient and family for home care:

- The importance of completing the prescribed medication regimen as ordered; potential drug side effects and their management, including manifestations that necessitate stopping the drug and notifying the healthcare provider
- Recommendations for limiting activities and increasing rest
- Maintaining adequate fluid intake to keep mucus thin for easier expectoration
- Ways to maintain adequate nutritional intake, such as small, frequent, well-balanced meals
- The importance of avoiding smoking or exposure to secondhand smoke to prevent further irritation of the lungs
- Manifestations to report to the healthcare provider, such as increasing shortness of breath, difficulty breathing, increased fever, fatigue, headache, sleepiness, or confusion
- The importance of keeping all follow-up appointments to ensure disease cure.

The accompanying Case Study & Nursing Care Plan provides further nursing interventions for patients treated in the community.

Evidence for Nursing Care

The Patient with Pneumonia

Selected resources that nurses may find helpful when planning evidence-based nursing care follow.

- Cuccio, L., Cerullo, E., Paradis, H., Padula, C., Rivet, C., Steeves, S., & Lynch, J. (2012). An evidence-based oral care protocol to decrease ventilator-associated pneumonia. *Dimensions of Critical Care Nursing, 31*(5), 301–308.
- Echevarria, I. M., & Schwoebel, A. (2012). Development of an intervention model for the prevention of aspiration pneumonia in high-risk patients on a medical-surgical unit. *MEDSURG Nursing, 21*(5), 303–308.
- Lyerla, F., LeRouge, C., Cooke, D. A., Turpin, D., & Wilson, L. (2010). A nursing clinical decision support system and potential predictors of head-of-bed position for patients receiving mechanical ventilation. *American Journal of Critical Care, 19*(1), 39–47. doi:10.4037/ajcc2010836
- Melnyk, B. M. (2011). Nursing interventions to improve outcomes in hospitalized adults. *Worldviews of Evidence-Based Nursing, 8*(4), 252–255.

Patients with respiratory compromise or who are older or debilitated may require home care assistance to remain at home. Provide referrals to home intravenous services, home health nursing services, and home maintenance services as indicated. Community services such as Meals-on-Wheels can provide support to reduce the energy demands of meal preparation.

THE PATIENT WITH SEVERE ACUTE RESPIRATORY SYNDROME

Severe acute respiratory syndrome (SARS) is a lower respiratory illness of unknown etiology first described in people in Asia in February 2003. Cases were identified in patients in North America, South America, Europe, and Asia before the outbreak was contained (CDC, 2012a). The primary population affected by SARS is previously healthy adults ages 25 to 70 years. According to the CDC, no new cases have been identified worldwide since 2004. In 2012, Middle East respiratory syndrome (MERS), a new SARS-like coronavirus, was identified. Genomic testing revealed the novel virus is closely related to the SARS virus. The World Health Organization (WHO) reported in November 2012 that nine cases of the novel coronavirus had been identified since September 2012, with five deaths (WHO, 2012a). Vaccine development is under way (National Institute of Allergy and Infectious Diseases [NIAID], 2014).

Pathophysiology

A coronavirus not previously identified in humans is the infective agent responsible for SARS. This virus appears to spread primarily by contact with respiratory secretions. Other potential sources of the infection are through direct contact with an infected person or contaminated object, and exposure of the eyes or mucous membranes to respiratory secretions (CDC, 2012a). Contact with contaminated water or sewage may transmit the disease, suggesting a fecal–oral transmission route as well.

The virus infects cells of the respiratory tract, leading to surface necrosis and sloughing of pneumocytes in the alveolar spaces and formation of hyaline membranes (a fibrin and protein film that interferes with gas exchange within the alveoli). The alveolar damage is accompanied by inflammation of interstitial pulmonary tissues with infiltration by lymphocytes and monocytes. The virus also is found in the blood, urine, and feces.

Manifestations and Complications

The incubation period for SARS was generally 2 to 7 days, although it was as long as 10 days in some people. Fever higher than 38°C (100.4°F) is typically the initial manifestation of the disease. After 1 to 2 days, respiratory manifestations of SARS develop, including nonproductive cough, shortness of breath, dyspnea, and possible hypoxemia. Respiratory symptoms may worsen, progressing to respiratory distress, during the second week of the illness. Acute respiratory distress syndrome (ARDS) or multiorgan dysfunction (refer to Chapter 11) may develop. The overall mortality rate for SARS was about 11%. The disease is less severe in children than in adults (CDC, 2012a; WHO, 2012a).

●○● INTERPROFESSIONAL CARE

Prompt identification of SARS or related novel respiratory viruses, infection control measures, and reporting of the disease are vital to

CASE STUDY & NURSING CARE PLAN A Patient with Pneumonia

Mary O'Neal is a 35-year-old executive assistant and a part-time college student. On returning home from class one evening, she begins to feel chilled. She alternates between chills and sweats all night. Staying home from work, she remains in bed most of the next day. Her fever continues, and she develops a cough and dull aching chest pain. When the cough becomes productive of rust-colored sputum the following day, she seeks medical treatment from her family physician.

ASSESSMENT

Debby Kowalski, RN, the family practice clinic nurse, admits Mrs. O'Neal to the clinic and obtains the nursing assessment. Mrs. O'Neal denies any previous history of respiratory diseases "other than the usual colds, flu, and such." She also denies any history of smoking or medication allergies. She says her symptoms began abruptly with the onset of the chills. She describes her chest pain as a dull ache that was initially substernal but now is localized in her lower lateral right chest. The pain increases with deep breathing, coughing, and moving. Her cough is increasing in frequency and severity, and her sputum appears rusty brown. Her vital signs are BP 116/74 mmHg, P 104 bpm and regular, R 26/min, T 38.7°C (101.8°F). Skin warm and flushed, with no evidence of cyanosis. Respirations shallow, unlabored; respiratory excursion equal. Diminished breath sounds in bases bilaterally, crackles noted in right posterior and lateral base. Faint pleural rub heard at right midaxillary line.

A STAT CBC shows a WBC of 18,900/mm^3; differential shows increased numbers of neutrophils and immature WBCs (bands). Ms. Kowalski has Mrs. O'Neal rinse with an antiseptic mouthwash and collect a sputum specimen for culture and Gram stain prior to seeing the healthcare provider.

The healthcare provider orders a chest x-ray after examining Mrs. O'Neal. Based on her history, examination, and the chest x-ray, he makes the diagnosis of acute bacterial pneumonia, probably pneumococcal. He prescribes oral penicillin V, 500 mg every 6 hours for 10 days. He asks Mrs. O'Neal to return for a follow-up appointment in 10 days and refers her back to Ms. Kowalski for appropriate teaching.

DIAGNOSIS

- *Ineffective Breathing Pattern* related to pleuritic chest pain
- *Hyperthermia* related to inflammatory process
- *Deficient Knowledge* related to diagnosis of pneumonia and its treatment

EXPECTED OUTCOMES

- Patient will maintain normal pulmonary function.
- Patient will describe measures to minimize elevations in body temperature.
- Patient will identify a schedule for taking her medication that will facilitate compliance with the regimen.
- Patient will describe manifestations that should be reported to the healthcare provider.

PLANNING AND IMPLEMENTATION

- Assess knowledge and understanding of pneumonia and its effects.
- Assist to develop a medication schedule that coordinates with normal daily routine.
- Teach about the following:
  a. Importance of avoiding use of a cough suppressant except at night to facilitate rest
  b. Ways to increase fluid intake to reduce fever and maintain thin mucus for easy expectoration
  c. Beneficial effects of rest, especially during the acute phase of her illness
  d. Safe use of aspirin and acetaminophen to reduce fever
  e. Importance of taking all prescribed medication doses as scheduled
  f. Common side effects of penicillin V and their management
  g. Early manifestations of penicillin allergy that necessitate stopping the medication and notifying the healthcare provider
  h. Signs of complications of pneumonia or worsening pneumonia to report

EVALUATION

The sputum culture confirms *S. pneumoniae* as the cause of Mrs. O'Neal's pneumonia. When she returns for her follow-up appointment, she reports that she began to feel better after 2 days on the penicillin and returned to work the following Monday. Her examination reveals good breath sounds throughout with no adventitious sounds.

Clinical Reasoning in Patient Care

1. Do any of the factors identified in the case study increase Mrs. O'Neal's risk for acute bacterial pneumonia?
2. Mrs. O'Neal's WBC differential showed increased neutrophil and band counts. Describe the reason for and effect of this change.
3. Even though Mrs. O'Neal has no history of medication allergies, anaphylactic shock remains a potential risk. Describe the sequence of events leading to anaphylactic shock, its initial symptoms, and immediate nursing interventions.
4. Had Mrs. O'Neal required hospitalization to treat her acute pneumonia, interruption of her usual activities and responsibilities could lead to anxiety. Develop a care plan for this situation, using the nursing diagnosis *Ineffective Role Performance* related to hospitalization.

See Evaluating Your Response in Appendix B.

control these potentially fatal diseases. Healthcare providers and public health personnel should report cases of SARS or other nonpathogen-identified cases to state and local health departments to determine if a novel virus may be the cause.

DIAGNOSIS

Diagnostic testing for SARS may include the following:

- *Serology tests* (including ELISA or immunofluorescence tests) for antibodies to the coronavirus may be performed, but often are undetectable during the acute stage of the illness.
- *Reverse transcriptase–polymerase chain reaction (RT-PCR)* testing of respiratory and blood samples provides a rapid mechanism for identifying the virus, but only about 33% of early samples are positive.
- *Chest x-ray* may be normal or show interstitial infiltrates in a focal or generalized patchy pattern. In late stages of SARS, consolidation may be evident.
- *Pulse oximetry (oxygen saturation)* often shows hypoxemia in the respiratory phase of the illness.
- *Complete blood count (CBC)* often demonstrates a low lymphocyte count early in the disease. Leukopenia and thrombocytopenia may develop at the peak of the respiratory illness.
- *Creatinine phosphokinase (CPK* or *CK)*, *ALT*, and *AST* levels may be markedly increased in SARS.

- *Sputum specimen* is obtained. Gram stain and culture are performed on the specimen to rule out other causes of pneumonia.
- *Blood culture* may be done to identify possible bacteremia.

MEDICATIONS

At this time, no medications have been shown to be consistently effective in treating SARS. Antibiotic and/or antiviral therapy targeted at community-acquired forms of pneumonia may be administered if the diagnosis is unclear.

INFECTION CONTROL

Because healthcare workers are at risk for developing SARS after caring for infected patients, infection control precautions should be immediately instituted when SARS is suspected. Standard precautions (see Appendix A) are implemented along with contact and airborne precautions. The CDC (2012a) recommends hand hygiene, gown, gloves, eye protection, and an N95 respirator to prevent transmission of SARS/novel coronavirus in healthcare settings.

When patients with SARS/novel coronavirus are managed in the community, they are advised to remain home for 10 days after the fever has resolved and until respiratory symptoms are absent or minimal. Members of the household are advised to wash hands frequently or use alcohol-based hand rubs. The patient is advised to cover the mouth and nose with tissue when coughing or sneezing and to wear a surgical mask during close contact with uninfected people. Sharing of utensils, towels, and bedding should be avoided. Routine cleaning (e.g., washing with soap and hot water) is adequate to disinfect objects and no special precautions are necessary for disposing of waste.

TREATMENTS

Care of the patient with SARS/novel coronavirus is supportive. Oxygen may be administered to treat hypoxemia. Intubation and mechanical ventilation may be required if respiratory failure or acute respiratory distress syndrome (ARDS) develops.

●○● NURSING CARE

Nursing care of the patient with SARS/novel coronavirus focuses on preventing spread of the disease to others and providing respiratory support.

Health Promotion

Use respiratory and contact infection control precautions in addition to standard precautions when caring for all patients with suspected SARS/novel coronavirus to prevent spread of the disease to healthcare workers or other patients.

Assessment

See the Manifestations and Interprofessional Care sections for the assessment of the patient with SARS/novel coronavirus.

Focused assessment data for the patient with suspected SARS/novel coronavirus include the following;

- *Health history:* current symptoms, including fever, malaise, shortness of breath, and cough; onset of symptoms; recent international travel or exposure to an individual known to have SARS/novel coronavirus
- *Physical assessment:* vital signs including temperature; respiratory status, including respiratory rate, depth, and effort; presence of cough; adventitious lung sounds.

Priorities of Care

Collaborating with the interprofessional team to ensure adequate treatment of the underlying respiratory infection while providing care that supports the respiratory function and reduces spread of the disease is a priority of nursing care.

Diagnoses, Outcomes, and Interventions

The patient with SARS/novel coronavirus poses a risk for spread of the infection to healthcare workers and others. In addition, while many people with this disease experience only mild symptoms and recover fully and uneventfully, others develop severe respiratory distress and may require significant respiratory support. Gas exchange may be impaired, leading to significant hypoxemia. In addition to the nursing diagnoses discussed in the previous section on pneumonia, *Impaired Gas Exchange* and *Risk for Infection* are priority nursing diagnoses.

Impaired Gas Exchange

SARS/novel coronavirus causes hypoxemia of varying degrees in affected patients. Significant hypoxemia may necessitate intubation and mechanical ventilation to support cellular function until recovery occurs.

Expected Outcome: Patient will experience improved ventilation and adequate oxygenation as evidenced by blood gas levels within normal limits for the individual patient.

- Monitor vital signs, color, oxygen saturation, and arterial blood gases. Assess for manifestations such as anxiety or apprehension, restlessness, confusion or lethargy, or complaints of headache. *These assessment data alert the nurse and care providers to potential hypoxemia or hypercapnia due to impaired gas exchange.*

SAFETY ALERT

Promptly report signs of respiratory distress, including tachypnea, tachycardia, nasal flaring, use of accessory muscles, intercostal retractions, cyanosis, increasing restlessness, anxiety, or decreased level of consciousness. These may be early manifestations of respiratory failure and inability to maintain ventilatory effort.

- Promptly report worsening arterial blood gases and oxygen saturation levels. *Close assessment of these values allows timely intervention as needed.*
- Maintain oxygen therapy and mechanical ventilation as ordered. Hyperoxygenate prior to suctioning. *Oxygen and mechanical ventilation support alveolar gas exchange. Hyperoxygenation prior to suctioning reduces the degree of hypoxemia that occurs during suctioning.*
- Place in Fowler's or high-Fowler's position. *Sitting positions decrease pressure on the diaphragm and chest, improving lung ventilation and decreasing the work of breathing.*
- Minimize activities and energy expenditures by assisting with ADLs, spacing procedures and activities, and allowing uninterrupted rest periods. *Rest is vital to reduce oxygen and energy demands.*

SAFETY ALERT

Avoid sedatives and respiratory depressant drugs unless mechanically ventilated. These medications can further depress the respiratory drive, worsening respiratory failure.

- If intubation and mechanical ventilation are necessary, explain the procedure and its purpose to the patient and family, providing reassurance that this *temporary* measure improves oxygenation and reduces the work of breathing. Alert that talking is not possible while the endotracheal tube is in place, and establish a means of communication. *Thorough explanation is important to relieve anxiety.*

See the section in Chapter 37 on respiratory failure for more information about caring for a patient who is intubated and mechanically ventilated.

Risk for Infection

The spread of SARS is a risk both in the healthcare facility and the community in which the patient resides. Respiratory and contact precautions are recommended to prevent the spread of SARS/novel coronavirus via respiratory secretions or contact with the virus.

Expected Outcome: Patient will describe measures to protect healthy tissue and prevent infection.

- Place the patient in a private room with airflow control that prevents air within the room from circulating into the hallway or other rooms. A negative-flow room in which air is diluted by at least six fresh-air exchanges per hour is recommended. *A negative-flow room and multiple fresh-air exchanges dilute the concentration of virus within the room and prevent its spread to adjacent areas.*
- Use standard precautions and respiratory and contact isolation techniques as recommended by the CDC, including wearing respirators, gowns, and eye protection when caring for patients with SARS/novel coronavirus. *These measures are important to prevent the spread of SARS to others.*
- Discuss the reasons for and importance of using respiratory and contact isolation procedures during treatment. *Maintenance of infection control precautions during and immediately following the febrile and respiratory phases of SARS is vital to prevent its spread to healthcare workers and the community.*
- Place a mask on the patient when transporting to other parts of the facility for diagnostic or treatment procedures. *Covering the patient's nose and mouth during transport minimizes air contamination and the risk to visitors and personnel.*
- Inform all personnel having contact with the patient of the diagnosis. *This allows personnel to take appropriate precautions.*
- Assist visitors to mask prior to entering the room. *Providing visitors with appropriate masks or respirators reduces their risk of infection.*
- Teach the patient how to limit transmitting the disease to others:
  a. Always cough and expectorate into tissues.
  b. Dispose of tissues properly, placing them in a closed bag.
  c. Wear a mask if sneezing or unable to control respiratory secretions.
  d. Do not share eating utensils, towels, bedding, or other objects with others, because this disease can also be spread by contact with contaminated objects.

  Teaching appropriate precautions helps prevent the spread of SARS/novel coronavirus to others while allowing as much freedom from restraints as possible.

Continuity of Care

Many patients with SARS/novel coronavirus experience only mild symptoms and are appropriately cared for in the community. Teaching about home care and infection control precautions is vital to prevent spread of this disease to the community. Include the following topics when teaching for home care:

- The disease, its origin, and how it is spread
- Manifestations of impaired respiratory status to report to the healthcare provider
- Preventing spread of the disease to others:
  - Cover the mouth and nose with tissues when coughing or sneezing. Personally dispose of tissues in a paper bag or the garbage. Wear a surgical mask during close contact with other members of the household.
  - Limit interactions outside the home; do not go to work, school, or other public areas until you have been free of fever for 10 days and your respiratory symptoms are resolving.
  - Remind all members of the household to wash hands (or use an alcohol-based hand sanitizer) frequently, particularly after direct contact with body fluids.
  - Do not share eating utensils, towels, or bedding with others. These items can be cleaned with soap and hot water between uses. Clean contaminated surfaces with a household disinfectant.
- Monitoring uninfected members of the household for signs of the illness (Instruct to report fever or respiratory symptoms to the healthcare provider.)

THE PATIENT WITH A LUNG ABSCESS

A **lung abscess** is a localized area of lung destruction or necrosis and pus formation. The most common cause of lung abscess is aspiration and resulting pneumonia. Risk factors, therefore, are those for aspiration: decreased level of consciousness due to anesthesia, injury or disease of the central nervous system (CNS), seizure, excessive sedation, or alcohol abuse; swallowing disorders; dental caries; and debilitation secondary to cancer or chronic disease. Lung abscess also may occur as a complication of some types of pneumonia, including those due to *Staphylococcus aureus*, *Klebsiella*, and *Legionella*.

Pathophysiology and Manifestations

A lung abscess forms after lung tissue becomes consolidated (i.e., after alveoli become filled with fluid, pus, and microorganisms). In up to 89% of patients, anaerobic organisms are identified. Consolidated tissue becomes necrotic. This necrotic process can spread to involve the entire bronchopulmonary segment and progress proximally until it ruptures into a bronchus. With rupture, the contents of the abscess empty into the bronchus, leaving a cavity filled with air and fluid, a process known as *cavitation*. If purulent material from the abscess is not expectorated, the infection may spread, leading to diffuse pneumonia or a syndrome similar to acute respiratory distress syndrome (ARDS, discussed in Chapter 37).

Manifestations of lung abscess typically develop about 2 weeks after the precipitating event (aspiration, pneumonia, and so on). Their onset may be either acute or insidious. Early symptoms are those of pneumonia: productive cough, chills and fever, pleuritic chest pain, malaise, and anorexia. The temperature may be significantly elevated, 39.4°C (103°F) or higher. When the abscess ruptures, the patient may expectorate large amounts of foul-smelling, purulent, and possibly blood-streaked sputum. Breath sounds are diminished, and crackles may be noted in the region of the abscess. A dull percussion tone is also present.

●○● INTERPROFESSIONAL CARE

The diagnosis of lung abscess usually is based on the history and presentation. The CBC may indicate leukocytosis. Sputum culture may not show the organism involved unless rupture occurs. Chest x-ray shows a thick-walled, solitary cavity with surrounding consolidation, although differentiating lung abscess from consolidation can be difficult until cavitation occurs.

Lung abscess is treated with antibiotic therapy, usually intravenous clindamycin (Cleocin), amoxicillin-clavulanate (Augmentin), or penicillin. Antibiotic therapy should be continued until the chest radiograph improves, usually at least 1 month. Postural drainage may be ordered to relieve obstruction and promote drainage. In some cases, bronchoscopy is used to drain the abscess. If the pleural space becomes involved, a chest tube (*tube thoracostomy*) may be used to drain the abscess. See the section on pneumothorax for further discussion of chest tubes.

●○● NURSING CARE

Although most patients with lung abscess recover fully with appropriate antibiotic treatment, rupture and drainage of the abscess into a bronchus is a frightening experience. Nursing care needs of the patient relate primarily to maintaining a patent airway and adequate gas exchange. The following nursing diagnoses may be appropriate for the patient with lung abscess:

- *Risk for Ineffective Airway Clearance* related to large amounts of purulent drainage in bronchi
- *Impaired Gas Exchange* related to necrotic and consolidated lung tissue
- *Hyperthermia* related to infectious process
- *Anxiety* related to copious amounts of purulent sputum.

Patient and family teaching focuses on the importance of completing the prescribed antibiotic therapy. Most lung abscesses are successfully treated with antibiotics; however, treatment may last up to 1 month or more. Emphasize the importance of completing the entire course of therapy to eliminate the infecting organisms. Teach about the medication, including the name, dose, and desired and adverse effects. Stress the need to contact the healthcare provider if symptoms do not improve or if they become worse. Infection from lung abscess can spread not only to lung and pleural tissue but systemically, causing sepsis. If postural drainage is ordered, teach the patient and family how to perform this procedure. When procedures such as bronchoscopy or thoracostomy are performed to drain the abscess, provide preoperative teaching and instruction on postoperative care.

THE PATIENT WITH TUBERCULOSIS

Tuberculosis (TB) is a chronic, recurrent infectious disease that usually affects the lungs, although any organ can be affected. Caused by *Mycobacterium tuberculosis*, TB is uncommon in the United States, especially among young adults of European descent.

M. tuberculosis is a relatively slow-growing, slender, rod-shaped, acid-fast organism with a waxy outer capsule, which increases its resistance to destruction. Although the lungs are usually infected, TB can involve other organs as well. It is transmitted by *droplet nuclei*, airborne droplets produced when an infected person coughs, sneezes, speaks, or sings. The tiny droplets can remain suspended in air for several hours. Infection may develop when a susceptible host breathes in air containing droplet nuclei and the contaminated particle eludes the normal defenses of the upper respiratory tract to reach the alveoli.

Pathophysiology

PULMONARY TUBERCULOSIS

Minute droplet nuclei containing one to three bacilli that elude upper airway defense systems to enter the lungs implant in an alveolus or respiratory bronchiole, usually in an upper lobe. As the bacteria multiply, they cause a local inflammatory response. The inflammatory response brings neutrophils and macrophages to the site. These phagocytic cells surround and engulf the bacilli, isolating them and preventing their spread. *M. tuberculosis* continues to slowly multiply; some mycobacteria enter the lymphatic system to stimulate a cellular-mediated immune response (refer to Chapter 13 to review immune responses). Neutrophils and macrophages isolate the bacteria but cannot destroy them. A granulomatous lesion called a *tubercle*, a sealed-off colony of bacilli, is formed. Within the tubercle, infected tissue dies, forming a cheeselike center, a process called *caseation necrosis*.

If the immune response is adequate, scar tissue develops around the tubercle, and the bacilli remain encapsulated. These lesions eventually calcify and are visible on x-ray. The patient, while infected by *M. tuberculosis*, does not develop TB disease. If the immune response is inadequate to contain the bacilli, the disease of TB can develop. Occasionally, the infection can progress, leading to extensive destruction of lung tissue. In *primary tuberculosis*, granulomatous tissue may erode into a bronchus or into a blood vessel, allowing the disease to spread throughout the lung or other organs. This severe form of TB is uncommon in adults (Huether & McCance, 2011).

A previously healed TB lesion may be reactivated. *Reactivation tuberculosis* occurs when the immune system is suppressed due to age, disease, or use of immunosuppressive drugs. The extent of lung disease can vary from small lesions to extensive cavitation of lung tissue. Tubercles rupture, spreading bacilli into the airways to form satellite lesions and produce tuberculosis pneumonia. Without treatment, massive lung involvement can lead to death, or a more chronic process of tubercle formation and cavitation may result. People with chronic disease continue to spread *M. tuberculosis* into the environment, potentially infecting others. The Pathophysiology Illustrated feature on pages 1130–1131 illustrates the pathogenesis of TB.

Patients with HIV disease are at high risk for developing active TB, due to primary infection or reactivation. HIV infection suppresses cellular immunity, which is vital to limiting the replication and spread of *M. tuberculosis*.

FAST FACTS

- The organism causing TB, *Mycobacterium tuberculosis*, is spread through droplet nuclei that remain suspended in air for several hours.
- A tubercle is a sealed off colony of bacilli; if it ruptures, organisms spread, leading to tuberculosis pneumonia.
- Primary or secondary TB lesions may affect other body systems such as the kidneys, genitalia, bone, and brain.

MANIFESTATIONS AND COMPLICATIONS

The initial infection causes few symptoms and typically goes unnoticed until the tuberculin test becomes positive or calcified lesions are seen on chest x-ray. Manifestations of primary progressive or reactivation TB often develop insidiously and are initially nonspecific (see the accompanying Manifestations box). Fatigue, weight loss, anorexia, low-grade afternoon fever, and night sweats are common. A dry cough develops, which later becomes productive of purulent and/or blood-tinged sputum. It is often at this stage that the patient seeks medical attention.

Tuberculosis empyema and bronchopleural fistula are the most serious complications of pulmonary TB. When a TB lesion ruptures, bacilli may contaminate the pleural space. Rupture also may allow air to enter the pleural space from the lung, causing pneumothorax.

EXTRAPULMONARY TUBERCULOSIS

When primary disease or reactivation allows live bacilli to enter the bronchi, the disease may spread through the blood and lymph system to other organs. These distant disease metastases may produce an active lesion, or they may become dormant and reactivate at a later time. Extrapulmonary TB is especially prevalent in people with HIV disease.

MILIARY TUBERCULOSIS *Miliary tuberculosis* results from hematogenous spread (through the blood) of the bacilli throughout the body. Miliary tuberculosis causes chills and fever, weakness, malaise, and progressive dyspnea. Multiple lesions evenly distributed throughout the lungs are noted on x-ray. The sputum rarely contains organisms. The bone marrow is usually involved, causing anemia, thrombocytopenia, and leukocytosis. Without appropriate treatment, the prognosis is poor.

GENITOURINARY TUBERCULOSIS The kidney and genitourinary tract are common extrapulmonary sites for TB. The organism spreads to the kidney through the blood, initiating an inflammatory process similar to that which occurs in the lungs. Reactivation can occur years after the original infection. As the lesion then enlarges and caseates, a large portion of the renal parenchyma is destroyed. The infection then can spread to the rest of the urinary tract, including the ureters and bladder. Scarring and strictures commonly result. In men, the prostate, seminal vesicles, and epididymis may be involved. In women, TB may affect the fallopian tubes and ovaries.

Manifestations of genitourinary tuberculosis develop insidiously. Symptoms of a urinary tract infection, including malaise, dysuria, hematuria, and pyuria, develop. Flank pain may be present. Men may develop manifestations of epididymitis or prostatitis: perineal, sacral, or scrotal pain and tenderness; difficulty voiding; and fever. Women may have manifestations of pelvic inflammatory disease, impaired fertility, or ectopic pregnancy.

MANIFESTATIONS OF PULMONARY TUBERCULOSIS

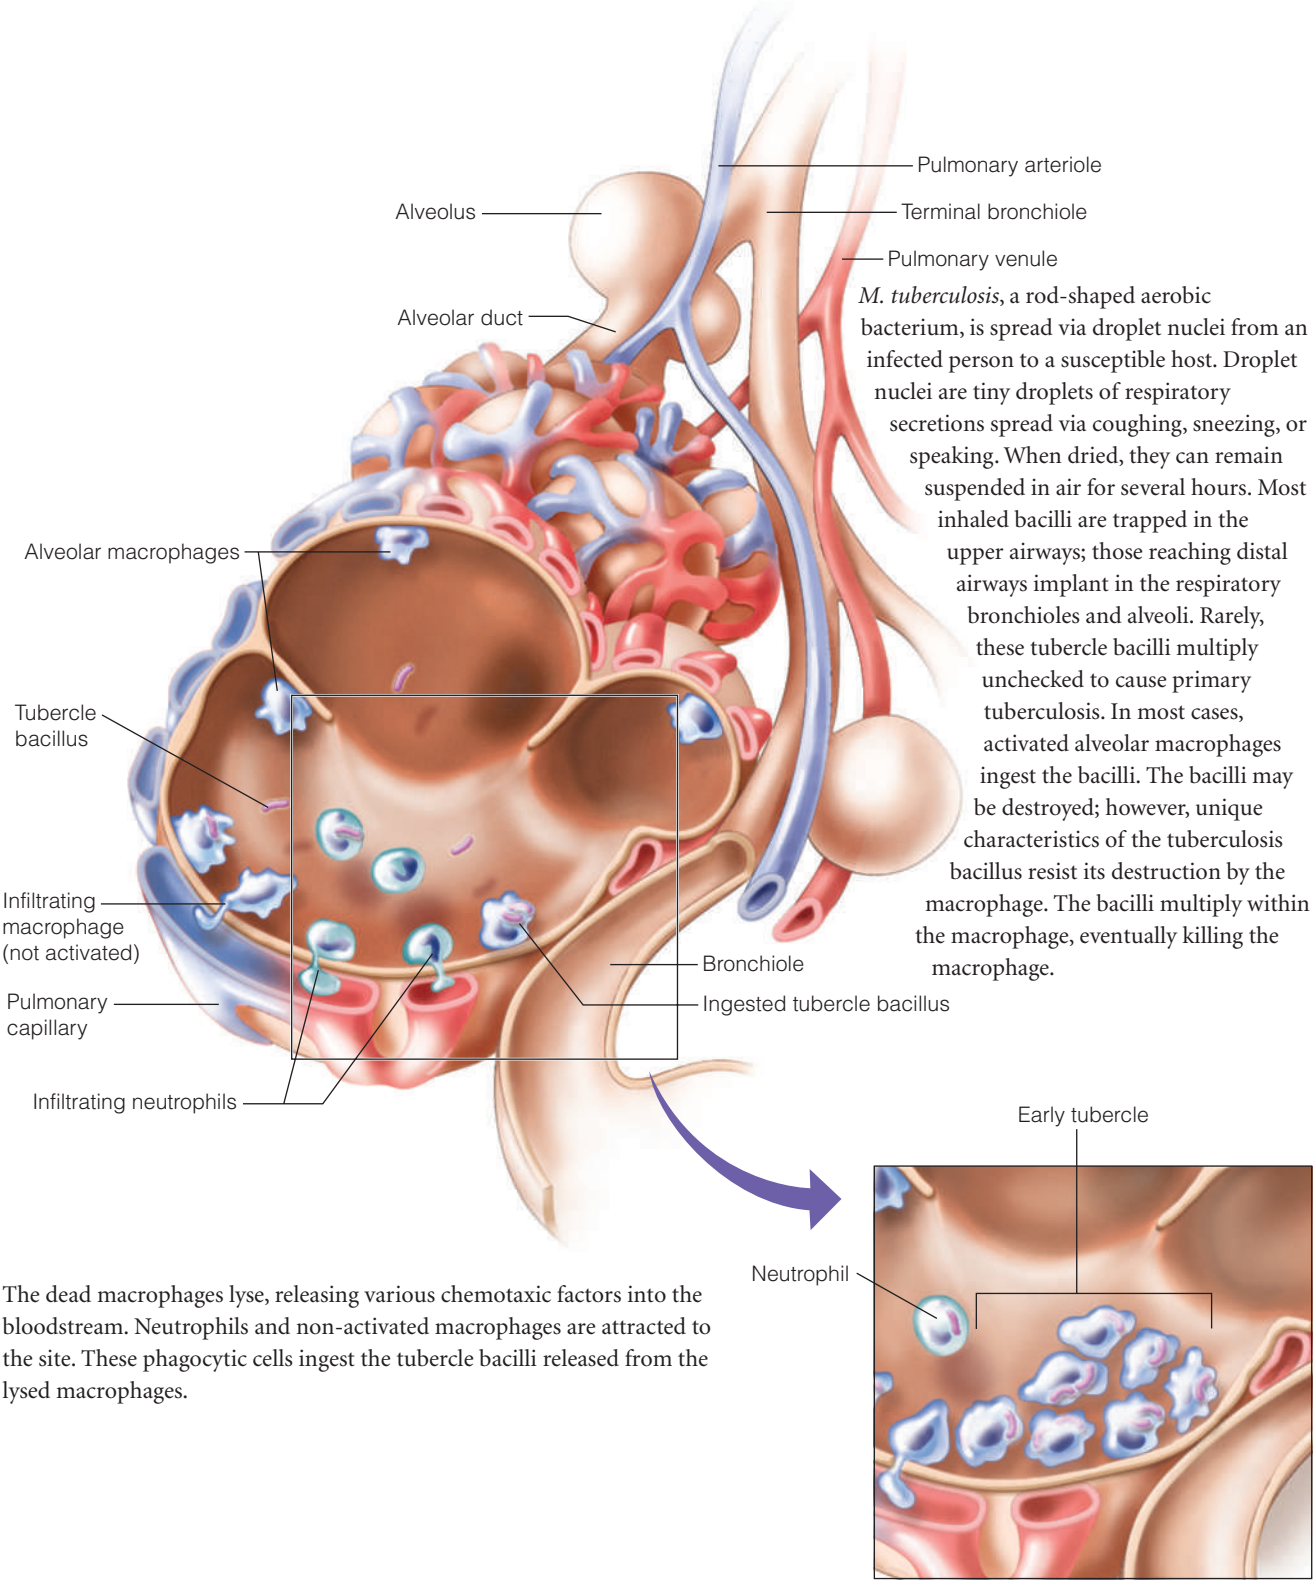
- Fatigue
- Weight loss
- Anorexia
- Low-grade afternoon fever and night sweats
- Cough: initially dry, later productive of purulent and/or blood-tinged sputum

TUBERCULOSIS MENINGITIS Tuberculosis meningitis results when TB spreads to the subarachnoid space. In the United States, this complication most often affects older adults, usually from reactivation of latent disease. Manifestations develop gradually, with listlessness, irritability, anorexia, and fever. Headache and behavior changes are common early symptoms in the older adult. As the disease progresses the headache increases in intensity, vomiting develops, and the level of consciousness decreases. Convulsions and coma may follow. Without appropriate treatment, neurologic effects may become permanent.

SKELETAL TUBERCULOSIS TB of the bones and joints is most likely to occur during childhood, when bone epiphyses are open and their blood supply is rich. The organisms spread via the blood to vertebrae, the ends of long bones, and joints. Immune and inflammatory processes isolate the bacilli, and the disease often becomes evident years or decades later.

Tuberculous spondylitis usually involves the thoracic vertebrae, eroding vertebral bodies and causing them to collapse. Significant kyphosis develops, and the spinal cord may be compressed. The large, weight-bearing joints (hips and knees) are most often affected by tuberculous arthritis, although other joints may be affected, particularly if they have been previously damaged. The involved joint is painful, warm, and tender.

INCIDENCE AND PREVALENCE

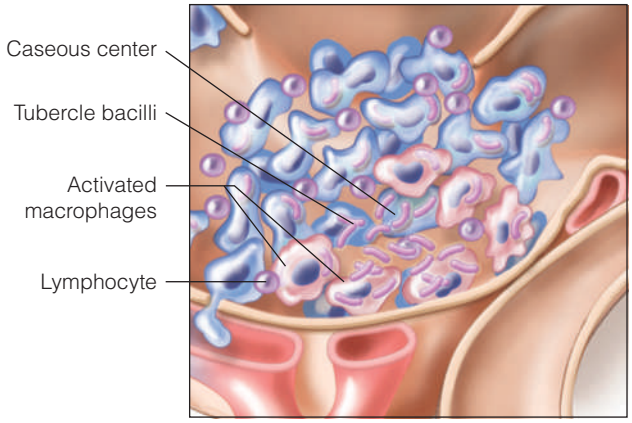


The incidence of TB fell steadily until the mid-1980s, thanks to improved sanitation, surveillance, and treatment of people with active disease. The late 1980s and early 1990s saw a resurgence of the disease, attributed primarily to the HIV/AIDS epidemic, the emergence of multiple-drug-resistant (MDR) strains of TB, and social factors such as immigration, poverty, homelessness, and drug abuse. Today, the TB rates have been dropping since 1993. In 2011 the CDC reported a 3.1% decrease from 2009 (CDC, 2011b). This decline can be attributed to TB-control programs that emphasize promptly identifying new cases and initiating and completing appropriate therapy.

Worldwide, TB continues to be a significant health problem, with an estimated 2 billion people (one-third of the world's population) infected by *M. tuberculosis*. An estimated 8.8 million cases of TB develop annually, with the majority (81%) occurring in the developing countries of Asia, Africa, the Middle East, and Latin America. TB accounts for an estimated 1.45 million deaths each year (CDC, 2012b).

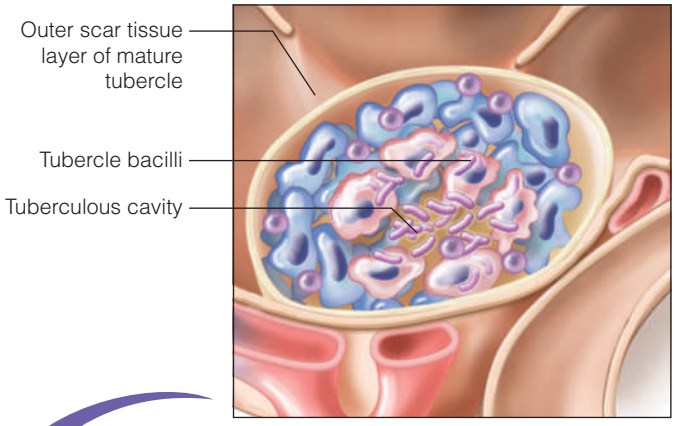
Today, TB in the United States primarily affects immigrants, those infected with HIV, and disadvantaged populations. See the Focus on Cultural Diversity box regarding the primary populations affected by TB. Poor urban areas are hit the hardest—areas that are also affected by the epidemics of injection drug use, homelessness, malnutrition, and poor living conditions. Overcrowded institutions also contribute to the spread of TB; transmission in hospitals,

PATHOPHYSIOLOGY ILLUSTRATED

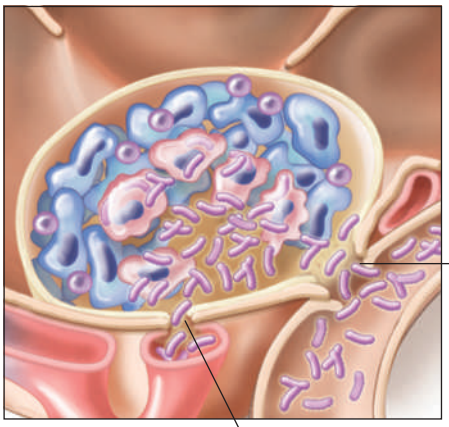


The Pathogenesis of Tuberculosis

M. tuberculosis, a rod-shaped aerobic bacterium, is spread via droplet nuclei from an infected person to a susceptible host. Droplet nuclei are tiny droplets of respiratory secretions spread via coughing, sneezing, or speaking. When dried, they can remain suspended in air for several hours. Most inhaled bacilli are trapped in the upper airways; those reaching distal airways implant in the respiratory bronchioles and alveoli. Rarely, these tubercle bacilli multiply unchecked to cause primary tuberculosis. In most cases, activated alveolar macrophages ingest the bacilli. The bacilli may be destroyed; however, unique characteristics of the tuberculosis bacillus resist its destruction by the macrophage. The bacilli multiply within the macrophage, eventually killing the macrophage.



The dead macrophages lyse, releasing various chemotaxic factors into the bloodstream. Neutrophils and non-activated macrophages are attracted to the site. These phagocytic cells ingest the tubercle bacilli released from the lysed macrophages.



PATHOPHYSIOLOGY ILLUSTRATED (*continued*)

After several weeks, a delayed hypersensitivity response to bacterial antigens destroys many of the macrophages. Concurrently, a cell-mediated immune response activates additional macrophages, which ingest and destroy the bacilli. The lysed macrophages and bacilli are surrounded by a mass of live, activated macrophages and lymphocytes. Scar (granulomatous) tissue forms, encapsulating the primary lesion. Most lesions calcify and are visible on x-ray. These lesions may remain dormant for a year or more (in some cases, many years) before being reactivated to produce secondary or reactivation tuberculosis.

When the immune and macrophage-activating responses are weakened by age or disease (e.g., HIV disease), the tuberculosis bacilli continue to multiply within the lesion. The caseous material at the center of the lesion liquefies, and the lesion grows.

The enlarging lesion damages surrounding bronchial walls and blood vessels. Granulomatous tissue surrounding the lesion can erode into a bronchus, forming an air-filling cavity. Within this cavity, the bacilli multiply, spreading into the airways and the environment via infected sputum. Bacilli multiply, spreading into the airways and the environment via infected sputum. Bacilli also spread via the blood and within macrophages to regional lymph nodes, and from there to many organs and tissues. Resulting extrapulmonary lesions evolve in the same sequence as pulmonary lesions.

homeless shelters, drug treatment centers, prisons, and residential facilities has been documented. People with altered immune function, including older adults (see the box on page 1134) and people with AIDS are at particular risk for TB. Some strains of *M. tuberculosis* have become resistant to the first-line drugs used to treat the disease (isoniazid and rifampin), with the highest number of MDR TB cases at 13.3% between 2004 and 2005, but dropping to 1.2% of all reported cases in 2010 (CDC, 2011b). In 2006, the WHO added the category of extensively drug resistant TB (XDR TB) to describe the rare TB case that is resistant to the first-line TB drugs, as well as at least one of the second-line TB drugs (kanamycin, capreomycin, or amikacin) and at least one drug in the quinolone antibiotic subclass (WHO, 2012c). Only one case of XDR TB was reported in the United States in 2010 (CDC, 2011b).

FAST FACTS

- Worldwide, approximately 44% of identified *M. tuberculosis* strains are MDR, demonstrating resistance to at least isoniazid and rifampin.
- Of MDR TB strains identified worldwide, 9.4% are XDR. XDR TB is resistant to isoniazid and rifampin, as well as at least three of the six main classes of second-line TB drugs (WHO, 2012b).
- The prevalence of MDR and XDR TB in the United States is lower among U.S.-born individuals, at about 1% of cases. However, reported MDR TB occurring in foreign-born persons increased from 25.3% in 1993 to 82% in 2010 (CDC, 2011a; WHO, 2012c).

RISK FACTORS

The risk for infection by *M. tuberculosis* is affected by characteristics of the infectious person, the extent of air contamination, duration of exposure, and susceptibility of the host. The number of microbes in the sputum, frequency and force of coughing, and behaviors such as covering the mouth when coughing affect the production of droplet nuclei. In a small, closed, or poorly ventilated space, droplet nuclei become more concentrated, increasing the risk of exposure. Prolonged contact, such as living in the same household, increases the risk. Less-than-optimal immune function, a problem for people in lower socioeconomic groups, injection drug users, the homeless, people with alcoholism, and people with HIV infection, increases the susceptibility of the host. See the accompanying box on page 1134.

●○● INTERPROFESSIONAL CARE

TB was a major public health concern earlier in this century, before the development of effective sanitation measures and drug treatment. Developing drug-resistant strains, susceptibility of people with HIV disease, and inadequate access to healthcare for high-risk populations contribute to the continuing significance of TB as a significant public health threat. Interprofessional care, therefore, focuses on the following:

- Early detection
- Accurate diagnosis
- Effective disease treatment
- Preventing TB spread to others.

Hospitalization is rarely required to treat TB. With appropriate treatment, patients become noninfective to others fairly rapidly. However, a patient with active TB may be admitted for a concurrent problem or a complication of the disease. Nurses and other healthcare workers are at risk for exposure if the disease has not yet been diagnosed. When a patient with TB is institutionalized, maintain respiratory isolation to minimize the risk of infection to other patients and to healthcare workers.

Noncompliance with prescribed treatment is a major problem in treating active TB: The patient can continue transmitting the disease to others, and drug-resistant strains of bacteria can develop when treatment is incomplete. TB must be reported to local and state public health departments; contacts are identified and examined. People who share living or work environments with the patient are tested and receive prophylactic treatment. Continuing contact with patients who have active TB is vital to ensure effective cure.

FOCUS ON CULTURAL DIVERSITY

Tuberculosis

- The TB case rate for foreign-born U.S. residents is nine times higher than that for people born in the United States (CDC, 2011b).
- Asians and Pacific Islanders living in the United States have the highest case rates, nearly 20 times higher than that for Whites.

SCREENING

The tuberculin test is used to screen for TB infection. A cellular, or delayed hypersensitivity, response to *M. tuberculosis* develops within 3 to 10 weeks after the infection. Injecting a small amount of *purified protein derivative (PPD)* of tuberculin any time thereafter activates this response, attracting macrophages to the area and causing a pronounced local inflammatory response. The amount of induration surrounding the injection site is used to determine infection (see Table 36–5 and Figure 36–6 ■). It is important to remember that

TABLE 36–5 Interpreting Tuberculin Test Results

Area of Induration	Significance
< 5 mm	Negative response; does not rule out infection.
5–9 mm	Positive for people who: • Are in close contact with a patient with infective TB. • Have an abnormal chest x-ray. • Have HIV infection or are immunocompromised. • Have an organ transplant. Negative for all others.
10–15 mm	Positive for people who have other risk factors: • Birth in a high-incidence country • African American, Hispanic, Asian American in poverty areas • Injection drug use • Residence in a long-term care facility, correctional institution, residential care setting, homeless shelter • Medical risk factors (e.g., malnutrition, diabetes, others).
> 15 mm	Positive for all people

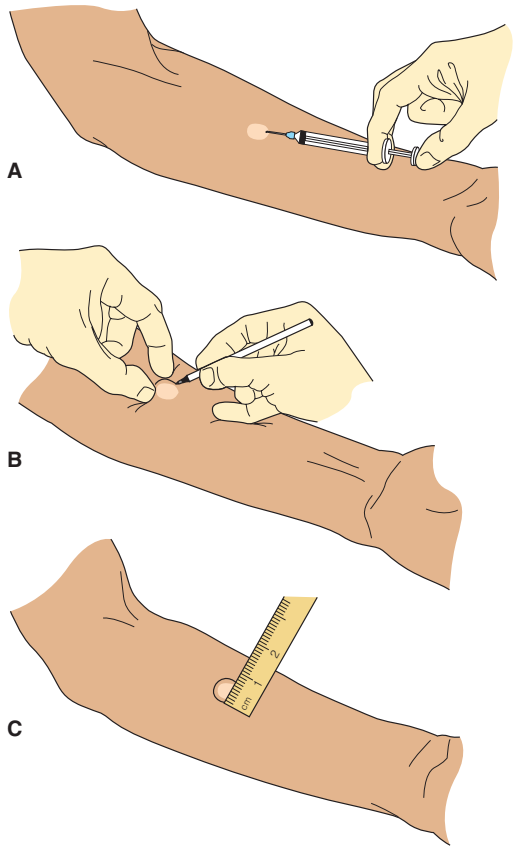


Figure 36–6 ■ A, Intradermal injection for tuberculin testing. B, The injection causes a local inflammatory response (wheal). C, Measurement of induration following tuberculin testing.

a positive response indicates that infection and a cellular (T-cell) response have developed; however, it does not mean that active disease is present or that the patient is infectious to others.

Several methods are currently available for tuberculin testing:

- *Intradermal PPD (Mantoux) test:* 0.1 mL of PPD (5 tuberculin units, or TU) is injected intradermally into the dorsal aspect of the forearm. This test is read within 48 to 72 hours, the peak reaction period, and recorded as the diameter of induration (raised area, not erythema) in millimeters.
- *Multiple-puncture (tine) test:* A multiple-puncture device is used to introduce tuberculin into the skin. This test is less accurate than other testing methods. A vesicular reaction is considered positive; any other reaction must be confirmed using a Mantoux test.

Although it is impractical and unnecessary to screen the entire population, the CDC recommends screening people in the following risk groups:

- People with or at high risk for HIV infection
- Close contacts of people who have or are suspected of having infectious TB
- People with medical risk factors, such as silicosis, chronic malabsorption, end-stage renal failure, diabetes mellitus, immunosuppression, and hematologic and other malignancies
- People born in countries with a high prevalence of TB
- Medically underserved, low-income populations, including racial and ethnic minorities
- People with alcoholism and those who inject drugs
- Residents and staff of long-term residential facilities, such as long-term care facilities, correctional institutions, and mental health facilities.

False-negative responses are common in people who are immunosuppressed. A two-step procedure may be necessary to elicit a positive response. If the first test elicits a negative response, a second PPD test is given 1 week later. If the second test also is negative, the patient either is free of infection or is *anergic* (unable to react to common antigens). This two-step procedure is recommended for long-term care residents and workers.

DIAGNOSIS

A positive tuberculin test alone does not indicate active disease. Sputum tests for the bacillus and chest x-rays are routinely used to diagnose and evaluate active disease. A series of three consecutive early-morning sputum specimens is typically examined for bacilli. Use special procedures or personal protective devices when obtaining sputum specimens. If possible, collect specimens in a room equipped with airflow control devices, ultraviolet light, or both. Alternatively, have the patient step outside to collect the specimen. Wear a mask capable of filtering droplet nuclei when collecting sputum specimens. Aerosol therapy, percussion, and postural drainage may help the patient produce sputum. Occasionally, tracheal suctioning, bronchoscopy, or gastric lavage may be necessary to obtain a specimen. See the Diagnostic Tests table in Chapter 34 for nursing care related to bronchoscopy.

- *Sputum smear* is microscopically examined for *acid-fast bacilli*. *M. tuberculosis* resists decolorizing chemicals after staining. This property is called *acid fast*. The acid-fast smear provides a rapid indicator of the tubercle bacillus.
- *Sputum culture* positive for *M. tuberculosis* provides the definitive diagnosis. However, *M. tuberculosis* is slow growing, requiring 4 to 8 weeks before it can be detected using traditional culture techniques. Automated radiometric culture systems (such as Bactec) allow detection of *M. tuberculosis* in several days.
- Once the organism is detected, *sensitivity testing* is performed to identify appropriate drug therapy.
- *Polymerase chain reaction (PCR)* permits rapid detection of DNA from *M. tuberculosis*.
- *Chest x-ray* is ordered to diagnose and evaluate TB. Typical findings in pulmonary TB include dense lesions in the apical and posterior segments of the upper lobe and possible cavity formation.

Prior to initiating antituberculosis drug therapy, several additional diagnostic tests should be done to establish baseline data for monitoring potential adverse effects of the drugs:

- *Liver function tests* are obtained prior to treatment with INH as this drug is hepatotoxic.
- A thorough *vision examination* is done prior to treatment with ethambutol, a commonly used antituberculosis medication. Optic neuritis is a potential adverse effect of this drug. Periodic eye examinations are scheduled during the course of therapy.
- *Audiometric testing* is performed before streptomycin therapy is initiated. Ototoxicity is a significant adverse effect of streptomycin and other aminoglycoside antibiotics. Hearing also is evaluated periodically during the course of therapy to detect any hearing loss.

NURSING CARE OF THE OLDER ADULT

Tuberculosis

The prevalence of active TB is significantly higher among older Caucasian adults in the United States than it is in young adults (CDC, 2011b). Of cases among older adults, approximately 90% occur due to reactivation of the dormant bacteria. Older adults are at increased risk for reactivation TB due to age-related decreases in cell-mediated immunity. Chronic illnesses, poor nutrition, gastrectomy, alcoholism, or the long-term use of steroids and immunosuppressive agents may also reactivate dormant TB lesions.

Presenting symptoms of TB in the older adult are often vague, including coughing, weight loss, anorexia, or periodic fevers. These signs and symptoms should not be dismissed as a normal part of aging.

Residents of nursing homes are at increased risk for acquiring TB because of group living. Yearly tuberculin skin testing with purified protein derivative (PPD) is often required by state health departments. If the initial test is negative, a repeat PPD in 1 to 2 weeks is recommended. This improves sensitivity to the test so that silent cases of TB are not missed. A chest x-ray and sputum culture for acid-fast bacilli are obtained if the PPD is positive.

Successful treatment for TB includes taking at least two drugs for at least 6 to 9 months to totally eradicate the organism. Older adults usually do not develop drug-resistant forms of TB because they acquired the disease prior to emergence of drug-resistant strains.

ASSESSING FOR HOME CARE

Community-dwelling older adults are susceptible to TB as well as those in care facilities. The older adult with respiratory symptoms often is treated presumptively for pneumonia, without a sputum smear and Gram stain. Older adults living in the community may not have had a tuberculin test or chest x-ray for many years.

Assess risk factors for TB:

- General health and nutritional status, including intake of specific nutrients such as vitamin D (lack of vitamin D is associated with a higher risk of developing active TB)
- Presence of a chronic disease such as silicosis, diabetes, alcoholism, or HIV infection; past history of a gastrectomy
- Past history of a positive tuberculin test that now has converted to negative
- Medications such as corticosteroids or other immunosuppressive drugs.

Assess living and social situation:

- Natural light and ventilation in the home
- Access to clean water, cooking facilities, grocery stores, and other services
- Possible exposure to infected people, for example, sharing a household with someone with active TB, crowded living facilities, homelessness, frequent participation in senior activities, volunteer work in residential care facilities or other institutional settings
- Access to healthcare.

TB is typically treated in the community; hospitalization or institutionalization rarely is necessary or desirable. For the older adult being treated for active TB in the community, assess the following:

- Knowledge and understanding of the disease and the prescribed treatment regimen
- Mental status and ability to follow prescribed regimen and precautions to avoid exposing others to the disease
- Transportation and ability to access healthcare services on a regular basis
- Financial resources to complete treatment and follow-up care
- Need for home health or social services to ensure adequate treatment.

TEACHING FOR HOME CARE

Teaching focuses on improving the older adult's ability to self-manage the disease and treatment. Teach about TB and how it is spread. Emphasize the importance of taking all medications as prescribed and complying with follow-up appointments and testing. Discuss the importance of the following:

- Using disposable tissues to contain respiratory secretions, especially during the first 2 weeks of treatment when the disease may be transmitted to others
- Avoiding exposure to crowds or people with infectious diseases
- Eating a well-balanced diet with adequate nutrients
- Getting adequate rest, sleep, and exercise to maintain good general health
- Ensuring that housemates or others having frequent contact with the patient are tested and receive prophylactic treatment if indicated.

Teach about possible side effects of the prescribed medications and the importance of reporting these to healthcare providers:

- Peripheral neuropathy (numbness, tingling, or a burning sensation of the extremities) may occur with isoniazid (INH). Pyridoxine (vitamin B_6) often is prescribed to prevent this adverse effect.
- Both INH and rifampin may cause hepatitis. Avoid alcohol while taking these drugs, and report any manifestations such as nausea and anorexia, jaundice, a change in urine or stool color, or pain in the upper right quadrant.
- Rifampin may cause an orange-red coloration of saliva and urine.
- Streptomycin can affect hearing and balance; promptly report any changes, as they may be irreversible.
- Ethambutol may affect red-green color discrimination and visual acuity. Use caution when driving or walking in unfamiliar areas and promptly report any vision changes.

MEDICATIONS

Chemotherapeutic medications are used both to prevent and treat TB infection. Goals of the pharmacologic treatment of TB are to do the following:

- Make the disease noncommunicable to others.
- Reduce symptoms of the disease.
- Effect a cure in the shortest possible time.

Prophylactic treatment is used to prevent active TB. Patients with a recent skin test conversion from negative to positive are often started on prophylactic therapy, especially when other risk factors are present. Prophylactic therapy also is used for people in close household contact with an individual whose sputum is positive for bacilli. Single-drug therapy is effective for prophylactic treatment, whereas treatment of active disease always involves two or more chemotherapeutic medications. For adults, INH, 300 mg per day for a period of 6 to 12 months, is commonly used to prevent active TB.

When INH prophylaxis is contraindicated, bacillus Calmette-Guérin (BCG) vaccine may be prescribed. This vaccine is widely used in developing countries. BCG is made from an attenuated strain of *M. bovis*, a closely related bacillus that causes TB in cattle. In the United States, BCG vaccine is recommended only for infants, children, and healthcare workers with a negative tuberculin test who are repeatedly exposed to untreated or ineffectively treated people with

active disease. After vaccination with BCG, a positive reaction to tuberculin testing is common. Periodic chest x-rays may be required for screening purposes.
