Perioperative Considerations in Liver Disease

Anatomy

THE LIVER AND BILIARY TREE are derived from the endoderm of the dorsal foregut during the late third to the early fourth week of gestation. By the sixth week, the fetal liver primarily serves as a hematopoietic organ, while critical biologic functions such as glycolysis, bile acid synthesis, and metabolic waste processing are managed by the maternal liver through fetoplacental circulation. Oxygenated blood is shunted from the placenta to the right atrium through the ductus venosus. Functional closure of the ductus begins immediately after birth, with complete functional closure occurring in up to 95% of infants by 2 weeks of age. Anatomic closure takes place shortly thereafter.

The functional development of the liver is reflected in the complex changes that are seen regarding hepatic enzyme efficiency and metabolic performance that occur throughout gestation. In the early gestation period, the liver is the primary site of hematopoiesis. Hepatic hematopoiesis develops in utero at 5 to 6 weeks gestation, followed closely by protein synthesis.[1] The ability to metabolize carbohydrates and lipids begins by 10 weeks gestation, followed by the development of drug-metabolizing systems. Several patterns of hepatic enzyme development have been described that correlate with the needs of the developing fetus.[2]

At the time of delivery, the liver weighs between 120 and 160 g but remains structurally and physiologically immature. Peripheral branches of the intrahepatic biliary system require an additional 4 to 8 weeks before they can be identified histologically. The liver is composed of eight structurally independent segments, each with a feeding hepatic artery, portal vein, draining hepatic vein, and bile duct. Segment 1 is the caudate lobe. Segments 2 and 3 form the left lateral segment, and with segment 4, the left lobe of the liver is defined. Segments 5, 6, 7, and 8 constitute the right lobe of the liver.

The liver receives blood from two sources: the portal vein that drains the spleen and intestine, and the hepatic artery that provides systemic oxygenated blood directly to biliary epithelium and to the hepatic sinusoids. The portal vein accounts for approximately 70% of the blood flow to the liver. In the hepatic sinusoids, the hepatic arterial and portal venous blood mix and intercalate among hepatocytes, fenestrated sinusoidal cells, and a host of resident immune cells (e.g., Kupffer cells). Sinusoids drain into terminal hepatic venules, which eventually coalesce to form the left and right hepatic veins. The veins merge into the inferior vena cava immediately before entering the right atrium. At any given time, the liver contains approximately 13% of the circulating blood volume.

During the neonatal period, liver function is immature and its ability to metabolize and clear most xenobiotics is poor. Factors believed to affect the clearance of medications include hepatic blood flow and the developmental status of hepatic transport and enzyme systems. Size alone does not account for this observed degree of immaturity, because the fetal and neonatal liver account for a greater percentage of body weight than the adult counterpart (3.6% of body weight vs. 2.4% in adults).[3] The neonatal liver contains approximately 20% fewer hepatocytes than the adult liver, and the cells are almost one-half the size of adult hepatocytes. These structural features may play some role in the functional deficiencies exhibited by infant livers. Cellular growth and hypertrophy of the liver continue at a rapid pace into young adulthood.

The structural unit of the liver parenchyma is the lobule, a hub-and-spoke structure with the central vein serving as the hub that is bordered by portal tracts, which contain a bile duct and tributaries of the portal vein and hepatic artery. While the mixed venous and arterial blood flows from the portal triad to the central vein, bile flows in the opposite direction through a canalicular matrix that then enters the bile ductule in the portal tract. The functional unit of the liver is the hepatic acinus, which is centered on the portal track and extends in three concentric zones (i.e., zones of Rappaport) outward to the central vein (Fig. 30.1). The more central zones (zones 1 and 2) are most active in oxidative processes, whereas the distal zone 3, which is closer to the central vein, depends on glycolysis and is more susceptible to ischemic and toxic injury.

Principles of Hepatic Drug Metabolism

Lipid solubility, an important and desired feature of many anesthesia drugs, allows passive diffusion across cellular membranes. Lipophilic drugs are also difficult to excrete. They have a propensity to

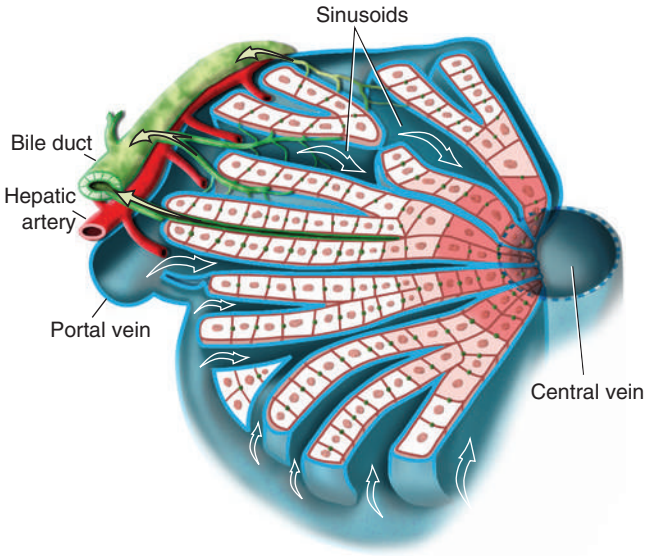

FIGURE 30.1 Blood flows from the hepatic arteries and portal vein along sinusoids toward the central vein. The hepatic triad consists of the bile duct, a branch of the portal vein, and the hepatic artery, with zone 1 *(white)* surrounding the triad, followed by zone 2 *(pink)* and zone 3 *(red)*. Cytochrome P-450 expression is higher in zone 3 with more extensive drug metabolism. (From Oinonen T, Lindros KO: Zonation of hepatic cytochrome P-450 expression and regulation. *Biochem J.* 1998; 329:17–35.)

TABLE 30.1 Major Human Liver Cytochrome P-450s

P-450	Substrate	Inhibitors	Inducers
CYP1A2	Caffeine Clozapine Estradiol Theophylline	Fluvoxamine Furafylline	Omeprazole Tobacco smoke
CYP2A6	Halothane Nicotine	Methoxsalen	
CYP2C8	Rosiglitazone Taxol		Phenytoin Rifampin
CYP2C9	Diclofenac Ibuprofen Tolbutamide Warfarin	Sulfaphenazole	Rifampin Secobarbital
CYP2C19	Omeprazole	Fluvoxamine Ketoconazole	
CYP2D6	Codeine Chlorpromazine Desipramine Dextromethorphan Encainide Haloperidol Metoprolol	Fluoxetine Quinidine	
CYP2E1	Acetaminophen Halothane	Disulfiram	Ethanol Isoniazid
CYP3A4	Cyclosporin A Estradiol Indinavir Lovastatin Midazolam Nifedipine Quinidine Docetaxel	Delavirdine Erythromycin Grapefruit juice Ketoconazole Ritonavir Troleandomycin	Carbamazepine Phenobarbital Phenytoin Rifampin St. John's wort Troglitazone

accumulate in the body's fat stores and then slowly recirculate from deep compartments back into plasma. Renal and biliary excretion of lipid-soluble compounds can result in their resorption across their respective membranes. A major role of the liver is to transform lipid-soluble drugs into water-soluble compounds that become easily excreted metabolites. An interesting example of the need for this biotransformation is the anesthetic compound thiopental, which if not transformed into its less lipophilic counterpart, would have a plasma half-life of approximately 25 years.[1]

The primary family of liver enzymes assigned the task of metabolizing these exogenous substances is the cytochrome P-450 (CYP) family. *P* designates a red *pigment*, which is related to a heme molecule and absorbs light at a wavelength of 450 nm.[4] The primary reactions involved in the drug biotransformation and metabolism are hydroxylation and conjugation. Hydroxylation prepares the metabolite for conjugation (i.e., phase II reaction). The CYP family of enzymes is responsible for most phase I reactions, and the members were first thought to be chemically similar to mitochondrial cytochromes (see Chapter 7).

PHASE I REACTIONS

The CYP enzymes likely evolved as a mechanism by which the host was able to protect itself from toxins ingested from the environment. Most enzymes involved in hepatic drug metabolism are categorized in three distinct families: CYP1, CYP2, and CYP3. Each family is further divided into subfamilies that are designated with capital letters and numbered in the order in which they were discovered. The CYP enzymes are generally conserved across species, but their regulation and catalytic activity vary among species, which highlights the challenges associated with laboratory analysis of drug metabolism.[4]

Genetic and nongenetic factors contribute to the variability in the enzymatic activity seen across all CYP enzymes.[5] Genetic factors that have been shown to impact CYP variability include specific polymorphisms, gene expression regulation, and sex.[6] For example, approximately 5% of Caucasian populations lack CYP2D6 activity, which is associated with altered metabolism of some drugs.[7] A lack of CYP2D6 activity enhances the effect of drugs such as haloperidol and metoprolol that require the enzyme for efficient metabolism, whereas codeine, which is metabolized to morphine by CYP2D6, provides little analgesia in a child with CYP2D6 deficiency.[8] Furthermore, ethnicity is emerging as an important factor contributing to CYP pharmacokinetics and significant differences are now being appreciated between cohorts with differing racial makeup[9,10] (see Chapter 6).

Nongenetic factors that influence CYP activity include concomitant disease states, malnutrition,[11] and exposure to a host of pharmacologic and naturally occurring compounds. Many drugs can inhibit or stimulate the enzyme system (Table 30.1[12]). Inhibition of the CYPs occurs when drugs compete for the same enzyme. The degree to which this competition becomes clinically important depends on five factors: the relative amount of the specific CYP, the concentrations of each drug, the degree of pharmacologically active metabolite generated through this system, the importance of the enzyme in elimination of the drugs, and the therapeutic index of the drug.[4]

Enhanced CYP expression occurs after amplified transcription of the specific gene that is induced by a variety of compounds. For example, rifampin and phenytoin induce CYP3A4 by binding the cytosolic human pregnenolone-X-receptor (hPXR) or the steroid and xenobiotic receptor (SXR).[13] The activated receptor translocates into the nucleus, where it binds the regulator elements of the CYP3A4 gene and promotes increased transcription of CYP3A4, which can lead to toxic concentrations of intermediate compounds, as is the case with erythromycin, or to subtherapeutic concentrations of cyclosporine in transplant recipients.[14]

CYTOCHROME P-450 ACTIVITY

The superfamily of CYP enzymes is divided into subfamilies based on sequence homology and on demonstration of broad substrate specificities. An important example is the CYP3A subfamily, which is the most abundant group of cytochromes involved in the metabolism of xenobiotics. The three identified isoforms are CYP3A4, CYP3A5, and CYP3A7. CYP3A4 is the most abundant single enzyme in the human liver, accounting for the metabolism of approximately 50% of clinically used pharmaceuticals.[15] CYP3A5 is more commonly found in the kidneys and lungs and to a lesser degree in the liver. CYP3A7 is the predominant isoform in the neonatal liver but is replaced after birth by CYP3A4. Given its critical involvement in hepatic biotransformation of xenobiotics, the CYP3A4 family of enzymes is used to study estimated hepatic drug clearance in various age and gender groups.

Changes in the distribution and activity of the CYP enzyme systems occur with hepatic growth and maturation (Fig. 30.2). The CYP3A family is homogeneously distributed across the liver parenchyma in the fetal liver and shortly after birth. However, during postnatal growth, expression of the CYP3A protein shifts toward the periportal region of the acinus (i.e., Rappaport zone 1). By adulthood, expression of CYP2A becomes increasingly limited to the zone 1 and zone 2 hepatocytes, with sparse expression occurring in zone 3.[16] Other examples of developmental changes in the CYP system include the CYP2C and CYP 3A3/4 subfamilies, which have negligible expression in the first few weeks of life.[17,18] CYP2D6 reaches adult activity levels within 1 month chronological age; variability thereafter is determined primarily by genetic polymorphisms.[19]

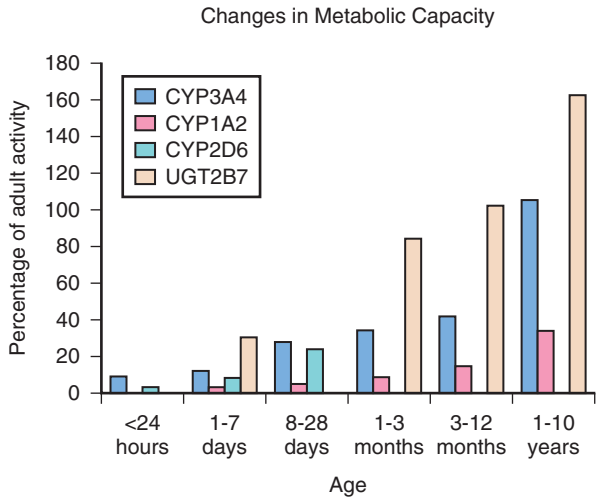

FIGURE 30.2 Changes in metabolic capacity versus percentage of adult activity. (Modified from Kearns G, Abdel-Rahman SM, Alander SW, et al. Developmental pharmacology—drug disposition, action, and therapy in infants and children. *N Engl J Med.* 2003;349:1157–1167.)

Changes in activity of CYP enzyme families and subfamilies have correlated with drug clearance. For example, midazolam clearance correlates with changes in CYP3A4 activity, with decreased clearance in fetal neonatal livers and with adult clearance rates achieved by 3 months of age.[20,21] In contrast, CYP3A7 activity peaks at about 1 week postpartum and steadily diminishes during the first year of life, reaching approximately 10% of fetal liver activity by adulthood. In all, the advancements in the understanding of CYP ontogeny have led to improved integration of physiologic, developmental, and physiochemical knowledge to design more accurate pharmacokinetic modeling systems and guide optimal dosing regimens for children.[22]

PHASE II REACTIONS

Conjugation of lipophilic compounds increases their water solubility to facilitate renal excretion.[23,24] Conjugation reactions (i.e., glucuronidation, sulfation, glutathione conjugation, acetylation, and methylation) are generally decreased in infants compared with adults.[25]

Glucuronidation is catalyzed by uridine 5′-diphosphate (UDP)–glucuronosyltransferase (UGT) family of enzymes, which are derived from assimilation of proteins from separate genes or alternate splicing from single-gene transcripts.[26] UGT enzymes are responsible for the metabolism of several drugs, including phenols, estrogens, and opioids (see Chapter 7).[27] As with the CYP enzymes, individual UGT enzymes demonstrate substrate specificity and can act in concert to metabolize single compounds. Glucuronidation is not fully active in neonates because of decreased mRNA transcript production.[28] As such, this population is at risk for toxic drug accumulation (e.g., chloramphenicol causing the grey baby syndrome).[29] Hepatic UGT enzyme concentrations are reduced during fetal and early postnatal development. At 3 months of age, the levels of many UGTs are 25% of those in adults.[30]

UGT1A enzyme activity, which is involved in the conjugation of bilirubin and ethinylestradiol, is decreased in the fetus, but it increases to adult rates within 3 to 6 months after a term delivery.[31] UGT1A6, which conjugates acetaminophen and naproxen, has 10% of adult activity in the fetus and neonate, and it achieves only 50% of adult activity by 6 months of age.[25] UGT2B7 is active in the metabolism of the nonsteroidal antiinflammatory drugs (NSAIDs) naloxone, morphine, and lorazepam. Fetal activity of this enzyme approaches 10% to 20% of adult levels, with a rapid increase to adult levels by 2 months of age.[32]

Sulfation is accomplished by sulfotransferases, a family of cytosolic enzymes that are divided into two categories: catechol and phenol sulfotransferase. These enzymes conjugate inorganic sulfate from 3′-phosphoadenosine-5′-sulfophosphate (PAPS) with compounds containing functional hydroxyl groups. The catechol transferases develop earlier in fetal life than the phenol counterparts and appear to exhibit decreased activity in the developing neonate. Although specific sulfotransferase substrates require identification, the activity of these enzymes is increased in fetuses and neonates compared with adults and theorized to be an efficient conjugation pathway in this age group. Interestingly, with the obesity epidemic, UDP-UGT and sulfotransferase expression and function are altered in patients with nonalcoholic fatty liver disease.[33]

Glutathione *S*-transferases (GSTs) conjugate glutathione with a broad spectrum of lipophilic and electrophilic compounds. The family of GSTs is composed of up to five different groups

in various classes designated μ, α, θ, σ, and π, which are derived from at least three genetic loci.[34] Tissue-specific expression of these enzymes has been demonstrated, with the liver expressing the greatest amount of protein. Variable time-dependent expression has also been shown, with α- and π-class GSTs having enhanced expression between 16 and 24 weeks gestation, whereas only the α-class enzymes predominate in the neonate and adult liver.[35] The hepatic π-class enzymes disappear from their hepatocellular location by 6 months of age and can be found only in the epithelial cells of the biliary canaliculi. Variations in the developmental expression of this class of enzymes have made it challenging to fully appreciate what is likely a multitude of clinical interactions.[35]

Acetylation reactions are catalyzed by *N*-acetyltransferases, which transfer an acetyl group from acetyl coenzyme A to a variety of substrates (e.g., *p*-aminobenzoic acid, *p*-aminosalicylic acid, procainamide). Two genes, *NAT1* and *NAT2*, are responsible for yielding two specific enzymes with different allelic forms. Despite having 87% sequence homology, these enzymes exhibit different substrate specificities.[36] Both are cytosolic enzymes involved in the biotransformation of several drugs and the bioactivation of several human carcinogens. NAT1 is present in multiple fetal and postnatal tissues and accounts for the most *N*-acetyltransferase substrate metabolism in children younger than 1 year of age. NAT2 is located primarily in the liver and becomes the dominant acetylator after 1 year of age. NAT2 has polymorphisms with enzyme kinetics that differentiate patients with slow or rapid acetylation capabilities. Infants younger than 1 year of age usually are slow acetylators; subsequent age-dependent alterations lead an individual's targeted acetylator status.[37] Individuals who are genetically destined for rapid acetylation manifest this feature by 2 to 4 years of age.

Anesthetic Agents

INHALATION ANESTHESTC METABOLISM

Inhalational anesthetics are poorly metabolized, with 15% to 20% of halothane undergoing biotransformation. Although both oxidative and reductive pathways are involved, the primary pathway of metabolism of halothane is through oxidation to a reactive intermediate, trifluoroacetyl chloride,[38] which then undergoes glutathione conjugation.[39]

Isoflurane is metabolized by CYP2E1 to a limited extent (0.2%).[40] Isoflurane is excreted as inorganic fluoride and trifluoroacetic acid after oxidative metabolism in the liver.[41] Desflurane is the least metabolized (0.02%) of the volatile anesthetics, which is approximately 10% of the rate of isoflurane.[42] Both are metabolized in the liver along similar paths because the urinary metabolite for desflurane, trifluoroacetic acid, is the same as for isoflurane.

Only 2% to 5% of inhaled sevoflurane is metabolized in humans by means of the hepatic CYP2E1 enzyme, as occurs for the other ether anesthetics.[43] Oxidation of sevoflurane generates the intermediate formyl fluoride, a highly reactive species thought to generate liver protein adducts. Carbon dioxide and inorganic fluoride are released through this oxidative mechanism, and the final product is hexafluoroisopropanol, which undergoes glucuronide conjugation and is further excreted in the urine (see Chapter 7).[44]

NEUROMUSCULAR BLOCKING DRUGS

Neuromuscular blockade is achieved by depolarizing or nondepolarizing neuromuscular blocking drugs (NMBDs) (see Chapter 7). The only depolarizing agent still in use is short-acting suxamethonium (i.e., succinylcholine).[45] Succinylcholine is hydrolyzed completely by plasma cholinesterases, which are synthesized by the liver.[46] Enzyme activity varies with age, but it is decreased in liver disease and has been used as a metric of liver prognosis.[47,48]

Nondepolarizing NMBDs are divided into aminosteroids (i.e., pipecuronium, pancuronium, vecuronium, and rocuronium) and benzylisoquinolinium diesters (i.e., doxacurium, atracurium, and cisatracurium besylate). Renal and hepatic diseases affect their safety and efficacy.[49] Hepatic elimination depends on protein binding, hepatic blood flow, and drug extraction. The volume of drug distribution is increased in hepatic disease, leading to lower concentrations. In children with cholestatic liver disease, such as biliary atresia, uptake of these compounds by the liver is decreased, which reduces plasma clearance and prolongs their effects.[50,51] Approximately 75% of the administered dose is bound to plasma proteins, with most bound to albumin. Despite these problems, children with liver disease and a correspondingly low albumin concentration are at minimal risk for the adverse effects from this group of drugs.[52]

Rocuronium is an analog of vecuronium with a more rapid onset of action. Unlike other aminosteroids, which largely undergo renal excretion, only 12% to 22% of rocuronium is cleared through the kidney.[53] In patients with hepatic disease, the volume of distribution of rocuronium increased by 33% compared with healthy controls,[54] and patients with cholestasis exhibit prolonged duration and a longer recovery index after repeated uses.[55] In patients undergoing liver transplantation, the clearance of rocuronium was only slightly reduced by the diseased native liver compared with the functioning allograft and healthy individuals.[56] Reduced infusion requirements of rocuronium during liver transplantation may indicate graft dysfunction.[57]

Hepatic elimination of the benzyl isoquinolinium agents is poorly understood, but hepatic dysfunction has been observed to affect their effectiveness. Despite increased concentrations in biliary secretions, the pharmacokinetics of doxacurium are unchanged in the presence of hepatocellular injury, but recovery indexes are prolonged.[58] Although no longer available in the United States, mivacurium is a mixture of three stereoisomers. Clearance of the *trans-trans* and *cis-trans* isomers is reduced in patients with liver disease,[59] whereas clearance of the *cis-cis* isomer is unchanged. Prolonged recovery occurs as a result of a decrease in plasma cholinesterases in significant liver disease.[59] Clearance of cisatracurium is decreased, although patients with liver disease experience no delay in recovery and minimal delay in onset of action. Children with liver disease, regardless of cause, usually tolerate this class of compounds, and there is no observed toxicity.[60]

SEDATIVES, OPIOIDS, AND LIVER DISEASE

The commonly used sedatives midazolam, propofol, and ketamine undergo hepatic metabolism through oxidation and conjugation. These compounds are all lipid soluble, and their effects are altered by liver disease.[61] Midazolam has an extraction ratio of 0.3 to 0.5 and depends on both hepatic blood flow and intrinsic clearance. Midazolam may have an increased clearance rate if hepatic blood flow is increased. In children with cirrhosis, the clearance of midazolam is halved with a corresponding doubling of the half-life compared with healthy controls.[62,63] With 95% to 97% of midazolam bound to albumin, diseases that decrease the concentration of albumin dramatically increase the free fraction of drug, which leads to a greater effect.[29,64,65] Propofol has high intrinsic clearance and blood flow changes determine clearance. Although clearance is through a combination of both UGT and CYP enzymes (CYP2B6, 2C9, 2A6), hepatocellular injury does not alter its

pharmacokinetics.[66] Ketamine is also highly lipophilic and undergoes metabolism in the liver. However, unlike the other drugs described, it does so through methylation, and its clearance is minimally affected by liver dysfunction.[67]

Clinical effects from opioids result from their binding to opioid receptors. A greater serum concentration of opioid binds a greater number of receptors, resulting in a correspondingly greater opioid effect. Hepatic clearance and protein binding govern the serum concentration of an opioid.[68] Most opioids are oxidized in the liver. However, morphine and buprenorphine undergo glucuronidation, and remifentanil is metabolized by plasma and tissue esterases, enzymes that are mature in term neonates. The ability of the diseased liver to oxidize opioids is diminished, leading to increased oral bioavailability owing to decreased first-pass metabolism and decreased drug clearance. The clearance of morphine, despite being metabolized by glucuronidation, is also negatively affected by the presence of cirrhosis.[69]

Clearance of drugs that are highly extracted by the liver, such as meperidine and morphine, depend on hepatic blood flow (i.e., perfusion limited clearance).[70,71] Clearance (CL) is a function of hepatic blood flow (Q_H) and the extraction ratio (E_H), describing the ability of the liver to efficiently remove the drug from the circulation:

$$CL_H = Q_H \times E_H$$

When E_H is greater than 0.7, as with meperidine, lidocaine, and pentazocine, CL_H approaches Q_H. Conditions that alter hepatic blood flow, such as cirrhosis, portal vein thrombosis, and portacaval shunting, significantly alter opioid clearance. Drugs with a low E_H, such as diazepam, methadone, and naproxen, do not depend on hepatic blood flow. The metabolic activity of the liver and the plasma protein-binding fraction affect the clearance to a greater degree. The hepatic clearance of these drugs is described by the following equation:

$$CL_H = CL_{INT} \times f_u$$

In the formula, f_u is the fraction of unbound drug and CL_{INT} describes the metabolic activity. When f_u is small as with methadone (<0.1), clearance is mainly affected by reduced enzyme capacity.[68]

The pharmacology of the opioids is variably affected by liver disease. The analgesic effect of codeine, obtained after its demethylation to morphine, is reduced in the presence of liver disease. Liver disease can affect glucuronidation and thereby decrease clearance and prolong the half-life of morphine.[72] The protein binding and clearance of alfentanil are reduced in the presence of hepatic dysfunction,[73,74] whereas the half-life and volume of distribution of methadone are increased.[75] The pharmacokinetics of fentanyl, remifentanil, and sufentanil are unchanged in the presence of significant hepatic dysfunction.[76–78] Because the degree of hepatic dysfunction exhibits interindividual variability, the level of adverse events of these medications also varies. Careful monitoring of children with liver disease is required when administering opioids.

Anesthetic Effects on Hepatic Cellular Functions

CARBOHYDRATES

Glucose metabolism is influenced by the availability of the substrate, the rate of entry into cells, and the ability of the target organ to convert glucose into energy or to use it to synthesize fats. In healthy individuals, hepatic glucose production accounts for most whole-body glucose production and is narrowly regulated directly and indirectly by insulin.[79] Insulin directly inhibits gluconeogenesis and glycogenolysis by binding to insulin receptors in the liver, thereby diminishing hepatic glucose production. Of the glucose available to the liver, about 50% undergoes glycolysis and is converted to energy. Between 30% and 40% is converted to fat for storage, and 10% to 20% is shunted to glycogen.[80] Anesthetics inhibit glucose uptake by hepatocytes, an action referred to as the *anti-insulin effect of anesthesia*.[81] Although all inhalational anesthetics exhibit this tendency, halothane has the greatest impact on serum glucose, with isoflurane and sevoflurane having lesser effects.[82] Inhalational anesthetics at 1 to 2 minimal alveolar concentrations (MACs) inhibit glucose uptake by up to 50%. The combined effects of anesthetics and stress from surgery or trauma increase the serum glucose concentration, which is one reason glucose-containing intravenous fluids are no longer recommended for most healthy children undergoing elective surgery.

PROTEIN SYNTHESIS

The impact of anesthesia and surgery on protein synthesis and metabolism is poorly understood. Albumin, a large, soluble, single-polypeptide protein with a molecular weight of 66 kD, is an important protein synthesized by the liver. Between 6 and 12 g of albumin are produced each day, and production can increase twofold to threefold according to the individual's needs. Albumin functions as a binding and transport protein and maintains colloid oncotic pressure. Hepatic dysfunction may result in decreased synthesis of albumin and other proteins. Anesthetics may also inhibit protein synthesis. Diethyl ether causes reversible inhibition of protein synthesis in rat hepatocytes,[83] whereas halothane and enflurane block protein synthesis in a dose-dependent manner.[84] Halothane, sevoflurane, and enflurane inhibit protein synthesis and secretion, which may be an early indicator of hepatic cytotoxic injury.

BILIRUBIN METABOLISM

Bilirubin, the end product of heme metabolism, is converted to unconjugated bilirubin by macrophages in the spleen and bone marrow and transported to the liver bound to plasma albumin. Unconjugated bilirubin is transported into the hepatocyte by bile acids and bacterial endotoxins. In the hepatocyte, bilirubin is conjugated with glucuronate, taurine, and, to a lesser extent, glucose by glucuronyl transferase. Deficiencies of glucuronyl transferase manifest clinically in Gilbert syndrome, with more severe forms in Crigler-Najjar syndrome types I and II. Gilbert syndrome affects 2% to 13% of individuals, who have increases in the unconjugated fraction of bilirubin associated with stress or fasting. Although postoperative jaundice has been described, Gilbert syndrome has not been associated with serious adverse effects in the perioperative period.[85] Patients with Crigler-Najjar syndrome can be managed safely by minimizing their exposure to drugs that may displace bilirubin from albumin and by using anesthetics that undergo minimal hepatic metabolism.[86,87]

HEPATOTOXICITY

Increases in serum aminotransferase concentrations and bilirubin up to two times the upper limit of normal occur commonly in the postoperative period.[88,89] These increases are typically self-limited and inconsequential. However, serious liver injury can be caused by anesthetics.[90,91] The Drug-Induced Liver Injury Network (DILIN), established by the National Institutes of Health in 2003, has and continues to standardize the nomenclature and causality

assessment of drug-induced liver injury (DILI).[92,93] Diagnosis of DILI is entertained when increases in alanine aminotransferase (ALT), aspartate aminotransferase (AST), alkaline phosphatase, γ-glutamyl transferase (GGT), and bilirubin occur coincident with xenobiotic exposure. Patterns of injury are classified as (1) hepatocellular, with predominantly increased ALT and AST levels; (2) cholestatic, with increases in alkaline phosphatase, GGT, and bilirubin; (3) and mixed pattern, with features of both hepatocellular and cholestatic injury. Although not specific to anesthetic medications, recent DILIN analyses conclude that mortality from DILI in individuals with preexisting liver disease or concomitant severe skin reactions is significantly greater than in patients without.[93] In April of 2012 the website LiverTox (https://livertox.nlm.nih.gov) was launched as a joint effort of the Liver Disease Research Branch of the National Institute of Diabetes and Digestive and Kidney Diseases (NIDDK) and the Division of Specialized Information Services of the National Library of Medicine (NLM), National Institutes of Health. The purpose of LiverTox is to provide up-to-date, accurate, and easily accessed information on the diagnosis, cause, frequency, patterns, and management of liver injury attributable to medications, herbals, and dietary supplements.

It is important to note that even though increases in liver-specific enzymes may reflect drug-induced injury, they are in fact poor markers of liver function. In the absence of a unique test to assess liver function, surrogate markers for liver dysfunction include a prolonged prothrombin time (PT) greater than 15 seconds or an international normalized ratio (INR) greater than 1.5, or both. Other clinical and biochemical markers, such as hypoalbuminemia, hypoglycemia, and an altered mental status, should be included in the assessment of hepatic dysfunction, but they can also result from conditions unrelated to liver function, such as malnutrition, protein-losing enteropathy or nephropathy, or medications for sedation or pain management. It is critical that in the setting of suspected drug-induced liver injury (elevated AST, ALT, bilirubin, and so on) that liver function is also determined.

An additional confounder relating to the incidence of anesthesia-induced liver injury is the increasing obesity epidemic in children. The growing disease burden associated with nonalcoholic fatty liver disease and nonalcoholic steatohepatitis have raised concerns that these children may be at increased risk for DILI.[94] Obesity and hypercholesterolemia can induce CYP2E1, which may facilitate development of liver injury.[95] Few data are available to guide the best practice of anesthesia for the obese child, and adequately powered prospective studies are needed.

Perioperative Considerations in Liver Disease

Patients with known or suspected liver disease should be assessed for hepatocellular and bile duct injury, coagulopathy, ascites, and encephalopathy. Hepatopulmonary syndrome and portopulmonary hypertension are rare but important complications in children with known chronic liver disease, and they may serve as relative or absolute contraindications to elective surgery.[96,97] Perioperative mortality is greatest among those who have acute hepatitis compared with those with chronic liver disease.[96,98,99] The physiologic stress associated with surgical procedures decreases portal blood flow. Liver disease may decrease the degree to which hepatic artery blood flow can compensate for reduced portal blood flow, which can increase the risk of developing ischemic injury.

Parenteral nutrition–associated liver disease (PNALD) occurs in children requiring parenteral nutrition for longer than 60 days. Children with short bowel syndrome are at greatest risk for PNALD. Aside from the disturbances to hepatic and portal blood flows in children with liver disease, those exposed to total parenteral nutrition (TPN) are at increased risk for perioperative glucose derangements.[100–102] Frequent perioperative glucose monitoring with adjustment of dextrose infusion appears to be the standard of care, which is associated with various rates of tapering TPN. A survey administered to members of the Study Group on Pediatric Anesthesia found that approximately 50% of respondents checked glucose levels as often as every 1 to 2 hours. They also found that 19% discontinued TPN and administered a glucose-containing solution, whereas 35% decreased the fluids to one-half of maintenance rates and 33% continued maintenance rates unchanged.[103]

Liver Transplantation

The first successful pediatric liver transplant was performed by Tom Starzl and colleagues in 1967, but the history of liver transplantation actually began in 1955 with Stuart Welch in Albany and Jack Cannon at UCLA. Welch was the first to describe auxiliary liver transplantation in the dog and Cannon was the first to attempt orthotopic liver transplantation (OLT) in dogs. Unfortunately, none of the dogs survived the operation.[1] Francis Moore and Tom Starzl continued research with the dog model. From 1958 to 1959, they each successfully transplanted the liver, but all of the dogs died within 4 to 20 days from rejection. These deaths highlighted the barriers that prevented the first OLT application in humans.

In the early stages of animal experimentation, the main barriers to success involved surgical technique, organ preservation, and immunosuppression. The livers were initially preserved with chilled electrolyte solutions such as lactated Ringer's and normal saline; preservation time was only 5 to 6 hours. In 1987, the University of Wisconsin developed a solution that increased the preservation of livers to 18 to 24 hours. The third barrier, immunosuppression, was the most significant and likely explained most of the canine deaths. Medawar[1a] reported the role of the immune system in organ rejection. Since that time several unsuccessful attempts to deliberately weaken the immune system and control rejection had failed. It was not until an animal model demonstrated that the combination of azathioprine and prednisone were synergistic and ameliorated rejection. This combination was first used in human kidney transplants and then expanded to liver transplantation.

The first human liver transplantation was performed in 1963 in a 3-year-old boy with biliary atresia. This attempt ended in failure secondary to fatal intraoperative hemorrhage from venous collaterals. Six more attempts at three different institutions (Denver, Boston, and Paris) produced the same result. Attempts to control the intraoperative hemorrhage with coagulation factor replacement and ε-aminocaproic acid resulted in clots and fatal pulmonary emboli in the veno-venous bypass system. Inadequate immunosuppression played a significant role in these fatalities as well. At that time a self-imposed moratorium was established. In 1967, antilymphocyte globulin was introduced, providing lymphoid depletion and supplemented azathioprine and prednisone to provide better immunosuppression,[2] allowing Starzl to successfully transplant a liver in a 1-year-old with hepatoblastoma who survived for 13 months.

Despite the initial success of the first pediatric liver transplant, the 1-year survival rate in subsequent transplant patients remained no greater than 50%. With the introduction of cyclosporine in 1979, the 1-year patient survival increased to 70%.[3,4] In 1989, tacrolimus replaced cyclosporine[5] and the 1-year patient survival further increased to approximately 80%.

EPIDEMIOLOGY AND DEMOGRAPHICS

There has been a steady increase in the number of liver transplants performed yearly in the United States (from 1713 per year in

1988 to 7127 per year in 2015). The vast majority of this increase is attributed to adult transplants. The total number of pediatric liver transplants in 1990 was 513; this increased to 589 in 2000 and has essentially remained unchanged over the past 15 years with 580 in 2015. The increase from 1990 to 2015 is only a 13% increase compared with the 200% increase in adults (2177 in 1990 to 6547 in 2015) (United Network for Organ Sharing [UNOS] Scientific Registry, 2016; https://www.unos.org/data/).

Indications for liver transplantation in children include the presence of an underlying primary liver pathology with acute or chronic liver failure caused by cholestatic liver disease, acute hepatic failure, metabolic disorders, cirrhosis, tumors, and other derangements (e.g., Budd-Chiari syndrome) (Table 31.1). The most common cause for liver transplantation in children is cholestatic liver disease secondary to biliary atresia.[6,7] This is especially true in patients younger than 1 year of age, in whom it accounts for ≥50% of liver transplants. Biliary atresia continues to be the most common overall cause for liver transplantation and the most common cholestatic cause, but cholestatic liver disease secondary to total parenteral nutrition (TPN) has become more prominent over the past 10 years, accounting for just over 4% of all pediatric liver transplants. After cholestatic liver disease, acute hepatic failure and metabolic disorders are the next most common causes for pediatric liver transplantation. Historically, the most common metabolic disorders in decreasing frequency were α_1-antitrypsin deficiency, tyrosinemia, Wilson disease, oxalosis, and glycogen storage diseases. The most common disorders have changed. Maple syrup urine disease (MSUD) is now the most common, with cystic fibrosis the second most common metabolic indication for pediatric liver transplantation (UNOS/Organ Procurement and Transplantation Network [OPTN]; https://www.unos.org/data/).

The cause for acute or fulminant hepatic failure is not known in most pediatric patients. A viral cause (A, B, or C) may account for almost half of the acute hepatic failures in infants and children. Acetaminophen is the most common overall cause of drug- or toxin-induced liver failure.[8]

There are few absolute contraindications to pediatric liver transplantation. Children with neoplastic processes such as hepatocellular carcinoma and infections with human immunodeficiency virus (HIV) have received transplants. However, patients with acute infections from bacterial or fungal agents, metastatic neoplasm, or disease processes that are considered an immediate threat to life (severe cardiopulmonary disease, sepsis/septic shock) generally do not undergo transplantation.

Allocation of the available livers to the appropriate recipients has been a challenge. Initially liver transplant candidates were prioritized based on geographic location and medical condition defined by the Child-Turcotte-Pugh (CTP) score. Patients were ranked as status 1, 2a, 2b, or 3. Status 1 patients received the highest priority and were defined by the presence of acute liver failure of less than 6 weeks or a failed liver transplant within 1 week. Status 2a, 2b, and 3 were defined by their CTP score and time on the wait-list.[9] Efforts by the UNOS/OPTN Liver Disease Severity Scale (LDSS) committee to identify predictors of mortality in children with chronic liver disease resulted in the implementation of the **M**odel for **E**nd-Stage **L**iver **D**isease (MELD) and the **P**ediatric **E**nd-Stage **L**iver **D**isease (PELD) severity score in 2002.[10] The PELD score incorporates variables for age, growth failure, serum albumin, bilirubin, and international normalized ratio (INR). PELD formerly applied to children younger than 18 years old; this was changed in 2005 to include children 12 years of age or younger. The MELD score is now used for children 13 years of age or older.[11] Serum creatinine was incorporated into the MELD score because it predicts mortality for adult patients awaiting liver transplantation. Although serum creatinine may predict survival after liver transplantation, it does not predict mortality in the child awaiting liver transplantation.[12]

TABLE 31.1 Primary Diagnosis of Liver Disease in Pediatric Patients: 1988–2015

Primary Diagnosis	
Total	13,340
Cholestatic	52.0%
Biliary atresia	
TPN-induced cholestasis	
Alagille syndrome	
Primary sclerosing cholangitis	
Secondary biliary cirrhosis	
Familiar cholestasis (Byler's, others)	
Biliary hypoplasia	
Primary biliary cirrhosis	
Neonatal cholestatic disease	
Other causes of cholestasis	
Acute hepatic necrosis	13.3%
Neonatal hepatitis	
Drug-induced	
Hepatitis A	
Hepatitis B	
Hepatitis C	
Unknown	
Other causes of hepatic necrosis	
Metabolic Disorder	12.9%
α_1-Antitrypsin	
Cystic fibrosis	
Wilson disease	
Tyrosinemia	
Oxalosis	
Glycogen storage disease	
Maple syrup urine disease	
Hemochromatosis	
Other metabolic disorders	
Cirrhosis	8.0%
Idiopathic	
Autoimmune	
Hepatitis C	
Chronic active hepatitis	
Hepatitis B	
Drug/toxin	
Hepatitis A	
Combined exposure (alcohol, hepatitis A, B, C)	
Alcoholic	
Other causes of cirrhosis	
Hepatic tumors	4.8%
Hepatoblastoma	
Hepatocellular carcinoma	
Hemangioendothelioma	
Benign tumor	
Other tumors	
Other	9%
Congenital hepatic fibrosis	
Budd-Chiari syndrome	
Graft versus host secondary to nonliver toxicity	
Trauma	
Other miscellaneous diagnoses	

The allocation of deceased liver donors has changed with the new MELD/PELD policy. Prior to this policy, organs from donors younger than 18 years were distributed only to pediatric recipients. With the new policy, the donor graft is first allocated to a status 1 pediatric recipient in the local region. If none is available, it is offered to the next status 1 adult in the region. If no status 1 adult is available, the liver is made available to pediatric patients with a greater than 50% risk of mortality. Adults with mortality risk greater than 50% are next, and then all pediatric patients are offered the liver over all other adult candidates. If there are no appropriate pediatric recipients in the region, the donor organ is offered to the national pool.[9] The introduction of the MELD/PELD score has decreased the wait time for transplantation. Analysis of pre- and post-MELD/PELD data indicate that the median time to transplant, defined as the number of days for half of the new registrants to receive organs, decreased from 981 days in 2002 to 361 days in 2007.[11]

Survival for deceased donor transplants is an age-dependent variable. Infants younger than 1 year had the lowest 3-month and 1-year survival at 88% and 83%, respectively, compared with older children. However, if the infant recipient survives the first year, the survival rate increases. In fact, the 5-year survival (84%) is the greatest for infants younger than 1 year. The 10-year survival is 77% for infants younger than 1 year, 79% for children 1 to 5 years of age, and 81% for children 6 to 11 years of age.[11]

There also appears to be a difference in recipient survival between living donor and deceased donor grafts. Children receiving a living donor organ had 10-year survival rates greater than 90%, whereas recipients of deceased donor organ had a 10-year survival rate less than 90%.[13] In addition to survival, other outcomes still need to be evaluated in children (e.g., growth and cognitive function).[14]

PATHOPHYSIOLOGY OF LIVER DISEASE

The liver is the only organ that can regenerate itself when damaged. The stigmata and multiorgan involvement from end-stage liver disease occurs because of loss of hepatocytes and the resulting fibrosis. The hepatic injury and loss of hepatocytes leads to decreased synthetic function. This cellular dysfunction results in coagulopathy, hypocholesterolemia, hypoalbuminemia, and encephalopathy. Attempts at regeneration result in fibrosis and destruction of the portal triad with increased resistance to blood flow through the liver. Portal hypertension is the final consequence of this increased resistance. Much of the characteristic features of liver disease occur because of portal hypertension, specifically varices (esophageal, bowel), hemorrhoids, ascites, spontaneous bacterial peritonitis, splenomegaly with thrombocytopenia, and hepatic encephalopathy.

Cardiac Considerations

Cardiac disturbances occur because of altered physiology, congenital heart defects, and toxic medication adverse effects. A hyperdynamic circulation with a compensatory increase in cardiac output (CO) secondary to vasodilation characterizes the altered cardiac physiology from liver disease. Vasodilation is central to the hyperdynamic circulation that accompanies portal hypertension. It likely is the result of the presence of vasoactive mediators. These mediators or gut-derived "humoral factors" (nitric oxide [NO], tumor necrosis factor [TNF]-α, endocannabinoids) enter the systemic circulation through portosystemic collaterals and bypass the hepatic detoxification that usually occurs.[15] Shunting also occurs in the skin and lungs. Mixed venous saturation is increased in patients with liver disease. Poor oxygen extraction and increased CO likely explain the increased mixed venous saturation. The arterial-venous oxygen difference is reduced because of decreased oxygen consumption and hypoxia from arterial-venous shunting.

Cardiomyopathy associated with portal hypertension is well described in adults but is not well characterized in children with liver disease. However, children with liver disease can have a cardiomyopathy for other reasons. Inborn errors of metabolism and other syndromes are associated with cardiomyopathies and cardiac anomalies. Some of the inborn errors include Wilson disease, oxalosis, glycogen storage disease type III, tyrosinemia, and Gaucher disease.[16] Tacrolimus and cyclosporine A have also been associated with hypertrophic cardiomyopathy in animal studies and in pediatric liver transplant recipients.[17–20] Other studies have demonstrated that the cardiac function is generally well preserved in pediatric liver transplant patients who are receiving tacrolimus, but there may be evidence of subtle cardiovascular changes that predispose a small percentage of patients to develop hypertrophic cardiomyopathy.[21,22] Alagille disease is commonly associated with congenital heart disease (CHD) such as pulmonary stenosis, coarctation, tetralogy of Fallot, and atrial and ventricular septal defects. Diastolic dysfunction has been associated with increased mortality after transplantation.[23]

QT prolongation of the electrocardiogram (ECG; see Chapter 16) has been described in adult patients with alcoholic liver disease and may be associated with sudden cardiac death.[24] A decrease in K^+ currents in cardiomyocytes in rats with cirrhosis may provide a possible mechanism for the QT prolongation. Children with liver failure have also been shown to have an increase in QTc interval. A QTc greater than 450 msec has been reported in 18% of children with liver disease.[25] These findings may increase the risk of ventricular arrhythmias; however, there are conflicting data regarding resolution after liver transplantation.[25,26] Nonselective β-blockade has also been shown to reduce the QT prolongation, but it is unclear if this reduces the risk of arrhythmias or improves survival.[27,28] Although previous data suggested prolonged QT did not predict survival,[29,30] more recently the presence of prolonged QT was associated with a greater PELD score and portal hypertension. Pediatric patients with chronic liver disease and prolonged QT may be at increased risk of mortality while waiting for a transplant.[31]

Pulmonary Considerations

Pulmonary hallmarks of liver disease are hypoxia and pulmonary hypertension. Hypoxia can occur for several reasons including hepatopulmonary syndrome (HPS) and $\dot{V}/\dot{Q}$ mismatch from atelectasis owing to ascites, hepatosplenomegaly, or pleural effusions. HPS is characterized by hypoxia from intrapulmonary arteriovenous shunting (caused by increased angiogenesis)[32] and intrapulmonary vascular dilatation.[33] The diagnosis is made by demonstrating either arterial hypoxia (Pa_{O_2} <70 mm Hg) or an increased alveolar-arterial gradient greater than 20 mm Hg in the setting of pulmonary vascular dilatation. Intrapulmonary vascular dilatation can best be demonstrated using echocardiography or a lung perfusion scan with macroaggregated albumin.[34] HPS occurs in at least 15% to 20% of adults with cirrhosis.[35] HPS has been reported in infants 6 months of age and is described in 0.5% to 20% of all children with liver disease. It appears to be more prevalent in children with biliary atresia and polysplenia syndrome.[36,37] When adjusted for the severity of hepatic disease, HPS does not affect mortality.[38] A normal pulse oximetry value in

children with cirrhosis does not necessarily rule out HPS. Children with normal pulse oximetry may exhibit other criteria for the diagnosis (intrapulmonary vasodilatation and alveolar-arterial gradient greater than 15 mm Hg) and may be at increased risk for morbidity and mortality.[39]

Treatment for hypoxia is long-term supplemental oxygen. Definitive treatment may occur with liver transplantation. One case series described seven children with HPS who had successful transplants; all seven children recovered from their HPS postoperatively. The average time required to correct hypoxia after transplantation was 24 weeks.[40]

Portopulmonary hypertension (PPH) is defined by the World Health Organization (WHO) as pulmonary artery hypertension (pressure >25 mm Hg) in the setting of normal pulmonary capillary wedge pressure and portal hypertension.[41] The incidence of PPH is 0.2% to 0.7% in adults with cirrhosis but increases to 3% to 9% in adults presenting for liver transplantation.[42] The number is not known in children and is limited to case reports and case series. Evidence from case series and autopsy data suggest that the incidence of PPH is 0.5% to 5% in children with portal hypertension.[43,44] Signs and symptoms on presentation were new heart murmurs, dyspnea, and syncope. Echocardiography can successfully identify pulmonary hypertension in children and adult patients with PPH.[45] The severity of PPH predicts mortality. Adult patients with mild PPH had no increase in mortality during liver transplantation. However, those patients who underwent OLT with moderate PPH (pulmonary artery pressure [PAP] = 35–45 mm Hg) had a 50% mortality rate and those with severe PPH (PAP >50 mm Hg) had a 100% mortality rate.[46]

There are no definitive guidelines for the management of children with PPH. Early identification is essential, and all children who present for liver transplantation should be evaluated for the presence of PPH with echocardiography.[43,47] If present, cardiac catheterization needs to be performed to confirm the diagnosis, measure PAPs, and assess the response to NO and epoprostenol. Children who respond to medical management may be candidates for liver transplantation.[48] Otherwise, severe PPH is generally a contraindication for liver transplantation because of the increased risk of mortality.

Neurologic Considerations

Hepatic encephalopathy (HE) is a neurologic complication of liver disease classified as either acute (seen in fulminant hepatic failure) or chronic (seen in chronic cirrhosis or chronic portal hypertension). Minimal encephalopathy, diagnosed with neuropsychological testing, may be present in as many as 50% of children with chronic liver disease.[49] The pathophysiology is not entirely known but cerebral edema is a feature of both acute and chronic HE. The cerebral edema is more severe in acute HE and can result in increased intracranial pressure (ICP). Ammonia is repeatedly implicated in the pathogenesis of HE and may participate in the process by causing astrocyte to swell, resulting in low-grade cerebral edema.[50,51] The two major sources of ammonia in humans are catabolism of endogenous protein and gastrointestinal absorption of exogenous protein. Bacterial breakdown of nitrogen-containing products in the gut results in ammonia formation, which is then absorbed in the portal circulation. Factors that can increase blood ammonia concentrations can exacerbate the signs and symptoms of HE. These typically include increased catabolism from infection or increased gut absorption from high-protein diets, constipation, and gastrointestinal bleeding. Other factors that have been implicated in the exacerbation of HE include benzodiazepines, hyponatremia, and inflammatory cytokines, which may all share a final common pathway to increase cerebral edema.

Management of HE should begin with assessing the child's ability to manage his or her airway. Children with grade 3 and 4 HE may require tracheal intubation to protect the airway to ensure adequate oxygenation and ventilation. Otherwise, management typically focuses on reducing gastrointestinal production and absorption of ammonia. Lactulose is often prescribed to create an osmotic diarrhea and to acidify the lumen of the gut to trap ammonia and minimize absorption. Antibiotics such as neomycin and metronidazole have been used to kill the gastrointestinal bacteria involved in metabolizing nitrogen products to ammonia. Other medications include sodium benzoate, which combines in the liver with ammoniagenic amino acids, such as glycine, to facilitate their excretion.[52] Ornithine aspartate may also provide a substrate to the liver for enhancing the urea cycle and glutamine synthesis and to reduce ammonia concentrations. Flumazenil has been postulated to reduce the symptoms of HE by inhibiting endogenous benzodiazepines and γ-aminobutyric acid. However, this benefit was not demonstrated in children who received 0.01 mg/kg flumazenil for HE in the setting of fulminant hepatic failure.[53]

Patients with fulminant hepatic failure can have increased ICP, which is the major cause of mortality and may be a contraindication for liver transplantation. Intracranial hypertension occurs in 38% to 81% of patients with fulminant hepatic failure.[54] ICP is often monitored in patients with fulminant hepatic failure with grade 3 to 4 HE. However, there is a risk of intracranial hemorrhage secondary to coagulopathy. This risk can be reduced by replacing clotting factors and platelets and by placing an epidural rather than a subdural ICP monitor.[55] Management strategies for patients with increased ICP should focus on maintaining a cerebral perfusion pressure greater than 60 mm Hg and an ICP less than 20 mm Hg. Often this includes tracheal intubation and ventilation. Patients should be positioned with their heads midline and slightly elevated to 30 degrees to facilitate venous drainage. Ventilation should focus on achieving a $PaCO_2$ of 30 to 35 mm Hg with minimal positive end-expiratory pressure (PEEP). Medical management to reduce ICP includes administering thiopental or propofol to minimize stimulation and to reduce ICP.[56] Mannitol can be administered if ICP remains increased. Hypothermia has also been described in a small trial with 14 patients with fulminant hepatic failure; maintaining core body temperature at 32°C to 33°C reduced ICP, but the impact on outcome is less certain.[57] Orthotopic liver transplantation is the definitive treatment for patients with acute or chronic HE.

Hematologic Considerations

Anemia is common and occurs because of a combination of gastrointestinal bleeding, poor nutritional state, and decreased erythropoietin production from renal failure. Portal hypertension can result in splenomegaly, which causes platelet sequestration and thrombocytopenia. All the coagulation factors (except factor VIII) are synthesized in the liver. As synthetic function declines, coagulation factor production diminishes. The reduction in bile salt also decreases the absorption of fat-soluble vitamins (A, D, E, K) and contributes to the deficiency of factors II, VII, IX, and X. The result is an elevated prothrombin time (PT) and partial thromboplastin time (PTT). Patients with acute or fulminant hepatic failure can present with a hematologic profile similar to disseminated intravascular coagulation (DIC).

Renal Manifestations

Renal failure is common in patients with acute and chronic liver disease and its cause is multifactorial. Renal failure can be classified as prerenal azotemia, acute tubular necrosis (ATN), or hepatorenal syndrome. Prerenal azotemia from hypovolemia occurs secondary to diuretic therapy, gastrointestinal bleeding, splanchnic pooling, and sepsis. ATN occurs because of decreased central blood volume secondary to central splanchnic pooling and decreased prostaglandin synthesis. The hepatorenal syndrome is characterized by renal failure in the setting of liver failure and portal hypertension. The incidence in adults with chronic liver disease is approximately 10% to 15%. The lower incidence in children (5%) possibly reflects the lack of criteria for the diagnosis of hepatorenal syndrome in children.[58] It occurs secondary to intense renal vasoconstriction from activation of the renin-angiotensin, arginine vasopressin, and sympathetic nervous systems. This activation is a homeostatic response to the profound splanchnic vasodilation that occurs in patients with portal hypertension.[59] Hepatorenal syndrome appears similar to prerenal azotemia (increased serum creatinine, decreased urine Na (U_{Na} <10 mM, fractional excretion of sodium [FE_{Na}] <1%]) but it is differentiated by its lack of response to a fluid challenge (see Chapter 28). Hepatorenal syndrome is classified into two types. The rate of progression of renal failure distinguishes the two types. Type 1, which has a worse prognosis, is characterized by a rapid progression of renal failure with a 100% increase in serum creatinine in less than 2 weeks. It usually occurs in acute liver failure. Type 2 progresses over weeks to months and usually occurs in children with chronic liver disease. Regardless of the type, prognosis is poor in patients with hepatorenal syndrome with a mortality rate of 80% to 95%.[58] The definitive treatment for hepatorenal syndrome is liver transplantation because the renal failure is reversible if the liver is replaced.[60]

The primary goal in the management of patients with liver disease and renal failure is to exclude treatable and reversible causes of renal failure such as nephrotoxins (e.g., nonsteroidal antiinflammatory drugs), hypovolemia (e.g., diuretics, gastrointestinal bleeding), and sepsis (e.g., spontaneous bacterial peritonitis [SBP]). All nephrotoxins should be stopped and patients should be given a fluid challenge, ideally with a colloid solution. If sepsis is suspected, extensive cultures should be obtained and nonnephrotoxic antibiotics should be started.

Pretransplant renal function predicts mortality in adults undergoing transjugular intrahepatic shunt and liver transplantation. This underscores the importance or renal function and explains why serum creatinine is used in the MELD score. Preexisting renal failure is also a major determinant of survival after liver transplantation in adults. Efforts to improve renal function pretransplant may improve posttransplantation outcome.[61] It is not clear whether serum creatinine is a predictor of mortality in children with liver disease.[12] Type 1 hepatorenal syndrome can be managed by treating reversible causes such as providing antibiotic treatment for spontaneous bacterial peritonitis before transplantation. Critically ill children may require continuous renal replacement therapy (continuous venovenous hemofiltration, continuous venovenous hemodiafiltration) and vasopressors as a bridge to transplantation.[62]

Metabolic Considerations

Metabolic derangements include glucose, ammonia, electrolyte, and acid-base disturbances. Electrolyte abnormalities include hyponatremia, hypokalemia and hyperkalemia, hypocalcemia, and hypomagnesemia. Hypoglycemia may occur in patients with fulminant hepatic failure or abrupt discontinuation of TPN, but hyperglycemia is more common in the intraoperative and postoperative period.

PREOPERATIVE EVALUATION

The preoperative evaluation begins with a history and physical examination to identify the primary cause of liver failure and to identify liver and non–liver-related alterations in physiology that may affect the anesthetic and surgical plan. A complete review of systems identifies most of the perioperative concerns (Table 31.2).

The primary cardiovascular concerns include acquired cardiomyopathies from liver disease and inborn errors of metabolism, congenital cardiac defects, and QT prolongation. Aside from a cardiovascular physical examination, the preoperative cardiac evaluation should include an echocardiogram and 12-lead ECG.

The pulmonary manifestations of concern include hypoxia and PPH. Oxygen saturation on room air and with oxygen identifies hypoxic patients and their response to oxygen. Children with significant intrapulmonary shunts from HPS will not increase their oxygen saturation significantly. HPS can be diagnosed by demonstrating intrapulmonary vascular dilatation on echocardiography with macroaggregated albumin.[34]

PPH can usually be identified on echocardiography (if a tricuspid regurgitation jet is present). Patients suspected of having PPH should undergo cardiac catheterization to define the severity of pulmonary hypertension and to assess the response to pulmonary vasodilators (NO, epoprostenol). Children with severe pulmonary hypertension (PAP >50 mm Hg) are at increased risk of perioperative mortality and liver transplantation may be contraindicated.[46]

Anemia and thrombocytopenia are common in children with liver disease and a complete blood cell count should be obtained. In addition, because of the decreased synthetic function of the liver and because of decreased vitamin K absorption, concentrations of clotting factors II, VII, IX, and X may be decreased. A PT, PTT, and platelet count should also be obtained before starting surgery.

Renal failure is common and predicts decreased survival during the posttransplant period in adults.[63] Samples for blood urea nitrogen (BUN) and serum creatinine (SeCr) testing should be obtained.

Children should be evaluated for evidence of altered mental status, particularly those with acute hepatic failure. Increased ICP is common and it is a common cause of mortality in those with fulminant hepatic failure. Altered mental status may also be caused by HE. An ammonia concentration should be obtained as part of their evaluation. Children with advanced HE (grade 3 and 4) may require orotracheal intubation to protect their airway and mechanical ventilation to control $PaCO_2$.

Baseline laboratory values should be obtained for liver function tests, sodium, potassium, calcium, glucose, and albumin. Hyponatremia and hypokalemia are common with diuretic therapy. Patients may have already received citrated containing blood products and may be hypocalcemic secondary to the chelation of calcium. Hypoglycemia occurs secondary to depleted glycogen stores in the failed liver and/or removal of long-term TPN.

A key portion of the preoperative evaluation is the preparation of the patient (child or adolescent) and the family for the anticipated risks, benefits, and clinical course. Specifically, a critically ill child will likely remain intubated and mechanically ventilated in the immediate postoperative period and may have significant facial and extremity edema. Infants and children with less severe disease or disease that does not result in portal hypertension (e.g., MSUD) may be extubated at the end of surgery. Similarly,

TABLE 31.2	Preoperative Evaluation of Liver Transplant Candidates
History and Physical Examination	
Cause for liver failure	
Identifiable syndrome or metabolic disorder	
Past medical history: non–liver-related medical problems (e.g., asthma)	
Past surgical history: portoenterostomy (Kasai), previous anesthetic concerns	
Medications: diuretics, lactulose	
Allergies	
Family history of anesthesia-related problems	
NPO history	
Cardiovascular	
Echocardiography: to identify cardiomyopathy, pulmonary HTN, congenital cardiac defects, and intrapulmonary vasodilation	
Electrocardiogram: to identify arrhythmias and QT prolongation	
Pulmonary	
Oxygen saturation (possible arterial blood gas): to assess hypoxia, A-a gradient (HPS)	
Chest x-ray: to identify pleural effusions and central line position	
Hematology	
Complete blood cell count: to assess anemia, leukocytosis/leukopenia (sepsis)	
Prothrombin time and partial thromboplastin times	
Platelet count	
Thromboelastography	
Renal	
Blood urea nitrogen	
Creatinine	
Bicarbonate: to assess degree of metabolic acidosis	
Neurologic	
Assessment of increased intracranial pressure in acute/fulminant hepatic failure	
Hepatic encephalopathy: ammonia level	
Electrolytes	
Na^+ and K^+: hyponatremia and hypokalemia secondary to diuretics	
Calcium	
Albumin	
Magnesium	
Glucose	

A-a gradient, alveolar-arterial gradient; *HPS,* hepatopulmonary syndrome; *HTN,* hypertension; *NPO,* nothing by mouth.

informing the family about the potential number and location of the intravascular catheters and their associated risks can be helpful in preparing them to see their child after surgery. Informed consent should also include a discussion about the use of blood products and risks associated with prolonged positioning (peripheral nerve injury, occipital alopecia).

INTRAOPERATIVE CARE

Appropriate intraoperative care of the pediatric liver transplant patient requires an understanding of the surgical and anesthetic issues. Several factors affect the patient's physiology, including the underlying pathophysiology of liver disease, surgery, and response to anesthetic drugs. The surgical approach for OLT in children is similar to that for adults. The major difference is the smaller size of the recipient. The obstacles imposed by the size of the patient include a smaller blood volume, more challenging vascular access, size restriction of donor graft, veno-venous bypass (VVBP), and surgical complications such as hepatic artery thrombosis.

Anesthetic management begins with a thorough preoperative evaluation. Children older than 1 year will likely be anxious during the preoperative period. They can be premedicated with an anxiolytic like midazolam, which may be administered intravenously, orally, nasally, or rectally. Patients with HE should not receive premedication with midazolam.

Most children are regarded as having a full stomach because of delayed gastric emptying from ascites, gastrointestinal bleeding, HE, and the nonelective nature of most transplants. The exception may be those presenting for an "elective" transplant without any stigmata of portal hypertension (e.g., Crigler-Najjar syndrome or MSUD). Patients considered to have a full stomach should receive a rapid sequence induction (RSI). Induction agents should be tailored to meet the needs of the patient, but etomidate (0.2–0.3 mg/kg), propofol (2–4 mg/kg), or ketamine (2 mg/kg) are suitable options. Appropriate muscle relaxants for RSI include succinylcholine and high-dose rocuronium.[64] The trachea should be secured with a tracheal tube. Some children may require greater inspiratory pressures to achieve adequate ventilation in the intraoperative and postoperative period compared with unaffected children because of atelectasis from pleural effusions and ascites, surgical retractors placed on the abdominal and chest wall, and a tight abdominal closure; a cuffed tracheal tube is appropriate for these children. PEEP should be used in all patients. PEEP (10 cm H_2O) has no negative effects on liver function in donors.[65]

Children who are not at risk for aspiration may have an inhalation induction with sevoflurane and nitrous oxide. The use of nitrous oxide is not recommended after induction of anesthesia because it may distend the bowel and expand gas emboli. Anesthesia is typically maintained with an inhalational agent, an opioid, and a neuromuscular blocking drug. Isoflurane and sevoflurane are commonly used because they are readily available, undergo minimal hepatic metabolism, and have minimal adverse effects on the liver.[66,67] Desflurane also undergoes minimal hepatic metabolism and appears to be quite safe, although there are three cases reports of hepatotoxicity after desflurane exposure.[68] Sevoflurane provided more stable hemodynamics than desflurane in one study.[69] Propofol (with or without remifentanil, total intravenous anesthesia [TIVA], see Chapter 8) is also an option to maintain anesthesia during liver transplantation. It is relatively short-acting and even though the primary metabolic pathway is hepatic, there appears to be extrahepatic metabolism in the lung, kidney, and intestine.[70,71] Neuromuscular blockade can be maintained with a variety of agents. Rocuronium, vecuronium, pancuronium, atracurium, and cisatracurium have all been described. Pancuronium may have the added advantage of increased heart rate, long duration, and reduced cost. The disadvantage of pancuronium, rocuronium, and vecuronium is their partial hepatic metabolism (see Chapter 7), but this can be overcome with appropriate monitoring and dose adjustments. Dose requirements of continuous infusions of rocuronium, vecuronium, and pancuronium are reduced during the anhepatic phase of liver transplantation but return to initial infusion rates after reperfusion.[72] There is no change in the dose requirements of atracurium during the anhepatic phase.[73] Atracurium or cisatracurium may be ideal

in patients with combined hepatic and renal insufficiency because they do not rely on hepatic or renal function for elimination.

The liver metabolizes all opioids, with the exception of remifentanil, which is metabolized by plasma and tissue esterases. The metabolic pathway for most opioids is oxidation, although morphine undergoes glucuronidation.[74] There is evidence that the elimination half-life and clearance of alfentanil and fentanyl are not dramatically altered in patients with cholestatic and cirrhotic liver disease.[75,76] Fentanyl, sufentanil, alfentanil, and morphine have all been described and used in children undergoing liver transplantation. Fentanyl is commonly selected and is usually administered as a bolus during induction (2–10 μg/kg) and maintained as an infusion throughout the anesthetic and the immediate postoperative period (2–5 μg/kg per hour).

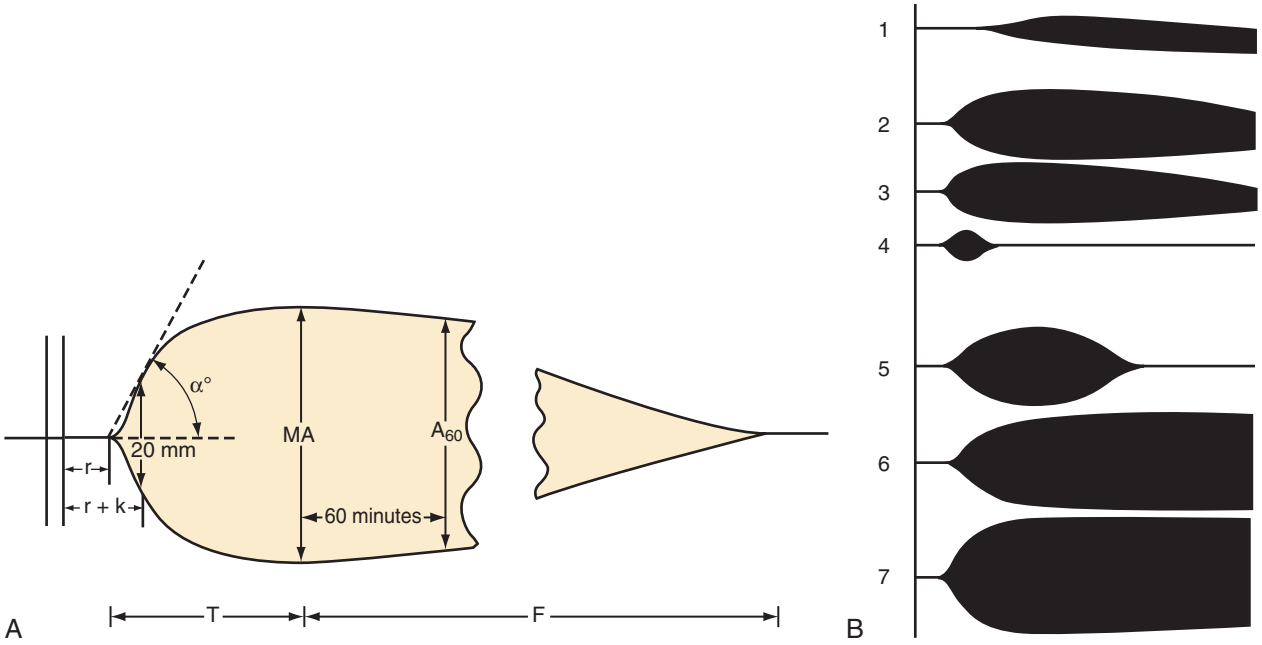
Vascular access is important for resuscitation and monitoring. At least two peripheral IV catheters should be placed along with a central venous line (CVL) for administration of drug infusions, vasopressors as indicted, and assessment of volume resuscitation. The CVL can also be used to monitor trends in central venous pressure (CPV) and measure superior vena cava oxygen saturation (a surrogate marker for SvO_2). Larger patients can tolerate rapid infusion catheters. Blood loss can be significant during liver transplantation with estimates between 0.5 and 25 blood volumes (mean = 3.95 blood volumes).[77] Fluid warmers and infusion devices (Level 1 Fast Flow Fluid Warmer, Smiths Medical, Rockland, MA; Belmont Rapid Infuser, Belmont Instrument Corporation, Billerica, MA) need to be available to facilitate volume resuscitation if massive hemorrhage occurs (see Chapters 12 and 52). The early version of the Level 1 Fast Flow Fluid Warmer was associated with massive air emboli but the newer models are equipped with air detectors. Nevertheless, all air needs to be removed from the infusion bags before starting the device.[78] The Belmont Rapid Infuser is not routinely used in infants or small children (see Chapter 52). The choice of resuscitation fluids should be limited to 0.9% normal saline solution and PlasmaLyte. Lactated Ringer's solution is not recommended because the lactate will remain unmetabolized during the anhepatic stage. Many patients with liver disease are hypoalbuminemic, so the use of 5% albumin is appropriate. However, 5% albumin is hypertonic owing to a large sodium concentration and care must be taken when administering this to children with hyponatremia because it may correct the hyponatremia too rapidly and cause adverse cerebral pressure changes.

Standard monitoring should include ECG, pulse oximetry (upper and lower extremities), noninvasive blood pressure, invasive arterial blood pressure, CVP, and temperature. Other high-technology monitoring commonly used in adult liver transplantation includes transesophageal echocardiography (TEE), continuous cardiac output (CCO) catheter, bispectral index (BIS), VVBP, and more than one arterial catheter. There are limitations to the use of these monitors in children because of patient size; TEE, CCO, BIS, and VVBP are used in 0%, 7.7%, 15.4%, and 7.7% of U.S. pediatric transplant centers, respectively.[79] The recent development of continuous noninvasive or minimally invasive CO monitors such as the Cardiotronic ICON (Osypka Medical, La Jolla, CA), which simply requires four ECG pads to assess changes in bioimpedance (approved by the U.S. Food and Drug Administration [FDA] for use in neonates) or small esophageal Doppler monitors (Deltex Medical, Chichester, West Sussex, England) (FDA-approved for use in children weighing 3 kg or more) may prove to be of great value in the future (see Chapter 52).[80,81]

Hematologic and electrolyte changes are common during liver transplantation, and measurements of arterial blood gases, sodium, potassium, calcium, magnesium, hemoglobin platelets, and coagulation parameters (PT, PTT, fibrinogen and D-dimers, thromboelastography [TEG]) need to be performed frequently throughout the procedure. Most centers use either portable devices or an operating room laboratory to obtain these data. Assessment of coagulation variables can be obtained with TEG) (E-Fig. 31.1). Point-of-care testing with TEG may reduce transfusion requirements in patients having liver transplants.[82,83] However, only 28% of U.S. pediatric transplant centers used TEG.[79]

Acid-base disturbances commonly occur during liver transplantation. Children with renal disease may have a preexisting metabolic acidosis from increased bicarbonate elimination. A metabolic acidosis is typically present during the dissection and anhepatic phase of surgery but it is usually most pronounced immediately following reperfusion. Lactic acid and citrate (from blood products) are not metabolized during the anhepatic phase and contribute to the acidosis. Cross-clamping of the inferior vena cava [IVC] and aorta alters blood flow to gut and lower extremity tissue beds and may also contribute to the development of a lactic acidosis. Once the liver graft begins to function, a metabolic alkalosis can develop as the lactate and citrate are metabolized.[77]

During the dissection and anhepatic phase there are several causes of hyperglycemia. Serum glucose will increase if there is an exogenous source or if there is altered glucose metabolism. Exogenous sources of glucose include glucose from blood products,[77] dextrose-containing IV fluids, and damaged hepatocytes from the liver graft.[84] Typically glucose concentrations will increase immediately after reperfusion. Glucose uptake is altered from the administration of methylprednisolone because of steroid-induced insulin resistance. Hepatic denervation likely results in alterations in insulin and glucose clearance during the postoperative period and may explain the frequent occurrence of impaired glucose tolerance and diabetes in liver transplant recipients.[85,86]



Positioning is critical to prevent soft tissue and peripheral nerve injuries. All extremities should be padded and all cables and wires need to be wrapped and protected from the skin. The head should be rotated and repositioned periodically to prevent the development of a pressure sore and alopecia. To minimize the risk of peripheral neuropathy, the upper extremities should not be abducted more than 90 degrees and the wrists should not be hyperextended for the arterial catheter.

SURGICAL TECHNIQUE

The surgical approach can be divided into four stages: hepatectomy, anhepatic, reperfusion, and biliary reconstruction.

Hepatectomy (Stage 1)

The initial description of OLT is referred to as the "classic" technique. In the classic approach, the liver is dissected to its vascular supply and the suprahepatic and infrahepatic vena cava (VC) are clamped along with the portal vein and hepatic artery. The liver is removed en bloc (Fig. 31.1). The disadvantage of this approach is the VC cross-clamp and the associated reduction in preload. The piggyback technique was described 1989 and is the preferred approach for pediatric transplants because there is more flexibility with the organ size and it requires only partial clamping of the VC.[87,88] The liver is dissected away from the IVC, the short hepatic veins, portal vein, and left, right, and middle hepatic vein. The infrahepatic VC of the donor is oversewn and the suprahepatic VC is anastomosed to the native hepatic veins (Figs. 31.2 and 31.3). This requires only partial clamping of the IVC. A portocaval shunt can be established for patients who do not tolerate clamping

E-FIGURE 31.1 A, The reaction time *r* as measured by thromboelastography (TEG) denotes the time to onset of the start of coagulation and should be 6 to 8 minutes. It represents the rate of thromboplastin formation. Prolongation of this portion of TEG usually represents factor deficiency and is treated with the administration of fresh frozen plasma (FFP). The coagulation time (*r* + *k*) is the period between the start of the TEG recording and the time to the generation of an amplitude of 20 mm. It is a measurement of the speed of solid clot formation. The clot formation rate is measured by the α angle and normally is greater than 50 degrees. Abnormalities of the α angle represent platelet function, fibrinogen, and the intrinsic pathway. The α-angle abnormalities are usually corrected by cryoprecipitate administration. The maximum amplitude (*MA*) is most indicative of platelet function and normally measures between 50 and 70 mm. **B,** Abnormalities of coagulation noted before surgery. **1:** there is prolongation of the *r* time and a diminution of the α angle, as well as the MA. **2:** improved coagulation during stage 1 is noted, as there is administration of FFP and platelets as the surgery progresses. Note the improved *MA* and *r* time. There is also an improved α angle. **3:** TEG representative of the continued coagulopathy seen during stage 2 of the surgery. Note the progressive diminution of the MA and the progressive tapering of the MA, which suggest possible fibrinolysis. **4:** a classic representation of fibrinolysis seen in stages 1 and 2. **5:** fibrinolysis on graft reperfusion. Note that, in this case, the clot formed takes somewhat more time before dissolution occurs. **6:** Amicar-treated TEG, demonstrating dramatic improvement of the fibrinolytic stage. Note the improved MA and *r* time, and α angle. **7:** the end TEG showing a normal coagulation profile, which is representative of normal liver function from the graft, as well as continued administration of coagulation factors. (From Scott V, Davis PJ. Autologous transfusion in orthotopic liver transplantation. In: Salem MR, editor. *Blood Conservation in the Surgical Patient*. Baltimore: Williams & Wilkins; 1996:340.)

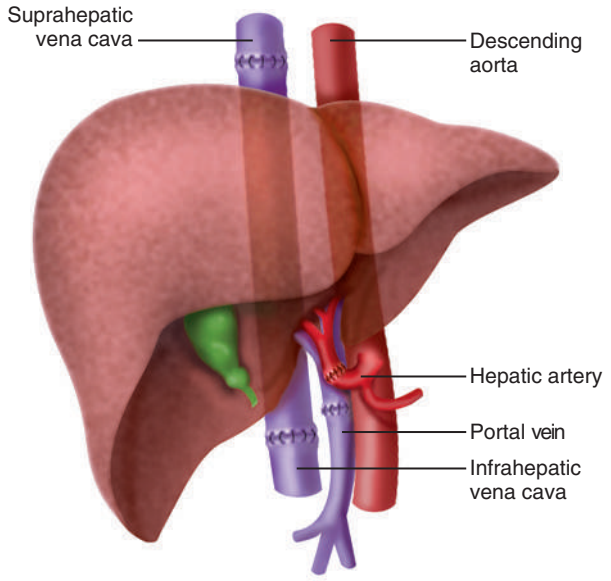


FIGURE 31.1 The classic approach for orthotopic liver transplantation. The suture lines are visible at the suprahepatic and infrahepatic anastomoses. (From Starzl TE, Iwatsuki S, Van Theil DH, et al. Evolution of liver transplantation. *Hepatology* 1982;2[5]:614–636.)

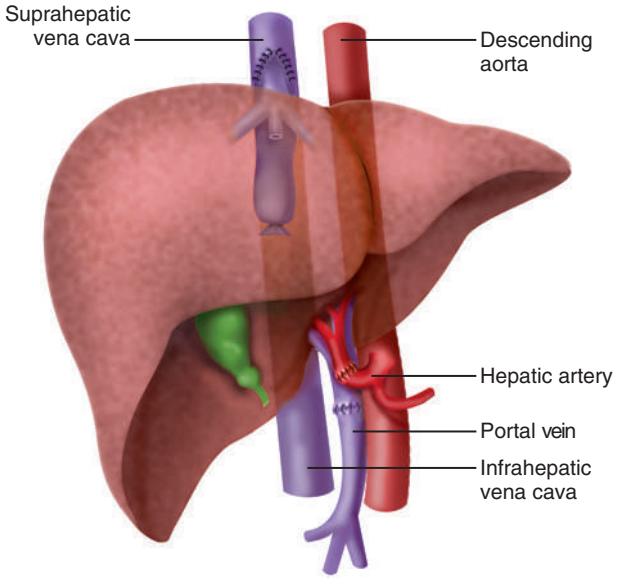

FIGURE 31.2 The piggyback technique preserves the inferior vena cava (IVC). This is the view of the liver graft after the recipient's hepatic confluence is anastomosed to the donor's IVC (the infrahepatic IVC of the donor is ligated). (From Tzakis A, Todo S, Starzl TE. Orthotopic liver transplantation with preservation of the inferior vena cava. *Ann Surg.* 1989;210[5]:649–652.)

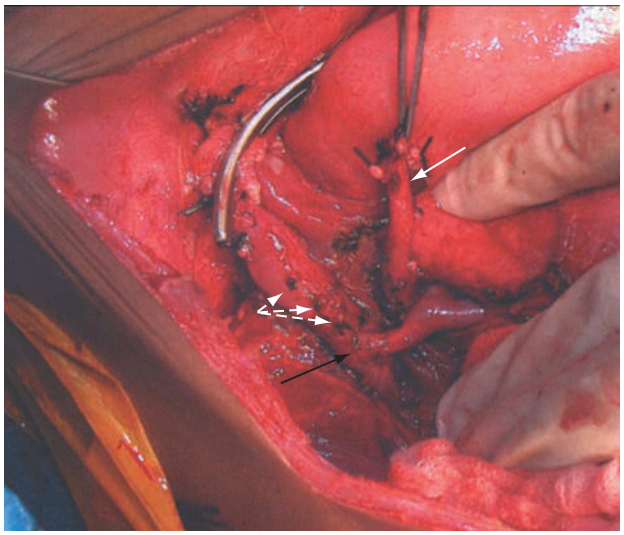

FIGURE 31.3 The native liver has been removed. There is a clamp across the right, middle, and left hepatic veins. The *black arrow* shows the portacaval shunt. The *white arrow* shows the hepatic artery. The *dashed white arrows* show the short hepatic veins. (From Kuo PC, Davis RD. *Comprehensive Atlas of Transplantation.* Philadelphia: Lippincott Williams & Wilkins; 2005:132.)

of the portal vein (see Fig. 31.3). Typically, these are patients who have not developed collateral flow secondary to portal hypertension (e.g., MSUD).

Several physiologic considerations that take place during the hepatic dissection affect the anesthetic management. Hypotension is common and can occur as the result of changes to the cardiovascular, hematologic, and metabolic systems. The most common cause of hypotension includes hypovolemia secondary to hemorrhage and third-space volume losses. Resuscitation with citrated blood products can result in hypocalcemia and surgical manipulation can cause mechanical compression of the IVC or right ventricle. Bleeding occurs from fragile collaterals, adhesions from prior surgery (e.g., Kasai procedure), and coagulopathy.[89] Blood conservation with a reduction in allogeneic blood exposure may have a significant benefit on perioperative morbidity including infections, intensive care unit (ICU) stay, and hospital stay.[90] One technique to reduce blood loss is the maintenance of low CVP (decrease of 30% from baseline) as has been described in adults. The reported benefit of a low CVP is less bleeding with subsequent decrease in allogeneic blood requirements and decreased morbidity.[88] Some studies have also suggested an overall reduction in morbidity and 1-year mortality.[91,92] The technique is controversial and the potential risks include end-organ injury, such as renal or graft failure.[93] This technique has not been described in the pediatric liver transplant population.

Hematologic abnormalities include anemia, thrombocytopenia, coagulation factor deficiency, and low fibrinogen.[94] A progressive coagulopathy can develop during this stage. Metabolic derangements including hyperkalemia, hypocalcemia, hypomagnesemia, and acidosis occur from volume resuscitation with blood products.

Anhepatic Stage (Stage 2)

The anhepatic phase begins once the hepatic veins, hepatic artery, and portal vein are cross clamped. The dissection of the recipient's liver is completed and the organ is removed. This phase ends when the hepatic and portal vein cross clamps are removed and the graft is reperfused.

Cardiovascular changes that occur during this stage can result in hypotension. This occurs from the inferior vena cava cross-clamp, which decreases the preload. Hemodynamically, CO, CVP, and PAP decrease while systemic vascular resistance increases.[89] Preload should be gently augmented to maintain mean arterial pressure (MAP) with the minimum filling pressures possible. Hypervolemia may cause hepatic congestion during reperfusion. Inotropic agents

such as dopamine or epinephrine may be needed to maintain mean arterial blood pressure. A portocaval shunt may mollify some of these hemodynamic changes by preserving preload from the portal vein. (If VVBP is planned, it is initiated during this period.) Unmetabolized citrate causes hypocalcemia and hypomagnesemia since it chelates both cations. Acidosis occurs from the unmetabolized citrate, lactate, and other acids. Bicarbonate may be administered if there is a significant metabolic acidosis, although there is no evidence that this improves outcomes.[95] In fact, a mild metabolic acidosis during reperfusion may not be detrimental since it will be later offset by the metabolism of citrate, which produces bicarbonate.

Once the liver is on the surgical field warm, ischemia time begins. The time to reperfusion will be brief and steps need to be in place for reperfusion. The potassium should be low-normal and the calcium should be high-normal, hemoglobin should be maintained between 9 and 10 g/dL. If the potassium is greater than 5 mEq/L, steps need to be taken to reduce it. This includes increasing the serum pH with hyperventilation and the administration of sodium bicarbonate (1–3 mEq/kg). Glucose and insulin can be administered to acutely reduce the potassium concentration as well (see Chapters 7 and 27). Potassium-wasting diuretics such as furosemide (0.5–1 mg/kg) can also be used. Administering fresh blood or washed red blood cells will minimize the increase in potassium during transfusion therapy. β_2-Agonists may decrease potassium and can be used. Calcium and epinephrine should be immediately available for reperfusion.

Reperfusion (Stage 3)

The liver graft can be reperfused once the hepatic and portal vein anastomosis are complete. Before reestablishing hepatic blood flow, the graft is flushed to remove the preservation solution to minimize the reperfusion syndrome.

Many changes can occur acutely during the reperfusion period secondary to cardiovascular, hematologic, and metabolic derangements. Reperfusion syndrome is characterized by a decrease in MAP of greater than 30%.[96] Factors participating in this event include myocardial dysfunction, arrhythmias, and bleeding. The myocardial dysfunction is attributed to the release of NO and TNF-α.[97] Cardiovascular collapse can occur and patients may require epinephrine to correct the hemodynamic effects of reperfusion.[96] Hyperkalemia is a common event immediately following reperfusion and may cause ventricular arrhythmias.[98] Hyperkalemia should be treated with calcium chloride (10–30 mg/kg) initially to stabilize the cardiac membrane and then insulin and dextrose, hyperventilation, furosemide, β_2-agonists, and sodium bicarbonate to decrease the serum potassium concentration (see previous section). The increased potassium content of the preservation solution is the cause of hyperkalemia. The University of Wisconsin solution, a very commonly used preservation solution, contains large amounts of potassium (120 mmol/L). Histidine-tryptophan-ketoglutarate solution was introduced in 1980 as a cardioplegic solution and contains significantly less potassium (10 mmol/L) than University of Wisconsin solution.[99] A recent study comparing the two solutions found equal 1-month and 1-year graft survival with histidine-tryptophan-ketoglutarate and University of Wisconsin solution. The viscosity is reduced with histidine-tryptophan-ketoglutarate solution and may introduce itself more easily into the vascular spaces in the donor liver.[100] Although hyperkalemia is the hallmark electrolyte disturbance in the immediate reperfusion period, hypokalemia is more common in children throughout the intraoperative period and may require correction.[101]

Fibrinolysis can occur after reperfusion and in one study it occurred in 60% of children and 80% of adults.[102] This occurs from increased tissue plasminogen activator activity and decreased synthesis of fibrinolysis inhibitors. Heparin effect occurs from endogenous heparinoids from the graft and residual heparin from the preservation and the release of tissue plasminogen activator from endothelial cells of the revascularized graft. Antifibrinolytic medications blunt this process, but there is concern that there may be an association with antifibrinolytics and intraoperative thrombotic events (hepatic artery and portal vein thrombosis) in pediatric patients receiving liver transplants. Children can have a mixed coagulation picture after transplantation and may be hypercoagulable because of a decrease in protein C and antithrombin III.[103] This may result in hepatic artery thrombosis.[104–106] Tranexamic acid, ε-aminocaproic acid, and other methods to reduce transfusion needs in adult liver transplants have been advocated, but there are no pediatric transplant data to support or refute the use of tranexamic acid or ε-aminocaproic acid and the adult series have small sample sizes.[107–109]

Biliary and Hepatic Artery Reconstruction (Stage 4)

The final step is reestablishing hepatic artery blood flow and reconstructing the biliary system. The hepatic artery may require an anastomosis via a conduit to the infrarenal aorta in infants. This requires temporary cross-clamping of the aorta. Biliary reconstruction is established by either directly connecting the graft and the recipient's common bile ducts or by connecting the common duct of the graft to a Roux-en-Y limb of the recipient's jejunum.

During biliary reconstruction, metabolic and hematologic alterations are addressed. As the liver graft begins to function the citrate administered during the previous three phases is metabolized and the patient can develop a metabolic alkalosis**.** One of the hemodynamic goals includes maintaining a normal CVP. If the CVP is increased (>8–10 mm Hg), there is concern that the liver graft can become congested and not function normally. The risk of hepatic artery thrombosis ranges from 0% to 25% and is greater in infants and children.[105,106] This risk may be increased if the PT and PTT are corrected to normal values. Also, the viscosity from a greater hematocrit may increase the risk of hepatic artery or portal vein thrombosis. The hematocrit does not need to be corrected to normal values; maintaining the hematocrit at 8 to 9 g/dL is safe and reasonable. Surgical techniques to reduce the risk of hepatic artery thrombosis include anticoagulation with heparin, dextran, aspirin, and alprostadil.

Split Liver Techniques and Living Donor Liver Transplants

Advances in surgical technique, tissue preservation, and immunosuppression have improved the survival in patients undergoing liver transplantation. The result is more patients waiting for liver transplantation without an increase in available organs. Children are at a disadvantage because of the size limitations. Two techniques have attempted to address these issues. In 1984, Bismuth and Houssin split an adult liver and transplanted it into a child.[110] The reduced liver technique does not increase the number of available grafts and efforts were made to perform split liver techniques to make two grafts from one adult donor. The initial results were poor, with an increase in complications and mortality.[111,112] The technique has evolved and today the graft is split while still in vivo (in the heart-beating donor) compared with ex vivo (splitting performed after the graft is removed from the donor). This decreases cold ischemia time and facilitates hemostasis

of the liver edge. The result is improved patient and graft survival.[113] Patient survival has increased from 60% to 70% in the 1990s to 80% to 90% in 2003. In one series, 218 split liver technique grafts were transplanted between 1995 and 2002; overall patient survival at 1 year was 81.7% and overall graft survival was 75.8%. Surgical complications that caused a return to the operating room were bleeding (9.2%), bowel perforation (8.3%), and biliary problems (7.5%). Hepatic artery complications occurred in 6.7%.[113]

Living donor liver transplantation was first described in 1989.[114] The result has been a reduction in mortality among children awaiting liver transplantation. The benefit of a living donor (especially if related) is improved posttransplant results because of better graft quality, shorter ischemic times, and better immune compatibility. One- and five-year patient survival rates were 94% and 92%, respectively.[115] The left hepatic segment is removed for pediatric recipients, whereas the right hepatic lobe is removed for adult recipients. The regenerative capacity of the liver allows the donor to regenerate the liver without hepatic insufficiency. Despite the success of this technique for the recipients, there is considerable risk to the donor. Complications include exposure to blood products, short- and long-term peripheral nerve injuries, biliary leakage, abdominal wall defects, pleural effusions, pneumonia, pulmonary emboli, and death.[115,116]

OUTCOMES

The Studies of the Pediatric Liver Transplantation (SPLIT) registry was initiated in 1995 and consists of 38 centers in the United States and Canada. These centers contributed 85% of the pediatric liver transplants in 2002. Transplants performed more recently had improved survival rates. In the past, age younger than 1 year was considered an increased risk factor for mortality, but over the past 20 years there is little difference between patients younger than 2 years and those older than 2 years. There is also no significant difference between male and female gender.[114]

Review of the MELD/PELD data indicates that survival also depends on the preoperative MELD/PELD score. Patients stratified to status 1 had a lower 1-year survival rate compared with other transplant recipients (76% vs. 87%). Adults with greater MELD scores (scores >35) demonstrated decreased 1-year patient and graft survival. Pediatric patients with greater PELD scores showed a trend toward decreased 1-year patient and graft survival but the association was not statistically significant. The overall 1-year survival rate remained excellent at >85%.[117] Cognitive outcomes appear to be reduced in pediatric recipients of liver transplants; long-term cognitive and academic deficits persist with verbal comprehension, working memory, mathematical computation, and executive deficits.[118] Factors that seemed to predict cognitive deficits included operative complications and intraoperative transfusion volume.[119] Conversely, liver transplantation improved global functioning in some children.[120]

IMMEDIATE POSTOPERATIVE CARE

At the completion of the surgery the child is transported to the ICU. Much of the preoperative pathology still exists in the postoperative period. Patients with underlying cardiac, pulmonary, and renal dysfunction will be more difficult to manage.

Patients continue to lose intravascular volume after liver transplantation because of ongoing bleeding and third-space losses. These losses need to be replaced to maintain a normal CVP and adequate urine output (0.5–1 mL/kg per hour). Replacement with a lactate-free isotonic solution (0.9% normal saline solution and PlasmaLyte) and albumin is appropriate. Particular attention should be paid to children with underlying ventricular dysfunction or PPH because they will not tolerate fluid overload. In adults, there is some evidence that fluid overload was responsible for ICU readmission in liver transplant patients.[121] This, however, must be balanced against the risks of hypovolemia, which could cause renal failure and may increase the risk of hepatic artery thrombosis. Preexisting pulmonary hypertension does not dissipate immediately and children who previously took prostaglandins need to continue these infusions in the operating room and into the postoperative period. Systemic hypertension is common after liver transplantation and has been described in as many as one-third of the patients.[122] It is typically related to cyclosporine therapy or chronic kidney disease.[123,124]

Almost all children require tracheal intubation and mechanical ventilation in the immediate postoperative period; however, some centers extubate those who are stable immediately after surgery. Early extubation may be associated with decreased morbidity and improved graft and recipient survival.[125] It is unclear if postoperative intubation is just an association or a cause of adverse outcomes. Children who may be appropriate candidates for early extubation (extubation in the operating room) include those with reduced blood loss, hemodynamic stability, alveolar-arterial gradient less than 150 mm Hg, and absence of HE.[126] Children with significant comorbidities such as respiratory insufficiency and reoperation are more likely to require reintubation.[127]

Postoperative ventilation may be more appropriate for smaller children that have received a relatively large graft and in children with underlying lung disease (HPS). Ascites, pulmonary edema, and pleural effusions have been described after transplantation (possibly associated with the degree and duration of preoperative portal hypertension) and may necessitate prolonged mechanical ventilation.[128] Efforts to minimize atelectasis include positive-pressure ventilation with PEEP. Diuretics may be needed on the second or third postoperative day to treat edema and effusions. There is speculation that prolonged mechanical ventilation may have a negative effect on the hemodynamics of transplant patients and may contribute to overall morbidity and mortality.[129] Increased levels of PEEP may contribute to this morbidity. Some have advocated for early extubation to decrease the incidence of pulmonary complications and to facilitate discharge from the ICU.[122]

Renal failure secondary to hepatorenal syndrome usually resolves after successful liver transplantation. The goal in the immediate postoperative period is to maintain normovolemia and to avoid nephrotoxic agents. These include aminoglycoside antibiotics and immunosuppressant agents such as cyclosporine and tacrolimus. The immunosuppressant agents may need to be delayed until renal function begins to improve.

Neurologic complications after liver transplantation are also common. In the adult population these complications occur in 10% to 30% of patients.[130] Pediatric information is lacking. In adults, the complications present as encephalopathy, seizures, or coma. The causes of encephalopathy and coma include drugs (immunosuppressive agents such as tacrolimus and OKT3), infection (meningitis and brain abscess), strokes (bleeding), and hyponatremia with central pontine myelinolysis. The most common cause of seizures is an adverse drug reaction associated with immunosuppressant drugs.[131] Hyponatremia can contribute to neurologic complications and needs to be corrected. The correction should be done slowly to minimize the risk of central pontine myelinolysis. Correction no greater than 0.5 mEq/L per hour is considered safe. If the correction proceeds faster than the recommended rate, there is some evidence in the animal model that

dexamethasone administered within 6 hours of the correction may minimize the risk of central pontine myelinolysis.[132]

Surgical complications that occur after transplant include vascular complications, acute rejection, and infections; frequent monitoring for their occurrence is important to ensure prompt management. Vascular complications include hepatic artery thrombosis, portal vein thrombosis, bleeding, and bowel perforation.[122,133] Hepatic artery thrombosis is identified with frequent hepatic Doppler flow imaging. Patients may undergo anticoagulation with aspirin, heparin, dextran, and alprostadil to reduce the risk of thrombosis.[133] Infections are common in immunosuppressed transplant patients and contribute to significant morbidity. The primary source for infections appears to be central venous access lines, percutaneous catheter drainage, and mechanical ventilation. Acute rejection should be suspected in patients with fever and increased liver enzymes. The diagnosis is made by histologic examination.[122]

Rejection is an immune response and efforts to understand and control this immune response lie at the heart of transplant medicine. Initial efforts to control the response involved suppressing the recipient's immune system. There has been a move away from immunosuppression to immunotolerance. Immunotolerance describes the concept of immune cells from both the recipient and the donor coexisting without attacking each other.[134] The goal of immunosuppression medication is to reach this state of tolerance. In this state of immunotolerance, minimal immunosuppression can be used. The benefits of decreasing immunosuppression include the reduced risk of infection, hypercholesterolemia, malignancy, hypertension, and diabetes mellitus. Protocols to induce tolerance include exposing patients to lymphoid-depleting agents (antilymphoid antibody) such as antithymocyte globulin before liver engraftment to reduce the antidonor response to a more controllable range and allow maintenance therapy (tacrolimus) to begin with one agent. Other agents are added if there is evidence of rejection.[135] The immunosuppressant agents currently used include calcineurin phosphatase inhibitors, such as tacrolimus and cyclosporine, that provide the mainstay of therapy. Other options include azathioprine or mycophenolate mofetil for patients who cannot tolerate the calcineurin phosphatase inhibitors because of toxicity. Adverse effects of the calcineurin phosphatase inhibitors include hypertension, tremor, and renal failure. Newer agents such as monoclonal antibodies against interleukin 2 (IL-2) are also being used.[136]

LONG-TERM ISSUES

Recipients of liver transplants return to the operating room for a variety of reasons (central line placement, wound irrigation, dental rehabilitation, bowel obstruction, cholangiogram, biliary dilation, esophagogastroduodenoscopy). A primary concern in the posttransplant patient is the adverse effects of immunosuppressant agents. Most organ systems become involved and a thorough review of systems is important.

The cardiovascular effects of immunosuppressant agents include hypertension from cyclosporine and cardiomyopathy (rare) from tacrolimus.[19,137] Renal insufficiency can occur secondary to cyclosporine, diuretics, or hypertension. Baseline BUN and creatinine should be obtained preoperatively in patients with a history of renal insufficiency, and medications or their active metabolites (e.g., morphine 6-glucuronide, aminoglycosides) that are renally cleared will need to be adjusted or avoided. Hyperkalemia may accompany renal failure and should be evaluated before induction of anesthesia.

Pediatric recipients of a liver transplant can have multiple hematologic abnormalities. Azathioprine can cause anemia, leucopenia, and thrombocytopenia. Another cause of anemia includes unrecognized gastrointestinal bleeding from steroid-induced ulcers. Patients who have been taking azathioprine should have a complete blood cell count before surgery, particularly if they are having a procedure that may involve blood loss.

The endocrine effects of chronic steroid exposure include diabetes, growth retardation, and adrenal insufficiency. Patients receiving long-term steroid therapy need stress-dose steroids during the perioperative period (see Chapter 27). Those receiving insulin for diabetes need intraoperative blood glucose monitoring and dextrose-containing IV fluids if they are hypoglycemic or are at risk of developing hypoglycemia.

Most recipients of a liver transplant have been exposed to multiple procedures and may have significant anxiety in the preoperative period. These patients should receive an anxiolytic to minimize the anxiety and to reduce the risk of postoperative behavioral changes.[138] Midazolam is an appropriate and safe medication provided there is no evidence of residual HE. Anesthesia can be induced with an inhalational technique provided the liver graft is functioning normally and no oral intake (NPO) guidelines have been followed. Children who are hospitalized, with sepsis, bleeding, encephalopathic, or rejecting should have an IV induction and their airways secured with an tracheal tube. Isoflurane, sevoflurane, and desflurane are used for maintenance of anesthesia.

Renal Transplantation

The causes of end-stage renal disease in children are different than those in adults. The main causes in adults are diabetes, hypertension, and polycystic kidney disease, whereas in children, the main causes are congenital obstructive uropathies, renal dysplasia, and acquired lesions such as glomerulosclerosis.[139] There are approximately 700 to 800 pediatric renal transplants performed yearly in the United States.[140] Both graft and patient survival have improved dramatically over the past four decades.[139–142] Improvements in immune-suppression therapies, advancements in surgical technique, improved donor selection, and a greater understanding of pediatric pharmacokinetics have all contributed substantively to improving patient survival and quality of life. Age-related changes in survival continue to exist and differ slightly from the earliest years of transplantation. Children younger than 5 years have better graft survival, whereas adolescents have the worse outcome (Fig. 31.4).[139] Graft survival from living-related donors (LDs) appears slightly better than from deceased donors (DDs): 86% versus 83%. Multivariate analysis of risk factors for graft loss include black race, history of prior transplantation, more than five transfusions, and HLA-B mismatch (Table 31.3).[141]

PATHOPHYSIOLOGY

The pathophysiology of renal disease in children involves cardiovascular, hematologic, and metabolic abnormalities. Cardiovascular changes include hypertension, coronary artery disease, dyslipidemia, left ventricular hypertrophy, and diastolic dysfunction.[143–156] Anemia occurs with a loss of renal function and as a consequence of decreased erythropoietin production.[157–159] Growth retardation is common, thought to be due to a combination of protein and calorie malnutrition, growth hormone resistance, anemia, renal bone disease, and chronic metabolic acidosis. In some instances, steroids used to treat an underlying pathology can further exacerbate growth retardation. Metabolic abnormalities and fluid and

electrolyte disturbances are common in renal failure and are a consequence of the kidney's inability to eliminate waste products and regulate fluids and electrolytes. Hyperkalemia is a potential life-threatening complication of end-stage renal disease. Metabolic acidosis is a consequence of the failing kidney to excrete an acid load and can exacerbate hyperkalemia. Renal osteodystrophy occurs secondary to an increased concentration of parathyroid hormone and to decreased concentrations of active vitamin D. Because growth retardation and nutritional insufficiency are common in children with end-stage renal disease, cognitive function[160–165] and development can also be impaired.[160–163]

SURGICAL TECHNIQUE

The surgical techniques used in the pediatric recipient differ from those in adults and depend on the child's size and underlying preexisting abnormalities. The surgical approach to kidney transplants involves intraperitoneal or extraperitoneal approaches. The extraperitoneal approach may be more technically difficult in younger patients. Removal of native tissue can be performed either concurrently or (ideally) in advance. Native nephrectomy may be required for polycystic kidney disease, uncontrollable hypertension, urinary tract infection, or nephrotic syndrome with its associated hypoalbuminemia, malnutrition, and hypercoagulability.[166–169] Native nephrectomy at the time of transplant increases operative time, cadaveric graft ischemic time, and is also a risk factor for ATN in the grafted organ.

In children who weigh more than 20 kg, the surgical approach is similar to that in adult transplant patients. A lower-right quadrant incision is used, the kidney is placed in the iliac fossa, and the vascular anastomoses are to the common iliac vein and artery.[167,168] This extraperitoneal approach has the advantage of increased ease of future graft biopsy and ability to resume peritoneal dialysis in case of delayed graft failure.[139] In the past, the donor organs for renal transplantation in children who weighed less than 20 kg were restricted to those that were size-compatible organs. These small cadaveric donor organs presented technical challenges, sometimes resulting in a vascular thrombosis, acute rejection, and graft loss.[139,170–172] An adult-sized donor kidney is now used in infants and young children. The surgical approach may use a midline incision with mobilization of the cecum and right colon or an alternate approach involving a right-lower quadrant incision and an extraperitoneal dissection. The donor organ may be anastomosed to either the common iliac artery and vein, or directly to the aorta and VC.[167,168,173–177]

ANESTHETIC MANAGEMENT

Preoperative Evaluation

Immediately before transplantation, the child should be hemodynamically stable and fluid/electrolyte imbalances corrected before transplantation. It is important to assess the urine output of the patient (anuric, polyuric) so that appropriate intraoperative fluid replacement can be administered before unclamping of the donor organ during surgery. Active infection is a contraindication to transplantation; any concurrent systemic disorders should be optimized. The NPO status of the child should be determined and because of the unexpected nature of cadaveric organ availability, many patients who present for cadaveric transplantation require full stomach precautions. Finally, the child's need for premedication should be assessed and either an oral or IV anxiolytic (midazolam) administered. If time permits, patients may receive immunotherapy perioperatively to assist the development of immunotolerance[178] of the implanted graft and, potentially, to delay the administration of the nephrotoxic calcineurin phosphatase inhibitors. Infusion of these induction antilymphocyte antibody agents (alemtuzumab [Campath], antilymphocyte globulin [equine] [Atgam], and antithymocyte globulin [Thymoglobulin]) cause a cytokine release. This cytokine response, which includes fever, chills, rigors, and malaise, can be attenuated by pretreatment with acetaminophen, corticosteroids, and diphenhydramine.[178,179]

Anesthetic Induction

Induction of anesthesia can involve IV or inhalational agents. Succinylcholine may be used in the absence of contraindications such as hyperkalemia (see Chapter 7). One should not assume immediate resumption of renal function by the new graft. Because renal failure affects both protein binding and volume of distribution, anesthetic agents and adjuncts should be titrated to effect. Preferential use should be made of drugs that undergo organ-independent elimination (cisatracurium, remifentanil), do not rely exclusively on the kidney for metabolism (propofol), have

metabolites that are inactive (midazolam, fentanyl), or do not depend on renal elimination (morphine-6-glucuronide). Drug metabolites that are eliminated through the kidney and are toxic (i.e., meperidine) should be avoided entirely. Although rocuronium is excreted in the urine and bile, children with renal failure do not have an increased sensitivity to the drug. The onset of action of rocuronium is delayed in renal compromise, but duration of action is similar to normal children.[180]

Monitors and Vascular Access

Standard monitors, including invasive arterial and central venous catheters if indicated, should be placed after induction of anesthesia. The need for vascular access should reflect third-spacing requirements and the potential for brisk blood loss inherent in a long intraabdominal procedure in which the surgeon will be directly accessing large vessels. Urine output may not reflect intravascular volume status secondary to native renal dysfunction, discontinuity between the grafted organ and the urinary catheter, or polyuria in the reperfused graft.[166,167] Smaller-sized children will have the most severe fluid shifts and will be the most vulnerable to graft hypoperfusion. In addition, the use of adult donors in small infants sequesters a disproportionate amount of the infant's blood volume and CO,[166,167,181,182] necessitating large amounts of fluids or blood transfusion to adequately perfuse the transplanted organ. Therefore central venous and arterial catheters to monitor intraoperative and postoperative pressures are extremely useful.[166,167,182]

Maintenance of Anesthesia

Combined general-regional techniques have been used, but they have been associated with larger intraoperative fluid requirements and the need for IV opioid supplementation in half the patients.[183] Virtually all combinations of anesthetic agents and anesthetic adjuncts have been used. A hypnotic drug supplemented with an opioid to minimize the inhalational anesthetic requirements is common. Avoiding nitrous oxide in a long intraabdominal case is prudent. One nonrandomized, single-center study of 240 patients reported similar creatinine values in patients anesthetized with sevoflurane and isoflurane with slightly greater blood urea values and reduced urine volumes in the sevoflurane patients.[184] However, no negative outcomes data exist for the use of sevoflurane in renal transplant recipients.[184,185]

The anesthetic management plan should take into account hemodynamic conditions necessary for adequate perfusion of the donor organ. Optimal hemodynamic conditions for reperfusion are more important when a large size discrepancy exists between the native organ and the graft. The extreme of this situation would be in the infant receiving an adult graft. In children, recommendations for CVP range from 8 to 12 cm H_2O to 16 to 20 cm H_2O,[175,182] with most centers using a pressure in the middle.[167] Some authors suggest a systolic blood pressure in excess of 120 mm Hg[167] and MAP greater than 65 to 70 mm Hg.[167,186] In the smaller child, blood sequestration in the graft will constitute a significant portion of the patient's total blood volume,[167,182,186] and the anastomosis will likely require the clamping, and subsequent unclamping, of the aorta. Both preload supplementation with blood, crystalloid, and colloid, and possible dopamine infusion to optimize CO may be necessary.[167,186] Furosemide and mannitol are administered at the completion of the vascular anastomoses to promote a diuresis. Sodium bicarbonate is also administered after aortic unclamping to attenuate the underlying acidosis,[166–168,187] which worsens during the procedure. Frequent monitoring of the patient's blood gas and electrolytes is essential to detect the possibility of hyperkalemia. Hyperkalemia can be treated with hyperventilation, calcium and bicarbonate, glucose and insulin, and β-adrenergic agents. Avoidance of blood products is desirable, as patients with more than five lifetime transfusions are at increased risk of ATN, but transfusion may be necessary in an infant receiving an adult kidney. Although anemia should be avoided in the chronic management of the renal transplant patient, an optimal hematocrit in the immediate postoperative period has not been identified.

Immediate Postoperative Management

In the immediate postoperative period, maintenance of the child's blood volume remains important. Most patients can be extubated in the operating room. In small children, volume resuscitation required to adequately perfuse the graft may preclude early extubation.[168,175,182,183] Maintenance of an adequate blood volume continues into the postoperative period, where usually copious urine output is replaced milliliter for milliliter.[166–168,176,182] Prevention of graft hypoperfusion and subsequent ATN potentially prevents acute rejection,[171] as ATN in the early postoperative period is a major risk factor for graft loss.[188,189] Maintenance of the circulating blood volume continues to be important even in the late postoperative period.

LONG-TERM ISSUES

Much has been accomplished in preservation of graft function for kidney transplant patients. Unfortunately, cardiovascular morbidity, infection, and malignancy are the major long-term concerns. Almost half of renal transplant recipients die with a functioning graft.

Infection

Increased success in immunotolerance for transplant recipients places the patient at risk for opportunistic infections. After the first 5 months, infection is now a greater cause of hospitalization in the transplanted patient than acute rejection. In particular, fungal infection is a significant risk for graft loss.[189,190] Epstein-Barr virus (EBV)-related adenotonsillar hypertrophy is common in the transplant population, occurring in 11 of 16 patients in one series.[191] Risk factors for EBV-related adenotonsillar hypertrophy include young age and seronegativity at time of transplant.[192,193] Post-transplant lymphoproliferative disorder (PTLD), a result of EBV infection, is common, occurs earlier in the renal transplant population (1%–2% within the first 5years after transplant) but is not a contraindication to later retransplantation.[194–197]

Malignancy

Malignancy is a major concern after renal transplantation in children. The incidence of malignancy is estimated to be 10 times greater than that of the general pediatric population. The crude estimate is about 2.5%, with greater than 82% lymphoproliferative in nature.[142]

Summary

Anesthetic management of the pediatric renal transplant patient may be complicated by many factors. Impaired renal function may be present before and after transplant. Comorbidities because of impaired renal function are numerous and may require altered anesthetic management. Although the renal transplant patient has a lifetime of medical issues, the continued function of the transplanted kidney allows for near-normal function, growth, and development. Therefore the ultimate goals of management are the preservation of the graft, thereby improving the quality of life.[198]

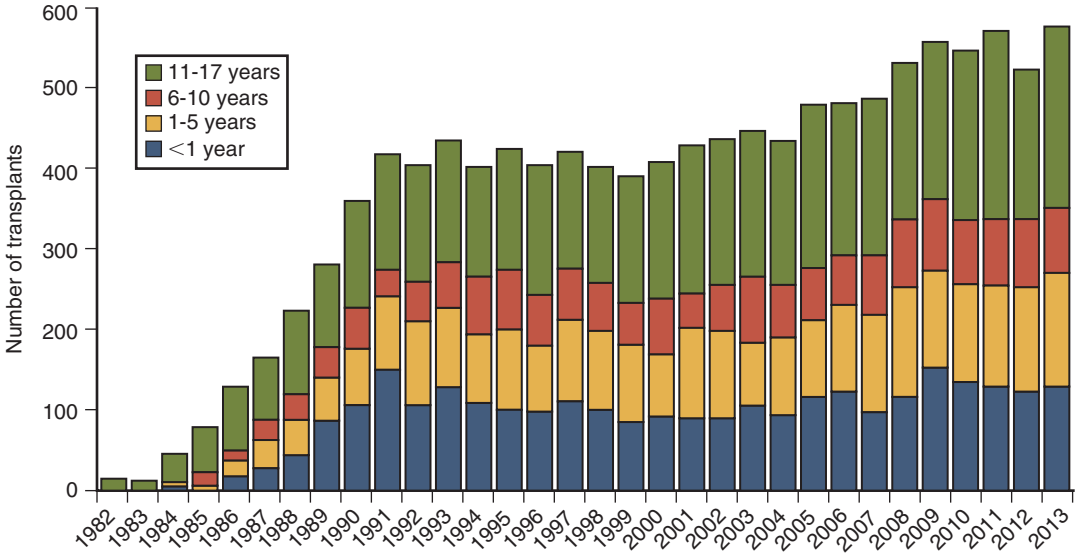

FIGURE 31.5 Age distribution of pediatric heart recipients by year of transplant. (Figure 1 from Dipchand AI, Rossano JW, Edwards LB. The Registry of the International Society for Heart and Lung Transplantation: Eighteenth Official Pediatric Heart Transplantation Report—2015; focus theme: early graft failure. *J Heart Lung Transplant.* 2015;34[10]:1233–1243.)

Cardiac Transplantation

Adrian Kantrowitz performed the first heart transplant in an infant in 1967.[199] Since that time, pediatric heart transplantation has matured considerably and is now an established treatment for children with CHD and heart failure unresponsive to other therapy. The indications for pediatric cardiac transplantation continue to evolve; however donor organ availability remains the major limiting factor.[200,201] Improved graft and child survival, fewer side effects, and an improved quality of life are the result of advancements in immunosuppression coupled with a better understanding of rejection. Unfortunately, infection, rejection, and posttransplant neoplasia continue to be the major causes of death.

DEMOGRAPHICS AND EPIDEMIOLOGY

Cardiac transplantation is a valuable treatment option for a broad range of causes of pediatric heart failure. The distribution of pediatric heart transplant recipients by age has remained stable for over 20 years with approximately 24% of the pediatric recipients younger than 1 year of age, 23% between 1 and 5 years, 15% between 6 and 10 years, and 38% between 11 and 17 years (Fig. 31.5).[202] The most common indication for transplantation in children varies by age group. In infants younger than 1 year of age, the primary indication for cardiac transplantation is a severe structural congenital cardiac defect, and the secondary indication is cardiomyopathy.[202] Cardiomyopathies represent the most common indication for heart transplant in children between 1 and 17 years of age, whereas CHD represent a decreasing proportion with increasing age (Fig. 31.6).[202]

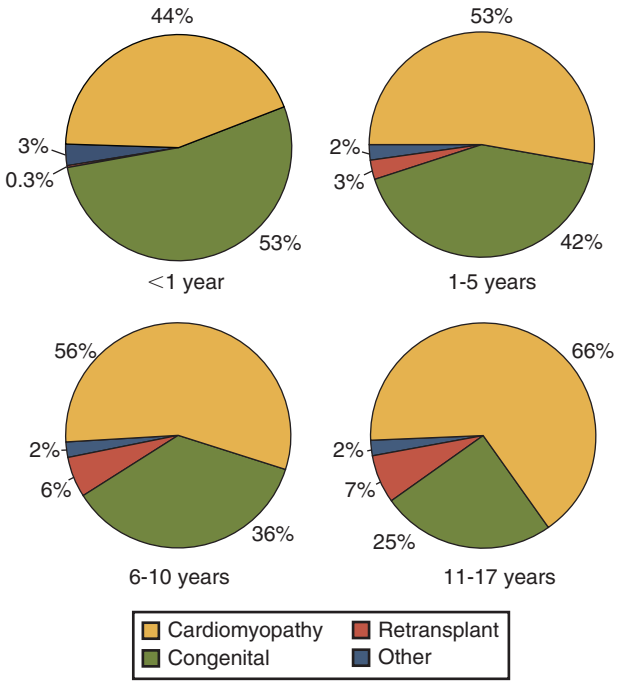

FIGURE 31.6 Diagnosis in pediatric heart transplant recipients by age group. (Figure 3 from Dipchand AI, Rossano JW, Edwards LB. The Registry of the International Society for Heart and Lung Transplantation: Eighteenth Official Pediatric Heart Transplantation Report—2015; focus theme: early graft failure. *J Heart Lung Transplant.* 2015;34[10]:1233–1243.)

PATHOPHYSIOLOGY OF THE DISEASE

The key to safe perioperative management of children presenting for heart transplantation requires an understanding of the basic cardiac anatomy and pathophysiology. Many transplant recipients with CHD have underlying lesions that alter the balance between systemic and pulmonary blood flow. The hemodynamic effects that accompany normal anesthetic management can radically alter this balance and thereby result in the recipient's deterioration. Other recipients have marginal CO secondary to their underlying myopathies or structural defects that hinder normal myocardial function.

CONGENITAL HEART DISEASE

This group of children includes those with complex lesions for which no option for palliation exists, children with end-stage heart failure after surgical repair of congenital heart defects, children with failed palliation for single-ventricle physiology (Fontan type), and neonates with hypoplastic left heart syndrome (HLHS). This population of patients is growing in incidence at U.S. centers that perform large-volume heart transplants, which are defined as those performing greater than 10 pediatric heart transplants per year.[202] Patients with CHD that undergo transplantation may have undergone surgical palliation with successful early results. They present later in life with dilated cardiomyopathies secondary to long-standing valvular regurgitation, ventricular outflow tract obstruction, or dysrhythmias. The majority of these children have single-ventricle physiology and are referred to as "failing the Fontan" procedure.[203–207] Although the right ventricle has been shown to be capable of adapting to work as the "systemic" ventricle in cases of HLHS or in children who have undergone an "atrial-type" switch operation for transposition of the great vessels, systemic right ventricles fail with time and develop both systolic and diastolic dysfunction. Transplantation is indicated in these children when they have acute decompensated heart failure refractory to medical therapy and not amenable to other reparative surgery or palliation.

DILATED CARDIOMYOPATHY

Dilated cardiomyopathy is the most common cardiomyopathy and reason for heart transplantation in children. The etiology is often unknown, but causes include infectious, drug-induced, ischemic, metabolic (disorders of fatty acid, amino acid, glycogen and mucopolysaccharide metabolism), or neuromuscular/genetic/mitochondrial disorders.[208,209] Dilated cardiomyopathy is characterized by systolic dysfunction and ventricular dilation with signs and symptoms of congestive heart failure. Predictors of poor outcome include a family history of cardiomyopathy, syncope, ventricular arrhythmia, left ventricular end-diastolic pressure greater than 25 mm Hg, and left ventricular ejection fraction less than 30%.

HYPERTROPHIC CARDIOMYOPATHY

Hypertrophic cardiomyopathy is a concentric thickening of the left ventricular wall not caused by a downstream obstruction that can lead to both a fixed and a dynamic obstruction to left ventricular outflow (see Chapter 16). A large septal muscular prominence can lead to mitral regurgitation secondary to abnormal systolic anterior motion of the mitral valve leaflets. The majority of hypertrophic cardiomyopathy is idiopathic (>70%), whereas inborn errors of metabolism (e.g., Pompe disease), malformation syndromes (e.g., Noonan, Beckwith-Wiedemann syndromes), and children with neuromuscular disorders account for the remainder.[210] Those who present as infants with hypertrophic cardiomyopathy have the worst outcome. If there is evidence of obstruction, more than 25% of infants will manifest congestive heart failure with symptoms of a failure to thrive and feeding intolerance. Risk factors for sudden death include a family history of sudden death,[211,212] marked concentric left ventricular wall thickness, age at presentation, and a smaller fractional shortening *z* score.[213] The indication for transplantation is a progression to dilated or restrictive cardiomyopathy.

RESTRICTIVE CARDIOMYOPATHY

Restrictive cardiomyopathies are uncommon disorders with generally poor prognoses that are associated with infiltration of the myocardium, such as glycogen storage disease, amyloidosis, mucopolysaccharidosis, hemochromatosis, sickle cell disease,[214] and sarcoidosis. Myocardial infiltration results in diastolic dysfunction and diminished stroke output. Endocardial fibroelastosis also causes a restrictive cardiomyopathy and an increased pulmonary vascular resistance (PVR).[215,216] The increased PVR is secondary to an increased left ventricular end-diastolic pressure with associated increases in pulmonary arterial pressure. The poor survival rates after diagnosis of restrictive cardiomyopathy prompt early consideration for transplantation.[217]

REPEAT TRANSPLANTATION

Repeat transplantation is not common in pediatrics, representing only 3.6% of all transplants in 2013[202]; the median age for retransplant is ~10 years after the primary transplant.[218] The indications for cardiac retransplantation are for patients with at least moderate graft vasculopathy with or without abnormal ventricular function.[200] Overall survival is less compared with primary transplantation.[219]

CONTRAINDICATIONS

Contraindications to pediatric cardiac transplantation include multiple severe congenital anomalies, marked prematurity (<36 weeks), low birth weight (<2 kg), ectopia cordis, diffuse pulmonary artery hypoplasia, pulmonary venous hypoplasia, active malignancy, active infection, severe metabolic disease, and irreversible noncardiac end-organ damage. These contraindications are considered by some to be relative, rather than absolute, contraindications to cardiac transplantation. For instance, combined heart/liver, heart/lung, heart/kidney transplants are not uncommonly performed,[220,221] whereas advances in HIV treatment have led to the consideration of transplantation in HIV-positive patients.[200,222] PVR, and the potential reversibility of an elevated PVR, is usually assessed during cardiac catheterization. Although the upper limit of PVR associated with successful cardiac transplantation has not been established in children, most centers generally limit transplantation to those with a PVR less than 6 Wood units/m^2 or a transpulmonary pressure gradient of 15 mm Hg or less.[223] Some centers accept an increased PVR; however, it is understood that there is a greater risk of early mortality from right ventricular failure.[224,225] Finally, severe psychosocial problems that may impede proper postoperative care, the lack of reliable caretakers, and an unstable family structure are critical factors in the decision to offer transplantation as a treatment option.

WAIT-LIST AND DONOR SELECTION

The wait-list mortality rate for pediatric heart transplant recipients was 17% in the United States between 1999 and 2006.[226] Infants experience the greatest wait-list mortality with risk factors that include weight less than 3 kg, high level of invasive support, and children with CHD requiring prostaglandin infusion.[227] Several attempts to decrease the wait-list time and mortality implemented in July 2016 by UNOS and OPTN included redefining the criteria for pediatric heart status 1A and 1B criteria, as well as criteria and allocation priority for ABO-incompatible (ABOi) heart transplants.[228] The immaturity of the infant immune system and the lack of production of ABO antibodies during the first 3 to 6 months of life provide a unique opportunity for ABOi heart transplantation. Multiple studies have documented similar survival and freedom from rejection similar to ABO-compatible donors;[229] ABOi heart transplantation has succeeded in reducing wait-list time mortality in Canada,[230] but this result has not yet been documented in the United States.[227,231] In an effort to increase infant donor heart utilization, UNOS/OPTN changed the isohemagglutinin

titer to 1:16 from 1:4 or less for status 1A/1B candidates who are 1 year or older but registered before their second birthday.

Donor selection for pediatric heart transplantation is often complicated by difficult social settings associated with the death of the donor. The increasing frequency of donation after circulatory determination of death also creates a potentially controversial mechanism to increase the donor pool.[232,233] Donor size is also an important factor to consider in pediatric cardiac transplantation. Donor-to-recipient weight ratios up to 3.0 have been used successfully. In a comparison with more equally matched donor/recipient weight ratios, children who received hearts from oversized donors had no differences in ICU ventilator days, fractional shortening as assessed by echocardiography, ability to close the chest, or duration of inotropic support.[234] In contrast to the use of oversized donor organs, undersized donor organs were associated with an increased rate of donor organ failure. Recipient PVR is a major determinant for appropriate donor selection, and larger donor hearts should be considered for those with increased PVR to permit the right ventricle to compensate for the increased afterload.[235] Myocardial preservation of the donor organ is aimed at minimizing the ischemia time. Ischemic times of 6 hours were thought to be ideal, but pediatric allograft ischemic times have been extended to 8 hours with few adverse consequences.[236,237]

PREOPERATIVE EVALUATION

A comprehensive, multidisciplinary evaluation of a potential cardiac allograft recipient is required to determine the recipient's suitability for transplantation. This evaluation includes an assessment of the child's underlying cardiopulmonary, hepatic, renal, neurologic, infectious disease, and immune system status, as well as socioeconomic and psychosocial function (Table 31.4).

Assessment of cardiopulmonary function usually begins with a thorough history with attention to exercise tolerance, oxygen requirements, and need for diuretics and inotropic support. Examination of the ECG, chest radiographs, echocardiograms, and Holter monitors may be helpful in the discovery of pleural or pericardial effusions, conduction disturbances, cardiac function, and arrhythmias. Radionuclide angiography may be useful in defining systemic ventricular dysfunction in children with complex cardiac morphology. The pretransplant assessment ultimately includes cardiac catheterization with angiography. The anatomy and hemodynamics of the recipient must be carefully delineated because these factors influence anesthetic management, surgical donor harvesting, and recipient transplant technique. For instance, in children with unrepaired HLHS, the donor harvest team must harvest a large segment of donor aorta to facilitate reconstruction of the recipient aorta. Determination of the pulmonary vascular resistance index (PVRI), transpulmonary gradient (TPG), and reactivity of the pulmonary vascular bed to pharmacologic manipulation is crucial to the assessment of suitability for cardiac transplant:

$$\text{PVRI (units/m}^2\text{)} = \text{PAP (mm Hg)} - \text{PAWP (mm Hg)/CI (L/min/m}^2\text{)}$$

$$\text{TPG (mm Hg)} = \text{PAP (mm Hg)} - \text{PAWP (mm Hg)},$$

where PAP is the mean pulmonary artery pressure, PAWP is the mean pulmonary artery wedge pressure, and CI is the cardiac index.

An endomyocardial biopsy can identify acute myocarditis and myocardial infiltrates. Pulmonary function studies may be useful in older children with chronic lung disease.

Laboratory evaluation should include serum electrolytes, complete blood cell count with differential, coagulation profile, viral titers for possible latent viral infections such as cytomegalovirus (CMV) and EBV, and metabolic or genetic workups. Donor matching is based on ABO typing, although transplantation of ABOi hearts is an increasingly used option in infants[238,239] and is also being offered to older children.[240,241] The use of triple-volume

exchange transfusions also minimizes the potential reaction to maternally transmitted preformed ABO antibodies.[242]

The recipient's blood is also screened for antibodies against sera of random blood donors and, if reactive, a serum crossmatch with the donor may be performed. Panel reactive antibodies are preformed circulating human leukocyte antigen (HLA) alloantibodies that, in high titers, are associated with diminished graft survival.[243–245] These antibodies arise from the use of homograft material in CHD patients and homologous blood products; thus blood products should be avoided if possible in the pretransplant period. HLA antibodies are divided into complement-fixing and non–complement-fixing antibodies, with complement-fixing antibodies more likely involved with acute allograft antibody-mediated rejection.[246] The C1q single-antigen bead (SAB) assay is a useful tool to detect only complement-fixing antibodies.[247] The presence of C1q SAB-positive donor-specific antibodies correlates with antibody-mediated rejection.[248] Treatments to reduce panel reactive antibodies have included IV immunoglobulin, cyclophosphamide, and plasmapheresis.[249] Rituximab, an anti-CD20 antibody that targets B-cells, and bortezomib, a proteasome inhibitor directed against plasma cells, can be used to reduce circulating antibodies.[250,251]

The mean time from listing for transplant to actual surgery is about 3 months but varies with the child's age, blood group, and list status. UNOS has developed allocation procedures that give priority to the most urgently ill children (Table 31.5). Status 1A patients are the most ill, and are either supported by continuous mechanical ventilation, have ductal-dependent circulation, with CHD requiring IV inotrope, or any child who requires the assistance of a mechanical circulatory support device. Status 1B patients do not qualify for pediatric status 1A but require an infusion of one or more inotropic agents or they are less than 1 year old with a diagnosis of hypertrophic or restrictive cardiomyopathy. Medical stabilization while on the wait-list frequently includes the use of diuretics, inotropic agents, arrhythmia therapy, oxygen or subatmospheric oxygen, and mechanical ventilation if warranted. β-Blockade therapy (carvedilol) is also used in the management of children with dilated cardiomyopathy and chronic heart failure.[252,253] Those with severe chamber enlargement, arrhythmias, and low CO may require systemic anticoagulation to prevent thrombus formation and systemic embolization. Implantable defibrillators have been effective in children large enough for these devices, and biventricular pacing is showing promise as well.[254,255]

TABLE 31.5 OPTN/UNOS Heart Allocation Policy

Pediatric Status 1A Requirements
1. Continuous mechanical ventilation and admitted to the hospital where the candidate is registered
2. Assistance of an intraaortic balloon pump and admitted to the hospital where the candidate is registered
3. Ductal dependent pulmonary or systemic circulation, with ductal patency maintained by stent or prostaglandin infusion and admitted to the hospital where the candidate is registered
4. Congenital heart disease diagnosis, requiring infusion of multiple intravenous inotropes or a high dose of a single intravenous inotrope, and admitted to the transplant hospital where the candidate is registered
5. Assistance of a mechanical circulatory support device
Pediatric Status 1B Requirements
1. Infusion of one or more inotropic agents but does not qualify for pediatric status 1A
2. Less than 1 year old at the time of the candidate's initial registration and has a diagnosis of hypertrophic or restrictive cardiomyopathy

Children with end-stage myocardial failure will require mechanical circulatory support as a bridge to transplantation (see Chapter 21). The proportion of children bridged to transplant from mechanical circulatory support has steadily increased from 22% in 2005 to 34% in 2013.[202] Extracorporeal membrane oxygenation (ECMO) remains a time-limited bridge to transplant, whereas ventricular assist devices (VADs) such as the Berlin Heart EXCOR (Berlin Heart GmbH, Berlin, Germany) in infants allows for more prolonged support with fewer complications. The Berlin EXCOR regulatory database shows a median duration of support of 40 days, with 75% survival at 12 months.[256] Intracorporeal continuous flow devices such as the HeartMate II (Thoratec, Pleasanton, CA) and HeartWare HVAD (HeartWare Systems, Framingham, MA) are used for adolescents and larger children. The use of these mechanical circulatory support devices has improved survival on the wait-list; however, sepsis, neurologic injury, bleeding, and thromboembolic events are also serious complications of mechanical circulatory support.[257,258] Transplantation from ECMO continues to be associated with perioperative and early posttransplant mortality; however, children with transplantation from mechanical circulatory support devices such as a VAD have survival similar to those undergoing transplantation without mechanical circulatory support.[202,259]

CHD is the primary indication for cardiac transplantation in infants younger than 1 year of age, and many of these recipients will have HLHS. The patency of the ductus arteriosus must be maintained with prostaglandin E_1 initially as a continuous infusion and perhaps by stenting the ductus in the catheterization laboratory later if a suitable donor organ is not found. Alteration of flow across the atrial septal defect can be addressed as well by the interventional cardiologist (see Chapter 22). If the balance between systemic and pulmonary blood flow cannot be managed medically, pulmonary artery banding may be necessary to reduce pulmonary over-circulation while waiting for a donor organ.

SURGICAL TECHNIQUE

The original orthotopic technique devised by Lower and Shumway in adults was popular for many years in pediatric cases when the anatomy was straightforward.[260] This technique avoided individual systemic and pulmonary venous anastomoses by leaving a large cuff of right and left atrial recipient tissue behind and anastomosing the donor right and left atria to these cuffs. The resulting atrial chambers were a combination of donor and recipient atria that contracted asynchronously. Because the atrial contribution to CO may be augmented with total cardiac transplantation, most centers have converted to the "bicaval" technique with a modification to use the standard left atrial anastomosis.[261–263] This technique improves sinus node function, causes less tricuspid regurgitation, and improves exercise tolerance.[264,265]

Cardiac transplantation in children with CHD may require surgery of greater complexity involving reconstruction of the great vessels or alterations in venous anastomoses. It is important that the donor-harvesting team understand the recipient's anatomy and the potential harvest needs that may require large portions of aorta, pulmonary arteries, and venae cavae. In children with HLHS who require aortic arch reconstruction, deep hypothermic circulatory arrest may be necessary.[266–268]

The recipient is placed on cardiopulmonary bypass (CPB) after median sternotomy with aortic and bicaval cannulation.

Cannulation may be modified depending on the cardiac anatomy encountered. The aorta is cross-clamped, and both the aorta and the pulmonary artery are divided at the level of their semilunar valves. The superior and inferior vena cavae are transected, preserving a cuff of atrial tissue on each to facilitate the anastomoses. The interatrial groove is prepared, and an encircling left atriotomy is performed and the recipient heart is removed from the field. The donor organ is prepared and brought to the field. The left atrial anastomosis is completed first, followed by the aortic anastomosis. A vent is placed in the left ventricular cavity for decompression and evacuation of air as the caval anastomoses are completed while the child is rewarming. The cross-clamp is removed, and the donor heart is reperfused while the pulmonary arterial anastomosis is completed. Ventilation is resumed, and the child is separated from CPB after return of cardiac function is documented by TEE. Epicardial pacing wires are placed, mediastinal drainage tubes are positioned, and the chest is closed.

INTRAOPERATIVE PROBLEMS AND MANAGEMENT

Some children listed for cardiac transplantation may be hemodynamically stable and living at home. In these children, preoperative fasting and NPO status may be an issue when a donor organ becomes available. The anesthesiologist must carefully assess the relative risks of a full stomach compared with the potential complications associated with an unexpected difficult airway in a child undergoing a rapid-sequence induction. It is equally likely that the pediatric recipient is hospitalized and requires a host of treatments designed to promote hemodynamic stability while a donor organ is sought. These children have minimal cardiovascular reserve. Anesthetic agents, positive-pressure ventilation, and surgical stress frequently result in hemodynamic instability. Anesthetic preparation should include the immediate availability of a variety of medications for the perioperative manipulation of myocardial function and hemodynamics. Vasoactive drugs and inotropic agents such as epinephrine, phenylephrine, dopamine, dobutamine, isoproterenol, milrinone, nitroprusside, and nitroglycerin should be readily available.[269] For children with underlying CHD, the anesthesiologist needs to understand the child's underlying pathophysiology. The anesthetic management before CPB is similar to that for nontransplant cardiac surgery. For children with end-stage myocardial dysfunction, the sympathetic nervous system is chronically activated with downregulation of the cardiac β_1-receptors and an impaired response to β-agonists.[270] Reduced renal perfusion (reduced filtration) stimulates the renin-angiotensin system, leading to increases in vasoconstriction, venoconstriction, and increased intravascular volume. These compensatory changes further aggravate the congestive heart failure by increasing preload and afterload. A dysfunctional, dilated myocardium is very sensitive to changes in preload, afterload, heart rate, and contractility. Both systolic and diastolic myocardial function are impaired, and a high mean atrial pressure is needed to ensure adequate ventricular filling volume. Increasing heart rate results in a decreased diastolic filling time and, therefore, a diminution in stroke volume because of the poor systolic and diastolic ventricular function, atrial pressure increase, and atrial enlargement. There is a loss of preload reserve, resulting in CO becoming more dependent on the heart rate. Finally, small increases in afterload result in an increased end-systolic volume, decreased stroke output, and a further decrease in CO. Naturally, dysrhythmias are poorly tolerated in these children.

Coordination of the arrival of the child to the operating room with the donor team ensures the briefest possible ischemic time for the donor organ. Premedication is best administered under monitored conditions. If the child was receiving supplemental oxygen, it should be continued during the preinduction period. Before induction, monitoring devices such as ECG, noninvasive blood pressure cuff, and pulse oximeter are applied. Meticulous airway management is critical because hypoxemia and hypercarbia may alter PVR and further depress CO. A wide variety of anesthetic agents have been used depending on the nature of the cardiac disease and the risk of pulmonary aspiration. After induction, invasive monitoring does not differ from that used during routine pediatric cardiac open-heart surgery. Some centers avoid right internal jugular vein cannulation because that vessel may be repeatedly accessed for posttransplant endomyocardial biopsy. TEE is useful to assess graft function, mechanical issues, and pulmonary hypertension. In children, TEE has been shown to be cost-effective and clinically useful.[271] Many experienced centers do not use pulmonary artery catheters routinely because the value of the information gained does not warrant the additional risk. In children who have undergone multiple cardiac operations, the potential risks of reoperation should be addressed and include the need for adequately sized vascular catheters, the availability of blood products and a rapid transfusion device in the operating room, the preparation for alternate cannulation sites, and the use of antifibrinolytics. The use of ultrafiltration during CPB may be beneficial by removing free water, hemoconcentrating the red blood cells and coagulation factors, and modulating the inflammatory response.[272–277]

Anesthesia is generally maintained with opioids, benzodiazepines, isoflurane, and a nondepolarizing neuromuscular blocking drug.[269] In children with CHD, this anesthetic technique preserves CO better than some inhalational agents, provided the heart rate is maintained.[278] In the preparation for termination of CPB, it is critical that the hemodynamics are optimized. A stable cardiac rhythm and acceptable heart rate are desirable. Chronotropic support using IV therapy with β-adrenergic agents such as epinephrine or the use of epicardial pacing may be needed to maintain an appropriate heart rate between 120 and 150 beats/minute. The denervated transplanted heart does not respond in the normal fashion to hypotension. Medications with indirect cardiac effects such as atropine, glycopyrrolate, or ephedrine will likewise be ineffective. Direct-acting medications such as dopamine, dobutamine, epinephrine, or isoproterenol are required if inotropic or chronotropic support is needed (Table 31.6).[279] Some children benefit from vasodilator infusions to improve left ventricular stroke volume and CO.[280] The use of inotropic agents to separate from CPB and provide early postoperative stability is common, and the choices are based largely on the perceived balances between pulmonary and systemic vascular resistance and myocardial dysfunction to blood pressure and CO.[269] Ventilation should be managed to ensure mild respiratory alkalosis and adequate oxygenation. Factors that potentially increase PVR such as hypothermia, acidosis, hypercarbia, hypoxemia, increased adrenergic tone secondary to light anesthesia, and polycythemia should be eliminated. Children with increased PAP before bypass show a greater response to ventilatory changes than those without increased PAP. In addition, children with CHD and associated pulmonary hypertension may develop severe pulmonary hypertension in response to hypoxemia.[281–283] The narrow range of afterload that the donor right ventricle is capable of handling is critical; if success in managing the pulmonary hypertension with conservative methods fails, more aggressive pharmacotherapy is warranted. The use of prostaglandin, prostacyclin, nitroglycerin, high-dose milrinone, calcium channel blockers, sildenafil, and inhaled NO

TABLE 31.6 Properties of Vasoactive Drugs After Heart Transplantation

Drug	Peripheral Vasoconstriction	Cardiac Contractility	Peripheral Vasodilation	Chronotropic Effect	Arrhythmia Risk

(iNO) have all been effective in treating pulmonary hypertension in children (see Chapter 18).[284–296] In extreme cases, mechanical assist devices or ECMO have been used (see Chapter 21).[297,298]

Dysrhythmias may be common in the postbypass period and, depending on the technique of implantation, there may be two independent P waves on the ECG, one from the recipient sinoatrial node and the other from the donor sinoatrial node. It is only the donor sinoatrial node that transmits impulses to the atrioventricular node and thus to the ventricle. The most common dysrhythmias are junctional rhythms, underscoring the utility of direct-acting β-agonists and epicardial atrioventricular sequential pacing. This denervated state results in the loss of the baroreceptor reflex, forcing CO to become primarily dependent on venous return and circulating catecholamines and thus unable to respond acutely to changes in the circulating blood volume and blood pressure.[299,300]

After separation from CPB, hemodynamic stabilization, and control of surgical bleeding, protamine sulfate is administered slowly to reverse anticoagulation. Risk factors for hypotension in children after protamine administration include female sex, larger protamine doses, and smaller heparin doses.[301] Transfusion of blood products should be guided by the balance of the need weighed against the associated risks of administration. Significant acid-base and electrolyte disturbances may be associated with large volume transfusions. These disturbances may be decreased by washing the cells before transfusion.[302–304] Donor blood should be screened for CMV and, ideally, CMV-negative recipients should receive blood screened negative for CMV.[305] Leukocyte reduction by filtration may be associated with a diminished risk of exposure to CMV through transfusion.[306,307] Another concern associated with transfusion in cardiac transplant recipients is the risk of transfusion-associated graft-versus-host disease (TAGVHD). This results from active T lymphocytes in the transfused blood of a recipient who is unable to reject them, such as a neonate, those undergoing chemotherapy, and the otherwise immunocompromised child.[308,309] To limit the risk of TAGVHD in cardiac transplant recipients, some centers routinely gamma-irradiate cellular blood products before administration. At recommended doses, gamma irradiation has an insignificant effect on platelet, red blood cell, or granulocyte function but it may increase the potassium concentrations (see Chapter 12).[310]

Transport of the child from the operating room proceeds as in any other open-heart procedure. In selected recipients with excellent allograft function and hemodynamics, extubation of the trachea is possible in the operating room or within a few hours of arrival in the ICU. It is important that these children are comfortable but otherwise ventilating adequately to prevent atelectasis, hypoxemia, or hypercarbia that may increase PAP and thus strain the donor right ventricle. Sedative agents such as dexmedetomidine may facilitate early extubation in these children.[311] Other children may require sedation and mechanical ventilation because of hemodynamic instability or delayed sternal closure, particularly if a large donor-to-recipient size mismatch is present.

IMMEDIATE POSTOPERATIVE MANAGEMENT

Early postoperative management consists primarily of maintaining hemodynamic stability. Infusions and volume needs are adjusted to maintain an optimal balance of preload, afterload, CO, and peripheral perfusion. Attention should be directed toward maintaining normal acid-base and electrolyte balance. In some children, pulmonary hypertension remains a serious concern and management of sedation, ventilation, inotrope infusions, and pulmonary vasodilator administration is required to optimize right ventricular function. Ventilation modes may need to be adjusted to reduce the mean intrathoracic (airway) pressure. Additional approaches for management of right ventricular function are illustrated in Fig. 31.7. Renal dysfunction continues to be a major source of morbidity and mortality after cardiac transplantation; the UNOS database showed a 7% incidence of perioperative renal failure after pediatric heart transplants.[312] There was a significant risk for decreased posttransplant survival rates in children with posttransplant renal failure. Risk factors for developing posttransplant renal failure include the use of ECMO and the need for mechanical ventilation and inotropic support at the time of transplant listing. A peritoneal dialysis catheter placed during transplantation can be used to reduce ascites and improve ventilatory mechanics in those with right-sided heart dysfunction and in the treatment of renal insufficiency. Arrhythmias in the postoperative period may herald rejection.

Induction of immunosuppression can begin with corticosteroids, antithymocyte immunoglobulin, or IL-2 receptor antagonists. Induction therapy has increased from 59% of pediatric transplant patients during the years of 2004 to 2009 to 68% from 2009 to June 2014, although there is no evidence to support improved graft survival in primary pediatric heart transplantation with induction.[202] However, transplant recipients with panel reactive antibodies greater than 50% or with CHD were found to benefit from induction immunosuppression through improved survival.[313] Maintenance therapy is guided largely by institutional experience

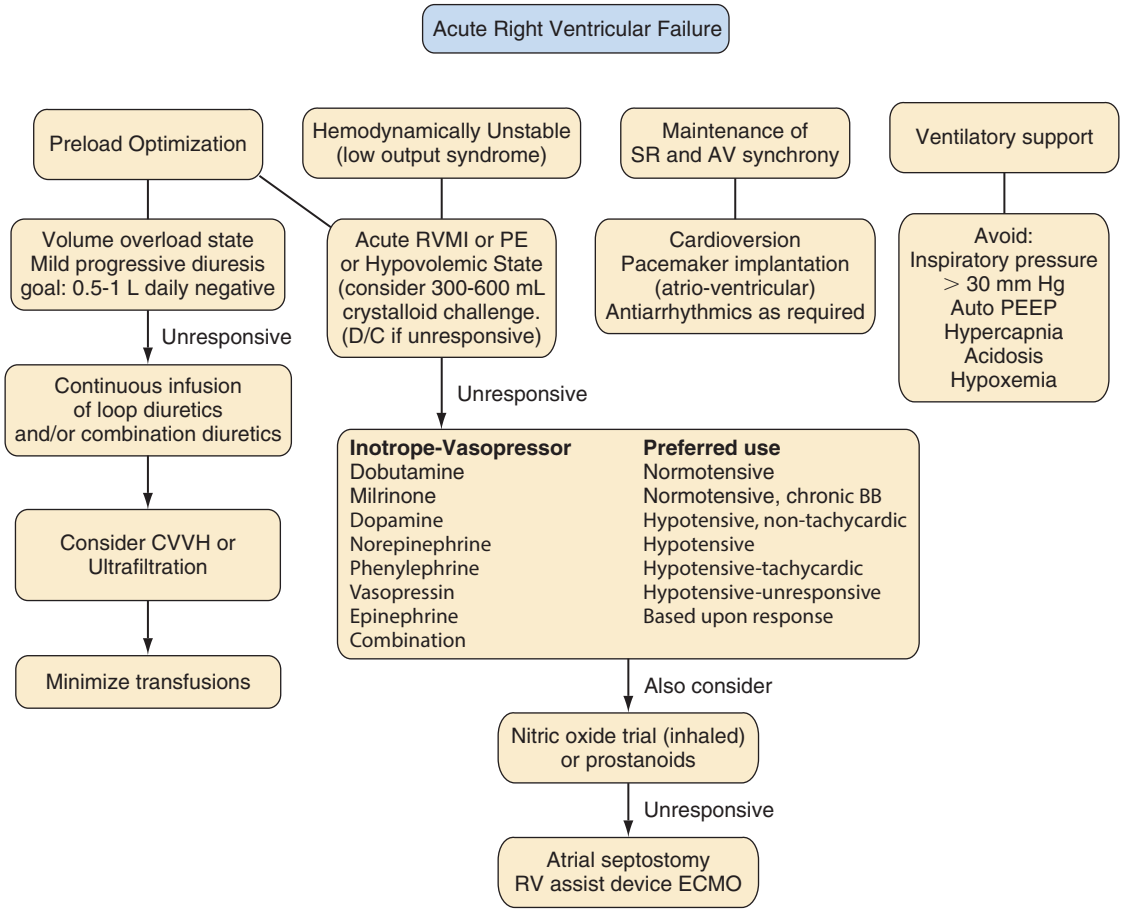

FIGURE 31.7 Management of right ventricular dysfunction. *AV,* atrioventricular; *BB,* beta blocker therapy; *CVVH,* continuous venovenous hemofiltration; *D/C,* discontinue; *ECMO,* extracorporeal membrane oxygenation; *MI,* myocardial infarction; *PE,* pulmonary embolism; *PEEP,* positive end-expiratory pressure; *RV,* right ventricular; *RVMI,* right ventricular myocardial infarction; *SR,* sinus rhythm. and the recipient's clinical profile. The goal of maintenance therapy is to prevent acute and chronic rejection while minimizing the adverse effects of immunosuppression. All maintenance regimens involve a calcineurin phosphatase inhibitor (tacrolimus more commonly than cyclosporine) along with antiproliferative agents such as azathioprine or mycophenolate mofetil (CellCept). Corticosteroids may also be used, although most centers limit or avoid their long-term use. Sirolimus (rapamycin) is a macrolide antibiotic that acts synergistically with the calcineurin phosphatase inhibitors and can be used to reduce the dose of cyclosporine or tacrolimus. Sirolimus may also inhibit the process of coronary arteriopathy.[314]

First-line therapy for acute rejection is high-dose corticosteroids. Other agents, including monoclonal and polyclonal anti–T-lymphocyte antibodies, are reserved for refractory or recurrent severe acute rejection or rejection with severe hemodynamic compromise. Recurrent moderate rejection is usually controlled with modulation of the maintenance therapy dosing.[315]

Graft failure continues to remain the major cause of death after transplantation, with the greatest mortality risk in the first year post transplant (Table 31.7).[202] Fortunately, there has been a decline in early rejection in the more recent era, decreasing from 60% to only 40% in the first year after transplant.[316] Some studies suggest that transplant before 1 year of age offers protection from episodes of acute rejection and significantly greater freedom from rejection and time to first rejection.[317] Monitoring and diagnosis of allograft rejection remain a challenge. The clinical assessment includes nursing and parental accounts of changes in the child's activity and appetite, nausea, emesis, malaise, resting heart rate 15 to 20 beats/minute above normal, and presence of ectopy. Echocardiography plays a very important role in the postoperative follow-up, especially in neonates. These studies are performed frequently, especially in the first months after transplant. Acute changes in left ventricular end-diastolic dimension, posterior wall thickness, and shortening fraction are potential signs of acute rejection.[318] Endomyocardial biopsy remains the gold standard in the diagnosis of acute cardiac allograft rejection. It provides tissue for both precise documentation of the presence or absence of rejection and allows more accurate titration of immunosuppression to avoid the adverse effects of increased use of immunosuppression based on clinical and noninvasive examinations only. Biopsy specimens are also analyzed for signs of humoral and vascular rejection. The biopsy specimen is examined for evidence of lymphocytic accumulations in the graft interstitium and

perivascular tissue, and in severe forms of cellular rejection, myocardial necrosis and polymorphonuclear cell infiltrates. Over time, it is also possible to develop chronic rejection, which is primarily a vasculopathy[319] that involves vascular inflammation with binding of IgG and/or IgM and complement. This produces a diffuse and concentric stenosis affecting the mid and distal coronary arteries and is often asymptomatic. Although annual coronary angiography is recommended, accelerated graft arteriosclerosis is underestimated angiographically.

SURVIVAL AND QUALITY OF LIFE

The survival of pediatric heart transplant recipients continues to improve. The overall median survival for pediatric heart transplant recipients is grouped by age at time of transplantation, with a median of 20.6 year for infants, 17.2 years for children with transplants at 2 to 5 years of age, 13.9 years for children with transplants at 6 to 10 years of age, and 12.4 years for adolescents with transplants at 11 to 17 years of age (Fig. 31.8).[202] Mortality in the first year after the transplant is the greatest, so the median conditional survival after 1 year is even better (Fig. 31.9). The most common causes of death in the first year after transplant include graft failure (28%), multisystem organ failure (16.6%), acute rejection (12.2%), cerebrovascular event (9.1%), and non-CMV infection (8.5%) (see Table 31.7). By 10 years after transplant, graft failure and coronary artery vasculopathy account for the majority of mortality. Patients who had transplants for the diagnosis of CHD have a greater risk for mortality after transplantation compared with those with a diagnosis of cardiomyopathy (Fig. 31.10). Other risk factors for mortality in the first year after transplant include retransplant, pretransplant ECMO support, and pretransplant dialysis.[202]

Pediatric cardiac recipients often return to the operating room for noncardiac procedures. Preoperative evaluation requires an understanding of the unique features associated with the transplanted heart, such as its denervation, risk of vasculopathy (coronary artery disease), and arrhythmias.[269] The interaction of the immunosuppressive regimens with anesthetic agents and their association with hypertension and renal dysfunction are additional considerations. Medication and monitoring choice should be tailored to the individual needs of the child to minimize anesthetic morbidity. Most medically stable cardiac transplant patients can undergo routine noncardiac surgical procedures in a similar fashion to children without transplants (see Chapter 23). It is important to remember that reflex mechanisms are impaired in the denervated heart and changes as a result of light anesthesia, hypovolemia, or contractility will be delayed until circulating catecholamines can influence the cardiac β-receptors directly.[320,321] As cardiac transplant patients live longer, the risks of coronary vasculopathy increase, with coronary ischemia becoming a major concern. Therefore

TABLE 31.7 Risk Factors for 1-Year Mortality: Pediatric Heart Transplants (January 2002–December 2015)

Cause of Death	N (493)	Percent
Graft failure	138	28
Multisystem organ failure	82	16.6
Acute rejection	60	12.2
Cerebrovascular event	45	9.1
Infection, non-CMV	42	8.5

attention to the maintenance of coronary perfusion is paramount. As in all immunocompromised patients, these children are vulnerable to infection, and strict adherence to aseptic and sterile technique is mandatory.

Pediatric Lung and Heart-Lung Transplantation

DEMOGRAPHICS AND EPIDEMIOLOGY

Pediatric lung and heart-lung transplant patients are similar and share many underlying disease management processes. These children, with end-stage pulmonary and cardiopulmonary disease, undergo a variety of pretransplant and posttransplant interventions and require special considerations in all phases of their anesthetic care. While the first adult lung transplant was performed in 1962, it was another two decades before pediatric lung and heart-lung transplantation occurred. Advances in surgical technique and immunosuppressive therapy ushered in the modern era of lung transplantation in the early 1980s. Lung and heart-lung transplantation became a well-accepted treatment for children with end-stage pulmonary and cardiopulmonary disease.[322] The first successful pediatric heart-lung transplant was performed at the Children's Hospital of Pittsburgh in 1985. Since 1988, there have been ~199 heart-lung transplants performed in the United States. Pediatric lung transplantation followed in Toronto in 1986. Since 1988, there have been 1237 lung transplants with over 1800 in adults and children performed in the United States.[323] In 2015, 23 hospitals performed 86 pediatric lung transplants and 5 centers performed 9 heart-lung transplants.[324]

Patients listed on all transplant waiting lists continually exceed donor supply. Donor identification and management are more selective for heart-lung and lung transplant candidates compared with donors for isolated heart transplants. Thoracic capacity of the lung donor should not be greater than that of the recipient because the mismatch increases risk of postoperative atelectasis and infections in the transplanted lungs.[325] While the trend is an increase in organ donations, donor supply remains the largest obstacle in transplantation. As many as one-third of children listed die before receiving lung transplantation. Patients aged 12 to 17 years have the greatest mortality of 19.7 per 100 transplant wait-list years.[326–328] The average waiting time for cadaveric lungs is 20 months for adolescents and 6 to 12 months for children younger than 2 years.

A variety of strategies, including television, radio, and print advertisements, have been used to increase donation. Everyone in the United States may declare themselves a potential donor when obtaining a driver's license. Some states (e.g., Pennsylvania) requires nurses to ask family members of patients whose wishes are not known at their time of death whether they consent for donation. Barriers to donation may fall with education. More often it takes a dramatic event, such as the death of Nicholas Green, a seven-year-old American shot in the head by a random act of violence and subsequently declared brain dead while vacationing in Italy in 1999, to effect change. Nicholas' parents donated his organs, saving seven Italian citizens. In the wake of the publicity of this tragedy and subsequent organ donations, signed organ donation cards in Italy quadrupled and donations tripled. Nicholas' father, as is common among donor families, found solace in helping others: *"There is some consolation with the process. It puts something on the other side of the balance. It will never bring my son back, but it can help somewhat with the grief."*[329]

PATHOPHYSIOLOGY OF THE DISEASE

The indication for lung and heart-lung transplantation is severe end-stage pulmonary disease for which there is no other medical treatment and a life expectancy less than 18 months. The listing criteria for the prospective transplant patient additionally include consideration of the functional status of the patient, the patient's hemodynamic parameters, and the natural history of the underlying disease. Most pediatric lung transplant patients are between 11 and 17 years old, although there is a smaller subset of children younger than 2 years of age.[330] The most common underlying disease in the older pediatric lung transplantation is cystic fibrosis. Cystic fibrosis accounts for nearly half of all pediatric lung transplants. Ninety-five percent of nontransplanted patients with cystic fibrosis will eventually die from pulmonary causes. Factors associated with a less than 50% expected survival for the patient with cystic fibrosis include an FEV_1 less than 30%, PaO_2 less than 55 mm Hg, or a $PaCO_2$ greater than 50 mm Hg.[331] Pulmonary vascular disease accounts for nearly a quarter of the remaining transplants. Infants requiring transplantation most often have a variety of relatively rare diseases, such as surfactant B deficiency, primary alveolar proteinosis, or pulmonary vascular disease (Table 31.8).[332] These infants are often severely ill at the time of their transplants and are frequently intubated and ventilated or on ECMO support.[333,334] Independent risks for mortality after lung transplant include repeat transplant, mechanical ventilation at time of transplant,[332] and CHD.[335,336] Primary contraindications for lung transplantation are (1) active malignant disease within the prior 2 years, (2) significant active infectious processes (including HIV and hepatitis B and C), (3) significant coexisting cardiac disease, (4) hepatic or renal disease (although these patients may be candidates for multiple-organ transplants), (5) collagen vascular disease, (6) major irreversible neurologic injury, and (7) patient or family history of poor medical compliance or severe psychiatric illness that would preclude the patient from effective posttransplant care. Relative contraindications include (1) significant musculoskeletal disease, (2) invasive ventilation, (3) colonization with atypical mycobacterium or fungi, (4) poor nutritional status (body mass index [BMI] at either extreme), and (5) inability to reduce dependency on corticosteroids. A lung allocation score is calculated for each patient on the waiting list who is 12 years or older.[337] The score is based on the individual patient's age, underlying illness, forced vital capacity, functional status, and need for supplemental oxygen.[338] UNOS also includes ABO compatibility and distance between the donor and the recipient in its considerations for organ allocation.

UNOS adopted a new allocation system for children younger than 12 years of age in 2012. There are now two distinct priority levels, with the most ill children given a priority 1 ranking. Priority 1 candidates have respiratory failure requiring continuous mechanical ventilation, a fractional inspired oxygen (FIO_2) greater than 0.5 to maintain arterial oxygen saturation levels of more than 90%, an arterial or capillary PCO_2 of more than 50 mm Hg, or a venous Pco_2 of more than 56 mm Hg and/or significant pulmonary hypertension despite medical therapy. Children not meeting the above conditions are listed as priority 2. Donor lungs are first allocated to the priority 1 candidate longest on the waiting list who matches the donor's blood type and size. If there is no suitable priority 1 candidate, the lungs are then offered to the priority 2 candidate with the most waiting time.

Donor sources include organs from brain dead individuals, non-heart-beating donors (NHBD), and LDs. Donor care is critical. For lung donation, the donor should have been intubated

COPD, chronic obstructive pulmonary disease; *IPAH,* idiopathic pulmonary arterial hypertension.

less than 5 days to decrease the risk of lung injury, particularly ventilator-associated pneumonia. The donor should have no active infection and tracheal secretions must be void of infection. The donor should have either a Pa_{O_2} greater than 300 mm Hg at an F_{IO_2} of 1.0 or greater than 100 mm Hg at an F_{IO_2} of 0.4 with an inflation pressure less than 30 cm H_2O, a tidal volume of 15 mL/kg, and a PEEP of 4. In anticipation of lung donation and lung protection, the donor is maintained euvolemic to slightly hypovolemic, with CVPs ranging from 8 to 10 mm Hg. Once harvested, the lungs are perfused with a preservative solution and prostaglandins. The lungs are inflated and the trachea stapled closed to maintain an inflated position. The organs are then transported to the recipient at a temperature of 4°C. Ischemic times of less than 8 hours are desired, while less than 3 to 4 hours is ideal.[339]

The NHBD for lung transplant is also another source for organ donations[340]; NHBDs are typically younger than traditional donors. Eleven centers have performed more than 300 adult and pediatric controlled NHBD lung transplants (withdrawal of support from ICU patients). One center has performed 29 adult and pediatric uncontrolled (out of ICU arrest) NHBD lung transplants.[341]

Living-related donation of adult lobes for transplantation into the child offers an additional organ donor source as well as elective transplant scheduling.[342,343] Inherent size mismatch limits use of this technique to children 5 years and older. Typically, the left lower lobe is harvested from one donor with the right lower lobe harvested from another donor. The harvest technique is similar to a lobectomy; however, the harvested lobes require an appropriate length of bronchus as well as adequate vascular pedicles. Donor morbidity is significant.[344]

PREOPERATIVE EVALUATION

Children listed for lung transplantation undergo an extensive workup that includes chest radiographs, pulmonary function tests, arterial blood gas, complete metabolic panel, ECG, and echocardiogram. Those with pulmonary hypertension and/or associated cardiac defects will also require cardiac catheterization to better define the anatomy and hemodynamic profile—specifically, PVR.

SURGICAL TECHNIQUE

Children most commonly receive bilateral lung transplants with the use of CPB[345–347] through a bilateral anterolateral transsternal "clamshell" incision. As much dissection as possible is carried out before instituting CPB. Bilateral bronchial anastomosis has been found to produce better results without the concern for tracheal stenosis. The most popular technique is the telescoping anastomosis in which the larger bronchus is telescoped several centimeters over the smaller bronchus portion with peribronchial tissue wrapped around the anastomosis to ensure blood supply, because bronchial blood supply is not reestablished. If the older end-to-end anastomosis technique is used, an omental wrap is placed around the suture line. The pulmonary artery is reanastomosed after the bronchus is reanastomosed. The pulmonary venous component of the donor lung includes an atrial cuff, which is sutured directly to the left atrium of the recipient. This avoids the complication of pulmonary vein stenosis. While donor lungs are selected for size match, occasionally lungs are too large and cannot be used in total without exposing the recipient to significant areas of atelectasis. In this instance, volume reduction of the donated lung is performed to remove areas prone to atelectasis.[348–351]

Single lung transplants are uncommon in children and are specifically avoided in cystic fibrosis patients to avoid soiling from the remaining diseased lung. If single lung transplantation is performed for a non–cystic fibrosis patient, the most diseased lung is transplanted. Additionally, if emphysematous changes are present, the most emphysematous lung is removed to decrease the risk of compression of the donor lung. Single lung transplants are most often performed without cardiopulmonary bypass. After anesthesia is induced, single lung ventilation is achieved, a thoracotomy is performed, and the bronchus and vessels are exposed. A test occlusion by the surgeon of the pulmonary artery to the

proposed explant lung is then performed to evaluate the ability of the patient to hemodynamically tolerate the procedure without CPB. Presuming the patient tolerates the test clamp, the surgery proceeds with the removal of the native diseased lung. The donor lung is anastomosed by first connecting the pulmonary vein atrial flap to the native left atrium followed by reanastomosing the pulmonary artery, and then the smaller of the two bronchial ends is telescoped into the other with an overlap of one cartilage ring. The lung is then gently inflated. Air within the lung vasculature is vented via the pulmonary artery or the atrial cuff with the left atrium partially occluded. Once de-airing is accomplished, ventilation and perfusion of the donor lung are both established.

INTRAOPERATIVE PROBLEMS AND MANAGEMENT

Patients arriving for lung and heart-lung transplant are often critically ill. The anesthesiologist commonly has limited time to collate all data and perform the preoperative evaluation. Although preoperative anxiolysis may be beneficial, it is important to not significantly decrease respiratory drive and worsen hypoxemia, hypercarbia, and right heart failure. Commonly used premedications include midazolam, ketamine, and dexmedetomidine.

Before transplant, patients commonly have a "full stomach" because of the often short interval between their notification of impending transplant and the timing of the transplant itself. In such circumstances, a rapid sequence or modified rapid sequence should be used to facilitate induction of anesthesia. A one-size-fits-all anesthetic technique is not appropriate for heart-lung and lung transplants. The choice of induction agents is broad and must consider comorbid illnesses, such as significant right heart dysfunction, or other congenital anomalies in addition to the end-stage pulmonary disease.

Once standard monitors have been applied, propofol, etomidate, ketamine, or volatile anesthetics may be considered as primary induction agents either alone or in combination with narcotics or benzodiazepines. Ketamine does not appear to significantly alter PVR in infants[352] and may be considered as a first-choice drug.[352–355] Given the desire to rapidly intubate and control the airway, a relatively rapid onset neuromuscular blocking agent, such as high-dose rocuronium, is most commonly used.[67] Much of the peritransplant anesthetic considerations focus on the optimization of PVR, particularly with heart-lung transplant patients, and those with significant pulmonary hypertension and right heart dysfunction. Increases in PVR may cause acute right ventricular failure, resulting in reduced CO. Right-sided pressures may increase such that significant right-to-left shunting occurs through intracardiac defects and results in desaturation.

Initial ventilator settings must consider the underlying disease process. Fibrotic lungs may be better served by smaller tidal volumes with a faster respiratory rate that allows for a decreased peak inspiratory and plateau pressures while preserving minute ventilation. Conversely, severe obstructive disease may be best served by a slower respiratory rate, and a prolonged expiratory time. This can prevent hyperinflation (auto-PEEP). PEEP may be beneficial to improve oxygenation and ventilation and decrease atelectasis. Should hemodynamic collapse occur with the institution of positive-pressure ventilation in a patient with severe obstructive lung disease, dynamic hyperinflation should be immediately considered among the possible etiologies. Both dynamic hyperinflation and PEEP, by increasing intrathoracic pressure, may decrease venous return and cause hemodynamic compromise, particularly in relatively hypovolemic patients. Rapid treatment is provided by just disconnecting the patient from the ventilator circuit and allowing the patient to exhale. When ventilation is reinstituted, care must be taken to allow for adequate expiratory time.

Maintenance anesthesia is most commonly a balanced anesthetic, typically opioid-based and supplemented with volatile anesthesia to ensure amnesia. Volatile anesthetic–based techniques are less common because of their cardiovascular depression and vasodilation. Furthermore, volatile anesthetics blunt hypoxic pulmonary vasoconstriction and may make it more difficult to maintain adequate oxygenation should off-CPB lung transplantation be desired. Regional anesthesia may also be considered for intraoperative and postoperative care. Because of the typical use of CPB and its need for systemic heparinization, epidural thoracic catheters used for postoperative pain control are generally placed postoperatively when the patient's coagulation profile has normalized. Additionally, the anesthesiologist commonly administers preoperative antibiotics and immunosuppressive medications required for transplantation. Many transplant centers include the use of immunosuppressive induction therapy, and more than half of all recipients are now receiving either IL-2 receptor antagonists or cytolytics.

The vast majority of pediatric lung transplants are performed with the assistance of CPB, in contrast to the non-CPB technique most commonly used for adults. There are several reasons for this distinction, particularly when considering the two most common indications for pediatric lung transplantation. Cystic fibrosis patients have a significant risk of cross-contamination of the donor lung during a bilateral sequential lung transplant. This risk of soiling is minimized by the simultaneous removal of both lungs. Pediatric patients with pulmonary hypertension are frequently too unstable to tolerate single lung ventilation. Additionally, many children are too small to accommodate a double-lumen tube and single lung ventilation may be difficult. CPB alleviates these issues and allows the surgeon a quiet field with good exposure and predictable hemodynamics, thus speeding the time for anastomosis and decreasing the overall ischemic time.

Nonetheless, if the patient undergoes either single lung transplant or off-pump sequential bilateral lung transplant, continual vigilance and reassessment of the patient's condition is required. These patients are extremely ill, and undergo dramatic homeostatic perturbations. Single lung ventilation often precipitates hypoxemia and hypercarbia. The combination of increased afterload on the right heart by clamping of the pulmonary artery along with hypercarbia and hypoxemic-induced pulmonary hypertension on the other lung may precipitate right heart failure. Pulmonary vascular dilators and inotropes, such as milrinone, prostaglandins, and NO, along with maintaining adequate right-sided filling pressures may be used to diminish pulmonary hypertension. Nonetheless, continued right heart failure may necessitate CPB. If the patient tolerates pulmonary artery clamping, the gas exchange typically improves as the shunting through the nonventilated lung is stopped and the perfusion-ventilation mismatch is diminished.

Bilateral sequential lung transplants performed on CPB do not offer these problems. Nonetheless, CPB comes with a cost. During CPB the patient is typically cooled to 32°C, which introduces the concerns associated with moderate hypothermia. Gas exchange may worsen because of reperfusion injury, pulmonary edema, and decreased lung compliance. CPB also results in inflammatory mediator release that contributes to the reperfusion injury in the transplanted lungs. The systemic heparinization required for CPB increases the risk for perioperative bleeding and the need for transfusion of blood products. Packed red blood

cells, platelets, and clotting factors are typically required. Fibrinolytics may somewhat mitigate bleeding.

When the procedure is performed with CPB, airway management is performed with a single-lumen tracheal tube. Cuffed tracheal tubes are typically chosen for the ability to provide a better tracheal fit and allow for the potential ventilation of the lungs with relatively high pressures. In the rare circumstances that the operation of pediatric lung transplantation is performed without CPB, single lung ventilation will be required. Double-lumen tubes may be used in older patients (see Chapter 15). If a double-lumen tube is used, it is exchanged for a single-lumen tube at the conclusion of the operation unless there is a desire to continue with differential lung ventilation or there is a concern about lung soiling. In small children, either a bronchial blocker or selective intubation of a single bronchus may be considered. These options, however, preclude the ability to suction the nonventilated lung. Once the patient has been intubated, additional invasive monitoring is placed, typically an arterial catheter and a central venous catheter, along with two large-bore IV catheters. Some centers place a pulmonary artery catheter in addition to or in place of the percutaneous CVL. Occasionally, the surgeon will place a right atrial catheter. If a pulmonary artery catheter is placed, it must be withdrawn into the main pulmonary artery before the pneumonectomy. A TEE probe is then placed to assist in evaluation of residual cardiac abnormalities and cardiac performance, particularly right ventricular performance, both with pretransplant and posttransplant cardiac assessment.[356]

Perioperative bleeding is common, both in the operating room after coming off CPB and in the immediate postoperative period. Extensive pulmonary to systemic collaterals, coagulopathies caused by hepatic dysfunction, and adhesions from prior surgeries or cystic fibrosis may make the surgical dissection difficult and precipitate blood loss. Fibrinolytics have been demonstrated to reduce bleeding in patients with prior thoracic surgery.[357]

Those with cystic fibrosis are uniformly colonized with bacteria, so after the native lungs are removed, their tracheal stump is irrigated with antibiotic solution to reduce contamination of the transplanted lungs. Despite best efforts, these patients occasionally develop sepsis or a syndrome similar to septic shock owing to liberation of bacteria and toxic mediators during the removal of the native lungs. These patients require intensive therapy and most often do poorly.

After the first lung has been implanted, a small amount of blood is allowed to eject into the pulmonary artery while the second lung is anastomosed, thereby reducing the ischemic time for the first lung. After the second lung is implanted, the lungs are ventilated to remove areas of atelectasis. Posttransplant ventilation strategy limits tidal volumes to maintain peak inspiratory pressures less than 35 cm H_2O and PEEP in the range of 5 to 10 cm H_2O. It is typical to augment myocardial performance with inotropic support before termination of CPB. Occasionally, a combination of inotropes, dilators, or vasopressors may be required. Some centers routinely use NO and/or prostaglandin E_1 (PGE_1) to reduce PVR, while others reserve their use only for those in whom pulmonary hypertension is problematic. Fiberoptic bronchoscopy may be performed to assess the bronchial anastomotic sites in the operating room along with a lung perfusion scan performed within the first 24 hours postoperatively.

In the heart-lung transplant patient, weaning from CPB is analogous to that for cardiac transplantation as described earlier. There remains the need to support the denervated heart with adequate fluids and inotropy. Maintaining adequate fluid status in these patients may require a bit more effort because of increased bleeding compared with heart transplant patients. Bleeding is further exacerbated in these patients owing to extensive collaterals and bronchial circulation, which have often developed. Blood products are uniformly required in these patients.

The onset of acute graft dysfunction may present with persistent hypoxemia after weaning from CPB. While this may be attributable to relatively reversible causes, such as inadequate ventilation, atelectasis, or right ventricular dysfunction with right-to-left shunting, a more ominous problem may be reperfusion injury. Free radicals and inflammatory mediators are readily produced by the lung during both the ischemic time as well as during reperfusion. Reperfusion injury is correlated with longer ischemic times and presents as hypoxemia in the face of adequate ventilation and no other clear etiology of the hypoxemia. Pink frothy secretions noted in the tracheal tube may indicate reperfusion injury. PGE_1 may reduce reperfusion injury risk and symptoms. The optimal ventilation strategy aims to maintain oxygenation and ventilation with adequate PEEP and as low a peak inspiratory pressure as possible. FIO_2 is targeted to keep the PaO_2 less than 120 mm Hg to avoid oxygen toxicity. NO, a potent smooth muscle relaxant, has not been shown to prevent reperfusion injury when administered prophylactically. However, NO in the dose range of 20 to 60 ppm has been demonstrated to be effective in patients with increased pulmonary artery and right heart pressures coupled with hypoxemia.[358–363] Inhaled prostacyclin has also been demonstrated to be safe and effective in the treatment of pulmonary hypertension and reperfusion injury.[364] Occasionally, all these measures are inadequate and ECMO is instituted to allow the donor lungs to recover.[365–368]

IMMEDIATE POSTOPERATIVE MANAGEMENT

Immediate postoperative care is individualized based on the child's age, pretransplant diagnosis, and pretransplant comorbidities. Older patients with cystic fibrosis require mechanical ventilation for several days with their time to discharge from the critical care unit averaging less than 1 week.[369] After extubation, these patients may require supplemental oxygen for exercise therapy. Non–cystic fibrosis infants and children, typically more acutely ill before transplant, require an average of more than 3 weeks of mechanical ventilation and average nearly 2 months of critical care stay.[370] These younger transplant patients are smaller, have an increased incidence of airway complications, and may suffer from associated congenital cardiac defects. Patients with significant pretransplant pulmonary hypertension often manifest significant hemodynamic instability postoperatively. As such, these patients remain intubated, sedated, and frequently paralyzed for the first 2 postoperative days.

The cough reflex is absent and mucociliary transport is disrupted across the bronchial suture line in posttransplant patients, necessitating aggressive chest physiotherapy to avoid lung congestion that could lead to infection and respiratory failure. Frequent tracheal suctioning is mandatory; therapeutic bronchoscopy for pulmonary toilet may also be required. In addition to the risk for infections owing to pulmonary considerations, surgical sites, catheters, and drains add to the risk of infection. Prophylactic antibiotics are given perioperatively, including antivirals and antifungals, particularly if underlying fungal infection or viral infection (such as CMV) are present in either the donor or recipient.[371]

Postoperative pain control with judicious use of opioids is critical to ensure effective pulmonary toilet. Patient-controlled analgesia may be considered in patients capable of using such a

device. Regional anesthesia may also be used, but because of the systemic heparinization in CPB, many are reluctant to place a catheter before bypass. If regional anesthesia is desired, a thoracic epidural or paravertebral catheters may be placed postoperatively when the coagulation status of the patient has normalized. Dexmedetomidine may also be used for adjunct pain management by providing arousable sedation with minimal effect on respiratory drive with the additional benefit of opioid sparing.

LONG-TERM CONCERNS

With the large endothelial surface in the lungs and the resulting large number of immunologically active cells that predispose to major histocompatibility class antigens, and an extreme lymphocyte-directed host response, immunosuppressive drugs are used in larger doses in lung transplant and heart-lung transplant patients than in other organ transplants. Induction immunosuppression is used in more than half of the heart-lung and lung transplant centers.[372] Most transplant centers use a continuing multiple-drug immunosuppressive regimen.[373] The International Pediatric Lung Transplant Collaborative has recommended that tacrolimus, mycophenolate mofetil, and prednisone constitute the mainstay of immunosuppressive therapy. The most widely used regimens rely on a calcineurin phosphatase inhibitor coupled with a cell cycle inhibitor and a corticosteroid. The most commonly used calcineurin phosphatase inhibitors are cyclosporine and tacrolimus. Both work similarly, and both have significant side effect profiles. Neither one appears to offer a significant benefit over the other in preventing bronchiolitis obliterans (BO) from occurring. The major adverse effects of tacrolimus include hyperglycemia, alopecia, possibly worsening renal function, and possibly increased risk of PTLD. Cyclosporine's major adverse effects include hypercholesterolemia, hirsutism, gingival hyperplasia, and hypertension. Cyclosporine may prolong the neuromuscular blockade of atracurium and vecuronium.[374] Cyclosporine blood concentrations must be monitored closely, particularly in cystic fibrosis patients who are prone to variable absorption. Increased concentrations of cyclosporine have been implicated in central nervous system adverse effects such as seizures, headaches, and even strokes.[375,376] Steroids are included in nearly all lung transplant programs. Over time, the steroid dose is weaned to prevent complications such as hyperglycemia and osteoporosis, yet at 1 and 5 years after transplant, nearly all lung transplant patients continue to take prednisone. Cell cycle inhibitors are used in addition to the calcineurin phosphatase inhibitors and corticosteroids. Mycophenolate use is increasing, but as yet there has been no clearly demonstrated benefit over azathioprine. Azathioprine may prolong the neuromuscular blockade of succinylcholine.[374] Sirolimus acts by blocking IL-2–induced T-cell proliferation. Its role as a primary medication is limited by its hindrance of wound healing, potentially contributing to a dehiscence. It may be used as rescue therapy in patients with BO with mature suture lines.

A variety of perioperative complications may occur (Table 31.9).[377] More than one-third of patients who receive chronic immunosuppression develop hypertension during the first posttransplant year. By 5 years, that number has reached almost three-quarters of all survivors. Additionally, a number of these children, particularly those receiving tacrolimus, develop chronic renal insufficiency with decreasing creatinine clearance. Chronic kidney disease is a major comorbidity in pediatric lung transplant recipients.[378,379] More than one-third of patients have a degree of renal dysfunction within 7 years of transplantation. Occasionally, renal insufficiency progresses such that the child requires dialysis and renal transplantation.[380] Renal dysfunction is associated with increased mortality.

Posttransplant airway complications may be devastating.[381] While life-threatening bronchial dehiscence is uncommon, bronchial stenosis and tracheomalacia remain problematic.[382,383] Bronchial stenosis may be related to relative ischemia at the anastomotic site, recurrent infections, and possibly high-dose corticosteroids. Initial treatment of stenosis is balloon dilation; however, up to half of the patients with bronchial stenosis will require placement of bronchial stents. In younger patients, dynamic obstruction may be a complication that makes extubation difficult. This dynamic airway obstruction usually is self-limited, improves over time, and does not require intervention. Posttransplant patients are followed closely for signs of rejection, infection, and/or bronchiolitis obliterans. Pulmonary function test results are monitored. The choice of anesthetic for posttransplant patients must be individualized, accounting for comorbidities such as continued right heart dysfunction, decreased ability to handle

secretions, and particular caution regarding any potential to cross the bronchial suture line. Flexible fiberoptic bronchoscopies with bronchoalveolar lavage and transbronchial biopsies are the most common indications for anesthesia in posttransplant patients.[384] Bronchoscopies are performed at regular intervals, typically every 3 months, to evaluate even very early pathologic changes. Flexible fiberoptic bronchoscopies are most frequently performed with children under general anesthesia. A laryngeal mask airway is the preferred manner of airway management. The laryngeal mask airway lumen is significantly larger than that of the corresponding tracheal tube and allows the bronchoscopist to use a larger fiberoptic bronchoscope, facilitating improved view, improved suctioning, and easier bronchoalveolar lavage along with enhancing the ability to obtain adequate transbronchial biopsies.[385]

Acute rejection is common in the first several weeks to months after transplant. While acute rejection is often asymptomatic, fever and dyspnea may be present. Radiographic findings may include infiltrates and pleural effusions. Pulmonary function tests may demonstrate a decreased FEV_1 and forced vital capacity. Diagnosis is confirmed by bronchoscopy, bronchoalveolar lavage, and transtracheal biopsy. Acute rejection is graded on a scale of A0 to A4. Grade A2 scores and above are treated with increased immunosuppression. The major manifestation of chronic rejection, BO,[386] occurs in up to 50% of all post–lung transplant patients within 5 years of transplant. BO is the leading cause of death after the first posttransplant year. It presents as progressive deterioration of exercise tolerance and deterioration in airflow. BO is characterized by fibrosis of small airways and thickening of blood vessels. Diagnosis is defined by a decrease in FEV_1 compared with the immediately previous FEV_1.[387] Known risk factors for BO include prolonged ischemic time of the donor lung, more than two rejection episodes, and age greater than 3 years.[332] Unfortunately, there is no consistently reliable treatment for BO. A variety of immunosuppressive medications have been used with variable results. The primary treatment is immunosuppressive prevention of acute rejection and prompt CMV treatment. In severe instances of BO, retransplantation is the only treatment option.

Posttransplant vascular complications are uncommon, but when they do occur are most commonly caused by mechanical obstruction of blood flow secondary to redundant tissue in either the pulmonary artery or at the cuff of the atrial tissue, impeding venous return. Vascular complications may be difficult to distinguish from reperfusion injury, presenting with increased right-sided and PAPs with pink frothy secretions in the tracheal tube. Pulmonary arterial or venous stenosis may be diagnosed in the operating room or at bedside with a TEE; in some cases cardiac catheterization may be required. Depending on the findings, the patient may be treated with a stent placed during cardiac catheterization or reoperation to alleviate the stenosis. Additionally, transplanted lungs do not have lymphatics reanastomosed; this loss of lymphatic drainage increases the risk for pulmonary edema postoperatively. Increased parenchymal water and increased vascular filling further serve to decrease the compliance of the posttransplant lungs.[388]

Transplanted lungs are denervated. While this produces minimal effect on airway reflexes, mucociliary transport, and bronchial reactivity,[389] the larger effect is the loss of stimuli to the respiratory drive center and a loss of coordination of the respiratory accessory muscles. This discoordination may be visually apparent. Additionally, in the early posttransplant period, patients often demonstrate episodes of bradycardia. A late effect is a tendency toward an increased sympathetic tone and an increased heart rate.[390]

Phrenic, recurrent laryngeal, and vagus nerve injuries are common after lung transplant.[391] While phrenic nerve injury is typically transient, the resulting diaphragmatic paralysis may result in prolonged need for mechanical ventilation or even consideration of placement of a diaphragmatic pacer. Recurrent laryngeal nerve injury may occur in up to 1 of every 10 pediatric lung transplant patients. The left recurrent laryngeal nerve–induced vocal cord paralysis is the most common, although most children will recover.[391]

Gastroesophageal reflux disease (GERD) is a considerable post–lung transplant problem, which provides an additional risk factor for BO.[392,393] GERD and gastroparesis may be precipitated by vagal nerve injury. Not only do recurrent aspiration pneumonias contribute to transplanted lung failure, but delayed gastric emptying results in unreliable absorption of the patient's immunosuppressive drugs. A number of patients with GERD require a Nissen fundoplication.[394] Additionally, children with cystic fibrosis have a high incidence (10%) of intestinal obstruction after lung transplantation. These children may require gastrostomy, jejunostomy, or other procedures for ileus.[395]

Postlung transplant graft rejections are common. Older children average 10 times more episodes of rejection than infants.[317,391] The signs and symptoms of rejection are nonspecific.

CMV is one of the most common infections in the posttransplant patient. CMV infections may present with mild symptoms, but they may progress to pneumonitis, gastrointestinal symptoms, or even a sepsis syndrome with multiorgan failure. CMV has been associated with both acute cellular rejection and chronic rejection.[396,397] Antiviral medications have decreased the severity of this infection.[398] Prophylactic treatment is often considered if either the donor or the recipient were CMV positive. Children with cystic fibrosis remain at a greater risk for infection postoperatively with *Pseudomonas aeruginosa* or fungal organisms.

A number of malignancies have been reported in the children with cystic fibrosis after transplantation, at greater rates than their age matched counter parts, and may be attributed to immunosuppressive therapy. PTLD has a greater incidence in lung and heart lung transplant patients than in other solid organ transplant, perhaps owing to the greater level of immunosuppression required. Even in this group of children, the cystic fibrosis subgroup after transplant has an increased incidence of PTLD. PTLD includes a group of tumors, ranging from B-cell hyperplasia to immunoblastic lymphoma. Mortality from PTLD has been reported to be up to 60%; a number of these deaths have been attributed to graft failure as a result of treating the PTLD by decreasing immunosuppressive therapy. As many as 25% of children with cystic fibrosis develop PTLD. PTLD is, in most cases, associated with EBV infection, either as a reactivation of the virus with immunosuppression or with new infection acquired from the donor lung. EBV is uncommon in patients who are seropositive for EBV before transplant. For those who are seronegative before transplant, EBV-associated disease occurs in one in five patients. The diagnosis of PTLD is made by the symptoms, biopsy, and the presence of EBV DNA or RNA in the biopsied tissue. PTLD presents with a variety of nonspecific symptoms including a mononucleosis-type syndrome. The most common symptoms include elevated temperature, lymphadenopathy and gastrointestinal symptoms. Most PTLD occurs in the first year after transplant. EBV infection results in both a humoral and cellular immune reaction. In immunodeficient patients, the normal immune responses are blunted. The natural regulation by T cells and natural killer cells is impaired. Natural killer cells function is impaired for several months after transplant. The immunosuppression required to

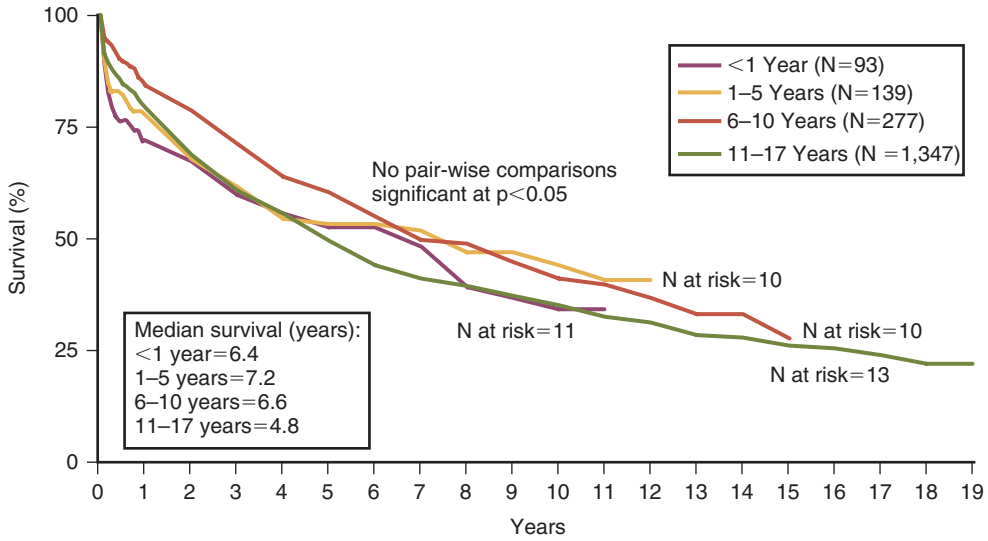

FIGURE 31.11 Pediatric lung transplants. Kaplan-Meier survival by recipient age group (transplants: January 1990–June 2013). (From Figure 10; Goldfarb SB, Benden C, Edwards LB, et al. The registry of the international society for heart and lung transplantation: eighteenth official pediatric lung and heart-lung transplantation report—2015; Focus theme: early graft failure. *J Heart Lung Transplant*. 2015;34(10):1255–1263.)

prevent graft rejection impairs T-cell immunity and allows for unchecked proliferation of EBV-infected B cells.

The treatment of PTLD is reduction or withdrawal of immunosuppressive therapy.[399,400] Unfortunately, reduction or withdrawal of immunosuppressive therapy places these children at risk for graft failure. Additional effective treatments include localized excision of the lesion, antiviral therapy,[401] monoclonal antibodies,[402] interferon,[403,404] immunoglobulin, and cytotoxic T lymphocytes.[405] Chemotherapy does not appear to offer an advantage and may worsen survival.[400]

Dysrhythmias, although possible, are relatively uncommon (<5%) after transplant and typically do not require treatment. Atrial dysrhythmias associated with extensive left atrial suture lines were among the first dysrhythmias to be described.[406,407] However, the types of dysrhythmias after lung transplant surgery includes functional escape rhythm, nonsustained ventricular tachycardia, accelerated junctional rhythm, sinus bradycardia, nonsustained supraventricular tachycardia, ectopic atrial tachycardia, and second-degree heart block; treatment is not generally required.[408] Postoperative lung transplant patients fall behind their contemporaries in height and weight, and their growth curves lie between the 5 and 10 percentiles for age, with the overall growth rate only two-thirds of the predicted value. It appears, based on pulmonary function tests, radiographic studies, and histologic examination, that the growth of the transplanted lung(s) in the recipient is appropriate for the recipient's height and weight. Functional reserve capacity,[409] airway size,[410] and absolute number of alveoli increase as height and weight grow in a manner comparable to their normal counterparts. Furthermore, recipients of mature living-related lobar lungs are also noted to grow. Transplanted mature lung lobes expand and fill the entire chest. In these mature lung lobes, however, while the airways appear to grow in size, the alveoli appear to become distended rather than increasing in absolute number. Pediatric post–lung transplant survival after the first year has remained the same for the past 20 years.[411] The 5-year survival of the transplant patients exceeds 50%. This follows overall 1- and 3-year survival rates of 75% and 66% of the patients, respectively.[372]

Idiopathic pulmonary hypertension patients do slightly better with 1- and 5-year survival rates of 95% and 61%, respectively, but they still have a median survival posttransplant of 5.8 years (Fig. 31.11).[412]

Infants have a substantive early death rate of 25%. Patients with significant pretransplant pulmonary hypertension and those receiving retransplants also have a greater than average death rate. More than one-half of the early (first month) deaths in all ages are due to primary graft failure. The primary causes for later deaths are infections, BO, and malignancies. The leading cause of death from 1 month through 1 year is non-CMV infections. The leading cause of death from 1 to 3 years is BO followed by non CMV infections. After 3 years, BO is the leading cause of death, accounting for nearly half of all deaths. Most malignancies are from PTLD. In those patients who do survive, more than 75% of them have minimal limitation on activity at 1, 3, and 5 years after transplant, respectively.

Almond CS, Morales DL, Blackstone EH, et al. Berlin Heart EXCOR pediatric ventricular assist device for bridge to heart transplantation in US children. *Circulation*. 2013;127(16):1702-1711.

The use of ventricular assist devices as a bridge to transplantation has increased significantly over the past decade. The authors describe the overall Berlin Heart EXCOR experience in U.S. children and found that lower patient weight, reduced renal or hepatic function, and use of biventricular device support was associated with death. This paper provides important information in regard to predicting the risk profile when deciding to initiate mechanical support for a patient.

Dharnidharka VR, Fiorina P, Harmon WE. Kidney transplantation in children. *N Engl J Med*. 2014;371(6):549-558.

This review paper summarizes the latest surgical and immunologic advances in pediatric kidney transplantation. The paper includes outcome data of graft and patient survival broken down by patient age and era of time that the transplant was performed.

Henderson HT, Canter CE, Mahle WT, et al. ABO-incompatible heart transplantation: analysis of the Pediatric Heart Transplant Study (PHTS) database. *J Heart Lung Transplant*. 2012;31(2):173-179.

This paper demonstrated equal 1-year survival and rejection outcomes for ABO-incompatible and ABO-compatible heart transplant recipients by analyzing data from the Pediatric Heart Transplant Database. The results from this paper add to the favorable data collected from similar analyses suggesting that UNOS reevaluate the policy of giving priority of ABO-compatible over ABO-incompatible hearts, thus increasing organ availability to children.

Lee J, Yoo YJ, Lee JM, et al. Sevoflurane versus desflurane on the incidence of postreperfusion syndrome during living donor liver transplantation: a randomized controlled trial. *Transplantation*. 2016;100(3):600-606.

This prospective, randomized, controlled trial investigated postreperfusion syndrome and use of vasoactive agents in 62 adult liver transplant recipients receiving either sevoflurane or desflurane. There was significantly less postreperfusion syndrome (38% vs. 77%) and vasoactive agent (19% vs. 45%) use in adults receiving sevoflurane. There does not appear to be an advantage to using desflurane over sevoflurane during reperfusion.

Sorensen LG, Neighbors K, Martz K, et al. Longitudinal study of cognitive and academic outcomes after pediatric liver transplantation. *J Pediatr*. 2014;165(1):65-72.e2.

This is a prospective multicenter longitudinal study investigating intellect, academic performance, and executive function over time. Pediatric liver transplant recipients 2 or more years after liver transplant were evaluated at 5 to 6 years and 7 to 9 years. A pattern of cognitive and academic deficits were detected in patients that persisted over time. Factors that seemed to predict cognitive deficits included operative complications and intraoperative transfusion volume.

ANESTHESIA FOR ORTHOPEDIC AND SPINAL SURGERY provides a multitude of challenges. Children often present with concomitant diseases that affect cardiovascular and respiratory function. The ability to maintain a clear airway during anesthesia is not straightforward for some children, such as those with arthrogryposis multiplex congenita.[1] Operating times can be protracted. Significant blood loss can occur that requires strategies for blood product management and transfusion reduction (see Chapter 12). Major trauma causing orthopedic injuries invariably involves other organ systems that may adversely interact with or compromise anesthesia management (see Chapter 39). The risks of pulmonary aspiration of gastric contents and the requisite fasting times, after even minor trauma involving an isolated forearm fracture, continue to be debated. Fat embolus is uncommon in children with long-bone fractures but should be considered in any child with hypoxia and altered consciousness in the perioperative period.[2] Tumor surgery may be complicated by chemotherapy, altered drug disposition, or bone grafting considerations akin to those for plastic and reconstructive surgery (see Chapter 35), and complex postoperative pain management may be required (e.g., phantom pain, reflex sympathetic dystrophy) (see Chapter 45).

Children with chronic illnesses present repeatedly for surgical or diagnostic procedures. A single bad experience can blight attitudes about anesthesia for a long time. Positioning children on the operating table involves care, especially for those with limb deformities and contractures (Video 32.1). Padding, pillows, and special frames are required to protect against damage from inadvertent pressure ischemia while achieving the best posture for surgery. Plaster

application, particularly around the hip, should allow for bowel and bladder function, avoid skin breakdown caused by pressure or friction, and allow access to epidural catheters. Postoperative management of casts on peripheral limbs must account for the possibility of compartment syndromes attributable to restrictive casts or compartment pathology. Major plexus blocks may mask pressure effects under plaster casts or compartment syndrome, but epidural blocks using low-dose amide anesthetics do not mask the discomfort of pressure.[3,4] Intraoperative temperature regulation may be affected by tourniquet application or disease (e.g., osteogenesis imperfecta, arthrogryposis multiplex congenita). The use of radiology is common during orthopedic surgery; anesthesiologists should take precautions against excessive radiation exposure.

Regional anesthesia (see Chapter 42) reduces anesthesia requirements intraoperatively and provides analgesia postoperatively. The use of ultrasound techniques to locate neural tissue improves the rate of successful blocks and reduces local anesthetic doses (see Chapter 43).[5,6] This has heralded increasing use of peripheral nerve blockade rather than central blockade for unilateral lower limb surgery. Acetaminophen (paracetamol) and nonsteroidal antiinflammatory drugs (NSAIDs) are the most common analgesics prescribed for moderate pain. Regular administration of acetaminophen and NSAIDs decreases the amount of systemic opioids administered,[7] but NSAIDs decrease osteogenic activity and may increase the incidence of nonunion after spinal fusion.[8,9] Intravenous acetaminophen improves the early effectiveness of this drug before the child is able to tolerate oral intake, but this formulation is not available in all countries.[10] Long-term pain associated with limb-lengthening techniques (e.g., Ilizarov frame) may require oral opioids after hospital discharge.

Scoliosis Surgery

Children presenting for scoliosis surgery represent a spectrum, ranging from uncomplicated adolescents to severely compromised patients with neuromuscular disease, respiratory failure, and cardiac problems. The age range at presentation varies from infancy to young adulthood. Anesthesia techniques for scoliosis surgery vary with individual patient requirements.[11,12] Approaches aimed at minimizing blood loss and transfusion requirements have progressed from extremes of hypotension and hemodilution to a more balanced approach involving moderate degrees of both, use of antifibrinolytic agents, predonation programs, and intraoperative cell salvage. The impact of anesthetic agents on complex physiologic signals has become increasingly important as more sophisticated measurements of neural transmission using somatosensory evoked potentials (SSEPs) and motor evoked potentials (MEPs) have become the standard of care.

TERMINOLOGY, HISTORY, AND SURGICAL DEVELOPMENT

Early Hindu literature (3500 to 1800 BC) describes Lord Krishna curing a woman whose back was "deformed in three places."[13] The terms scoliosis (i.e., crooked), kyphosis (i.e., humpbacked), and lordosis (i.e., bent backward) originated with the Greek physician Galen. *Scoliosis* is a lateral deviation of the normal vertical line of the spine, which is greater than 10 degrees when measured by radiographs. Scoliosis consists of a lateral curvature of the spine with rotation of the vertebrae within the curve. *Lordosis* refers to an anterior angulation of the spine in the sagittal plane, and *kyphosis* refers to a posterior angulation of the spine as evaluated on a side view of the spine. Curves may be simple or complex, flexible or rigid, and structural or nonstructural. Primary curves

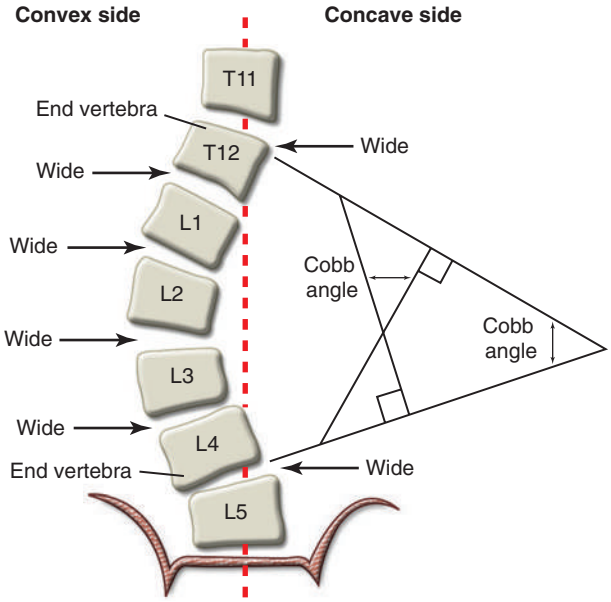

FIGURE 32.1 Diagram of an anteroposterior spinal radiograph shows the Cobb method of scoliosis curve measurement.

are the earliest to appear and occur most frequently in the thoracic and lumbar regions. Secondary (or compensatory) curves can develop above or below the primary curve and evolve to maintain normal body alignment. Various combinations of curve types have different pathophysiologic consequences.

The magnitude of the scoliosis curve is most commonly measured using the Cobb method.[14] Measurement is made from an anteroposterior radiograph and requires accurate identification of the upper and lower end vertebrae involved with the curve. These vertebrae tilt most severely toward the concavity of the curve. The Cobb method of angle measurement is shown in Fig. 32.1.

Hippocrates (circa 400 BC) developed treatments that relied primarily on manipulation and traction, using an elaborate traction table called a *scamnum*.[15] Nonsurgical treatments for spinal deformities persisted until 1839, when a surgical treatment in the form of a subcutaneous tenotomy and myotomy was described by a French surgeon, Jules Guerin.[16]

Posterior spinal fusion was first described by Russell Hibbs for tuberculous spinal deformity in 1911.[17] The original spinal instrumentation system was the Harrington rod system.[18] Modification of this technique that allowed segmental fixation of the rods and early mobilization followed.[19] These systems treated the lateral curve but did not allow for correction of the axial rotation. Subsequent developments allowed both corrections by cantilever maneuvers using Cotrel-Dubousset instrumentation.[20]

Pedicle screws rather than hooks were the next advance. They were initially used as a distal anchor for lumber curves and were found to enhance correction and stabilization, even when used with hooks for the more proximal curves (i.e., hybrid constructs).[21] Pedicle screw instrumentation techniques for total curve correction offer better curve correction than hook techniques [22] and the hybrid pedicle screw and hook technique.[23] Sublaminar polyester bands are often used as part of the hybrid technique in children with dysmorphic or osteoporotic spines because of concerns about pedicle screw placement,[24] although bands may be associated with more neurologic complications.[25]

CLASSIFICATION

Classification of scoliosis deformities is imperfect because the systems used are clinically rather than etiologically based. Most classifications are surgically based and used for surgical decision making. Curves can be described on the basis of age at onset, associated pathology, and anatomic configurations of the curve, such as single, double, or triple curves; amount of pelvic tilt; curve flexibility; and three-dimensional (3D) analysis of the curve.[26] A classification that could indicate the risk of an adverse outcome of anesthesia, particularly respiratory failure, would be of clinical benefit. Children younger than 5 years of age with early-onset scoliosis or with independent cardiac or pulmonary disease appear to be at increased risk for respiratory failure, whereas those with idiopathic scoliosis in whom the curve develops at adolescence appear to have minimal risk.[27] A classification adapted from that proposed by the Scoliosis Research Society in 1973 remains relevant for anesthesiologists (Table 32.1).[28]

TABLE 32.1 Classification of Scoliosis With Associated Key Anesthetic Risk Factors

Classification	Issues Associated With Scoliosis Surgery	Increased K^+ With Succinylcholine	Expected High Blood Loss	Respiratory Complications and Ventilatory Support
Idiopathic				
Infantile <3 years	Repeat operations, small size		✓	✓
Juvenile 3–9 years				
Adolescent 9–18 years	Regarded as cosmetic by patient; perfect result expected			
Congenital				
Bony abnormalities	Acute angle deformity; high risk of spinal cord injury, genitourinary malformations			
Neural tube defects				
Meningomyelocele, spina bifida, syringomyelia	Latex allergy, pressure sores, hydrocephalus, Arnold-Chiari and Chiari malformations (avoid neck extension)			
Neuromuscular				
Neuropathic				
Upper motor neuron				
Cerebral palsy, cerebral hypoxia	Upper airway obstruction, recurrent pneumonia, postoperative pain management		✓✓	✓✓
Lower motor neuron				
Poliomyelitis				
Myopathic				
Progressive				
Duchenne muscular dystrophy	Cardiomyopathy, mitral valve prolapse, conduction abnormalities	✓	✓✓	✓✓
Spinal muscular atrophy	Electrocardiographic abnormalities	✓	✓	✓
Facioscapulohumeral muscular dystrophy	Hypertrophic cardiomyopathy, cardiac failure	✓		
Other				
Friedrich ataxia		✓		
Neurofibromatosis	Hypertension, other neurofibromas			
Mesenchymal				
Marfan syndrome	Mitral and aortic regurgitation			
Mucopolysaccharidoses (e.g., Morquio syndrome)	Atlantoaxial subluxation, difficult intubation			
Arthrogryposis	Difficult intubation, severe contractures		✓	
Osteogenesis imperfecta	Small size			
Trauma				
Tumor				

✓, anesthetic risk is likely; ✓✓, anesthetic risk is very likely.
Modified from Goldstein LA, Waugh TR. Classification and terminology of scoliosis. *Clin Orthop Relat Res.* 1973;93:10–22.

The Lenke classification system, developed in 2001 for idiopathic scoliosis, provides a means to categorize curves and guide surgical treatment.[29] It is increasingly used by the surgeons as an integral part of their decision making.[30] Major and structural minor curves included in the instrumentation and fusion are used for the classification, and the nonstructural minor curves are excluded. The system has three components: curve type, a lumbar spine modifier, and a sagittal thoracic modifier. The resulting six curve types have specific radiographic characteristics that differentiate structural and nonstructural curves as proximal thoracic, main thoracic, and thoracolumbar/lumbar regions such that the number, curve type, and main structural curves are related as follows:

Type 1, main thoracic: single; main thoracic structural curve
Type 2, double thoracic: double; proximal, and main thoracic structural curves
Type 3, double major: double; main thoracic (major curve) and thoracolumbar/lumbar structural curves
Type 4, triple major: triple; all three structural curves
Type 5, thoracolumbar/lumbar: single; thoracolumbar/lumbar structural curve
Type 6, thoracolumbar/lumbar main thoracic: double; thoracolumbar/lumbar (major curve) and main thoracic structural curves

In types 1 through 4, the main thoracic curve is the major curve, and in types 5 and 6, the thoracolumbar/lumbar curve is the major curve.

PATHOPHYSIOLOGY AND NATURAL HISTORY

Vertebral rotation and rib cage deformity usually accompany any lateral curvature. With progression of the curve, the vertebral bodies in the area of the primary curve rotate the convex aspect of the curve and the spinous process to the concave side. This vertebral rotation can be determined by measurement of the position of the pedicles from the midline (i.e., Moe method).[31] The vertebral bodies and the discs develop a wedge-shaped appearance, with the apex of the wedge toward the concave side. On the convex side of the curve, the ribs are pushed posteriorly, which narrows the thoracic cavity and causes the characteristic hump. On the concave side, the same rotation forces the ribs laterally, with consequent crowding toward their lateral margins (Fig. 32.2). These changes result in an increasingly restrictive lung defect. Exactly when this becomes a problem depends on the child's accompanying pathology. The thoracic and lumbar regions are the most common sites of the primary curve. In children in whom the primary curve is in the lumbar region, the rotation of the vertebral bodies and spinous processes should be taken into consideration when spinal or epidural insertion is attempted because the spinal canal is relatively displaced toward the convex aspect of the curve.

The physical distortion in the thorax results in restriction of lung volumes and function. Ventilation depends on the mobility of the thoracic cage, the volume of each hemithorax, and the muscle power and elastic forces required to move the thorax. Children with idiopathic scoliosis with a mild decrease in vital capacity also have reduced forced expired volume at 1 second (FEV_1), gas transfer factor, and maximal static expiratory airway pressures (PEmax) (see Fig. 13.4 and Table 13.2). The predominant deformity of lateral flexion and vertebral rotation results in the lung on the concave side being able to achieve a near-normal end-expiratory position but not end-inspiratory position, whereas the lung on the convex side achieves a normal end-inspiratory position but cannot reach a normal end-expiratory position. The concave side contributes less than normal at total lung capacity, resulting in a decrease in PEmax. Similarly, because the convex side does not reach a normal end-expiratory position, the intercostal muscles and hemidiaphragm will be less efficient, resulting in a reduced maximum static inspiratory airway pressure (PImax), although this reduction may not be quite so marked.[32] The main effect of scoliosis on respiratory function is mechanical, and the anatomic changes in the chest wall cause impaired movement and reduced compliance. Potential long-term respiratory problems when these defects are left untreated include hypoxemia, hypercarbia, recurrent lung infections, and pulmonary hypertension.

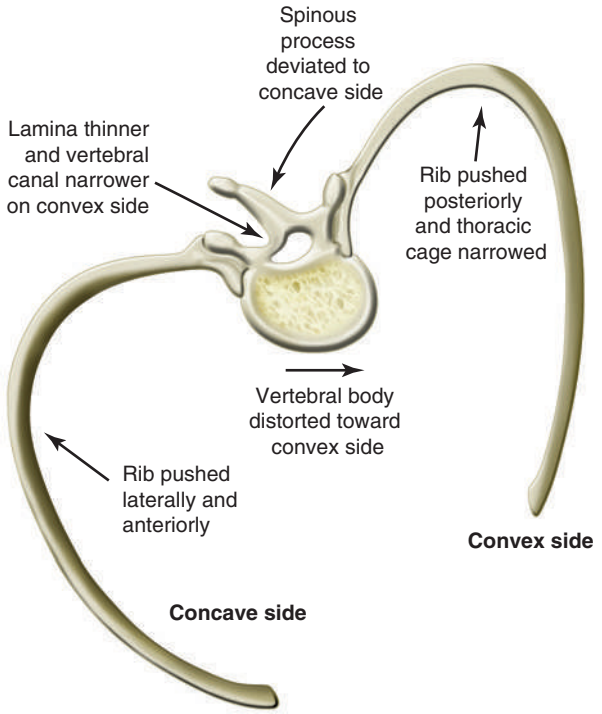

FIGURE 32.2 Characteristic distortion of the vertebra and ribs in thoracic scoliosis. (Modified from Kleim HA. Scoliosis. In: *Ciba Foundation Symposium*. Vol. 1. Summit, NJ: Ciba; 1978:609; Anesthesia for orthopaedic surgery. In: Gregory GA, ed. *Pediatric Anesthesia*. 3rd ed. Edinburgh: Churchill Livingstone; 1994.)

Congenital, Infantile, and Juvenile Scoliosis: Early-Onset Scoliosis

Congenital spinal anomalies are caused by failures of formation and segmentation that result in scoliosis and kyphosis. The hemivertebra, caused by failure of formation, is the most common anomaly. Fully segmented hemivertebrae contribute to progressive deformity during periods of rapid spinal growth (e.g., the first 5 years of life). The most severe deformities are seen in the thoracolumbar spine. Congenital spinal anomalies may be associated with malformations of the ribs, chest wall, and hemifacial microsomia.[33] Children with congenital scoliosis have an associated 25% risk of urologic and 10% risk of cardiac abnormalities. Bracing or casting techniques are not effective for this form of scoliosis. These children may have obstructive lung disease in addition to their restrictive impairment, possibly owing to mainstem bronchial compression from spine rotation.[34] Surgical options for these children include fusion in situ, convex hemiepiphysiodesis,

hemivertebra excision, growing rods, and vertical expandable prosthetic titanium rib (VEPTR) treatment.[35] Although short-term correction is easily achievable, a short thoracic spine or even thoracic insufficiency syndrome (inability of the thorax to support normal breathing and lung growth) can result.[36] Approximately one-half of the children who have extensive thoracic fusions and those whose fusions involve the proximal thoracic spine develop restrictive pulmonary disease (FEV_1 <50%).[37] Expansion thoracoplasty and stabilization using a VEPTR may be used.[38]

Infantile and juvenile scoliosis are part of the spectrum of idiopathic scoliosis but are considered here because they manifest and require treatment at an early age. Infantile scoliosis accounts for less than 1% of idiopathic scoliosis and is defined as scoliosis appearing between birth and 3 years of age.[35] It usually occurs in the thoracic spine, and the curve is usually convex to the left. Bracing and serial casting techniques are used for infantile scoliosis; improvement and resolution in some cases have been achieved at 9-year follow-up.[39]

Treatment of infantile scoliosis may begin as early as 4 to 5 months of age or as soon as the diagnosis of scoliosis has been made. Body casting appears useful in selected children, such as those with smaller, flexible spinal curves, but curve progression and the need for secondary treatments affect a significant proportion of these children.[40] Bracing is considered when the curve reaches 30 degrees.[35] Success has also been reported for more severe curves (60 degrees) when casting was started before 20 months.[41] After induction of anesthesia, the child is positioned on the frame (first described by Cotrel and Morel[41a]), securing the pelvis to the caudal end of the frame and tethering the head by a chin strap to the rostral end. The spine is mildly distracted, but the main maneuver derotates the spine through the ribs (Fig. 32.3A). General anesthesia with tracheal intubation is required to facilitate positioning the child, stretching the spine, and molding the body cast. Hemoglobin desaturation frequently occurs when the cast is molded to correct the spinal deformity. Hypoxemia or breathlessness may occur following cast application. Peak Inspiratory pressure (PIP) may double if using positive-pressure ventilation intraoperatively; this can be partially improved by cutting a window in the cast.[42]

An oral airway is also needed to prevent compression of the tracheal tube after the chin strap is applied and tightened (Fig. 32.3A). After the cast has hardened, it is cut back and trimmed to maintain the correction to the spine while facilitating breathing, gastrointestinal function, and day-to-day living (see Fig. 32.3B). Halo traction may be used to stretch and improve the curves but infections occur in ~50%.[43]

Juvenile idiopathic scoliosis represents 10% to 15% of idiopathic scoliosis and is defined as scoliosis that is first diagnosed between the ages of 4 and 10 years. Approximately 20% of these children and those with infantile scoliosis with a curve greater than 20% have an underlying spinal condition, most commonly Arnold-Chiari malformation and syringomyelia.[44] Although bracing is used to manage these curves, almost all children in this group with curves greater than 30% require surgical intervention.[45]

Growing rods may be used for congenital, infantile, or juvenile scoliosis to maintain the correction obtained at initial surgery while allowing spinal growth to continue. Several procedures are required before a definitive fusion.[46] All the systems (i.e., growing rods and VEPTR) have a moderate complication rate (i.e., rod breakage and hook displacement).VEPTR systems are being used to correct large-magnitude curves in this group of children when conservative treatment is inadequate.[47]

FIGURE 32.3 **A,** Nonoperative correction of scoliosis in infants and toddlers may be achieved with repeated casting. **B,** Cutting and trimming of the cast allows correction of the spine while facilitating daily living.

Idiopathic Scoliosis

Although adolescent idiopathic scoliosis is relatively common, severe morbidity is seen only in children with early-onset (infantile or juvenile) idiopathic scoliosis.[48] Respiratory deterioration alone is seldom the reason for surgery in those who develop scoliosis after the age of 5 years.[27] This is explained by the fact that the respiratory alveoli are mature by this age.[49,50]

Scoliosis evolves during growth spurts. The earlier the age of onset and the more immature the bone growth at the time the process begins, the more severe the outcome. The relentless progression of infantile-onset idiopathic scoliosis with rapidly deteriorating curves and lung function is often not amenable to surgery. Treatment involving spinal instrumentation and anterior epiphysiodesis does not prevent the reappearance of the deformity or the decrease in pulmonary function.[51]

Pulmonary impairment correlates directly with the magnitude of the thoracic curve. Severity of the scoliosis is the most accurate predictor of impaired lung function.[52] The morphology of the

thoracic curve, the number of vertebrae in the major curve, and the rigidity of the curve also are associated with deteriorating pulmonary function.[53] Conventional wisdom has held that there is minimal impact on the vital capacity until the curve exceeds 60 degrees, with clinically relevant decreases in respiratory function occurring only after the thoracic scoliosis has progressed beyond 100 degrees.[37] However, children with adolescent idiopathic scoliosis may have pulmonary impairment that is disproportionate to the severity of the scoliosis since it occurs before the curve reaches 100 degrees. Forced vital capacity (FVC) may decrease below normal (<80% of predicted) after the magnitude of the thoracic curve exceeds 70 degrees; FEV_1 decreases below normal after the main thoracic curve exceeds 60 degrees.[38] Twenty percent of children with a thoracic curve of 50 to 70 degrees have moderate or severe pulmonary impairment (i.e., <65% of predicted) (Fig. 32.4A).[54] Those with thoracic hypokyphosis are more likely to have moderate or severe pulmonary impairment; complex curves have a greater prevalence of moderate or severe pulmonary impairment, and the number of vertebrae in the thoracic curve is the most significant predictor of impaired respiratory function (see Fig. 32.4).[55] Children with a structural cephalad thoracic curve, a major thoracic curve spanning eight or more vertebral levels, or thoracic hypokyphosis are at increased risk for moderate to severe pulmonary impairment. Bracing patients with adolescent idiopathic scoliosis (AIS) decreases the progression of high risk curves[56] but is associated with worse pulmonary function test (PFT) results at the time of surgery.[57]

Neuromuscular Scoliosis

Children with neuromuscular scoliosis have the burden of deteriorating muscle function in addition to mechanical distortion. Crowding of the ribs on the concave side of the curve limits chest wall expansion, and the sitting posture restricts diaphragmatic

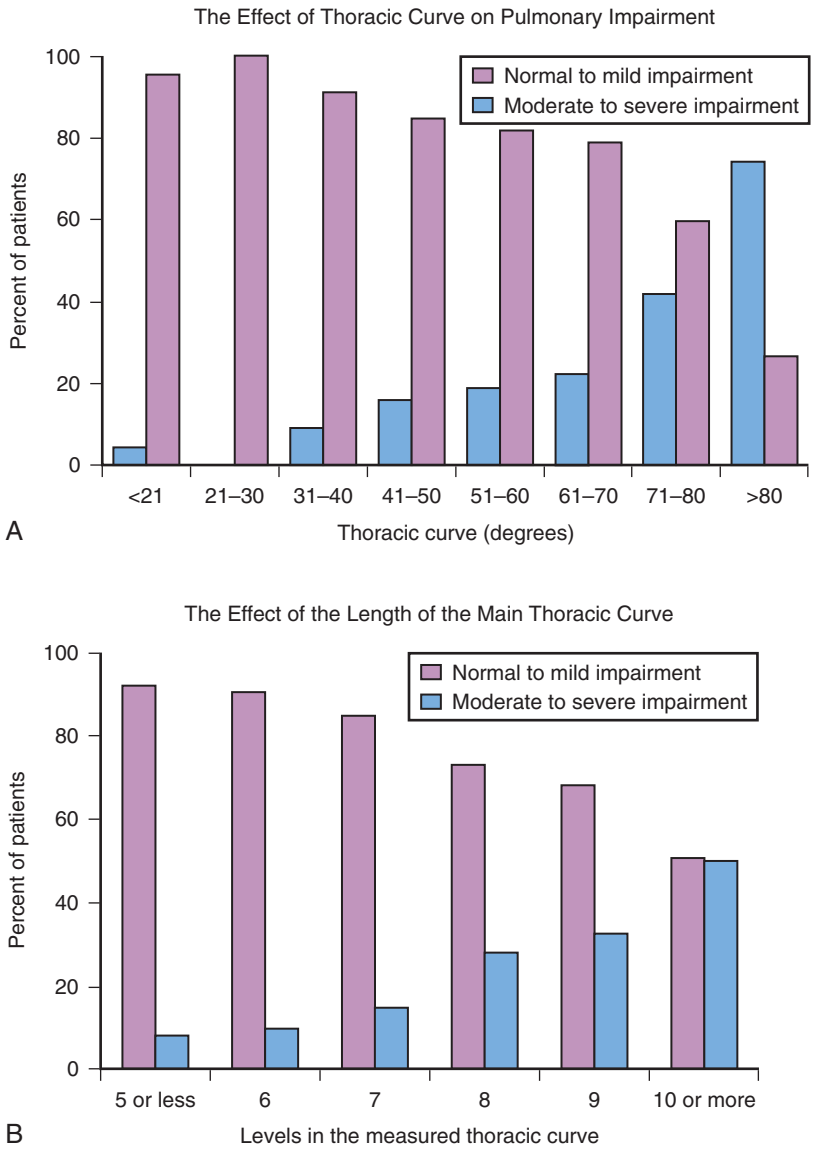

FIGURE 32.4 A, The bar graph demonstrates increasing pulmonary impairment with increasing curve severity as measured by degrees. **B,** Pulmonary impairment increases with increasing length of the thoracic curve. (From Newton PO, Faro FD, Gollogly S, et al. Results of preoperative pulmonary function testing of adolescents with idiopathic scoliosis. A study of six hundred and thirty-one patients. *J Bone Joint Surg Am*. 2005;87:1937–1946.)

excursion. This inevitably leads to more rapid deterioration in the curve and respiratory function. These children also have the potential for rapid and unpredictable deterioration of the curve.[39] It is important to consider the natural history of the specific neuromuscular disease when trying to balance the risks of surgery against conservative management.

Children with Duchenne muscular dystrophy (DMD) suffer from progressive muscular weakness and increasing disability until death occurs, usually by the beginning of the third decade.[58] These children tend to become wheelchair-bound by 8 to 10 years of age because of increasing motor muscle weakness. Scoliosis then progresses with an acute deterioration during the growth spurt between the ages of 13 and 15 years, such that it becomes difficult or impossible to sit unaided. After the lumbar curve exceeds 35 degrees, further progression becomes inevitable.[59] A normal cough requires an inspiratory effort of more than 60% of total lung capacity and effective glottic closure to produce an effective peak flow (more than 160 L/minute in adults). Forced expiratory flows are typically reduced in proportion to the decrease in lung volume. As muscle weakness progresses, patients hypoventilate, initially at night. If nocturnal ventilatory support is not provided at this stage, diurnal hypercapnia will result.[60]

There have been two significant changes in the overall management of children with DMD: the use of steroids and the earlier use of nocturnal noninvasive positive-pressure ventilation (NPPV). Steroid treatment in the early phase of the disease appears to slow disease progression for a few years; treatment with prednisone can stabilize strength and function for 6 months to 2 years.[61,62] This may delay the presentation of children for corrective surgery. Earlier adoption of nocturnal NPPV for nocturnal hypoventilation improves survival and quality of life. Clinically unsuspected nocturnal hypoventilation occurs in about 15% of patients with DMD and can be predicted by moderate impairment according to PFT results (FVC <70% and FEV_1 <65% of predicted) and scoliosis. Those with nocturnal hypoventilation have increased gas trapping, decline of muscle strength, and worse perception of health status despite NPPV.[63]

A 2007 multidisciplinary "Consensus Statement on the Respiratory and Related Management of Patients with Duchenne Muscular Dystrophy undergoing Anesthesia or Sedation" provided recommendations to standardize the approach to these patients[64] and others with flaccid neuromuscular diseases undergoing anesthesia. The most important of these recommendations are as follows: an FVC <50% of predicted indicates an increase in postoperative respiratory complications; an FVC <30% suggests a further increase in risk. PFTs should be part of the preoperative evaluation when possible and should include FVC, PImax, PEmax, peak cough flow, oxygen saturation by pulse oximetry (SpO_2) on room air, and partial pressure of carbon dioxide ($PaCO_2$) if the SpO_2 value is less than 95%. Consider preoperative training and postoperative use of NPPV if FVC is less than 50% of predicted, and strongly consider NPPV if FVC is less than 30%. Consider preoperative training and postoperative use of manual and mechanically assisted cough in those with impaired cough. In older children, this can be predicted by a peak cough flow less than 270 L/minute or maximal expiratory pressure less than 60 cm H_2O. Strongly consider planning to extubate the trachea directly to NPPV when the FVC is less than 30%.

Dilated cardiomyopathy occurs in up to 90% of DMD individuals older than 18 years of age; the severity of their physical disability often masks the clinical symptoms of cardiac failure. Cardiomyopathy is responsible for 20% of deaths, but this proportion may increase in the future for individuals in whom NPPV prevents respiratory-related mortality[62] (see also Chapter 23).

Risk Minimization and Improving Outcome From Surgical Intervention

RESPIRATORY FUNCTION AND OTHER COMPLICATIONS IN THE EARLY POSTOPERATIVE PERIOD

Decreases in lung volumes and flow rates similar to thoracic and upper abdominal surgery occur after scoliosis surgery. The FVC and FEV_1 decrease with a nadir at 3 days and are about 60% of preoperative values 7 to 10 days after surgery (Fig. 32.5). It is not until 1 to 2 months after surgery that PFTs approach baseline values. The magnitude of this decrease is not affected by the type of surgery performed or whether the scoliosis has an idiopathic or neuromuscular cause.[65] Surveys from the British Scoliosis Society and Scoliosis Research Society report mortality rates of 1.5 to 1.9 per 1000 cases,[66,67] with a smaller rate in children with AIS (0.4 per 1000) and a greater rate in those with neuromuscular disease (3.6 per 1000). [67] Overall, deep infections occurred in 2.8% and permanent neurologic defect in 0.45% of children.[66]

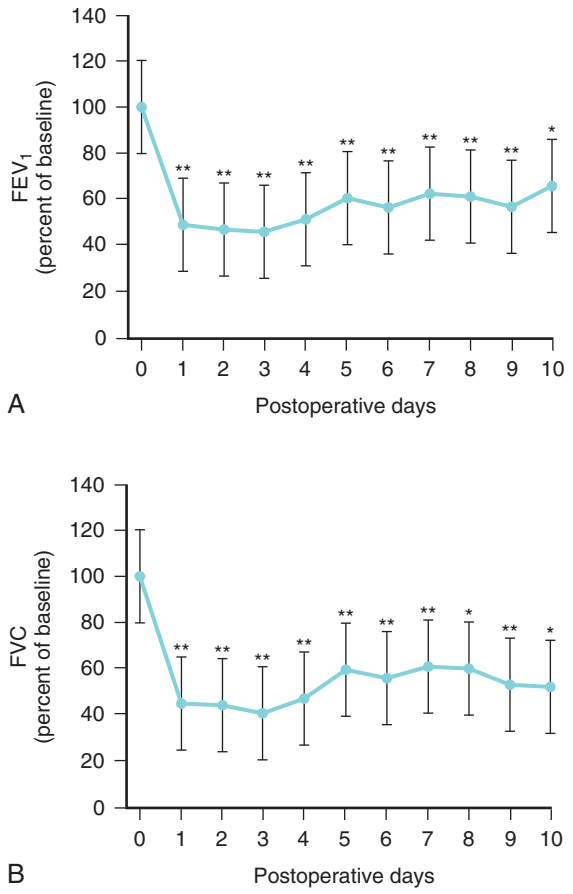

FIGURE 32.5 A, Changes in forced expiratory volume in 1 second (FEV_1) during the 10 days after scoliosis surgery. **B,** Changes in forced vital capacity (FVC) during the 10 days after scoliosis surgery. (From Yuan N, Fraire JA, Margetis MM, et al. The effect of scoliosis surgery on lung function in the immediate postoperative period. *Spine* 2005;30:2182–2185.)

Early-Onset Scoliosis

Early-onset scoliosis (EOS) has a dismal prognosis when untreated, and repeated spinal lengthening procedures are associated with a complication rate of 80% and a mortality rate of 18%.[68] Magnetic growing rods, by reducing the number of operative interventions, may be associated with fewer complications and improved pulmonary function.[69]

Idiopathic Scoliosis

Complications in children with AIS are uncommon but an increased body mass index is associated with a threefold increase in postoperative adverse events. Instrumentation of more than 13 segments and operation times longer than 6 hours are associated with an increased length of stay. Any complication during the hospital stay is associated with readmission; the most common cause is surgical site infection (SSI).[70] Scheuermann kyphosis is associated with an 8- to 10-fold increase in major complications, SSI, and reoperations compared with AIS.[71]

Neuromuscular Scoliosis

Children with neuromuscular disease are more likely to require prolonged mechanical ventilation after spinal surgery because of more severe preoperative respiratory impairment.[72] The marked decrease in vital capacity and peak flows is undoubtedly related to the risk of postoperative complications, but determining when it is no longer safe to anesthetize those with a restrictive lung defect remains an imperfect science.

Equipment is available to assist the postoperative management of children with impaired respiratory function. The routine use of NPPV and cough augmentation therapy should be planned if the preoperative FVC is less than 30%. Cough augmentation can be provided manually by hyperinflation and forced expiration, alone or together, and by mechanical insufflation-exsufflation (MIE) therapy.[73] The effectiveness of MIE may be limited in children with a weak or enlarged tongue if it blocks exsufflation flow.

Less extensive surgery with the newer pedicle screw systems decreases the need for pelvic fixation to correct pelvic obliquity. The procedures require less extensive surgery and shorter operating times, which may benefit children with impaired respiratory function.[74–77]

Respiratory complications after surgery for AIS are relatively uncommon; however, these complications are fivefold greater in children with neuromuscular scoliosis.[78,79] Anterior spinal procedures are associated with a greater incidence of complications than posterior spinal fusion; some consider this to be the main risk factor for postoperative respiratory complications.[79] Current pedicle screw systems may decrease the need for anterior procedures, thereby decreasing the complication rate.[80]

Atelectasis, infiltrates, hemothoraces, pneumothoraces, pleural effusions, and prolonged intubation have the greatest incidence, whereas pneumonia, pulmonary edema, and upper airway obstruction occur less frequently. These problems are more common when the scoliosis is associated with developmental delay; the greatest complication rate is in those with cerebral palsy and flaccid neuromuscular scoliosis.[78–81] Respiratory complications increase as the severity of scoliosis and degree of respiratory impairment increase but complication rates vary considerably. Children with neuromuscular scoliosis have a respiratory complication rate of 15% to 30%[81–85] and minimal mortality. One study, which separated three groups according to respiratory impairment (FVC <30%, FVC = 30% to 50%, FVC >50%), reported an overall complication rate of 31% independent of the degree of respiratory impairment,[81] perhaps reflecting improvement with modern management techniques (Table 32.2).

Children with cerebral palsy have additional problems associated with their lack of muscular control (e.g., swallowing incoordination, excessive salivation, gastroesophageal reflux) and sometimes have developmental delay that contributes to a postoperative complication rate of 30%.[82,83,86] Nonambulatory children and those with curves greater than 60 degrees are at increased risk for major complications; nonambulatory patients are almost four times more likely to have a major complication.[86] Gastrointestinal dysmotility in cerebral palsy patients can be exacerbated after scoliosis surgery and cause persistent vomiting and bloating.[87] Pancreatitis may occur in up to 30% of cerebral palsy patients after surgery, with a greater incidence among those with documented gastroesophageal reflux and reactive airway disease.[88]

Surgical Site Infection

SSI results in high morbidity and cost. Rates are much greater after non-idiopathic scoliosis repair, increasing from 2.6% with AIS to 9.2% with neuromuscular scoliosis. The most common pathogens are *Staphylococcus aureus*, coagulase-negative staphylococci, and *Pseudomonas aeruginosa*.[89] Almost half of the infections in children with neuromuscular scoliosis contain at least one gram-negative organism. Despite this, there is little evidence to support the use of intravenous (IV) vancomycin or gentamycin powder to the surgical site or graft.[90] More severe curves, nonambulatory status, and increased length of stay increase the risk of infection.[91]

LONG-TERM CHANGES

Idiopathic Scoliosis

Improvements in pulmonary function are not impressive after correction of idiopathic scoliosis. Early studies suggested that spinal fusion stabilized the respiratory dysfunction that existed preoperatively but failed to offer any improvement.[92] Improvements are possible in certain subgroups of patients with some surgical techniques, but it takes months to years for pulmonary function to improve. Children with a preoperative curve less than 90 degrees undergoing a posterior procedure experienced an increase in vital capacity of slightly greater than 10%, maximum voluntary ventilation, and maximum respiratory mid-flow rate after 2 years; this

TABLE 32.2 Incidence of Pulmonary Complications[81]

Forced Vital Capacity	Total Number of Patients	Patients With Pulmonary Complications	Pneumonia	Atelectasis	Pneumothorax	Ventilator Care (>3 days)
<30%	18	6	3	0	1	2
30%–50%	18	7	3	1	0	4
>50%	38	10	2	1	0	7

improvement did not occur in those who underwent anterior surgery.[93] Harrington rod instrumentation in children with idiopathic scoliosis resulted in only a small improvement in vital capacity.[94]

The newer instrumentation systems (e.g., Cotrel-Dubousset instrumentation) allow segmental realignment and approximation, resulting in further improvements in pulmonary volumes.[95] Pulmonary function returns to preoperative values within 3 months after the posterior approach using the newer instrumentation systems, with additional improvements occurring and being sustained for 2 years.[96] Pedicle screws provide greater curve correction in AIS, with a trend toward improved pulmonary function after 2 years compared with other instrumentation techniques.[23] Lung volumes measured by 3D computed tomographic scans do not change even with an increase in patient height, suggesting a dynamic improvement from hemithoracic symmetry rather than a static benefit.[97,98] A 10-year follow-up analysis demonstrated an absolute increase in the FVC (3.66 L from 3.25 L) and FEV_1 (3.10 L from 2.77 L) but no changes in percent of predicted values in children who underwent a posterior fusion only. In the same analysis, those with chest wall disruption experienced no change in FVC and FEV_1 over 10 years, but a significant decrease in predicted FVC (79% vs. 85%,) and FEV_1 values (76% vs. 80%).[99]

Chest cage disruption (i.e., thoracoplasty or anterior thoracotomy) is associated with reduced pulmonary function at 3 months and a 10% to 20% decrease in total lung capacity (TLC) and FVC. These values do not return to baseline until 1 to 2 years after surgery. Improvements in lung function with this approach rarely occur.[48,49] Video-assisted thoracoscopic surgery (VATS) for anterior release and instrumentation results in less pulmonary morbidity and a smaller decrease in pulmonary function at 3 months. One year after surgery, values for children treated thoracoscopically return to baseline, but this did not occur for those undergoing open thoracotomy (Fig. 32.6).[100,101] Two- and five-year follow-up evaluations of those undergoing VATS showed no significant changes with regard to the correction of the major Cobb angle (56% ± 11% and 52% ± 14%, respectively) or average predicted TLC (95% ± 14% and 91% ± 10%).[102]

Changing surgical techniques may challenge these findings in the future because some surgeons think that anterior fusions with modern systems offer short-term benefits of reduced blood loss and transfusion and long-term benefits owing to shorter fusions, better maintenance of thoracic kyphosis, and improved spontaneous lumbar curve correction. A 2-year postoperative study concluded that VATS for thoracic curves and open procedures for thoracolumbar curves resulted in minimal to no permanent pulmonary impairment 6 months after the procedure compared with posterior spinal fusion, despite a short-term decrease observed after VATS.[103]

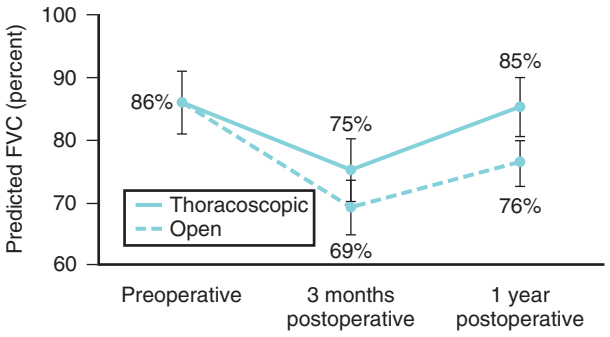

FIGURE 32.6 Changes in percent of forced vital capacity (FVC) for thoracoscopic versus open anterior instrumentation during the first year after surgery. (From Faro FD, Marks MC, Newton PO, Blanke K, Lenke LG. Perioperative changes in pulmonary function after anterior scoliosis instrumentation: thoracoscopic versus open approaches. *Spine* 2005;30:1058–1563.)

Neuromuscular Scoliosis

Improvements in the scoliosis angle and the degree of pelvic obliquity are achieved after spinal instrumentation in children with neuromuscular disease. Significant improvement in the quality of life perceived by the child or caregiver and in the ability to sit unaided, particularly if children are unable to do so beforehand.[104–108] There is little evidence for any improvement in respiratory function in this group of children, although there may be a period of delay or even stabilization of the inevitable deterioration of respiratory function.[58,105,109] Other investigators have shown no difference in respiratory function after 5 years compared with patients managed conservatively[107,110] or an early loss in vital capacity after surgery with a progressive decrease of 25% over 4 years, with 66% of children requiring mechanical respiratory assistance by that time.[106] A Cochrane review failed to find any data evaluating the effectiveness of scoliosis surgery in patients with DMD, leaving them to suggest: *"Patients should also be informed about the uncertainty of benefits on long-term survival and respiratory function after scoliosis surgery."*[111]

Some retrospective analyses, however, deserve consideration. A review of the long-term survival of children with DMD after spinal surgery and nocturnal ventilation demonstrated that those having spinal surgery and ventilation had a median survival of 30 years, whereas those receiving nocturnal ventilation only survived to 22.2 years. This result occurred despite a decrease in mean vital capacity from 1.4 L to 1.13 L in the first postoperative year.[112] Posterior spinal fusion for scoliosis in DMD was associated with a significant slowing in the rate of decrease in respiratory function; the rate of 4% per year before surgery decreased to 1.75% per year (over 8 years) after surgery.[113] In a study of 14 children with DMD and an FVC of less than 30%, the mean rate of decrease in percent of FVC after surgery was 3.6% per year. Most children and parents thought scoliosis surgery improved their function, sitting balance, and quality of life and gave it high satisfaction scores.[114]

Less outcome information is available for children with cerebral palsy. Surgery is perceived as having a positive impact on patients' quality of life, overall function, and ease of care by parents and other caregivers,[115] despite the high complication rates described earlier. A 3-year follow-up after a pedicle screw construct for scoliosis, which reduced the mean Cobb angle to 31 degrees, demonstrated improved functional ability in 42% of children. Most children had improved sitting balance and nursing care requirements. A 32% complication rate occurred; most were pulmonary in origin but ultimately reversible. One study reported two perioperative deaths and one transient neurologic deficit caused by screw impingement among 56 patients.[80]

Less morbidity has been claimed for the same-day (one-stage) surgery compared with the two-staged approach in children with neuromuscular disease requiring anterior and posterior spinal surgery.[116,117] However, it seems reasonable to avoid anterior thoracotomy in neuromuscular patients in view of the poor respiratory function after chest cage disruption.[96,100] Currently, pedicle screw systems in children with neuromuscular scoliosis produce outcomes similar to those of earlier systems but with shorter operating times and less blood loss.[75]

Spinal Cord Injury During Surgery

ETIOLOGY

Spinal cord injury can occur by four main mechanisms: direct contusion of the cord during surgical exposure; contusion by hooks, wires, or pedicle screws; distraction by rods or halo traction; and reduction in spinal cord blood flow.[118] Epidural hematoma should be included in the differential diagnosis of deficits occurring postoperatively. The areas of the spinal cord most vulnerable to ischemic injury are the motor pathways, which are supplied by a single anterior spinal artery. This is fed in a segmental manner by the radicular arteries that arise from the vertebral, cervical, intercostals, lumbar, and iliolumbar arteries. The largest radicular artery is the artery of Adamkiewicz, which arises between T8 and L4. A watershed area between T4 and T9 is prone to ischemia because the blood supply in this region of the cord is poorest.[119] Paraplegia is the most feared neurologic complication, but partial spinal cord injury resulting in areas of localized weakness and numbness as well as bladder and bowel disturbances also have been reported.

The increasing use of pedicle screws in spinal surgery raises the possibility of increased risk to individual nerve roots. A systematic review of pedicle screw complications that involved a total of 4570 pedicle screws in 1666 patients reported an overall 4% malposition rate that increased to 16% in studies that systematically examined their patients postoperatively.[120] Eleven patients required revision surgery for the malpositioned screws, and there was one temporary neurologic complication (i.e., epidural hematoma). No vascular injuries were reported, although six cases of aortic abutment were described.

RISK OF SPINAL CORD INJURY AND SPINAL CORD MONITORING

Surveys undertaken by the Scoliosis Research Society investigating idiopathic scoliosis reported in 1975 an incidence of neurologic impairment of 0.72%,[121] which in 2000 had decreased to 0.3%. All of the deficits were partial cord lesions.[118] Patients with curves greater than 100 degrees, congenital scoliosis, kyphosis, and postirradiation deformity appear to be at greatest risk for complications. The use of pedicle screws may have increased the immediate neurologic complication rate. In 2007, 9 neural complications were reported among 1301 patients, for an incidence of 0.69%. Three thecal penetrations occurred, two as a result of pedicle screws, all without sequelae. There were two nerve root injuries and four spinal cord injuries, all of which resolved within 3 months.[122]

A retrospective review of 19,360 cases of pediatric scoliosis showed significantly different overall complication rates among idiopathic (6.3%), congenital (10.6%), and neuromuscular (17.9%) scoliosis. Neurologic deficits had a different distribution, with the greatest rate among congenital cases (2%), and smaller rates with neuromuscular (1.1%) and idiopathic scoliosis (0.8%).[123] Mortality rates of 0.3% were observed for neuromuscular and congenital scoliosis, with an idiopathic scoliosis rate of 0.02%. Rates of new neurologic deficits were greater with anterior screw–only constructs (2%) or wire constructs (1.7%) than with pedicle screw constructs (0.7%). Surgery for high-grade spondylolisthesis appears to be associated with a particularly high risk of neurologic deficit with a rate of 11.5%.[124]

Spinal cord function is monitored to ensure that the complication rate is as small as possible. The Scoliosis Research Society issued a position statement concluding that neurophysiologic monitoring can assist in the early detection of complications and can possibly prevent postoperative morbidity. For any monitoring technique to be effective, it needs to have a sensitivity and specificity that allows true changes to be immediately recognized with very low false-negative and false-positive results to allow the problem to be reversed or prevented. Recognition of the limitation of individual techniques has seen the development of increasingly sophisticated monitoring systems to identify and minimize this risk. Older tests, such as the wake-up test and ankle clonus test, have largely been superseded by monitoring of SSEPs, MEPs, and triggered electromyographic (EMG) techniques The importance of using a multimodal approach is increasingly recognized[125–128]; the capabilities and limitations of the various techniques are summarized in E-Table 32.1.

METHODS OF MONITORING SPINAL CORD FUNCTION

Wake-Up Test

The wake-up test measures gross motor function of the upper and lower extremities.[129] The test requires limiting or reversing muscle relaxation and reducing the depth of anesthesia sufficiently to enable the patient to follow commands during the surgery; failure to move the feet and toes while being able to squeeze a hand suggests a problem with the spinal cord. When the test was initially described, 3 of 124 patients were identified as having no movement and were saved from paraplegia.[129] A major concern is that the test is conducted after maximal spinal correction, which may occur after any neurologic insult has occurred; however, removal or modification of the spinal instrumentation within 3 hours of the onset of the neurologic deficit has been reported to prevent permanent neurologic sequelae.[130] However, the wake-up test is unlikely to detect isolated nerve root injury or sensory changes and is limited to patients with an appropriate developmental age who can follow instructions.

With the clinical application of SSEP and MEP monitoring (Fig. 32.7) well established and in the absence of intraoperative changes, there is no justification to perform the wake-up test.[131] Nonetheless, some surgeons still regard the wake-up test to be the gold standard, and it may be used to confirm changes demonstrated by SSEP or MEP monitoring.[132] Risks associated with the wake-up test include lack of nerve root and sensory information, accidental extubation, dislodgment of the instrumentation, intraoperative recall with subsequent psychological trauma, air embolism, and cardiac ischemia. If a wake-up test is planned, it is prudent to warn the patient at the preoperative visit that they will be awakened during the surgery (but reassure them that they should not feel pain) and the wound will be filled with saline to reduce the risk of an air embolism.

Ankle Clonus Test

The ankle clonus test uses the clonus that occurs just before consciousness is regained during wakening from anesthesia. Rhythmic muscle contractions are thought to result from spinal reflexes returning while the higher neurologic centers remain inhibited by anesthesia, and the oscillations demonstrate an intact spinal cord. Inability to demonstrate clonus suggests spinal cord injury.[133] Like the wake-up test, it is a post hoc test rather than real-time monitoring. However, in a review of more than 1000 patients undergoing spinal procedures in which six postoperative neurologic deficits occurred, this test identified all the deficits but produced three false-positive findings, giving a sensitivity of 100% and a specificity of 99.7%. In comparison, the wake-up test

E-TABLE 32.1 Intraoperative Electrophysiologic Monitoring in Spinal Surgery

Modality	Anatomy	Not Addressed	Anesthetic Concerns	Temporality	Risks
Wake-up test	Gross motor function	Nerve roots, sensation	Only short-acting, reversible agents should be used	1 point, difficult to repeat	Self-extubations, missed focal deficit, delayed warning
SSEP	Ascending pathways; dorsal column proprioception and vibration	Focal motor pathway injury, nerve roots	Muscle relaxants helpful, volatile anesthetics inhibit, balanced by <50%; no dose-related barbiturate inhibition	3- to 5-minute summation	Missed focal motor and nerve root injury; delay in warning during summation
tcMEP	Anterior spinal grey matter of descending pathways; 4%-5% of motor neuron pool in corticospinal tract	Sensation, complex motor movement	TIVA best, limited muscle relaxant (CMAP)	1 point, easily repeated	Concern for patient movement
nMEP	Whole cord with significant antidromic column component	Nerve roots, possibly no true motor data	Inhaled anesthetics acceptable; however, no muscle relaxant if CMAP recording	1 point, easily repeated	Possible lack of true motor data
sEMG	Nerve root: assessment in selected myotomes	Sensation, anterior descending motor pathways	No muscle relaxants, inhalational anesthetic okay	Continuous	
tEMG	Nerve root: stimulator (pedicle screw) to end muscle	Sensation, anterior descending motor pathways	No muscle relaxants, inhalational anesthetic okay	1 point, easily repeated	Concern about patient movement

CMAP, compound motor action potential; *nMEP*, neurogenic (spinal cord) motor evoked potentials; *sEMG*, spontaneous electromyography; *SSEP*, somatosensory evoked potentials; *tcMEP*, transcranial motor evoked potentials; *tEMG*, triggered electromyography; *TIVA*, total intravenous anesthesia.
Modified from Malhotra NR, Shaffrey CI. Intraoperative electrophysiological monitoring in spine surgery. *Spine* 2010;35:2167–2179.

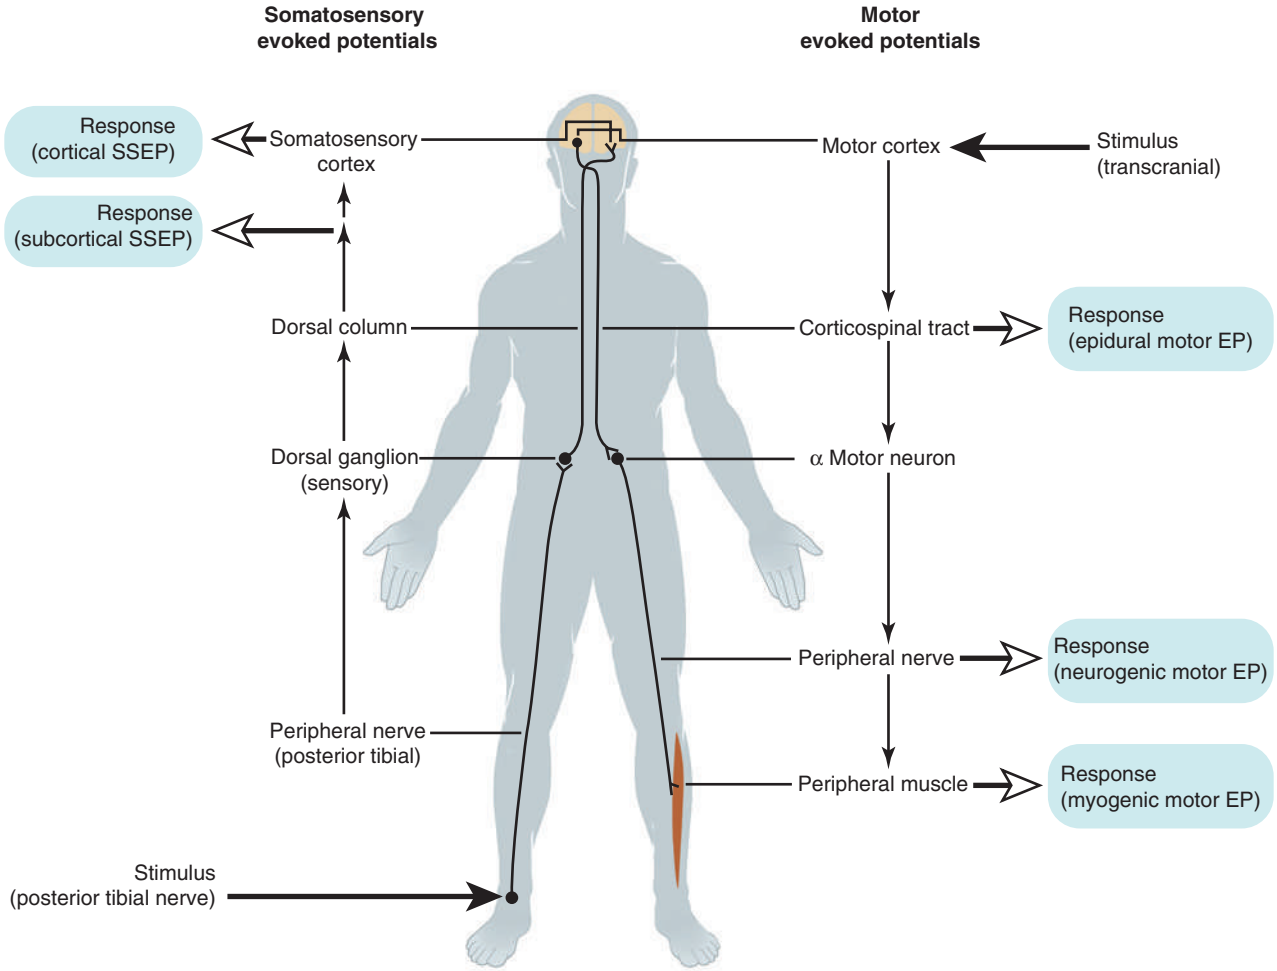

FIGURE 32.7 Comparison of pathways involved in somatosensory evoked potential (SSEP) and motor evoked potential (motor EP) monitoring. (Modified from de Haan P, Kalkman CJ. Spinal cord monitoring: somatosensory- and motor-evoked potentials. *Anesthesiol Clin North Am.* 2001;19:923–945.)

produced false-negative results for four of the five patients who developed deficits.[133]

Somatosensory Evoked Potentials

SSEPs involve stimulating a peripheral nerve and measuring the response to that stimulation using scalp electrodes (i.e., cortical SSEPs).[134,135] Alternatively, the response can be measured subcortically near the spinal cord by electrodes placed in the epidural space, interspinous ligament, or spinous processes of the vertebrae.[136] An intranasally placed pharyngeal electrode can act as a surrogate for these. The advantage of the subcortical evoked potential is that the responses are more stable, reproducible, and resistant to the effects of anesthesic agents.

The signal produced with SSEP monitoring travels from the peripheral nerve through the nerve root and up the ipsilateral dorsal column. The impulses then cross over at the level of the brainstem and progress rostrally through the thalamus to the primary sensory cortex. Up to 30% of patients with AIS may have preoperative abnormal SSEP signals.[137]

The rationale for using SSEP to monitor motor deficits is based on the fact that the sensory tracts are in proximity to the motor tracts of the spinal cord. Injury to the motor tracts indirectly affects the sensory tracts and causes changes in the SSEP. When spinal cord function is significantly impaired, there is usually an increase in latency and a decrease in amplitude in the SSEP, with eventual loss of signal. A 10% increase in latency of the first cortical peak (P1) or 50% decreases in the peak-to-peak amplitude (P1N1) constitute an indication for intervention.[138,139] Although SSEP signals primarily monitor transmission through the sensory dorsal columns, they are effective,[139] and SSEP monitoring is associated with a 50% decrease in the incidence of neurologic deficits.

It is unusual for motor tract injury to occur when SSEPs remain unchanged, but false-positive and false-negative results have been reported.[139,140] Seventy percent of the postoperative complications were detected by the monitor, but 30% (false negatives) were not detected. Pedicle screw misplacement leading to radiculopathy may not be detected by SSEP monitoring.[141] Several case reports of paraparesis also attest to the limitations of SSEP monitoring. These problems are caused by injury occurring outside the monitored domain of SSEP rather than a failure of this modality. These concerns encouraged development of methods to monitor the motor tracts of the spinal cord. SSEP monitoring

is possible in patients with cerebral palsy, whereas MEP monitoring may not be.[142]

Motor Evoked Potentials

The motor pathways can be activated by transcranial stimulation of the motor cortex or by spinal cord stimulation. Transcranial stimulation is achieved using electrical or magnetic stimulation applied to the scalp. Electrical stimulators are most commonly used in spinal surgery and operate by applying high-voltage pulses to the scalp using corkscrew, needle, or surface electrodes. The stimulation pulses can be applied as single stimuli or brief pulse trains with intervals between the pulse trains. Multiple stimuli result in a stronger signal with less variability owing to temporal summation of the excitatory postsynaptic potential.[143] Epilepsy and proconvulsant medicines are considered relative contraindications to MEP monitoring because of concerns about brain injury from prolonged seizure activity caused by the electrical current required for stimulation.[144,145] Not surprisingly, MEPs may be difficult to record and interpret in patients with cerebral palsy and should not be attempted if the child has seizures.

MEP monitoring may be a problem in younger children, particularly those younger than 6 or 7 years of age.[144,146] Use of a spatial summation technique in addition to temporal summation increased the success rate from 78% to 98% over all ages. Using this technique along with ketamine anesthesia in children younger than 6 years of age, reliable MEPs were documented in 98% (111 of 113) of children older than 6 years of age and in 86% (18 of 21) in children younger than 6 years of age.[146] There is also evidence that younger children require a greater stimulating voltage and pulse train frequency for MEP monitoring, probably because of immaturity of the central nervous system, specifically the descending corticospinal tracts.[147]

Spinal cord stimulation is achieved electrically and can be applied using electrodes placed outside or inside the spinal cord rostral to the area of interest. Single stimuli rather than brief pulse trains typically are used for spinal cord stimulation.[148] This approach is not commonly used in scoliosis surgery.

Responses can be recorded anywhere distal to the area of interest. They have included the lower lumbar epidural space (i.e., epidural MEP), peripheral nerve (i.e., neurogenic MEP), and peripheral muscles using compound muscle action potential (CMAP) (see Fig. 32.7).[149] Each recording site has its limitations regarding the accuracy of the information displayed and the susceptibility to anesthetic drug interference. Epidural MEPs are the least affected by neuromuscular blocking drugs (NMBDs), but they monitor only conduction in the corticospinal tract and provide no information about the anterior horn grey matter.[150] They have a much slower response to acute spinal cord ischemia compared with myogenic responses (i.e., CMAPs).[151] Neurogenic MEPs are also resistant to anesthetic interference but appear to not accurately measure motor conduction. Most of the spinally elicited peripheral nerve responses seen with neurogenic MEPs occur through the dorsal columns in a retrograde fashion and are sensory rather than motor.[152] Anterior spinal cord injury has been demonstrated with normal neurogenic MEPs.[153] CMAPs after transcranial stimulation are thought to be exclusively generated by motor tract conduction, and unlike epidural MEPs, they include the ischemia-sensitive anterior horn alpha motor neurons.[149] These responses are very sensitive to anesthetic agents. The responses obtained with CMAPs after spinal cord stimulation also appear to contain signals that include transmission through the dorsal columns and may represent a mixed response.[154]

One outstanding problem with MEP monitoring is deciding when and how much change in the signal is indicative of spinal cord ischemia. Some centers use the same criteria they adopted for SSEP monitoring, whereas others require a greater degree of change, such as a 75% decrease in amplitude.[155] An amplitude decrease of 80% at one of six sites using transcranial myogenic MEP monitoring was demonstrated to have a sensitivity of 1.0 and a specificity of 0.91 when used as the sole monitor during spinal surgery.[156] A 65% decrease in amplitude identified all postoperative motor deficits (SSEP changes identified only 43%) in children with idiopathic scoliosis.[157] An alternative technique of measuring MEP has been described in which a minimum threshold for producing a response is established, and a significant increase in that threshold is used to signal a problem.[158] Supportive data for this technique are lacking.

The dorsal columns may be injured without involvement of the motor tract.[159] Occasionally, adverse changes in SSEPs occur without changes in MEPs.[148,160] Because of these reports, MEP monitoring should be used in addition to SSEP monitoring rather than as a replacement.[125–128,161] Whether SSEP monitoring alone is sufficient to reliably identify neurologic deficits remains debatable, with some institutions reporting sensitivity of 95%, specificity of 99.8%, a positive predictable value of 95%, and a negative predictive value of 99.8% for this monitoring.[162] However, multimodal intraoperative monitoring (combination of SSEP and MEP) demonstrated improved sensitivity when compared with either modality alone.[163]

Triggered Electromyographic Techniques

The increasing use of pedicle screws allows greater curve and rotational correction than earlier techniques but has an additional risk of direct nerve root trauma. Triggered EMGs using a monopolar needle or bipolar handheld stimulator have been described, with a threshold stimulation level of more than 8 mA considered to be normal, 5 to 8 mA to be critical, and less than 5 mA to be pathologic, indicating that there was not enough distance between the screws and the neural tissue.[161] This technique requires monitoring rectus abdominis or intercostal muscles when used for thoracic curves.[164,165]

Preoperative Assessment and Postoperative Planning

RESPIRATORY ASSESSMENT AND PLANNING FOR POSTOPERATIVE VENTILATORY SUPPORT

The preoperative pulmonary assessment should identify patients at increased risk for postoperative respiratory compromise. Since patients with idiopathic scoliosis generally have less compromised pulmonary function, most studies have focused on non-idiopathic patients.[78] The rate of postoperative pulmonary complications correlates broadly with the decrease in vital capacity.[72,166,167] Vital capacity less than 30% to 35% of predicted values indicates marginal respiratory reserve and a level at which complications and a need for postoperative respiratory support are likely. Many patients with these low vital capacities are unable to cough effectively, rendering them prone to postoperative atelectasis, pneumonia, and respiratory failure.

Studies of a mixed population of disorders (but a limited number with neuromuscular disorders) with a vital capacity less than 40% reported that despite the occurrence of short-term and middle-term pulmonary complications, these patients can be

successfully discharged home, although some require prolonged postoperative ventilation.[168,169] Modest numbers with a vital capacity less than 25% of the predicted value are included in these studies and do not have greater complication rates than those with greater vital capacities. Anterior or combined approaches increase the likelihood of respiratory complications, particularly owing to pleural effusion.[168,169]

Children with neuromuscular scoliosis are likely to need postoperative ventilation that is often prolonged.[72,167] These patients may also have abnormalities in the central control of breathing and impaired airway defense mechanisms. Impaired coordination of laryngeal and pharyngeal muscles may result in impaired swallowing and inadequate cough with increased risk of aspiration. Initial research suggested that as the vital capacity decreased to less than 35% of predicted, most patients would need a brief period of postoperative ventilation.[101] The earlier use of nocturnal NPPV and use of NPPV in the postoperative period may alter our perception of this risk by decreasing the impact or severity of postoperative respiratory complications while allowing children with increasingly severe respiratory impairment to be considered for surgery. Scoliosis surgery can be successfully undertaken in patients with a vital capacity less than 35% of predicted, often with no more than 24 hours of planned ventilation followed by a period of noninvasive ventilation (e.g., bilevel positive airway pressure [BiPAP]).[72,81,170,171] In one study (n = 30), the overall complication rate was similar whether the FVC was greater than or less than 30%, and the average hospital stay was approximately 3 weeks (see Table 32.2). Tracheostomy was required in two children, and the overall pulmonary complication rate was 30%[171]; similar results are reported by others.[81] It seems reasonable to anticipate using noninvasive ventilator support for several days after spine stabilization surgery in children with a vital capacity less than 25% of predicted values. Children with a mean FVC of 20% of predicted have been successfully managed with a brief period of postoperative ventilation and transition to BiPAP within 48 hours.[172]

Whether a child should be denied surgery requires consideration of individual patient factors. The successful management of children with a vital capacity of 15% to 20% of predicted has been reported, although the sample size was small.[168–171] Although the risk of an unsuccessful outcome can increase at this level of pulmonary dysfunction, individual circumstances may justify the risk. The successful introduction of perioperative NPPV will likely lead to children who were previously considered unsuitable for surgery now being offered surgery, challenging the established limitations.[173]

CARDIOVASCULAR ASSESSMENT

Many children with complex cardiac comorbidities can successfully undergo scoliosis surgery as a result of improvements in understanding, monitoring, anesthesia, and surgical techniques. A greater need for blood transfusion should be expected. A preoperative curve greater than 80 degrees is a risk factor for major complications in children who have had congenital cardiac defects corrected.[174] Children with residual cardiac abnormalities will require prolonged stays in the intensive care unit and hospital. Those with single ventricle or Fontan physiology have increased morbidity and mortality.[175] Increased bleeding is almost always a problem because of high venous pressures; the need for inotropic support and the occurrence of arrhythmias and pleural effusions are common.[175]

Muscle disorders may affect the myocardium and the skeletal system. Children with DMD develop a cardiomyopathy in the second decade that may be difficult to evaluate because the child is wheelchair bound by that age. Sinus tachycardia is an early manifestation. Cardiac function deteriorates during early adolescence[176] as more than 90% of adolescents with DMD have subclinical or clinical cardiac involvement.[177] Echocardiography is an essential aspect of the preoperative evaluation of any wheelchair-bound patient presenting for scoliosis surgery (see also Chapters 17 and 23). Cardiac magnetic resonance imaging may be better than echocardiography for assessment of children with DMD.[178]

POSTOPERATIVE PAIN MANAGEMENT

Scoliosis surgery is associated with severe pain that lasts for at least 3 days.[179] Effective analgesia minimizes postoperative respiratory complications by allowing deep breathing, chest physiotherapy, early ambulation, and rehabilitation. Postoperative pain may be managed with systemic or epidural analgesics. A multimodal approach is likely to be most effective.

Intraoperative Intrathecal and Intravenous Opioids

Intraoperative intrathecal morphine (2–5 μg/kg) has provided potent analgesia during the first 24 hours after spinal fusion in children.[180,181] Intrathecal morphine also decreases the amount of remifentanil required intraoperatively, contributing to less pain when remifentanil is discontinued.[182,183] However, perioperative administration of IV morphine, when using remifentanil as part of the anesthesia technique, does not result in any measurable benefit.[184]

Methadone (0.2 mg/kg) decreases pain scores and opioid requirements for 36 hours in children undergoing surgery, but it seems to have been ignored in modern practice.[185] This drug is used in adult spinal surgery and reports of its use in children are increasing.[186,187] An IV bolus (0.25 mg/kg) followed by an infusion (0.1–0.15 mg/kg per hour) for 4 hours during spinal surgery has been proposed to maintain adequate plasma concentrations for 24 hours.[187]

Nonsteroidal Antiinflammatory Drugs

NSAIDs, but not acetaminophen, impair fracture healing in animal models.[188] Cyclooxygenase-2 (COX-2) activity plays an important role in bone healing, and the use of NSAIDs decreases osteogenic activity that may increase the incidence of nonunion after spinal fusion.[8,9] The effect on osteogenic activity is dose dependent and reversible.[189] Similar effects have not been demonstrated in humans and the use of these drugs after scoliosis surgery varies in different parts of the world.[190] Nonetheless, based on animal evidence, NSAIDs should be used with caution and in consultation with the surgeon during the first 3 to 5 days after scoliosis surgery.[191]

Systemic Analgesics

Morphine remains the mainstay of systemic analgesic regimens. Morphine infusions of 20 to 40 μg/kg per hour are required during the first 48 hours after surgery. Achieving a balance of effective analgesia while avoiding sedation can be difficult in children with neurodevelopmental delay. Regular evaluation of these children is important if complications are to be avoided. Patient-controlled analgesia (PCA) is appropriate for children older than 6 to 7 years of age. It can be used with a typical bolus dose of 20 μg/kg and a lockout interval of 5 to 10 minutes. The use of a background morphine infusion may be effective in some patients, although its inclusion is controversial.[192,193] Our preference is to use a nighttime background infusion at 5 to 10 μg/kg per hour but to use PCA alone during the day (see also Chapter 44). The addition of acetaminophen improves analgesia but does not decrease opioid

requirements.[194] Nurse- and parent-controlled analgesia are effective if the child is too young or unable to use PCA.[195] Intrathecal morphine plus PCA appears to offer the optimal combination of effective analgesia and minimal adverse effects in patients with idiopathic scoliosis compared with PCA morphine alone or epidural morphine.[196] The demands/deliveries ratio of PCA is predictive of increased opioid requirements, with a ratio greater than 1.5 associated with greater pain scores, opioid-related adverse effects, and duration of hospitalization; a ratio greater than 2.5 suggests a benefit from switching opioids.[197]

Low-dose ketamine infusion (0.05-0.2 mg/kg per hour) has been used as an adjunct to morphine infusions or PCA, although its role is debated.[198–203] Ketamine may be initiated intraoperatively (initial infusion of 5 μg/kg per minute, decreasing to 2 μg/kg per minute at the end of surgery) as part of the anesthetic technique to minimize the hyperalgesia reported after high-dose remifentanil infusions. A postoperative 72-hour ketamine infusion did not decrease morphine consumption or pain scores.[204] Ketamine added to morphine PCA has produced mixed results, with no clear beneficial effect in orthopedic surgery, despite such evidence being apparent for thoracic surgery.[205] If added to PCA, the optimal combination of morphine/ketamine is a 1:1 ratio.[201] Although scoliosis is a very painful surgery, it is probably best to reserve the use of ketamine for those with significant preoperative pain or morphine-resistant pain.

Gabapentin and pregabalin may provide some benefit with an opioid-sparing effect,[206] although postoperative nausea and vomiting benefits are limited.[207] Gabapentin (15 mg/kg followed by 5 mg/kg three times daily for 3 days) reduced morphine consumption by about 30% during the study period but without any improvement in morphine's adverse effects. Improved pain relief was observed only until the morning after surgery.[208] All the effects of gabapentin for postoperative pain may have been overestimated by statistically significant small study effects.[209]

Epidural Analgesia

Continuous epidural analgesia using single- and double-catheter techniques may provide effective analgesia after spinal surgery.[210] The single-catheter technique using bupivacaine-fentanyl and sited at T6-7 for patients undergoing a mean 12-level scoliosis surgery resulted in analgesia similar to that of PCA but with more postoperative nausea and vomiting and pruritus. Bowel sounds returned earlier in the epidural group, but liquid intake and hospitalization time were similar.[211] Similar results were reported with a bupivacaine-morphine combination in patients undergoing 10-level spinal fusions. Full diet and discharge from hospital were achieved one-half day earlier with the epidural technique than with PCA.[212] A retrospective review of more than 600 patients treated with an epidural or PCA for analgesia after scoliosis surgery that involved an average 8.5 fused segments confirmed the effectiveness of epidural analgesia.[213] In that study, a bupivacaine-hydromorphone epidural combination effectively controlled the pain, although it was associated with more complications. Respiratory depression and transient neurologic changes were the most common complications observed. Thirteen percent of patients with an epidural catheter required discontinuation of the epidural, most commonly for inadequate pain relief.[213] Effective analgesia and a large incidence of postoperative nausea and vomiting and pruritus have been features of studies that combined bupivacaine and morphine.[214,215]

Patient-controlled epidural analgesia (PCEA) has been successfully used in children older than 5 years of age for orthopedic surgery and thoracotomies.[216] In scoliosis surgery, the pain score with PCEA with bupivacaine and hydromorphone was slightly superior to that with PCA, although there was a 37% failure rate with the former.[217] PCEA with a single- or double-catheter technique (as discussed later), depending on the number of spinal segments involved, with a combined bupivacaine-fentanyl-clonidine solution effectively controlled pain with a relatively small incidence of complications.[218]

Improved pain control and bowel function with decreased adverse effects may be possible by using a double-epidural technique using moderate amounts of fentanyl and clonidine with local anesthetics.[219] Double-epidural techniques use an upper catheter positioned in the upper to middle thoracic segments and a lower catheter at the upper to middle lumbar level.[220,221] This technique improved pain control and was associated with fewer gastrointestinal adverse effects when compared with a single epidural catheter and morphine PCA.[210]

Anesthetic and Intraoperative Management

POSITIONING AND RELATED ISSUES

The patient must be positioned so that extreme pressure points are avoided, the limb positions are adjusted to prevent nerve injury, and the abdomen is free to minimize venous congestion. This is usually achieved by the use of the Relton-Hall frame or a variant.[222] The frame consists of four well-padded supports arranged into V-shaped pairs, with the upper pads supporting the thoracic cage and the lower pair supporting the anterolateral aspects of the pelvic girdle at the anterior iliac crests. The arms must not be abducted or extended more than 90 degrees from their natural position. The weight of the arms is evenly distributed across the forearm to avoid pressure on the ulnar nerve at the elbow. The range of motion of the shoulders should be assessed preoperatively for optimal positioning during anesthesia. This can present quite a challenge in children with severe deformities, and creative positioning may be required. In some centers, the nipples are covered with Tegaderm (3M, St. Paul, MN) and positioned free of direct pressure. It is also essential that the head is maintained in a neutral position and that pressure is evenly distributed between the forehead and face, avoiding direct pressure on the eyeballs. Care must be taken to avoid any direct pressure on the knees, and the patient's weight should be distributed throughout the lower limb (Fig. 32.8). Reston self-adhering foam (3M, St. Paul, MN) may be used to pad the pelvic brim and knees.

Not all spinal tables and frames affect cardiac function in the same way. There is some evidence that the Jackson spine table (Mizuho OSI, CA, USA) or longitudinal bolsters have fewer effects on cardiac function, whereas Wilson and Andrews frames may negatively impact cardiac function.[223] However, an average decrease in cardiac index of 18.5% (0.5 L, 95% confidence e interval [CI] 0.3–0.7L) was observed after placing patients prone on the Jackson table, without a significant change in blood pressure.[224] The use of two chest pads rather than a single pad with the Jackson frame results in smaller average and maximum chest pressures at the expense of increasing the pelvic pressures.[225]

Postoperative visual loss is an uncommon, unpredictable, and devastating complication associated with spinal surgery in the prone position. It may occur in up to 0.2% of cases, and although most of the reports involve adult patients, older children are not immune.[226,227] The most common cause is ischemic optic

neuropathy, but the cause remains obscure. Prolonged operating time (>6 hours) and increased or uncontrolled blood loss are features of most reports.[228–231] The phenomenon is unrelated to pressure on the globe and usually occurs without evidence of any other ischemia-related complications.[231] There are conflicting reports regarding the association with issues such as hypotension, controlled hypotension, anemia, hemodilution, blood loss, rotational positioning of the head, diabetes, and others.[228,231–233]

TEMPERATURE REGULATION

The long preparation time and exposure of undraped patients on a spinal frame render them susceptible to hypothermia. Hypothermia is associated with hemodynamic instability and increased blood loss.[234] A threefold increase in surgical wound infection occurs with a 2°C-decrease in core temperature.[235] Preoperative warming reduces the amount of time that the patient is hypothermic during surgery by almost 2 hours without affecting the temperature at the end of surgery.[236] Efforts should be made to increase the ambient temperature in the operating room while the patient is prepared for surgery. Subsequent hypothermia can be minimized if the room temperature is maintained at 24°C during this period rather than at 18°C to 21°C, as is often encountered during surgery.[237] After the patient has cooled during preparation and positioning, it may take several hours before the core temperature begins to return toward normal. Even with forced-air warming systems, it is often difficult to restore normothermia because only a small amount of the patient's body is exposed to these devices. It may be possible to position a warming blanket underneath the frame so that warming from below and above occurs (see Fig. 32.8 and Video 32.1).

PATIENT MONITORING

Patient monitoring needs to be tailored to the individual case, but at minimum, arterial oxygen saturation, end-tidal carbon dioxide (CO_2), electrocardiographic (ECG) patterns, core temperature, and urine output should be recorded. In most cases, invasive arterial and central venous pressures are monitored because of large blood losses, fluid shifts, and the risk of cardiovascular instability. Externally applied pressure by the surgeon during dissection or curve correction may compromise cardiac function or filling. Central venous pressure is an accurate and valid measurement in the prone position, providing the zero is adjusted for the patient's position on the spinal frame. Patients with a significant kyphotic component are at increased risk for venous air embolism and should be monitored for this possibility. Depth of anesthesia monitoring should be considered; particularly when MEP monitoring limits the concentrations of anesthetic drugs and total IV anesthesia (TIVA) is used. Care should be taken when positioning the head because pressure on the forehead by the sensor while the patient is in the prone position for many hours may cause erythema, localized swelling, and tissue necrosis; contact dermatitis from the adhesive has been reported.[238] Mixed venous oxygen tension trends may be helpful for children with myocardial compromise. Transesophageal echocardiography can be useful for determining ventricular filling and function when hemodynamic compromise is identified or suspected preoperatively.

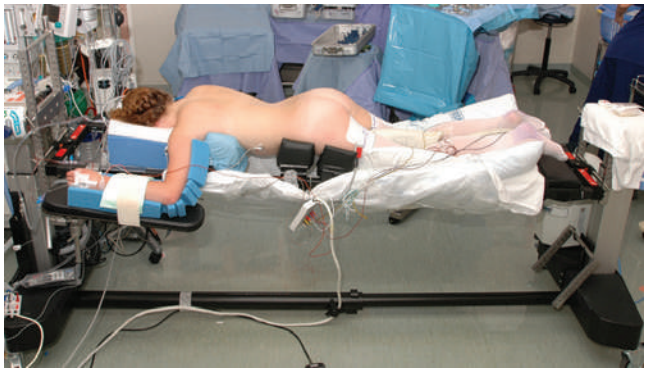

FIGURE 32.8 Positioning on the Orthopedic Systems Incorporated (OSI) Jackson frame (Mizuho OSI, CA, USA), showing protected pressure points and an underframe forced-air warming blanket.

MINIMIZING BLOOD LOSS AND DECREASING TRANSFUSION REQUIREMENTS

Scoliosis surgery involves exposure of a large wound over a considerable period. Positioning the patient with the abdomen free to avoid venous compression is important to control and minimize blood loss. Increased intraabdominal pressure attributable to positioning can double intraoperative blood loss.[239]

More blood tends to be lost in posterior spinal fusion procedures than in anterior procedures. This loss probably corresponds to the greater number of vertebral levels fused with the posterior approach. Blood loss increases as the number of vertebrae included in the fusion increases. The estimated blood loss (EBL) is approximately 750 to 1500 mL in patients with idiopathic scoliosis, or 60 to 150 mL per vertebral segment fused. The blood loss of 1300 to 2200 mL (100–190 mL per vertebral segment) is significantly greater in patients with cerebral palsy. Children with DMD experience the largest EBL: 2500 to 4000 mL (200–280 mL per vertebral level).[240]

Children with neuromuscular scoliosis demonstrate a prolonged prothrombin time and a decrease in factor VII activity intraoperatively, suggesting that consumption of clotting factors and dilution of clotting factors enhance the blood loss.[241] It has been postulated that children with DMD lack dystrophin in all muscle types and that the poor vascular smooth muscle vasoconstrictor response may be a factor in the increased blood loss.[242] Hypothermia exacerbates blood loss by decreasing platelet function, decreasing coagulation factor activity, and slowing vasoconstriction.[234]

Adverse reactions to blood appear to be more common in children than adults, with human error as the most common cause.[243] Several techniques have been used to decrease blood loss and minimize exposure to blood products (see also Chapter 12).

Hypotensive Techniques

Controlled hypotension has been used to minimize blood loss during scoliosis surgery since it was first described more than 30 years ago. A greater than 50% decrease in blood loss with a decreased need for blood replacement and a reduced operating time was demonstrated in early studies. Ganglion-blocking agents (i.e., pentolinium and trimethaphan) have been superseded by β-blockers, direct arterial vasodilators, calcium channel blockers, and α_2-agonists. It remains uncertain whether the reduced blood loss results from the reduced blood pressure[244] or reduced cardiac output.[245] A target mean arterial pressure (MAP) of 50 to 65 mm Hg has been recommended. Although this appears to be safe, concerns that the margin of safety for optic, cerebral, and spinal cord ischemia has reduced the use of controlled hypotension, particularly for operations of prolonged duration. Additionally,

there is the potential that periods of unexpected hypovolemic hypotension may exacerbate and complicate drug-induced (controlled) hypotension.[246,247] The incidence of these feared complications is fortunately very small with or without hypotension. Renal function appears well preserved even when hypotensive anesthesia is used during scoliosis surgery.[248,249] Because of these concerns and the concomitant use of hemodilution, less extreme degrees of hypotension are usually used. Robust data supporting the beneficial effects of controlled hypotension in scoliosis surgery are limited, although clear benefits have been demonstrated for orthognathic and orthopedic surgery.[250,251]

In modern practice, moderate hypotension with good control of the heart rate can often be achieved without the use of specific vasoactive drugs by using a remifentanil infusion titrated to the desired blood pressure.[252] Although not considered a hypotensive agent, intrathecal morphine decreases blood loss and may facilitate blood pressure control, particularly with a remifentanil infusion. At an analgesic dose of 5 μg/kg, a decrease in EBL from 41 to 14 mL/kg has been reported.[181] Using this technique, blood pressure control can frequently be achieved without any additional agents. The use of an anesthetic combination of less than 1 minimum alveolar concentration (MAC) of inhalational agent plus remifentanil with clonidine (2 μg/kg)[253] provides controlled hypotension in most patients without the need for additional agents. Dexmedetomidine may be used as part of a technique for controlling blood pressure.[254,255] Its use resulted in a mean blood pressure of 66 mm Hg (a 20% decrease compared with nonuse), with reduced blood loss (782 vs. 465 mL) and fewer children requiring transfusion.[256]

Short-acting calcium channel blockers have been used to control hypotension in patients undergoing scoliosis surgery, and although these agents are effective, experience is limited. The blood loss during nicardipine for hypotension was less at the same MAP compared with sodium nitroprusside, although blood pressure returned to baseline more slowly (27 vs. 7 minutes) with the former.[257,258] Clevidipine has been used without evidence of clear benefit, but it may be associated with an increase in heart rate.[259] If a hypotensive technique is to be used, invasive arterial monitoring is essential, and central venous pressure catheters are useful for the safe conduct of anesthesia (see also Chapter 12).

Hemodilution

Decreasing the hemoglobin concentration by removing red blood cells and replacing the volume with a combination of crystalloid and colloid means that for a given volume loss, fewer red blood cells are lost (see also Chapter 12). The decreased metabolic rate during anesthesia suggests that oxygen delivery can be maintained with a reduced hemoglobin concentration if normovolemia is maintained.

It has been estimated that more than 2 to 3 units of blood must be removed during hemodilution to significantly reduce transfusion requirements. Hemodilution modeling in adult patients has suggested that as many as 5 units of blood must be removed before there is a decrease in transfusion requirements.[260] Deciding on the degree of hemodilution and establishing a threshold for transfusion may be difficult. In scoliosis surgery, reduction to an initial hematocrit of 30% has been effective for reducing and minimizing transfusion requirements.[261] Some posit that only modest benefits are gained from this technique.[262] Hypotensive anesthesia, hemodilution, and a cell saver used as part of a "bloodless surgery" program with erythropoietin and supplemental iron resulted in an average EBL of 855 mL (blood returned by the cell saver averaged 341 mL), with an average decrease in hemoglobin after surgery of 3.1 g/dL.[263]

Tachycardia and hemodynamic instability are common at hemoglobin concentrations less than 7 g/dL. Myocardial ischemia becomes a risk at hemoglobin concentrations less than 5 g/dL.[264] At this level of anemia, cyanosis cannot develop because 5 g/dL of desaturated hemoglobin is required for cyanosis to be detected. Extreme hemodilution techniques such as these are reserved for patients who oppose blood transfusion. One report detailed patients who had hemodilution during scoliosis surgery to a hemoglobin concentration of 3 g/dL in the absence of preexisting cardiac disease.[265] Cardiac output increased by more than 30%, with only a modest increase in heart rate and decrease in blood pressure.[265] Although no cerebral sequelae were reported, *this degree of extreme hemodilution is not recommended.*

Autologous Predonation

Preoperative strategies, including predonation of blood and preoperative red cell augmentation, may be used alone or in addition to intraoperative techniques to minimize exposure to blood (see also Chapter 12). In idiopathic scoliosis surgery, preautologous blood donation plus intraoperative red cell salvage and controlled hypotension resulted in an average EBL of 1055 mL, avoided transfusion, and decreased the hematocrit by only 10% 35.6% preoperatively to 32.4% at discharge.[266] The advantages of preoperative erythropoietin in addition to preautologous blood donation include a greater preoperative hemoglobin concentration and fewer donated units. Its effect on blood use depends on the total blood loss.[267,268] In children with neuromuscular scoliosis, erythropoietin alone did not affect the amount of blood transfused, although the preoperative and discharge hematocrits were greater in treated patients.[269]

Antifibrinolytic Agents

The use of synthetic antifibrinolytic agents to decrease perioperative blood loss after scoliosis surgery has produced mixed results. To be most effective, an effective plasma concentration of the antifibrinolytics should be established before skin incision (see also Chapter 20). ε-Aminocaproic acid (Amicar) decreases the EBL by 25% during the perioperative period,[270] mainly attributable to decreasing the postoperative suction drainage.[271] In contrast, an initial dose of tranexamic acid (10 mg/kg) followed by an infusion of 1 mg/kg per hour failed to significantly decrease blood loss in a small sample.[272] High-dose tranexamic acid (100 mg/kg loading dose, followed by an infusion of 10 mg/kg per hour), reduced blood loss by 40% but did not affect transfusion requirements. Post hoc analysis in patients with secondary (neuromuscular) scoliosis showed significant reduction in blood loss and transfusion requirements.[273] The correct dose of tranexamic acid remains elusive, but it may be one-half of the high-dose reported previously.[274]

A meta-analysis of aprotinin, tranexamic acid, and ε-aminocaproic acid on blood loss and use of blood products in children undergoing scoliosis surgery showed that all antifibrinolytic drugs decreased the amount of blood transfused and that aprotinin, tranexamic acid, and ε-aminocaproic acid were equally effective.[275] A similar meta-analysis of major pediatric surgery showed that in the scoliosis studies, aprotinin and tranexamic acid reduced blood loss compared with placebo (385 mL, 95% CI 42–727 mL vs. 682 mL, 95% CI 214–1149 mL).[276] In all operations, both drugs also decreased red blood cell transfusion. Demonstration that tranexamic acid is as effective as aprotinin is fortunate, because aprotinin has been withdrawn in many countries after reports of increased morbidity

and mortality in adults after cardiac surgery.[277] However, after a review of the evidence, aprotinin has been reintroduced in Canada, citing off-label use of the drug as the cause of complications. Studies are being conducted in the United States. Use of ε-aminocaproic acid reduced mean intraoperative blood loss (1125 mL vs. 2194 mL), total perioperative blood loss (1805 mL vs. 3055 mL), and transfusion requirements (660 mL vs. 1548 mL) compared with placebo.[278] However, a multicenter study involving 37 hospitals across the United States suggested that ε-aminocaproic acid but not tranexamic acid use was associated with a lower odds ratio (0.42) of transfusion in patients with AIS, but neither drug resulted in a decrease in odds for children with neuromuscular scoliosis.[279]

Reduced blood loss has significant cost savings from decreased operating room time and blood product use.[280] Desmopressin is ineffective in decreasing blood loss associated with spinal surgery. Initial beneficial results with desmopressin[281] have not been reproduced in patients with idiopathic scoliosis[282,283] or in those with neuromuscular scoliosis.[284,285]

Intraoperative Salvage of Shed Blood

Decisions concerning the use of intraoperative salvage of shed blood (e.g., cell saver) depend on the anticipated blood loss, size of the child, and use of other methods to minimize blood transfusion, such as predonation and hemodilution (see also Chapter 12). It is important to have some idea of the blood loss associated with idiopathic scoliosis in your institution when deciding to use cell saver techniques. For example, the cell saver was found to be beneficial in less than 5% of adolescents with idiopathic scoliosis involved with an autologous predonation program or modest intraoperative hemodilution in one institution.[261] At another institution, however, allogeneic transfusion rates were reduced from 55% to 18% when the cell saver was used. The allogeneic transfusion relative risk was 2.04 for patients undergoing surgery lasting longer than 6 hours and 5.87 for patients not receiving cell saver blood.[286] Donor transfusion reduction is most effective when intraoperative cell salvage is combined with either preoperative autologous blood donation or postoperative collection and retransfusion.[287]

Pediatric systems are available with small spinning bowls (55 to 75 mL). These systems benefit children with smaller body weights and greater than anticipated blood loss such as patients with neuromuscular scoliosis undergoing extensive spinal fusion.[288,289] Among children undergoing anterior instrumentation for thoracolumbar curves, cell saver use decreased the number requiring allogenic blood transfusion from 39.4% to 6.7% and with similar mean postoperative hemoglobin values (10.2 vs. 9.6 g/dL).[290]

MANAGING BLOOD LOSS

Autologous blood donation before surgery requires an organized schedule of donation with or without the administration of erythropoietin.[291,292] This may be the safest and most effective method of avoiding or minimizing the use of allogenic blood products.[293] A predonation program was effective in minimizing blood exposure in AIS patients undergoing surgical correction for their scoliosis. A mean of 3.7 units of blood was donated by each patient before surgery, and 97% of adolescents avoided the use of allogeneic blood during and after surgery.[291] Similar results have been reported without predonation. Ninety-five percent of patients with AIS avoided transfusion just by using a cell saver with a transfusion trigger of 7 g/dL. The average drop in Hb was 4.1 g/dL with nadir on postoperative day 2.[294] However, preoperative blood typing for crossmatch is always warranted.

Measurement of blood loss during scoliosis surgery is difficult. Accuracy is lost as measurements embrace blood suctioned from the operative field that includes irrigation fluid, weighing or estimating blood collected on swabs and sponges, approximations of blood on drapes and gowns, and estimations of evaporation from the wound.

The decision about when to administer blood component therapy (i.e., non–red cell blood components) is often based on clinical judgment. Dilutional thrombocytopenia is expected only after several blood volumes have been lost and depends on the preoperative platelet count (see also Chapter 12). Platelet concentrations should be measured after loss of one blood volume and at periodic intervals after this. Dilution of coagulation factors may also lead to surgical bleeding when only packed red blood cells are used to replace blood loss. Prolongation of prothrombin time and activated partial thromboplastin time may occur when the blood loss exceeds one blood volume, and these times should be checked at this time. These coagulation tests are not usually associated with increased bleeding until values are greater than 1.5 times mean control values, at which time increased surgical bleeding can be effectively treated with fresh frozen plasma.[295] Platelet counts after one blood volume loss, whether associated with normal or abnormal clotting, were within the normal range.[295] Blood component therapy should probably be based on abnormal clotting test results, uncontrolled bleeding, or the absence of normal clotting in the surgical field. It is preferable to intervene with blood component therapy before uncontrolled bleeding develops. If pooled blood in a dependent part of the operative field fails to show evidence of clotting, it is time to transfuse with blood components, starting with fresh frozen plasma and administering platelets only if this approach is not effective.[295]

Massive transfusion protocols, in which predefined ratios of red blood cells, plasma factors, and platelets (usually in a 1:1:1 ratio) are administered early in the resuscitation phase of massive trauma, are being increasingly used in all situations of uncontrolled blood loss (see Chapter 12).[296,297] Evidence that these protocols decrease morbidity and mortality in the trauma setting has resulted in their implementation in surgery, in which significant and uncontrolled bleeding may be expected.[298,299] By adopting these protocols, proportionally greater quantities of factors and platelets are transfused compared with conventional approaches in severe hemorrhage, but it is associated with increased survival.[300] However, there is no evidence that this approach is beneficial in elective surgery.

The thromboelastogram is useful in refining blood product administration if multiple blood volumes are required for resuscitation.[298,300] Scoliosis surgery in patients with neuromuscular scoliosis or cerebral palsy, particularly in those with severe complex curves in whom pelvic stabilization and iliac crest grafts are considered, fulfill these criteria. In this group of patients, early administration of blood and factors using a massive transfusion protocol may be beneficial.[301] Recombinant factor VIIa may be a useful therapy for patients with a dilutional coagulopathy who are unresponsive to blood component replacement therapy. Successful use with doses as small as 20 μg/kg has been described in spinal surgery.[302–305]

EFFECTS OF ANESTHETICS ON SOMATOSENSORY EVOKED AND MOTOR EVOKED POTENTIALS

Anesthetic agents act by directly inhibiting synaptic pathways or by indirectly changing the balance of inhibitory and excitatory

influences.[306,307] The greater the number of synapses and the more complex the neuronal pathway being monitored, the greater the potential impact of anesthetic agents on the evoked potentials. Most anesthetic agents depress the amplitude and increase the latency of SSEPs and MEPs. For this reason, cortical SSEPs are more sensitive than spinal cord– or brainstem-measured SSEPs. MEPs are susceptible to anesthetic agents at three sites: the motor cortex, the anterior horn cell, and the neuromuscular junction. Consequently, transcranial stimulation with peripheral muscle detection (using CMAPs) is most susceptible to anesthetic interference. Although inhalational anesthetics and most IV anesthetics markedly depress SSEPs and MEPs, ketamine and etomidate appear to enhance the amplitudes of both, possibly by attenuating inhibition.[307]

Inhalational Anesthetics

Inhalational anesthetics cause a dose-dependent depression of both SSEP and myogenic MEP, although at equipotent concentrations, the MEP is affected to a greater degree than the SSEP. This means that while inhalation agents can be used during SSEP monitoring, they often need to be administered in subanesthetic doses during MEP monitoring. Adequate cortical SSEPs and subcortical SSEPs can be measured with up to 1 MAC of isoflurane, sevoflurane, and desflurane, although some increase in latency and decrease in amplitude may be detected.[308,309] It is important to maintain constant end-tidal concentrations throughout anesthesia after baseline measurements have been established. The concentrations of these inhalational anesthetics that allow adequate monitoring are significantly less than was possible with halothane.[310]

Myogenic MEPs (i.e., CMAPs) are recordable only at low concentrations of inhalational anesthetics. The exact concentration depends on the system being used and is greatly influenced by the number of pulses in the stimulus. Single-pulse transcranial stimuli may be inhibited by end-tidal concentrations as small as 0.2 MAC and abolished by end-tidal concentrations as small as 0.5 MAC.[311–313] This suppression can be partially overcome by using greater intensity stimuli with multipulse stimulation of up to 6 pulses per stimulus. An increasing number of patients lose recordable myogenic MEPs, even when multipulse stimuli are used, as the concentration of inhalational anesthetic exceeds 0.5 MAC. At end-tidal concentrations in excess of 0.75% isoflurane, monitoring conditions become unacceptable.[314–318] Stimulus intensity and pulse train frequency probably are factors in determining successful myogenic MEPs with inhalational anesthetics. Using direct stimulation of the cortex during craniotomy, CMAP was easily recordable at 1 MAC of isoflurane and sevoflurane.[319] Similar results have been demonstrated with sevoflurane using transcranial stimulation.[320] Information regarding desflurane is limited, and although it causes a dose-dependent depression, myogenic MEPs have been successfully recorded at 0.5 MAC.[318,321] Using a multipulse stimulation technique, intraoperative recording of MEPs was equally successful during desflurane or propofol anesthesia.[322] Desflurane anesthesia allowed MEP monitoring when used to provide a depth of anesthesia that maintained the bispectral index (BIS) at 40 to 60 or at a concentration of 0.6 to 0.8 MAC.[323,324] There was no difference in the amplitude or latency of SSEPs compared with propofol (150–300 μg/kg per minute) titrated to a similar BIS.[324] Low-dose desflurane is a viable alternative to propofol infusion and may be associated with a quicker wake-up time.[324]

Nitrous Oxide

Nitrous oxide reduces the amplitude of the cortical SSEP, but comparisons with other inhalational anesthetics are limited. Nitrous oxide (0.5 MAC) depresses SSEPs to a greater extent than isoflurane at a similar MAC.[325] Similarly, 66% nitrous oxide depressed SSEPs to a greater extent than propofol (6 mg/kg per hour; 100 μg/kg per minute).[326] Nitrous oxide depresses myogenic MEPs.[309] The effect relative to other inhalational anesthetics is difficult to determine. Nitrous oxide appears to affect CMAP amplitude to a lesser extent than isoflurane.[327] Multipulse stimulus techniques can partially reverse nitrous oxide–induced depression of amplitude. Compared with a propofol infusion designed to maintain a target concentration of 3 μg/mL, 50% nitrous oxide decreases CMAPs with single or paired stimuli to a lesser extent.[328] When 60% nitrous was added to low-dose propofol infusion at a target concentration of 1 μg/mL, adequate CMAPs were obtained using multipulse transcranial stimulation.[329] Conversely, the addition of nitrous oxide to a variety of different total IV techniques significantly depressed the CMAP such that some were not recordable.[330] With the widespread availability of remifentanil and the variable but mostly negative effects of nitrous oxide on SSEP and MEP signals, the latter is best avoided when monitoring spinal cord potentials.

Propofol

Propofol decreases the amplitude of the cortical SSEP, but adequate signals can be recorded, even in the presence of nitrous oxide, at doses used for anesthesia (6 mg/kg per hour; 100 μg/kg per minute).[331] Propofol better preserves cortical SSEP amplitude and provides a deeper level of hypnosis as measured by processed electroencephalographic values than combinations of low-dose isoflurane and nitrous oxide or low-dose isoflurane or sevoflurane alone.[332–334]

Propofol depresses the amplitude of myogenic MEPs. In addition to its cortical effect, it suppresses activation of the alpha motor neuron at the level of the spinal grey matter.[335,336] Low-dose propofol infusions have become popular as part of the anesthetic technique used with MEP monitoring owing to the rapid improvement of signals when the drug is terminated and because multipulse stimulation techniques can improve the response amplitude.[315,337] Propofol, even in combination with nitrous oxide, depresses multipulse transcranial CMAPs less than isoflurane.[315] Propofol (5 mg/kg per hour; 83 μg/kg per minute) combined with 66% nitrous oxide produced satisfactory CMAP recordings in 75% of patients when a four-pulse stimulation sequence was used. In contrast, no recordings were possible with 1 MAC of isoflurane.[316] The infusion rates or target concentrations that allow acceptable myogenic MEP recordings vary considerably and reflect different adjuvants (e.g., opioids, ketamine, nitrous oxide), degrees of neuromuscular blockade, and transcranial pulse rates. Propofol at a target of 4 μg/mL or at an infusion rate of 6 mg/kg per hour (100 μg/kg per minute) produces acceptable signals with multipulse stimuli.[337–339] Target-controlled infusion models have poor performance characteristics in children undergoing scoliosis repair. Using the Paedfusor model, measured propofol concentration was almost always greater than predicted (see Chapter 8).[340] Because MEPs appear particularly sensitive to depth of anesthesia, it is important that a BIS monitor is used with propofol infusions.

α_2-Adrenoreceptor Agonists: Clonidine and Dexmedetomidine

The cerebral effects of the α_2-agonists appear to act mainly at the locus coeruleus, rather than by the more generalized inhibition of synaptic pathways, as in the case of general anesthetics.[341] Clonidine at IV doses of 2 to 5 μg/kg had minimal effects on cortical SSEPs

when added to isoflurane.[342–344] In view of its lack of effect on SSEPs and its anesthetic-sparing properties with inhalational agents and propofol,[344–346] it seems reasonable to consider clonidine at a dose of 2 to 4 μg/kg as part of an anesthetic technique. Dexmedetomidine has similar beneficial properties on SSEPs.[347,348]

There are no published studies on the effects of clonidine on MEPs, but a few publications have examined dexmedetomidine and MEPs with variable results.[349–352] Dexmedetomidine, like other anesthetic agents, produces a dose-dependent depression of MEPs, rendering the ability to interpret these signals dependent on the depth of anesthesia. This suggests that the depth of anesthesia should be monitored when recording MEPs to maintain a plane of anesthesia that is adequate to prevent recall but still ensure meaningful MEP signals. When dexmedetomidine is added to a propofol infusion, it decreases the dose of propofol required to maintain anesthesia at a BIS of 40 to 60 by more than 50%, provides moderate hypotension, decreases blood loss, and allows monitoring of MEPs and SSEPs, but at the expense of slightly prolonged waking.[256] During the loading dose of dexmedetomidine, MEP decreased transiently in some patients in parallel with a decrease in the BIS from 50 to 30. However, the BIS rebounded to greater than 40 once the maintenance infusion was started.

We have observed similar effects with clonidine as an adjunct; a temporary decrease in MEPs sometimes occurs if clonidine is administered too rapidly, but the signals improve if the BIS is maintained in the 50 to 60 range.

Opioids

Alfentanil, fentanyl, sufentanil, and remifentanil minimally depress SSEP and MEP signals.[353,354] Dose-dependent depression of the CMAP occurs at doses of opioids that far exceed those used in clinical anesthesia.[355,356] Comparison of alfentanil, fentanyl, and sufentanil at doses sufficient to suppress noxious stimuli suggested that sufentanil exerted the least effect of the three opioids.[355] A similar study that included remifentanil showed that it depressed the signals the least, with CMAPs measurable at infusion rates of 0.6 μg/kg per minute.[356] It is likely that greater doses can be used if clinically indicated.

Ketamine and Etomidate

Ketamine enhances the cortical SSEP amplitude and has a minimal effect on subcortical and peripheral SSEP responses.[357] It also produces minimal effects on the myogenic MEP responses as a bolus of 0.5 mg/kg [358] or when used in moderate doses (1-4 mg/kg per hour; 17-83 μg/kg per minute) as a supplement to a nitrous oxide–opioid anesthesia.[358,359] Experimental evidence suggests S(+)-ketamine modulates the CMAP by a peripheral mechanism at or distal to the spinal alpha motor neuron.[360] Ketamine (4 μg/kg per minute) has been successfully used with MEP monitoring during propofol-remifentanil anesthesia for scoliosis correction.[146,361]

Although capable of inducing general anesthesia, etomidate behaves more like ketamine in its effect on evoked potentials. It improves the quality of SSEPs and enhances the amplitude of MEPs.[362] It produces minimal changes in MEPs compared with barbiturates or propofol.[335] Etomidate infusions (10-35 μg/kg per minute) produce adequate MEP monitoring signals.[358,363] Concerns regarding adrenocortical depression with etomidate infusions remain and limit its widespread use.[364] Bolus doses of etomidate, however, can transiently depress MEPs.[358] A new etomidate analog is under investigation that will have a half-life of minutes with no associated adrenocortical depression and no active metabolites[365,366]; when commercially available, this drug may provide an alternative to propofol.

Midazolam

IV midazolam (0.2 mg/kg) decreases the SSEP amplitude by 60%.[367] This does not occur with subcortical SSEPs, for which a slight increase in latency but no change in amplitude has been demonstrated.[368] Although midazolam (0.5 mg/kg) caused marked depression of MEPs in nonhuman primates that persisted during awakening,[369] this finding does not hold true in human studies. MEP amplitude was unaffected by a midazolam-ketamine infusion technique compared with propofol-ketamine or propofol-alfentanil techniques.[330] Midazolam did not suppress myogenic MEPs, even at doses sufficient to produce anesthesia.[356] Effects were similar to those with etomidate.[356]

Neuromuscular Blockade

NMBDs exert little or no effect on the SSEP. They prevent or limit recording of CMAPs during myogenic MEP recording because of their effects on the neuromuscular junction. Partial neuromuscular blockade, however, is commonly used during MEP monitoring because it improves conditions for surgery by providing adequate muscle relaxation when retraction of the tissues is required and limits any patient movement during the stimulus generation. Partial muscle relaxation may also reduce noise caused by spontaneous muscle movement. Constant neuromuscular blockade must be maintained during the procedure. Many centers avoid neuromuscular blockade after intubation, the initial incision, and muscle dissection.

Two methods have been used to assess the degree of neuromuscular blockade for MEP monitoring. One is measurement of the amplitude of the CMAP produced by single supramaximal stimulation (T1) before an NMBD is administered. When T1 is maintained between 20% and 50% of the baseline level, reproducible CMAP responses can be obtained with a degree of muscular blockade that allows surgery.[363,370] The other technique is adjustment of the neuromuscular blockade based on the train-of-four responses. Comparison of the fourth twitch (T4) with that of first twitch (T1) suggests acceptable CMAP monitoring is possible when two of the four twitches remain.[370–372] Neuromuscular blockade should be evaluated in the specific muscle groups that are used for electrophysiologic monitoring because different muscle groups have different sensitivities to the NMBDs. Patients with preoperative neuromuscular dysfunction tend to demonstrate greater effect after partial neuromuscular blockade than those with normal preoperative motor function. It is appropriate to avoid neuromuscular blockade in most of these patients.[363]

CHOOSING ANESTHETIC DRUGS AND TECHNIQUES

The choice of anesthesia depends on the patient's pathology and the type of electrophysiologic monitoring for the operation. A marked increase in the use of MEPs and advances in MEP techniques have occurred worldwide. CMAPs appear to provide the most useful data for minimizing the risk of spinal cord injury.

The key to success is to use a technique that allows a stable concentration of the hypnotic component of anesthesia. There are nominal differences between the inhalational anesthetics (<1 MAC) and propofol (<6 mg/kg per hour; 100 μg/kg per minute). Concentrations of the inhalational anesthetics approaching 1 MAC are now compatible with multipulse MEP monitoring systems that did not appear possible several years ago. Short-acting medications offer greater flexibility if the monitored signals deteriorate.

The use of a remifentanil infusion allows a rapidly titratable analgesic component with minimal effect on spinal cord monitoring. Clonidine or dexmedetomidine may be used to decrease the concentration of hypnotic drugs during SSEP monitoring and MEP monitoring, but the depth of anesthesia should be also be monitored. Although propofol infusions appear to have become a popular anesthetic technique, there is no reason desflurane at equi-anesthetic doses should not be used with the benefit of a quicker wake-up, should neuromonitoring signals rapidly deteriorate.

Ketamine as the main component of anesthesia may improve MEP monitoring because it better preserves the MEP signals and allows reduced doses of other hypnotic agents to be used, but low-dose ketamine used as an adjunct to a conventional anesthetic does not. If processed electroencephalographic monitoring is used to determine anesthetic depth, the addition of ketamine may confound the reading by increasing it.[373,374] This occurs despite a deepening level of hypnosis.[373] An NMBD improves the SSEP monitoring and may be used in conjunction with MEP monitoring within the confines described earlier. However, even in patients with idiopathic scoliosis, adequate operating conditions after the initial muscle dissection can be produced in the absence of neuromuscular blockade. In the absence of muscle relaxation, muscle contractions, including those of the masseter muscles, occur during stimulation. In this situation, it is prudent to insert a bite block to prevent obstructing the tracheal tube or to intubate the patient nasally.

Tourniquets

INDICATIONS AND DESIGN

The tourniquet was used by the Romans to control bleeding during amputation.[375] The arterial tourniquet is used during orthopedic procedures to reduce blood loss and provide good operating conditions, for IV regional blockade and sympathectomy, and for isolated limb perfusion in the management of localized malignancy.[376]

The word *tourniquet* is derived from the French verb *tourner,* meaning "to turn," referring to the twisting or screwing action applied to the constricting bandage to tighten it. In 1873, von Esmarch introduced the use of a flat rubber bandage wrapped repeatedly around a limb.[375] Although this rubber bandage is still used to render a limb bloodless, the pneumatic tourniquet, introduced by Cushing in 1904, has replaced the rubber bandage to maintain ischemia. Compressed nitrogen or air is used for inflation. The target pressure is preset, and compensatory feedback mechanisms maintain that pressure during inflation. Curved and wider tourniquet cuffs, which are designed to fit conical limbs, are associated with lower arterial occlusion pressures than standard cuffs.[377] A soft dressing applied to the limb before tourniquet application helps to prevent wrinkles and blisters that may occur when the skin is pinched.[378] Adequate exsanguination can also be achieved by elevation of the arm at 90 degrees or the leg at 45 degrees for 5 minutes.[379,380]

PHYSIOLOGY

Ischemia

Ischemia leads to tissue hypoxia and acidosis. The severity and consequences of the associated changes (e.g., increased capillary permeability, coagulation alteration, cell membrane sodium pump activity) depend on the tissue type, duration of ischemia, and collateral circulation. Muscle is more susceptible to ischemic damage than nerves. Histologic changes are more pronounced in muscle beneath the tourniquet compared with muscle distal to the tourniquet.

Reperfusion

Reperfusion removes toxic metabolites and restores energy supplies. There is a sudden release of lactic acid, creatinine phosphokinase (i.e., creatine kinase), potassium (peak increase of 0.32 mEq/L), and CO_2 (peak increase of 0.8–18 mm Hg) when the cuff is deflated suddenly. Metabolic changes increase after longer periods of ischemia but return to baseline within 30 minutes. Muscle damage may release myoglobin, which can collect in the collecting tubules of the kidney, precipitating renal failure.

Systemic effects after deflation of the tourniquet include a shift of blood volume back into the limb with a transient decrease in blood pressure that is exacerbated by a postischemic reactive hyperemia in the limb. CO_2 release transiently increases the minute volume. The rapid increase in CO_2 is also associated with a transient (8–10 minutes) increase in cerebral blood volume that may affect patients with raised intracranial pressure.[376]

Increased microvascular permeability of muscle and nerve tissue occurs with tourniquet release after 2 to 4 hours of ischemia. Interstitial and intracellular edema and capillary occlusion owing to endothelial edema and leukocyte aggregation may take months to resolve.

Ischemic Conditioning

Short periods of ischemia followed by reperfusion render muscle more resistant to subsequent ischemia. Ischemic preconditioning improves skeletal muscle force, contractility, and performance and decreases fatigue of skeletal muscle. This preconditioning may enable prolongation of orthopedic and reconstructive procedures.[381]

COMPLICATIONS

Local Complications

Muscle Damage

Histologic changes in the muscle beneath the tourniquet occur after 2 hours of tourniquet time (at 200 mm Hg [26.7 kPa]), but similar changes can occur in the distal ischemic muscle after 4 hours of tourniquet use. Direct pressure and mechanical deformation contribute to increased severity of muscle damage under the cuff.[376] These changes include an increase in the number of inflammatory cells in the perivascular space, focal fiber necrosis, and signs of hyaline degeneration.

The combination of muscle ischemia, edema, and microvascular congestion contributes to posttourniquet syndrome: edema, stiffness, pallor, weakness without paralysis, and subjective numbness of the extremity without objective anesthesia. The common use of postoperative casts may conceal the true incidence of this syndrome. Recovery usually occurs over 7 days.[382]

Nerve Damage

The cause of nerve injuries after tourniquet use probably is direct compression under the cuff rather than ischemia. Sheer forces that are maximal at the upper and lower edges of the tourniquet cause the most damage. These forces are greater with the Esmarch bandage than with the pneumatic tourniquet. The incidence of nerve injuries in the upper limb (1 case per 11,000 patients) is greater than in the lower limb (1 case per 250,000 patients); the radial nerve is the most vulnerable nerve in the upper extremity, and the sciatic nerve is the most vulnerable in the lower extremity.[383]

Vascular Damage

Arterial injury is uncommon in children. It is an injury of adults with atheromatous vessels, and the tourniquet should be avoided in patients with absent distal pulses, poor capillary return, a calcified femoropopliteal system, or a history of vascular surgery on the involved limb.[384]

Skin Safety

Pressure necrosis and friction burns may occur with poorly applied tourniquets, and some form of skin protection should be used routinely.[385] A "limb protection sleeve" may help reduce wrinkling, shearing, and pinching of soft tissues. Chemical burns may result from antiseptic skin preparations that seep beneath the tourniquet and are then retained and compressed against the skin.

Tourniquet Pain

The tourniquet causes a vague, dull ache that becomes intolerable after approximately 30 minutes.[386] This pain is associated with an increase in heart rate and blood pressure that is not ameliorated by general anesthesia and neuraxial blockade.[386] The pain is transmitted by unmyelinated C fibers, which are normally inhibited by fast pain impulses transmitted by myelinated A-delta fibers, but in this case, mechanical compression reduces transmission through the larger A-delta fibers.[387] Narrow silicon ring tourniquets may be associated with less pain than wide tourniquets.[388]

Systemic Complications

Temperature Regulation

The combination of decreased heat loss from the ischemic limb and reduced heat transfer from the central to ischemic peripheral compartment increases core body temperature.[389,390] Bilateral tourniquets increase the temperature more than unilateral tourniquets.[390] Children who require intraoperative tourniquets should not be aggressively warmed during surgery.[390] Redistribution of body heat and the efflux of hypothermic venous blood from the ischemic area into the systemic circulation after deflation of the tourniquet decreases the core body temperature, which may switch off thermoregulatory vasodilation and decrease the skin-surface temperature.[391]

Deep Vein Thrombosis and Emboli

The incidence of emboli after release of the tourniquet in children is unclear. The tourniquet appears to have no influence on deep vein thrombosis, but release of the tourniquet may be associated with an increased risk of embolism in adults. Some clinicians have suggested that heparin be used during total joint arthroplasty in adults to prevent emboli formation,[392] although this practice is not routine in children. Some surgeons use such therapy in adolescents.

Sickle Cell Disease

Hypoxia, acidosis, and circulatory stasis contribute to the sickling of sickle cells in susceptible individuals. However, several institutions routinely use tourniquets in children with sickle cell disease while maintaining acid-base status, hydration, and oxygenation throughout the procedure.[393,394] Each case must be assessed individually for the balance between the advantages of a bloodless field and the risks of precipitating sickling crises (see Chapter 10).

Drug Effects

Antibiotics given after the tourniquet is inflated do not produce effective concentrations in the blood and tissue of the ischemic limb. Inflation of the tourniquet should be delayed at least 5 minutes after administration of the antibiotics.[395,396] Medications administered before inflation of the tourniquet may be sequestered in the ischemic limb and then re-released into the systemic circulation when the tourniquet is deflated. The antibiotic effect depends on the amount of antibiotic sequestered, the tissue binding, and the concentration-response relationship for the antibiotic, although the impact is minimal for most medications used in anesthesia. Volume of distribution may be reduced if the drug is administered after the tourniquet is inflated, but the plasma clearance remains unaffected.

RECOMMENDED CUFF PRESSURES

Most clinicians limit the duration of tourniquet inflation to a maximum of 1.5 to 2 hours. Techniques such as hourly release of the tourniquet for 10 minutes, cooling of the affected limb, and alternating dual cuffs may reduce the risk of injury.[397] Nerve and muscle injuries that occur beneath the tourniquet cuff are related to the pneumatic pressure. Consequently, the minimum pressure that maintains ischemic conditions should be sought. Hypotensive anesthetic techniques have been used in adults to reduce the need for high cuff inflation pressures,[398] but there seems to be little need for this in children. One study recommended that the arterial occlusion pressure in each child should be measured by Doppler and the tourniquet pressure set to 50 mm Hg in excess of this value.[399] Alternatively, the tourniquet pressure may be set to 20 mm Hg in excess of the arterial occlusion pressure for similar results.[400] However, these empiric formulas ignore the typical fluctuations in blood pressure that occur during surgery. The optimal tourniquet pressure may be one that fluctuates with the systemic blood pressure.[401] Maximum mean pressures recommended for the upper and lower extremities are 173.4 ± 11.6 mm Hg (range, 155–190 mm Hg) and 176.7 ± 28.7 mm Hg (range, 140–250 mm Hg), respectively.[399] Wider cuffs exert less force per unit area and reduce the risk of local sequelae. Recommendations for adults suggest that the cuff should exceed the circumference of the extremity by 7 to 15 cm. This is difficult to achieve in infants, in whom the proximal limb length is proportionally shorter than in adults and the wide cuffs impinge on the surgical field. New disposable narrow elastic ring tourniquets may improve access for short-duration adult surgery, but concerns about injury risk limit their use in children.[402]

Acute Bone and Joint Infections

The mainstays of management for osteomyelitis and septic arthritis are antibiotics and surgical drainage. The incidence of these infections is increasing, particularly in immunocompromised children with HIV infection. Tuberculosis remains a scourge in many developing countries. Mortality rates for hospital-acquired staphylococcal disease in compromised children[403] and community-acquired disease in healthy children[404–406] range from 8% to 47% for those presenting with severe sepsis.[407] *Mycobacterium* and *Staphylococcus* species resistant to conventional antibiotics increase morbidity and mortality rates.

PATHOPHYSIOLOGY

Staphylococcus aureus is the most common pathogen. Osteomyelitis develops after bacteremia and occurs mostly in prepubertal children. Normal bone is highly resistant to infection, but *S. aureus* adheres to bone by expressing receptors for components of bone matrix, and the expression of collagen-binding adhesin

permits the attachment to cartilage.[408] After the microorganisms adhere to bone, they express phenotypic resistance to antimicrobial treatment.[408]

The metaphyseal region around the growth plate is the predominant area of infection. Sluggish blood flow in the metaphysis predisposes children to bacterial infection, and endothelial gaps in developing vessels allow bacteria to escape into the metaphysis. Subsequent abscesses may decompress into the joint or subperiosteally. Infection may involve adjacent tissue planes, and hematogenous spread causes multiple pathologic processes beyond the primary site of infection.

Septic arthritis is more common in neonates because transphyseal vessels link the metaphysis and epiphysis. Growth plate and epiphyseal destruction may occur in this age group. Articular cartilage damage is attributable to the release of proteolytic enzymes by the pathogen and activated neutrophils.

CLINICAL PRESENTATION

Most children with staphylococcal disease present with musculoskeletal symptoms and fever, but those with disseminated disease may be critically ill (4%–10%) with severe sepsis, lung disease, and extracutaneous foci.[404,405] One report found that one-half of extracutaneous foci of staphylococcal infection were not detected on hospital admission, and one-third of these lesions were observed for the first time at autopsy.[403] There is often a history of trauma.[404,405] An absolute polymorphonuclear cell count of greater than 10,000/mm^3 or an absolute band-form count of greater than 500/mm^3, or both, correlates with the presence of one or more inadequately treated sites of staphylococcal infection.[403] Tuberculosis is the great mimic and must always be suspected in endemic areas.

Diagnosis is confirmed by blood, bone, or joint aspirate culture. Radiologic procedures (e.g., plain radiographs, computed tomography, magnetic resonance imaging, radionuclide scans) are often required to identify foci, and the anesthesiologist is often requested to provide sedation.[409]

TREATMENT OPTIONS

Antibiotic therapy is the mainstay of treatment. Initial antibiotic choice is dictated by age and by local pathogen and sensitivity profiles. Antibiotic treatment should be extended to cover gram-negative enterococci in neonates and *Streptococcus* in older children. *Haemophilus influenzae* remains a pathogen in unvaccinated regions. Surgical decompression of acute osteomyelitis that is responding poorly to antimicrobial therapy may release intramedullary or subperiosteal pus and lead to clinical improvement. Pus within fascial planes also requires release. Venous thrombosis attributable to pus in soft tissue planes around major joints was associated with a high mortality rate in one series.[404] Determining and eradicating the primary focus improves the mortality and reduces recurrence rates.[410] An aggressive search for foci and surgical drainage of infective foci is required.

Highly active antiretroviral therapy (HAART) has positively altered the mortality rates for HIV-infected children. However, acute bone and joint infections still occur,[411] and these drugs can cause significant morbidity resulting from changes in fat distribution, lipid profiles, glucose concentrations, homeostasis, and bone turnover.[412] Infarction may replace infection as the major cause of morbidity and mortality from HIV.[412] It is uncertain whether HAART should be continued during acute osteomyelitis. Worsening cell-mediated immune function may occur during tuberculosis treatment if HAART is continued.[413] The combination of HIV infection and tuberculosis can be lethal in children; antituberculosis treatment is continued for 12 to 18 months.

ANESTHESIA CONSIDERATIONS

Anesthesiology services are commonly required for sedation during diagnostic investigation, anesthesia for surgical exploration and release of pus or fixation of pathologic fractures, management of pulmonary complications (e.g., intercostal chest drain insertion, pleurodesis), central venous cannulation for long-term antibiotic treatment, and analgesic modalities.

Children with disseminated staphylococcal disease may be critically ill with multisystem disease and require fluid volume augmentation, inotropic support, positive-pressure ventilation, extracorporeal renal support, and coagulation factor replacement. Others may appear clinically stable before induction of anesthesia; the assessment of hypovolemia in children is subject to moderate to poor interrater agreement.[414] IV access and rehydration are required before beginning anesthesia to avoid a precipitous blood pressure drop immediately after induction. Bacteremic showering during manipulation and drainage of pus causes further decompensation. Excessive bleeding owing to altered coagulation status should also be anticipated.

The presence of a septic arthritis in the shoulder or neck may cause cervical ligamentous laxity predisposing to C1–2 subluxation during intubation.[415] Pneumatoceles from staphylococcal pneumonia can rupture during positive-pressure ventilation. A spontaneous breathing mode, however, may be difficult to achieve because of laryngospasm, breath-holding, increased secretions, and bronchospasm. The use of NMBDs and positive-pressure ventilation in these patients with a low threshold for introducing inotropes to support the cardiovascular system is an easier option. Vigilance is required for acute pneumothorax.

Myocarditis, pericarditis, and pericardial effusions compromise myocardial function. A 12% prevalence of infective endocarditis among children with hospital-acquired *S. aureus* bacteremia has been reported.[416] This prevalence of infective endocarditis is frequently associated with congenital heart disease and the necessity for multiple blood cultures.[416] The incidence of infective endocarditis among children with community-acquired disease without preexisting cardiac abnormalities is low,[404] suggesting that echocardiography could be reserved for children with preexisting cardiac disease, those with suspicious clinical findings, those whose temperature fails to stabilize, or those who have prolonged bacteremia without an obvious source of infection.

PAIN MANAGEMENT

Morphine and acetaminophen are the analgesics commonly used for postoperative pain management. The use of tramadol in children is increasing as our understanding of the pharmacokinetics of this medication increases.[417,418] The low incidence of respiratory depression and constipation, fewer controls on use, and similar frequency of nausea and vomiting (10%–40%) compared with opioids make tramadol an attractive alternative.[419–421] NSAIDs are relatively contraindicated in the presence of coagulation disorders, altered renal function, and COX-2–mediated osteogenesis.

The performance of regional blockade in children with acute bone or joint infection is controversial. There are no studies addressing the risk/benefit ratios of regional techniques in this population. It seems reasonable to use these techniques only after 24 hours of appropriate antibiotic therapy in apyrexial children who show no signs of a coagulopathy.

Common Syndromes

Children with some specific conditions present repeatedly for orthopedic procedures. It is worthwhile maintaining a database that details their anesthetic management. There should be 24-hour access to standard texts or electronic information concerning anesthesia and uncommon pediatric diseases.

CEREBRAL PALSY

Clinical Features

Cerebral palsy is an umbrella term that describes a group of nonprogressive, but often changing, motor impairment syndromes caused by lesions or anomalies in the brain that occur during the early stages of its development.[422] It is the leading cause of motor disability during childhood, with a prevalence of approximately 2 per 1000 live births in developed countries.[423]

Disorders include cognitive impairment, sensory loss (i.e., vision and hearing), seizures, and communication and behavioral disturbances. Systemic disorders resulting from cerebral palsy affect the gastrointestinal, respiratory, urinary tract, and orthopedic systems. Cerebral palsy is divided into three broad categories: spastic (70%), dyskinetic (10%), and ataxic (10%). Children with spastic cerebral palsy commonly present for orthopedic procedures because of contractures at major peripheral joints.[424,425] Functional improvement after surgery in children with spastic diplegia and spastic hemiplegia is better than in those suffering spastic quadriplegia.[424]

Orthopedic Considerations

Orthopedic manipulations form only part of the treatments designed to improve performance or improve the ease of care.[426] Management, including orthopedic surgery, physical and occupational therapy, recreational therapy, orthotics, and assistive devices, improves functional outcomes. Medical modalities such as intramuscular injections of botulinum toxin and intrathecal administration of baclofen by means of an implanted pump may also be of benefit.[427] Selective dorsal rhizotomy has been used to control spasticity.[428,429]

The indications for and timing of surgical interventions vary. Gait analysis increases the age of the patient at the first orthopedic surgical procedure, and botulinum toxin type A treatment delays and reduces the frequency of surgical procedures on the lower extremities.[430,431] Bone and soft tissue surgical procedures are designed to lengthen or weaken spastic muscles to give opposing muscles a chance to attain muscle balance.

Anesthetic Considerations

Children with cerebral palsy who present for orthopedic surgery often have previous experience with operating rooms. They should be handled with sensitivity because communication disorders and sensory deficits may mask mildly impaired or normal intellect. They may be accompanied by a parent or caregiver or be premedicated for induction of anesthesia or in the recovery room. If there is a communication problem, the parent or caregiver should be present before and after anesthesia.[424,432] These children have an increased risk of postoperative complications, which correlates with the severity of the child's preoperative condition.[433] Preoperative risk factors associated with increased risk included an American Society of Anesthesiologists physical status score exceeding 2, history of seizures, upper airway hypotonia, general surgery procedures, and adults.[433]

Medical conditions (e.g., seizure control, respiratory function, gastroesophageal reflux) should be optimized preoperatively. Contracture deformities, spinal deformities, decubitus ulceration, and skin infection must be considered when positioning the child for anesthesia and surgery. Poor nutritional status affects postoperative wound healing and the risk of infection. Concurrent medications may influence anesthesia; sodium valproate can cause platelet dysfunction and affect drug metabolism, and anticonvulsant use increases resistance to NMBDs.[434] A history of latex allergy should be sought because of exposure to latex allergens from an early age.[435]

IV access may be difficult. Drooling, a decreased ability to swallow secretions, and gastroesophageal reflux may dissuade some from performing inhalational inductions in these children, although there is no evidence that a rapid-sequence induction is safer. Succinylcholine may be used because it does not cause hyperkalemia in these children, whose muscles have never become denervated. Noncommunicative or nonverbal children with cerebral palsy require less propofol to obtain the same BIS values (i.e., 35–45) than do otherwise healthy children.[436] The MAC of halothane is 20% less in children with cerebral palsy regardless of whether they took anticonvulsant drugs (MAC of 0.62 and 0.71, respectively).[437]

Intraoperative hypothermia is common in children with disordered temperature regulation cause by hypothalamic dysfunction, reduced muscle bulk, and fat deposits. Thermal homeostasis should be managed aggressively from the moment the child enters the operating room.

Extensive plaster casting is an important component of bone and soft tissue surgical procedures. These casts may conceal blood loss, and limb swelling within the cast may contribute to compartment syndromes. Plaster jackets and hip spicas have been associated with mesenteric occlusion and acute gastric dilatation.

Pain and spasm are regular features postoperatively. Epidural analgesia is particularly valuable when major orthopedic procedures are performed. Occasionally, two epidurals at different spinal sites may be required for multilevel surgery. The addition of either fentanyl or clonidine to bupivacaine in an epidural reduced the incidence of muscle spasm, although the incidence of vomiting was greater in the fentanyl group.[438] Systemic benzodiazepines, baclofen, dantrolene, and clonidine have been used to reduce muscle spasms. Selective dorsal rhizotomy is associated with severe pain, muscle spasms, and dysesthesia. Epidural and intrathecal forms of morphine as well as IV morphine and midazolam have been used to control this pain.[439] Oral benzodiazepines may be required to reduce the incidence and severity of muscle spasms but should be used with caution if combined with opioid analgesia.

Pain assessment is difficult in these children, but several scoring systems are available (see also Chapter 44).[440,441] The opinions of parents and caregivers are extremely valuable in the assessment of pain and discrimination from other factors, such as irritability on anesthetic emergence, poor positioning, a full bladder, or nausea.

SPINA BIFIDA

Spina bifida is characterized by developmental abnormalities of the vertebrae and spinal cord that may be associated with changes in the cerebrum, brainstem, and peripheral nerves. The failure of fusion of the vertebral arches is commonly known as *spina bifida*. *Spina bifida occulta* refers to spina bifida that occurs when skin

and soft tissues cover the defect. *Spina bifida aperta* is used to describe lesions that communicate with the outside as a meningocele or a myelomeningocele (incidence of 1 per 1000 live births). The myelomeningocele sac contains nerve roots that do not function below the level of the lesion.

Clinical Features

Nerve root dysfunction results in muscle paralysis and a neurogenic bowel and bladder. Eighty percent of children develop hydrocephalus because of aqueductal stenosis (Arnold-Chiari [type II] malformation). Skeletal abnormalities such as clubfoot and congenital dislocation of the hip are common. Scoliosis may result from congenital vertebral abnormalities or, more commonly, abnormal neuromuscular control. Epilepsy and learning disorders can also occur, but most children have normal intelligence.

Orthopedic Considerations

Denervation causes muscle imbalance that results in abnormalities at the hip, knee, and foot. The aims of surgery are to reduce flexor posture at the hip and knee and plantigrade feet. Children with clubfeet, hip subluxation, or scoliosis commonly present for orthopedic correction.

Anesthetic Considerations

The potential for infection of the central nervous system dictates closure of the sac within the first few days of life. Subsequent surgical procedures and urinary catheterizations set the stage for sensitivity to latex.[442] Primary prophylaxis (i.e., avoiding all latex materials and using a latex-free operating room) is recommended for prevention of latex allergy and anaphylaxis.[443]

Preoperative assessment should include motor and sensory deficits, respiratory and renal function, and functioning of a ventriculoperitoneal shunt. Positioning on the operating table may require additional pillows for support of limbs with contractures. As a result of hypesthesia in the lower extremities, IV cannulae can be inserted painlessly. However, venous access is usually poor in the lower extremities because of limited limb use. The risk of endobronchial intubation is increased because of a short trachea (36% of children).[444] Kyphoscoliosis may distort tracheal anatomy. Renal dysfunction may dictate the choice of NMBD as well as the avoidance of NSAIDs. Succinylcholine may be used because it does not cause hyperkalemia in these children.[445] A reduced hypercapnic ventilation response means that these children should be closely observed in the recovery period.

OSTEOGENESIS IMPERFECTA

Osteogenesis imperfecta (OI) is thought to have afflicted Ivar the Boneless (Ivar Ragnarsson), a Viking chieftain who led a successful invasion of the East Anglia region of England in AD 865. Because he "had legs as soft as cartilage," he was unable to walk and had to be carried on a shield. Ivar's name is also associated with an early form of thoracoplasty. When King Ælla of Northumbria was captured, Ivar subjected him to the horrific "Blood Eagle" ordeal. His ribs were torn out and folded back to form the shape of an eagle's wings, and his lungs were removed.

Clinical Features

OI is a genetically determined disorder of connective tissue that is characterized by bone fragility. The disease state encompasses a phenotypically and genotypically heterogeneous group of inherited disorders that result from mutations in the genes that code for type I collagen.[446] The disorder manifests in tissues in which the principal matrix protein is type I collagen—mainly bone, dentin, sclerae, and ligaments. Musculoskeletal manifestations vary in severity along a continuum ranging from perinatal lethal forms with crumpled bones to moderate forms with deformity and propensity for fracture to clinically silent forms with subtle osteopenia and no deformity.[446]

Classification (types I through IV) is based on the timing of fractures or on multiple clinical, genetic, and radiologic features. Type I is the most common (1 case per 30,000 live births), and types I and type IV have autosomal dominant inheritance patterns. These children have the classic triad of blue sclera, multiple fractures, and conductive hearing loss in adolescence. Bowing of the lower limbs, genu valgum, flat feet, and scoliosis develop with age. Type IV is characterized by osteoporosis, leading to bone fragility without many of the other features of type I. Types II and III are more severe forms of OI and have autosomal recessive inheritance patterns. Molecular genetic studies have identified more than 150 mutations of the *COL1A1* and *COL1A2* genes, which encode for type I procollagen.[446]

Orthopedic Considerations

The goals of treatment of OI are to maximize function, minimize deformity and disability, maintain comfort, achieve relative independence in activities of daily living, and enhance social integration. Physiotherapy, rehabilitation, and orthopedic surgery are the mainstays of treatment for moderate and severe forms of OI.[447] Medical treatment with the antiresorptive bisphosphonates (e.g., pamidronate) can decrease pain, lower the fracture incidence, and improve mobility.[448] Initial investigations have demonstrated an acceptable safety profile for pamidronate, although long-term follow-up data are lacking and will be necessary for the development of responsible therapeutic guidelines.[449] Long-term IV bisphosphonate therapy was associated with higher *z* scores for lumbar spine, bone mineral density, and vertebral reshaping, but long-bone fracture rates were still common and the majority of patients developed scoliosis.[450] Medical therapies other than bisphosphonates, such as growth hormone and parathyroid hormone, have only minor roles; gene-based therapy remains in the early stages of preclinical research.[451,452]

Operative intervention is indicated for recurrent fractures or deformity that impairs function.[446] Fractures in mild to moderately severe cases of OI type I are treated using the same methods as for patients without OI. Deformed bones that are fracturing are realigned, frequently followed by providing external or internal support. In selecting various modes of treatment, it is important to consider the natural history of the particular type of OI and to set realistic goals.[453–457]

Anesthetic Considerations

In common with other children suffering chronic disabilities, children with OI are veterans of the operating room. Chronic pain from frequent fractures complicates handling; deafness may hinder communication. Preoperative assessment centers on the chest wall deformity because it determines the severity of restrictive lung disease and subsequent cardiovascular compromise. Neck mobility, mouth opening, and dentition should also be assessed.

There is a risk of further fractures with positioning, tourniquet application, airway handing, and use of a blood pressure cuff. Invasive pressure monitoring may be less traumatic than a blood pressure cuff for some patients. If noninvasive blood pressure monitoring is used, less frequent monitoring of the blood pressure is recommended if possible. A laryngeal mask airway may avoid

pressure from face masks. An individual history may help determine the risk/benefit ratio for each child. Succinylcholine has the potential to cause fasciculation-induced fractures.

Abnormal temperature homeostasis may result in intraoperative hyperthermia that may be severe and accompanied by tachycardia and metabolic acidosis. This response is different from that of malignant hyperthermia in that there is an absence of respiratory acidosis and muscle rigidity.[458] Surface cooling is usually effective in restoring thermal homeostasis.

DUCHENNE MUSCULAR DYSTROPHY

Clinical Features

DMD is the most common of the progressive muscular dystrophies. It is an X-linked recessive disorder with an incidence of 3 per 10,000 births (see also Chapter 24). The *DMD* gene (located at Xp21.2) codes for a large sarcolemmal membrane protein, dystrophin, which is associated muscle cell membrane integrity and signal transduction. Dystrophin is missing or nonfunctional in DMD patients; both sexes can carry the *DMD* mutation, but girls rarely exhibit signs of the disease.

Children usually present before school age with a waddling gait and later develop a lumbar lordosis and difficulty climbing stairs. Children use their arms to assist standing up (i.e., Gowers sign) because of proximal weakness of the hip girdle. Distal muscles, such as the calves, appear hypertrophied. The disease process is progressive, with increasing muscle weakness occurring with age. These boys often become wheelchair-bound by 10 to 11 years of age. Respiratory weakness, often exacerbated by scoliosis and by difficulty swallowing secretions related to pharyngeal involvement, can progress to a terminal pneumonia in the late teenage years.[459] By late adolescence, most children with DMD have cardiac disease, whether it is an abnormal electrocardiogram, arrhythmias, or a cardiomyopathy. Death from cardiorespiratory failure usually occurs before age 30, although respiratory support is extending life expectancy.

DMD is not a static disease but evolves in end-organ implications with age. In early childhood, skeletal muscle is constantly catabolized and becomes unstable. The use of membrane-destabilizing medications such as succinylcholine and potent inhalational anesthetics (halothane in particular) in these young children can result in hyperkalemia, rhabdomyolysis, and cardiac arrest.[460] However, after the children reach adolescence, the bulk of the skeletal muscle catabolism has arrested, and membrane-destabilizing medications are left with no substrate. Succinylcholine and potent inhalational anesthetics may be used in the majority of cases without sequelae in adolescents with DMD who are undergoing scoliosis surgery and instrumentation,[461] although other anesthetic techniques are generally recommended (see also Chapter 24). In contrast to its very limited effect on cardiac and smooth muscles in childhood, in adolescence DMD may cause substantive and life-threatening cardiac complications. The anesthesiologist must appreciate the developmental changes of DMD with age and recognize the varying risks that may be associated with the use of succinylcholine and inhalational anesthetics in children and adolescents with this disease.

DMD can affect cardiac smooth muscle. Right ventricular function may be compromised by nocturnal oxygen desaturation and sleep apnea contributing to pulmonary hypertension. Sinus tachycardia and arrhythmias may occur at an early age, but clinically apparent cardiomyopathy usually does not develop before 10 years of age. One-third of children have some degree of intellectual impairment.

DMD should be suspected in male preschool children with delayed walking ability; measurement of high serum creatinine phosphokinase concentrations provides a screening tool. Steroids are increasingly used for the management of DMD because they appear to increase muscle mass by decreasing protein breakdown.[462]

Becker muscular dystrophy (BMD) is a milder form of DMD with an onset at puberty or later in adolescence. Clinical expression varies, but even adolescents presenting with mild or subclinical weakness can develop cardiomyopathy with age progression. Death from cardiac or respiratory failure does not usually occur until the fourth or fifth decade. Because of improvements in respiratory care, dilated cardiomyopathy has become the major cause of death.[463]

BMD is an autosomal recessive myopathy that also results from mutations of dystrophin caused by a deletion of the exons 11 to 13 in the *DMD* gene (located at Xp21.2).[464] Dystrophin exerts its effect at the voltage-gated chloride channel 1 (CLCN1). Genetic analysis is an essential step in confirming the diagnosis. Additional EMG procedures may be of diagnostic value even when muscle biopsy may reveal no evidence of dystrophy.

Of importance to anesthesiologists, two-thirds of patients with mild or subclinical BMD have evidence of right ventricular dilation, and one-third have evidence of left ventricular dysfunction.[465] A thorough cardiac evaluation (similar to that for DMD) is recommended before scoliosis surgery.[463] Hyperthermia and heart failure, mimicking malignant hyperthermia and hyperkalemia with rhabdomyolysis after inhalational agents, have been reported in patients with BMD.[466,467] Therefore inhalation agents and succinylcholine should be avoided in these patients. Despite these reports, the relationship between BMD and malignant hyperthermia remains unclear.

Orthopedic Considerations

Orthopedic surgery is indicated to improve or maintain ambulation and standing. Early treatment of contractures of the hips and the lower limbs prevents severe contractures and delays the progression of scoliosis.[468] Techniques designed to improve deformities and permit early postoperative mobilization include subcutaneous release of contracted tendons and percutaneous removal of cancellous bone with corrective manipulation of the feet. Maintenance of upright posture extends the ability of patients to attend to the tasks of daily living.[469] Spinal deformities attributable to muscle imbalance or a collapsing spine are corrected to improve or maintain sitting posture. Spinal fusion may also decrease the rate of deterioration of respiratory function, although this has been questioned.[470]

Anesthetic Considerations

Respiratory and cardiovascular compromise dominates preoperative assessment. Deformities and contractures of limb joints hinder vascular access, regional anesthetic techniques, and positioning on the operating table. Hypertrophy of the tongue[471] may cause difficulty during intubation. Gastric motility is delayed, and gastric emptying times are prolonged.[472] Tracheobronchial tree compression has been described in a child positioned prone for spinal instrumentation.[473] These children often have greater blood loss during surgery. The precise cause remains unclear, but it may be because fat and connective tissue have replaced muscle or because of abnormalities in the blood vessels.[242]

Nondepolarizing NMBDs have a slow onset and prolonged duration of action.[474–476] All NMBDs should be monitored with

a peripheral nerve stimulator.[477] *Succinylcholine is contraindicated in these children because of the risk of hyperkalemia, muscle rigidity, rhabdomyolysis, myoglobinuria, arrhythmias, and cardiac arrest.* There is no known link between DMD and malignant hyperthermia.[478,479] The predominant candidate gene (*RYR1*) for malignant hyperthermia is located on the long arm of chromosome 19, whereas the *DMD* gene is located on the short arm of the X chromosome.[480] Although inhalational anesthetic agents continue to be used in young children with DMD, rhabdomyolysis and hyperkalemia have been reported in the recovery room after halothane, isoflurane, desflurane, and sevoflurane anesthesia.[481–485] Potent inhalational anesthetics are best avoided in young children with DMD; instead, alternative anesthetics that do not trigger rhabdomyolysis and hyperkalemia, such as propofol, ketamine, opioids, α_2-agonists, and benzodiazepines, are preferred.[486] Ketamine supplemented with dexmedetomidine or propofol has proven useful for brief procedures such as muscle biopsy.[487,488]

Regional techniques such as epidurals may be technically more difficult because of kyphoscoliosis and obesity. The use of ultrasound-guided peripheral nerve blockade can improve the quality and reduce complications of neuronal blockade.[6] Opioids are not contraindicated in the postoperative period but should be used with caution in children with respiratory compromise. Tramadol is an effective alternative. Noninvasive ventilation support using BiPAP or continuous positive airway pressure is sometimes required after major surgery or in those already receiving this treatment overnight.

ARTHROGRYPOSIS MULTIPLEX CONGENITA

Clinical Features

Arthrogryposis multiplex congenita is a spectrum syndrome of multiple, persistent limb contractures often accompanied by associated anomalies, including cleft palate, genitourinary defects, gastroschisis, and cardiac defects.[489] The incidence is 1 case per 3000 births. Joint contractures are present at birth and are a result of immobility in utero, commonly related to a neurogenic abnormality or myopathy.[490] These children have been likened to a "thin, wooden doll," because muscles connected to affected joints are atrophic and replaced by fibrous tissue and fat.[491] The temporomandibular joint may also be involved, causing restricted mouth opening (microstomia) and micrognathia. Scoliosis commonly develops. Restrictive lung disease, rib cage deformities, and pulmonary hypoplasia predispose to recurrent chest infections.

Orthopedic Considerations

The aim of surgery is to improve function. Most operations involve the soft tissues, tendons, and osteotomies of the lower limbs and hips.[492] Upper limb surgery is less common. Extension contracture of the elbow joint makes it impossible to reach the mouth or to perform hygienic necessities. Improvement in passive elbow flexion by capsulotomy or in active flexion by triceps transfer can increase independence and personal hygiene. When both arms are involved, consideration may be given to maintaining one arm in flexion for reaching the head and mouth passively or even actively and one arm in extension for basic hygiene cares.[493]

Anesthetic Considerations

Arthrogryposis multiplex congenita is commonly associated with other syndromes that may complicate anesthesia.[489,494] Venous cannulation is difficult because veins tend to be small and fragile. The concavity of joints is difficult to access. Regional blockade can also be difficult, although use of ultrasound improves success rates for the femoral and sciatic nerve block.[495] Care must be taken in positioning the patient on the operating table and protecting skin overlying bony joints to prevent pathologic fractures.

These children should be evaluated for a difficult airway because of temporomandibular joint limitation and micrognathia.[496–498] Fusion or underdevelopment of the first and second cervical vertebrae may further complicate laryngoscopy and tracheal intubation with a severe reduction in neck mobility. Tracheal intubation may become progressively more difficult with age. During infancy, however, evaluating mouth opening may be difficult; it may be necessary to insert a tongue blade into the mouth to determine whether the mandible can be distracted from the maxilla.

Succinylcholine has been used without incident in these children, although teleologically, the use of a depolarizing muscle relaxant in the presence of anterior horn cell disease is contentious. The response to nondepolarizing NMBDs should be monitored.

Hyperthermia and persistent tachycardia have been reported during general anesthesia.[489,499–501] These signs occur irrespective of the anesthetic agent and are not associated with malignant hyperthermia. In this case, hyperthermia responds to simple cooling techniques.

Pulmonary dysfunction and an increased sensitivity to opioids dictate suitable monitoring postoperatively. Regional techniques may be difficult in the presence of contractures, but if successful, they offer intraoperative and postoperative analgesia.[491] Success can be improved by using ultrasound-guided techniques.

ANNOTATED REFERENCES

Harper CM, Ambler G, Edge G. The prognostic value of preoperative predicted forced vital capacity in corrective spinal surgery for Duchenne's muscular dystrophy. *Anaesthesia*. 2004;59:1160-1162.

Performing scoliosis surgery on children with Duchenne muscular dystrophy who have a forced vital capacity (FVC) of 30% has been questioned because of the high incidence of postoperative pulmonary complications. This clinical paper demonstrated that with careful attention to detail, children with an FVC less than 30% can undergo scoliosis surgery with results similar to those with an FVC greater than 30%. Early extubation followed by the use of noninvasive ventilation was identified as key to reducing respiratory complications.

Holdefer RN, Furman M, Sangare Y, Slimp JC. A comparison of the effects of desflurane versus propofol on transcranial motor-evoked potentials in pediatric patients. *Childs Nerv Syst*. 2014;30:2103-2108.

Mackenzie WG, Matsumoto H, Williams BA, et al. Surgical site infection following spinal instrumentation for scoliosis: a multicenter analysis of rates, risk factors, and pathogens. *J Bone Joint Surg Am*. 2013;95:800-806.

This multicenter retrospective review of surgical site infections from pediatric hospitals in the United States demonstrated rates increasing from 2.6% in those with AIS to 9.2% in those with neuromuscular scoliosis (NMS). Almost all infections involving gram-negative organisms occurred in patients with NMS, and half of the infections in these patients contained at least one gram-negative organism. Whether targeted antimicrobial prophylaxis in these patients will reduce the high infection rate is currently unknown.

Malhotra NR, Shaffrey CI. Intraoperative electrophysiological monitoring in spine surgery. *Spine*. 2010;35:2167-2179.

The authors undertook a pooled data analysis to review intraoperative neuromonitoring changes that occur during the course of spine surgery, and they describe the appropriate application of this monitoring.

Martin DP, Bhalla T, Thung A, et al. A preliminary study of volatile agents or total intravenous anesthesia for neurophysiological monitoring during posterior spinal fusion in adolescents with idiopathic scoliosis. *Spine*. 2014;39:E1318-E1324.

These two studies demonstrate that adequate neurophysiologic status using SSEPs and MEPs during scoliosis surgery can be obtained with either a desflurane- or propofol-based anesthetic technique. Current prevailing opinion appears to favor a total IV anesthetic (propofol) technique, but desflurane is an acceptable alternative. Both studies used modest doses of either agent (0.6–0.8 MAC desflurane, propofol 150–300 μg/kg per minute) adjusted to keep the BSI between 40 and 60. Adequate SSEPs and MEPs were obtained in all patients, but a higher stimulating voltage was required in both papers when desflurane was used. A potential benefit of desflurane is a shorter wake-up time, which may be advantageous if signal changes are observed.

McLeod LM, French B, Flynn JM, et al. Antifibrinolytic use and blood transfusions in pediatric scoliosis surgeries performed at US children's hospitals. *J Spinal Disord Tech*. 2015;28:E460-E466.

This cohort of more than 4000 scoliosis surgeries from U.S. children's hospitals challenges the information from randomized clinical trials and systematic reviews suggesting antifibrinolytic use reduces the odds of transfusion. ε-Aminocaproic acid but not tranexamic acid was associated with lower odds of transfusion in AIS patients, whereas neither drug had benefits in those with NMS.

Yuan N, Fraire JA, Margetis MM, et al. The effect of scoliosis surgery on lung function in the immediate postoperative period. *Spine*. 2005;30:2182-2185.

This study clearly demonstrated the dramatic decrease in pulmonary function in the days after scoliosis surgery, readily explaining why children are at risk for pulmonary complications during this period. Pulmonary function tests (FEV_1, FVC, FEV_1/FVC, and $FEF_{25-75\%}$) were measured daily for 10 days after scoliosis repair. Results of pulmonary function tests decreased by up to 60% after surgery, with a nadir at 3 days. The FEV_1 and FVC values were still only at 60% of the preoperative values on the 10th postoperative day.

33 Otorhinolaryngologic Procedures

RAAFAT S. HANNALLAH, KAREN A. BROWN, AND SUSAN T. VERGHESE

Anesthesia for Otologic Procedures
Myringotomy and Ventilating Tube Insertion
Middle Ear and Mastoid Surgery
Cochlear Implants
Anesthesia for Rhinologic Procedures
Adenotonsillectomy
Preoperative Evaluation
Anesthetic Management and Postoperative Considerations
Discharge Policy for Ambulatory Adenotonsillectomy
Posttonsillectomy Bleeding
Peritonsillar Abscess
Anesthesia for Endoscopy
Diagnostic Laryngoscopy and Bronchoscopy
Upper Airway Obstruction
Laryngotracheobronchitis (Croup)
Acute Epiglottitis
Obstructive Laryngeal Papillomatosis
Aspirated Foreign Bodies
Tracheostomy
Laryngotracheal Reconstruction
Tracheocutaneous Fistula
Airway Trauma

OTORHINOLARYNGOLOGIC PROCEDURES REPRESENT a large segment of elective surgery in infants and children. Anesthetic management is provided by both pediatric and general anesthesiologists, commonly in ambulatory surgery centers and office practices.[1] Additionally, anesthesiologists are often consulted to help manage potentially life-threatening pediatric otolaryngologic emergencies. These include airway obstruction caused by croup, foreign body aspiration, airway trauma, bacterial tracheitis, and, rarely, acute epiglottitis.[2] In both the elective and emergent scenarios, it is essential to understand the pathophysiology, and to discuss the anesthetic plan in advance with the surgeon who will frequently be sharing the airway with the anesthesiologist. This ensures safe anesthetic management and ideal conditions for both children and surgeons.

Anesthesia for Otologic Procedures

MYRINGOTOMY AND VENTILATING TUBE INSERTION

Chronic serous otitis media is common in young children. If untreated or poorly managed, it can lead to hearing loss and formation of cholesteatoma. When conservative medical management fails, surgical drainage of accumulated middle ear fluid is indicated. Myringotomy creates an opening in the tympanic membrane through which fluid can drain. If only a myringotomy is performed, the drainage path is occluded when the incision heals. Therefore myringotomy is frequently accompanied by placing a small plastic tube (a variation of the grommet or the T-tube) in the incision in the tympanic membrane to serve as a stent for the ostium, facilitating continuous drainage from the middle ear until the tubes are naturally extruded in 6 to 12 months, or surgically removed at an appropriate time.

Children with cleft palate have a high frequency of middle ear disease compared with those without a cleft because of associated abnormalities of the cartilage and muscles surrounding the eustachian tubes. Surgical drainage and ventilation tube insertion is a standard treatment for chronic otitis media in these children; this is usually performed at the time of cleft repair.

Most young children require general anesthesia for tympanotomy tube placement, although occasionally older children tolerate the procedure with only topical anesthesia. This may be accomplished by iontophoresis or instillation of EMLA (eutectic mixture of local anesthetics) cream, which remains in the ear canal for an hour and is then suctioned out before the procedure.

Myringotomy with tube insertion is a very brief operation, usually performed in the ambulatory surgery setting using a potent inhalational agent (e.g., sevoflurane), oxygen, and nitrous oxide administered by face mask with spontaneous respiration. An oropharyngeal airway may assist in maintaining a patent airway when the head is laterally rotated and together with resting the forearm of the anesthesiologist on the table, reduces head movement during respiration (which is amplified through the microscope). Gentle manual assistance of ventilation can also reduce head movement. Occasionally, a laryngeal mask airway (LMA) may be used in children in whom the procedure is expected to be prolonged (e.g., children with narrow ear canals) or those with a difficult airway. Most children can be managed safely without intravenous (IV) access,[3] but it is recommended to have IV equipment set up on standby. Some children with severe underlying medical or surgical conditions will require IV access despite the anticipated brief duration of the minor procedure. Although premedication is often omitted because its duration of effect exceeds that of the procedure, an anxious child may still benefit from a sedative premedication and/or having the parents present during induction of anesthesia.

In some instances, it is desirable to remove a retained tympanotomy tube. This can be easily accomplished in the surgeon's office without anesthesia; however, some stiff-flanged grommet tubes require general anesthesia for removal. If the incision does not heal spontaneously, a paper patch or fat graft may have to be applied over the ostium to stimulate healing of the tympanic membrane. The anesthetic would be the same as that for the tube placement, except that nitrous oxide is best avoided to minimize the chance of graft dislodgment (see later discussion).

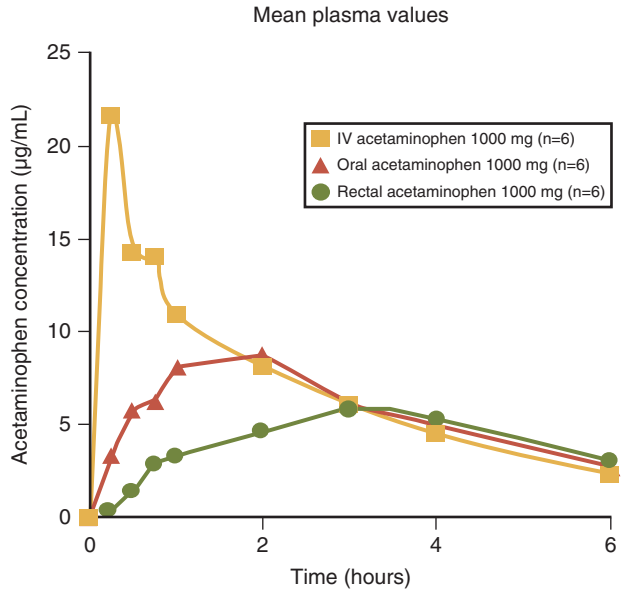

FIGURE 33.1 Plasma time-concentration profile for 1000 mg acetaminophen via three routes: intravenous, oral, and rectal (IV, PO, and PR, respectively). PR acetaminophen reflects standardization of 1300 mg dose to 1000 mg (linear kinetics). (Adapted from: Singla NK, Parulan C, Samson R, et al. Plasma and cerebrospinal fluid pharmacokinetic parameters after single-dose administration of intravenous, oral, or rectal acetaminophen. *Pain Pract.* 2012;12[7]: 523–532.)

Discomfort after myringotomy and tube insertion is usually managed by the administration of nonsteroidal antiinflammatory drugs (NSAIDs) such as acetaminophen, ketorolac, or opioids. The recommended dose of acetaminophen to achieve therapeutic blood concentrations is 10 to 20 mg/kg when administered orally, and 30 to 40 mg/kg when administered rectally.[4–6] Oral acetaminophen is very rapidly absorbed, achieving therapeutic blood concentrations within minutes, whereas rectal acetaminophen is slowly absorbed, with a time to onset of action of 60 to 90 minutes, and a time to peak effect of 1 to 3 hours (Figs. 4.2 and 33.1).[7–10] Consequently, the oral route is preferred for this procedure.

Preschool-aged children who receive sevoflurane without an analgesic for myringotomy and tube insertion may exhibit emergence delirium and postoperative agitation (see Chapter 4). Although pain may be partially responsible for these responses, their etiologies are not completely understood. Because the procedure is so brief and IV access is not usually established, intranasal (IN) fentanyl, 1 to 2 µg/kg, has been shown to provide analgesia and to reduce the frequency of emergence agitation.[11,12] Other analgesics, including IV/intramuscular (IM) ketorolac (0.5–1 mg/kg), or rectal diclofenac or IN butorphanol (25 µg/kg), and IN dexmedetomidine (1–2 µg/kg), reduce the pain after myringotomy and tube insertion.[13–15] However, larger doses of dexmedetomidine (2 µg/kg) significantly prolong the duration of stay in the postanesthesia care unit (PACU). A large retrospective pediatric study of bilateral myringotomy and tube insertion found that the combination of IM fentanyl (1.5–2 µg/kg) and ketorolac (1 mg/kg) was strongly associated with superior PACU analgesia and reduced the need for oxycodone rescue without clinically significant increases in recovery time or the incidence of emesis. This dual therapy appears similarly effective in children of European Caucasian, African ancestry, or those of Hispanic ethnicity.[16] A nerve of Arnold block is also a reasonable alternative (see Chapter 42).[17] Emergence delirium is often brief (lasting 10–20 minutes) and, provided that analgesia has been addressed, can be managed by maternal or nurse comforts (e.g., cuddling) without pharmacologic intervention. Voluntary rather than forced oral fluid administration reduces the incidence of postoperative nausea and vomiting (PONV).[18]

Children with chronic otitis media frequently have persistent rhinorrhea and suffer recurrent upper respiratory tract infection (URI) (see Chapter 13). Eradication of middle ear congestion and improved fluid drainage often resolves the concomitant symptoms. The frequency of perioperative complications in children with mild URIs is similar to that in children who are asymptomatic. In general, morbidity is not increased in children who present for minor surgery with acute, uncomplicated mild URIs, provided tracheal intubation can be avoided.[19,20] Canceling this surgery because of rhinorrhea or recurrent mild respiratory symptoms is not usually justifiable as the vicious cycle of repeated URIs and chronic ear infections require an intervention (e.g., myringotomy) to break the cycle. It is, however, recommended that children with respiratory symptoms have their oxygen saturation (SpO_2) measured before induction of general anesthesia, and that supplemental oxygen be administered postoperatively to those whose SpO_2 readings are less than 93%.[21]

MIDDLE EAR AND MASTOID SURGERY

Tympanoplasty and mastoidectomy are two of the most common major ear operations performed in children. General anesthesia usually consists of an inhalational anesthetic and IV opioids. Surgical identification and preservation of the facial nerve are necessary because of its proximity to the surgical field. To ensure the facial nerve can be identified using electrical stimulation, neuromuscular blockade is usually avoided. If a neuromuscular blocking drug (NMBD) must be used, a small dose should be given to facilitate tracheal intubation; if an NMBD is used for maintenance, suppression of the twitch response should not exceed 70%.

To gain access to the surgical site, the child's head is placed on a headrest, which may be positioned below the operating table. In addition, extreme degrees of lateral rotation may be required to visualize the middle ear anatomy. The anesthesiologist and surgeon must be especially vigilant to ensure that nerves, muscles, and bony structures are not injured as a result of this unusual positioning; the sternocleidomastoid muscles generally limit the safe degree of lateral head rotation. Left or right tilting (airplaning) of the operating room (OR) table minimizes the need for extreme lateral head rotation, which is an important consideration for children with Down syndrome. The laxity of the ligaments of the cervical spine, as well as immaturity of the odontoid process in children with Down syndrome, predisposes them to C1–C2 subluxation; 15% to 31% of children with Down syndrome or achondroplasia have atlantoaxial instability.[22–25] Anteroposterior positioning requires the utmost care to avoid injury.

Positioning of the OR table to allow access to the respective middle ear and accommodate all the extra surgical equipment can also pose a challenge. Depending on the room configuration, the table may be rotated 90 degrees or even 180 degrees away from the anesthesia machine, necessitating the use of an extra-long breathing circuit (Fig. 33.2). As a result of the limited access to the airway, very careful attention must be paid to securing the tracheal tube. Draping must allow immediate access to the airway should that be required.

Bleeding must be kept to a minimum during surgery on the small structures of the middle ear; relative hypotension (i.e.,

mean arterial pressure 10%–25% less than baseline) may help to reduce bleeding. Concentrated epinephrine solution (1 : 10,000) is frequently applied to the tympanic membrane to induce vasoconstriction of the blood vessels. Close attention should be paid to the dose of epinephrine used to prevent arrhythmias and wide swings in blood pressure. The maximum dose of topical epinephrine is 10 µg/kg, which may be repeated after 30 minutes. Alternatively, topical oxymetazoline 0.05% may be used to induce vasoconstriction.

The middle ear and sinuses are air-filled, nondistensible cavities; an increase in the volume of gas within these cavities increases the pressure. Nitrous oxide diffuses along a concentration gradient into air-filled middle ear spaces more rapidly than nitrogen moves out because nitrous oxide is 34 times more soluble in blood than nitrogen. The middle ear is vented through the opening of the eustachian tube. Normal passive venting of the eustachian tube occurs at 20 to 30 cm H_2O pressure. Nitrous oxide increases the pressures within the middle ear such that they exceed the ability of the eustachian tube to vent the middle ear within 5 minutes, leading to pressure buildup.[26] If the function of the eustachian tube is compromised during the surgical procedure, then pressure in the middle ear can further increase. Venting the middle ear occurs intermittently, and leads to constant fluctuations in middle ear pressure that cause movement of the tympanic membrane.[27] During procedures in which the tympanic membrane is replaced or a perforation is patched, nitrous oxide should be discontinued before the application of the tympanic membrane graft to reduce the potential for pressure-related displacement.[28] The omission of nitrous oxide does not significantly increase the requirements (minimum alveolar concentration) for the less-soluble inhaled anesthetics (desflurane and sevoflurane) in children.[29] After nitrous oxide is discontinued, it is quickly reabsorbed, creating a void in the middle ear, with resulting negative pressure. This negative pressure may result in serous otitis, disarticulation of the ossicles in the middle ear (especially the stapes), and hearing impairment, which may last up to 6 weeks postoperatively. The use of nitrous oxide may increase the incidence of postoperative nausea and vomiting (PONV), as a direct result of negative middle ear pressure during recovery. The negative pressure created by the reabsorption of nitrous oxide stimulates the vestibular system by producing traction on the round window. Although all children are at risk for PONV, older children and adolescents, in particular, are at the greatest risk.[30] Multimodal prophylactic administration of antiemetics (e.g., dexamethasone and ondansetron) is usually warranted. Local infiltration of the great auricular nerve can provide pain relief equivalent to that of opioids and may reduce the incidence of opioid-induced vomiting (see Chapter 42).[31]

A smooth, quiet emergence is desirable. Deep tracheal extubation can be accomplished if the child breathes spontaneously during the last 15 to 20 minutes of surgery, the concentration of inhalational anesthetic is greater than 1.3 times the minimal alveolar concentration, and opioids are titrated to produce regular slow respirations. Gentle suctioning of the oropharynx and possibly the use of IV lidocaine (1–1.5 mg/kg) in children older than 1 year of age can minimize or even prevent coughing after the tracheal tube is removed. Alternately, total IV anesthesia may be used for middle ear procedures because nitrous oxide is avoided, postoperative vomiting is reduced and the frequency of emergence delirium is minimal (see Chapter 8).

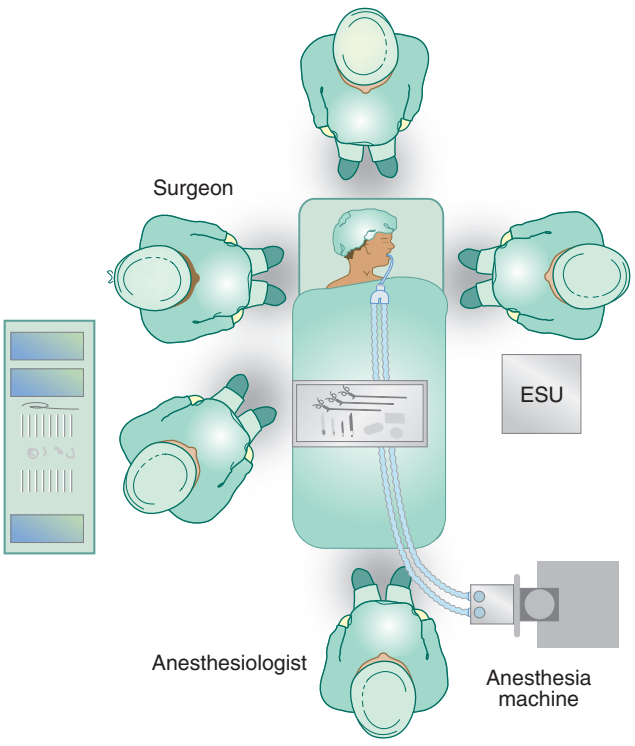

FIGURE 33.2 An operating room table turned 180 degrees may limit access to the child during ear surgery. *ESU* is the electrosurgical unit.

COCHLEAR IMPLANTS

The first multichannel cochlear implant was developed in Australia in 1978. After a series of clinical trials, the US Food and Drug Administration (FDA) approved the use of the Australian cochlear implant in adults in 1985, and subsequently in infants and children as young as 6 months of age.[32] In recent years, the indications for cochlear implants have broadened and continue to evolve. With the application of universal neonatal hearing screening programs, a large pool of hearing-impaired infants has been identified. The benefits of early intervention with cochlear implants are being explored. Younger children with severe to profound hearing loss markedly improve their auditory, speech, and language skills after cochlear implants, and more of these children can be mainstreamed with their age-appropriate hearing peers when they receive an implant early in life. Experience has shown that cochlear implant surgery is safe in infants older than 6 months of age, provided that special attention is paid to the physiologic and anatomic differences present in this age group. The majority of children presenting for surgery have no significant health issues other than deafness. However, in a recent review, 40% had comorbidities that have been categorized into syndromes associated with deafness, problems associated with premature births, neurologic problems, and cardiac abnormalities.[33] For these children, the availability of skilled postoperative nursing and a pediatric intensive care unit (ICU) are essential.[34]

Surgery requires meticulous care with hemostasis, soft tissue dissection, and bone drilling because bleeding from bone can be difficult to control and can complicate the surgical outcome. The surgical procedure itself needs the facial nerve to be identified; thus if an NMBD is used for intubation, spontaneous recovery should be confirmed and communicated to the surgeon. Postoperative fitting of the externally worn speech processor is very important for successful use of the cochlear implant. However, this fitting process can be difficult, particularly in infants and young children,

because of limited communication capabilities. Electrically elicited stapedius reflex thresholds (ESRTs) obtained intraoperatively are used to determine the maximum comfort level, which is defined as the loudest sound tolerated without pain. It has been used for postoperative speech processor fitting, although the influence of anesthetics on the threshold values must be taken into account. More reliable threshold values can be obtained by adjusting the dosage of hypnotics to achieve a lighter level of hypnosis during ESRT measurement.[35] In most children, increasing the concentration of inhalational anesthetics increases the stapedius reflex threshold, whereas propofol and nitrous oxide have minimal effects on the ESRT. Consequently, total IV anesthesia (TIVA) is popular in some countries. Dexmedetomidine has been used to decrease inhaled anesthetic requirements, prevent intraoperative hypertension (and bleeding), and ensure a smooth emergence. As always, appropriate communication with the surgeon and audiologist will help ensure a successful outcome.

While cochlear implants are indicated in children with profound sensoneural or nerve deafness, many children with conductive hearing loss who cannot use traditional hearing aids (because of draining ears or chronic infection) can be candidates for bone-anchoring hearing aid devices (BAHA). The BAHA implant is a titanium device placed in the skull behind the ear and vibrates the bone to transmit sound directly to the inner ear. Although most children who are BAHA candidates are older than 5 years of age, some infants can now be fitted. The surgical and anesthetic approach is less challenging than that for cochlear implants.

Anesthesia for Rhinologic Procedures

Chronic sinusitis in children can be caused by antibiotic-resistant bacteria and is usually treated with broad-spectrum antibiotics. In some children with obstructive adenoid pads, adenoidectomy will improve the signs and symptoms of sinusitis. Functional endoscopic sinus surgery (FESS) using sharp biting instruments and/or a microdebrider has become the primary method of surgical therapy for chronic sinusitis.[36] Current techniques aim to leave the mucosa intact to prevent scarring in the frontal recess. Although sometimes controversial, there is no evidence at present that FESS affects facial growth in children. Of interest to the anesthesiologist is that many children who require FESS have coexisting medical problems, such as asthma and cystic fibrosis. These conditions must be optimized before surgery (see Chapter 13).

An alternative to FESS is balloon sinuplasty. This technique uses ballooned catheters to dilate the maxillary, frontal, and sphenoidal natural ostia without bone or soft tissue removal.[37] This should result in less bleeding and reduced anesthetic morbidity.

Anesthetic management usually requires tracheal intubation to secure the airway; the use of an oral preformed tracheal tube (e.g., the Ring-Adair-Elwyn [RAE] tube) allows secure fixation to the mandible and unobstructed access to the maxilla and sinuses. The use of a cuffed tracheal tube is particularly advantageous to eliminate a gas leak that could fog up the endoscopic instruments. A throat pack is frequently inserted to absorb blood in the oropharynx and limit the gas escaping around an uncuffed endotracheal tube (ETT). It is critically important that the pack is removed before tracheal extubation. Occasionally, an LMA may be used to facilitate a quick "second look."

Because bleeding is inevitable with this surgery and can interfere with the surgical exposure, packing the nasal cavity with a vasoconstricting solution before surgery is common. Typically used topical vasoconstrictors include oxymetazoline 0.025% to 0.05%, phenylephrine 0.25% to 1%, and less frequently, cocaine 4% to 10%. It is important for the anesthesiologist to be aware of the type and dose of the vasoconstrictor and to ensure that no more than the maximum effective dose is applied. Application of topical phenylephrine or other potent vasoconstrictors to mucous membranes or open surgical sites can cause severe hypertension, reflex bradycardia, and even cardiac arrest.[38] Hypertension induced by topically applied vasoconstrictors often resolves spontaneously and may not require aggressive treatment. The use of β-adrenergic blockers or calcium-channel blockers to control blood pressure in these circumstances can depress cardiac output, leading to pulmonary edema and cardiac arrest.[38] It is recommended that the initial topical dose of phenylephrine should not exceed 20 μg/kg in children.[38]

Corticosteroids, such as IV dexamethasone (0.25–0.5 mg/kg), are usually administered to reduce swelling and scarring. Frequently, the surgeon will want to leave an absorbable stenting material, such as MeroGel (Medtronic ENT, Jacksonville, FL), at the end of surgery. Unfortunately, this will interfere with nasal breathing and may increase the incidence of emergence delirium. An anesthetic technique that ensures adequate analgesia and rapid return of consciousness at the end of surgery is therefore desirable. One of the authors (RSH) has found that a combination of desflurane, fentanyl, and low-dose propofol works well in this regard. Alternatively, a pure TIVA technique (propofol + remifentanil) or desflurane + remifentanil can be used; the remifentanil dose is adjusted to the desired mean arterial pressure.

A unilateral or bilateral infraorbital nerve block can also be performed via the intraoral or extraoral route to provide analgesia (see Chapter 42).[39] One further concern is the need to avoid NSAIDs in children with asthma and sinusitis secondary to nasal polyps (Samter triad).[40,41]

Adenotonsillectomy

Adenotonsillectomy is one of the oldest pediatric surgical procedures, yet its conduct and practice continue to evolve. In the past decade, notable changes have been introduced. These include the indications for adenotonsillectomy, the criteria for postoperative hospital admission, and recommended postoperative analgesic regimens. Additionally, the American Academy of Otolaryngology-Head and Neck Surgery (AAO-HNS) no longer recommends prophylactic antibiotics during adenotonsillectomy surgery.[42–44]

Adenotonsillectomy is one of the most commonly performed pediatric surgical procedures worldwide; one in eight American children will undergo adenotonsillectomy.[45] Chronic or recurrent tonsillitis and obstructive adenotonsillar hyperplasia are the major indications for surgical removal (Table 33.1). Surgical treatment is required when tonsillitis recurs despite adequate medical therapy, when associated with peritonsillar abscess, or when acute or chronic airway obstruction compromise breathing. Halitosis, persistent pharyngitis, and cervical adenitis may accompany chronic tonsillitis. Tonsillar hyperplasia may lead to chronic airway obstruction, resulting in obstructive sleep apnea (OSA), failure to thrive, swallowing disorders, speech abnormalities, pulmonary hypertension, right-sided heart failure, and eventually cor pulmonale (Fig. 33.3). Certain children with cardiac lesions may be at risk for endocarditis caused by recurrent streptococcal bacteremia secondary to infected tonsils and will require prophylactic antibiotics (see Chapter 16).

Adenoidectomy is usually performed in conjunction with tonsillectomy, although in some situations it is performed as the sole

surgical procedure. Indications for adenoidectomy alone include chronic or recurrent purulent adenoiditis, recurrent otitis media with effusion secondary to adenoidal hyperplasia, and chronic sinusitis. Advanced degrees of adenoidal hyperplasia may lead to nasopharyngeal obstruction, obligate mouth breathing, poor feeding resulting in failure to thrive, speech disorders, and sleep-disordered breathing (SDB). Long-standing nasal obstruction can result in orofacial abnormalities with a narrowing of the upper airway and dental abnormalities (so-called adenoid facies or long face syndrome).

Surgical techniques for adenotonsillectomy include guillotine and snare techniques, cold and hot knife dissection, suction, radiofrequency ablation, and unipolar and bipolar electrocautery techniques. Electrocautery dissection offers two advantages over the other techniques with less intraoperative blood loss and a reduced risk of postoperative hemorrhage, although these are offset, in part, by more pain and poor oral intake postoperatively.

A meta-analysis of 23 retrospective studies (N = 13,537 children) reported an overall frequency of postoperative complications after adenotonsillectomy of 19%. Respiratory compromise was the most frequent complication (9.4%) followed by secondary hemorrhage (5–10 days after surgery) (2.6%).[46] Age has a major influence on these complications. Children older than age of 10 years more commonly have a secondary hemorrhage, whereas younger children more commonly have both poor oral intake and respiratory complications. The majority of children younger than 3 years of age experience airway problems after adenotonsillectomy for obstructive breathing.[47,48]

Surgical complications after adenotonsillectomy are rare but include uvular amputation, uvular edema, velopharyngeal insufficiency, and nasopharyngeal stenosis. Atlantoaxial subluxation manifesting as neck pain and torticollis, mandibular subluxation and condylar fracture, cervical adenitis, and cervical osteomyelitis have also been reported.[49,50] Bleeding, burns, and airway fires account for over one-third of malpractice claims associated with this procedure.[51] The mortality associated with adenotonsillectomy is estimated at 1 per 16,000 to 1 per 41,000 procedures.[49,52,53] Throat pain, otalgia, emesis, poor oral intake, and dehydration are common morbidities.

PREOPERATIVE EVALUATION

The general health of the child and the indications for surgery must be reviewed. URIs are frequent in these children and can interfere with the timing of adenotonsillectomy because the risk of respiratory compromise and hemorrhage is increased.[49,54–56] Obese children often have SDB and they are at increased risk for postoperative hemorrhage.[57–62] A history of bleeding tendencies requires investigation. Medications that interfere with coagulation include aspirin, NSAIDs, and valproic acid. Discontinuation of these drugs preoperatively is sometimes problematic, and preoperative consultation with neurology, cardiology, and hematology specialists may be indicated.

A careful cardiorespiratory history and physical examination is essential. Children with chronic tonsillar hypertrophy may have long-standing hypoxemia and hypercarbia, which can lead to cor pulmonale (see Fig. 33.3). The oropharynx should be evaluated and the tonsillar size classified (Fig. 33.4).[63] In some centers, a complete blood cell count and coagulation profile is required before adenotonsillectomy. There is no evidence that routinely performed preoperative coagulation studies are beneficial unless they are indicated by history or the presence of a disorder of hemostasis.[64,65] The indications for the procedure should be clearly delineated in the surgical plan of care.

Special Considerations for the Child With Obstructive Sleep Apnea Syndrome

SDB describes abnormal breathing patterns during sleep. These abnormal patterns include obstructive breathing, including snoring, paradoxical chest wall motion, and increased respiratory effort, apneas, hypopneas leading to hypercarbia, and desaturation followed by arousals. The spectrum of SDB ranges from primary "benign" snoring to the obstructive sleep apnea syndrome (OSAS). The Childhood Adenotonsillectomy Trial (CHAT), a randomized controlled trial, compared watchful waiting for 7 months with early adenotonsillectomy in more than 400 children with OSAS. The primary outcome, attention and executive function, did not differ between the two groups. However, secondary outcomes for polysomnographic, behavioral, and quality-of-life metrics normalized in 79% of the children after adenotonsillectomy compared with 46% who did not undergo adenostonsillectomy.[45,66]

The single most important task during the preoperative evaluation of the child for adenotonsillectomy is to distinguish the child with the OSAS

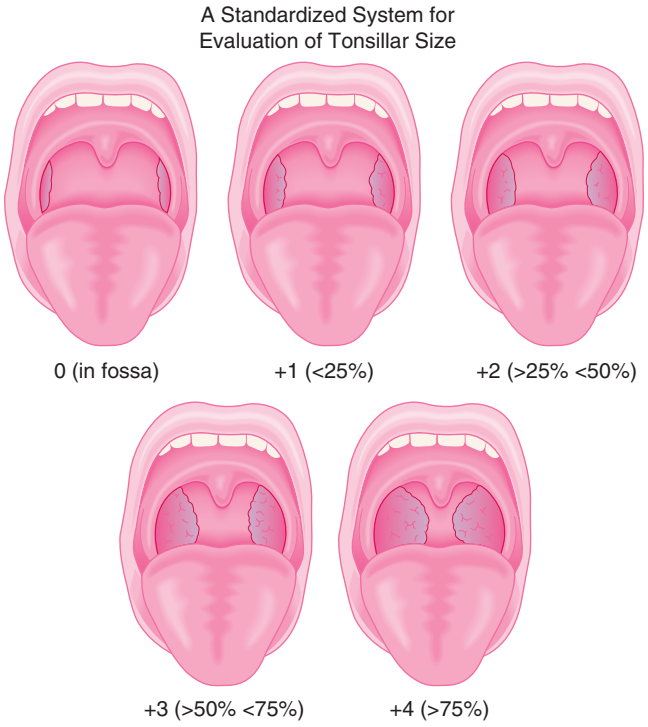

FIGURE 33.4 Classifying tonsil size may be helpful in evaluating the degree of airway obstruction. Children classified as +3 or greater (i.e., having more than 50% of the pharyngeal area occupied by hypertrophied tonsils) are at an increased risk of developing airway obstruction during anesthetic induction. (Modified from Brodsky L. Modern assessment of tonsils and adenoids. *Pediatr Clin North Am*. 1989;36[5]:1551–1569; illustration by Jon S. Krasner.)

from the child with isolated obstructive breathing (e.g., primary snoring) and chronic infectious tonsillitis, because the former children are at greater risk for developing severe perioperative respiratory adverse events (PRAEs), possibly including death, after adenotonsillectomy.[67–72] Several recent studies have reported unexpected deaths after adenotonsillectomy from presumed sleep apnea after discharge from a monitored setting, including to home.[59,72,73] A meta-analysis of 3 retrospective studies (N = 371 children) revealed that children with OSAS proven by polysomnography (PSG) criteria have a 5-fold increase in the odds for PRAEs compared with children without OSAS. In contrast, they were less likely to have postoperative hemorrhage (odds ratio 0.4, 95% confidence interval [CI] 0.2–0.7).[46]

The OSAS encompasses a range of severity. At the most extreme, it includes pulmonary and systemic hypertension, cor pulmonale, ventricular hypertrophy, the metabolic syndrome, neurocognitive dysfunction, and life-threatening nocturnal hypoxemia.[74–77] Because adenotonsillectomy is often the initial treatment for OSAS, the majority of these children may present with a spectrum of disease affecting multiple organ systems. Failure to thrive is common. Infections affecting the lower respiratory tract have been linked to chronic aspiration.[78]

A high index of suspicion is required to identify the child with OSAS on clinical criteria. Clinical criteria do not always distinguish primary snoring from OSAS in children.[79] There is a greater incidence of OSAS in Asian and African American populations.[80,81] African American children desaturate more profoundly during sleep-related obstructive airway events than do Caucasian and Hispanic children.[82] Obese children (BMI > 95th percentile) are at greater risk for OSAS and postoperative hemorrhage.[59,73] Anatomic features may underlie the pathogenesis of OSAS; common medical conditions and syndromes that predispose to the development of OSAS are listed in Table 33.2. Infants who have suffered an acute life-threatening event (ALTE) have a greater incidence of OSAS in childhood and adolescence.[83–85]

Parents should be asked if the child snores loudly, if the snoring can be heard through a closed door, if there are gasps or pauses in respirations, if there is daytime somnolence, night terrors, nocturnal enuresis, attention deficit disorder, or poor school performance.[62,86,87] However clinical features obtained from demography, parental report, and physical findings do not robustly identify OSAS severity[88,89] and parental report of symptoms has a poor positive predictive value.[90–94]

Although it is important to recognize the significance of OSAS in children who are scheduled for adenotonsillectomy, children who do not meet the criteria for OSAS but who have less severe forms of SDB, such as upper airway resistance syndrome (UARS) or obstructive hypopnea, may also be at increased risk for morbidity after surgery. Guidelines for the perioperative management of these children continue to be developed.[71,87,95,96]

The obstructive events that characterize OSAS result in recurrent episodes of hypoxia, hypercarbia, and sleep disruption, a trilogy that has been linked to the development of medical sequelae that accompany severe OSAS. The severity of OSAS is assessed by the frequency and severity of the obstructive respiratory events during sleep; both occur most often during rapid eye movement (REM) sleep. The frequency and severity of obstructive events worsen after midnight.[97–99]

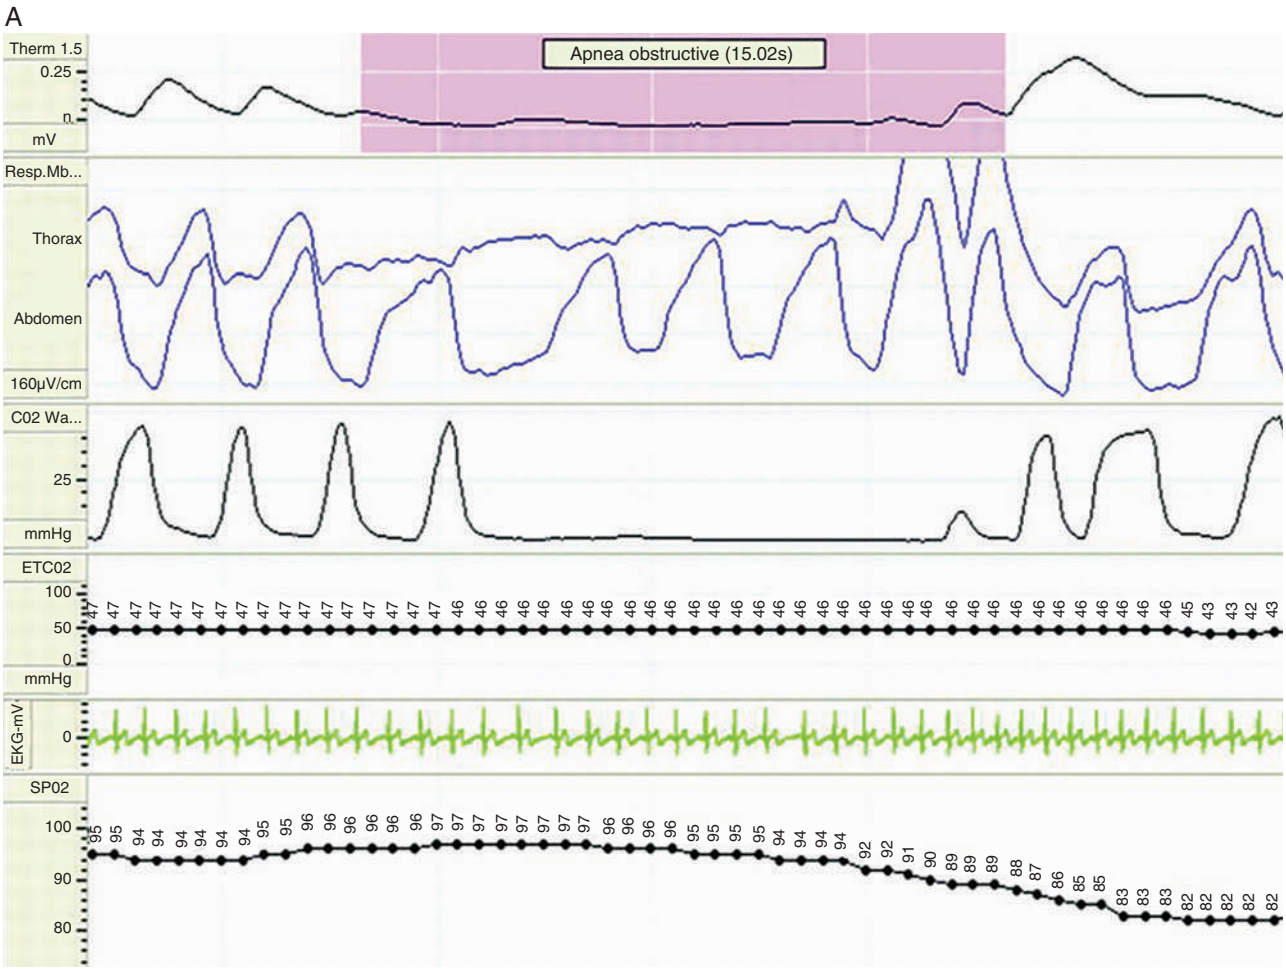
The polysomnogram (PSG) is the gold standard diagnostic test for evaluation of SDB. The PSG simultaneously records the electroencephalogram, electromyogram, electrocardiogram,

pulse oximetry, airflow, and thoracic and abdominal movement during sleep (Fig. 33.5). Some cardiorespiratory studies limit the recording devices to pulse oximetry with sensors for thoracic and abdominal movement. A common definition of OSA in children is an obstructive effort that includes more than two obstructive breaths, regardless of the duration of the apnea.[97] An obstructive apnea index of 1 is the cutoff for normality in children.[100] The diagnostic criteria for pediatric OSAS according to the American Academy of Sleep Medicine are: mild OSAS corresponds to an apnea index >1 <5 events per hour; moderate OSAS corresponds to an apnea index >5 <10 events per hour, and severe OSAS corresponds to an apnea index ≥10 events per hour.[71,76] Apneas are classified as central, obstructive, and mixed (see Fig. 33.5). A central apnea occurs when there is no apparent respiratory effort. An obstructive apnea is associated in the presence of apparent, often vigorous, inspiratory efforts that are ineffective because the upper airway is not patent. A mixed obstructive apnea is diagnosed when both central and obstructive components are present without interruption by effective respirations.

Hypopnea is defined as a reduction in airflow of more than 50%.[97] The apnea hypopnea index (AHI) is the summation of the number of obstructive apnea and hypopnea events and is analogous to the respiratory disturbance index (RDI). The PSG study also records oxygen-desaturation indexes.

Metrics obtained during PSG predict the risk of PRAEs; a detailed history from the parents will also help to assess children likely to be at risk (Table 33.3). An RDI of greater than 20 events per hour is associated with breath-holding during induction, whereas an RDI greater than 30 is associated with laryngospasm and desaturation during emergence.[101] Ten obstructive events per hour during a screening polysomnogram is the threshold for severe PRAEs.[68] A preoperative RDI, analogous to the AHI, above 19 events per hour may predict persistent OSAS in long-term follow-up.[79,102,103]

Fewer than 10% of children in North America are assessed with PSG before adenotonsillectomy.[104] Many tertiary care children's hospitals in the United States do not have uniform criteria for routinely performing PSG before adenotonsillectomy (Fig. 33.6).[105] The notion that PSG should be reserved for children with medically complex conditions and evaluation of persistent SDB despite adenotonsillectomy is contentious.[106] If PSG is not available, or is considered too costly, other diagnostic tests for OSAS may be considered. Many parents will record audio and/or



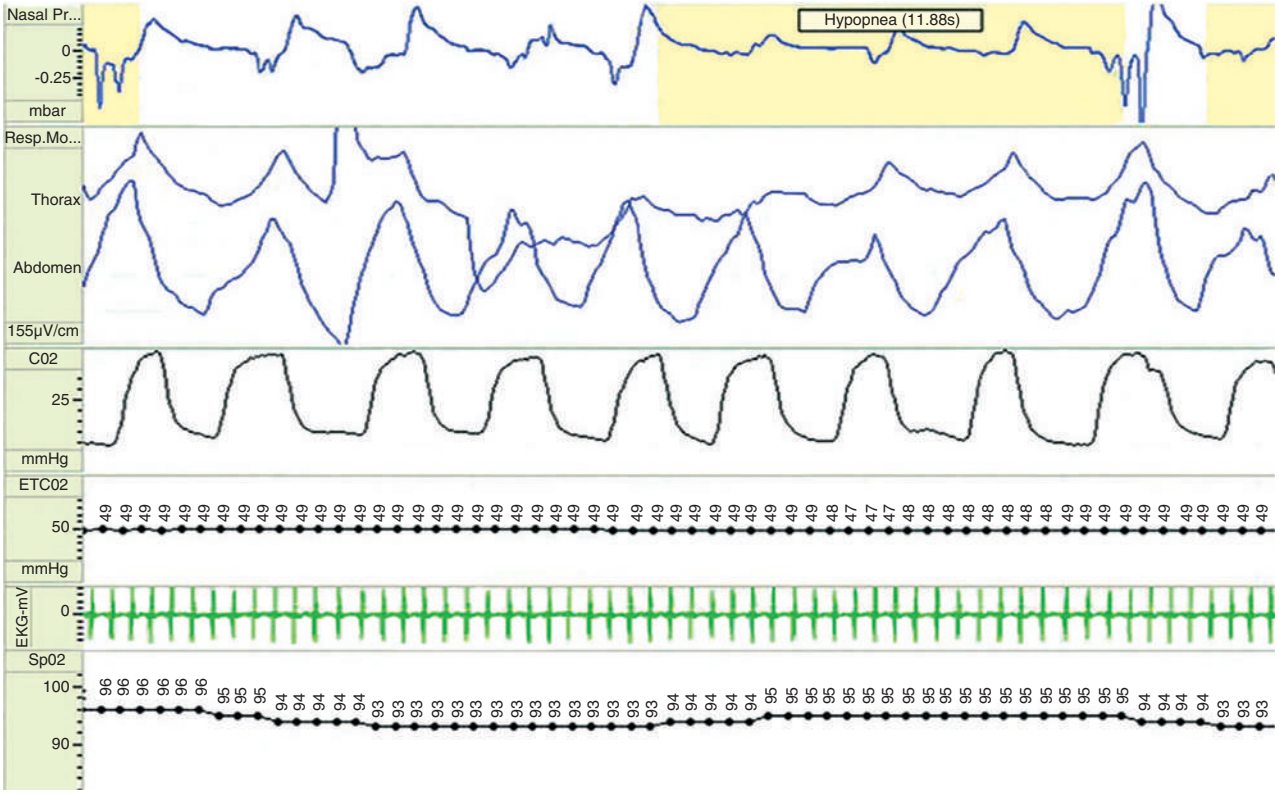


FIGURE 33.5 Typical polysomnographic recordings demonstrating obstructive apnea **(A),** hypopnea **(B),** and central apnea **(C)**. (From Schwengel DA, Sterni LM, Tunkel DE, Heitmiller ES. videotapes of their child's breathing pattern during sleep. These have reasonably high positive and negative predictive values.[107,108] Although home sleep apnea tests are increasingly used in adults, there are no published guidelines for their use in children. Nap PSG is an abbreviated study that records sleep and breathing in the laboratory during daytime naps. Because of the limited recording time and the likely absence of REM sleep, they are best regarded as screening tools.[109]

Sleep evaluation with oximetry alone offers a low-cost, easy-to-use alternate test to PSG.[104,110,111] Published normative data in children indicate that the 2.5th percentile for the baseline SpO_2 is 95%. The nadir saturation (nSAT) is the lowest SpO_2 recorded during sleep and correlates inversely with the AHI.[102] An nSAT of 92% is the minimum normal SpO_2 in children[100,104,112]; however, an nSAT of <80% is a robust predictor of the risk for PRAEs and sensitivity to opioids.[67,70,113]

A commonly reported index of desaturation events, the oxygen desaturation index (ODI), is the number of decreases in SpO_2 ≥4% from baseline (ODI_4). In children, the 95th percentile for the ODI_4 is 2.2 episodes per hour. The ODI_4 is a sensitive metric used to evaluate the response to adenotonsillectomy in long-term outcome follow-up.[104] As obstructive respiratory events in children usually occur during REM and stage 2 sleep, the desaturation events tend to cluster at 60- to 90-minute intervals. A cluster of desaturation is defined as 5 or more decreases in SpO_2 (≥4%) within a 10- to 30-minute interval.[46] At least 3 clusters of desaturation with at least 3 SpO_2 decreases to less than 90% during a 6-hour nocturnal oximetry recording is diagnostic of OSA: positive predictive value for an AHI >1 event per hour of 97%; sensitivity 40%. For ≥2 clusters of desaturation along with at least 1 decrease in $Sp≥_2$ to ≤90% increases the sensitivity of this measurement to predict OSA to 80%.

The McGill Oximetry Scoring (MOS) system further classifies the severity of nocturnal hypoxemia (Fig. 33.7). The MOS correlates

TABLE 33.3 Clinical Diagnostic Criteria for Pediatric Obstructive Sleep Apnea Syndrome

1. Predisposing physical characteristics
   a. Body mass index greater than 95th percentile for age and gender
   b. Craniofacial abnormalities affecting the airway
   c. Anatomic nasal obstruction
   d. Tonsils nearly touching or touching in the midline
2. History of apparent airway obstruction during sleep *(two or more of the following)*
   a. Loud snoring (loud enough to be heard through a closed door)
   b. Frequent snoring
   c. Observed pauses in breathing during sleep
   d. Frequent arousals from sleep
   e. Intermittent vocalization during sleep
   f. Parental report of restless sleep, difficulty breathing, or struggling respiratory efforts during sleep
   g. Child with night terrors
   h. Child sleeps in unusual positions
   i. New-onset nocturnal enuresis
3. Somnolence (one or more of the following)
   a. Parent or teacher comments that the child appears sleepy during the day, is easily distracted, is overly aggressive, or has difficulty concentrating
   b. Child often is difficult to arouse at the usual awakening time

Note: If signs and symptoms in at least two categories are present, there is a significant probability of moderate obstructive sleep apnea (OSA). If severe abnormalities are present, children should be treated as having severe OSA.
Modified from Table 1 in American Society of Anesthesiologists. Practice guidelines for the perioperative management of patients with obstructive sleep apnea: an updated report by the American Society of Anesthesiologists Task Force on Perioperative Management of Patients with Obstructive Sleep Apnea. *Anesthesiology* 2014;120:268–286.

(With permission from Nardone HC, McKee-Cole KM, Friedman NR. Current pediatric tertiary care admission practices following adenotonsillectomy. *JAMA Otolaryngol Head Neck Surg.* 2016;142[5]:452–456. doi:10.1001/jamaoto.2016.0051.)

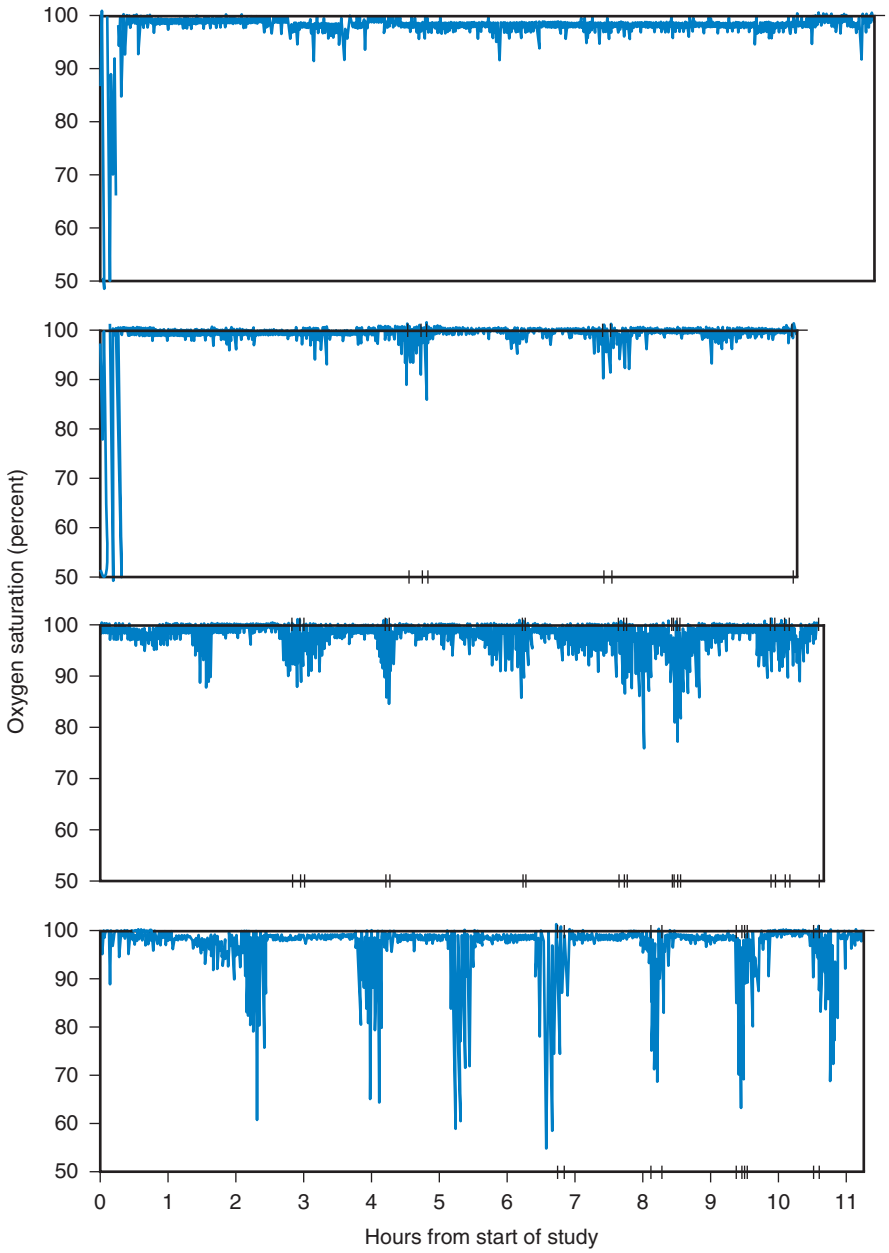

FIGURE 33.7 Representative figures for McGill oximetry scores 1 to 4 (*top to bottom*). McGill oximetry scores 2 to 4 are abnormal in that they all show at least three clusters of desaturation. The severity of the Spo_2 nadir determines the score such that McGill oximetry scores 2, 3, and 4 correspond to Spo_2 nadirs of less than 90%, less than 85%, and less than 80%, respectively. (From Nixon GM, Kermack AS, Davis GM, et al. Planning adenotonsillectomy in children with obstructive sleep apnea: the role of overnight oximetry. *Pediatrics* 2004;113[1 Pt 1]:e19–25.)

with both the AHI and the risk of PRAEs after adenotonsillectomy in children. The MOS4 is defined as >3 decreases in Spo_2 to <80%; corresponding to a mean AHI of 40 events per hour. The risk for major PRAEs, including reintubation, for children with MOS4 managed with a standard opioid regimen was 20% to 24%.[114]

These findings are clinically relevant in at least two respects: the morphine (or morphine equivalent) dose required to achieve a uniform analgesic endpoint in children with OSAS who exhibited a preoperative nSAT <85% was half that required in controls (Fig. 33.8).[115] In updated statements from both the American Academy of Pediatrics (AAP) and the AAO-HNS, the criteria to admit children after adenotonsillectomy is an nSAT <80%.[43,44]

Consultations to plan the perioperative care of children with severe OSAS are important. In contrast to children without OSAS, children with severe OSAS may require additional preoperative testing. A capillary blood gas sample collected in the morning may reveal an increased concentration of bicarbonate, consistent with a chronic respiratory acidosis. A preoperative electrocardiogram or echocardiogram may show evidence of right ventricular hypertrophy and/or pulmonary hypertension. A chest radiograph may demonstrate lower airway disease or cardiomegaly.

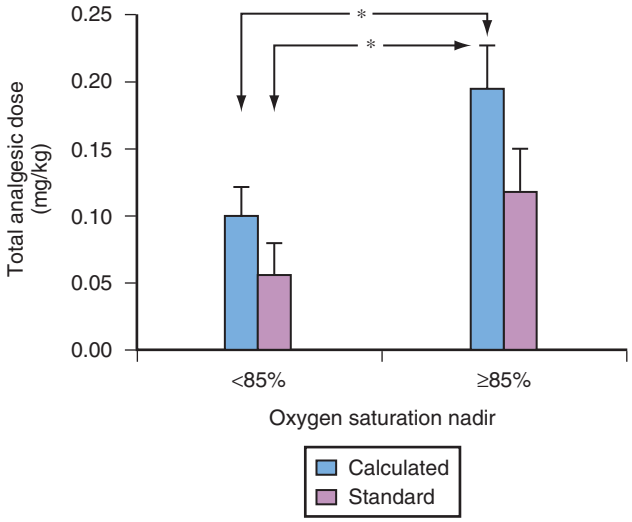

FIGURE 33.8 The total analgesic dose of morphine required to achieve a uniform analgesic endpoint in children with obstructive sleep apnea (OSA). Children were grouped by severity of OSA into those who had a preoperative Spo_2 nadir of <85% or ≥85%. The asterisks indicate post hoc differences between groups, $P < 0.05$. (From Brown KA, Laferrière A, Lakheeram I, Moss IR. Recurrent hypoxemia in children is associated with increased analgesic sensitivity to opiates. *Anesthesiology* 2006;105[4]:665–669.)

In a review of 9023 children with a mean age of 3.8 years evaluated over a 7-year period, 35 (0.4%) required urgent adenotonsillectomy within 48 hours of PSG.[116] Urgent adenotonsillectomy for severe OSAS is associated with significant respiratory morbidity after surgery.[69,116,117] On occasion, adenotonsillar hypertrophy may progress to compromise the upper airway during wakefulness. In some instances, the anesthetic considerations for obstructed and difficult airways may overlap; some may develop postobstructive pulmonary edema after intubation or surgery. Young children with profound oxygen desaturation during sleep, high obstructive indexes, and carbon dioxide (CO_2) retention may require admission to the pediatric ICU for optimization before and/or after adenotonsillectomy.[114,118]

Although adenotonsillar hypertrophy is the primary cause of OSAS in children, those with comorbidities such as obesity, Down syndrome, and craniofacial abnormalities may experience airway obstruction that is unrelated to the tonsils and adenoids.[119] Diagnostic, preoperative evaluation of these airways such as cine magnetic resonance imaging (MRI) and sleep endoscopy may be required before surgery; combinations of sevoflurane, propofol, remifentanil, dexmedetomidine, and ketamine anesthesia have been used.[119] Dexmedetomidine, an α-agonist, mimics non-REM sleep, facilitating the maintenance of airway patency. However, as obstructive events in pediatric OSA occur primarily during REM sleep, dexmedetomidine may not replicate the breathing pattern during natural sleep.

Sleep endoscopy, also known as drug-induced sleep endoscopy (DISE), is a technique that enables the surgeon to evaluate the level of obstruction in an anesthetized child with suspected OSAS.[120] The considerations for DISE are complex, requiring endoscopic evaluation of an obstructive airway in the supine position during spontaneous ventilation. Administration of lidocaine and oxymetazoline to the nasal mucosa may be useful. When DISE is indicated in children whose clinical evaluation is unremarkable or when OSAS persists after adenotonsillectomy, it should be performed by experienced otolaryngologists and anesthesiologists. A retrospective study determined that the frequency of oxygen desaturations to <85% during DISE with dexmedetomidine and ketamine was less than with either propofol alone or a combination of propofol and sevoflurane.[121]

ANESTHETIC MANAGEMENT AND POSTOPERATIVE CONSIDERATIONS

The anesthetic goals for adenotonsillectomy are to (1) provide a smooth, atraumatic induction; (2) provide the surgeon with optimal operating conditions; (3) establish IV access for volume expansion and medications as indicated; and (4) provide rapid emergence so that the child is awake and able to protect the recently instrumented airway. The need for a premedication is determined during the preanesthetic evaluation. *Children with symptoms of SDB who require premedication should be closely observed*, although the desaturation is transient and infrequent (1.5% of cases) after oral midazolam premedication.[122] *In children with severe OSA, premedication with short-acting, reversible drugs is advised and monitoring with pulse oximetry is indicated.*[122]

The anesthetic techniques for adenotonsillectomy are varied and include the choice of an inhalational or TIVA technique, the choice of an ETT or LMA, and the choice of spontaneous or controlled ventilation. Children who are scheduled for adenotonsillectomy have a greater incidence of airway reactivity and laryngospasm than those undergoing non-airway surgery. Of the currently available inhalational agents, sevoflurane provides a smooth induction of anesthesia. Maintenance of anesthesia with desflurane (for those whose airway is secured with an ETT) provides a rapid emergence and recovery.[123,124] An infusion of dexmedetomidine (1 to 2 μg/kg IV over 5 to 10 minutes) combined with an inhalation agent can provide satisfactory intraoperative conditions for adenotonsillectomy without adverse hemodynamic effects. However, clinical experience and a recent study suggest a quicker time frame (0.49 μg/kg over 5 seconds) might be safe.[125] Some authors have reported good results with a single IV dose of clonidine (1 μg/kg).[126]

Cuffed ETTs have become increasingly used in children of all age groups,[127] preventing the air leak and the consequent bubbling of gas in secretions and blood that can interfere with surgery. These tubes also minimize pollution by anesthetic gases and may decrease the risk of an airway fire when electrocautery is used.

Blood, secretions, and/or irrigation fluids may be present in the oropharynx at the conclusion of surgery and should be carefully suctioned by the surgeon or the anesthesiologist before emergence from anesthesia. Emptying the stomach with an orogastric tube, a maneuver frequently performed by surgeons under direct vision after completion of surgery, does not reduce the incidence of PONV.[128]

Many anesthesiologists prefer to wait until the child is fully awake before removing the ETT as the presence of an intact airway and pharyngeal reflexes are of utmost importance in preventing aspiration, laryngospasm, and airway obstruction.[129] However, with current surgical (use of electrocautery) and anesthetic (dexmedetomidine) techniques, a careful deep extubation is frequently chosen. The incidence of major respiratory complications requiring positive airway pressure, administration of drugs, airway manipulation, or instrumentation after deep or awake extubation is similar (~11%).[130] At the time of extubation, a common practice is to position the child in the lateral "recovery" or "tonsil" position with the head slightly down to permit blood and secretions to pool in the dependent cheek and drain out of the mouth rather than

accumulate at the laryngeal inlet. The child should remain in the tonsil position postoperatively, while being carefully observed and monitored during transport to the PACU. The lateral position has the additional benefit of increasing both the cross-sectional area of the upper airway and total volume of the upper airway compared with children in the supine position.[131]

The use of the LMA for adenotonsillectomy was described in 1990, but it was not until the availability of a model with a flexible spiral, metallic reinforced shaft that made it practical for use in adenotonsillectomy (E-Fig. 33.1).[132,133] Advantages cited for the LMA over the ETT included a decrease in the incidence of postoperative stridor and laryngospasm[134]; recent evidence disputes these advantages.[135]

Analgesic Management

Children experience significant pain and severe functional limitations for up to 7 days after adenotonsillectomy.[136,137] Recovery from pain and return to normal daytime activities are considerably faster after isolated adenoidectomy.[137] Surgical technique has a major impact on the speed of recovery from pain because electrocautery techniques are generally associated with greater pain, presumably owing to increased thermal injury,[138–140] although this remains controversial.[141] Intracapsular tonsillectomy causes less pain and morbidity than the conventional extracapsular techniques and the outcomes appear comparable[142–144]; this technique may provide an alternative that may reduce the risk for posttonsillectomy apnea because of the reduced pain.

Infiltration of local anesthetics into the tonsillar fossa during tonsillectomy decreases postoperative pain, but the pain relief is brief (E-Fig. 33.2).[145] Life-threatening complications have been reported after local anesthetic infiltration in the tonsillar fossa, including intracranial hemorrhage, bulbar paralysis, deep cervical abscess, cervical osteomyelitis, medullopontine infarct, and cardiac arrest. The risks associated with injection of local anesthesia in the tonsillar fossa may outweigh its potential benefits, particularly in inexperienced hands.[146,147]

Over the past decade, there has been a shift away from opioids as the mainstay of perioperative analgesia to nonopioid regimens, including dexmedetomidine, acetaminophen, NSAIDs, dexamethasone, and ketamine. An infusion of dexmedetomidine (2 µg/kg IV over 5 to 10 minutes followed by 0.7 µg/kg per hour) may reduce postoperative opioid requirements.[148] After larger doses of dexmedetomidine (2 and 4 µg/kg), the opioid-free interval increases and the postoperative opioid requirements decrease; however, duration of stay in the PACU is markedly prolonged.[149]

A single intraoperative dose of dexamethasone reduces postadenotonsillectomy pain and edema when electrocautery has been used. These doses overlap the doses of dexamethasone to mitigate PONV (see later text). Dexamethasone (0.3–1 mg/kg) administration is associated with reduced parental- and physician-rated pain scores after adenotonsillectomy (Table 33.4).[139] The minimum morphine-sparing dose for dexamethasone is reported to be 0.5 mg/kg.[150] The use of dexamethasone in adenotonsillectomy remains routine in most US centers. Single doses of dexamethasone have not been associated with aseptic necrosis of the hip or infections, but have been responsible for precipitating the acute tumor lysis syndrome.[151–153]

In 2008, a report suggested that posttonsillectomy bleeding was increased in children who had received dexamethasone up to 0.5 mg/kg (maximum 20 mg).[158] A retrospective review of 31,934 children investigated whether a single IV dose of either dexamethasone or hydrocortisone administered on the day of surgery resulted in posttonsillectomy hemorrhage that required reoperation.[159] The rate of reoperation for secondary hemorrhage in children who received either steroid, 1.2% (adjusted odds ratio 2.5, 95% CI 1.5–4.2), was significantly greater than that in those who received steroids, 0.5% ($P < 0.001$)[159]; this finding was not present in adults. However, several subsequent studies have refuted these claims.[160–164] The consensus opinion and practice is that a single intraoperative dose of dexamethasone does not cause clinically important hemorrhage. Despite concerns that the routine use of NSAIDs for adenotonsillectomy might increase the risk for postadenotonsillectomy hemorrhage,[165,166] the AAO-HNS now recommends their use for postoperative analgesia. An audit of more than 4800 pediatric tonsillectomies in which the NSAIDs diclofenac and ibuprofen were routinely used, reported a primary hemorrhage rate of 0.9%.[167] Because the effects of ketorolac on platelet function are reversible, the effect depends on the presence of ketorolac within the body.[168] Unlike the effect of aspirin on bleeding, the effects of these NSAIDs is short-lived. However, we recommend avoiding NSAIDs, especially ketorolac, *during* surgery. When used for postoperative analgesia, they should be administered after hemostasis is achieved.[169] The use of ibuprofen in children who have been taking aspirin can result in severe posttonsillectomy bleeding.[170]

A recent editorial suggested that perhaps we need a clean start with a new class of analgesic drugs such as selective cyclooxygenase-2 (COX-2) inhibitors for adenotonsillectomy patients.[171] Although not available in the United States, parecoxib is a selective COX-2 inhibitor drug that reduces the production of inflammation-promoting prostaglandins. It spares platelet aggregation, bronchial tone, and gastric mucosal integrity unlike nonselective NSAIDs, and may reduce the need for rescue morphine and decreased the frequency of vomiting after adenotonsillectomy.[172,173] Celebrex, a COX-2 available in the United States, reduces early postoperative pain and the need for supplemental analgesics.[173a] More evidence is

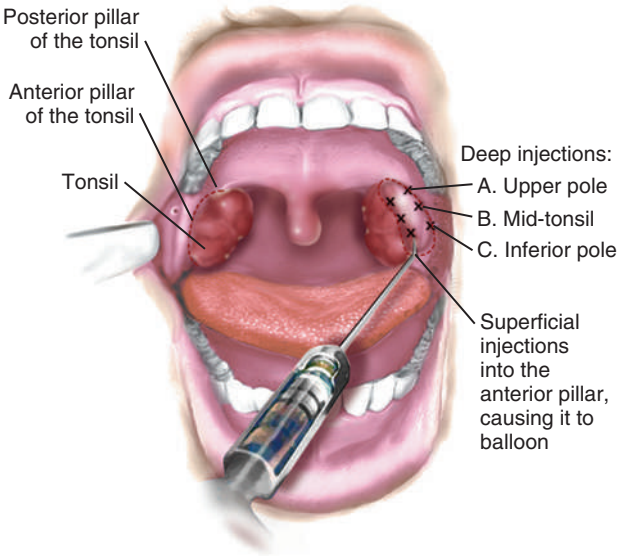

TABLE 33.4 Effect of Single Intraoperative Dose of Dexamethasone on Postoperative Pain in Pediatric Tonsillectomy or Adenotonsillectomy: a Comparison of Randomized, Double-Blind Studies

Source	No. of Children	Dexamethasone Dose	Electrocautery Technique	Effect on Pain
Catlin and Grimes[154]	25	8 mg/m^2	No	No difference

needed before COX-2 agents can be recommended for children during adenotonsillectomy.

Acetaminophen is commonly used as a component of multimodal analgesic approach in these children.[174] An IV formulation of acetaminophen is available in many countries, offering the theoretical advantage of greater predictability than the oral and rectal routes (see Fig. 33.1). Although the peak blood concentration is greater, the duration of analgesia after 15 mg/kg of IV acetaminophen is less than that after 40 mg/kg given rectally.[175] Reports of 10-fold overdoses of IV acetaminophen with near-catastrophic outcomes in infants should alert clinicians to potentially fatal dosing errors with this medication.[176,177]

Postdischarge pain management strategies vary among practitioners and institutions. Acetaminophen, dexamethasone, and ibuprofen are frequently prescribed in various combinations. Acetaminophen and NSAIDs (e.g., ibuprofen and diclofenac) have additive effects, prolonging the duration of analgesia when combined[178,179]; codeine is no longer indicated (see later text). Oxycodone may be used in older children. Scheduled dosing of any combination of these drugs is more effective than as-needed (pro re nata [PRN]) dosing in reducing pain intensity.[180]

Postoperative Nausea and Vomiting

Emesis and poor oral intake are common comorbid conditions after adenotonsillectomy. Opioids increase the incidence of PONV, with two-thirds of treated children experiencing PONV.[167,181–184] Propofol,[185,186] ondansetron,[187–189] and dexamethasone[190,191] are widely used to reduce the incidence of emesis after adenotonsillectomy. A single intraoperative dose of dexamethasone reduces the incidence of emesis during the first 24 hours after adenotonsillectomy.[192] The number of children needed to treat was only four, which means that the use of dexamethasone in four children undergoing adenotonsillectomy results in one less child experiencing PONV. In addition, children who received dexamethasone were more likely than those receiving placebo to advance to a soft diet on postoperative day 1, with a number needed to treat of five. Given the antiemetic and possible morphine-sparing advantages of a single dose of dexamethasone, and its low cost and safety profile, the evidence suggests that routine use of dexamethasone reduces morbidity after adenotonsillectomy in children.[139,192] The smallest effective dose remains unclear. One study reported no difference in postoperative vomiting, pain scores, time to first liquid, and time to first analgesics among IV dexamethasone doses between 0.0625 and 1.0 mg/kg (Fig. 33.9).[190]

Postdischarge vomiting continues for days in some children. The use of at-home oral ondansetron disintegrating tablets may prevent emesis during the first 3 days after adenotonsillectomy.[193] Acupuncture, acupressure at the P6 (Nei-Kuwan) point, as well as therapeutic suggestion, have also been used with variable results.[194–196]

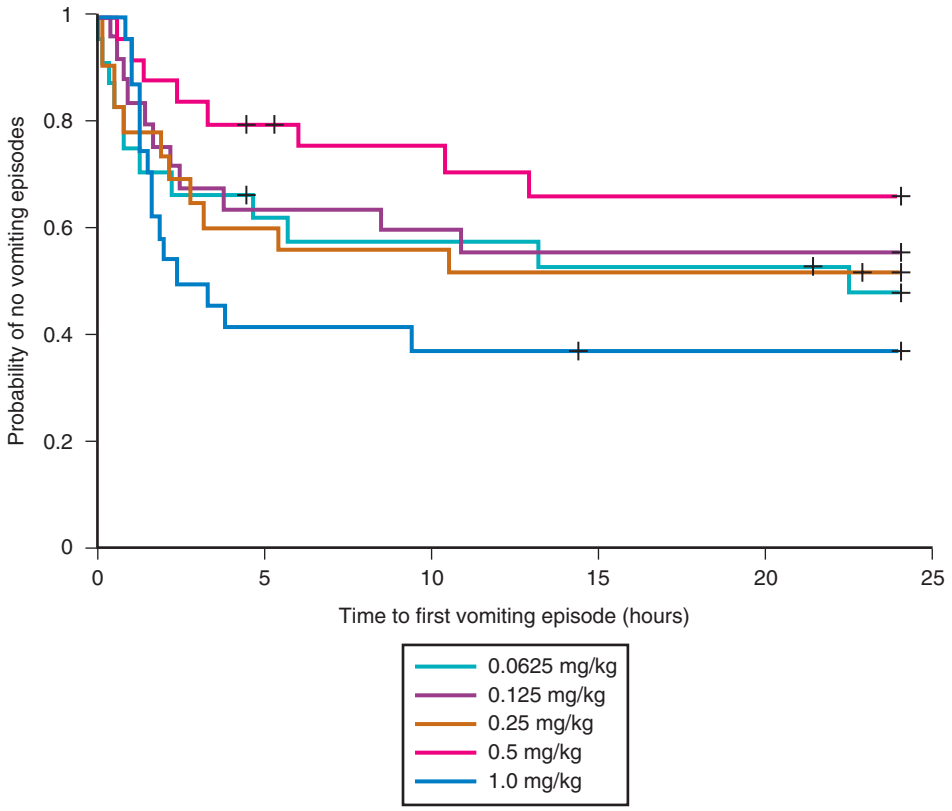

FIGURE 33.9 No dose-escalation response to dexamethasone to prevent vomiting in children undergoing tonsillectomy. Time-to-event analysis for first vomiting episode was performed; tick marks indicate time of censoring for patients who did not have complete follow-up ($N = 13$). No significant difference was found between dose levels, $P = 0.28$ (Cox proportional hazard likelihood ratio test). (Redrawn with permission from Kim MS, Coté CJ, Cristoloveanu C, et al. There is no dose-escalation response to dexamethasone [0.0625–1.0 mg/kg] in pediatric tonsillectomy or adenotonsillectomy patients for preventing vomiting, reducing pain, shortening time to first liquid intake, or the incidence of voice change. *Anesth Analg 2007*. 104[5]:1052–1058.)

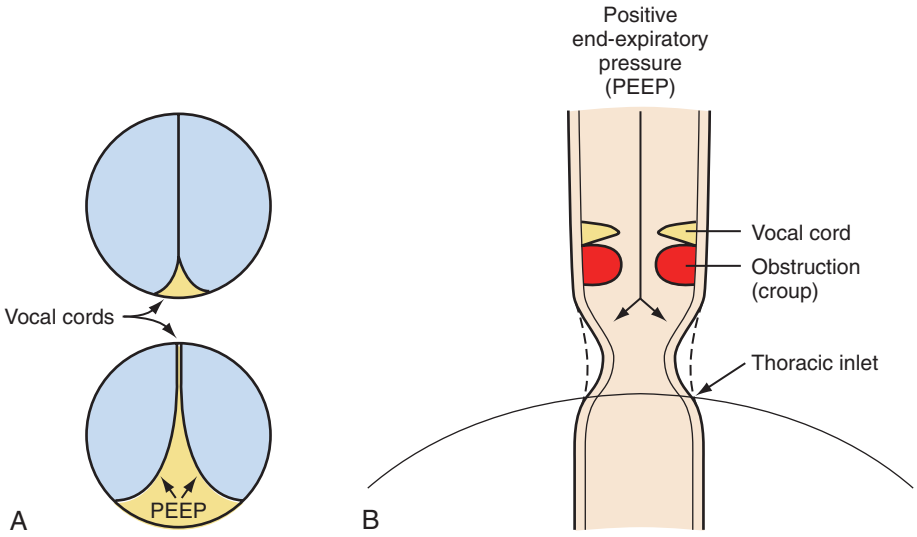

FIGURE 33.10 When a child has upper airway obstruction caused by laryngospasm **(A)** or mechanical obstruction **(B),** application of approximately 10 cm H_2O of positive end-expiratory pressure (PEEP) during spontaneous breathing often relieves obstruction. PEEP helps to hold the vocal cords apart **(A)** and the airway open (*dashed lines* in **B**). (From Coté CJ. Pediatric anesthesia. In Miller RD, ed. *Miller's Anesthesia*. 8th ed. New York: Churchill Livingstone; 2012.)

Special Considerations for Children With OSA

Children with OSA who require premedication should be closely observed because transient oxygen desaturation that did not require any intervention has been reported in 1.5% of children with OSA who received 0.5 mg/kg oral midazolam.[122] This study excluded those with severe OSAS. Accordingly, caution should be exercised when premedicating children with severe OSAS.

Induction of Anesthesia

Compared with children undergoing adenotonsillectomy for chronic tonsillitis, children with OSAS experienced more respiratory complications during anesthetic induction including supraglottic obstruction and desaturation.[46,101] The vulnerability of the upper airway musculature described for halothane in cats[197] has subsequently been reported for most anesthetic agents in humans, resulting in a graded reduction in airway caliber with increasing anesthetic concentrations.[198–202] As airway collapse occurs in the upper two-thirds of the pharyngeal airway[201] during induction, airway obstruction may require a jaw thrust maneuver, insertion of an oral or nasopharyngeal airway, and/or the application of continuous positive airway pressure (CPAP). The application of CPAP acts as a pneumatic splint to increase the caliber of the pharyngeal airway (Fig. 33.10).[203] Of equal importance, CPAP increases longitudinal tension on the pharyngeal airway, thereby decreasing the collapsibility of the upper airway (see Fig. 14.10), and increases lung volumes.[204,205] Small increments in CPAP between 5 and 10 cm H_2O increase the dimension of the pharyngeal airway dramatically (Fig. 33.11).[206,207] In children with severe OSA, it is prudent to consider securing IV access before induction of anesthesia to expedite administration of an NMBD or IV agents should pharyngeal obstruction or laryngospasm occur.

Analgesic Management in Children With OSA

Severe OSA is characterized by recurrent episodes of hypoxia and hypercarbia during sleep. In animal models, exposure to intermittent hypoxia during development is associated with an increase in the density of μ-opioid receptors in the respiratory-related areas of the brainstem. The cellular mechanism whereby this increased density is achieved has yet to be elucidated, but it may represent an adaptive response to the effects of recurrent intermittent hypoxia that allows μ-receptor–mediated opioid respiratory effects to predominate.[208–211]

In young children with severe OSA, the severity of the nocturnal oxygen desaturation correlates with the sensitivity to exogenously administered opioids (Fig. 33.12).[115,212,213] The morphine dose

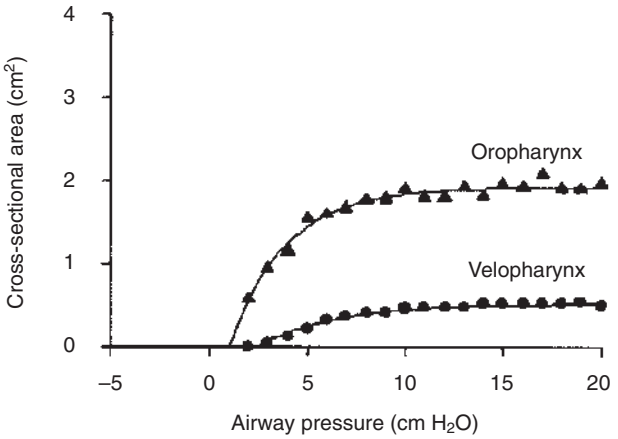

FIGURE 33.11 The relationship between airway pressure and the cross-sectional area of the pharynx. Maximal airway dimension is achieved between 15 and 20 cm H_2O. At reduced airway pressures, around 5 cm H_2O, small increments in airway pressure make a large difference in airway caliber. (From Isono S, Tanaka A, Nishino T. Dynamic interaction between the tongue and soft palate during obstructive apnea in anesthetized patients with sleep-disordered breathing. *J Appl Physiol*. 2003;95[6]:2257–2264.)

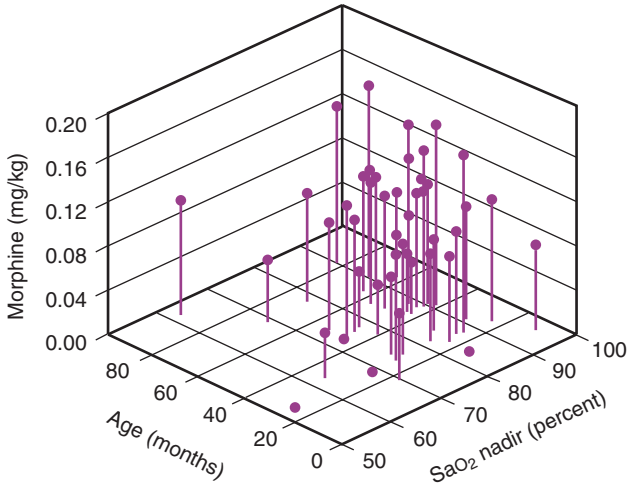

FIGURE 33.12 Relationship between morphine requirement, age, and the preoperative arterial oxygen-saturation nadir in 46 children who were otherwise well. The lengths of the stems supporting the 46 dots are proportional to the morphine dose. The stems in the foreground are shorter than those in the background, indicating a significant correlation between the three variables. SaO_2, arterial oxygen saturation. (From Brown KA, Laferrière A, Moss IR. Recurrent hypoxemia in young children with obstructive sleep apnea is associated with reduced opioid requirements for analgesia. *Anesthesiology* 2004;100[4]:806–810.)

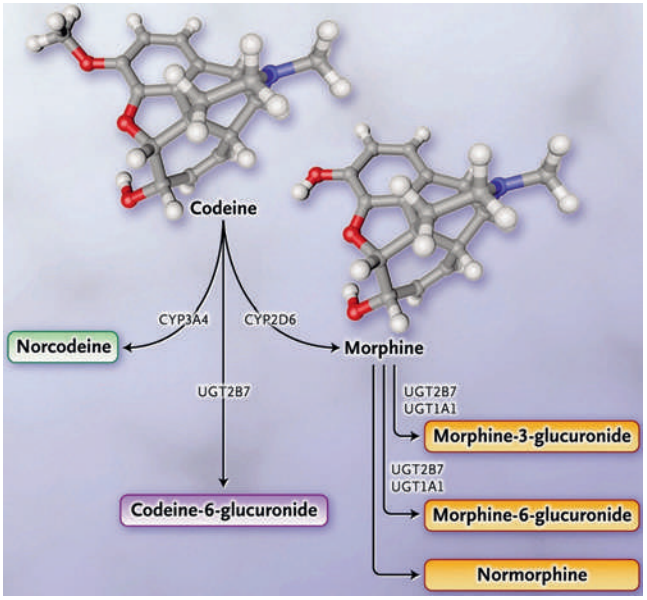

FIGURE 33.13 Codeine metabolic pathways. The CYP-2D6 pathway is responsible for converting the prodrug codeine to the active drug morphine. (From Racoosin JA, Roberson DW, Pacanowski MA, Nielsen DR. New evidence about an old drug—risk with codeine after adenotonsillectomy. *N Engl J Med.* 2013;368[23]:2155–2157 [June 6, 2013] with permission.)

required to achieve a uniform analgesic endpoint in children with OSA who exhibited a low preoperative nSAT (<85%) (see Fig. 33.8) was less than in those whose preoperative nSAT was 85% or more.[115] Children with severe OSAS who exhibit nocturnal hypoxemia require OSA-appropriate opioid regimens. Young age was also associated with an increased sensitivity to opioids. In a retrospective review of 880 children, of whom 116 had PSG-confirmed OSA, a total intraoperative opioid administration of 0.1 mg/kg or more of morphine equivalents increased the risk for intraoperative respiratory complications (adjusted odds ratio of 0.4, 95% CI 0.2–0.8).[130] *An unforeseen risk of perioperative opioid use in children with severe OSA is that age-appropriate doses of opioids may produce exaggerated respiratory depression.* Of children with severe OSAS who were anesthetized with halothane, 46% experienced apnea after a single IV dose of fentanyl (0.05 µg/kg) compared with 4% of controls.[214] This increased sensitivity to the respiratory depressant effects of fentanyl in children with OSAS is supported by the exaggerated respiratory depression to subsequent administration of a uniform dose of fentanyl in rat pups exposed to intermittent hypoxia.[215] Hence, allowing spontaneous respirations during maintenance of anesthesia enables an assessment of the response to small challenges of opioid analgesics.[213,216] In this manner, the anesthesiologist can assess the sensitivity of the child with OSAS to opioids; controlling respirations precludes such an evaluation. Sleep fragmentation blunts the arousal response to acute airway occlusion during sleep.[217,218] In addition, exposure to intermittent hypoxia during development is associated with an increase in the arousal latency to hypoxia.[219–221] Morphine acting at the level of the basal forebrain blunts arousal.[222] If the increased sensitivity to both the analgesic and respiratory effects of exogenously administered opioids reported in children with OSA extends to arousal mechanisms, the use of opioids in children with severe OSA may further impair arousal mechanisms. This heightened sensitivity may have been a contributing factor in the reports of death from apparent apnea after hospital discharge,[59,72,73,223] prompting the shift to nonopioid and reduced opioid postoperative analgesic regimens.[179,224,225]

Guidelines for the perioperative management of OSAS[112] suggest that the use of codeine, previously thought to be a "low-risk" oral opioid commonly used in the ambulatory setting, is problematic. Codeine is a prodrug that is metabolized by the cytochrome P450 debrisoquine 4-hydroxylase (CYP2D6) to its active analgesic morphine metabolites (Fig. 33.13). The CYP2D6 gene displays polymorphism, including gene duplication that results in ultra-rapid metabolism, which for prodrugs such as codeine, results in a greater fraction of morphine.[226] Respiratory arrest after codeine has been reported in both adults and children who are ultra-rapid metabolizers of codeine.[227–229] Whereas the ultra-rapid metabolizing genotype is present in 3% of Caucasians, it is present in 10% to 30% of Arabian and Northeast African populations. In contrast, almost 10% of children lack CYP2D6, rendering codeine an ineffective analgesic because there is no conversion to morphine. Given the broad variability in codeine metabolism and our lack of knowledge of which polymorphism is carried by each child, the FDA recently required that the manufacturers of all codeine-containing products add a boxed warning to the labeling of their product that describes the risk posed by codeine after a child has undergone tonsillectomy or adenoidectomy and codeine use is restricted in such patients.[230,231] On April 20, 2017, that warning was changed to a *contraindication* in children <18 years of age undergoing tonsillectomy. One approach to manage pain in children at home has been to determine the 2D6 genotyping. In one report of more than 600 children with sickle cell disease who required codeine for painful crises, those who were ultra-rapid or poor metabolizers of 2D6 were treated with analgesics other than codeine and the remainder were treated with codeine; no complications

occurred.[232] For children after tonsillectomy, hydrocodone and oxycodone are also affected by polymorphisms in 2D6, thereby rendering them vulnerable to the same risks as those conferred by codeine. The French Society of Otorhinolaryngologists and the Swedish ENT Association for Otorhinolaryngology, Head and Neck Surgery formulated guidelines to manage posttonsillectomy pain in their respective countries.[225,233] With the demise of codeine, the French guidelines based their postoperative treatment on tramadol, whose metabolism by 2D6 is considered less variable in analgesic potency than codeine, whereas the Swedish guidelines adopted a pain management strategy based on oxycodone among other medications. Some have advocated oral morphine to treat these children postoperatively. The pharmacokinetics of oral morphine in children differ substantively from those in adults.[234,235] Initial studies with oral morphine to supplement NSAIDs after tonsillectomy have shown that it does not improve analgesia, but increased side effects such as hemoglobin desaturation.[236,237] Further studies are required before a consensus regarding the optimal pain management strategy for children after tonsillectomy can be recommended.

One very important observation worth emphasis is that children with severe OSA may be exquisitely sensitive to the respiratory depressant effects of opioids such that the usual doses should be reduced by ½ to ⅔ of the usual starting dose and then titrated to effect. Obese, African American, and Hispanic children are at increased risk. The report of two children who died in the PACU after tonsillectomy, presumably after removal of monitors during emergence, and another who died within a hospital ward emphasizes the insidiousness of this issue and why increased vigilance is needed.[59]

Neural Blockade

Blockade of neural input to the upper airway dilator musculature in children with OSA is also problematic. Serious life-threatening complications, including severe upper airway obstruction (UAO) and pulmonary edema, have been reported after local anesthetics have been infiltrated in the tonsillar fossa to prevent pain after adenotonsillectomy. The pharynx in children with OSA is not only smaller in size,[201,238] but also more collapsible, even during wakefulness.[239–241] Topical anesthesia applied to the mucosa of the pharynx of children with OSA reduces the caliber of the pharynx and may thereby compromise airway patency.[242]

Extubation Strategy and Management of the Postoperative Period in Children With OSA

Full antagonism of neuromuscular blockade is strongly recommended as residual neuromuscular blockade in the PACU will selectively depress the function of the upper airway dilators relative to the diaphragm, promoting collapse of the pharyngeal airway.[243] Antagonism of neuromuscular blockade with atropine and neostigmine after tonsillectomy has been associated with less PONV than antagonism with glycopyrrolate and neostigmine.[244]

The trachea is usually extubated when the child is fully awake. Techniques that involve minimally stimulating the airway have been suggested.[129] Although the incidence of major respiratory complications after deep or awake extubation is similar, a greater proportion of children in the awake extubation group had PSG-proven OSA.[130] Placing a nasopharyngeal or oropharyngeal airway before extubation is sometimes useful.[95]

Several other factors may increase the risk of respiratory difficulties after adenotonsillectomy in children with OSAS. For reasons that are unclear, children with severe OSAS, whose adenotonsillectomy was performed in the morning, were less likely to desaturate when managed in a PACU setting than those whose surgery was performed in the afternoon.[245] Two drugs, atropine and naloxone, have the potential to augment the function of the upper airway. Atropine administered after induction of anesthesia decreased the risk of postadenotonsillectomy respiratory complications.[69] Of possible relevance is the report that blockade of the muscarinic receptors in the rat hypoglossal nucleus enhances activity of the genioglossus muscle.[246] Agonists of opioid μ-receptors depress activity in the pharyngeal dilator muscles, including the genioglossus muscle.[209,247–249] Given the increased sensitivity to both analgesic and respiratory effects of exogenously administered opioids in children with severe OSAS, a similar sensitivity may also apply to the pharyngeal musculature. Small doses of naloxone may alleviate UAO after adenotonsillectomy if a relative "overdose" of exogenous opioids has been administered.

Children with OSAS continue to demonstrate obstructive apnea and desaturation in the immediate postoperative period. Avoiding opioids, or using both age- and OSAS-appropriate opioid regimens (⅓ to ½ the normal starting dose) in both the intraoperative and postoperative periods, decreases the frequency of these events.[96] Measures to support airway patency in the postoperative period include insertion of a nasal airway, administration of noninvasive ventilatory support (e.g., CPAP), reintubation, ventilation, and the administration of bronchodilators, racemic epinephrine, and heliox. Bilevel positive airway pressure and/or CPAP may be useful in children with preexisting neurologic disorders.[250] However, nasal secretions may be copious after adenotonsillectomy, limiting the efficacy of noninvasive ventilatory support. Children with complex medical diseases, who are critically dependent on the function of upper airway musculature, may benefit from delayed extubation. Acute relief of chronic UAO favors the exudation of intravascular fluid into the pulmonary interstitium and noncardiogenic pulmonary edema, which may present preoperatively, intraoperatively, or postoperatively. Supportive measures include the administration of oxygen, tracheal intubation, mechanical ventilation with positive end-expiratory pressure, and administration of furosemide.[251–253]

Despite removal of the hypertrophied tonsils and adenoids, children with OSAS continue to demonstrate obstructive apnea and desaturation during sleep on the first night after adenotonsillectomy, with the frequency of the obstructive events and the severity of desaturation usually greater in those children with severe OSAS (Fig. 33.14).[254,255] This underscores the need to admit these children for continuous overnight monitoring postoperatively. In addition to pulse oximetry, common monitors include photoplethysmography, transthoracic impedance, and capnography. The majority of desaturation events on the first postoperative night are the result of obstructive apnea.[254] Obstructive respiratory efforts act to change thoracic impedance. A limitation of this monitor is that it will falsely detect paradoxical chest wall motion as breathing when in fact the airway is obstructed.[256,257] Nasal capnography is poorly tolerated in postoperative children and nasal secretions may be problematic. Transcutaneous CO_2 monitors may be useful in somnolent children. The AAP and the AAO-HNS now recommend that children with an AHI >24 or an AHI >10 events per hour be admitted to the hospital after adenotonsillectomy.[43,71] Current pediatric tertiary care admission practices after adenotonsillectomy show considerable variability among institutions despite clear guidelines from several societies (Fig. 33.15).[105]

Long-term follow-up studies more than 6 months after tonsillectomy in children with OSAS show that symptoms completely resolve in those with mild OSAS (AHI <10) but are persistent in up

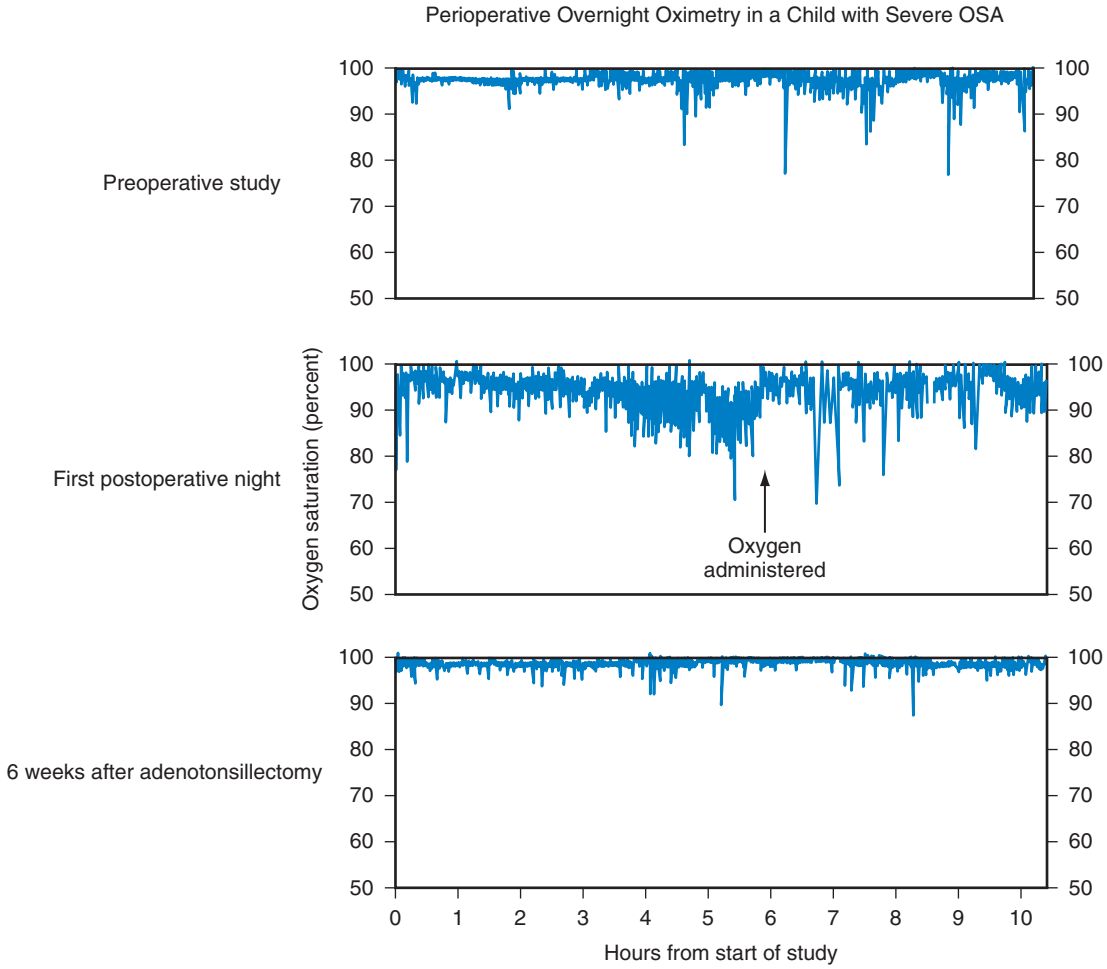

FIGURE 33.14 Three oximetry trend records from an otherwise healthy child. The *x*-axis is time ranging from bedtime on the left to arousal the following morning on the right. The *top* panel is the preoperative record showing clusters of desaturation. The *middle* panel is the record from the first night after adenotonsillectomy. With sleep onset, a decrease in saturation is evident that worsens after midnight. Oxygen therapy is administered after midnight (*arrow*). The *bottom* panel is the recording 6 weeks after adenotonsillectomy, which is within normal limits. (From Nixon GM, Kermack AS, McGregor CD, et al. Sleep and breathing on the first night after adenotonsillectomy for obstructive sleep apnea. *Pediatr Pulmonol.* 2005;39[4]:332–338.)

to 35% of those with severe OSAS (AHI >20).[258–260] Furthermore, recent epidemiologic evidence suggests that residual SDB is more likely to be present after adenotonsillectomy in older children (>7 years of age) and obese children. It has also been suggested that obese children with large tonsils and OSA also show evidence of systemic inflammatory disease that persists after tonsillectomy.[258,261]

DISCHARGE POLICY FOR AMBULATORY ADENOTONSILLECTOMY

Although children undergoing adenotonsillectomy for obstructive breathing without apnea may undergo ambulatory surgery, those with OSAS should not. The AAO-HNS revised the clinical practice guidelines for tonsillectomy in children, including indications for postoperative hospitalization.[42,87]

In otherwise healthy children, conversion from ambulatory to inpatient status was most frequently prompted by respiratory events in children whose indication for surgery was obstructive breathing.[262] In a retrospective review of 6681 cases, implementation of these guidelines decreased the overall rate of unplanned admission to the hospital after adenotonsillectomy from 2.4% to 1.4%,[263] reducing the indications for respiratory complications from 9% to zero and for hemorrhage from 3% to zero.[48,264] A systematic reduction in postoperative morphine use was associated with a reduced rate of hospital admission from 8% to 2.4%.[167] A systematic use of age- and OSAS-appropriate opioid regimens reduced the incidence of PRAEs and the recovery time.[96]

In North America, the indication for adenotonsillectomy in 77% of children is obstructive breathing.[262,265,266] The reality is that fewer than 10% are evaluated with a sleep test before surgery. The challenge is to evaluate the severity of SDB based on clinical criteria alone.[89] Different algorithms are available to guide the disposition of children with OSAS and the indications for postoperative admission (Fig. 33.16).[87,95,257] Because the onset of respiratory complications in children with severe OSAS may be delayed,[68,245,254] practice guidelines from the AAO-NHS, the AAP, and the American Society of Anesthesiologists all recommend that discharge criteria from a monitored setting should include observation with SpO_2 monitoring during sleep. A survey of North

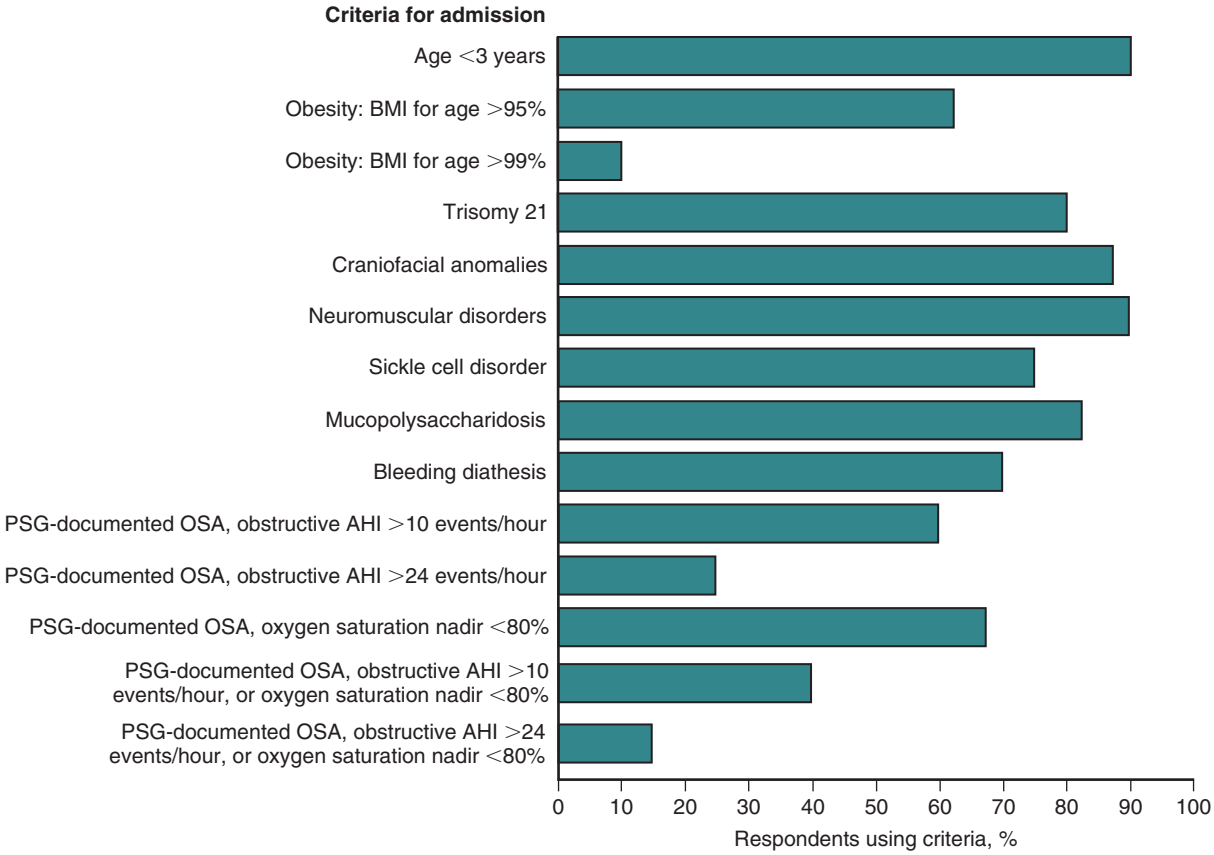

FIGURE 33.15 Admission criteria after adenotonsillectomy. Percentage of respondents from 72 pediatric otolaryngology divisions at tertiary care children's hospitals using the criteria shown as an indication for admission. It is surprising and counterintuitive that the children with documented obstructive sleep apnea (OSA) and the highest apnea hypopnea index (AHI) or desaturation (<80%) criteria had the lowest use by otolaryngologists. *BMI,* body mass index; *PSG,* polysomnography. Current pediatric tertiary care admission practices following adenotonsillectomy. *JAMA Otolaryngol Head Neck Surg.* 2016;142[5]:452–456. doi:10.1001/jamaoto.2016.0051 March 24, 2016.)

TABLE 33.5 Criteria for Overnight Admission After Tonsillectomy and Adenoidectomy

- Obstructive sleep apnea
- Sleep disturbance
- <3 years of age
- Craniofacial abnormalities (e.g., Down syndrome, Treacher Collins syndrome)
- Lives >1 hour away
- Lives in an unstable home environment that precludes adequate supervision
- Postoperative problems (e.g., fever, failure to take oral fluids, or continued vomiting)
- Possible or documented coagulopathy
- Extreme obesity

From Zalzal G: Personal communications, survey of major pediatric hospitals, 2006.

American pediatric tertiary centers showed that 73% complied with this recommendation, although 93% had a minimum time for observation with a median of only 2 hours (Fig. 33.17).[105] This 2-hour period of observation will not detect delayed onset of sleep-related respiratory compromise and may explain the deaths from apparent apnea after adenotonsillectomy.[72,73] Table 33.5 presents common admission criteria for children undergoing elective tonsillectomy.

Special Considerations in Medically Complex Children With OSAS

Severe Obesity

Obese children often have SDB and severely obese children undergoing tonsillectomy had a significantly greater incidence of comorbid conditions than normal children. Severely obese children (body mass index [BMI] >98th percentile) have an almost 9-fold increase in the odds for perioperative respiratory adverse events (PRAEs), a greater incidence of bleeding,[59,73] and an increase rate of unplanned admission to hospital after adenotonsillectomy.[267]

Down Syndrome

The incidence of OSAS in children with Down syndrome may be as great as 50%.[104] Nocturnal oximetry may be the preferred first test as these children may not be cooperative for a PSG study. An abnormal MOS could help identify children with severe OSA. However, children with Down syndrome may exhibit an increased central apnea index and a reduced obstructive AHI without desaturation events, so that a negative MOS does not exclude severe OSA.

Pierre Robin Sequence

The Pierre Robin sequence (PRS) affects 1 in 3000 to 8000 live births. PRS is an association of micrognathia, glossoptosis, and airway obstruction and feeding difficulties within the first 24 hours after birth. Surgical management includes tongue-lip adhesion, subperiosteal release of the floor of the mouth, and mandibular distraction osteogenesis. Airway management may be a major challenge.[268]

Abnormalities of Ventilatory Control

Typically, oximetry studies in pediatric OSA show clusters of desaturation with an intercluster SpO_2 in excess of 90%. A low intercluster SpO_2 is reported in children with diseases of the lower airways, such as bronchiolitis, and abnormalities of ventilatory control.[269–271] As young children with undiagnosed disorders of ventilatory control may also have adenotonsillar hypertrophy, a low intercluster SpO_2 should prompt further investigation. Late-onset central hypoventilation syndrome, rapid-onset obesity hypoventilation hypothalamic and autonomic dysfunction (ROHHAD) syndrome, and the Prader-Willi syndrome may be associated with adenotonsillar hypertrophy.

POSTTONSILLECTOMY BLEEDING

Posttonsillectomy bleeding is a surgical emergency. It occurs either within the first 24 hours after surgery (primary bleeding) or 5 to 10 days after surgery when the eschar covering the tonsillar bed retracts (secondary bleeding). Primary bleeding is considered a surgical complication as the result of failure to establish surgical hemostasis, whereas secondary bleeding is attributed to nonsurgical complications, including certain medications, a bleeding diathesis, or infection. Obesity and older age are associated with an increased risk of immediate postoperative hemorrhage after outpatient tonsillectomy.[58,59,73] Approximately 75% of postoperative tonsillar bleeding occurs within 6 hours of surgery. Sixty-seven percent of cases of postoperative bleeding originate in the tonsillar fossa, 27% in the nasopharynx, and 7% in both.[272] It is considered a surgical complication that is responsible for converting tonsillectomy from ambulatory surgery to a hospital admission in 1.6% of cases.[262]

In a review of more than 9000 adenotonsillectomies in children performed with blunt and sharp (cold) dissection, the incidence of postoperative bleeding was 2.15%, with 76% of the hemorrhages occurring in the first 6 hours postoperatively.[273] The authors of an audit of 4800 pediatric tonsillectomies for which hemostasis was secured with electrocautery (hot) techniques reported a primary postoperative hemorrhage rate of 0.9%, with 83% presenting within 4 hours of surgery.[167] The consensus is that the period of observation for primary hemorrhage depends on the surgical technique: 6 hours and 4 hours, for cold and hot dissection, respectively,[167,272,273] although abbreviated periods of observation have been advocated by some.[262] IV steroid administration on the day of tonsillectomy in children was reported to be an independent risk factor for severe bleeding requiring reoperation.[159] The impact of revised practice

guidelines recommending against the prophylactic antibiotic use on the incidence of bleeding after adenotonsillectomy is still not clear. A retrospective review of 5359 cases reported the incidence of surgery for bleeding increased from 1.4% to 3.5% (95% CI 1.9% to 5.1%) after the change in practice.[274]

The management of anesthesia in this situation can be challenging even in the hands of an experienced pediatric anesthesiologist.[275] It often requires dealing with anxious parents, an upset surgeon, and a frightened anemic, hypovolemic child with a stomach full of blood. A thorough review of the anesthetic record of the original surgery will provide pertinent information about any existing medical condition, use of medications (such as aspirin), difficulty with airway management, and a rough estimate of intraoperative blood loss and fluid replacement, as well as the duration of known bleeding and the volume of blood vomited since the bleeding began. A quick history and examination of the child will provide vital information about the child's current volume status. A history of dizziness and the presence of orthostatic hypotension may suggest a loss of more than 20% of the circulating blood volume and the need for aggressive fluid resuscitation and crossmatch of blood before induction.[276] Even when severe hypotension is not present, the child with the bleeding tonsil may be hypovolemic with a decreased cardiac output secondary to ongoing blood loss. If blood loss is severe, and/or fluid resuscitation is not vigorous, lactic acidosis and shock will develop.

The compensatory response to acute blood loss is an outpouring of catecholamines. This causes peripheral vasoconstriction, which delays the clinical onset of hypotension in the awake child. When anesthesia-induced vasodilation occurs, profound hypotension may develop. Vigorous fluid resuscitation with crystalloids (repeated boluses of 20 mL/kg of balanced salt solution) and/or colloids is therefore the key to improve the cardiac output and achieve hemodynamic stability before induction of anesthesia. Hemoglobin or hematocrit determination should be interpreted in light of the child's volume status and the type of fluid resuscitation administered. If the hemoglobin concentration is reduced after fluid resuscitation, blood may be required; however, blood is rarely the primary solution for volume replacement in these children. If severe hypovolemia is suspected or if there may be a delay in obtaining blood, blood should be crossmatched for two or more units of packed red blood cells before the child reaches the OR. If a child bleeds after the tonsillectomy and a bleeding blood vessel is not identified, it may be necessary to measure the prothrombin time, partial thromboplastin time, platelet count, and a bleeding time to rule out a bleeding diathesis. *It cannot be overemphasized that the child must be adequately volume resuscitated before proceeding to the OR.*

A child who presents with a bleeding tonsil has a full stomach (filled with swallowed blood) and may still be hypovolemic. A child who is spitting bright red blood may quickly exsanguinate, but the bleeding may be temporarily controlled by compression of the carotid artery ipsilateral to the bleeding source. The anesthesiologist may have difficulty visualizing the larynx because of the bleeding tonsillar bed and clots in the pharynx. A stiletted ETT, two sets of well-illuminated laryngoscope blades and handles, and two large-bore Yankauer-type suction tubes must be available before induction of anesthesia (see also Chapter 4 and Fig. 39.5). On arrival in the OR and application of routine monitors, the child who is actively bleeding from the oropharynx should be preoxygenated while positioned in the left lateral position and head down to drain blood out of the mouth (Fig. 33.18). When rapid-sequence induction is performed, cricoid pressure (Sellick maneuver) should be applied by an assistant as the child loses consciousness to minimize the risk of aspirating blood into the lungs.[277] The child is then turned supine, and the trachea intubated, although intubation can be performed with the child in the left lateral decubitus position. That a rapid-sequence induction with cricoid pressure decreases the risk of aspiration in children with full stomachs is not evidence-based, although it is commonly practiced. Aspiration of blood into the lungs does not cause the same pathologic changes as acid particulate aspiration unless the volume of blood aspirated compromises pulmonary oxygenation. The use of a full induction dose of propofol in a hypovolemic child could result in significant hypotension. A reduced dose of these induction agents (e.g., propofol, 1–2 mg/kg), or ketamine (1–2 mg/kg) or etomidate (0.2 mg/kg) followed by atropine (0.02 mg/kg) combined with succinylcholine (1.5–2 mg/kg) or rocuronium (1.2 mg/kg) for tracheal intubation should facilitate a rapid control of the airway without hypotension. The change in systolic blood pressure after induction of anesthesia will provide an indication of the volume status of the child. The use of rocuronium instead of succinylcholine is cautiously recommended in these cases, particularly if sugammadex is unavailable; an unexpected difficult intubation combined with arterial bleeding in the oropharynx could rapidly lead to hypoxic brain damage if the airway cannot be secured in a timely manner and the child is paralyzed with a large dose of rocuronium. The surgeon should be scrubbed and immediately available to secure surgical airway if needed.

FIGURE 33.18 Preoxygenation with the patient in the lateral position to control posttonsillectomy bleeding before induction of anesthesia.

A cuffed ETT (0.5 mm ID smaller than the usual uncuffed for age or weight) with a stylet should be used to rapidly secure the airway and minimize the chance of aspirating blood. The sevoflurane or desflurane concentration should be titrated with nitrous oxide in oxygen[123] and supplemented with a small dose of opioid, such as fentanyl (1–2 μg/kg); this approach will facilitate a rapid recovery after surgery.[278] Often these surgeries are not excessively painful because surgery is limited to the area of bleeding. Controlling the bleeding vessel in the tonsillar bed can be accomplished rapidly if the blood pressure is maintained in the normal range. Hence, these surgeries are often quite brief and the anesthetic should be planned accordingly. Suctioning the stomach with a large-bore catheter under direct vision after the procedure does not guarantee an empty stomach, because much of the blood

may be clotted and the clots are often too large to pass through the catheter lumen. The use of prophylactic antiemetic therapy (e.g., ondansetron 0.1 mg/kg up to 4 mg) is indicated.

The most important postoperative consideration is to extubate these children when they are fully awake and able to control their airway reflexes. Extubating the trachea while the child is in the lateral position may be the safest practice to minimize the risk of aspiration. If there is a medical indication to substitute high-dose rocuronium (1.2 mg/kg) for succinylcholine, then a prolonged period of relaxation may be anticipated. Sugammadex may allow early reversal of residual deep neuromuscular blockade with high-dose rocuronium.[279–281] Postoperatively, a repeat determination of the hemoglobin level may be indicated.

PERITONSILLAR ABSCESS

Peritonsillar abscess (quinsy tonsil) occurs in older children and young adults. It is the most common deep neck-space infection treated by otolaryngologists. Infection originates in the tonsil and spreads to the peritonsillar space between the tonsillar capsule and the superior constrictor muscle, and usually into the soft palate in the region of the superior pole of the tonsil. Commonly cultured organisms include aerobes, such as *Streptococcus pyogenes, S. milleri, S. viridans,* β-hemolytic streptococci, *Haemophilus influenzae,* as well as anaerobes, such as *Fusobacterium* and *Prevotella* species.[282]

Clinically, these children present with fever, pharyngeal swelling, sore throat, dysphagia, odynophagia, and often trismus. Trismus is caused by compression of nerves by the tense peritonsillar mass, spasm of the pterygoid muscles, and inflammation of the muscles of the face and neck. Dehydration can ensue because of fever and the persistent difficulty with swallowing.

Preoperative evaluation includes careful assessment of the airway, with special emphasis on the degree of trismus. Blood specimens should be analyzed for total and differential white blood cell count to ascertain the response to the infection, and for cultures for appropriate antibiotic therapy. Computed tomography of the tonsillar area will identify airway deviation or compromise and the extent of spread of the abscess (Fig. 33.19); transcutaneous ultrasound has been increasingly used to confirm the diagnosis.[283]

While awaiting the results of the cultures, treatment should begin with establishing IV access, hydration, and appropriate antibiotic coverage. The majority of organisms, including anaerobes, are penicillin sensitive. Consequently, penicillin is usually the antibiotic of choice.[282] The three different procedures currently used to drain a peritonsillar abscess are needle aspiration, incision and drainage, and abscess tonsillectomy.[284] Most children undergo general anesthesia for treatment of peritonsillar abscess by incision and drainage, although in some centers, moderate to deep sedation has been successfully used.[285] If the abscess is small and well confined, immediate tonsillectomy is performed.

The anesthetic management of these children can be challenging. Rupture of the abscess and possible aspiration of purulent material during laryngoscopy and intubation should be avoided. Although the airway may appear to be compromised, most peritonsillar abscesses are in a fixed location in the lateral pharynx and do not interfere with mask ventilation. Visualization of the vocal cords is usually not impaired, because the pathology is supraglottic and well above the laryngeal inlet, although a right-sided abscess may interfere with the usual sweeping of the tongue to the left during laryngoscopy. Laryngoscopy must be carefully approached to avoid excessive manipulation of the larynx and surrounding structures. Occasionally, the pharyngeal swelling and the distortion of normal anatomy, along with excessive secretions, may create difficulty for laryngoscopy and intubation. The OR should be prepared as for any difficult airway case, with different sizes of ETTs, stylets, two sets of well-illuminated laryngoscopes, a GlideScope (Verathon, Bothell, WA) or other advanced airway device to facilitate difficult intubation, and a tonsil-tip suction catheter attached to a powerful suction device. The surgeon must be present in the OR during induction of anesthesia should airway obstruction occur. Equipment for cricothyrotomy or tracheotomy must be readily available.

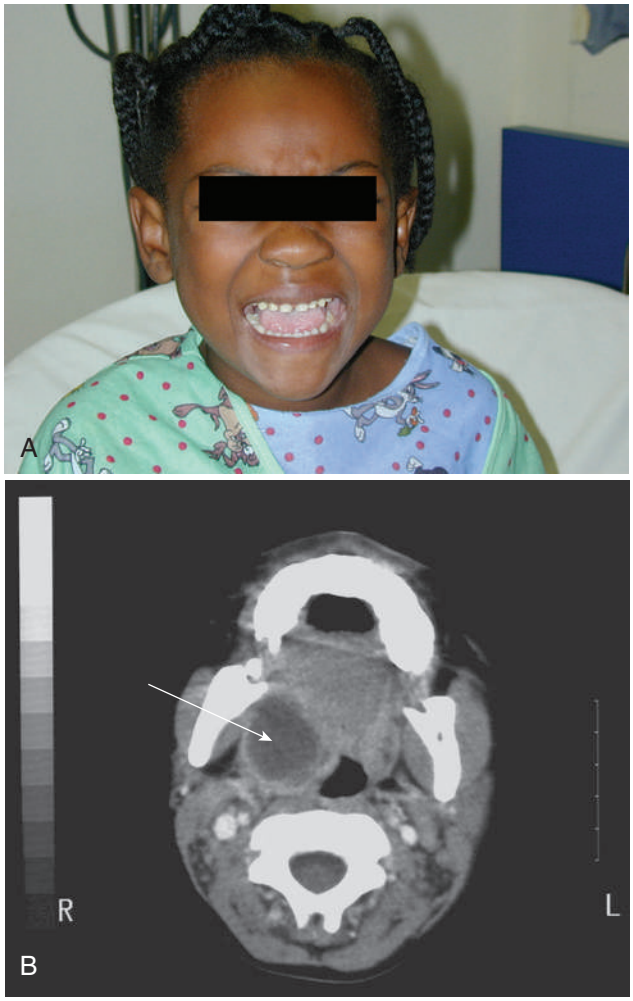

FIGURE 33.19 A, Peritonsillar abscess with trismus. **B,** Axial enhanced computed tomography scan through the oropharynx showing a 3-cm ring-shaped, enhancing, low-density mass (*arrow*) replacing the left tonsil, typical of a tonsillar abscess.

These children are often older and do not require preoperative sedation. If trismus is present, an inhalational induction should be performed, using sevoflurane and oxygen while the anesthesiologist assesses mobility of the temporomandibular joint under anesthesia. An oropharyngeal airway is best avoided, lest the abscess is traumatized. Usually awake trismus resolves once an adequate depth of anesthesia has been achieved. When this is confirmed, or if there was minimal trismus to begin with, then a short-acting NMBD (or propofol) should be given to facilitate tracheal intubation. Alternatively, if there is minimal trismus and the preoperative airway assessment indicates minimal distortion, a rapid-sequence IV induction after adequate preoxygenation may be the best way to avoid trauma to the pharyngeal structures while struggling with

a mask induction, needing to insert an oropharyngeal airway, and possibly rupturing the abscess.[2]

To avoid aspiration of purulent material during intubation and drainage, a cuffed ETT is recommended and the child is placed in Trendelenburg position. At the end of surgery, the trachea should be extubated with the child awake, preferably in the lateral decubitus position.[2]

Anesthesia for Endoscopy

Anesthesia for rigid bronchoscopy in young children presents a significant challenge. Not only does the child have a compromised airway, but that airway also must be shared with the surgeon. The importance of constant communication between the endoscopist and the anesthesiologist cannot be overstated. In general, the goals of anesthesia for endoscopy are analgesia, an unconscious child, and a quiet surgical field.[286] Coughing, bucking, or straining during instrumentation with a rigid bronchoscope may cause difficulty for the surgeon and damage the child's airway. At the conclusion of the procedure, children should be returned to consciousness quickly with airway reflexes intact to protect the recently instrumented airway. General principles for the anesthetic management will be outlined first. Disease-specific requirements will be discussed under appropriate subheadings.

For most children, a pulse oximeter, blood pressure cuff, electrocardiographic leads, and precordial stethoscope are applied before induction. Continuous monitoring of ventilation by capnography is not always possible during bronchoscopy, particularly when the Hopkins optical telescope is in place for optimal viewing. Clinical observation of the chest wall movement and the use of a precordial stethoscope are useful. In many cases, intermittent capnography is possible when the bronchoscope is withdrawn by the surgeon. Although greater than normal CO_2 tensions are inevitable with intermittent ventilation, they are generally well tolerated in the presence of sevoflurane or propofol. Hypoxia, on the other hand, is not well tolerated, and the procedure should be stopped while the child is oxygenated.

In many instances, endoscopists prefer that the child breathes spontaneously throughout the procedure; this allows observation of dynamic changes during respiration. Inhalation induction by mask is accomplished with oxygen and an inhalational agent, usually sevoflurane. Nitrous oxide can be used initially, if tolerated, to speed the induction and then discontinued before the examination. Once a sufficient depth of anesthesia has been achieved, IV access is established and the depth of anesthesia is increased. Alternatively, in those children in whom IV access was established before anesthesia, anesthesia may be induced IV with a sleep dose of propofol, followed by mask ventilation with a volatile agent. A hybrid technique that uses an inhalational agent supplemented by small increments of propofol is also common.

An antisialagogue (atropine or glycopyrrolate) may be administered IV to decrease secretions that may impair the view through the bronchoscope. Topically treating the vocal cords and subglottic airway with local anesthetic decreases the incidence of coughing or bucking during instrumentation, and allows the child to tolerate a lighter level of anesthesia. Lidocaine, usually 2%, is the most frequently used topical anesthetic. The dose of lidocaine should be limited to 3 to 4 mg/kg divided between the laryngeal and tracheal surfaces because rapid absorption via the tracheal mucosa occurs. It is important to confirm whether the surgeon intends to observe for movement of the vocal cords or evaluate tracheal or bronchial dynamics so that the anesthetic may be planned accordingly (i.e., spontaneous respirations preserved during light levels of anesthesia versus no respiratory efforts and the use of short-acting muscle relaxants).

DIAGNOSTIC LARYNGOSCOPY AND BRONCHOSCOPY

Although diagnostic laryngoscopy and bronchoscopy procedures are usually of brief duration, the anesthetic management can be challenging in small infants with an already compromised airway. Stridor, or noisy breathing caused by obstructed airflow, is a common indication for a diagnostic laryngoscopy and bronchoscopy in infants and children. Inspiratory stridor results from UAO, expiratory stridor and prolonged expiration result from lower airway obstruction, and biphasic stridor is present with mid-tracheal lesions (see Chapters 13 and 14). Subglottic stenosis may follow prolonged tracheal intubation in an infant who was born preterm.

The evaluation of a child with stridor begins with taking a thorough history. The age at symptom onset helps suggest a cause; for instance, laryngotracheomalacia and vocal cord paralysis are usually present at or shortly after birth, whereas cysts or mass lesions develop later in life (Table 33.6). Information indicating positions that make the stridor better or worse should be obtained, because placing a child in a position that allows gravity to aid in reducing obstruction can be of benefit during induction.

Physical examination reveals the general condition of a child or infant, as well as the degree of the airway compromise. Laboratory examination may include a chest radiograph and barium swallow, which can aid in identifying lesions that may be compressing the trachea. Computed tomography, magnetic resonance imaging, and tomograms may be helpful in isolated instances but are not routinely indicated.

Laryngomalacia is the most common cause of stridor in infants and most often results from a long epiglottis that prolapses

posteriorly and prominent arytenoid cartilages with redundant aryepiglottic folds that prolapse into the glottic opening during inspiration.[287] The definitive diagnosis is obtained by direct laryngoscopy and by rigid or flexible bronchoscopy.

Preliminary examination is usually carried out in the surgeon's office. A small flexible fiberoptic bronchoscope is inserted through the nares into the oropharynx. Nasal insertion provides an excellent view of the movement of the vocal cords and pharyngeal structures. Topically treating the nasopharynx with lidocaine facilitates passage of the nasal pharyngoscope or bronchoscope. Alternatively, the examination can be accomplished in the OR in a lightly anesthetized child during spontaneous respirations. Children must be spontaneously breathing so that the vocal cords move freely. After movement of the vocal cords is observed and recorded, the anesthetic level can be increased as appropriate, a rigid bronchoscope (or just the telescope in small infants) is inserted through the vocal cords, and the subglottic area, the lower trachea, and bronchi are evaluated.

The use of premedication in these children should be individualized. Small infants may be brought into the OR unpremedicated; older children may experience respiratory depression and worsening of airway obstruction if heavily premedicated.

Usually an inhalational induction with sevoflurane is performed. Nitrous oxide can be used initially, if tolerated, to speed the induction and then discontinued before the examination. Because sevoflurane is relatively insoluble and is rapidly eliminated, ventilation will be intermittently interrupted during the examination, and the Hopkins optical telescope prevents adequate ventilation through the smallest-diameter bronchoscopes, supplementation with IV agents, such as propofol (1-mg/kg boluses or a 50- to 100-µg/kg per minute infusion), may be necessary to maintain an appropriate depth of anesthesia. If an inhaled technique is used by insufflation, scavenging may be attempted by positioning a suction device near the child's mouth.

A propofol-based TIVA technique has the advantage that it can be given continuously during the procedure, resulting in a more stable level of anesthesia than can be achieved with inhalational agents and intermittent ventilation. Propofol can be supplemented with small (0.5–1.0 mg/kg) doses of ketamine to enhance analgesia. Opioids can also be used but will frequently induce apnea. Dexmedetomidine as a single IV bolus (0.5 µg/kg) or low-dose infusion can also be used to minimize the need for opioids.

The key to a stress-free bronchoscopy is properly applied topical anesthesia. Although topically treating the laryngeal structures with local anesthetic helps the child tolerate the procedure, it may interfere with assessment of normal vocal cord movement. After completion of pharyngoscopy and/or laryngoscopy, the surgeon generally proceeds to rigid bronchoscopy. The size of a rigid bronchoscope refers to the internal diameter (ID). Because the external diameter may be significantly greater than that of an ETT of similar size, care must be taken to select a bronchoscope of proper external diameter to avoid damage to the laryngeal structures (Table 33.7). The rigid bronchoscope can be used for ventilation through the side port attached to the anesthesia circuit with a flexible extension. It is often most useful to paralyze the child with a fixed lesion, which diminishes the risk of vocal cord injury secondary to movement. For nonfixed lesions, such as an aspirated foreign body, and for assessment for bronchomalacia or tracheomalacia, it is preferable to proceed with spontaneous ventilation, a deep level of anesthesia, and good topical anesthesia of the vocal cords and carina. Adequate oxygenation should be maintained in these infants throughout the procedure. Because ventilation may be intermittent and at times suboptimal, it is recommended that 100% oxygen be used as the carrier gas during the bronchoscopic examination. During ventilation of the infant with the optical telescope in place, high resistance may be encountered as a result of partial occlusion of the lumen. This is especially likely when the 2.5-, 3.0-, and 3.5-mm ID scopes are used. Large fresh-gas flow rates, large tidal volumes with high inflation pressures, and large concentrations of inspired inhalational anesthetic (or TIVA) are often necessary to compensate for leaks around the ventilating bronchoscope and the high resistance encountered when the optical telescope is in place. Hand ventilation at greater than normal rates is most effective in achieving adequate ventilation. Sufficient time for exhalation must be provided for passive recoil of the chest. Alternatively the surgeon may remove the optical scope, occlude the bronchoscope with his/her thumb, and allow unimpeded ventilation for several breaths. In small infants, there may be room for only the optical telescopic light source, which does not have a ventilation channel. In these cases, insufflation of oxygen via a small tube placed in the hypopharynx via the nose or mouth will delay the onset of desaturation in a spontaneously breathing child. If (when) desaturation occurs, the surgeon must stop and allow the child to be oxygenated before continuing with the examination.

At the conclusion of bronchoscopy, the surgeon may wish to determine the size of the larynx and determine the degree of airway narrowing. An uncuffed ETT is inserted beyond the narrowest portion of the obstructed airway, and the airway is assessed by applying positive pressure between 10 and 25 cm H_2O to the airway and listening with a stethoscope for an air leak around the ETT at the level of the suprasternal notch. The outer diameter of the appropriate ETT is compared with the inner diameter of the child's larynx and trachea, and the percentage of obstruction is calculated. Grade I obstruction involves up to 50% of the airway, grade II is from 51% to 70%, and grade III is greater than 70% (Fig. 33.20).[288]

An alternative method of ventilation during bronchoscopy is the Sanders jet ventilation technique. The principle of jet ventilation involves intermittent bursts of oxygen delivered at a maximum pressure of 50 psi from a hand-regulated pressure-reducing valve to the lungs, through a 16-gauge catheter attached to a rigid bronchoscope.[289] Current jet ventilators include adjustable pressure-control valves that permit attenuation of the peak pressure; the inflation pressure should begin at 10–15 psi and increase until

Grade II	51% obstruction	70% obstruction
Grade III	71% obstruction	99% obstruction
Grade IV	No detectable lumen	

FIGURE 33.20 A, Method for estimating the percentage of airway obstruction. After easy passage of an uncuffed endotracheal tube (*ETT*), a manometer is placed at the connection of the elbow of the anesthesia circuit and the ETT. A stethoscope is placed over the larynx and the circuit is slowly pressurized. The pressure at which a leak is auscultated (10–25 cm H_2O) is matched with the age of the child and the size of the ETT to estimate the percent of laryngeal narrowing shown in numbers in teal boxes. Clear boxes indicate the usual size ETT for child's age. Grade I, *light teal*; Grade II, *medium teal*; and Grade III, *dark teal*. **B,** Schematic representation of subglottic stenosis classification system. This chart is based on one institution's experience, and the manufacturer of the ETTs was not described, thus the actual external diameter of the ETTs used is unknown. *ID*, internal diameter. (Reproduced and modified with permission from Myer CM III, O'Connor DM, Cotton RT. Proposed grading system for subglottic stenosis based on endotracheal tube sizes. *Ann Otol Rhinol Laryngol*. 1994;103[4]:319–323.)

adequate chest movement is detected visually. Intermittent flow is accomplished by depressing the lever of an on-off valve. A jet of oxygen is released at the tip of the 16-gauge catheter, creating a Venturi effect that entrains room air into the bronchoscope. This jet of oxygen and room air mixture directly inflates the lungs. Exhalation is passive and depends on the recoil of the chest wall. Although this technique is usually effective for both oxygenation and ventilation in experienced hands, a number of potential problems exist. Because of potentially high inflation pressure, pneumothorax, pneumomediastinum, and death have

occurred.[290] Blood, infectious, or particulate matter in the airway may be forced distally by high-pressure bursts. There is also the possibility of hypoxemia in some children, because the high-pressure oxygen entrains room air, diluting the oxygen.

High-frequency jet ventilation is also possible for upper airway endoscopy and laryngotracheal surgery. Obstruction to expiratory flow is a major concern and is dependent on good positioning of the rigid laryngoscope. Complications, such as barotrauma, pneumopericardium, CO_2 retention, necrotizing tracheobronchitis, and gastric rupture, dictate a fastidious technique.[291]

Dexamethasone in a dose of 0.3 to 0.5 mg/kg IV (maximum dose, 10–20 mg) is frequently administered during the procedure to decrease postoperative laryngeal swelling and the possibility of croup. At the conclusion of rigid bronchoscopy, an ETT can be placed to control the airway during recovery or, if ventilation is adequate and the anesthetic depth is not excessive, the child can be allowed to emerge breathing 100% oxygen by a face mask.

Children who undergo supraglottoplasty for laryngomalacia pose a special challenge during and after surgery. The most common approach is division of the aryepiglottic folds and/or trimming of the arytenoid mucosa. This may be performed endoscopically around a small ETT or by surgical excision during suspension laryngoscopy. Because of concerns about postoperative airway edema, aspiration, or decompensation, these children must be watched closely either in an ICU or a monitored bed with continuous pulse oximetry.[292] Some of these children may need to remain intubated overnight if significant swelling is anticipated.

Upper Airway Obstruction

LARYNGOTRACHEOBRONCHITIS (CROUP)

Croup is a symptom complex of inspiratory stridor; suprasternal, intercostal, and substernal retractions; barking cough; and hoarseness that results from swelling of the mucosa in the subglottic area of the larynx.[2] Two common entities account for most cases of croup: spasmodic croup and laryngotracheobronchitis. Spasmodic croup has been diagnosed in about 3% of children with stridor.[293] The child is otherwise healthy and afebrile, presenting with nocturnal episodes of spasmodic cough, which is described as barking and high-pitched. The disease is self-limiting. In addition to viruses, allergic and psychological factors are blamed for this acute phenomenon. It differs from acute laryngotracheitis in that it is considered an allergic reaction to viral antigens rather than a true viral infection.[294] Besides lack of fever, spasmodic croup is usually remarkable for lack of severe laryngeal inflammation, and, in general, supportive therapy on an outpatient basis is all that is required.

Viral laryngotracheitis is by far the most common form of infectious croup. The disease has a gradual onset, usually after a URI in a young child. Low-grade fever is common. Children who have more than two episodes of croup requiring hospitalization should be evaluated for subglottic narrowing from stenosis or cysts. Clinical scoring systems based on objective criteria are helpful in following the progress of the disease and in judging the effectiveness of therapy (Table 33.8).[295]

Anteroposterior radiographs of the neck will confirm the diagnosis of the possibility of a foreign body in the airway (Table 33.9), but a lateral neck x-ray would be required to rule out epiglottitis.[296] The viral infection affects the subglottic region of the larynx, causing edema. The characteristic radiograph of croup, therefore, includes blurring of the tracheal air shadow on

TABLE 33.8 Clinical Croup Score

	0	1	2
Inspiratory Breath Sounds	Normal	Harsh with rhonchi	Delayed
Stridor	None	Inspiratory	Inspiratory/expiratory
Cough	None	Hoarse cry	Barking
Retractions	None	Flaring and suprasternal retractions	Flaring, suprasternal and intercostal retractions
Cyanosis	None	In air	In 40% O_2

TABLE 33.9 Differential Diagnosis of Croup and Epiglottitis

	Croup[a]	Epiglottitis
Incidence	More common	Less common
Obstruction	Subglottic	Supraglottic
Age	Younger (<3 years)	Older (3–6 years)
Etiology	Viral	Bacterial
Recurrence	Possible (5%)	Rare
Clinical Features		
Onset	Gradual (days)	Sudden (hours)
Fever	Low grade	High
Dysphagia	None	Marked
Drooling	None	Present
Posture	Recumbent	Sitting
Toxemia	None	Present
Cough	Barking	Usually none
Voice	Hoarse	Clear to muffled
Respiratory rate	Rapid	Normal/slow
Larynx palpation	Not tender	Tender
Leukocytosis	+ (Lymphocytic)	+++ (Polymorphonuclear cells)
Neck radiographs	Anteroposterior: steeple sign	Lateral: thumb-like mass
Clinical course	Longer	Shorter
Treatment		
Primary therapy	Medical and supportive	Secure airway first
O_2 and humidity	Essential	Usually desirable
Hydration	Oral or intravenous	Intravenous
Racemic epinephrine	Usually effective	No value
Corticosteroids	Controversial, commonly used	Not indicated
Antibiotics	Not indicated	Effective
Airway support	Occasionally needed (<3%)	Always indicated (100%)
Preferred airway	Nasotracheal Tracheostomy (rarely)	Nasotracheal
Extubation	4–7 days	1–3 days

[a]Foreign bodies in the airway should also be considered.

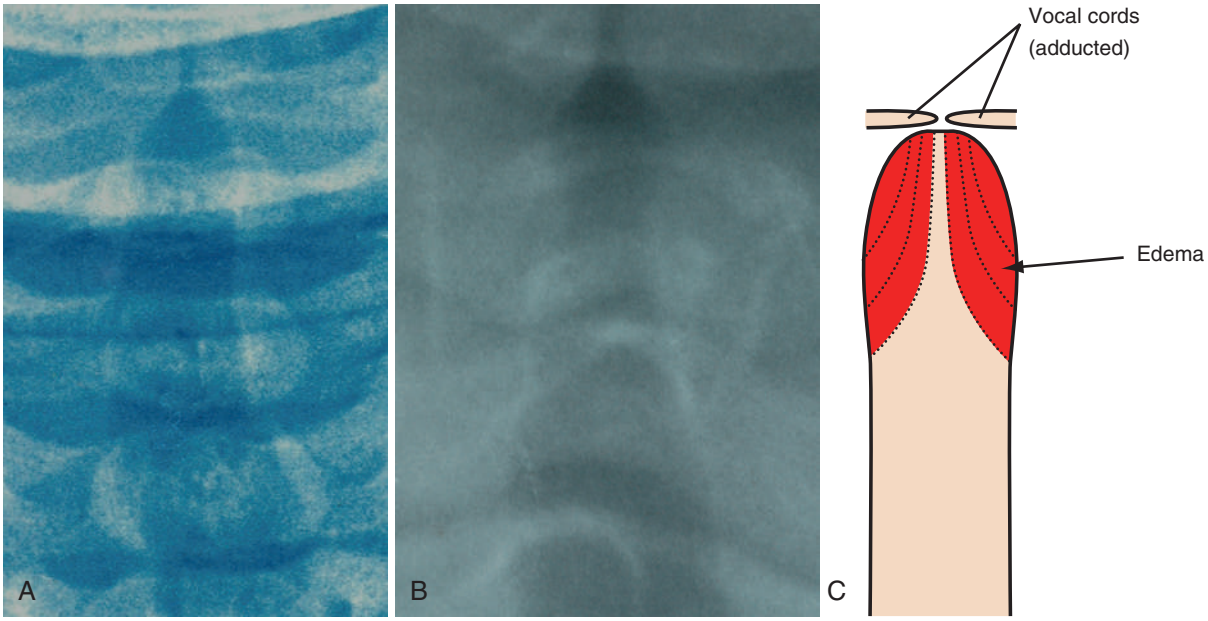

FIGURE 33.21 **A,** Xerogram radiograph of the normal upper airway (anteroposterior view). Note that the subglottic area is rounded. **B,** Laryngotracheobronchitis (croup) produces swelling (edema and inflammation), which obliterates the normal rounded subglottic area, producing the so-called sharpened pencil or steeple sign. **C,** Schematic representation showing progressive swelling of the subglottic area. For an additional view, see E-Fig. 31.3.

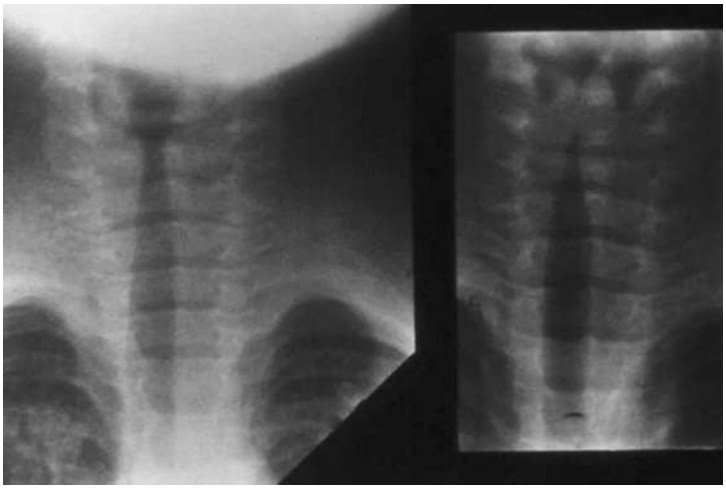
lateral neck films, and symmetric narrowing of the subglottic air shadow, described as a "church steeple" or "sharpened pencil" sign on anteroposterior films (Fig. 33.21 and E-Fig. 33.3). The lateral neck radiographs show normal supraglottic structures and normal epiglottic shadow.



Most cases will resolve quickly with simple conservative measures, such as breathing humidified air or oxygen. Less than 10% of cases require hospitalization because of significant respiratory difficulty, and fewer still require an artificial airway.[287] Humidification of inspired gases is usually effective in improving respiratory distress, and it prevents drying of secretions, although despite the popularity of cool mist therapy, it is not evidence-based practice.[297] Oxygen is obviously essential to prevent or to treat hypoxemia, which may result from ventilation-perfusion mismatching caused by accumulation of secretions. Hydration prevents thickening of tracheal secretions.

Racemic epinephrine is the most effective drug therapy for these children, although L-epinephrine has also been effective.[298] Racemic epinephrine is available as a 2.25% solution, which is diluted in water or saline solution, and administered either by intermittent positive-pressure ventilation via a face mask or nebulization.[299] Nebulized racemic epinephrine is administered in cases of mild-to-moderate obstruction. The solution is prepared by diluting a volume of 2.25% racemic epinephrine in 2 mL of saline solution or sterile water according to the child's weight in kilograms (i.e., 0.25 mL of racemic epinephrine for 0–20 kg, 0.5 mL for 20–40 kg, and 0.75 mL for >40 kg).[300] Because the duration of action of racemic epinephrine is brief, rebound edema may occur. Treatments are required every 1 to 2 hours, and the child should be observed for at least 2 hours after treatment. Racemic epinephrine is no longer available in many countries and L-epinephrine (1/1000) is equally effective; the dose of a 1% solution is 0.5 mL/kg (maximum 5 mL).

If treatment with nebulized epinephrine is unsuccessful, in addition to edema, the underlying problem may be obstruction caused by thick, inspissated secretions possibly related to bacterial superinfection, such as bacterial tracheitis.[301,302] In this situation, or if the child appears exhausted from the increased work of breathing, relief of the obstruction must be obtained through tracheal intubation, followed by pulmonary suctioning. The clinical assessment of "exhaustion" in children with croup may be difficult. An alternative approach is to consider intubating the trachea of children who have an SpO_2 <90% when breathing air, despite nebulized epinephrine and steroid treatment. Laryngotracheobronchitis is also a disease of the lower airways. An inability to clear secretions contributes to atelectasis and arterial oxygen desaturation. Tracheal intubation is often required to allow suctioning of the copious yellow secretions.

One large series (512 consecutive admissions in a single year) reported that approximately 6% of children who had sternal and chest retractions on admission and failed to respond to conventional medical therapy required tracheal intubation.[303] Intubation should be performed in the OR under controlled anesthetic conditions, as for a child with severe epiglottitis. The uncuffed tracheal tube selected should be at least one-half size smaller (0.5-mm ID) than would normally be chosen, to avoid aggravating the subglottic edema and possibly causing subglottic stenosis.[304–306] Children whose airways have been intubated are admitted to the ICU, and special care is provided for suctioning of inspissated secretions. The tracheal tube usually remains in place for 2 to 4 days.

Corticosteroid therapy for laryngotracheobronchitis has become the standard of care.[307] Single-dose corticosteroid therapy appears safe and effective,[308] although large studies of the risk of progression of viral infection or the development of secondary bacterial infections in moderate to severe laryngotracheobronchitis are lacking; reports suggest that IV dexamethasone (0.5–1 mg/kg) may be effective.[309] Rapid clinical improvement 12 and 24 hours after

E-FIGURE 33.3 Additional view of normal upper airway (*left*) and a child with laryngotracheobronchitis and the "steeple" or "sharpened pencil" sign (*right*) (see Fig. 33.21).

steroid treatment significantly reduces the incidence of tracheal intubation.[310–312] Antibiotics are generally not indicated in the treatment of uncomplicated viral croup.

The child is usually ready for extubation within 2 to 4 days. Criteria to consider include abatement of fever, diminished tracheal secretions, change in the character of secretions to a thin and watery type, and an audible air leak that develops around the nasotracheal tube as the edema subsides.

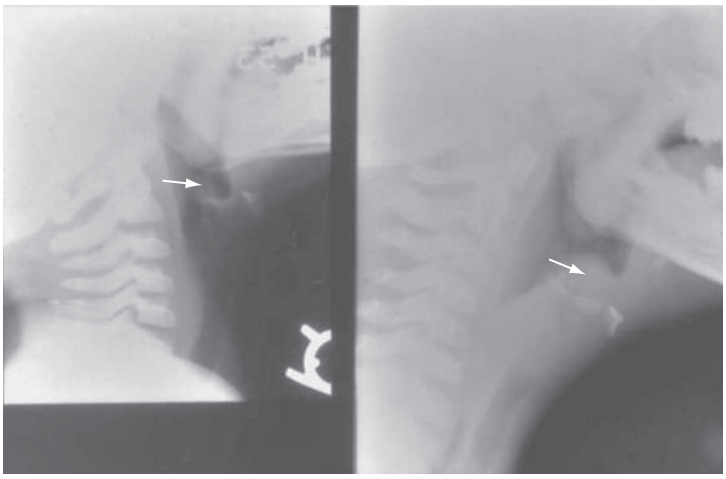
ACUTE EPIGLOTTITIS

Although rarely seen today, acute epiglottitis can be fatal because it can produce seemingly unprovoked sudden and complete airway obstruction. It is a clinical and pathologic entity that should more correctly be termed supraglottitis, because the arytenoids and aryepiglottic folds, as well as the epiglottis itself, are usually affected. All supraglottic structures become swollen and stiffened by inflammatory edema. Although the main focus of infection is the oropharynx, the disease produces a generalized toxemia. Epiglottitis is most common between the ages of 3 and 5 years, but it can occur in any age; historically, the causative organism was typically *H. influenzae* type B.[2,313–315] However, with the widespread use of *H. influenzae* vaccination, the incidence of epiglottitis in children has all but disappeared in medically advantaged countries.[316,317] *Streptococcus*,[318] *Staphylococcus*,[319] *Candida*,[320] and other fungal pathogens[321] have become more frequent causes of this now rare disorder in children,[322] although the incidence in adults has not diminished substantially.[323] It should be noted that vaccine failures may occur or parents may refuse proper immunizations of their child, resulting in susceptibility to *H. influenzae* type B infection.[324,325] Epiglottitis has become more a disease of adults.[326]

The onset is usually abrupt, with a brief history of high fever, severe sore throat, and difficulty in swallowing. Stridor, if present, is usually inspiratory, and because the subglottic structures are usually unaffected, there is little or no hoarseness. An expiratory snore, rather than inspiratory stridor can often be heard. The child appears toxic, and, in an attempt to improve airflow past the swollen epiglottis, assumes the sitting position, leaning forward in the sniffing position (E-Fig. 33.4). The mouth is open, with the tongue protruding. The child frequently drools because of difficulty and pain on swallowing. The mnemonic ***SNORED*** is often useful for diagnosis: **S**eptic, **NO** cough, **R**apid onset, **E**xpiratory snore, **D**rool.

In addition to high fever, other signs of generalized toxemia may include tachycardia, a flushed face, and prostration. The respiratory pattern is usually slow and quiet to allow more comfortable breathing.

Acute epiglottitis is a clinical diagnosis. It must remain prominent in the differential diagnosis of a child presenting with signs and symptoms of UAO. However, in some early cases, the clinical presentation alone may be inconclusive. If so, a lateral radiograph of the neck will usually demonstrate a swollen epiglottis and aryepiglottic folds (Fig. 33.22 and E-Fig. 33.5). The vallecula may be obliterated, but subglottic structures are usually clear. A physician capable of establishing an airway should always be in the child's attendance (especially if in a remote area of the hospital, such as the Radiology Department), because total airway obstruction can develop during the radiologic examination, especially if the child is forced to lie supine. This is one reason the use of lateral neck radiographs in the differential diagnosis of UAO is avoided. Examination of the pharynx and larynx should only be attempted in an area with adequate equipment and staff prepared to intervene should UAO develop; ideally, the OR. The safest, most conservative approach to the management of acute epiglottitis is to establish an artificial airway as soon as the diagnosis is made, and then, with the airway secured, to proceed with appropriate antibiotic and supportive therapy. The child should remain in the sitting position at all times and never be forced into the supine position. No attempts to examine the larynx should be made in the emergency room.[2]



These children should not be premedicated. Instead they should be brought to the OR calm and undisturbed. If it takes the presence of a parent to achieve this, then that is what should be done. In the OR, with equipment and personnel who can insert a surgical airway immediately present, a precordial stethoscope, pulse oximeter, and other standard monitors are applied. General anesthesia is induced with oxygen and sevoflurane with the child still sitting up (sometimes a parent may assist sitting on the OR table next to the child). Spontaneous respiration is continued as the child is gently allowed to recline. If the child is moribund, then, after preoxygenation with gentle CPAP, an awake intubation may be considered.

When a surgical stage of anesthesia is achieved, IV access is established and secured. A large fluid bolus of balanced salt solution is infused (20–40 mL/kg) because these children are often dehydrated and will require a deep plane of anesthesia to permit tracheal intubation while spontaneous respirations are preserved. Some anesthesiologists would also administer an antisialagogue to reduce secretions. Epiglottitis is marked by progressive swelling of the lingual surface of the epiglottis with resultant obliteration of the vallecula (see Fig. 33.22). Viewing the glottic opening without traumatizing the epiglottis may usually be accomplished by forcing the tip of the laryngoscope blade along the center of the base of the tongue into the vallecula, where the vallecula has been obliterated by the swollen lingual surface of the epiglottis (see Fig. 33.22C). Lifting the base of the tongue, without directly touching the epiglottis, can then expose the glottis. A stylet within the ETT may be helpful because it provides increased rigidity to facilitate introduction through a partially obstructed glottic aperture. The size of the ETT should be one-half size smaller (0.5-mm ID) than otherwise selected for the same age child. By choosing an ETT with a smaller ID than usual, one also lessens the risks of pressure necrosis on the mucosa. Fig. 33.23 illustrates a case of severe epiglottitis (before [A] and after [B] the airway was secured). A stiletted orotracheal tube is inserted first, and may be replaced by a nasotracheal tube of appropriate size. However, if the glottic opening was difficult to visualize, then no attempt should be made to replace the oral tube with a nasal one. The orotracheal tube may displace supraglottic edema, improving the view of the glottic opening and facilitating placement of the nasotracheal tube. An air leak at 20 to 25 cm of H_2O, when present, confirms the selection of an appropriate size tube. Because the airway obstruction in epiglottitis is supraglottic, not subglottic, the nasotracheal tube size is often the usual size or one-half size smaller for the child's age. A larger tube is not necessary and may contribute to the possible development of serious laryngeal complications, such as subglottic stenosis. The child should be able to breathe around the tube, as well as through it. If the anesthesiologist is unable to intubate the trachea, then a rigid bronchoscope should be used. If both of those maneuvers fail, then a tracheostomy or cricothyrotomy should be performed (see Fig. 14.25).[327,328]

Once the airway is secured, a culture of the pharynx and blood cultures are obtained, and aggressive medical therapy beginning with antibiotics should be commenced. It is recommended that

Note the marked thickening of the aryepiglottic folds (*A*), loss ("amputation") of the vallecula (*curved arrow*), swelling of the epiglottis (*E*), and distention of the hypopharynx (*H*). **C,** Schematic representation of epiglottitis demonstrating progressive swelling of the lingual surface of the epiglottis, resulting in "amputation" of the vallecula. Progressive swelling leads to trapdoor-like occlusion of the glottic opening (*curved arrow*). For additional views, see E-Fig. 33.5.

cephalosporins (such as ceftriaxone 50 mg/kg per day)[329–331] be used initially for antibiotic therapy, with the first dose immediately after the diagnosis is made and appropriate cultures taken.[2] The duration of the treatment is controversial, but at least 3 to 5 days of IV antibiotics followed by oral therapy is usually the minimum. Steroids are not indicated. Supportive measures include IV hydration, airway care, sedation as necessary, and acetaminophen for fever. Negative-pressure pulmonary edema can develop after tracheal intubation in children with severe epiglottitis.[251] When the child resumes swallowing and the fever abates, usually 24 to 48 hours after initiation of therapy, the acute supraglottic edema should be resolving and the child may be prepared for tracheal extubation.

OBSTRUCTIVE LARYNGEAL PAPILLOMATOSIS

Recurrent respiratory papillomatosis, also known as juvenile laryngeal papillomatosis, is the most commonly found tumor in the larynx and upper airway in children. Recurrent respiratory papillomatosis is caused by the human papilloma virus (HPV). The incidence is ~1 in 400 births, even though active or latent viral infection is present in 10% to 25% of pregnant women.[332] This disease is caused by HPV 6 and 11; the incidence may markedly

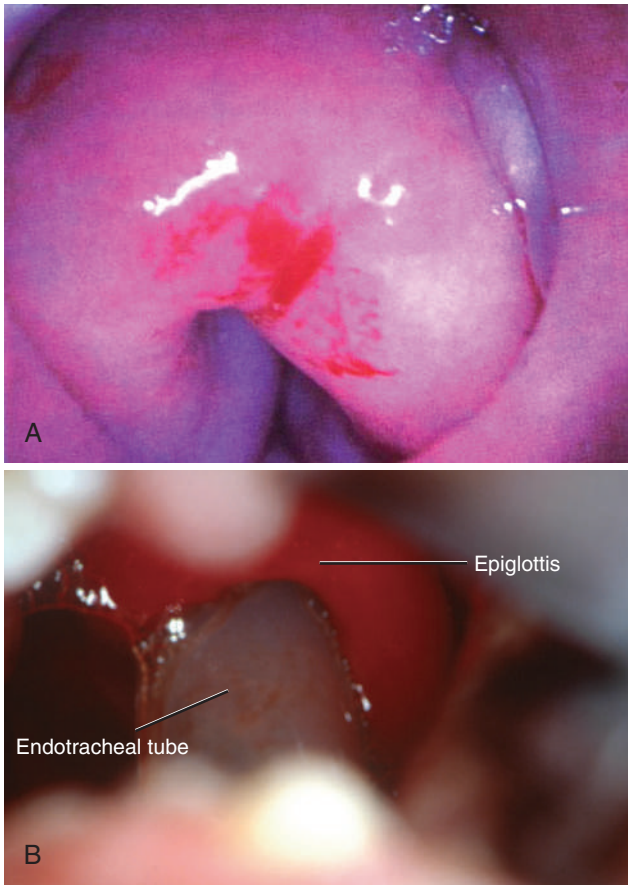

FIGURE 33.23 Acute epiglottitis. **A,** The entire upper airway is inflamed and there is marked swelling of the epiglottis. **B,** Photograph taken after securing the airway with an endotracheal tube.

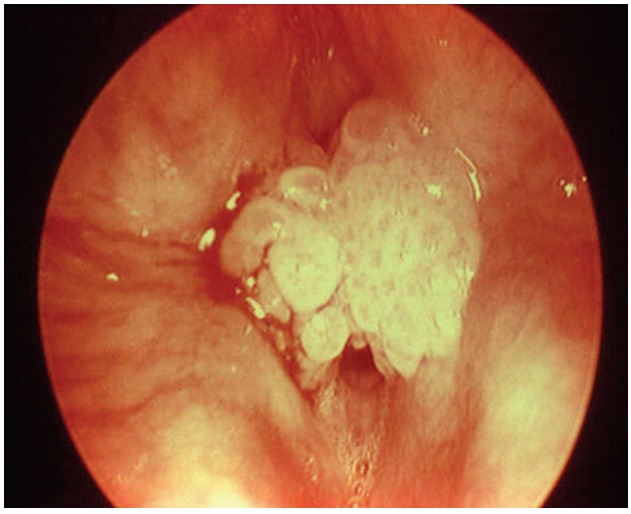

FIGURE 33.24 Large pedunculated papillomas obstructing the laryngeal inlet.

decrease in the future with the introduction of a maternal vaccine to prevent HPV infection for types 6, 11, 16, and 18.[333–336] The papillomas are usually found in the larynx on the vocal cord margins, epiglottis, pharynx, or trachea (Fig. 33.24). If left untreated, symptoms of aphonia, respiratory distress, hoarseness, stridor, right ventricular hypertrophy, and cor pulmonale may occur.

The current treatment is primarily surgical removal of the papillomatous tissue using the CO_2 laser under microscopic visualization. Alternatively, papillomas can be surgically debulked using an ultrasonic microdebrider or cup forceps before laser treatment. Topical application of mitomycin C (usually in combination with debulking procedures) has also been shown to be effective in suppressing these tumors. Nonsurgical treatment using interferon alfa-n1 has been beneficial in some children.[337] The main goal of the treatments is to reduce the bulk of the lesion without scarring and permanent damage to the underlying mucosa.

Because of the recurrent nature of this condition, most children will return frequently for treatment. Many may require monthly scheduled visits to the OR to prevent recurring obstruction. If some of these scheduled sessions are missed, or if the progress of the disease is accelerated, the child will present with an acute exacerbation of obstructive symptoms requiring emergent endoscopic resection. In all cases, it is important to obtain a careful history, including inquiry about changes in voice or increased difficulty breathing during daily activities, that may indicate progressive airway obstruction.

Because of frequent hospitalizations, these children become psychologically sensitized to the perioperative experience. Premedication is usually avoided if the degree of airway obstruction is significant and there are concerns about compromising spontaneous ventilation. In selected cases, when the children are extremely anxious and/or upset, the parents (or a child-life surrogate) may accompany the child to the OR for induction, to provide emotional support.

The perioperative care can be very challenging and often depends on the degree of obstruction to airflow and the type and location of the papillomas.[338–341] Pedunculated papillomas can produce complete ball-valve obstruction of the upper airway in certain positions. It is therefore prudent to avoid paralysis and to maintain spontaneous respirations until the airway is examined and the anesthesiologist is certain that assisted or controlled ventilation is possible. These children must be approached and monitored in the same manner as any child with anticipated severe airway obstruction (e.g., acute epiglottitis). The surgeon must be present in the OR when anesthesia is induced, with equipment immediately available to deal with complete airway obstruction, including rigid bronchoscopes and a tracheostomy-cricothyrotomy set. The problem of sharing the already compromised airway with the surgeon is worsened by the need to use a laser to excise these lesions. A laser (an acronym for **L**ight **A**mplified by **S**timulated **E**mission of **R**adiation) consists of a tube with reflective mirrors at either end with an amplifying medium between them to generate electron activity in the form of light. The CO_2 laser is the most widely used in medical practice, having particular application in the treatment of laryngeal or vocal cord papillomas, laryngeal webs, and resection of subglottic tissue and hemangiomas. A laser is useful for endoscopic procedures because the beam may be directed down open-tube endoscopes and is invisible, thereby affording the surgeon an unobstructed view of the lesion during resection. Laser energy is absorbed by tissue water, rapidly increasing its temperature, denaturing protein, and causing vaporization of the target tissue. The thermal energy produced by the laser beam cauterizes capillaries as it vaporizes tissues; therefore bleeding is minimal and very little postoperative edema occurs.

These properties give the laser a high degree of specificity; however, they also provide the route by which a misdirected laser beam may cause injury to a child or to unprotected OR personnel.[342] Laser radiation increases the temperature of absorbent

material; therefore flammable objects, such as surgical drapes, must be kept away from the path of the laser beam. Unprotected surfaces, such as skin, can be burned and must be shielded. Wet towels should be applied to cover the skin of the face and neck when the laser is being used to avoid burns from deflected beams.

The anesthetic management of these children depends on the approach the surgeon will use to remove the lesions. The basic choice is between intubation and nonintubation techniques. For the latter approach, the choice is between intermittent apnea versus jet ventilation.[290] The ETT used during laser surgery can affect the safety of the technique. All standard polyvinylchloride ETTs are flammable and can be ignited and vaporized by a laser beam. Although red rubber ETTs do not vaporize, they deflect the laser beam when wrapped with metallic tape. The metallic tape can only be applied along the stem of the tube down to the cuff; thus the laser may damage the tube below the vocal cords. Alternatively, non-latex ETTs are manufactured specifically for use during laser surgery. Some have a double cuff to protect the airway in the event the outer cuff is damaged by the laser beam. Others have a special matte finish that is effective in deflecting the laser beam along its entire length. Nonreflective flexible metal ETTs and specifically wrapped ETTs are also manufactured for use during laser surgery (Fig. 33.25). The outer diameters of these special tubes are considerably larger than the polyvinylchloride counterpart, especially in the small sizes. Thus they may not be appropriate for use in very small infants or children with a severely narrowed airway. Table 33.10 presents a variety of such specialized tubes compared with standard ETTs. Although these ETTs offer some advantage, they are considerably more expensive than metallic-tape–wrapped red rubber ETTs. A syringe or a bag (500 or 1000 mL) of normal saline solution should be immediately available to douse ignited tissues in the event of an airway fire.

Once the airway is secured, one anesthetic approach is to use intermittent apnea with paralysis, TIVA, and topical lidocaine. An antisialagogue, such as glycopyrrolate, is often given at the beginning of the anesthesia, together with dexamethasone (0.5 mg/kg [maximum dose 10–20 mg]) to reduce mucosal swelling resulting from repeated intubations. However, this dose of dexamethasone is empiric and not evidence-based. Anesthesia is typically induced with oxygen and sevoflurane while the anesthesiologist gradually assists respirations as the depth of anesthesia increases. Once IV access is established, the anesthesia is deepened further and the larynx is anesthetized with topical lidocaine (3–4 mg/kg). The airway is then evaluated and tracheal intubation performed. The ETT is usually several sizes smaller than what is normally appropriate for the child's age, because most of these children have some degree of laryngeal scarring from repeated resections, and there

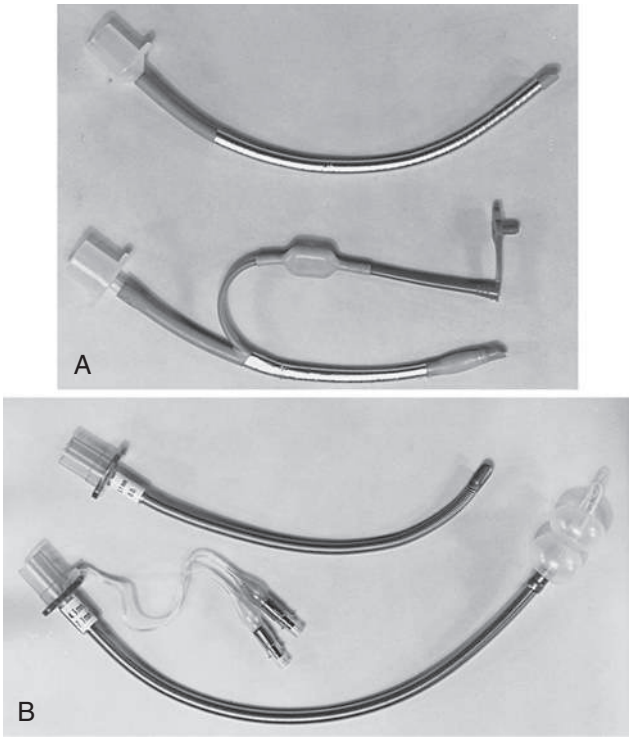

FIGURE 33.25 A, Cuffed and uncuffed red rubber endotracheal tubes may be wrapped with reflective metallic tape for use during laser airway surgery. Note that this metallic tape is not approved by the Food and Drug Administration for this application. Cuffed and uncuffed commercially available foil-wrapped laser tubes are available (Laser-Shield II, Medtronic Xomed, Jacksonville, FL). **B,** An example of several commercially available stainless steel laser endotracheal tubes (Becton, Dickinson and Company, Franklin Lakes, NJ). Note that the external diameters of these devices are greater than those of standard ETTs.

is the need to prevent the ETT from obscuring the surgeon's view and interfering with access to the lesions. If the surgeon is planning a non-laser approach, spontaneous ventilation can be maintained by first achieving an adequate depth of anesthesia and then insufflating oxygen in air to reduce the FIO_2 to 30% or less and inhalation agent (usually sevoflurane) via a very small tracheal tube. The use of a double-lumen central venous catheter for this purpose has also been described.[343]

Although the goal is to achieve the desired depth of anesthesia to secure the airway with the child still spontaneously breathing, partial obstruction is frequently encountered before an adequate depth of anesthesia for laryngoscopy is achieved. In these cases, thrusting the jaw forward and applying positive pressure in the anesthetic circuit will maintain an open airway in most situations (see Chapter 14). If complete obstruction is encountered, then a single IV bolus of propofol (2–3 mg/kg) or a short-acting NMBD may be necessary for immediate laryngoscopy and intubation or to allow the surgeon to perform rigid bronchoscopy.

Once the correct position of the ETT is confirmed, an NMBD (e.g., rocuronium) can be administered and the TIVA technique with propofol (200–300 μg/kg per minute) and fentanyl (2–3 μg/kg) or remifentanil infusion (0.1–0.25 μg/kg per minute or more, as needed) is started. Muscle relaxation is desirable to produce an immobile surgical field. A neuromuscular blockade monitor is recommended to assess the degree of relaxation.

An apneic anesthetic technique without an ETT offers the best unobstructed view of the larynx and avoids the presence of flammable material (e.g., the ETT) in the path of the laser beam. The child is positioned for suspension laryngoscopy with eyes protected with moist eye pads, and the otomicroscope and CO_2 laser equipment are aligned. The ETT is then removed and surgical resection is carried out during repeated periods of apnea. The need for reintubation is guided by the adequacy of oxygenation as reflected by the pulse oximeter. Reintubation can be readily performed by the surgeon by introducing the tracheal tube through the suspension laryngoscope under direct vision. After each reintubation, the lungs are ventilated manually to restore both the SpO_2 and end-tidal CO_2 to baseline. When those baselines are reached, the trachea is extubated and surgery can resume. This process is repeated until the surgery is complete.[2]

A modification of the apneic technique that avoids tracheal intubation is the jet ventilator. The operating laryngoscope may be fitted with a catheter through which O_2 flows, entraining ambient air. In this manner, the lungs are intermittently inflated by the pressure delivered by the jet. The advantage of this technique is twofold. The surgical field is extremely quiet because large excursions of the diaphragm are eliminated and ventilation is uninterrupted. However, transtracheal jet ventilation carries a greater risk of pneumothorax in children than the transglottic approach.[290] In the past, tension pneumothorax and pneumomediastinum occurred because of excessive peak inspiratory pressures during jetting. Maximum peak inspiratory jet pressures of approximately 15 mm Hg have reduced this risk dramatically. In morbidly obese children and those with severe disease of the small airways, effective ventilation may be difficult with this technique, and an alternate approach should be used.[344] In addition, jet ventilation may theoretically distribute papilloma virus throughout the tracheobronchial tree, although this technique continues to be used.

When surgery is completed, the ETT is reinserted and secured until the child is completely awakened. Postoperative measures to prevent laryngeal edema, such as racemic epinephrine inhalation and/or the use of dexamethasone, are usually indicated.

ASPIRATED FOREIGN BODIES

Curious young children push small objects into almost every orifice in their body. Objects inserted in the nose or ear are usually benign in nature and simple to remove once the child is anesthetized. Small button-sized battery foreign bodies require urgent removal because of their potential for extensive local damage.[345] Impacted or displaced objects present greater challenges for the anesthesiologist and endoscopist, and the danger of misplacement into the respiratory tract must always be considered.[346]

Tracheobronchial foreign body aspiration is most common in toddlers 1 to 3 years of age. The majority (95%) of foreign bodies lodge in the right main-stem bronchus.[347] A history of choking while eating or playing, persistent cough, or wheezing that does not respond to medical treatment may be the only manifestations. If the foreign body completely obstructs a bronchus or creates a ball-valve phenomenon, distal hyperinflation from air trapping may occur; a hyperinflated lung during the expiratory phase may be the only indication of an aspirated foreign body on chest radiography (Fig. 33.26). The more distal the object is lodged in the airway, the more atelectatic changes are noted.

Foreign bodies lodge in the trachea (<5% of airway foreign bodies) if they are too large to pass the carina.[348] The signs of a tracheal foreign body may include a brassy cough with or without abnormal voice, bidirectional stridor, or complete airway obstruction in the case of laryngeal foreign bodies. Any sharp object, or any object that causes acute UAO with cyanosis and an inability to maintain ventilation, requires emergent removal. Unroasted peanuts (with unsaturated double bonds in the oils) should be removed promptly because the oil can leach out and induce an inflammatory response, that may result in pneumonitis (Fig. 33.27).[349] In contrast, roasted peanuts (with saturated double bonds in the oils) may be present in the lungs for greater periods without inducing as severe an inflammatory response. In addition, peanuts tend to swell, fragment, and crumble over time, making removal "en bloc" extremely difficult. Most children who aspirate foreign bodies do not become cyanotic. However, the child who presents with a history of cyanosis after aspiration of a nut very likely has aspirated material into the trachea or into the lungs bilaterally (as in the case of a broken nut or multiple nuts) and should be assessed emergently. It should be noted that esophageal foreign bodies may compress the trachea as well (Fig. 33.28).

The anesthetic management of these children depends on the level, degree, and duration of obstruction. A child who aspirates a foreign body while eating, or soon thereafter, presents with the additional risk of a full stomach. Waiting for the stomach to empty may not be appropriate or even effective in the acute situation. IV metoclopramide (0.15 mg/kg) may be used to hasten stomach emptying but does not guarantee that the stomach empties.[350] If time permits, the administration of an anticholinergic agent may be useful to reduce secretions. In the debate of how best to anesthetize a child with a full stomach and a compromised airway from an aspirated foreign body, concern for the airway takes precedence over the full stomach and an inhalational induction is recommended.

One of the major controversies in the anesthetic management of foreign body aspiration is whether to control ventilation or allow spontaneous respirations during bronchoscopy.[351,352] Some endoscopists prefer a spontaneously breathing child to allow them to remove the lens from the end of the scope and use a large grabbing forceps to "grab" the foreign body as it is being retrieved out of the airway. Sevoflurane is the preferred inhalational anesthetic

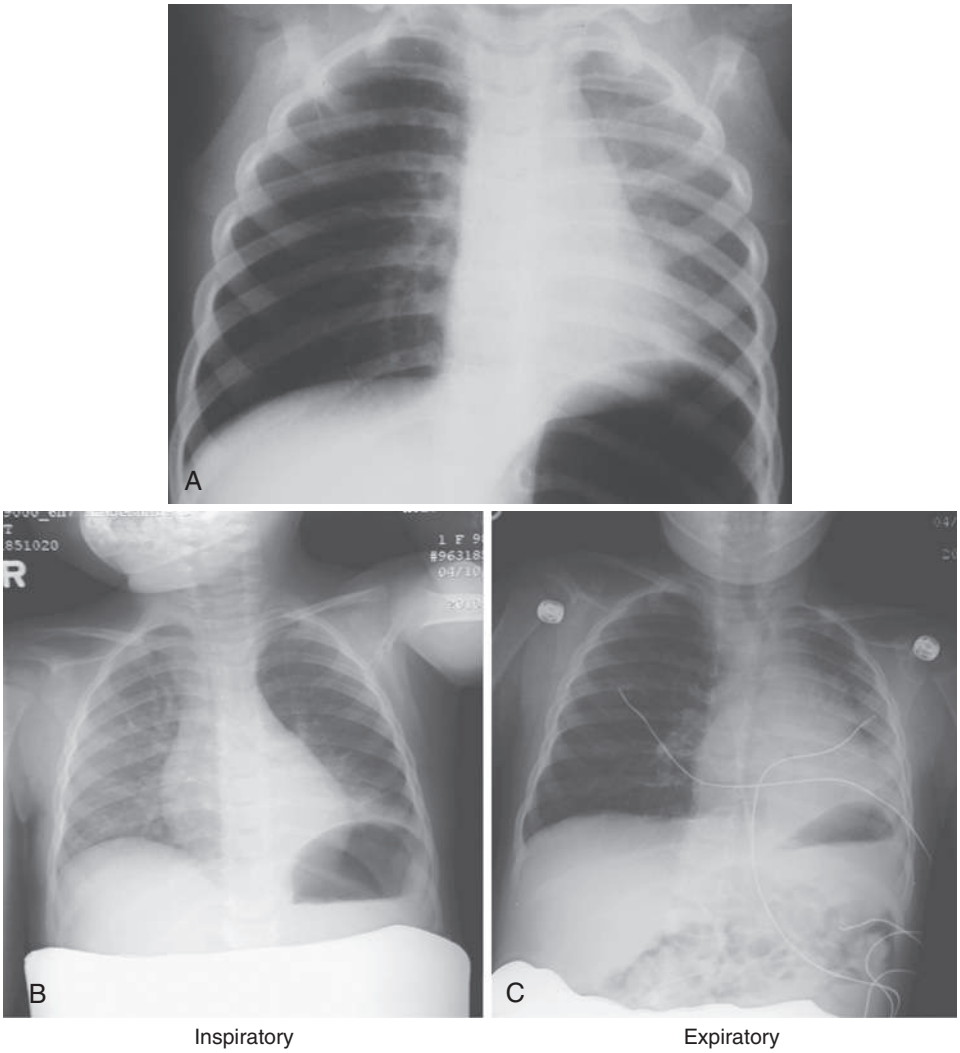

FIGURE 33.26 **A,** Expiratory radiograph of the chest demonstrates marked right-sided hyperinflation because of air trapping by the ball-valve effect of the foreign body. The chest radiograph may appear normal during inspiration after foreign body aspiration. **B,** A hyperinflated right lung and **C,** a leftward mediastinal shift during expiration suggest a foreign body in the right main-stem bronchus. FIGURE 33.27 A classic peanut in the bronchus. Note the irritation caused by the oil of the peanut.

in these children because it maintains spontaneous respirations, does not trigger upper airway reflex responses, and maintains hemodynamic stability.[353] Anesthesia is usually maintained with 100% oxygen and sevoflurane, or a propofol-based TIVA technique.[2] A propofol TIVA technique allows a steady level of anesthesia that is independent of ventilation and does not expose the OR personnel to waste anesthetic agents that inevitably egress from the airway around the bronchoscope. In some cases, a combined approach of sevoflurane in oxygen, as well as IV propofol or dexmedetomidine, may be used. Often these children have very irritable airways because of the presence of the foreign body. The use of topical lidocaine (3–4 mg/kg) divided between the laryngeal structures and tracheal mucosa may be used to suppress airway reflexes and prevent coughing and bronchospasm.

Tracheostomy

Tracheostomy in infants and children is usually performed electively, as a planned procedure after an airway has already been established

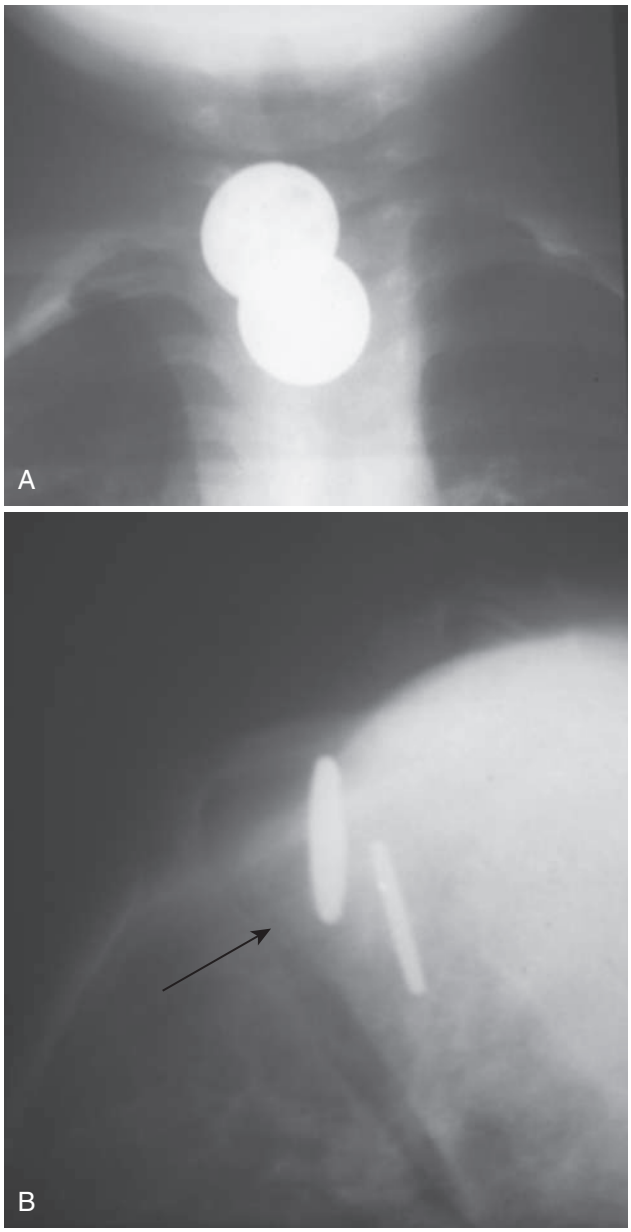

FIGURE 33.28 Anteroposterior **(A)** and lateral **(B)** neck radiographs of a child who swallowed two coins. Note tracheal compression caused by these foreign bodies in the esophagus (*arrow*).

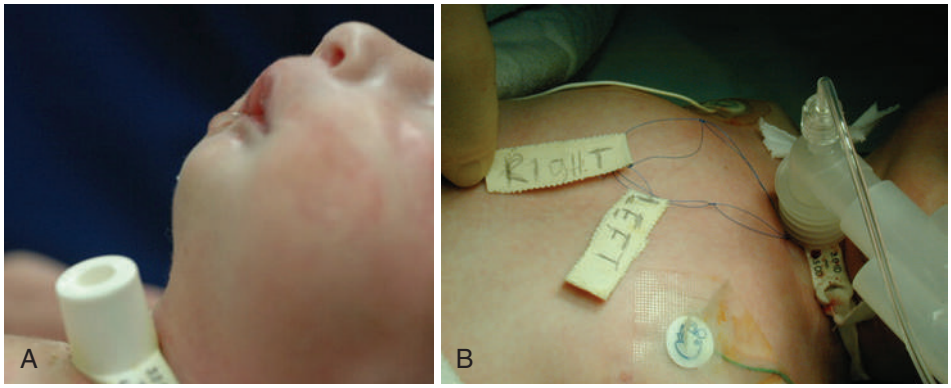
with an ETT. Indications for a planned tracheostomy include need for long-term ventilation or lesions such as congenital or acquired vocal cord paralysis, central hypoventilation syndrome (Ondine curse), craniofacial abnormalities (e.g., Pierre Robin malformation), persistent laryngotracheomalacia, and congenital or acquired subglottic stenosis.[354] Usually these children have had a period of watchful waiting, with the hope of avoiding tracheostomy. However, persistent hypoxemia, hypercarbia, intermittent obstruction that cannot be eliminated with the natural airway, or failed extubation will force the need to secure the airway via a tracheostomy. Children from intensive care sometimes require tracheostomy for long-term ventilation or secretion management. Still other children have acute deteriorations of the airway and require tracheostomy on an emergent basis.

In such cases, the surgeon will frequently want to perform a thorough examination of the airway (i.e., diagnostic laryngoscopy and bronchoscopy) before proceeding with the tracheostomy. This requires that the tracheal tube be removed, the airway examined with a rigid bronchoscope, and then the trachea reintubated for the procedure. After the diagnostic laryngoscopy and bronchoscopy and reintubation, the child is positioned supine, with the head maximally extended over a shoulder roll, and the head taped to the end of the bed. It is a good practice to have a separate clean anesthesia circuit, or an extension, to hand to the surgeon to connect to the freshly inserted tracheostomy cannula.



Anesthesia is maintained with spontaneous respirations of inhalational agents so that, if there is airway compromise at any point, the child may still be able to maintain oxygenation. One hundred percent oxygen should be administered throughout the procedure, because the airway may be lost at any time. If, however, electrocautery is required, then fire prevention precautions should be taken. IV opioids or local anesthetic infiltration, or both, should be used to manage postoperative pain. A thrashing, crying child who is in pain will compromise the integrity of the newly established surgical airway.

Children whose airways cannot be intubated may undergo an "awake" tracheostomy with sedation and local anesthesia. Ketamine is an attractive alternative, but promotes secretions, which may further compromise an already marginal airway; an antisialagogue may reduce the secretions. Children who can be anesthetized with an inhalational agent administered by mask, but who cannot be intubated because of severe subglottic stenosis or inability to visualize the vocal cords by direct laryngoscopy, may have the airway maintained with spontaneous ventilation and a face mask or an LMA until a surgical airway is obtained.

Once the trachea has been entered, a portion of the delivered tidal volume is lost through the incision, and ventilation may become inadequate. This is less of a problem if spontaneous respirations are maintained. It is prudent to leave the ETT within the lumen of the trachea but withdrawn just proximal to the tracheal incision, so that it can be readily advanced should difficulty be encountered with passing the tracheotomy tube. Once the tracheotomy tube is in place and ventilation is confirmed, the ETT is removed, the sterile distal end of the clean anesthesia circuit is attached to the tracheotomy tube (and the proximal end to the anesthesia machine), and the wound is closed. In the event of the tracheostomy tube becoming dislodged or removed, the tracheal incision will close and attempts at reinsertion may cause bleeding, the creation of a false passage, or trauma to the tracheal wall. The tracheal lumen is identified by internal traction sutures, which are placed by the surgeon at the end of the surgical procedure (E-Fig. 33.6). With the surgeon pulling up on the external ends of these sutures, the tracheal incision is identified and the tracheotomy is opened so that an artificial airway can be inserted. The child should not leave the OR without the potentially lifesaving sutures in place and their laterality (right vs. left) properly identified. Flexible fiberoptic bronchoscopy through the new tracheostomy tube is performed to confirm appropriate location of the tip of the tracheostomy tube above the carina with the child in the position for postoperative care.

Laryngotracheal Reconstruction

Glottic and subglottic stenosis, although rare, can be life-threatening and difficult to manage, from both the surgeon's and anesthesiologist's points of view. Congenital laryngeal atresia and congenital

E-FIGURE 33.6 Postoperative view of the tracheotomy tube in a child with Pierre Robin sequence **(A),** and of the stay sutures **(B),** which are identified and stabilized by tape as they emerge from the wound at the conclusion of the tracheotomy.

laryngeal webs can be incompatible with life unless an emergent tracheostomy is performed at birth. When diagnosed antenatally, such an intervention can be undertaken before placental separation, described as an operation on placental support, or the ex utero intrapartum treatment (EXIT) procedure (see Chapter 38). Unrecognized tracheal webs may result in death shortly after delivery. Treatment depends on the severity of laryngeal obstruction. In some instances, the defects are sufficiently severe to require immediate intubation or tracheostomy (see Fig. 38.13). Others may be discovered as an incidental finding while attempting to intubate the trachea for an unrelated surgical problem.[89,355] Most membranous defects can be broken by passing a bronchoscope through the lumen or incised using a surgical knife or scissors. Thin anterior webs can be managed by microendoscopic incision with a microsurgical knife or CO_2 laser, staging the procedure for each side separately to avoid recurrence. The anesthetic management is similar to that for children undergoing laser excision of laryngeal papillomatosis.

Acquired subglottic stenosis is usually the result of prolonged tracheal intubation for respiratory support of infants born prematurely. In older children, it is often the result of laryngeal trauma. Symptoms usually relate to airway, voice, and feeding and, in the case of a laryngeal insult, often occur 2 to 4 weeks later. Progressive respiratory difficulty with biphasic stridor, dyspnea, air hunger, and retractions are typical. These children usually have a tendency toward prolonged courses of URIs. Soft tissue radiographs of the neck and computed axial tomography will locate the exact site and length of the stenotic segment. Because both gastroesophageal and gastrolaryngopharyngeal reflux disease are thought to contribute to the development and exacerbation of subglottic stenosis, these conditions must be excluded, usually by a 24-hour esophageal pH probe placement. However, direct endoscopic visualization of the larynx is ultimately required to fully evaluate the stenosis. Rigid and flexible endoscopy of the airway and esophagus is performed in the OR. Because of the small diameter of the airway, the rigid rod-lens telescope and/or a flexible bronchoscope are used to visualize the larynx and trachea beyond the obstruction. The trachea is then intubated, and the degree of air leak around the ETT helps establish the degree of stenosis (see Fig. 33.20).

The surgical management of these infants must be individualized according to the degree of obstruction and the general condition of the child.[356] Most cases of moderate or severe subglottic stenosis require a tracheostomy at or below the third tracheal ring to establish a safe airway. The presence of a tracheostomy also helps to facilitate the airway management during subsequent procedures. For less severe cases, endoscopic balloon dilation or CO_2-laser endoscopic scar excision may be sufficient. This approach, however, has limited application in severe cases, and in some cases can be even detrimental by increasing the risk of unplanned urgent intervention compared with laryngotracheoplasty.[357]

The more severe cases of laryngeal stenosis require external reconstruction. Of the many available options, an anterior cricoid split operation and laryngotracheal reconstructions are more frequently used. The cricoid split operation is performed with the use of general endotracheal anesthesia. The largest possible tracheal tube is inserted through the nose. An incision is made through the cricoid, and the cartilage springs open. The ETT will be readily visible in the lumen. Frequently, the incision will be extended to include the proximal two tracheal rings and even the distal third of the thyroid cartilage (Fig. 33.29). Stay sutures are placed on each side of the incised cricoid, and the skin is loosely approximated. The ETT is left in place for about 7 days to act as a splint while the mucosal swelling subsides and the split cricoid heals. Endoscopy is not usually required, but corticosteroids are administered before extubation.

Open reconstructive surgical techniques are done at the youngest age possible to help the development of speech and language skills. They basically combine the use of laryngeal and cricoid splits, cartilage grafts, and stenting.

For laryngotracheal reconstruction procedures, the infant is positioned with a roll under the shoulders and the head is extended. The tracheostomy cannula is replaced with an ETT that is introduced through the stoma to allow easy and secure access to the airway. A sterile, shortened, preformed oral RAE tube is ideal to allow secure fixation. The distal end is cut to an appropriate length to avoid bronchial intubation and then sutured to the skin of the neck. A costal cartilage graft is harvested and fashioned to fit the intended site of transplantation (anterior or posterior splits). Repair of laryngotracheal stenosis in almost all cases, except anterior subglottic stenosis, requires brief stenting to keep the graft in place and lend support to the reconstructed area. Stents will counteract scar contracture and provide a scaffold for epithelium to cover the lumen of the airway. Many types of stents

(From Van Koevering KK, Hollister SJ, Green, GE. Advances in 3-dimensional printing in otolaryngology: a review. *JAMA Otolaryngol Head Neck Surg.* 2017;143[2]:178–183 [with permission].)

have been used. T-tubes are popular in adults, but are associated with more complications and blockage in children. The lower end of the stent is sutured in place during surgery. The stent is eventually removed endoscopically, after cutting the sutures and retrieving the tube.

Single-stage laryngotracheal reconstruction is sometimes used in children without significant obstruction. A full-length nasotracheal tube is used to support the graft for 3 to 7 days, depending on the type of graft. The advantages of immediate decannulation, and possible avoidance of a tracheostomy altogether, make this approach appealing in appropriate candidates (Fig. 33.30). The evolving technology of creating patient-specific three-dimensional (3D) printed models designed with the help of high-resolution imaging (e.g., computed tomography) is likely to revolutionize the approach to these cases through a more precise understanding of the anatomy (Fig. 33.31).[358–362] Additionally, 3D designed external stents will provide a completely new approach to these children (Fig. 33.31). The anesthetic challenges in these cases are many. The general condition of the child may not be perfect. Residual stigmata of prematurity are often present. The airway will be shared with the surgeon, and the tracheal tube that is placed in the stoma will need to be intermittently removed for surgical access and stent placement. A quiet surgical field is essential. The possibility of a pneumothorax during the cartilage graft harvesting should be kept in mind. The need to ensure that the stent, or the tracheal tube in case of a single-stage laryngotracheal reconstruction, is not dislodged in the ICU cannot be overstated. Accidental extubation cannot be allowed. A combination of sedation techniques and/or pharmacologic relaxation is necessary. The choice is often dictated by the individual policy in each ICU. Dexmedetomidine sedation may offer advantages as an alternative to propofol by providing a relatively rapid recovery from short-term sedation.[363,364]

TRACHEOCUTANEOUS FISTULA

Approximately 12% of children who have had their tracheostomy removed will retain a tracheocutaneous fistula.[365] Surgical repair is generally required to remove the fistula track, followed by a primary closure of the defect.[366–368] In some, this may be accomplished with simple endoscopic cauterization.[369] Usually there is a preliminary endoscopic assessment of the stoma site, removal of residual granuloma, and then a determination of the best approach to closure.[370] A multilayered closure is commonly used to close the fistula,[371,372] whereas others recommend direct primary closure of the defect.[373] The anesthesia approach generally includes maintenance of spontaneous respirations and methods to avoid coughing or straining at the time of extubation. The main concern is the potential for the development of subcutaneous emphysema caused by residual air leak if the child coughs or strains.[369,374–377] This complication may result in life-threatening pneumothorax or pneumomediastinum, which may occur up to 7 days after closure[370]; these complications require emergent removal of sutures, reestablishment of a tracheostomy, and thoracostomy and/or pericardial drainage.[378] Some children may require postoperative ventilation, but most are extubated and admitted for observation after extubation and conclusion of the surgery. The vast majority have an uneventful recovery.

Airway Trauma

Nasal fractures are frequently seen in older children and adolescents. They may result from a direct hit (fight) or an accident.[379] Because the nasal mucosa is very vascular, a lot of blood is usually swallowed. A stomach full of blood is to be assumed for the first 24 to 48 hours after the injury. A rapid-sequence intubation is the safest approach during that period. However, closed reduction of a nasal fracture is often delayed for a few days to allow swelling to subside. At that time, gastroparesis has resolved and an LMA may be considered. These operations can be very brief. Frequently,

the surgeon will leave a nasal pack in situ and apply an external splint over the nose. If a throat pack was not inserted, then the pharynx and stomach should be suctioned to remove blood that may have accumulated during the surgery. The tracheal tube or LMA should be removed only when the child is awake, cooperative, and understands the need for mouth breathing; a combative, semi-awake adolescent who is unable to breathe through the nose can hurt himself or herself and others.

Closed or open injuries to the larynx and trachea in children can result from bicycle accidents, falls, direct trauma from sharp objects, and, rarely, a "clothesline" injury. The more cephalad cervical position of the pediatric larynx behind the mandibular arch and the pliability of the cricothyroid structures usually limit the extent of injury and prevent severe fractures.[379] However, the small size of the laryngotracheal airway and the potential for massive soft tissue swelling because of the loose attachment of the submucosal tissue to the perichondrium make early diagnosis and treatment critical. The injury can range from minor laryngeal hematoma to a severe form of laryngotracheal separation. This extreme and often fatal condition can occur after a clothesline mechanism of injury and is often associated with bilateral vocal cord paralysis resulting from recurrent laryngeal nerve damage.[380] Hoarseness, cough, dyspnea, hemoptysis, and voice changes suggest laryngeal damage. Clinical subcutaneous emphysema, pneumothorax, and pneumomediastinum signify definite disruption of the laryngotracheal complex. Computed tomography is the most appropriate imaging modality to identify the extent of laryngeal injury.[381]

Positive-pressure ventilation by mask, excessive coughing, or struggling can worsen the subcutaneous emphysema and cause the airway to further deteriorate. Administration of nitrous oxide, application of cricoid pressure, multiple vigorous attempts at laryngoscopy and intubation, and passage of blind nasotracheal tubes or nasogastric tubes should be avoided to prevent further trauma by creating a false passage through a mucosal tear. A good approach to this type of injury, if the child is stable, is to use the fiberoptic bronchoscope to visualize the airway before tracheal intubation. Ideally, the airway should be secured in the OR after induction of general anesthesia with an inhalational agent, and with the child breathing spontaneously. However, tracheostomy below the level of the injury, under local anesthesia or over a bronchoscope, may be necessary if there is extensive injury to the mouth and larynx that requires major reconstruction.

Postoperatively, these children require management in a monitored setting, usually the ICU. The resolution of other complications, such as subcutaneous emphysema, pneumothorax, or pneumomediastinum, will dictate the duration of the child's stay. Postoperative analgesia must be carefully titrated to balance the need for pain relief with the adequacy of ventilation.

Retinopathy of Prematurity Treatment

THE INFANT OR CHILD who presents for elective ophthalmic surgery requires careful preanesthesia assessment. In addition to ophthalmologic issues, the infant or child may have associated or unassociated systemic disorders. In this chapter, we review the essential issues that should be addressed preoperatively and difficulties that may be anticipated in the perioperative period.

Many ophthalmologic diagnoses can be confirmed only by examining a cooperative infant or child. An examination under anesthesia (EUA) is essential for an accurate diagnosis and evaluation of many processes, including trauma, tumors, infiltrative diseases, coloboma, glaucoma and other vascular diseases of the retina, Coats disease, and incontinentia pigmenti. Inpatient preterm infants often require serial EUAs to monitor the development and progress of retinopathy of prematurity (ROP) and the response to previous therapies. These examinations are performed in the neonatal intensive care unit or operating room and may require either sedation or general anesthesia.[1] Inpatient trauma victims may require serial EUAs to monitor the development of glaucoma or retinal injury. Serial EUAs are also necessary to monitor progress during outpatient retinoblastoma radiation treatments. As a result, the anesthesiologist assumes an integral role as a member of the team, providing suitable conditions for the provision of pediatric ophthalmologic diagnostic and therapeutic techniques.

Ophthalmologic procedures that require an immobile child for maximal safety include surgery in which the globe is open (e.g., cataract removal), vitrectomy, laser or cryotherapy for retinopathy, retinal detachment repair, anterior chamber paracentesis, and repair of an open globe injury. Other procedures may require a child to be cooperative only for a nonpainful examination, but because the target organs (orbits) are close to the airway, a strategy must be devised to ensure safe airway management.

The child in need of ophthalmologic surgery typically requires general anesthesia or deep sedation rather than exclusive use of local or regional anesthesia. Many infants and children cannot cooperate for anything beyond a brief eye examination. Although the ophthalmologist may be able to tolerate small movements during an EUA, unnecessary head or eye globe movement during an ophthalmologic procedure should be prevented. Regional blocks (e.g., subtenon, retrobulbar, peribulbar) are infrequently performed for postoperative analgesia before emergence from general anesthesia[2]; all complications associated with these blocks identified in adults may also occur in children.[3,4]

Preoperative Evaluation

The perioperative environment should be welcoming to the child and family.[5,6] All team members should be comfortable with the anesthesia considerations for infants and children for ophthalmologic procedures.[6] Anticipation and prevention of postoperative nausea and vomiting (PONV) and understanding of anesthesia emergence and postoperative analgesia are essential.[7]

Before an elective ophthalmologic procedure, the child undergoes a thorough physical examination, including a review of all systems, and a complete medical history is obtained, including a surgical and anesthesia history, list of current medications, known allergies, and family history.[8] Because many ophthalmologic diagnoses are commonly associated with systemic conditions, all implications of the systemic illness are a concern for the anesthesiologist.

The physical examination should evaluate whether the ophthalmologic condition demands an alteration in airway management or affects the ability to obtain an appropriate mask fit. The airway should be carefully assessed for issues arising from other systemic

conditions. Assessments of cardiorespiratory and neurologic systems are important in formulating the anesthesia plan.

Common Ophthalmologic Diagnoses Requiring Surgery

Common pediatric diagnoses and surgical procedures are listed in Table 34.1. A diagnosis may exist in isolation or be one aspect of a more complex group of diagnoses. Many involve systemic illnesses, and the anesthesiologist should be familiar with the implications of ophthalmologic disease in these settings.

Some procedures and examinations can be performed without insertion of an artificial airway; however, communication with the ophthalmologist about position and possible immobility requirements is essential when planning the anesthetic prescription. Other procedures may be performed very quickly and require only induction of anesthesia (often by mask in children) and then removal of the face mask from the nasal bridge to give the ophthalmologist full access to both orbits, eyelids, and nasolacrimal ducts. With experience and the use of soft, inflatable-cushion face masks, a close fit can be obtained to reduce environmental contamination with anesthetic gases while maintaining a suitable plane of anesthesia. The EUA may be brief or intermediate in length, and as information is generated, surgical correction may be contemplated during the same episode of anesthesia, possibly requiring insertion of an artificial airway.

Communication and flexibility are essential since anesthesia may start with a plan for a brief EUA using an inhalational anesthetic with a face mask and no intravenous (IV) catheter; however, if corrective surgery becomes necessary, then airway control may require placement of a laryngeal mask airway (LMA) or tracheal tube. IV access is usually required to administer medications, including those to prevent or treat the oculocardiac reflex (OCR), postoperative pain, and nausea and vomiting.[9]

For procedures of brief or intermediate duration, the use of an LMA generally allows excellent access to all periorbital structures. Compared with mask anesthesia, the LMA has the advantage of decreasing environmental contamination by inhalational anesthetics. It is relatively easy to insert and remains secure while avoiding the need for the anesthesiologist to hold a face mask near the surgical site. Compared with a tracheal tube, an LMA does not increase the heart rate, blood pressure, and intraocular pressure (IOP) to the same degree.[10]

The more common ophthalmologic presentations and associated systemic illnesses or syndromes are listed in Table 34.2. Some conditions have significant cardiorespiratory and/or central nervous system (CNS) implications for perioperative management and should be fully evaluated before anesthesia (see Chapter 4). Many procedures are performed on preterm infants or formerly preterm infants, and appropriate monitoring for apnea spells after anesthesia is essential.[11,12]

TABLE 34.2 Ophthalmologic Conditions Associated With Systemic Syndromes and Illnesses	
Syndrome or Illness	**Ophthalmologic Conditions**
Fetal alcohol syndrome	Strabismus, optic nerve hypoplasia
Galactosemia	Neonatal cataracts
Mucopolysaccharidoses	Corneal involvement; may require transplantation
Retinitis pigmentosa	Heart block
Sturge-Weber syndrome	Glaucoma
Prematurity	Retinopathy of prematurity, strabismus
Fabry disease	Whorled corneal opacities
Tay-Sachs disease	Cherry-red macular spot
Osteogenesis imperfecta	Blue sclerae
Craniofacial syndromes (e.g., Crouzon, Apert, Pfeiffer)	Proptosis, strabismus, glaucoma

Ophthalmologic Conditions Associated With Systemic Disorders

PREMATURITY

The preterm infant may present for many surgical procedures early in life. ROP, congenital cataracts, and glaucoma may require surgery even when the infant weighs less than 1000 g. The preterm infant may have significant systemic illnesses. Common complications of prematurity include acute and chronic pulmonary disease,[13] respiratory failure and pulmonary hypertension, CHD (unrepaired or with a limited palliative repair), and intraventricular hemorrhage,[14] with or without obstructive hydrocephalus.

Acutely ill preterm infants and those younger than 1 year of age are at greater risk than older children and adults for perioperative complications.[15] Careful attention to airway management, assisted ventilation, and titration of oxygen therapy with specified goals are essential for success.[16] In preterm infants, whose airways are already intubated and whose lungs are ventilated mechanically, the anesthesiologist should confirm the position of the tracheal tube, transport the infant safely to the operating room, and limit the exposure to high concentrations of oxygen. Although institutional goals are not uniform regarding supplemental oxygen therapy,[17] communication with the neonatal team is often helpful in gauging the infant's previous oxygen requirement and current targeted goals (e.g., hemoglobin-oxygen saturation levels of 91%–95%).[18,19] Because most inhalational anesthetics impair hypoxic pulmonary vasoconstriction, a greater fraction of inspired oxygen (FIO_2) may be necessary to maintain the targeted hemoglobin saturation.

Hypercarbia and hypoxia may increase choroidal blood volume and increase IOP. Partial pressures of carbon dioxide (PCO_2) and oxygen (PO_2) should be monitored continuously and controlled. Infants may be at greater risk for the OCR than older children and adults, and IV access should be obtained before the surgical

procedure or any examination that may involve traction on the extraocular muscles or pressure on the globe.

Infants of extremely low birth weight require many weeks to grow and develop to a weight of approximately 1800 g and to maintain normothermia without special environmental control. These infants commonly have a history of short-term or intermediate-term assisted ventilation and may or may not require supplemental oxygen before an EUA or planned operative procedure for ROP.[20] Many of these infants undergo ophthalmologic examinations while their lungs are ventilated in the neonatal intensive care unit.[21] During surgical therapy (i.e., laser or cryosurgical stabilization) for ROP, these infants require anesthesia to provide optimal conditions (Fig. 34.1). Perioperative apnea may preclude tracheal extubation or require close postoperative monitoring after anesthesia.[11,12]

Perioperative apnea in the preterm infant is widely described.[11,12,22] Whether the child is still hospitalized or presenting for elective surgery as an outpatient, the preoperative assessment should determine the pattern and frequency of apnea before the planned surgical procedure and anesthesia. The current use of respiratory stimulants (i.e., caffeine or theophylline) and oxygen should be determined. Is an apnea monitor being used, or has it been discontinued? Guidelines have not been developed to manage some of the scenarios, but infants who continue to require supplemental oxygen, who are younger than 60 weeks postconceptional age, or who are monitored for apnea or bradycardia should have continuous cardiorespiratory and oxygen saturation monitoring postoperatively for at least 12 hours or until they are apnea free (see Chapter 4). The risk of apnea after general anesthesia and sedation decreases with advancing gestational age at birth and with advancing

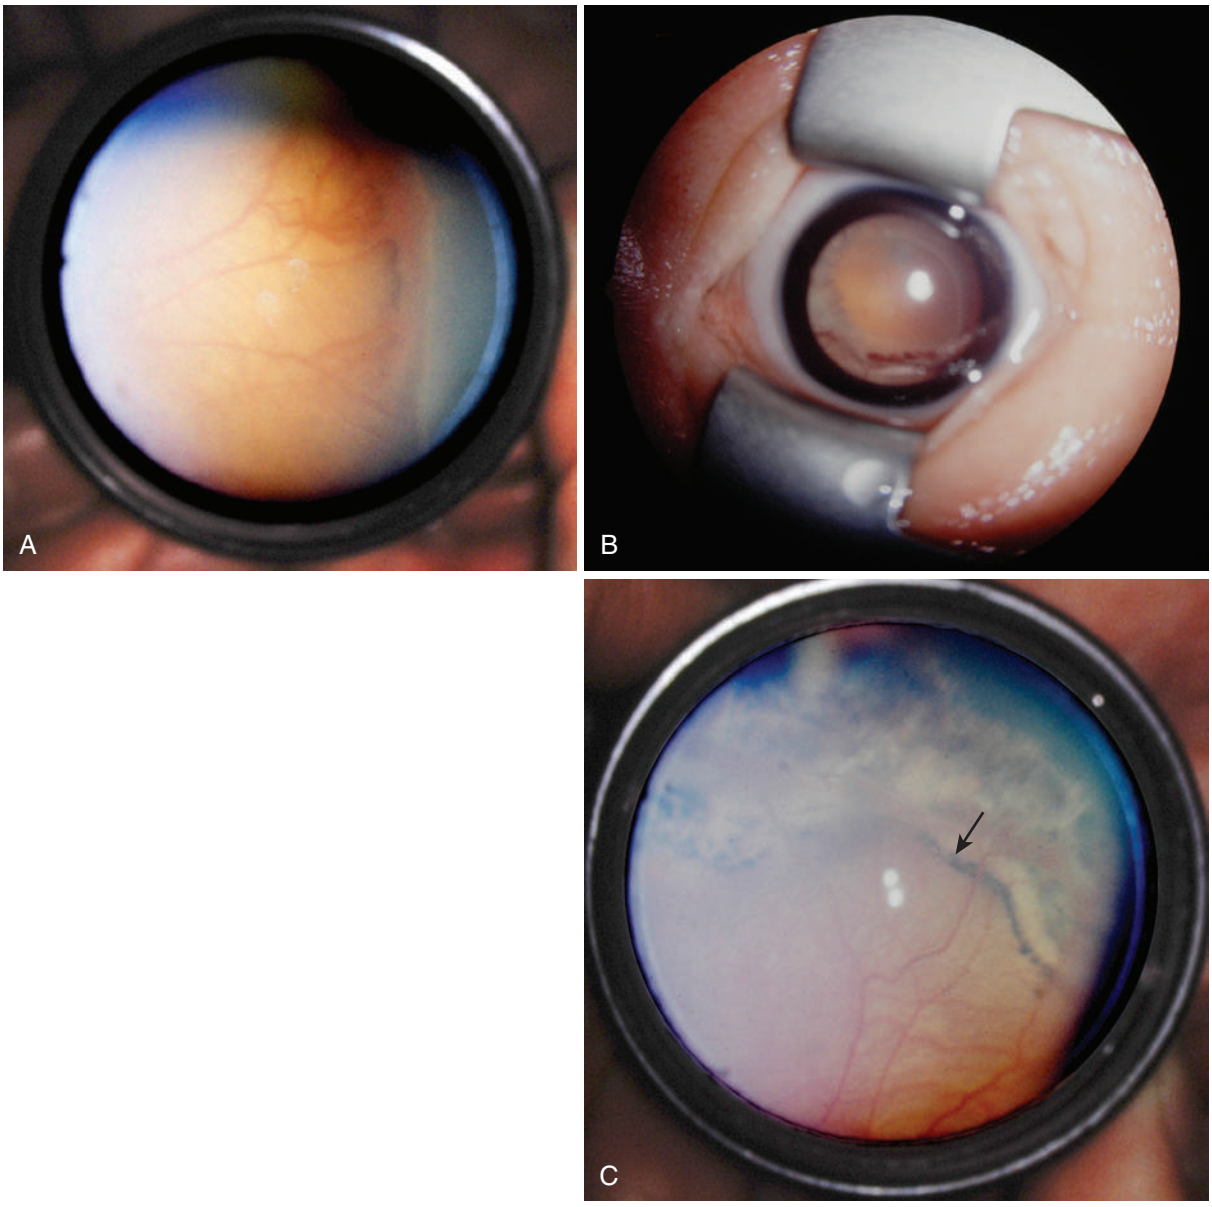

FIGURE 34.1 **A,** Grade III retinopathy of prematurity with neovascularization of the retina requires surgical therapy to halt the growth of vessels. **B,** Retinal detachment caused by retinopathy of prematurity. This degree of damage results in permanent visual impairment. **C,** Appearance after cryotherapy. Cryotherapy causes a well-demarcated ridge of tissue scarring *(arrow)* that prevents further growth of the neovasculature *(left to right in the middle).*

postnatal-postconceptional age. The risk of apnea is independent of opioid use; its multifactorial origins include the presence of general and neuraxial anesthetics and the immature CNS and respiratory center in the preterm infant. Flexible planning for possible postoperative ventilatory support is essential, and families should be informed of this possibility preoperatively.

The airway of the preterm infant who is younger than 52 to 60 weeks postconceptional age is usually intubated for ophthalmologic surgery (except for a very brief EUA) owing to the immature respiratory drive, unpredictable respiratory response to anesthetic agents, and possible lag before recovery of respiratory drive after completion of the procedure and discontinuation of anesthetic agents. If the infant does not appear to have a stable respiratory drive and strength after anesthesia, postoperative assisted ventilation should be continued as indicated; planning for this contingency is vital. *Ophthalmologic procedures may be brief and have a low risk of blood loss, but the risks of general anesthesia mandate full postoperative support.* Intensive care resources for assisted ventilation in preterm and formerly preterm infants should be available before embarking on anesthesia.

Although chronic lung disease related to prematurity is prevalent, its intensity has been reduced with the routine use of surfactant and advances in ventilator management strategies. Long-lasting respiratory effects from prematurity may include reactive airway disease, subglottic stenosis from prolonged intubation, and alveolar or interstitial disease with an oxygen requirement lasting weeks to years.[13] Because many anesthetics impair hypoxic pulmonary vasoconstriction, an increased oxygen requirement in the perioperative period should be anticipated. Tracheal intubation, a light level of anesthesia, or topical use of β-adrenergic antagonists may exacerbate reactive airway disease, requiring further treatment to reduce air trapping and hypercarbia.

In addition to assessing for airway and alveolar diseases, the anesthesiologist should determine whether pulmonary hypertension or right ventricular dysfunction is or was present.[23] Some infants may be receiving continuing oxygen therapy (and/or surfactant) as treatment for pulmonary hypertension and to reduce intermittent episodes of hypoxemia owing to crying or while sleeping. If pulmonary hypertension was diagnosed previously, an updated evaluation is warranted. Because pulmonary hypertension is exacerbated by hypoxia and hypercarbia, tracheal intubation is indicated to ensure control of ventilation and oxygenation. At emergence, pulmonary hypertension may be exacerbated as hypercapnia develops, causing physiologic or anatomic shunting with systemic hemoglobin-oxygen desaturation. Immediate and continued evaluation of the airway is imperative to rule out an independent respiratory contribution to the systemic hypoxia.

Congenital cardiac disease may be diagnosed in the preterm neonate, infant, or child who presents for ophthalmologic procedures. A patent ductus arteriosus may not close spontaneously or after administration of cyclooxygenase inhibitors. This may lead to persistent congestive failure, reduced pulmonary compliance, and complications of fluid management. Congenital cardiac anomalies require assessment before elective surgery. The various complex congenital cardiac lesions have a wide spectrum of interactions with multiple anesthetic agents.[24] Many cardiac conditions require surgery or palliation (e.g., systemic-to-pulmonary shunts) before elective ophthalmologic procedures. Correction of congenital heart disease (CHD) is limited by the difficulty of using cardiopulmonary bypass in infants weighing less than 2 kg. There may be an urgent need for ophthalmologic evaluation (e.g., congenital tumor, cataract, glaucoma) before repair of the congenital cardiac condition. Preoperative consultation with the infant's pediatric cardiologist can provide useful information on the infant's current ventricular function and the risk of dysrhythmias associated with cardiac defects. Medical management must be optimized before undertaking anesthesia and surgery.

Intraventricular hemorrhage is a major source of morbidity and mortality in preterm infants.[14] Obstructive hydrocephalus may occur and require cerebrospinal fluid diversion procedures to decompress the obstructed ventricular system and treat the associated increased intracranial pressure. Many of these infants require ophthalmologic surgery for repair of strabismus caused by a neurologic insult. If a ventriculoperitoneal shunt is in place, its proper function should be determined by direct evaluation. The anesthesiologist should assess whether there is inappropriate macrocephaly or a bulging or tense fontanelle. Obstructive hydrocephalus may occur after the infant's discharge from hospital, even though a ventriculoperitoneal shunt was not required previously. The preoperative assessment should include the child's developmental and neurologic status at the time of surgery. Because intraventricular hemorrhage is associated with long-term morbidity, any history of seizures should be elicited, and the antiepileptic drugs being used should be documented.

Preterm and small infants rapidly lose heat when anesthetized. Prevention of hypothermia is essential in the perioperative environment. Hypothermia can decrease metabolism of most drugs and depresses respiratory drive in preterm infants (see Chapter 37).

DOWN SYNDROME

Children with Down syndrome (i.e., trisomy 21) frequently present for ophthalmologic surgery because of associated pathologic processes such as neonatal cataracts, significant refractive errors (e.g., hypermetropia, astigmatism), strabismus, glaucoma, keratoconus, nasolacrimal duct obstruction, and nystagmus.[25–27] Infants with trisomy 21 should have an ophthalmologic evaluation in the neonatal period. If this requires an EUA, the anesthesiologist should be prepared for the extensive medical implications associated with trisomy 21.[28,29] Almost half of these infants are born with CHD, including septal defects, complete or partial atrioventricular canal, tetralogy of Fallot, transposition of the great arteries, and valvular insufficiency or stenosis. Any child with a left-to-right shunt may develop pulmonary hypertension, and children with Trisomy 21 develop irreversible pulmonary hypertension at an earlier age. Bradycardia (25%–60%) and hypotension (12%–73%) have been reported during sevoflurane anesthesia in these children.[30,31] The child's cardiac defects should be clearly defined before planning the anesthetic prescription (see Chapters 16 and 18).

Airway abnormalities such as narrowed nasopharyngeal passages, macroglossia, pharyngeal hypotonia, and subglottic stenosis, as well as obstructive sleep apnea, are frequently observed in children with Trisomy 21. These abnormalities may contribute to development of chronic intermittent hypoxia, further exacerbating pulmonary hypertension, and these children should be expected to demonstrate exacerbations of airway obstruction and hypoxia after general anesthesia.[32]

Children with Trisomy 21 have a wide spectrum of developmental delays. Cervical spine instability occurs, and occiput-C1 and C1-2 instabilities have been described.[33,34] Subluxation of the cervical spine has rarely been reported in these children during anesthesia. Nonetheless, the anesthesiologist and the surgeon should avoid extremes of neck flexion and extension and lateral rotation during head positioning for laryngoscopy and surgery. While the child is awake, the range of motion of the neck in flexion and

extension should be assessed, along with complaints of numbness or tingling in the hands or feet in a particular position. Previous spine and neck investigations or operations should be reviewed. No consensus exists for the need to radiologically investigate a child with Trisomy 21 who has an asymptomatic cervical spine, although many children are evaluated before 5 years of age.

Children with Trisomy 21 may be born with congenital hypothyroidism or it may develop at any time during their life span. If the child is found to have a goiter on examination or has symptoms consistent with hypothyroidism (i.e., prolonged jaundice, hypothermia, constipation, dry skin, macroglossia, or relative bradycardia), thyroid function studies should be obtained before anesthesia for an elective procedure. They may develop junctional bradycardia during sevoflurane anesthesia.[35] The bradycardia may be associated with or result from occult hypothyroidism.

ALPORT SYNDROME

Alport syndrome (i.e., progressive hereditary nephritis) is a disorder in a group of familial oculorenal syndromes that includes Lowe (oculocerebral) syndrome and familial renal-retinal dystrophy. Alport syndrome involves sensorineural hearing loss, progressive renal disease, and multiple ophthalmologic disorders, including cataracts, retinal detachment, and keratoconus.[36,37] Development of a myopathy and renal failure constitutes the major anesthesia concerns. If the patient has a myopathy, it is prudent to avoid succinylcholine and the risk of a hyperkalemic response and rhabdomyolysis. Renal insufficiency may alter the choice of pharmacologic agents to very–short-acting agents or agents that are not excreted by the kidney.

MARFAN SYNDROME, HOMOCYSTINURIA, AND EHLERS-DANLOS SYNDROME

Marfan syndrome, homocystinuria, and Ehlers-Danlos syndrome are considered together only from the perspective of a general body phenotype. The metabolic and molecular causes of these syndromes are well described.[38,38a] They share problems with connective tissue development, possible joint laxity, and cardiovascular disorders.

Marfan syndrome is caused by a defect in the fibrillin 1 gene (*FBN1*), which affects elastic and nonelastic connective tissues. These children have an increased risk of retinal detachment, lens dislocation, glaucoma, and cataract formation (E-Fig. 34.1).[39] They may have significant pulmonary (scoliosis) and cardiovascular problems,[40] which may include aortic, mitral, or pulmonic valve insufficiency. Preoperative cardiovascular evaluation is indicated to determine the progression of cardiovascular abnormalities that inevitably occur. Acute and chronic blood pressure control is essential to prevent aortic dissection.

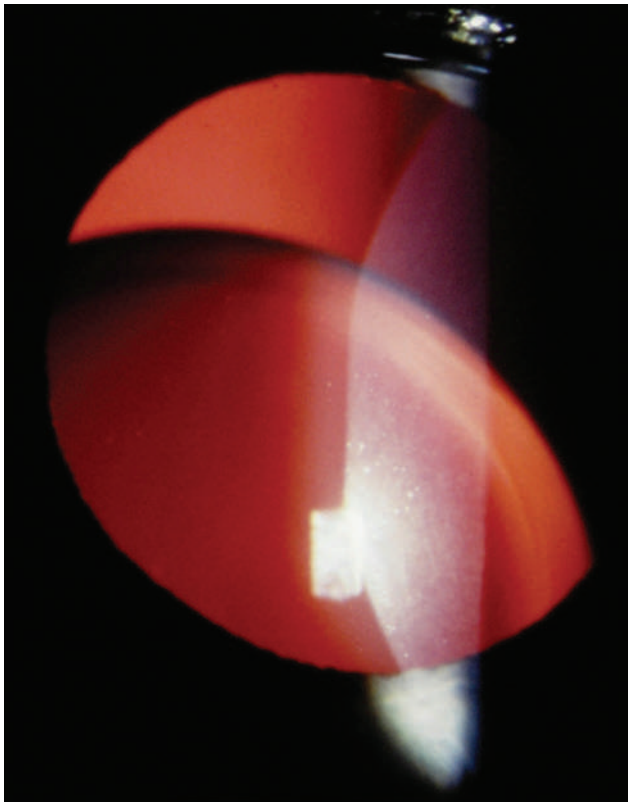
Homocystinuria has at least three forms and different inborn errors. Enzymatic deficiency of the metabolism of sulfur-containing amino acids causes the intermediate metabolite, homocysteine, to accumulate. These children suffer from cataracts, retinal degeneration, optic atrophy, glaucoma, and lens dislocation. The cardiovascular pathology includes coronary artery disease at a young age. Thromboembolic phenomena occur more frequently because they may be hypercoagulable.[41] Nitrous oxide should be avoided because it inhibits methionine synthase, further limiting the conversion of homocysteine to methionine.

At least 10 forms of Ehlers-Danlos syndrome have been described. Not all forms express significant ocular pathology. From the anesthesiologist's perspective, positioning is important to avoid trauma to the skin because these children develop hemorrhages with minor trauma and experience delayed wound healing. A thorough preoperative assessment should be performed for cardiac lesions. Hypertension should be avoided to reduce the risk of rupturing an aneurysm. The duration of effect of local anesthetics in patients with type III Ehlers-Danlos syndrome may be less than that in normal patients, and contingency plans should be in place to address these possibilities, including retrobulbar block or general anesthesia.[42]

MUCOPOLYSACCHARIDOSES

The mucopolysaccharidoses are a group of disorders with enzyme defects that result in incomplete degradation of glycosaminoglycans. Affected children have various degrees of cognitive dysfunction, macroglossia, airway obstruction, cervical spine instability, and systemic involvement with deposition of mucopolysaccharide material. This leads to cardiac and respiratory dysfunction, airway obstruction, corneal opacities, and glaucoma.

The systemic complications of these disorders are sufficiently severe that even well-planned anesthesia management for ophthalmologic procedures may cause death.[43] Airway management can be extremely difficult with poor mask fit, dynamic airway obstruction with narrowed passages, a floppy epiglottis, and difficulty visualizing the larynx.[44] Infiltrative material may be deposited in the laryngeal inlet and pretracheal tissues; an LMA is particularly useful in maintaining a patent airway. Tracheal intubation may require the use of advanced airway visualization and management techniques, and the anesthesiologist should have several plans for airway management (see Chapter 14). Cardiac evaluation should be considered before an elective procedure to assess ventricular function and arrhythmias. IV access may be difficult due to subcutaneous deposition of mucopolysaccharides.



CRANIOFACIAL SYNDROMES

Craniofacial syndromes may manifest as craniosynostosis or have only middle and lower facial structure involvement.[45] Apert and Crouzon syndromes are both disorders of craniofacial development, but syndactyly occurs only in the former (E-Fig. 34.2). They share the potential for many ocular disorders, including severe proptosis, making mask airway management difficult.[46] Other mutations of the fibroblast growth factor receptor 2 gene (*FGFR2*) cause Antley-Bixler and Pfeiffer syndromes. These children may develop chronic airway obstruction, and some have complete tracheal rings; tracheal narrowing should be anticipated, and smaller tracheal tube sizes should be used.

Children with asymmetry of facial and mandibular bone growth may present with limited mouth opening. Children with Goldenhar syndrome (i.e., hemifacial microsomia), Treacher Collins syndrome, and Pierre Robin sequence can be expected to present a challenge to airway management (see Chapters 14 and 35).[46a] Children with craniosynostosis have an increased risk of CHD and a cardiac evaluation should be performed before anesthesia.[47] Neurologic morbidity and seizure disorders occur more frequently in this group of patients.

PHAKOMATOSES

The phakomatoses are neurocutaneous syndromes with multiple ocular pathologic processes. These syndromes include neurofibromatosis,[48,49] encephalotrigeminal angiomatosis (i.e., Sturge-Weber syndrome),[50] tuberous sclerosis,[51,52] incontinentia pigmenti, and ataxia telangiectasia. CNS involvement varies with each of these diseases. Patients may have developmental delay, seizures, and significant neurologic morbidity. Preoperative electrolyte and

E-FIGURE 34.1 Patients with Marfan syndrome may present for surgical repair of ocular lens dislocation resulting from connective tissue defects. This photograph of a slit-lamp examination shows that the circular outer edge of the lens is displaced from its usual position. The capsule of the lens appears to be intact.

E-FIGURE 34.2 This child with Apert syndrome presented with hypertelorism, proptosis, and other pathologic ocular processes. Airway management and intravenous access in these cases are challenging for the anesthesiologist.

hepatic function studies should be assessed. Anticonvulsant drug history and effectiveness should be reviewed; continue these medications in the perioperative period.

OPHTHALMOLOGIC PHYSIOLOGY

Two major considerations of ophthalmologic physiology are of great interest to the anesthesiologist. The first is the dynamics of aqueous humor production and transport and the effects on IOP. The second is the OCR that may occur during any surgery around the orbit. Anesthetic agents affect the IOP. In a patient with a penetrating eye injury, any increase of IOP may be associated with extravasation of elements of the globe and irretrievable loss of vision.

INTRAOCULAR PRESSURE

IOP is the pressure exerted by the internal components of the globe on the covering (i.e., sclera and conjunctiva). The normal IOP is 12 to 15 mm Hg. An IOP greater than 20 mm Hg is considered abnormal. Aqueous humor is a clear fluid that is secreted by the ciliary body and released into the anterior chamber of the globe. It traverses the anterior chamber and bathes the iris. It flows through the canal of Schlemm into the pores of Fontana and then drains into the episcleral and then systemic veins (Fig. 34.2). The posterior chamber, which is larger than the anterior chamber, is composed of a gelatinous mix known as vitreous humor. The sclera and globe that encase the intraocular constituents are relatively noncompliant and are protected by the bony orbit. However, intraorbital masses may impinge on the globe and increase the relative IOP or alter the flow of aqueous humor, resulting in increased IOP. Any obstruction to the drainage of aqueous humor causes fluid to build up within the anterior chamber and increases IOP.[53] Increased central venous pressure (e.g., Trendelenburg position, coughing, Valsalva maneuver, straining, increased intrathoracic pressure) attenuates the drainage of aqueous humor from the eye and may further exacerbate the increased IOP. Arterial pressure changes within the normal range do not directly affect the IOP. However, as arterial blood pressure increases beyond the normal range, approximately 30% of the increase in systolic blood pressure is reflected in IOP increases.

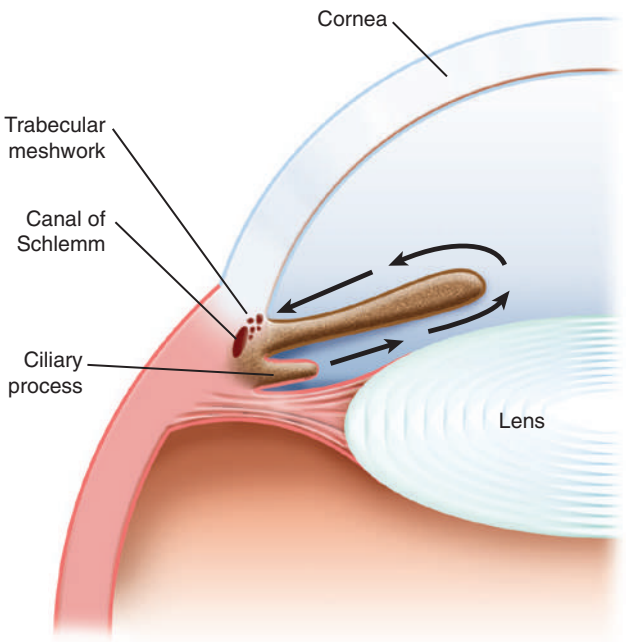


FIGURE 34.2 Aqueous humor is synthesized in the ciliary process and then circulates around the iris, past the lens, and into the anterior chamber. After flowing through the trabecular meshwork, aqueous humor enters the canal of Schlemm *(arrows)*, which drains into the episcleral venous system. Pathologic conditions that increase venous pressure, obstruct the canal of Schlemm, or increase aqueous humor production may increase intraocular pressure.

Aqueous humor formation is described in the following equation:

$$IOP = K[(OP_{aq} - OP_{pl}) + P_c],$$

where K is the coefficient of outflow, OP_{aq} is the osmotic pressure of aqueous humor, OP_{pl} is the osmotic pressure of plasma, and P_c is the capillary pressure. These variables allow calculation to intervene by increasing the plasma osmolality acutely with mannitol to lower the IOP. This increases the gradient of osmolality and draws water out of the aqueous humor, thereby reducing the IOP.

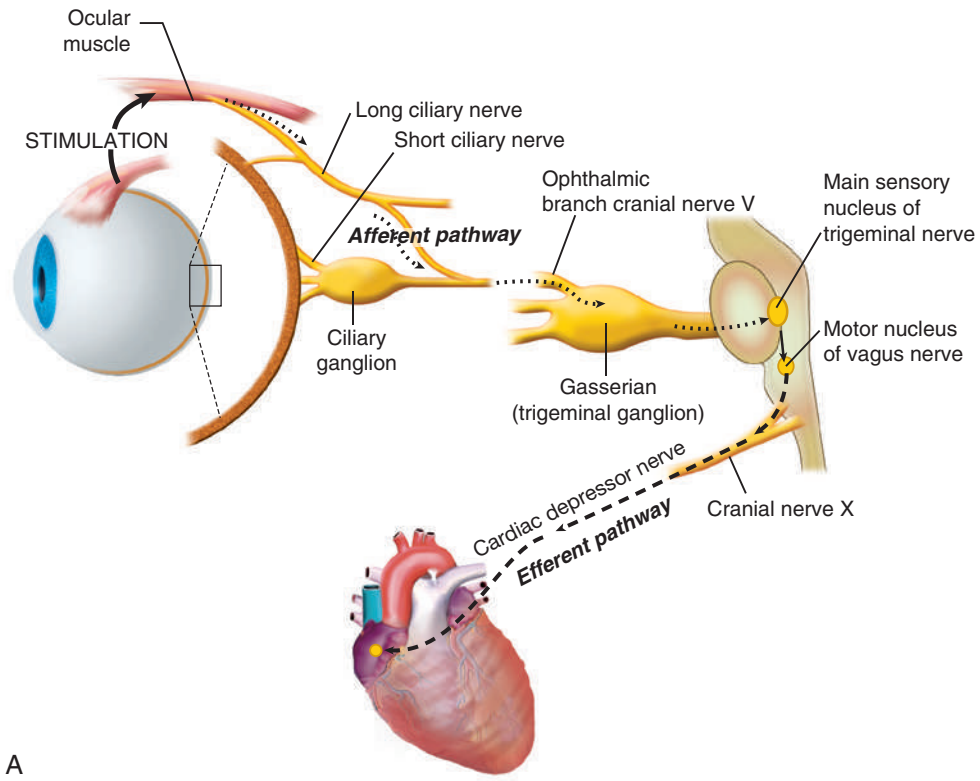
In the relatively noncompliant globe, any pharmacologic or metabolic process that increases choroidal blood volume (e.g., hypercapnia, coughing, increased central venous pressure) produces choroidal congestion and an increased IOP. Although well tolerated in the healthy eye, this congestion may lead to extrusion of contents if the globe is ruptured. The anesthesiologist should carefully control the child's physiology during the induction and maintenance of anesthesia to minimize increases in IOP, regardless of whether there is a preoperative concern about increased IOP.

Congenital or trauma-induced glaucoma requires therapy to reduce the IOP. If the IOP remains elevated, blood flow in the retina will be impaired, possibly leading to loss of vision. Unfortunately, there are many causes of glaucoma in childhood. Hypercarbia, hypoxia, and drugs known or suspected to increase IOP (e.g., succinylcholine, ketamine) should be avoided or used with care. Reducing a child's apprehension and crying and avoiding increases in central venous pressure are also important considerations.

The effect of succinylcholine on IOP is well documented.[54,55] Succinylcholine increases IOP 6 to 10 mm Hg, an effect that begins within 1 minute after administration and continues for up to 10 minutes, at which time the IOP returns to normal. This effect has been attributed to four possible mechanisms:

- Cycloplegia induced by succinylcholine, which obstructs the outflow of aqueous humor
- Tonic contraction of extraocular muscles
- Increased choroidal blood volume
- Relaxation of orbital muscles, which increases external pressure on the globe

Specific muscles develop a sustained tonic tension after succinylcholine that may in the presence of a ruptured globe cause extrusion of intraocular contents.[56] Extrusion in response to increased IOP depends on the diameter of the orifice; a smaller laceration (<2 mm) is less likely to facilitate extrusion of intraocular contents than a larger laceration (>4 mm). Pretreatment with a nondepolarizing agent (one-tenth the usual intubating dose) and paralysis with succinylcholine are still advocated by some anesthesiologists to minimize the risk of aspiration when dealing with an open globe injury. Alternatively, rocuronium (1.2 mg/kg IV) can provide optimal intubating conditions in 30 seconds for the child with an open globe injury while minimizing the risk for aspiration or succinylcholine-associated increases in IOP. Sugammadex has been used in Europe for some years and is now approved for use in the United States; concerns of prolonged paralysis from



rocuronium or a failed intubation are lessened since even profound neuromuscular blockade can be rapidly reversed.

Most general anesthetics decrease IOP,[57] although ketamine has been shown to increase IOP in some studies and decrease it in others–an effect that may be attributed to ventilation control and consequent Pa_{CO2} rather than the drug.[58–60] When IV access is unavailable or the cardiovascular status of the patient warrants the use of ketamine, the child's overall safety takes precedence over the possible ramifications of ketamine on IOP.

Measurement of IOP is performed by applanation tonometry on the external surface of the globe. Tonometry is often performed along with the EUA during general anesthesia to avoid an overestimation of IOP in struggling, uncooperative infants or children. Borderline measurements must consider the possibility of anesthetic agents temporarily reducing or increasing the IOP.

OCULOCARDIAC REFLEX

First described in 1908, the OCR is triggered during ophthalmologic surgery and other conditions.[53] Traction on the extraocular muscles and levator (eyelid elevator) or external pressure applied to the globe triggers an afferent signal through the trigeminal nerve that activates parasympathetic output through the vagus nerve, resulting in many types of dysrhythmias (Fig. 34.3A), which include sinus or junctional bradycardia, atrioventricular block, ventricular ectopy, and asystole (Fig. 34.3B). Retrobulbar block with local anesthetic may precipitate the trigeminovagal (oculocardiac) reflex as a result of external pressure sensed on the globe, and the local anesthetic may not completely prevent the OCR response to further surgical stimulation or manipulation. For this reason, an anticholinergic medication, such as atropine (20 µg/kg) or glycopyrrolate (10-20 µg/kg), is routinely given IV at induction of anesthesia or early

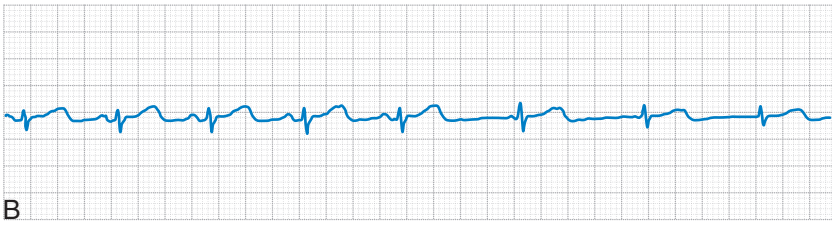


FIGURE 34.3 Traction on the extraocular muscles elicits the oculocardiac reflex. **A,** The afferent limb consists of the long and short ciliary nerves, which synapse in the ciliary ganglion *(dotted arrows).* The ophthalmic division of the trigeminal nerve (cranial nerve V) carries the impulse to the gasserian ganglion, and the arc continues to the sensory nucleus of cranial nerve V in the brainstem. Fibers in the reticular formation synapse with the nucleus of the vagus nerve (cranial nerve X). Efferent fibers from the vagus nerve terminate in the heart *(dashed arrow).* The neurotransmitter from the vagus nerve to the sinoatrial node is acetylcholine, and the reflex is blocked by antimuscarinic pharmacologic agents (i.e., atropine and glycopyrrolate). **B,** Electrocardiogram shows conversion from normal sinus rhythm to a nodal rhythm.

thereafter. Although these medications do not preclude the occurrence of bradycardia, both decrease its severity and duration. Because anticholinergics cause pupillary dilatation, they do not present a problem for the ophthalmologist, but they may slightly increase the IOP.

If significant bradycardia occurs, the anesthesia team should ask the surgeon to release the traction on the extraocular muscle or stimulation in the surgical field. An additional IV dose of atropine (5–10 μg/kg) usually interrupts the reflex and restores the heart rate, although the correction may be evanescent and the dysrhythmia may recur. IV epinephrine (1–10 μg/kg) is rarely necessary but should always be available. The anesthesiologist should ensure adequate oxygenation and ventilation because hypercarbia or hypoxia may compound or intensify the reflex activity.

Other strategies to attenuate the OCR include topically applied lidocaine[61] or IV ketamine.[62] In a four-armed study, the incidence of OCR with a ketamine-based anesthetic (10–12 mg/kg per hour) was less compared with the three other anesthetic regimens: propofol/alfentanil, sevoflurane/nitrous oxide, or halothane/nitrous oxide.[63] The prevalence of the OCR during sevoflurane and desflurane anesthesia was similar.[64]

Ophthalmologic Pharmacotherapeutics and Systemic Implications

Topical ophthalmologic medications are usually placed directly on the cornea or in the inferior cul-de-sac. Most of these agents need many minutes to 1 hour for maximal effectiveness and as such are usually administered soon after induction. Medications delivered topically to the eye are absorbed through the conjunctiva and nasal mucosa into the systemic circulation; their pharmacologic mechanisms of action predict the systemic consequences. Therefore some medications are diluted for use in children to reduce the concentration presented and possible systemic toxicity. Anticholinergics, sympathomimetics, and antihistamines can cause pupillary dilation and decrease the movement of aqueous humor, thus increasing the IOP. Table 34.3 lists the more commonly used pediatric topical agents.

Topical mydriatic agents dilate the pupil. The most common mydriatic is phenylephrine (2.5% solution), an α_1-adrenergic agonist that is rapidly absorbed but may cause significant hypertension in small infants. If severe hypertension occurs, reflex bradycardia may ensue.

Topical cycloplegic agents also dilate the pupil, as well as eliminate lens accommodation by paralyzing the ciliary muscle. This aids in retinal evaluation with the indirect ophthalmoscope and scleral depression and in evaluating refractive errors for which the child is using accommodation for compensation. These agents are muscarinic cholinergic antagonists (i.e., antimuscarinic agents). One such agent is cyclopentolate hydrochloride (0.5%), which can cause CNS toxicity with disorientation, seizures, and blurred vision. Atropine (0.5%–2.0%) and scopolamine (0.25%) solutions are also cycloplegics that dilate the pupil. Tropicamide (0.5% and 1.0%) is less commonly used in children. When systemically absorbed, these agents may cause antimuscarinic, anticholinergic toxicity, including tachycardia, dry mouth, pupillary dilation, flushing of the skin, heat intolerance or fever, and disorientation (E-Fig. 34.3).

β-Adrenergic blockers (e.g., timolol, betaxolol) are used to reduce IOP in the treatment of glaucoma. Systemic absorption causes symptoms of sympathetic nervous system blockade. β-Adrenergic antagonists induce bradycardia and cardiovascular collapse and may precipitate bronchospasm. If β-adrenergic intoxication is suspected, direct-acting cardiovascular stimulants (epinephrine) should be used to antagonize the β-adrenergic blockade rather than indirect-acting stimulants such as ephedrine.

Topical local anesthetics are infrequently used in children except for the very cooperative child for tonometry or removal of sutures. Proparacaine and tetracaine (ester local anesthetics) may be used topically, whereas lidocaine and bupivacaine (or levobupivacaine, ropivacaine, which are amide local anesthetics) are used for ophthalmic blocks. Ester local anesthetics confer a small risk for systemic toxicity because they are extensively metabolized by plasma cholinesterases. Ophthalmic amide agents, however, do have the potential to cause systemic toxicity (i.e., cardiac dysrhythmias and seizures), but these agents are not frequently used in children. Topical cocaine is rarely used in pediatric ophthalmology except to test for Horner syndrome and as a vasoconstrictor to reduce nasal bleeding during nasal and nasolacrimal duct surgery.

Nonsteroidal antiinflammatory drugs (NSAIDs) are used for certain inflammatory conditions of the eye, but perioperative use in a child is uncommon. Some NSAIDs (i.e., ketorolac and ibuprofen) pose a concern for ophthalmology because their anticoagulant profiles may increase local perioperative bleeding. However, five NSAIDs are approved for ocular use: diclofenac, bromfenac, flurbiprofen, ketorolac, and nepafenac. Diclofenac, bromfenac, and nepafenac are used postoperatively for their antiinflammatory effects. Ketorolac has been used to treat macular edema after cataract extraction.

Echothiophate (i.e., phospholine iodide) is a cholinesterase inhibitor used to induce miosis in the treatment of glaucoma. When absorbed systemically, it impairs plasma cholinesterase, reducing the metabolism of some drugs (e.g., succinylcholine) and prolonging their duration of action. Decreased metabolism of acetylcholine may result in increased relative cholinergic tone, inducing bradycardia and bronchiolar muscle activity and resulting in bronchospasm. Toxicity from echothiophate may be antagonized by administration of pralidoxime (2-pyridine aldoxime methyl chloride [2-PAM]) (25 mg/kg IV). Otherwise, its action to reduce effective systemic cholinesterases lasts 4 to 6 weeks.

Pilocarpine, a direct-acting cholinergic agonist that is commonly used to treat glaucoma, has replaced echothiophate iodide. Through multiple actions, it improves the flow of aqueous humor; if absorbed, it may acutely cause bradycardia.

Many vitreal substitutes are used in ophthalmologic procedures. They include nonexpansile and expansile gases (e.g., sulfur hexafluoride), perfluorocarbon liquids, and silicone oils. The anesthesia team should be informed when the ophthalmologist plans intraocular use of one of these substances. If a gas pocket is anticipated, nitrous oxide should be discontinued or avoided completely. The patient and parent should be informed of any intraocular gas use, and the patient should wear an alert bracelet for the expected duration of absorption, usually no longer than 6 to 12 weeks, so that inadvertent use of nitrous oxide does not occur during that interval. When a perforated globe is closed, any residual environmental air pocket can be expanded by nitrous oxide; increased ocular pressure and reduced retinal blood flow may result.

A novel agent being studied in the treatment of retinal angiogenic diseases (e.g., ROP, retinoblastoma) is bevacizumab (a recombinant monoclonal antibody), which inhibits the formation

E-FIGURE 34.3 Systemic absorption of ophthalmologic anticholinergic medications may result in toxic reactions, including facial or whole-body erythema, tachycardia, and seizures. This child has facial flushing from cyclopentolate absorption.

TABLE 34.3 Commonly Used Ophthalmologic Agents

Drug	Indication	Side Effect Profile
Cholinergic Agonists		
Carbachol	Induce miosis	Corneal edema, retinal detachment
Pilocarpine	Glaucoma	Corneal edema, retinal detachment
Cholinesterase Inhibitors		
Physostigmine	Glaucoma	Retinal detachment, miosis
Echothiophate	Glaucoma	Retinal detachment, miosis
Muscarinic Antagonists		
Atropine	Cycloplegic retinoscopy	Photosensitivity, blurred vision, increased heart rate, dry mouth
Scopolamine	Cycloplegic retinoscopy	Photosensitivity, blurred vision, increased heart rate, dry mouth
Homatropine	Cycloplegic retinoscopy	Photosensitivity, blurred vision, increased heart rate, dry mouth
Cyclopentolate	Cycloplegic retinoscopy	Photosensitivity, blurred vision, increased heart rate, dry mouth
Tropicamide	Cycloplegic retinoscopy	Photosensitivity, blurred vision, increased heart rate, dry mouth
Sympathomimetic Agents		
Dipivefrin	Glaucoma	Photosensitivity, hypersensitivity
Epinephrine	Glaucoma	Photosensitivity, hypersensitivity
Phenylephrine	Mydriasis	Photosensitivity, hypersensitivity
Apraclonidine	Glaucoma	Photosensitivity, hypersensitivity
Brimonidine	Glaucoma	Photosensitivity, hypersensitivity
Cocaine	Local anesthetic	Anisocoria, corneal injury, photosensitivity, hypersensitivity
Hydroxyamphetamine	Glaucoma	Anisocoria, photosensitivity, hypersensitivity
Naphazoline	Decongestant	Photosensitivity, hypersensitivity
Tetrahydrozoline	Decongestant	Photosensitivity, hypersensitivity
α- and β-Adrenergic Antagonists		
Dapiprazole (α)	Reverse mydriasis	Conjunctival hyperemia
Betaxolol (β_1-selective)	Glaucoma	Bradycardia, hypotension
Carteolol (β)	Glaucoma	Decreased heart rate, blood pressure, bronchospasm
Levobunolol (β)	Glaucoma	Decreased heart rate, blood pressure, bronchospasm
Metipranolol (β)	Glaucoma	Decreased heart rate, blood pressure, bronchospasm
Timolol (β)	Glaucoma	Decreased heart rate, blood pressure, bronchospasm
Recombinant Monoclonal Antibodies		
Bevacizumab	ROP, retinoblastoma, retinal venous thrombosis, diabetic retinopathy	Drug introduced directly into eye and systemic effects minimal

ROP, retinopathy of prematurity.
Modified from Brunton LL, Lazo, JS, Parker KL, eds. *Goodman and Gilman's The Pharmacological Basis of Therapeutics*. 11th ed. New York: McGraw-Hill; 2006.

of new blood vessels.[65–67] In the doses prescribed, it should not raise concerns for anesthesia. The visual outcome of any infant must be monitored for all perioperative care provided.

EMERGENT, URGENT, AND ELECTIVE PROCEDURES

One of the greatest controversies in pediatric anesthesia is defining the optimal technique to induce anesthesia in a child with an open globe injury and a full stomach.[56] The issue of aspiration while securing the airway versus the possible extravasation of intraocular contents caused by an increase in IOP is a difficult risk/benefit assessment. The debate is likely to continue because the risks are real and the incidence of either phenomenon is rare, difficult to study, and probably underreported.

Among adults, aspiration is an uncommon event with a small mortality rate. The incidence of aspiration in children is ~1/10,000 elective cases but is greater in emergent cases; mortality secondary to aspiration is less than 1/200,000 children.[68–71] The use of succinylcholine for rapid-sequence induction in the treatment of a perforated globe has been challenged because of its known propensity to increase IOP. High-dose rocuronium (1.2 mg/kg) has an onset equivalent to that of succinylcholine, provides excellent intubating conditions,[72] and offers the advantage of reducing IOP by blocking the neuromuscular junction of extraocular muscles. However, if the child is not adequately anesthetized and fully paralyzed during instrumentation of the airway, any episode of coughing, retching, or increased systolic blood pressure may increase IOP. Lidocaine (1–2 mg/kg IV) usually attenuates the hemodynamic responses to laryngoscopy and tracheal intubation, but this is not a consistent experience.[73,74] Pretreatment with opioids (0.05–0.15 μg/kg of sufentanil, 0.03 mg/kg of morphine, or 0.1 μg/kg of remifentanil) has been proposed to achieve a similar effect, although they are not consistently recommended. Opioids blunt the IOP response to intubation, but may also induce vomiting, indirectly increasing the IOP transiently.

IV access is essential for a rapid induction of anesthesia. In most instances, children with ruptured globes present with IV access because IV antibiotics must be started as soon as possible (i.e., within 6 hours of the rupture) to prevent endophthalmitis, which if untreated may result in complete loss of vision in the affected eye. In some instances, however, IV access has not been established. In this case, other options may be used to induce anesthesia. Of the approaches in the following list, the one most widely favored is ultrasound guidance:

- Ultrasound-guided IV catheter placement with topical anesthesia
- Intramuscular (IM) ketamine (and succinylcholine or rocuronium)
- Mask induction with sevoflurane or halothane
- Placement of a central line (e.g., femoral vein)
- Placement of an intraosseous needle
- Rectal methohexital or ketamine

The increase in IOP after IM succinylcholine is less than that after IV administration[75]; however, absorption of agents given IM varies widely. Although IM succinylcholine (4–5 mg/kg) will paralyze a child in 2 to 8 minutes depending on the dose, the child may cry from pain, develop hypertension, or vomit during the induction, all of which may increase IOP. Knowing that the airway reflexes are gradually lost after an IM injection in the child with a full stomach is a clinically important risk that must be considered when selecting a method to secure the airway. Placement of a central line may be challenging and potentially risky in a nonsedated or uncooperative child, although ultrasound has been used to secure femoral access.

Some clinicians recommend placement of an intraosseous needle for induction when IV access has not already been established. Even when preceded by local anesthesia infiltrated into the site of insertion of the needle, placement of an intraosseous needle may be poorly tolerated in conscious children, although the pain upon insertion is much less than when fluids are infused rapidly.

Despite the presence of a full stomach, a mask induction with sevoflurane may be used, but a deeper plane of anesthesia is required before inserting an IV line or manipulating the airway because coughing and vomiting may occur with a light plane of anesthesia. IV access should then be established. If this is unsuccessful, an IM dose of a neuromuscular blocking drug may be administered.[76–78] In this circumstance, IOP may increase and regurgitation remains a possibility. Rectal methohexital (30 mg/kg) is used only in infants; if the child evacuates part of the dose, induction is incomplete.[79] Because there is no reliable absorption of neuromuscular relaxant rectally, IM or IV administration is necessary.

A moderate approach to the child who needs emergent or urgent ophthalmologic surgery is to secure IV access as quickly and painlessly as possible (ultrasound with topical analgesia). An attempt is made to preoxygenate the child without causing distress. If a tight mask fit is not easily achieved, forcing the tight fit to the child's face is not desirable because of the likelihood of increasing the IOP as the child resists. Anesthesia may be induced via IV access with lidocaine, propofol, and rocuronium. After 30 to 60 seconds by the clock or with train-of-four monitoring, tracheal intubation is expeditiously performed and gastric contents evacuated. The ophthalmologist should be intimately involved in the induction. He or she can physically protect the injured eye with a metal or plastic shield to prevent further injury and assist the anesthesiologist by holding the tracheal tube and suction apparatus immediately within reach of the field of view of the airway, our preferred team approach.

Other urgent procedures may include treatment of retinopathy or decompression of orbital cellulitis. These procedures may be urgent but still allow several hours of *nil per os* (NPO) status. Concern about aspiration may not be as great. Nonetheless, the surgeon will wish to proceed as expeditiously as is safe. Options for induction and maintenance may or may not include succinylcholine.

Most ophthalmologic procedures are performed on a scheduled basis, allowing routine preoperative evaluation and planning. This includes establishing all relevant medical information about the child, implementing NPO status, and placing an IV catheter if desired.

INDUCTION AND MAINTENANCE OF ANESTHESIA

Infants do not generally require a premedicant for anxiolysis, and the use of premedication after the first year of life is usually discussed between the anesthesiologist and the parents and child. Separation anxiety or struggling during induction usually does not affect most ophthalmologic diagnoses, except for a penetrating eye injury, which may become worse if the child struggles. IV propofol, etomidate, or ketamine produce a smooth induction, as does an inhalational induction with oxygen, nitrous oxide, and sevoflurane or halothane. If laryngospasm develops during induction, an IV bolus of propofol (1–2 mg/kg IV) should be promptly administered. Atropine (20 μg/kg) may be given IV or IM before bradycardia occurs. IM succinylcholine or rocuronium may also break laryngospasm if an IV catheter has not been placed.[70–74,76–78,80–82] For elective tracheal intubation, an IV nondepolarizing muscle relaxant is preferred because succinylcholine may increases the IOP.

Alternative induction methods include IM ketamine (4–10 mg/kg) and, in infants, rectal methohexital (25–30 mg/kg). Ketamine may increase IOP, but it has been successfully used in ophthalmologic procedures in children.[62] Rectal methohexital has a dependable latency to induction of general anesthesia of 7 to 8 minutes, but its elimination can vary widely and its respiratory depressant effects may linger (see Chapter 7). Currently, rectal methohexital is infrequently used.

Tracheal intubation is our preference for most pediatric ophthalmologic procedures, except for a brief EUA or nasolacrimal duct probing. With the tracheal tube secured, the child and operating table may be safely turned 90 or 180 degrees for optimal positioning of the table and child for surgery.

An immobile child may be essential to ensure the optimal surgical outcome. If the surgeon requires immobility, a tracheal tube should be placed and neuromuscular relaxants administered. A cuffed or uncuffed oral Ring-Adair-Elwyn preformed tracheal tube (Mallinckrodt, Inc. St. Louis, MO) or straight tracheal tube may be used. The tracheal tube is secured so that the sterile surgical field is maintained during the procedure. Access to the tracheal tube and anesthesia circuit by the anesthesia care team without trespass of the surgical field is imperative. Extensions to the individual limbs of the anesthetic circle circuit have no bearing on the dead space of the breathing circuit, whereas extensions between the Y connector in the circuit and the patient (i.e., adjacent to the tracheal tube) add dead space that may increase $PaCO_2$.

Anesthesia can be maintained with a variety of techniques. Inhalational sevoflurane, isoflurane, or desflurane provide excellent conditions for maintenance of anesthesia[64] and rapid emergence. Total IV anesthesia is also gaining popularity (see Chapter 8) and reduces PONV. When neuromuscular blockade is necessary to reduce the potential for movement, we routinely

use nondepolarizing neuromuscular relaxants and train-of-four monitoring to ensure the adequacy of neuromuscular blockade. Carefully titrated doses of opioids are used as an anesthetic adjunct if postoperative pain is anticipated.

The anesthetic and type of surgery affect the incidence of PONV. Strabismus surgery in children is associated with the greatest incidence (45%–85%) of PONV.[83,84] The type of ventilation does not attenuate the incidence of PONV.[85] Large-volume (30 mL/kg) balanced salt solution replacement significantly decreases the incidence of PONV after strabismus surgery.[86] Avoiding opioids during strabismus surgery may also be effective.[87,88] Nonopioid analgesics such as acetaminophen,[89] diclofenac,[90] and ketorolac[87,88] may be used. If opioids are needed, short-acting medications are preferred: remifentanil, alfentanil, or fentanyl. Some evidence suggests that the more extraocular muscles that require surgery and specific muscles that require more traction (e.g., inferior oblique), the greater the incidence of PONV, although these data have not been firmly established.

A host of medications can significantly affect the risk of PONV.[91] Preoperative use of benzodiazepines,[92] avoidance of nitrous oxide,[93] and superhydration with balanced salt solutions[86]; use of propofol,[93,94] clonidine,[95] 5-HT_3 receptor antagonists,[96–100] dimenhydrinate,[101,102] metoclopramide,[100,103] or dexamethasone[104–108]; and delaying oral fluid ingestion after surgery[109] attenuate the incidence of PONV. With clonidine and 5-HT_3 receptor blockers, but not dexamethasone, there is a dose-response relationship with PONV.[95,96,104] Older antiemetics such as droperidol that have been very effective in attenuating the incidence of PONV[89,110–113] have fallen into disfavor because of their sedative side effects and concerns associated with prolonged QT intervals,[114] although the latter has not been a common problem in children.[115] Anesthesiologists have adopted a multimodal approach to PONV in the case of strabismus surgery.[115] A commonly used regimen includes premedication with oral midazolam, choice of anesthesia, superhydration with IV fluid, and the combination of 5-HT_3 receptor antagonists and dexamethasone. There is no evidence in children undergoing strabismus surgery that dosing of 5-HT_3 receptor antagonists at the end of surgery provides better protection against PONV than earlier in the surgery.[116] However, dosing of 5-HT_3 receptor antagonists during emergence in children with congenital prolonged QT interval increases the risk of adverse events.[117] There is a dichotomy of practice with respect to maintenance of anesthesia. Some avoid nitrous oxide, maintaining anesthesia by propofol infusion and including the previously mentioned supplementary medications. Others use nitrous oxide and an inhalational anesthetic for maintenance but also include the remainder of the preoperative and intraoperative supplementary medications.

IV fluid replacement can reduce PONV.[118] Children who present for elective surgery may drink clear fluids up to 2 hours before surgery, reducing the fasting period. However, it is important to identify those who have fasted for a prolonged period and to administer sufficient IV fluids to reestablish euvolemia, thus avoiding the activation of antidiuretic hormone and aldosterone that may cause fluid retention. When using balanced salt solutions, children should receive 20 to 30 mL/kg IV to reestablish euvolemia and to avoid activation of the antidiuretic hormone and aldosterone pathways. This should be followed postoperatively by a maintenance IV fluid infusion rate at one-half of the previously considered rate, using 2 mL/kg per hour for the first 10 kg, 1 mL/kg per hour for the next 10 kg, and 0.5 mL/kg per hour for every kilogram greater than 20 kg until the child takes fluids by mouth.[119–121] The incidence of PONV is reduced when large volumes of balanced salt solution (20–30 mL/kg) are administered intraoperatively compared with smaller volumes (10 mL/kg).[86] When the surgical procedure is not likely to involve an increased IOP, we routinely replace almost 100% of the calculated deficit. We have not observed children to experience urinary retention or hypertension from this strategy, most likely because children can redistribute the excess fluid more efficiently than adults.[122] However, if the duration of surgery exceeds 3 hours, we catheterize the bladder to reduce the risk of urinary retention and overdistention of the bladder.

At the completion of surgery, neuromuscular blockade is antagonized, maintenance agents are discontinued, and the child is allowed to awaken. Deep extubation is preferred by some to reduce coughing and increases in IOP at the time of extubation.[123] Others prefer extubating the trachea when the child is fully awake with intact airway reflexes, although coughing and increases in IOP may occur. For most procedures in children, a short interval of increased IOP does not damage a surgical correction, such as strabismus, ptosis, or ROP treatment. Appropriate postoperative analgesics may include local anesthetics, acetaminophen, and opioids. Nonsteroidal agents usually are not given to these children owing to concerns about perioperative bleeding at the surgical site because of their mild anticoagulant profile, but ketorolac has been useful.[87] Lorazepam may also have some utility.[92] Postoperatively, withholding oral fluids until the child expresses a desire to drink reduces the incidence of PONV.[109]

Specific Ophthalmologic Procedures

Strabismus repair is common in children.[99] Corrective surgery realigns the divergent visual axes of the eyes by detaching and reattaching extraocular muscles to the globes (Fig. 34.4). The procedures may be brief if only one or two muscles are involved. In infants, inhalational or IV induction is performed, and neuromuscular blockade is provided with nondepolarizing neuromuscular blocking drugs. Strabismus may be an isolated finding in a child or a manifestation of other systemic diseases or syndromes.[124] The anesthesiologist should carefully review the birth history, history of prematurity, CNS, disorders, syndrome identification, possible coexistent myopathy, and cardiovascular and respiratory history. If OCR is anticipated, prophylactic prevention with IV atropine or glycopyrrolate may be warranted. PONV is common and may be reduced by multiple strategies (Table 34.4).

We usually avoid the routine use of succinylcholine in children; however, in this circumstance, if succinylcholine is used, the surgeon should be informed because it may alter the forced duction testing and affect the planned repair.[125] After induction of anesthesia and tracheal intubation, the operating room table is rotated to permit complete access to the orbits. It is common to use a preformed tube that lies flat against the mandible.[126] The tracheal tube is positioned away from the surgical field. Ventilation may be spontaneous or controlled if the surgery is extraocular. If the surgery is intraocular or medical conditions dictate, controlled ventilation should be considered. Some anesthesiologists are willing to perform strabismus repair using an LMA with spontaneous ventilation.[127] Although regional block is performed in some adults, strabismus surgery in children is routinely performed with general anesthesia.

ANTERIOR CHAMBER PARACENTESIS

An anterior chamber paracentesis may be performed in children for evaluation of uveitis, infection,[128] or leukemia[129] or for removal of fluid to decrease IOP. Because the field needs to be sterile and

FIGURE 34.4 Strabismus repair is a common pediatric ophthalmologic procedure. The child demonstrates significant right esotropia that requires surgical correction.

TABLE 34.4 Antiemetic Strategies for Prophylaxis and Treatment of Postoperative Nausea and Vomiting

Strategy	Drug and Dose
Butyrophenone (dopamine antagonist)	Droperidol (10–70 µg/kg)
Serotonin ($5HT_3$ receptor antagonists)	Ondansetron (0.1 mg/kg) Granisetron (10–40 µg/kg) Dolasetron (0.35 mg/kg)
Propofol-based total IV anesthesia	Propofol (100–175 µg/kg per minute)
Local anesthetic	Lidocaine local-topical and systemic (1–1.5 mg/kg)
Opioid-sparing analgesics or anesthetics	Retrobulbar block with bupivacaine
Other pharmacology	Dexamethasone (10–500 µg/kg); maximum, 8 mg
	Dimenhydrinate (0.5–1 mg/kg)
	Metoclopramide (0.15–0.25 mg/kg)
	Benzodiazepines (e.g., lorazepam, midazolam) (10–100 µg/kg)
	Avoid nitrous oxide (N_2O)
	Avoid opioids
	Use ketorolac (Toradol) (0.5 mg/kg PO, IV, IM), acetaminophen (30–40 mg/kg PR or 15 mg/kg IV), or diclofenac (1 mg/kg PR), or short-acting opioids (e.g., remifentanil, alfentanil, fentanyl)
Nonpharmacologic adjuvants	IV hydration
	Gastric decompression

IV, intravenous; *IM*, intramuscular; *PO*, per os (oral); *PR*, per rectum (suppository).

the needle must enter a small target area of the anterior chamber, the child should undergo general anesthesia to make the field immobile for the surgeon.

DACRYOCYSTORHINOSTOMY

Infants may be born with nasolacrimal duct stenosis (i.e., congenital dacryostenosis) (Fig. 34.5 and E-Fig. 34.4). If conservative measures do not improve the drainage of tears, the ophthalmologist may need to dilate the duct or pierce a hole in the intact membrane using a metal probe.[130,131] These infants are induced with general anesthesia, and when the level of anesthesia is sufficient, the ophthalmologist completes the procedure in a few minutes. To confirm that the duct is patent, the ophthalmologist should establish metal-metal contact using one probe within the duct and a second probe within the nostril.[132] Alternatively, the ophthalmologist may inject

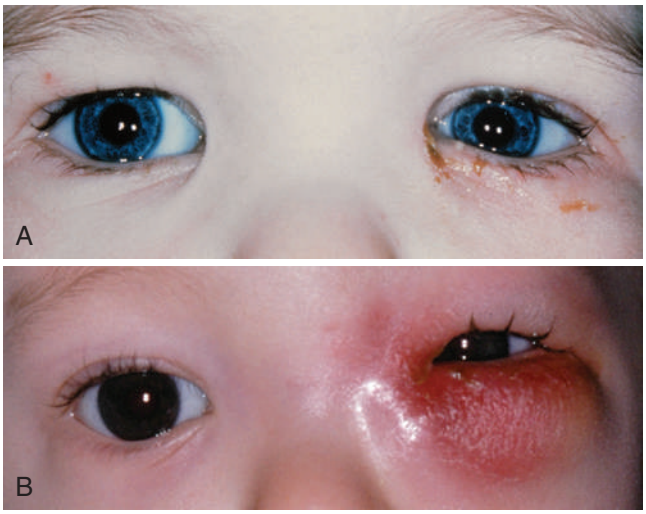

FIGURE 34.5 Nasolacrimal duct obstruction manifests with different degrees of infraorbital inflammation, from mild obstruction with minor infection and mucoid material accumulation **(A)** to severe obstruction with periorbital or preseptal cellulitis **(B)**. Both may require dacryocystorhinostomies.

fluorescein into the nasolacrimal duct and detect the fluorescein on a pipe cleaner in the nasal airway. In both instances, fluorescein or blood may reach the larynx and trigger breath-holding or laryngospasm. To avoid this, it is prudent to tilt the operating table to a 5- to 10-degree Trendelenburg position and place a small roll under the child's shoulders to pool the fluids away from the larynx. These secretions are suctioned out of the oropharynx and nasopharynx before emergence. Anesthesia may be maintained by face mask inhalation or with IV agents. The infant is awakened, and postoperative analgesia may be offered with acetaminophen or opioids, or both, as necessary.

Alternatively, an endonasal endoscopic approach may be used for complicated or recurrent dacryorhinocystotomy.[133,134] Endoscopic-assisted probing significantly increases the duration of the procedure and requires airway control to facilitate the surgeon's approach and to protect the child from aspirating blood during the procedure, but this approach yields results similar to an external approach.[135] In older children with bilateral obstruction, endoscope-assisted probing increased the long-term success rate.[136]

PTOSIS REPAIR

Ptosis (i.e., blepharoptosis) means "drooping of the eyelid." This condition can be congenital or acquired, and it may be associated with amblyopia or astigmatism. If eyelid closure is complete in infancy, occlusion amblyopia will occur, and this may require urgent attention. Otherwise, surgery for ptosis is often performed in later childhood. These children should be investigated for an underlying disease (e.g., muscle diseases such as myasthenia gravis, malignant hyperthermia).[137] The surgical approaches require a quiet surgical field, and the surgeon makes a great effort to produce a symmetric repair.

CATARACT SURGERY

Cataracts are opacifications of the lens of the eye (Fig. 34.6). Cataracts in children may be congenital, posttraumatic, or metabolic in origin.[138] Congenital cataracts require surgery very early in life to permit photostimulation of the retina.[139] Although the surgery can be performed as an outpatient, the formerly premature and young infant may require monitoring for postoperative anesthetic-induced

E-FIGURE 34.4 This child presented with bilateral congenital dacryocystoceles (i.e., small ectatic saccules of the nasolacrimal ducts) that will require surgical intervention. The procedure requires more time than unilateral duct probing to relieve the medial obstructions, and it may require airway instrumentation and control.

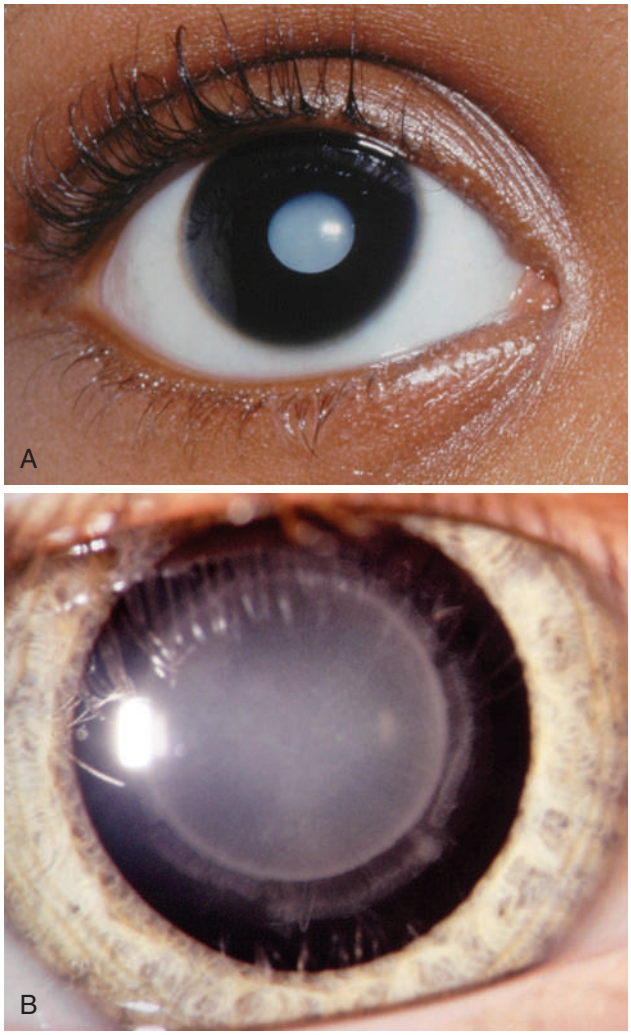

FIGURE 34.6 A, The right red reflex is absent in a child with a cataract that requires removal. **B,** The close-up photograph shows a nuclear cataract, which is associated with many inborn errors of metabolism in childhood. Cataracts that are not central or spherical may be caused by trauma or abuse.

respiratory depression or apnea. Cataracts are associated with some systemic diseases, and intraocular lens implants are often offered to improve the long-term visual prognosis.[140] The child should be examined carefully for dysmorphology, with close attention to issues of airway management and the cardiorespiratory system. One study demonstrated superior postoperative analgesia with a subtenon block compared with IV fentanyl.[141]

RETINOBLASTOMA

Retinoblasoma occurs in about 9000 children yearly.[142,143] Mutations in specific genes are believed to cause these tumors, which are the most common primary malignant tumors in children. The pathognomonic defect is a mutation in the *RB1* gene on chromosome 13. These tumors have a strong familial and hereditary component with sporadic mutations and may be unilateral or bilateral.[144] They are most commonly recognized by a lack of the typical red light reflex in the infant's pupil.[145] Treatment includes chemotherapy,[146] injection of bevacizumab,[147,148] intraarterial chemotherapy, and multiple treatments with proton beam radiation.[149,150] Many children retain useful vision with proton beam treatments and there does not seem to be an increased incidence of associated secondary malignacy.[151] These children require multiple anesthetics for the initial evaluation, CT planning, and construction of a fiberglass mask for immobilization during treatments. This is then followed by placement of central venous access, which allows all 25 to 30 subsequent treatments to be performed under deep propofol sedation with maintenance of a natural airway with spontaneous respirations. Children with extraocular disease are treated with larger doses of chemotherapy followed by delayed enucleation.[152]

ENUCLEATION

Enucleation of the eye may be necessary when a child has an intraocular tumor (e.g., retinoblastoma) (Fig. 34.7),[153] a ruptured globe or ocular trauma,[154] recurrent or chronic infections, or a blind, painful eye. *Leukocoria* is the term meaning "white pupil." The differential diagnosis is extensive and includes many intraocular tumors. Other disorders causing leukocoria include Coats disease, cataract, coloboma, and *Toxocara canis* infection. When necessary, the entire globe must be removed, and all bleeding points are coagulated. The OCR may occur during this procedure and may be attenuated by infiltration with a local anesthetic. Prophylactic antiemetics are often administered because PONV is common.

VITRECTOMY

Vitrectomy may be necessary for retinal injury or detachment induced in circumstances of nonaccidental trauma or ROP.[155] Any infant or child presenting acutely with a closed head injury from suspected abuse should have an ophthalmologic consultation to completely evaluate all orbital structures.[156] These delicate tissues may demonstrate pathology that requires long-term follow-up or urgent medical or surgical therapy. Glaucoma may occur with hyphema or lens subluxation or dislocation with tearing of the support tissue. Early diagnosis is paramount if surgical intervention is to have the greatest benefit.

RETINOPATHY OF PREMATURITY TREATMENT

Preterm infants may present with multiple ocular pathologic conditions, but none is more common than ROP. It has been extensively studied,[20] and multiple collaborative trials have reported their results and recommendations for medical and surgical interventions, including intravitreal bevacizumab.[157–166] The cause is unknown, but oxygen-related theories have been described for more than 40 years. Because of this concern, oxygen range targeting has become common[167–169] to reduce the oxidative stress[170] on the infant in general and to reduce the effect of oxygen on neovascularization in the eye.

Laser and cryotherapy are common treatments for this condition.[157,158] Because of the delicacy and exacting accuracy required in laser procedures, we routinely intubate the trachea and use neuromuscular relaxants. This facilitates the immobile field necessary for the surgeon and provides better perioperative physiologic stability for the infant.[171] The complications of prematurity determine whether extubation is possible, and many infants require postoperative ventilation, if only for a brief period or overnight.[172] The operative environment should be kept warm to reduce thermal stress on the infant.

ACKNOWLEDGMENT

We wish to acknowledge the prior contributions to this chapter of Susan A. Vassallo, MD, and Lynne R. Ferrari, MD.

Children with Down syndrome have multiple systemic conditions of importance to the anesthesiologist. They are not exclusively of interest owing to CHD. Anesthesia-related complications occur more frequently in children with Down syndrome than other children presenting for noncardiac surgery, and prevention of complications is essential by means of thorough evaluation and planning, particularly appropriate consultation with cardiologists regarding residual or current CHD and the possibility of cervical spine instability.

Saugstad OD, Aune D. In search of the optimal oxygen saturation for extremely low birth weight infants: a systematic review and meta-analysis. *Neonatology*. 2011;100:1-8.

Advances in neonatology continue to reduce morbidity and mortality for these fragile children. Oxygen-saturation targeting is becoming a mainstream technique. This has implications for the management and oxygen support strategies for infants coming to the operating room for ocular and other surgical procedures. Because volatile anesthetics impair hypoxic pulmonary vasoconstriction, a supplemental oxygen requirement should be anticipated, but oxygen-saturation targets should be considered for optimal care.

Shen YD, Chen CY, Wu CH, et al. Dexamethasone, ondansetron, and their combination and postoperative nausea and vomiting in children undergoing strabismus surgery: a meta-analysis of randomized controlled trials. *Paediatr Anaesth*. 2014;24(5):490-498.

This metaanalysis examined 13 randomized controlled trials and found that PONV occurred in 68% of placebo-treated children compared with 34% of dexamethasone-treated children and 37% of ondansetron-treated children. The combination was significantly more effective at reducing PONV than either drug alone.

Stephen E, Dickson J, Kindley AD, et al. Surveillance of vision and ocular disorders in children with Down syndrome. *Dev Med Child Neurol*. 2007;49:513-515.

Children with Down syndrome have many different ocular disorders. In addition to the multiple systemic issues of concern for the anesthesiologist described in the chapter, this reference provides insight into the ocular diseases that may require surgical therapy.

Trauma

PEDIATRIC PLASTIC SURGERY is performed in children of all ages, even in utero.[1] However, the majority of children who undergo plastic surgical and reconstructive procedures are between 2 and 9 years of age, with a median age of 5 years. A wide spectrum of associated craniofacial abnormalities, underlying medical conditions, and surgical procedures characterizes this pediatric population. Consequently, a thorough preoperative assessment, consultation with medical and surgical teams, and anticipation and preparation for potential complications are of paramount importance to ensure a successful perioperative outcome. Many procedures are performed on the head and neck and require thoughtful coordination between the anesthesiologist and surgeon. A thorough understanding of the procedure allows for selection of the optimal anesthetic plan. The incidence of major morbidity and mortality has been reduced over the past 30 years from 16.5% and 1.6% to less than 0.1% and 0.1%, respectively, in children undergoing major craniofacial surgeries.[2]

Cleft Lip and Palate

Cleft lip and palate are among the more common congenital malformations, occurring with an estimated incidence of approximately 1 in 600 births worldwide.[3,4] More common in males than in females and more common in Asians and Latin Americans and least in Africans, this malformation likely results from both environmental and genetic causes. Parental occupation, in particular paternal farming, increases the risk of cleft lip or palate in the offspring, whereas the maternal occupation presents no additional risk.[5] Folate metabolism disturbances and increased maternal homocysteine concentrations also may be contributory.[6] Cleft lip with or without cleft palate has been linked to several loci on chromosomes 1, 2, 4, 6, 14, 17, 19, and 22, suggesting a genetic basis for some of these anomalies.[7–10] Three genes have been associated with syndromic cleft lip and palate: T-box transcription factor-22, poliovirus receptor–like-1, and interferon regulatory factor-6 *(IRF6)*. Gene mutations have been identified in only a small fraction of nonsyndromic cleft lip and palate.

These disorders are associated with more than 400 syndromes; the more common syndromes are presented in Table 35.1. Cleft lip and palate begin as a defect in palatal growth in the first trimester of pregnancy. Fetal magnetic resonance imaging (MRI) provides a greater degree of resolution of defects in the posterior palate and lateral extent of cleft with greater diagnostic accuracy than ultrasound. MRI also enables early detection of potential syndromic conditions by providing a complete study of the fetal head and biometric development of the facial bones.[11]

Primary cleft lip repair is usually undertaken at approximately 2 to 3 months of age, whereas primary cleft palate repair occurs at 6 to 10 months. Surgery for lip or nose revision usually takes place in early childhood, and palatal revision and alveolar bone grafts occur at approximately 10 years of age. Rhinoplasty and maxillary osteotomy to complete the repair may take place at 17 to 20 years of age. Pharyngoplasty may be required for velopharyngeal incompetence secondary to anatomic or neurologic dysfunction to improve speech development and prevent nasal regurgitation during eating.

ANESTHETIC CONSIDERATIONS

Surgical correction of a cleft lip defect is usually performed at 2 to 3 months of age to allow sufficient time for maturation and associated abnormalities to become apparent. Preoperative assessment may reveal abnormalities such as mandibular hypoplasia in Pierre Robin sequence (PRS) (Fig. 35.1 and E-Fig. 35.1) or restricted neck movement as in Klippel-Feil syndrome (E-Fig. 35.2).[3] PRS is defined as the triad of micrognathia, glossoptosis (caudally displaced insertion of the tongue), and respiratory distress in the first 24 to 48 hours after birth. The presence of other anomalies might warrant additional clinical or laboratory investigations. Cleft lip repair usually involves minimal blood loss, so for children with hematocrit values greater than 30%, additional preoperative

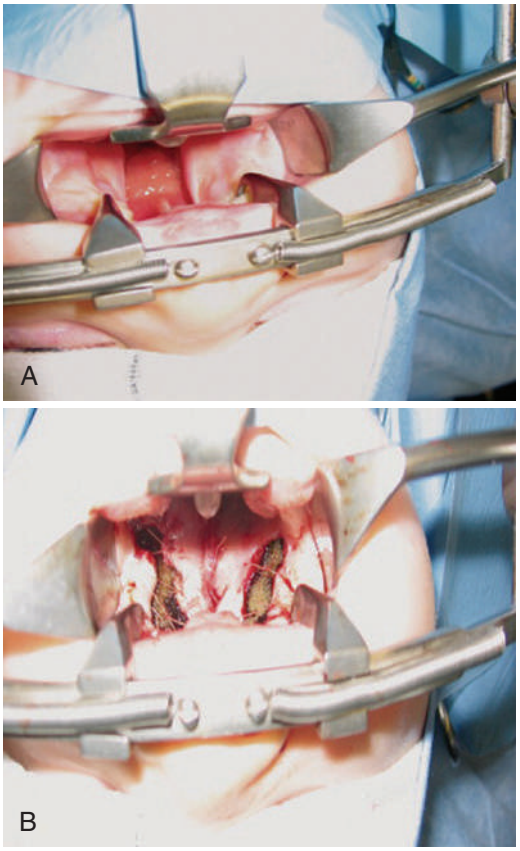
laboratory testing is unnecessary. A sample for type and screen is usually sufficient for infants with a hematocrit value less than 30%.[12]



The frequency of difficult airways in children with cleft lip and palate varies from 2.9% to 23%.[13–17] The incidence of difficult intubation in children with bilateral cleft is greater than that with unilateral cleft.[15] Furthermore, micrognathia is an independent predictor of a difficult airway. The incidence of difficult direct laryngoscopy is approximately 50% in children with micrognathia but only about 4% in those without. In infants and young children, micrognathia may be subtle and not always easily detected. However, the presence of microtia, which is associated with a 42% incidence of difficult intubation with bilateral compared with 2% with unilateral microtia, should prompt a closer examination of the mandible for hypoplastic growth and raise the possibility of a hemifacial microsomia or Treacher Collins syndrome.[18] Intubation difficulty (by direct laryngoscopy) with isolated micrognathia decreases with increasing age, with the greatest difficulty presenting in infants younger than 6 months. This has been attributed to rapid growth of the mandible, which catches up to the maxilla, thereby aligning the two bones, by 2 years of age in most cases. A careful review of previous anesthetic records may forewarn of a difficult airway. In a second study that reported the frequency of difficult intubations in young infants with cleft lip, cleft palate without PRS, cleft-lip-palate and cleft palate, and cleft palate with PRS was 0, 2.7%, 10%, and 23%.[17] Difficult airways increased with early airway and feeding problems ($P < 0.0001$). In the isolated cleft palate, a wider cleft was associated with a significantly more difficult laryngoscopy.

Induction of anesthesia via face mask is usually uncomplicated in infants with cleft lip and palate. Laryngoscopy should be performed using a straight blade via a right paraglossal approach (blade inserted into the pharyngeal gutter with tongue displaced to the left),[19] taking care to avoid dropping the blade into the cleft (see also Fig. 14.28A-C). If the mandible is hypoplastic, external laryngeal manipulation may be required to bring the larynx into view. In some centers, the tongue is sutured to either the mandible or lower lip to preclude airway obstruction in infants with PRS in the postnatal period. In such instances, the tongue cannot be displaced to the left to expose the larynx. To facilitate laryngoscopy in such cases, the tongue is first released from the lower lip using ketamine sedation followed by direct laryngoscopy. Alternatively, selection of a primary airway management strategy other than direct laryngoscopy (e.g., video laryngoscopy, fiberoptic intubation through a supraglottic airway) circumvents this problem and may be a preferable approach with a greater success rate on the first attempt (see Chapter 14).[20]

A variety of tracheal tubes can be used to secure the airway for cleft lip and palate surgery, although the ideal tracheal tube is perhaps the oral Ring-Adair-Elwyn (RAE) tube, which can be fixed centrally to the chin to facilitate optimal surgical access. It should be noted that preformed tracheal tubes vary in length from bend to tip for uncuffed and cuffed tubes.[21] Seven brands of preformed tracheal tubes were compared for the same size inner diameter tubes; the distance from the bend to the tip varied by 0 to 1 cm for oral cuffed tubes but 0 to 4 cm for uncuffed oral tubes. Of greater concern was that the variability for preformed nasal tubes was even greater; cuffed nasal tubes varied by 0 to 5.5 cm and uncuffed varied from 2 to 9 cm (bend to tip). The risk of an endobronchial intubation when a cuffed oral preformed tube replaced an uncuffed tube of the same diameter was 0%–27%, whereas when a cuffed nasal preformed tube replaced an uncuffed tube of the same size, the risk of an endobronchial intubation increased to 50%–100%. Thus the risk for endobronchial intubation varies among manufacturers and is greater with nasal than oral preformed tracheal tubes.

Throat packs usually impinge on the surgical field and are not normally required for cleft palate repair. Ventilation is usually controlled for the duration of the procedure (~1–2 hours). Inhalational or intravenous (IV) anesthetics combined with a short-acting opioid such as fentanyl (1–2 µg/kg) can be used for maintenance of anesthesia. Bilateral infraorbital nerve blocks may be used to provide postoperative analgesia for cleft lip repairs (see Fig. 42.12A-C and Chapter 42 videos). Such blocks reduce the need for opioids and antiemetics, improve the ability to feed,[22,23] and increase parental satisfaction.[24] Additional evidence suggests that the incidence of emergence agitation is reduced with the use of infraorbital nerve blocks.[25] A combination of infraorbital and external nasal nerve blocks for pain control after cleft lip repair is an alternative.[26]

During cleft palate surgery, the pharyngeal space is reduced dramatically; postoperative nasal trumpets may be required (often placed by the surgeon) to maintain airway patency and permit suctioning the airway without damaging the palatal repair (Fig. 35.2 and E-Fig. 35.3A and B). At the end of surgery, the trachea is extubated after the upper airway reflexes have returned and the child is completely awake. These children are at particular risk

E-FIGURE 35.3 Oral views before **(A)** and after **(B)** repair of cleft palate. Closure of the cleft palate is possible through tension-releasing incisions. The oropharyngeal space is dramatically reduced at the end of the procedure. Children unable to mouth breathe before surgery (e.g., those with a very small mandible) are dependent on patent nasal airways at the end of the procedure.

FIGURE 35.2 Nasal airways are often placed at the end of cleft palate or pharyngoplasty surgery to ensure that a patent airway is maintained.

for acute upper airway obstruction in the immediate postextubation period as a result of upper airway narrowing, edema, blood, and residual anesthetic effects.[27–32] Accordingly, it is very important to extubate the trachea only when the child is completely awake. Intraoperative dexamethasone (0.5 mg/kg) may be administered to mitigate postoperative airway edema. Late postoperative edema[33] and severe subcutaneous emphysema are additional complications. Upper respiratory tract infections are common in this age group. If airway infections are present, they should weigh heavily in favor of delaying surgery until they are resolved. Antibiotics may reduce the incidence of postoperative respiratory complications.[34] Adverse airway events, including postoperative airway obstruction, oxyhemoglobin desaturation, bronchospasm, laryngospasm, reintubation, and unplanned postoperative intensive care unit (ICU) admission have been identified in as many as 23% of children undergoing cleft palate repair[35]; the presence of a craniofacial syndrome, history of preoperative airway problems, and both surgeon and anesthesiologist inexperience were significantly associated with airway complications.

Arm restraints are used in many centers to prevent suture disruption. These children are monitored for signs of upper airway obstruction during the recovery period for approximately 48 hours.[27] As soon as the child is awake, feeding with clear fluids is allowed. Postoperative pain is managed with a combination of opioids and acetaminophen. Rectal acetaminophen administered before surgery did not reduce postoperative opioid requirements in children undergoing cleft palate repair. In part this may be attributed to local infiltration at the surgical site and the slow and variable absorption of acetaminophen by the rectal route. However, IV acetaminophen has opioid-sparing effects in these children that may be useful in certain scenarios.[36,37] Sphenopalatine and infraorbital nerve blocks (see Chapter 42, Fig. 42.12) with a long-acting local anesthetic can be placed at the end of the procedure to prevent pain after cleft lip and palate repair.[22] Palatal nerve block (nasopalatine, greater and lesser palatine)[38] or a bilateral suprazygomatic maxillary nerve block reduce postoperative pain and favor early feeding.[39]

Children who are scheduled for elective pharyngoplasty are usually school age, having undergone cleft palate repair at an earlier age. The primary objective of this procedure is to restore velopharyngeal competence for speech development, which can be achieved by a pharyngeal flap, sphincter pharyngoplasty, or palatal lengthening (Furlow double-opposing Z-plasty palatoplasty). The anesthetic goals and management are similar to those discussed for cleft palate repair.

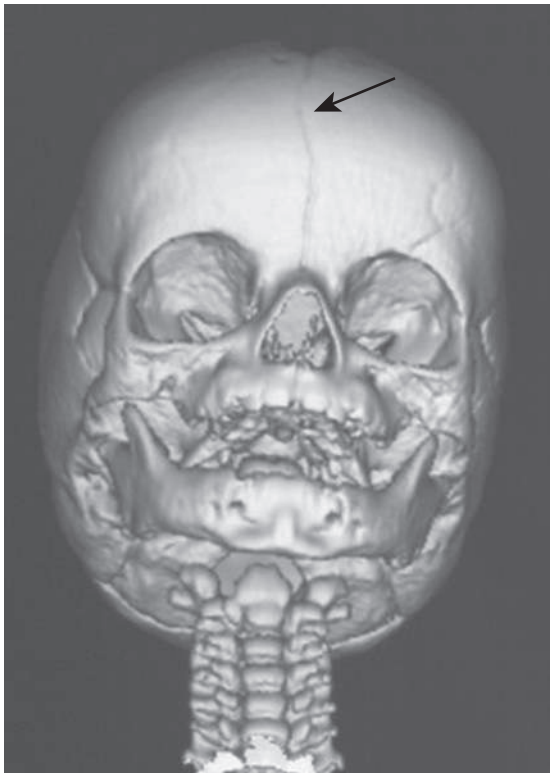
TABLE 35.2 Classification of Craniosynostosis

Nonsyndromic (primary) ~80%: Single suture closed, isolated finding
Syndromic ~20%: Two or more sutures closed, often with associated clinical findings. More than 150 syndromes have been described; the more common syndromes are as follows:
Crouzon
Apert
Pfeiffer
Saethre-Chotzen
Carpenter (acrocephalopolysyndactyly type II)
Muenke
Crouzonodermoskeletal
Shprintzen-Goldberg
Loeys-Dietz
Jackson-Weiss
Beare-Stevenson
Cole-Carpenter
Kleeblattschädel
Fibroblast growth factor receptor mutations 1 and 2
Metabolic and other causes
Rickets
Bone metabolic disorders (hypophosphatasia)
Achondroplasia
Prematurity

Craniosynostosis

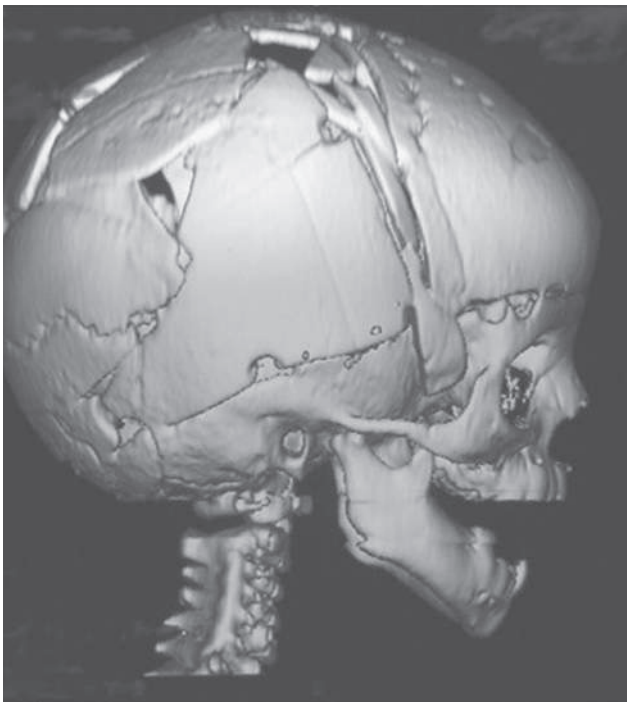
Craniosynostosis, a congenital anomaly in which one or more cranial sutures close prematurely, occurs in approximately 1 in 2000 to 3000 births, affecting males more frequently than females.[40–42] Embryologically, the cranial vault starts to ossify at 8 weeks after conception; fusion of the parietal and frontal bones is usually completed by 7 months after conception. Postnatally, the anterolateral fontanelle closes by 3 months, the posterior fontanelle by 3 to 6 months, the anterior fontanelle by 9 to 18 months, and the posterolateral fontanelle by 2 years. Premature osseous obliteration of a bony suture might result from the absence of osteoinhibitory signals from the suture. Craniosynostosis may be categorized as simple (or nonsyndromic) (60%-80% of cases), involving closure of one suture, or complex (or syndromic) (20%–30%), involving closure of two or more sutures and is often associated with a variety of clinical features and metabolic diseases (Table 35.2).[41,43,44]

FIGURE 35.3 Infant with classic craniosynostosis. The shape of the child's head may not reflect the severity of the defect. The defect is best appreciated by three-dimensional magnetic resonance imaging reconstruction.



In the child with craniosynostosis, fusion of a cranial suture restricts normal bone growth perpendicular to the affected suture. Compensatory growth and expansion of the cranial vault occurs parallel to the affected suture, and there is a characteristic skull deformity associated with the different sutures involved (Fig. 35.3 and E-Fig. 35.4).[41] The frequency of single suture closures varies with the specific suture: sagittal (50%), coronal (20%), and metopic (10%).[43] The coronal suture (especially bicoronal synostosis) is more commonly associated with syndromic craniosynostosis. Although approximately 80% of premature suture closures are isolated defects, the remaining 20% involve multiple suture closures associated with more than 400 syndromes that present with a myriad of clinical features (see Table 35.2); the more common syndromes that require craniofacial reconstruction are described later.[41,43] Syndromic craniosynostoses are commonly associated with gene defects in the fibroblast growth factor receptor (FGFR), which is involved in bone and cartilage development.

Apert syndrome occurs in less than 1 in 100,000 live births, usually as a sporadic mutation, although autosomal dominant inheritance patterns can occur with the *FGFR2* gene on chromosome 10. This syndrome phenotypically manifests as cloverleaf skull (craniosynostosis), hypertelorism, proptosis, midface hypoplasia, and syndactyly (upper or lower extremity). Development is often complicated by increased intracranial pressure (ICP) and obstructive sleep apnea (OSA).[45,46] Whether children with Apert syndrome develop normal intelligence quotients (IQs) is unclear; one study reported that 32% had IQs greater than 70.[47] The timing of cranial surgery may affect the child's IQ; surgery in the first year of life was associated with an IQ greater than 70 in more than 50% of children in one study, whereas surgery after the first year of life was associated with an IQ greater than 70 in only 7%.[47] Two other factors predicted improved IQ indexes: absence of a defect in the septum pellucidum and noninstitutional residence (i.e., family home residence). In contrast, more recent evidence failed to substantiate a salutary effect of early surgery on cognitive development. Indeed, cognitive development was related to the quality of the family environment and parental education and unrelated to brain malformation and the age of surgery.[48]



Crouzon syndrome is phenotypically similar to Apert syndrome but has different ophthalmologic defects, specifically, optic atrophy occurring in up to 20%, and the absence of hand and foot defects (e.g., syndactyly).[41,49] Fifty percent of Crouzon syndrome defects are sporadic mutations, and the remainder are familial with the same gene defect as Apert; *FGFR2* on chromosome 10. Pfeiffer syndrome occurs in approximately 1 in 25,000 live births. Most cases are familial with an autosomal dominant inheritance pattern that has its origin in defects in the *FGFR1* and *FGFR2* genes on chromosome 10, although many remain sporadic. The phenotype of Pfeiffer syndrome is similar to that of Apert syndrome but includes broad thumb, large first toe, polydactyly, and may be associated with a cartilaginous sleeve trachea. Children with Pfeiffer syndrome have normal intelligence. Carpenter syndrome is associated with craniosynostosis, syndactyly, cardiac defects, and obesity.[50] Cognitive impairment is common.[50] Muenke syndrome is more common, occurring in 1 in 30,000 births. It results from a mutation in the *FGFR3* gene. Affected patients have midface hypoplasia, ocular hypertelorism, strabismus, developmental delays, and intellectual disabilities.[41] A relatively new but rare syndrome, Shprintzen-Goldberg, is characterized by craniosynostosis and a phenotype that resembles that of Marfan syndrome.

Indications for cranial vault reconstruction include increased ICP, severe exophthalmos, OSA, craniofacial deformity, and psychosocial reasons. If uncorrected, the deformed cranium may cause severe neurologic sequelae, including visual loss and developmental delay.[51–63] Because rapid brain growth during infancy determines skull shape, surgical correction is undertaken within the first months of life to achieve the best cosmetic results.

Cranial vault reconstruction may involve the anterior or posterior aspect of the skull or both (total cranial vault reconstruction).[42] Less invasive approaches to correct craniosynostosis are available and may be associated with reduced morbidity. Surgical correction may use an open approach where the synostotic suture is excised followed by barrel-stave osteotomies to release the adjacent cranium and allow for normalization of skull shape with subsequent brain growth (Fig. 35.4 and E-Fig. 35.5). This technique is used in children younger than 6 months of age and is believed to be less invasive than total cranial vault reconstruction.[64,65] Endoscopic strip craniectomy is increasingly being used in early infancy because of benefits including reduced transfusion requirements and reduced hospital stay, compared with the open procedures. The principal disadvantage of endoscopic techniques is the requirement of 4 to 6 months of wearing a helmet postoperatively to promote normalization of skull shape.[42] Spring-assisted cranioplasty, a technique preferentially used in infants younger than 6 months, involves performing a midline osteotomy along the fused sagittal suture and placing springs across the osteotomy to increase the biparietal dimension.[42] Spring-assisted cranioplasty may be associated with reduced intraoperative blood loss, reduced transfusion requirement, and shorter duration of hospital stay.[66] In a single-center study of 100 children with spring-assisted craniosynostosis repair, no child was transfused and none was admitted to the ICU.[67] The primary disadvantage of this approach is the need for a second surgery to remove the springs. A meta-analysis

E-FIGURE 35.4 Frontal three-dimensional magnetic resonance imaging of a child with sagittal craniosynostosis. Note closed sagittal suture in the skull midline (*arrow*).

E-FIGURE 35.5 Three-dimensional magnetic resonance imaging of a child after extended strip craniectomy (see Fig. 35.4). This approach is commonly used in infants younger than 6 months of age. To protect the fragile skull bones, a protective helmet must be worn after surgery until cranial remodeling is complete.

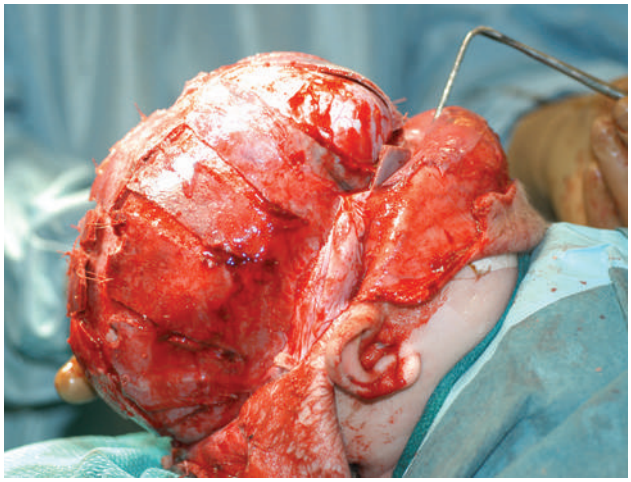


FIGURE 35.4 Child immediately before surgical closure after total cranial vault reshaping using strip craniectomy for sagittal craniosynostosis.

of the outcomes from calvarial remodeling, strip craniectomy, and spring-mediated cranioplasty in nonsyndromic sagittal synostosis demonstrated that the cephalic index (which is the ratio of the width of the outermost tables of the vault to the length of the outermost tables)[68] with calvarial vault was superior to strip craniectomy and that the former approach required more surgical time, involved more blood loss, a greater duration of stay, and greater costs than the other two approaches ($P < 0.0001$).[69]

The application of cranial vault distractors to achieve distraction osteogenesis is a technique increasingly used in children with syndromic forms of craniosynostosis.[70–72] This procedure involves a craniotomy (usually without reconstruction of the cut bone flap) combined with placement of distractors that are sequentially incrementally lengthened by turning an externalized screw beginning a few days postoperatively and continuing until the targeted cranial vault expansion is achieved. This technique has the advantage of shorter surgery and allows for greater expansion of the cranial vault than what can be achieved with a traditional cranial vault reconstruction. These children also need to return to the operating room for removal of the distraction hardware.

Preoperative assessment of children with craniosynostosis should focus on airway management, eye protection, and ICP. An important consideration in children with syndromic midfacial hypoplasia is its common association with OSA (50%–70% incidence) owing to associated narrowing of the nasopharyngeal space.[46,73,74] Although some recommend preoperative adenotonsillectomy to treat OSA in children with syndromic craniosynostosis, neither airway dimensions nor propensity toward airway collapse are improved. Midfacial advancement may be required to resolve OSA, and even then, residual airway obstruction may persist.[46,73] Preoperative endoscopy has been recommended to assess the severity of midfacial hypoplasia and whether OSA is likely to persist after midface advancement. Careful titration of opioids in the perioperative period is indicated if the child exhibits severe nocturnal desaturation (i.e., if the SaO_2 nadir is <85%) (see Chapter 33); children with OSA who have severe nocturnal desaturation require half the dose of opioids that children without nocturnal desaturation require, so a normal dose of opioid is actually a relative overdose in this population.[75] Upper airway obstruction may also occur postoperatively in children who received opioids as a direct effect of opioids on the hypoglossal nucleus.[76]

Preoperative laboratory assessment should include a complete blood cell count and a specimen for blood type, antibody screening, and crossmatching of blood. Many centers also routinely screen for coagulation abnormalities with a preoperative prothrombin time and the activated partial thromboplastin time.

Postoperative pain is generally not severe and is managed effectively with a combination of acetaminophen, nonsteroidal antiinflammatory drugs (NSAIDs), and IV opioids. Opioids remain the mainstay of pain management, but careful titration is indicated if OSA is present. Given the small incidence of craniosynostosis and the large variability in the management of these patients, multicenter trials are required to determine the optimal management strategy for these children.[77]

AIRWAY MANAGEMENT

Meticulous preoperative planning and evaluation of the airway are essential, particularly for children with known or possible OSA.[73] Upper airway obstruction following induction of anesthesia in children with midface hypoplasia should be anticipated. This is usually readily managed with a jaw-thrust/subluxation technique or insertion of an oral airway. Occasionally, however, face mask ventilation may prove challenging owing to difficulty obtaining a good mask seal.[78] External fixator devices on the face may also present challenges in managing the airway (E-Fig. 35.6), and it is essential to craft the optimal plan and make necessary preparations should problems arise (e.g., emergent hardware removal, wire cutting). A laryngeal mask is a valuable rescue tool in these scenarios and should be readily available before anesthetic induction.

In the majority of children with craniosynostosis, the anatomy of the mandible and the temporomandibular joint is normal, as are upper airway dimensions, resulting in an easy direct laryngoscopy and tracheal intubation. Rarely, mandibular hypoplasia may complicate an otherwise straightforward laryngoscopy and tracheal intubation. Abnormal neck mobility also may pose additional challenges for laryngoscopy and tracheal intubation.

BLOOD LOSS, COAGULOPATHY, AND HYPONATREMIA

Crystalloid solutions are commonly administered for minimal to moderate surgical blood loss and fluid shifts during craniosynostosis surgeries. Although lactated Ringer's solution (or Hartmann's solution) is most commonly used in North America, some advocate using normal saline solution because it may be less likely to induce hyponatremia and an acid-base disturbance than lactated Ringer's solution. However, a recent study comparing the two solutions suggests that normal saline solution is more likely to induce (metabolic) acidosis than lactated Ringer's solution in infants undergoing craniosynostosis.[79] Additionally, hyponatremia is usually mild, self-limited, and asymptomatic. The results of large adult cohort studies have demonstrated an association between hyperchloremic metabolic acidosis after normal saline and major complications, morbidity, mortality, and increased resource use.[80,81] Isotonic balanced solutions may be the best choice for crystalloid management.

Surgery for craniosynostosis is associated with the potential for cardiac arrest as a result of sudden massive blood loss or underestimated blood loss.[2,43,82,83] Although these procedures are extradural, significant bleeding from the scalp and cranium can occur, especially following inadvertent tears of dural venous sinuses. The blood loss can be so rapid during the surgery that the expression "trauma in progress" is applicable. The risks of massive blood loss and the need for invasive monitoring are primarily determined by the type of surgery.[83] In children undergoing endoscopic strip

E-FIGURE 35.6 External fixation devices present unique challenges to the anesthesiologist for orotracheal intubation. If necessary, these devices must be released to secure the airway.

craniectomy, weight less than 5 kg, those undergoing sagittal endoscopic craniectomy, those with syndromic craniosynostosis, and earlier date of surgery are associated with blood transfusion.[84] Some centers advocate commencing blood transfusions at the time of skin incision (particularly in infants) to prevent hemodynamic instability and the need for a rapid transfusion, but this must be tempered by whether the surgery is open or endoscopic (see later discussion).

To manage the large volume and rapidity of the blood loss, it is essential to establish large-bore peripheral venous access. Central venous access (see also Figs. 49.3 and 49.4), usually via the internal jugular vein, is most commonly reserved for children in whom obtaining adequate peripheral venous access proves difficult but overall has been used in a minority of cases for rapid transfusion.[85] Strategies that are important to preclude hyperkalemic cardiac arrest include infusing blood stored less than 7 days old (see Wake Up Safe; http://www.wakeupsafe.org/Hyperkalemia_statement.pdf?201501300915; accessed January 7, 2015) and (most importantly) avoiding hypovolemia.[86,87] If only older blood is available, it should be warmed and administered slowly through a peripheral IV line to reduce the risk that hyperkalemia is present when the blood reaches the right atrium.[42] Estimation of ongoing blood loss can be difficult because of the use of large volumes of irrigation fluid and difficulty quantifying blood loss onto surgical drapes and gowns.[88] Invasive arterial blood pressure monitoring and serial blood gas sampling are indicated in this type of surgery (see Fig. 49.11A-D). A urinary catheter should be inserted to monitor urine output.

Several blood conservation strategies have been proposed for this type of surgery, including preoperative recombinant human erythropoietin, acute normovolemic hemodilution, antifibrinolytics, and induced hypotension (see Chapter 12 for a more detailed discussion). Of primary importance is meticulous surgical technique and attention to hemostasis. Bleeding from the scalp incision may be reduced by infiltration with a dilute (1:400,000) epinephrine-containing solution. The use of the reverse Trendelenburg position may help to decrease venous pressure and blood loss from osteotomy sites but may increase the risk of venous air embolism (with a reported frequency of 5%–80%; see later discussion). For this reason, the horizontal position is preferred.

Blood-conserving dual therapy with recombinant human erythropoietin (to optimize preoperative hematocrit) and use of a cell saver has reduced transfusion in children undergoing craniosynostosis repair.[89] Administration of preoperative recombinant human erythropoietin, in combination with elemental iron (4 mg/kg per day orally to a maximum of 200 mg/day for 6 weeks) increases the preoperative hematocrit value and may decrease the need for autologous blood transfusion.[90,91] If iron stores are at all compromised, iron therapy combined with oral vitamin C (to increase gastrointestinal absorption) should begin 3 weeks before erythropoietin therapy.[92] Currently this technique is rarely used, likely because of high costs as well as the black box warning applied to synthetic erythropoietin drugs related to increased likelihood of major complications in adult populations receiving these drugs.

Little evidence exists to suggest that autologous blood donation decreases perioperative morbidity in craniosynostosis surgery.[93,94] While infants as young as 3 months have predonated, this technique is of questionable value and should not be pursued in this population. Instead, simpler and more cost-effective techniques should be used such as meticulous surgical attention to hemostasis and administration of antifibrinolytics.[95]

Acute normovolemic hemodilution is a labor-intensive technique in which blood is collected from the child after induction of anesthesia but immediately before surgery and replaced with an appropriate volume of crystalloid or colloid, such as 5% albumin. This technique has been used in combination with other techniques, especially preoperative erythropoietin to reduce transfusion in craniosynostosis surgery.[96,97] The maximum potential blood savings with this technique is modest at best.[98] Despite some reports of efficacy, owing to the labor-intensive nature of the technique and modest blood savings, this technique is rarely used in craniofacial surgery.

The coagulation profile and clotting factors after fresh frozen plasma (FFP) or 5% albumin during craniofacial surgery have been compared in a nonrandomized study in infants younger than 12 months of age.[99] The increases in activated partial thromboplastin time and decreases in the plasma concentration of factors XI and XIII and antithrombin III were less after intraoperative FFP than after 5% albumin. Fibrinogen concentrations remained stable in the FFP-treated group but decreased in the albumin-treated group. A hemostatic resuscitation strategy, similar to that used in massive hemorrhage from trauma, has been applied in pediatric craniofacial surgery. With this approach, blood loss is replaced using red blood cells and FFP in a 1:1 ratio. The central tenet of this approach is to prevent dilutional coagulopathy (see also Chapter 12). At one center where blood loss frequently exceeds a blood volume, FFP and packed red blood cells from the same blood donors were used for blood loss replacement; this technique essentially eliminated coagulopathy, resulted in fewer perioperative blood donor exposures,[100] and is most likely to be useful where blood loss is expected to approach or exceed the circulating blood volume. Recombinant factor VIIa has been used successfully for intractable hemorrhage during cranial vault reconstruction in an infant, although this was an extreme circumstance in an isolated case.[101]

Antifibrinolytic therapy may decrease blood loss during craniosynostosis repair in children. Tranexamic acid reduces blood loss and transfusions in pediatric craniofacial surgery[102,103]; the recommended dosing regimen is a loading dose of 10 mg/kg followed by a continuous infusion of 5 mg/kg per hour. The incidence of adverse events, including seizures and thromboembolic events, in children treated with or without antifibrinolytics during craniofacial reconstructive surgery was similar.[104]

Another antifibrinolytic, ε-aminocaproic acid (EACA), is effective in reducing bleeding in cardiac and spinal procedures. In observational studies, EACA has been associated with reduced blood loss and transfusion in craniosynostosis surgery; these findings have yet to be confirmed in a controlled study.[105,106] The dosing for infants undergoing craniofacial surgery is a loading dose of 100 mg/kg followed by 40 mg/kg per hour.[107] A recent single-center prospective study of 120 infants undergoing craniosynostosis repair used thromboelastography and the platelet fibrinogen product to guide the administration of blood products.[108] Using multivariate analysis and receiver operating curves to assess four parameters: K-time >2:1, MA <55 mm, α-angle <62 degrees, and the platelet-fibrinogen product <343, infants with all four predictors had a 92% probability of a blood loss of 60 mL/kg or more, whereas those with none of these parameters had an approximately 10% probability.

Induced hypotension, defined as a 10% to 20% reduction in the mean arterial blood pressure, may decrease intraoperative surgical blood loss and operating time,[109] although studies demonstrating its effectiveness and safety during craniosynostosis surgery are lacking. The lower limits of safe blood pressure reduction

in infants are unknown. A variety of pharmacologic agents have been used to induce hypotension, including inhalational agents, vasodilators, β-blockers, and remifentanil.[109,110] Invasive arterial pressure monitoring is essential whenever hypotensive anesthesia is used. Induced hypotension should be used with great caution in the presence of increased ICP because of the risk of compromising cerebral perfusion pressure (i.e., the difference between mean arterial pressure [MAP] and either ICP or central venous pressure, whichever is greater). The risks of inadequate cerebral and end-organ oxygen delivery during hypotension are magnified by coexistent anemia. It is considered prudent to maintain normovolemia and normocapnia when induced hypotension is used (see Chapter 12). Many practitioners have determined that the potential benefits (reduction of blood loss, shorter surgery) of this technique are outweighed by the risks (cerebral ischemia and irreversible brain injury, blindness, end-organ damage). Rather than an approach of induced hypotension, some use a strategy of deliberate normotension, where the anesthetic is tailored to avoid blood pressures greater than baseline.

Whether used alone or in combination,[97,111,112] the preceding techniques seldom obviate the need for any blood transfusions during craniofacial surgery. In a retrospective review of 60 children who underwent craniofacial surgery at a single institution, half of the children required fewer transfusions and had a reduced length of stay that were attributed to the preoperative use of iron and erythropoietin, the use of a blood-recycling device intraoperatively, and a reduced minimum hemoglobin concentration for transfusion (<7 mg/dL) compared with a placebo group.[113] Given the potential for acute large-volume blood loss IV access with large-bore catheters remains essential and at least 2 units of packed red blood cells (PRBCs) should be crossmatched and available in the operating room at all times. IV fluids should be administered via a fluid warmer to prevent hypothermia. Maintaining normothermia preserves coagulation function and theoretically reduces bleeding and transfusion-related complications.[114] Based on adult data, coagulopathy from dilution of soluble clotting factors on average develops when 142% of the circulating blood volume has been lost and replaced with PRBCs and crystalloid, and with thrombocytopenia developing after an average of 2.3 blood volumes were lost (see also Chapter 12).[115] Estimating the blood loss based on the number of blood volumes of blood products administered, physical estimates of blood loss, and an assessment of hemostasis in the surgical field are useful empiric and clinical indicators for the need for hemostatic blood product administration. Serial determinations of the international normalized ratio prothrombin time (INR), partial thromboplastin time (PTT), platelet count, and fibrinogen concentration and the use of thromboelastography help to identify coagulopathy and guide hemostatic blood product administration.[108,116]

Endoscopic repair of craniosynostosis has become a rapidly growing surgical approach to reduce bleeding and decrease morbidity.[117,118] Independent risk factors for bleeding during endoscopic strip craniectomy include low body weight (<5 kg), sagittal suture surgery (related to proximity to the sagittal venous sinus), syndromic craniosynostosis, and earlier date of surgery.[84]

Hyponatremia and cerebral salt-wasting syndrome are associated with craniosynostosis repair.[119–123] Both intraoperative and postoperative hyponatremia have been described, with the latter occurring in approximately 30% of children. In a retrospective review of a cleft palate and craniofacial database, postoperative hyponatremia was associated with preoperative increased ICP, blood loss, and female gender with normal preoperative ICP.[123] The average reduction in sodium concentration was more pronounced in children who received hyponatremic (hypotonic) (5% dextrose and 0.2% or 0.5% NaCl) compared with normonatremic (isotonic) postoperative IV fluids.[123] The perioperative use of balanced salt solutions is recommended to prevent hyponatremia (see also Chapter 9).

Increased Intracranial Pressure

Early surgery for craniosynostosis is often indicated to prevent increases in ICP.[44,45] One-third of children with craniofacial dysostosis syndrome and 15% to 20% of children with single-suture craniosynostosis have increased ICP (>15 mm Hg).[124] Approximately 40% to 50% of children with syndromic craniosynostosis have associated hydrocephalus, although differentiation from nonprogressive ventriculomegaly may be difficult.[124–126] Timing of surgery may affect neurocognitive development and intelligence because these are adversely affected by sustained increased ICP. Associated OSA resulting in hypoxemia and hypercapnia may lead to an increase in cerebral blood volume and thereby exacerbate intracranial hypertension.[127] Untreated intracranial hypertension may lead to optic atrophy and visual impairment.[49,128] As a consequence, when increased ICP has been identified either preoperatively or postoperatively, placement of a ventriculoperitoneal shunt should be considered[126]; this occurs more commonly in Crouzon and Pfeiffer syndromes.[126]

For children who present with signs of intracranial hypertension, it is important to follow basic principles of neuroanesthesia to prevent further increases in ICP and decreases in cerebral perfusion pressure (see also Chapter 26). It may be prudent to use protective measures to attenuate the hypertensive response to laryngoscopy and intubation, including the administration of a short-acting opioid, a β-blocker, or topical local anesthesia to the upper airway. Intraoperatively, the anesthesiologist faces numerous challenges to control ICP. Strategies to control ICP include mild to moderate hyperventilation (end-tidal carbon dioxide [$ETCO_2$] of 30 to 35 mm Hg), especially when signs of herniation are evident; avoidance of hypervolemia; and, where indicated, appropriate use of hypertonic (3%) saline solution, mannitol, furosemide, and dexamethasone to reduce ICP, reduce brain volume, and facilitate brain retraction. Although cranial vault reconstruction increases intracranial volume and reduces ICP,[129] children remain at risk of increased ICP after surgery and require close ophthalmologic and clinical follow-up, even after a cosmetically successful cranial expansion.[130,131]

Venous Air Embolism

Venous air embolism (VAE) may occur during any operative procedure in which the operative site is above the level of the heart and noncollapsible veins are exposed to atmospheric pressure.[132–139] The incidence of VAE in children undergoing craniectomy for craniosynostosis repair has been reported to be as great as 83%,[139] although hemodynamically significant VAE is rare. The incidence associated with endoscopic craniectomy may be as small as 2%.[84] Significant hypovolemia resulting from surgical blood loss can lead to a decrease in both systemic and central venous pressures and the development of a pressure gradient between the right atrium and the surgical site. This gradient increases the potential to entrain air via open dural sinuses or bony venous sinusoids.[139,140] If the entrained volume of air is sufficiently large, right ventricular outflow obstruction may ensue, causing acute right-sided heart failure and cardiovascular collapse. Smaller volumes of air may cause a reduction in cardiac output, hypotension, and myocardial or cerebral ischemia.[137] Transesophageal echocardiography

(documenting the presence of air in the right ventricular outflow tract), precordial Doppler ultrasonography (continuous windmill murmur), end-tidal carbon dioxide (precipitous decrease in carbon dioxide tension), and nitrogen monitoring (sudden increase in nitrogen concentration in the exhaled breath) have been used to identify VAE with different sensitivities, well before cardiovascular collapse occurs (see Figs. 26.6 and 26.7).[137,141–144] Applying bone wax to the open edges of cut bone, reducing the degree of or avoiding the reverse Trendelenburg position, maintaining positive-pressure ventilation with 5 cm of PEEP, and ensuring normovolemia help to prevent VAE. Fluid resuscitation, vasopressors, and aspiration of air from the right side of the heart may prevent episodes of VAE from progressing to cardiovascular collapse.[133,139,144]

Prolonged Surgery

As with all surgeries that last several hours, preventing the complications associated with prolonged anesthesia is paramount.[145] Nerve palsies, pressure ulcers of the skin, ophthalmic complications, hypothermia, and acidosis may occur. Careful positioning of the extremities, use of an egg-crate–type mattress or foam padding, and avoiding pressure to the eyes, particularly when the surgical procedure requires the prone position, will prevent the majority of these adverse outcomes. In children with proptosis, such as Crouzon syndrome, it may be necessary to suture the eyelids closed after applying lubrication to prevent corneal abrasions. Anterior ischemic optic neuropathy that can cause transient or permanent postoperative blindness is a rare complication that occurs in the absence of external pressure to the eyes.[146,147]

Hypothermia is another major concern and is a largely preventable complication when the appropriate steps are taken. Factors that predispose to hypothermia include the large surface area exposed during surgery and the potential infusion of large volumes of relatively cold IV fluids. Effective measures to prevent hypothermia include warming the operating room, the use of forced-air warmers and radiant warming lamps, insulating the child, and warming devices for blood and IV fluids. Preventing hypothermia and limiting blood loss and transfusion requirements are key factors in preventing the development of perioperative metabolic disturbance[148]; even mild hypothermia has been associated with increased blood loss and transfusion.[149]

Orbital Hypertelorism

The term *orbital hypertelorism* describes abnormally widely separated orbits. This deformity may occur in isolation or in association with other congenital abnormalities, such as facial clefts and Apert syndrome (Fig. 35.5). Surgical repair involves mobilization and repositioning of the orbit through either a subcranial approach, which leaves the roof of the orbit intact, or an intracranial approach via a frontal craniectomy. This procedure is performed in children older than 5 years of age who may have already undergone extensive surgical reconstruction. Surgical manipulation of the globe may elicit the oculocardiac reflex, resulting in bradyarrhythmias or asystole. Oculocardiac reflex may also occur during midface and orthognathic procedures (see also Fig. 34.3A and B).[150] These arrhythmias are usually without significant hemodynamic consequence and extinguish over time. Usually release by the surgeon of any orbital/periorbital pressure/tension being applied will allow the heart rate to return to normal. Hemodynamically significant bradycardia can be treated and further episodes prevented by administering a prophylactic anticholinergic such as atropine (10–20 μg/kg) or glycopyrrolate (5–10 μg/kg).

FIGURE 35.5 Child with Apert syndrome. Notable features include proptosis, cloverleaf skull, maxillary hypoplasia, and syndactyly (syndactyly is present in Apert syndrome but not in Crouzon syndrome).

After establishing IV access, the airway should be secured using a preformed orotracheal tube; confirmation of bilateral breath sounds is essential after positioning.[21] Blood loss from multiple osteotomies may be significant, and, as in the case of craniosynostosis surgery, methods to reduce the use of homologous blood should be considered. Intraoperative management follows the principles outlined for craniosynostosis surgery. At the conclusion of surgery, the trachea is extubated and the child is monitored overnight in a high-dependency setting with the capability of managing acute airway obstruction and monitoring of neurologic status.

Midface Procedures

Midface advancement to improve facial appearance is commonly required for children with maxillary hypoplasia, such as those with Crouzon, Apert (see Fig. 35.5), and Pfeiffer syndromes (E-Fig. 35.7).[151–153] This procedure is typically performed in children ages 5 to 7 years, although complications such as proptosis, corneal ulceration, ocular dislocations, and airway obstruction may necessitate earlier intervention.[153–156] A LeFort II procedure is similar to a LeFort III, with the difference that the osteotomy is oriented vertically through the infraorbital rim. Thus the nasal pyramid and the maxilla move forward as a single unit. Le Fort III osteotomy and monobloc procedures (Fig. 35.6) have the potential for significant complications, including massive blood loss, airway difficulties, blindness, cerebrospinal fluid leak, and infection.[145,147,157–159]

Anesthetic concerns are similar to those for orbital hypertelorism and craniosynostosis. Children with Apert and Crouzon syndromes often present with incomplete or complete nasal obstruction that

E-FIGURE 35.7 Child with Pfeiffer syndrome. Frontal view **(A)** and swimmer's view **(B)** illustrate many of the features of children with Pfeiffer syndrome, which include characteristic skull with craniosynostosis, proptosis, maxillary hypoplasia, and digit deformities. These children have characteristics similar to those of children with Apert syndrome but also have polydactyly. The defect has been traced to chromosomes 8 and 10; intelligence is normal.

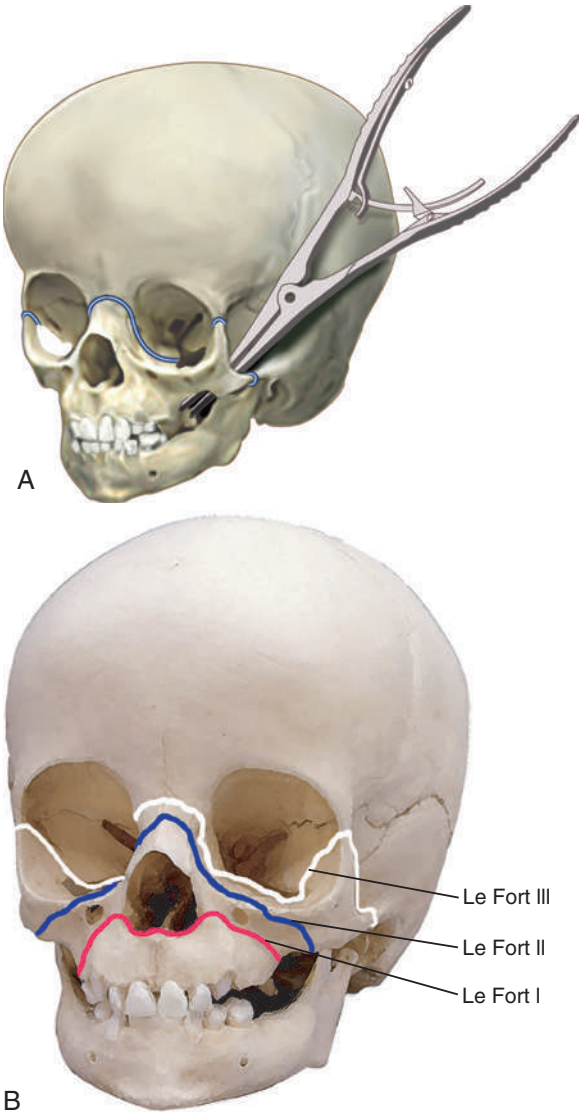

FIGURE 35.6 Le Fort III and monobloc procedures for correction of midface hypoplasia. **A,** The osteotomies in the Le Fort III procedure pass through the nasofrontal junction, across the medial orbital wall and floor, and into the inferior orbital fissure. A cut through the frontozygomatic suture, pterygomaxillary junction, and zygomatic arch allows separation of the midface. **B,** The monobloc procedures are similar, but the nasofrontal junction and frontozygomatic suture are not mobilized. This technique allows simultaneous correction of supraorbital and midface deformities at the expense of an increased incidence of postoperative complications.

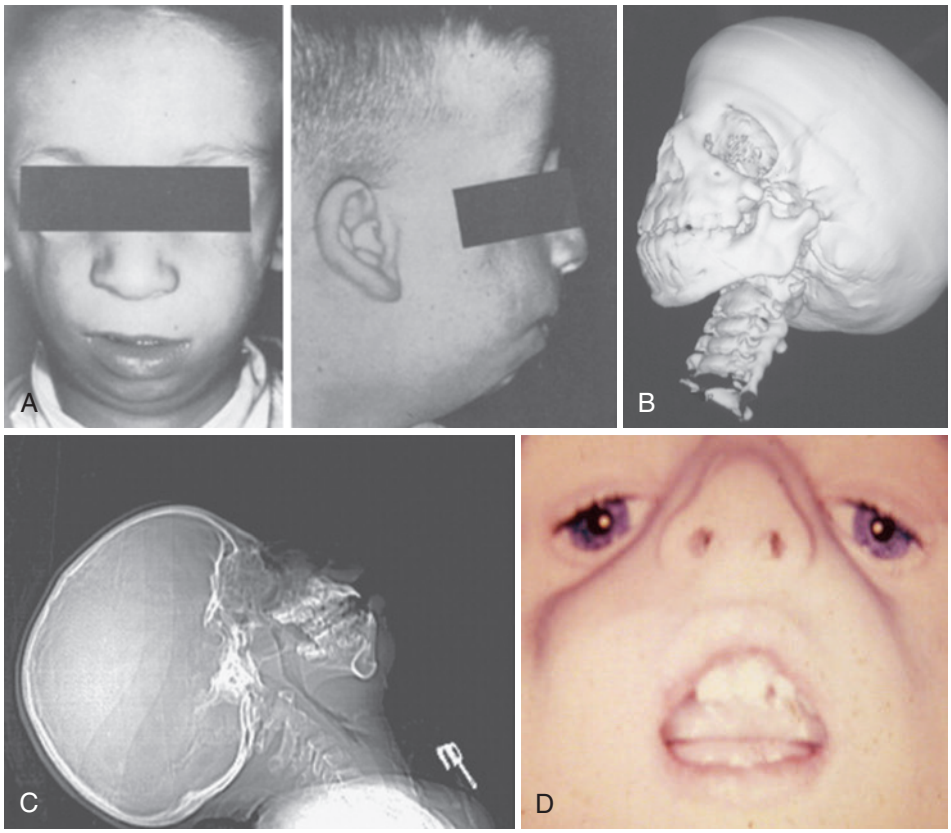
results from choanal atresia or midface hypoplasia. As a consequence, mask anesthesia can be difficult, even with an oral airway in situ. However, laryngoscopy and tracheal intubation in these children is usually uncomplicated. The diameter of the tracheal tube requires careful consideration because these children may require prolonged postoperative ventilation until postoperative facial and laryngeal edema has resolved. The decision to intubate the trachea via the oral or nasal route must be discussed with the surgeon before induction of anesthesia. A nasotracheal tube can be used throughout the procedure, or the surgeon may request an intraoperative change from the oral to the nasal tracheal position after completing the midfacial osteotomies.[160] To perform the latter maneuver, the anesthesiologist wears a sterile surgical gown and gloves and uses sterile equipment, including laryngoscope, Magill forceps, and tube exchange catheter (see E-Fig. 14.3A–H). Visualizing the glottis during surgery may be difficult because of the presence of airway edema and blood in the hypopharynx. A tube exchange catheter is passed through a naris and into the trachea alongside the orotracheal tube. The nasal tube is then passed over the exchange catheter, and its tip is positioned at the glottic opening. The oral tube is then removed, and the nasal tube is advanced (rotating the bevel 90 degrees clockwise or counterclockwise as needed to pass the vocal cords and arytenoids)[161,162] and visualized as it passes through the glottic aperture. Once the tube position is confirmed, the catheter is removed and the nasal tube is sutured securely to the nasal septum after confirmation of bilateral breath sounds.[21] Given the proximity of the tracheal tube to the surgical site, damage to the tracheal tube can occur during surgery.[163,164] Vigilance is required at all times to detect an accidental disconnection or damage to the tracheal tube. The anesthesiologist must be prepared to respond immediately to an unexpected interruption in ventilation and replace the tracheal tube. A nasogastric tube is placed after surgery to prevent gastric distention and reduce the likelihood of postoperative nausea and vomiting. A wire cutter must be available at the bedside at all times if intermaxillary fixation is used to stabilize the facial bones and mandible. In the ICU, the presence of an audible leak around the tracheal tube is an important criterion to determine absence of laryngeal or periglottic edema and therefore readiness for tracheal extubation.[163] Intraoperative blood loss is not typically as great as for craniosynostosis surgery. Hypotensive anesthesia may reduce or prevent the need for blood transfusions during maxillary orthognathic surgery.[165]



Hemifacial Microsomia, Treacher Collins Syndrome, and Goldenhar Syndrome

Hemifacial microsomias, also known as otomandibular dysostosis (Fig. 35.7), result from a malformation of the first and second branchial (or pharyngeal) arches. This is the second most common facial defect after clefts. These disorders are classified according to the classification **O**rbital distortion, **M**andibular hypoplasia, **E**ar anomaly, **N**erve involvement, and **S**oft tissue deficiency (OMENS).[3,166–169] Piezosurgery is a relatively new technique used to perform osteotomies using ultrasonic frequencies during mandibular distraction in children with hemifacial microsomia.[170] Airway difficulty increases with the complexity of the defect from unilateral to bilateral mandibular or temporomandibular involvement. The disorder may include mandibular hypoplasia, temporomandibular joint dysostosis, cleft palate, and auricular, ophthalmologic, and facial nerve defects. Goldenhar syndrome (Fig. 35.8 and E-Fig. 35.8) is the most common form of this disorder. Vertebral anomalies are present in 40% and congenital heart defects occur in 35% of children with this syndrome. Airway management is complicated by midfacial hypoplasia, asymmetry of mouth opening, and mandibular retrognathia. Overall, tracheal intubation in children with unilateral hemifacial microsomia is easy in 70% and very difficult in 9%.[166] In contrast, tracheal intubation in children with bilateral mandibular hypoplasia is evenly distributed among easy, difficult, and very difficult.[166] The airway anomalies associated with this syndrome predispose to OSA.

The craniofacial abnormalities of mandibular hypoplasia, macrostomia, and cleft palate in Treacher Collins syndrome (E-Fig. 35.9) often present difficulties for airway management

E-FIGURE 35.8 Goldenhar syndrome in a neonate. Note classic ear deformity and small mandible.

E-FIGURE 35.9 Treacher Collins syndrome. **A,** Note the hypoplastic mandible, triangular facies, and hypoplasia of the ear. In children with this syndrome, securing the airway becomes increasingly difficult with age. Congenital heart disease is common in children with Treacher Collins syndrome. **B,** Three-dimensional reconstructed magnetic resonance imaging. Note the sloped mentum with foreshortening of the ascending ramus of the mandible. The temporomandibular joint is malformed. **C,** Lateral radiograph showing the small mandible and glossoptosis. **D,** Close-up of the central facies.

FIGURE 35.7 Frontal **(A)** and lateral **(B)** views of unilateral hemifacial microsomia. In the lateral view, microstomia and mandibular and ocular deformities are evident. These children may present with either unilateral or bilateral hemifacial microsomia, a hypoplastic mandible and maxilla, and ear deformities.

FIGURE 35.8 Goldenhar syndrome in an infant. This is one of the most common forms of hemifacial microsomia. With unilateral hemifacial microsomia, the airway is usually managed and instrumented without difficulty, but with bilateral mandibular hypoplasia, the airway may be very difficult to manage in one third of afflicted children.

that increase with increasing age.[3,166] Other clinical features of the syndrome include hypoplastic zygomatic arches, ophthalmic features (including sloping palpebral fissures, coloboma of the eyes, and notched lower eyelids), microtia, choanal atresia, cardiovascular defects, and renal anomalies. Mandibular distraction osteogenesis is a surgical option considered when upper airway obstruction is due to mandibular deficiency. This avoids tracheostomy or other surgical intervention and allows for future growth of the mandible. Children with hemifacial microsomia have a poor psychosocial outcome.[171]

AIRWAY MANAGEMENT

Airway management of children with hemifacial dysostoses is traditionally known to be difficult. It is essential that all equipment for management of the difficult airway be present in the operating room before induction of anesthesia (or administration of sedatives/local anesthetic in cases where a sedated/awake approach is used) (see Table 14.10). For infants and children with difficult airways, an inhalational induction is the most commonly used technique. In contrast, in older children and adolescents, either an inhalational induction or IV sedation (using dexmedetomidine or propofol) with topical local anesthesia applied to the upper airway may be used to facilitate tracheal intubation. In all cases, it is essential that primary and backup plans for airway management be in place together with the equipment and personnel required to execute them.

A variety of techniques may be used to control the difficult airway, including a flexible fiberoptic bronchoscope, GlideScope (Verathon Inc., Bothell, WA), the Airtraq (Prodol Meditec S.A., Vizcaya, Spain) disposable optical laryngoscope, Truview Infant laryngoscope (Teleflex Medical, Netanya, Israel), supraglottic airway devices,[172] and others (see Chapter 14). We have used the two-person intubation technique, in which the first anesthesiologist applies external posterior laryngeal pressure while performing laryngoscopy to optimize the view of the glottis, while the second anesthesiologist inserts the tracheal tube into the trachea when the view is adequate (see Fig. 35.9).[173] The second anesthesiologist also may assist with more advanced airway management both in terms of helping to observe the child and assisting with the use of advanced airway devices.

Preformed tracheal tubes are generally used via the oral or nasal route, depending on the site of surgery. When a nasotracheal tube is used, it can be secured by suturing it to the membranous nasal septum or taping it after the skin has been prepared with benzoin. An oral tube may be wired to the mandible or to a non-deciduous tooth. Care must be taken to ensure that the tip of the preformed tube is mid-tracheal as the length of preformed nasotracheal and, to a lesser extent orotracheal tubes, exceeds that of the uncuffed version of the same diameter tube.[21] A laryngeal mask airway can be very effective in maintaining airway patency

FIGURE 35.9 Two-person intubation technique. The intubator (first person) performs laryngoscopy and manipulates the larynx with external laryngeal manipulation (gloved hands). With the larynx in view, the intubator cocks his or her head to the left while holding position and the assistant (second person, nongloved hand), who is standing on the intubator's right, then passes the tracheal tube through the larynx.[173]

during induction of anesthesia or as a guide to facilitate fiberoptic bronchoscopy.

For children with a history of upper airway obstruction or midfacial hypoplasia who present with a tracheostomy, the tracheostomy tube can be replaced with a cuffed tracheostomy tube or an armored tube that is sutured in place for the duration of the surgery. The use of a cuffed tracheostomy tube allows for separation of the aerodigestive tracts, controlled ventilation, delivery of adequate PEEP, and prevention of atelectasis during long procedures. Changes in the position of the head and neck can cause displacement of the tracheal tube, so care should be taken to confirm tracheal tube position after the child is positioned for surgery.[21,174] This is especially important for cranial vault procedures that involve extremes of neck extension, such as might occur during reconstruction of the supraorbital bar. Airway equipment and additional tracheal tubes must be available in the operating room at all times. It is essential to document an audible leak around the tracheal tube at the time of tracheal intubation (with the cuff on the tracheal tube deflated), because the presence of a leak is often used postoperatively to determine suitability for extubation when significant airway edema has developed. OSA associated with midfacial anomalies may result in upper airway obstruction during induction and emergence.[73,78]

Orthognathic Surgery

Malocclusion secondary to maxillary or mandibular hypoplasia (such as occurs in hemifacial microsomia and Treacher Collins syndrome), tumors, trauma, as well as temporomandibular joint dysfunction are generally accepted indications for orthognathic surgery. LeFort I procedures for maxillary hypoplasia involve a transverse incision through the maxilla to advance the upper teeth into normal occlusion with the mandible. These procedures are usually performed in adolescents because surgery is performed once maxillary and mandibular growth is complete. Because this age group usually exhibits increased perioperative anxiety, preoperative assurance and education as well as premedication with oral midazolam (0.3–0.5 mg/kg, up to 20 mg for older children and adolescents) or IV midazolam (2–4 mg) are often necessary.

Airway management is a major concern, particularly in children with a hypoplastic mandible or temporomandibular dysfunction.[3] A high index of suspicion for atlantoaxial instability is required if juvenile rheumatoid arthritis is the underlying disease process. The anticipated difficult airway can be managed using fiberoptic intubation, with sedation or topical local anesthesia or an inhalation induction and maintenance of spontaneous ventilation until the trachea is intubated, as discussed earlier. Tracheal intubation in children with adequate mouth opening can be managed with a video/indirect laryngoscope or using a laryngeal mask as a conduit for fiberoptic intubation. These techniques are best suited for orotracheal intubations; frequently for orthognathic surgery nasotracheal intubation (using a preformed tracheal tube) is the preferred method of tracheal intubation. Careful stabilization and fixation of the tube using transseptal suturing to prevent unintended extubation is often used.[21] Excessive pressure on the ala nasi (causing ischemia) can be avoided by fixing the nasal RAE tube to the forehead with the nasal curve positioned away from the ala. LeFort I advancements require close communication between the surgery and anesthesia teams because the nasotracheal tube can be dislodged once the maxilla is fully mobilized. An additional potential intraoperative complication is inadvertent cutting of the tracheal tube when the maxillary osteotomies are performed. If intermaxillary fixation is used postoperatively, wire cutters must be immediately available at all times while the child is monitored in an intensive care setting.

To reduce intraoperative blood loss, controlled hypotension is commonly used by means of any of a range of pharmacologic agents, including inhalational anesthetic agents, β-blockers, and remifentanil. The literature is extensive on the salutary effect of induced hypotension in reducing intraoperative blood loss and improving the quality of the surgical field during orthognathic surgery.[165,175–184] However, many practitioners have moved away from controlled hypotension because of concerns regarding complications, particularly blindness. Regardless of anesthesia technique, invasive arterial monitoring is indicated to facilitate intraoperative evaluation of blood gases and hematocrit. In many cases, a mild degree of hypotension is sufficient for optimal surgical conditions (systolic blood pressure 85–90 mm Hg), thus avoiding a greater degree of hypotension. Dexamethasone (0.5 mg/kg) may reduce postoperative airway edema.[185] After awakening the child and return of protective airway reflexes, the trachea is extubated and the child is monitored overnight in a high-dependency setting with the ability to establish an airway should acute airway obstruction develop. In some cases, at the conclusion of surgery mandibulomaxillary fixation may be used with either metal wires or elastic bands. Emergency wire cutters should be immediately available in the postoperative period in the event of the need for emergency airway management.

Cystic Hygromas and Hemangiomas

Cystic hygroma is a rare congenital malformation of the lymphatic system occurring with an incidence of 1 in 16,000 births, most frequently involving the axilla and neck (Fig. 35.10 and E-Fig. 35.10). The pathology consists of multiple loculated cysts that contain lymph fluid or blood (see Fig. 35.10B). In most cases, cystic hygromas are present at birth, although 80% to 90% are diagnosed within the first 2 years of life. The natural history is

E-FIGURE 35.10 A, Massive cystic hygroma. The bulk of the tumor is usually extraoral and extralaryngeal; however, extension into the tongue and supraglottic region may complicate direct laryngoscopy. Here, direct laryngoscopy and tracheal intubation were possible. **B,** The immediate postsurgical debulking of a cystic hygroma restores the native airway (if the hygroma compromised the airway) and a natural and cosmetic appearance to the infant. With time, many children outgrow the hygroma.

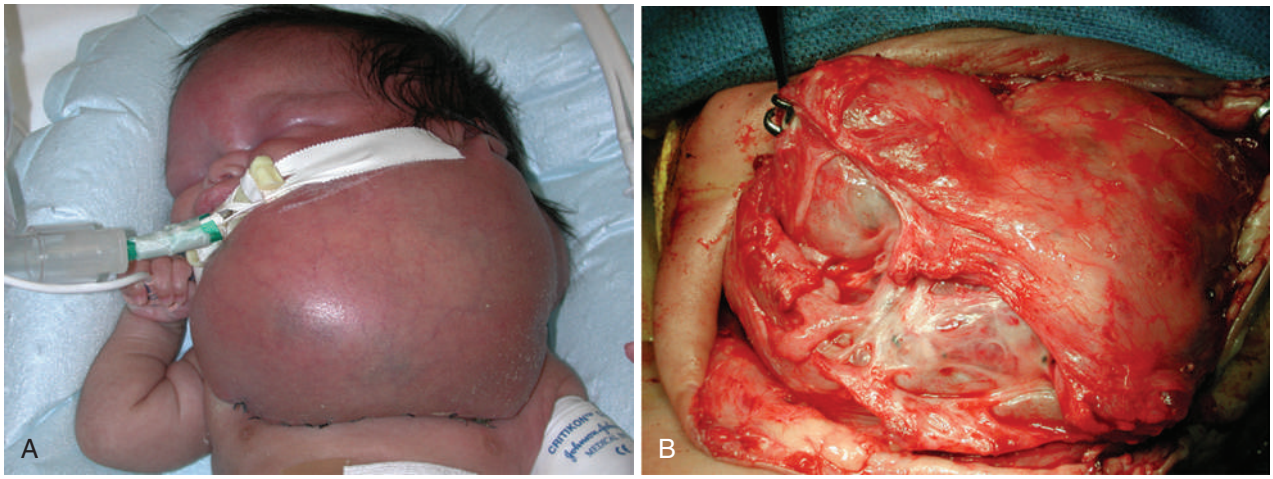


FIGURE 35.10 **A,** Cystic hygroma. Note that the bulk of the tumor is extraoral and extralaryngeal, although extension into the tongue and supraglottic region may complicate direct laryngoscopy. The tumor on the surface of the neck may rapidly expand owing to bleeding into the cysts or accumulation of fluid in the lymphatics. Such large tumors may put the overlying skin under great tension. They may also be situated such that they preclude tracheostomy. **B,** Gross pathologic condition in cystic hygromas consists of a combination of multiloculated cysts that may contain a combination of lymph fluid and blood. Debulking may result in substantial blood loss. Sequential debulking of the hygroma may be required as the residual cysts expand with fluid and blood and reexpand the hygroma.

spontaneous resolution, although most require repeated aspirations, sclerotherapy, or surgical excision to debulk the mass (see E-Fig. 35.10B).[186–188] Cystic hygroma can be associated with other chromosomal abnormalities such as Noonan and Turner syndromes, in which case the anesthetic management is guided by the underlying syndrome. Some children require an urgent tracheostomy at birth or in the first hours of life to relieve an obstructed airway (see Chapter 38). During the preoperative assessment, the airway should be examined and evaluated by radiographs for involvement of supraglottic and infraglottic structures. Acute airway obstruction can occur during induction if cystic lesions are present in the upper airway. Fiberoptic intubation may be required if the larynx is distorted by the lesions, in which case spontaneous ventilation should be maintained until the airway is secured.[189] Postoperative complications of surgical excision include laryngeal edema, airway obstruction, pneumonia, facial palsy, and infection.[186,187,190]

Hemangiomas, also known as juvenile or infantile hemangiomas, are the most common benign tumors in infancy, affecting up to 10% of infants.[191] The majority of hemangiomas are uncomplicated and require no treatment. The natural course begins with a proliferation phase that starts within the first few months of life, followed by an involution phase of variable length. It is estimated that involution occurs at a rate of 10% per year. Hemangiomas can affect all organs, and intervention is required when the lesion affects the function of vital organs such as the eyes, airway, or liver.[192] Hemangiomas that occur in the subglottic region must be considered in the differential diagnosis of a noninfectious cause of croup in infants younger than 3 months of age. When present around the eyes and on the face (Fig. 35.11), hemangiomas are often associated with lesions in the airway.[193,194] They can occur in any part of the airway and can cause airway and feeding difficulties. Airway procedures to resect or remove hemangiomas are generally undertaken between 1 and 11 months of age.[195] Limb hemangiomas generally present with cosmetic concerns and bleeding. Rarely, children with large hemangiomas develop high-output heart failure.

FIGURE 35.11 Facial hemangioma in the cheek of a child. The hemangioma involves the skin overlying the mandible centrally from the lower lip to the tip of the mandible. Hemangiomas vary widely in size but can enlarge precipitously as a result of bleeding into the tumor.

Treatment options for hemangiomas include nonintervention, systemic corticosteroid treatment, corticosteroid injection, surgical excision, and laser ablation. Propranolol is an emerging treatment option for hemangiomas.[196–199] It appears to act on hemangioma stem cells in a variety of ways, including through suppression of cyclic adenosine monophosphate–mediated kinase pathways,

promotion of cell death through adipogenesis, and downregulation of vascular endothelial growth factor.[200–202] It may be used in children without contraindications either as an oral monotherapy at a dose of 2 mg/kg per day divided into three doses or in combination with oral prednisone 3 mg/kg per day tapered after 4 to 6 weeks of therapy. Propranolol reduces the need for surgical intervention but requires 6 months to 1 year of therapy.[203] Surgical treatment is reserved for superficial hemangiomas in locations that are surgically accessible.[192] Laser treatment for superficial lesions is commonly performed as an outpatient procedure,[204] and routine anesthetic precautions should be taken. Children with hemangiomas who had airway procedures received more steroids and had increased admissions and mortality compared with those without airway procedures.[195]

Arteriovenous malformations are present at birth but can go unrecognized for years, especially when they are intracranial. Large arteriovenous malformations may cause high-output cardiac failure, necessitating therapeutic intervention. Treatment options may include chemotherapy, corticosteroid therapy, embolization, and surgical excision.[205–207] Children who undergo excision of the hemangiomas often require blood products during surgery, but platelets should be transfused with care because an accumulation within the malformation may increase its size.[208] NSAIDs should be avoided because of their effects on platelet function.

Möbius Syndrome

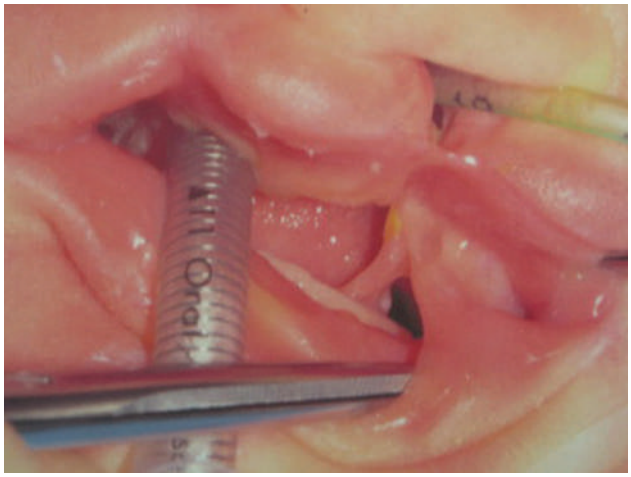
Möbius sequence is a rare neurologic disorder (2–20 in 1,000,000 births) characterized by congenital palsy of the facial (VII) and abducens (VI) cranial nerves, resulting in unilateral or bilateral facial weakness and defective extraocular eye movement (E-Fig. 35.11), which is now thought to arise from abnormal rhombencephalic development and is therefore primarily a disorder of the caudal brainstem.[209,210] These classic features may be associated with other cranial nerve palsies, ophthalmic abnormalities, developmental delay, and various craniofacial, limb, and musculoskeletal malformations, resulting in a variable pattern of clinical expression.[211–215] Involvement of cranial nerves IX and X is associated with pharyngeal dysfunction, dysphagia, feeding difficulties, retention of oral secretions, and recurrent aspiration pneumonia. Associated micrognathia, microstomia, limited mouth opening, and other orofacial abnormalities may make tracheal intubation difficult.[216] Other associations include gastroesophageal reflux, hypotonia of skeletal muscles, congenital cardiac abnormalities, spinal abnormalities, and peripheral neuropathies. Central alveolar hypoventilation has been described in association with Möbius sequence and may be secondary to hypoplasia of midbrain respiratory centers.[217] Central alveolar hypoventilation, compounded by upper airway hypotonia and the effects of sedatives, opioids, and anesthetic agents, can predispose to postoperative respiratory compromise. The absence of facial expression secondary to paresis of the facial nerve can make it difficult to assess and evaluate postoperative pain.[218] The anesthetic plan for the child with Möbius sequence must be tailored to the individual based on the clinical expression of the syndrome. There is a single, isolated report of fatal malignant hyperthermia in a 7-month-old. The absence of other reported cases renders a connection between malignant hyperthermia and Möbius syndrome exceedingly unlikely.[219]

The most common surgical procedure performed in children with Möbius sequence is segmental gracilis muscle transplantation, in which the muscle is transplanted to the face and revascularized to the facial artery and vein.[220] Motor innervation of the gracilis requires a functioning cranial nerve such as the masseter branch of the trigeminal nerve. The aim of this facial reanimation is to facilitate facial expression and provide lower lip support to reduce drooling and improve speech.[220] Anesthetic considerations include those for prolonged surgery, avoidance of neuromuscular block to facilitate intraoperative nerve stimulation, and avoidance of hypocapnia, hypothermia, and hypotension to ensure graft perfusion. The latter considerations are also applicable to the postoperative period. Other surgical procedures commonly performed in children with Möbius sequence include strabismus surgery and orthopedic procedures to improve limb function.

Congenital Intraoral Fibrous Bands

Congenital intraoral fibrous bands (e.g., pterygium syndrome and syngnathia) can present an almost impossible airway to secure even with advanced pediatric fiberoptic skills (E-Fig. 35.12). Syngnathia reduces mouth opening as a result of fusion of maxilla and mandible and often presents as a part of Van der Woude and popliteal pterygium syndromes.[221] These children often present with airway and feeding difficulties. Depending on the severity of the bands, these children may present formidable anesthetic challenges. IV ketamine anesthesia in the spontaneously breathing neonate may allow division of the adhesions in the first few days of life, precluding the need for a surgical airway or facilitating tracheal intubation if other surgery is required.[221]

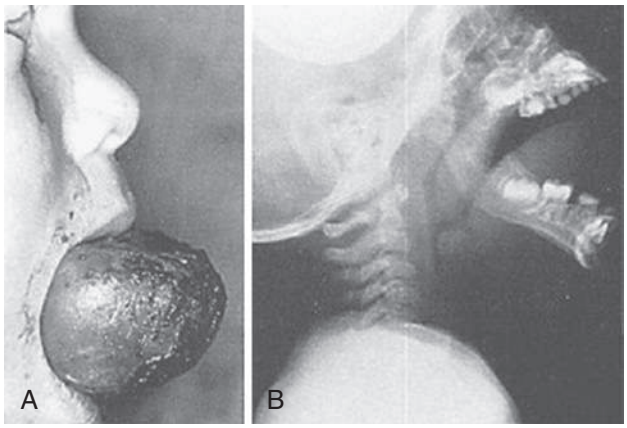
Intraoral Tumors



Intraoral tumors are rare in children (E-Fig. 35.13) but, if massive, may present great challenges in securing the airway. Those that present the greatest difficulties preclude visualizing the larynx (E-Fig. 35.14) and present an increased risk of intraoperative bleeding. Preoperative radiographic studies are required to delineate the extent of involvement of the upper airway and whether the supraglottic region or the nasopharynx is clear for passage of a bronchoscope. If the tumors are sufficiently large that laryngoscopy is precluded, fiberoptic nasal intubation must be considered. If the tumor is resectable, a tracheostomy could be a backup plan. The risk of bleeding depends on the vascularity of the tumor and whether the tongue is involved. If the vascular supply of the tumor can be isolated, bleeding should be easily controlled. If, however, the tumor cannot be separated from the tongue, bleeding can be controlled only by clamping the tongue (and lingual arteries) before resecting the tumor. This should prevent excessive blood loss and permit a hemostatic closure of the resected surface. The trachea should remain intubated postoperatively until both airway and lingual edema have abated.

Brachial Plexus Surgery

Brachial plexus injury occurs in 0.5 to 5 infants per 1000 live births as a result of birth trauma.[222,223] Erb palsy involves damage to nerve roots C5, C6, and C7, whereas Klumpke palsy involves roots C8 and T1.[223] Complete plexus palsies are the most devastating injuries, resulting in a flail and insensate arm.[223,224] Although 75% of brachial plexus injuries resolve spontaneously and completely within the first month after birth, 25% result in permanent disability and impairment.[223,225–227] Surgical intervention is indicated if the motor function does not improve after 3 months of age.[225,226] Clinically significant diaphragmatic palsy is associated with 2.4% of neonates with brachial plexus injury. In the very young, diaphragmatic palsy requires aggressive intervention before brachial plexus repair. For brachial plexus surgery to be successful, the



E-FIGURE 35.11 Child with Möbius syndrome. Preoperative **(A)** and 1-year postoperative **(B)** appearance. These children lack the muscles for facial expressions, most notably those for smiling.

E-FIGURE 35.12 Orotracheal intubation in a neonate with pterygium syndrome. Intraoral fibrous bands prevent direct laryngoscopy, necessitating the use of advanced fiberoptic airway skills to secure the airway.

E-FIGURE 35.13 Intraoral tumors that arise from the tongue may preclude direct laryngoscopy or, if sufficiently large, preclude visualizing the larynx. In this case, the tumor was carefully displaced to the left during direct laryngoscopy. The risk of manipulating a vascular tumor is bleeding.

E-FIGURE 35.14 A, Child with a massively protuberant tongue resulting from a hemangioma. **B,** Radiograph of the lateral profile of the child demonstrates a patent nasopharyngeal and periglottic aperture. This suggests that nasotracheal intubation is manageable.

nerve root cannot be completely avulsed from the spinal cord. Therefore detailed imaging is required to characterize the nature of the injury: avulsion of the nerve root from the spinal cord, disruption of the nerve within the nerve sheath, or disruption of the nerve and the nerve sheath. Because irreversible loss of the neuromotor end plate may occur, surgery is often undertaken before 12 months of age.[222,225,226,228–230] Microsurgical intervention is performed in infants with global lesions and Horner syndrome by 3 months of age. The aim is to improve function with no expectation of complete recovery; without intervention these children have severe functional deficits. Conversely, if recovery of the biceps occurs by 3 months, treatment is performed without microsurgical intervention.[231] The treatment of choice includes resection of neuromas with interpositional nerve grafting.[232] Nerve grafting is being increasingly performed for treating neonatal brachial plexus injury. Donor nerves include motor branches of C4, intercostal nerves, inferior branches of cranial nerve XI, pectoral nerves, and sural nerves.[233] Synthetic collagen nerve conduits have been approved as nerve guidance channels in microsurgery and may be an option for the future.[234]

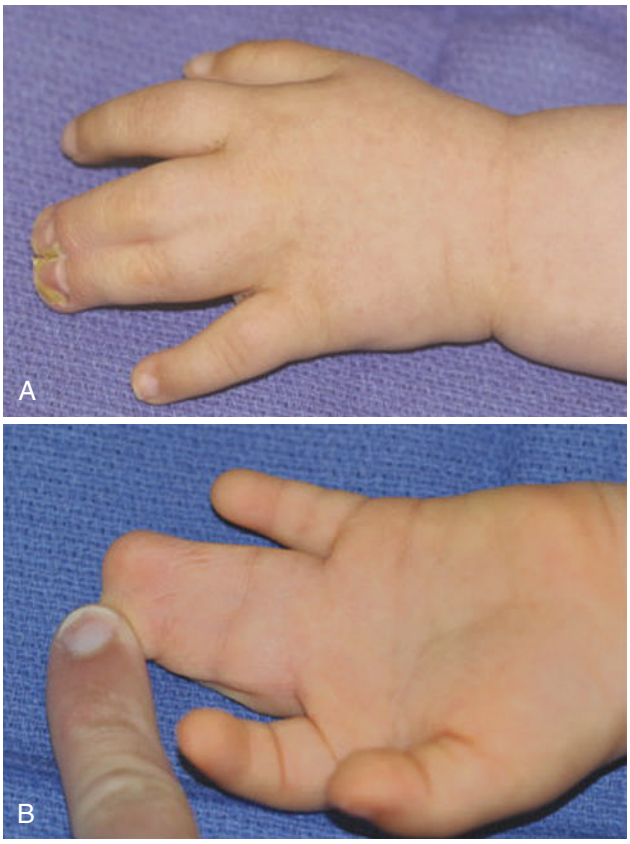
Preoperative MRI for assessing bone and joint deformities may require administration of general anesthesia. Repair of the brachial plexus may be challenging because the only extremity for IV access and monitoring (blood pressure and pulse oximetry) is the contralateral upper extremity. Both lower extremities are usually prepped and draped for harvesting the sural nerves or other donor nerves for the repair. Because these infants are usually 9 to 12 months of age, they are chubby, making IV access more difficult. This surgery often takes up to 12 hours, so the considerations for prolonged anesthesia must be invoked, such as protecting pressure points during positioning. Muscle relaxants are avoided to facilitate intraoperative electrophysiologic testing.[235] An indwelling urinary catheter is essential to decompress the bladder. Analgesic requirement is minimal except during brief periods of surgical stimulation. Remifentanil provides excellent intraoperative analgesia and permits rapid adjustment of the depth of anesthesia. Maintenance of normothermia and prevention of fluid overload are important during this prolonged surgery. Blood loss is minimal, and maintenance fluids usually suffice.[222] Prolonged administration of propofol is not recommended because of the risk of propofol infusion syndrome and delayed emergence. In its stead, remifentanil combined with inhalation agent or dexmedetomidine may be a more appropriate regimen. Postoperative analgesia requirements are minimal, and acetaminophen and NSAIDs usually provide adequate pain relief. Shoulder spica casts may be applied to avoid sudden neck movements postoperatively if the lower branches of the accessory nerve are used for reconstruction.[235]

Otoplasty

Protruding ears (commonly known as "bat ears") are common in the Caucasian population, occurring with an incidence of up to 5% (E-Fig. 35.15).[236] Children with protruding ears are generally healthy, with about two-thirds undergoing surgical correction before the age of 8 years or as soon as the child expresses concern about the deformity.[237] Younger children are more likely to require general anesthesia, whereas those older than age 8 years may tolerate the procedure using local anesthetic infiltration or nerve blocks.[238] Laser techniques are now used increasingly to perform cartilage reshaping.[239] The main complication of general anesthesia is postoperative nausea and vomiting, which can last up to 2 days after surgery in approximately 80% of children.[240] However, postoperative nausea and vomiting may be reduced by surgical and anesthetic techniques, including multimodal techniques with combined pharmacotherapy (ondansetron and dexamethasone), anesthetic maintenance with a propofol infusion, and avoidance of packing of the external auditory meatus and concha.[240,241] To provide optimal surgical access and positioning of the child, a preformed, low-profile tracheal tube, such as the RAE tube, may be required, but flexible laryngeal mask airways provide equally satisfactory conditions in the ventilated or spontaneously breathing child.[242] Infiltration with local anesthetic (usually <10 mL of 1% lidocaine with 1:100,000 epinephrine) attenuates the surgical stimulus and reduces the intraoperative opioid requirements. The use of a long-acting local anesthetic combined with a nerve block, acetaminophen, and NSAIDs provides adequate postoperative analgesia in most children. This multimodal approach may obviate the need for opioids and thereby reduce the incidence of postoperative nausea and vomiting.[243]

Congenital Hand Anomalies

Congenital limb malformations exhibit a wide spectrum of phenotypic manifestations. Syndactyly may occur as an isolated malformation (Fig. 35.12 and E-Fig. 35.16) or part of a syndrome, the most common being Apert syndrome but also with Poland syndrome, in association with skeletal abnormalities and gastrointestinal and cardiac malformations. Limb malformations are more frequent in males than females, and they affect both upper and lower limbs in approximately 50% of children with a deformity. Early separation of digits is favored if the ring and little fingers or index finger and thumb are involved, because the differing longitudinal growth rates will lead to greater deformities.[244] Surgery is usually



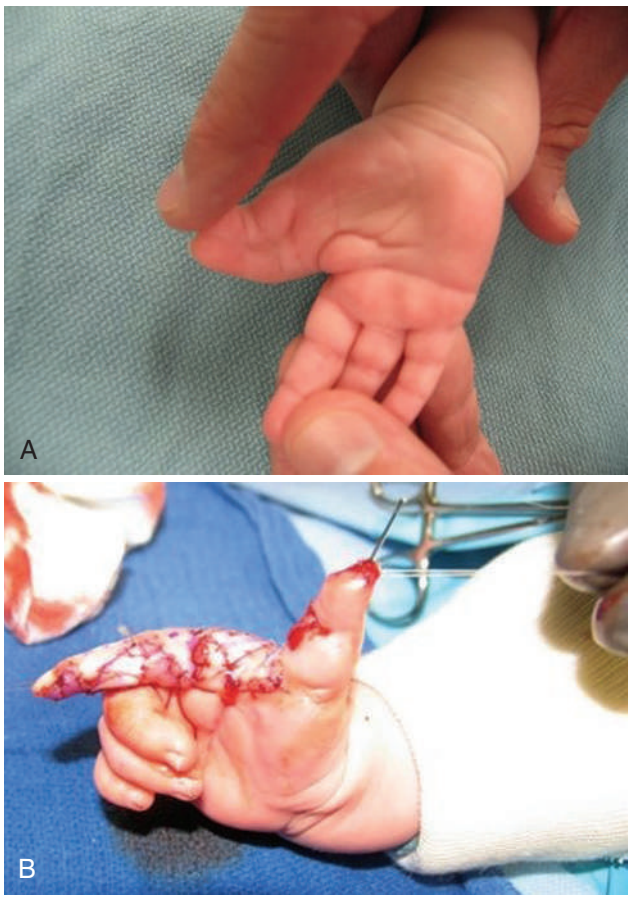


FIGURE 35.12 Syndactyly of the first and second digit of an infant: dorsal aspect **(A)** and volar aspect **(B)**.

E-FIGURE 35.15 Preoperative **(A)** and postoperative **(B)** appearance of a young girl with a left outstanding ear.

E-FIGURE 35.16 Preoperative **(A)** and postoperative **(B)** appearance of syndactyly of the thumb and index finger of the right hand of an infant. Skin is mobilized using a Z-plasty to cover the freed surfaces of the digits after their release.

performed between 6 and 18 months of age.[245,246] An association has been reported between syndactyly and prolonged QT interval, with life-threatening arrhythmias reported in one child during anesthesia.[247] Timothy syndrome is a multisystem disorder with cardiac, facial, limb, and neurodevelopmental features.[248]

Duplicated thumb can be present as an isolated anomaly and is present in approximately 1 in 3000 births. Hypoplastic thumbs are associated with systemic syndromes such as Holt-Oram syndrome; **V**ertebral, **A**nal, **C**ardiac, **T**racheal, **E**sophageal, **R**enal, **L**imb (VACTERL) anomalies; Fanconi anemia; Nager syndrome; and thrombocytopenia-absent radius.[249] A complete evaluation of the child is generally warranted because abnormalities can occur in the cardiovascular, neurologic, and hematopoietic systems.[249] Genetic testing is not generally needed in isolated thumb duplications.

Tissue Expanders

Tissue expansion has become a major treatment modality in the management of giant congenital hairy pigmented nevi (E-Fig. 35.17), hemangiomas, meningomyelocele, abdominal wall defects, and secondary reconstruction of extensive burn scars.[250–258] Tissue expanders effectively allow removal of the affected area and preserve sensation in a durable flap with minimal donor site morbidity.[259] These devices consist of a silicone shell that stretches to accommodate serial injections of saline solution when placed subcutaneously or, in the case of the scalp, under the galea, through an incision made in normal tissue adjacent to the lesion or defect (Fig. 35.13).[254,260] Osmotic tissue expanders have been used in burn scars, congenital nevi, alopecia, or foot deformities with reduced infection rates and low cost. Tissue expansion requires at least two surgical procedures—one to insert the expander and a second to remove it when expansion is complete; some children may require serial insertions or multiple expanders.[254] Reconstruction of areas of the head and neck constitute a particular challenge because expansion without oral, visual, or airway compromise is required.[261] Complications of tissue expansion include infection, skin erosion, leakage, migration, and flap necrosis.[257,262–265] Perioperative antibiotics are given at insertion and removal, although their effectiveness in preventing infection has not been established.[252,257,259,263,264]

Hairy Pigmented Nevi

Congenital melanocytic nevi characteristically vary in size, shape, surface texture, and hairiness. They are frequently excised because they are disfiguring and have the potential to become malignant. Serial surgical excision is common, but skin grafting and tissue expanders are also used (see E-Fig. 35.17).[259] The position and size determine the frequency of excision and anesthetic technique. If the face, head, or neck is involved, airway management should be discussed with the surgeon to allow optimal surgical access (Fig. 35.14).

In general, these children are healthy. In the cooperative and motivated child, subcutaneous infusion of a very dilute long-acting local anesthetic (e.g., ropivacaine 0.08%) mixed with epinephrine 1 : 1,000,000 can be used to provide painless tumescent anesthesia.[266] The local anesthetic is infused through a 30-gauge needle at an initial rate of 120 mL/hour. Blanching of skin identifies the area that is anesthetized. This method has been used successfully in children 7 years of age and older.[267] To avoid toxicity, local anesthetic volume and dosing guidelines should be followed (see Chapter 42). Repeated reconstructive procedures are often required, and attention should be paid to providing appropriate premedication where necessary (see Chapter 4).

Cosmetic Procedures

According to the American Society of Plastic Surgeons, the most common cosmetic surgeries performed in adolescents are nose reshaping, male breast reduction, ear surgery, laser hair removal, laser treatment of leg veins, and laser skin resurfacing.[268] Breast implants and liposuction are the most controversial cosmetic procedures performed, although combined they represent only 5% of cosmetic surgery in this age group. In 2011, 73% of male breast reduction and 28% of otoplasty occurred in this age group.[268] The breast augmentation procedures were performed on an outpatient basis.[269] These patients are generally healthy. Routine anesthetic induction with endotracheal intubation with no additional invasive monitoring is generally all that is required.

FIGURE 35.13 Tissue expander that is approximately 18 cm long. These expanders are inserted in a partially deflated state and then expanded by sequentially injecting saline solution over a period of weeks.

FIGURE 35.14 A heavily pigmented nevus covers the lateral aspect of the face from the eyebrow, over the bridge of the nose, and down to the skin covering the mandible. These large and disfiguring pigmented nevi must be resected in staged events.

E-FIGURE 35.17 Hairy nevi can cover expansive parts of the skin—in this case, from the midback to the upper legs bilaterally. To cover the resected area of skin, tissue expanders are widely used. In this case, two tissue expanders (*arrows*) provide enough additional skin to swing a flap over the resected area.

This group of patients may be at increased risk of postoperative nausea and vomiting and will benefit from multimodal prophylaxis. Postoperative discomfort is common, requiring administration of systemic opioids or nerve blocks.

Liposuction is usually scheduled as outpatient surgery, although extensive liposuction may require an overnight admission to the hospital. This latter procedure is associated with acute complications, including itching, bruising, and swelling; damage to nerves or vital organs; blood loss; and embolization of fat or blood. Lidocaine toxicity and fluid accumulation at the surgical site are directly proportional to the volume of aspirated fat and number of treated sites.[270] The maximum safe dose of lidocaine is 28 mg/kg without liposuction and 45 mg/kg with liposuction; the difference is likely attributable to the delayed absorption during liposuction.[271] However, surgeons are increasingly using bupivacaine without adequate clinical study to determine the appropriate dose, the maximum dose, and safety recommendations.[272]

Trauma

A considerable proportion of plastic surgical procedures in children are performed for trauma and emergency surgery. Procedures include treatment of simple lacerations, animal bites, tendon, nerve and vascular repair, reimplantation of digits and limbs, and treatment of burns (see Chapter 36). The cooperative and fasted child with minor trauma can often undergo minor surgical procedures using local anesthesia, commonly administered by the plastic surgeon in the emergency department. This can be supplemented with inhalation of a 50:50 mixture of nitrous oxide and oxygen (Entonox),[273] IV administration of small doses of a benzodiazepine and opioid (e.g., midazolam 50 μg/kg, and fentanyl 0.5 μg/kg) or ketamine according to locally established sedation protocols (see Chapter 48). Alternatively, a single-injection digital nerve block is safe and effective for minor surgical procedures.[274]

Surgery for extensive injuries to digits and limbs usually requires general anesthesia because children do not tolerate prolonged application of a tourniquet. The severity and urgency of the injury dictate the timing of the surgery. The general principles of care for the child with trauma should be followed (see Chapter 39), with particular attention directed to identifying more life-threatening injuries. For urgent surgery in the presence of a full stomach, precautions against aspiration of gastric contents should be considered. For postoperative pain control, a combination of regional anesthesia or systemic analgesia is usually adequate. Continuous brachial plexus or other nerve blocks may improve tissue perfusion[275] and facilitate cooperation during postoperative physiotherapy for procedures such as digital reimplantation. Continuous nerve block may attenuate the signs associated with compartment syndrome, and frequent and meticulous attention must be paid to perfusion of the extremity.

ANNOTATED REFERENCES

Antony AK, Sloan GM. Airway obstruction following palatoplasty: analysis of 247 consecutive operations. *Cleft Palate Craniofac J*. 2002;39(2):145-148.

Two hundred forty-seven children underwent palatoplasty, yielding a 6% incidence of perioperative airway obstruction. The airway obstruction occurred as late as 48 hours postoperatively. Of the 14 children with severe airway compromise, 12 required continued tracheal intubation, reintubation, and tracheostomy. Of these 14 children (93%), 13 had coexisting craniofacial abnormalities, with 7 having Pierre Robin sequence.

Faberowski LW, Black S, Mickle JP. Incidence of venous air embolism during craniectomy for craniosynostosis repair. *Anesthesiology*. 2000;92(1):20-23.

This case series of 23 children undergoing craniosynostosis reported an 83% incidence of venous air embolism using precordial Doppler monitoring. Although cardiovascular collapse did not occur, 32% developed hypotension. Detection and early intervention are important strategies to prevent cardiovascular collapse associated with this type of surgery.

Goobie SM, Haas T. Bleeding management for pediatric craniotomies and craniofacial surgery. *Paediatr Anaesth*. 2014;24(7):678-689.

This review summarizes patient blood conservation techniques and their application in pediatric craniofacial surgery and in children undergoing craniotomies. The management of massive blood loss and North American and European guidelines for transfusion management are discussed.

Goobie SM, Meier PM, Pereira LM, et al. Efficacy of tranexamic acid in pediatric craniosynostosis surgery: a double-blind, placebo-controlled trial. *Anesthesiology*. 2011;114(4):862-871.

This randomized, placebo-controlled trial examined the effects of tranexamic acid on blood loss during reconstructive craniosynostosis surgery. Both blood loss and blood transfusion requirements were significantly reduced, by almost 50%.

Jackson O, Basta M, Sonnad S, et al. Perioperative risk factors for adverse airway events in patients undergoing cleft palate repair. *Cleft Palate Craniofac J*. 2013;50(3):330-336.

Three hundred children younger than 2 years of age undergoing primary cleft palate repair using the modified Furlow technique were reviewed for the occurrence of perioperative adverse airway events. Adverse airway events occurred in 23% of patients overall. Airway complications were more likely in children with a craniofacial syndrome, preoperative airway problems, and with less experienced providers.

Lavoie J. Blood transfusion risks and alternative strategies in pediatric patients. *Paediatr Anaesth*. 2011;21(1):14-24.

This review summarizes blood conservation modalities such as acute normovolemic hemodilution, hypervolemic hemodilution, deliberate hypotension, antifibrinolytics, intraoperative blood salvage, and autologous blood donation. The transfusion triggers and algorithms and the current literature in blood transfusion alternatives are discussed.

Meier PM, Goobie SM, DiNardo JA, et al. Endoscopic strip craniectomy in early infancy: the initial five years of anesthesia experience. *Anesth Analg*. 2011;112(2):407-414.

This retrospective chart review studied 100 infants ranging from 4 to 34 weeks of age (weight: 3.2-10.1 kg) who underwent single and multiple endoscopic strip craniectomies. Four infants had a craniofacial syndrome; 87 infants underwent single and 13 multiple craniectomy. The risk factors for bleeding are identified, along with an emphasis on venous air embolism, intensive care unit admissions, and reoperation.

Nargozian C. The airway in patients with craniofacial abnormalities. *Paediatr Anaesth*. 2004;14(12):53-59.

This review summarizes the salient features and airway implications of the major craniofacial disorders that affect children, including Pierre Robin sequence, Treacher Collins syndrome, Goldenhar syndrome, and Klippel-Feil syndrome. The anatomic pathology is very well described, and the clinical implications of the pathologic condition are thoroughly discussed.

Summary

MILLIONS OF PEOPLE ARE TREATED FOR BURNS every year in the United States: hundreds of thousands of those who are hospitalized have a significant mortality rate.[1–3] The National Burn Repository Report for 2014 reviewed its 10-year experience (2003–2013)[4]; overall mortality from 191,848 records in both males (3.4%–2.7%) and females (4.6%–3.3%) was reduced compared with the previous epoch. Children younger than 5 years of age accounted for 19% of cases (27,379), with most children burned in their homes (~73%). The racial distribution was ~59% Caucasian, ~20% African American, 14% Hispanic, 2.4% Asian, and other ~5% with most pediatric injuries caused by scalds or contact with hot objects. Inhalation injury was reported in 5.4% of cases. Approximately 1861 cases were suspected child abuse. Mortality varied from 0.6% in those with less than 10% body surface area (BSA) burns to ~84% for those with more than 90% BSA burns. It is estimated that approximately 200,000 children with burn injuries are treated in the emergency department each year in the United States; the majority are younger than 6 years.[4,5] Children with burn injuries are well managed only when their care providers thoroughly understand the pathophysiologic and pharmacologic abnormalities associated with burn injury.[6,7] These abnormalities include metabolic derangements, neurohumoral responses, massive fluid shifts, sepsis, and the systemic effects of massive tissue destruction. In this chapter we address the pathophysiology, the initial evaluation and resuscitation, and the anesthetic and pain management of children with burn injuries. Some of the principles presented are the result of more than 40 years of experience in caring for children with burn injuries, and others are derived from experiences with adults and applied to children.

Approximately 486,000 people suffered burn injuries in the United States in 2015, with about 15,000 children hospitalized with burn injuries.[1] The mortality rate from burn injuries has declined steadily over the past decades, owing to the advent of dedicated hospital burn centers,[8,9] improved surgical techniques, and safer anesthetic management. However, almost 1100 children still die each year from fire and burn injuries (http://burninjuryguide.com/burn-statistics/). Safety prevention efforts such as smoke detectors have not reduced pediatric flame injuries because many flame injuries are related to children playing with matches,[10,11] although there has been a small overall decrease in total burn injuries to children.[12]

Pathophysiology

Thermal injury to the skin disrupts the vital barrier responsible for thermal regulation, bacterial defenses, and fluid and electrolyte balance.[13] Even minor, localized burn injuries may be associated with diffuse and dramatic systemic responses that can have an impact on all systems of the body.[6] Mediators released from the burned areas (complement, arachidonic acid metabolites, cytokines, and oxygen radicals) activate local and systemic inflammatory responses.[7,14] Abnormal cytokine values reflect the severity of injury, and these abnormalities may persist for years after injury.[15–19] Endotoxins are frequently detected immediately after the burn, correlate with burn size, and are predictive of multiorgan failure and the subsequent patient demise.[20] The clinical symptoms and pathologic changes are relatively more severe in children, and unfortunately the gravity of the injury is often underestimated because of their greater BSA/weight ratio (Fig. 36.1).[21,22]

Soon after the injury, massive fluid volumes shift from the vascular compartment to burned tissues and nonburned areas of the body resulting in hemoconcentration.[6,23] Despite this massive fluid loss, systemic blood pressure is usually maintained by vasoconstriction through an outpouring of catecholamines and antidiuretic hormone.[24] In the first 4 days after a moderate- or larger (~40% BSA)-sized burn, an amount of albumin equal to

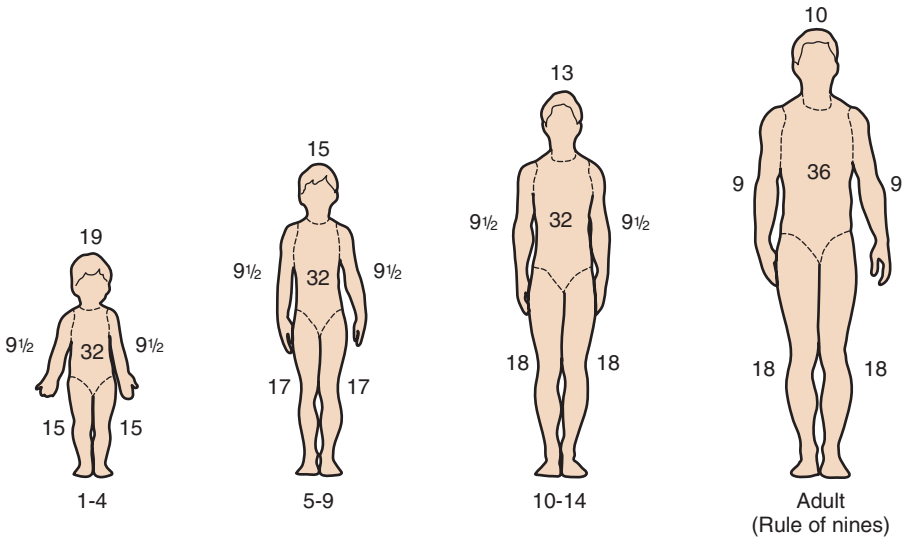

FIGURE 36.1 The different proportions of body surface area are illustrated for the calculation of percentage of burn according to a patient's age. Note the large proportion of body surface area that the head and face account for in an infant. (From Carvajal HF, Goldman AS. Burns. In: Vaughan VC III, McKay RJ, Nelson WE, eds. *Nelson's Textbook of Pediatrics*. Philadelphia: WB Saunders; 1975:281.)

approximately twice the total body plasma content is lost through the wound. In addition to the direct effects of the burn (thrombosis, increased capillary permeability), changes in vascular integrity occur in areas remote from the injury, resulting in widespread edema,[25] including life-threatening pulmonary edema.

A review of 821 pediatric patient outcomes noted a very high mortality rate when three or more organs failed. Respiratory failure occurred primarily in the first 5 days, cardiac and renal failure in the first 3 weeks, and hepatic failure with increasing the duration of hospital stay.[26]

CARDIAC

Immediately after an injury, cardiac output is dramatically reduced.[27,28] This is related to both the rapid reduction in circulating blood volume and the severe compressive effects of circumferential burns on the abdomen and chest that impair venous return.[29] Despite volume replacement and adequate cardiac filling pressures, cardiac output often remains reduced because of direct myocardial depression from circulating myocardial depressant factors such as interleukins, tumor necrosis factors, altered β-adrenergic receptor modulation,[30] or oxygen free radicals in victims with extensive third-degree burns.[31–34] Transesophageal echocardiography may be helpful in guiding supportive care in the early phase.[35] Our experience is that acutely burned children frequently require inotropic support during this acute period of depressed cardiac function; inotropes improve cardiac output while avoiding volume overload. Decreased cardiac output may also be caused by gram-negative sepsis or ongoing hypovolemia.

Children develop a hypermetabolic state 3 to 5 days after a burn injury. This state is associated with a twofold to threefold increase in cardiac output, which persists for weeks to months, depending on the extent of the injury and the time needed for wound closure; heart rate, cardiac output, cardiac index, and rate-pressure product are increased for at least 2 years after burns that involve 40% or more of BSA.[36] Some children develop a reversible cardiomyopathy.[37] Hypertension also occurs during this hypermetabolic period, which may in part, be related to inadequate pain control. However, mediators such as increased catecholamines, atrial natriuretic factor, renin-angiotensin, endothelin-1, vasopressin, and others can cause intermittent or persistent hypertension.[38–42] Closure of the burn wound usually decreases metabolic demand, resulting in a concomitant reduction in cardiac output.[43,44] Some children may benefit from treatment with propranolol, which reduces cardiac work and decreases the systemic inflammatory response but does not appear to have any impact on mortality.[45–47] Despite the widespread use of propranolol in both adults and children to attenuate this hypermetabolic response, neither randomized studies nor a consensus regarding the dosing have been forthcoming.[48]

PULMONARY

Pulmonary function may be adversely affected from the upper airway to terminal alveoli.[49,50] The upper airway is an excellent heat exchanger; just as it warms cold air, it cools hot air. The air in a closed space (e.g., house or automobile fire) may reach 538°C (1000°F) 2 feet above floor level; cooling of hot inspired air causes a severe thermal injury to laryngeal structures, particularly those above the glottis.[51] These airway burns cause massive edema of all laryngeal and tracheal structures above the carina (see later discussion). The thermal insult also injures or destroys the ciliated epithelium and mucosa in the proximal bronchi. The inhalation of toxic fumes, such as nitrogen dioxide and sulfur dioxide released from burning plastic that combine with water in the tracheobronchial tree to form nitric and sulfuric acids, may damage the distal bronchi and alveoli. These acid gases and phosgene are small aerosolized particles that penetrate deep into the tracheobronchial tree, damaging alveolar membranes and surfactant.[52] Thus upper airway injury is usually a thermal insult, whereas lower airway injury is a chemical or toxic insult. Wool and cotton combustion forms aldehydes, which in concentrations as small as 10 ppm may cause coughing and "respiratory braking" that reduce the rate and depth of breathing and cause pulmonary edema.[53,54] Combustion of synthetic materials (insulation, wall paneling), particularly in enclosed-space fires, releases hydrogen cyanide[55]

leading to histotoxic hypoxia and death,[56] while mimicking carbon monoxide (CO) poisoning.[57] Inhalation of hydrogen cyanide is an often unrecognized cause of immediate death.[58,59] The role of hydroxocobalamin in this setting is unclear but is recommended by some centers when cyanide toxicity is suspected.[60–63]

The overall effect of a pulmonary inhalation injury is necrotizing bronchitis, bronchial swelling, alveolar destruction, exudation of protein, loss of surfactant, loss of the protective bronchial lining, loss of cilial function, and bronchospasm, all of which contribute to the development of bronchopneumonia (Figs. 36.2 and 36.3).[49] Inhalation of particulate matter (smoke, soot) and lower airway edema also obstruct the airway mechanically. Edema of the bronchi, combined with loss of integrity of the pulmonary capillary endothelium, decreases pulmonary compliance. Circumferential chest burns may have a tourniquet-like effect that decreases chest wall compliance; escharotomy even in the prehospital setting may be lifesaving.[29,64] All of these injuries lead to ventilation-perfusion abnormalities and right-to-left intrapulmonary shunting, with hypoxemia and hypercarbia. In adults, the PaO_2/FIO_2 ratio and baseline carboxyhemoglobin (COHb) concentrations are predictive of mortality.[65] One center has reported improved early oxygenation in children with the use of high-frequency oscillation ventilation[66]; the use of extracorporeal membrane oxygenation has had mixed results with no apparent improvement in outcomes.[67]

One pediatric trial of inhaled heparin and acetylcysteine suggested a benefit with decreased airway cast formation and mucus plugging.[68] However, subsequent studies have yielded contradictory results.[69,70] CO inhalation can further compromise both hemoglobin's oxygen (O_2)-carrying capacity and its ability to deliver O_2 to tissues. CO also impairs O_2 usage at the cellular level (cellular respiration). Severe smoke inhalation alone may occur without externally visible injuries.[58,59,71] One clue that smoke inhalation has occurred is the presence of singed nasal hairs or nasal passages. Steam inhalation can also cause supraglottic edema that presents with symptoms similar to epiglottitis related to edema rather than infection.[72]

Reduction in cardiac output also can contribute to hypoxemia. Thus correction of arterial O_2 desaturation requires evaluation of

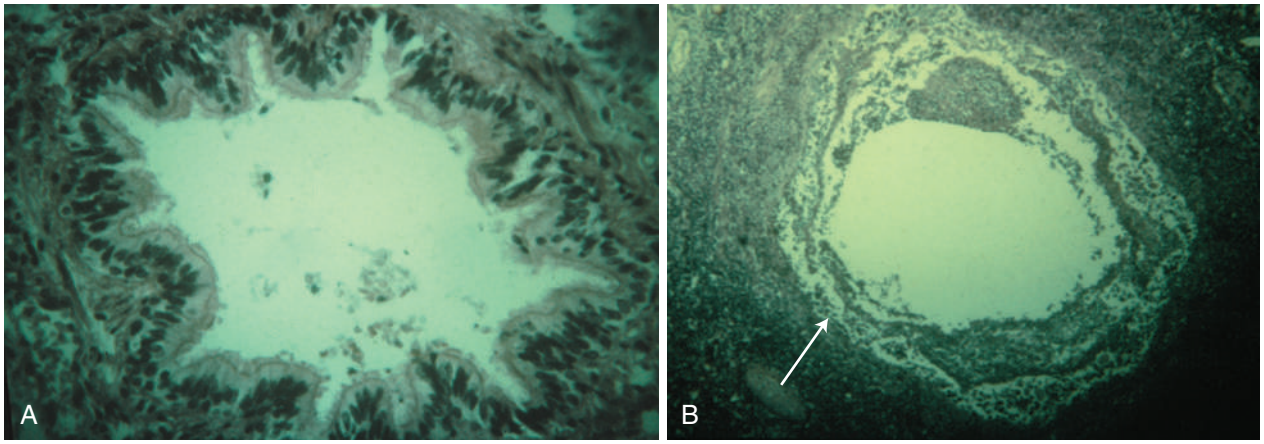

FIGURE 36.2 **A**, Cross section of a normal bronchiole. Note the ciliated epithelial layer. **B**, Compare with a cross section of a distal bronchiole from a child who died of an inhalation injury. Note the marked thickening of the bronchial wall, the massive inflammatory cell infiltrate, the sloughing of the mucosa *(arrow)*, and the total destruction of the ciliated columnar epithelium.

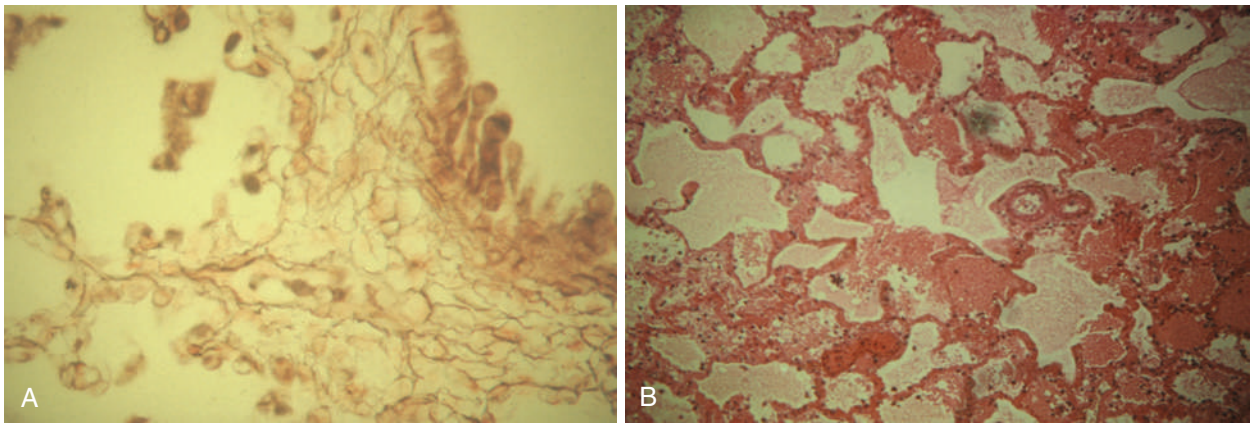

FIGURE 36.3 **A**, Normal alveoli. **B**, Inhalation alveolar injury is generally related to noxious fumes such as nitrogen dioxide and sulfur dioxide that are carried far down the tracheobronchial tree, combine with exhaled water, and form nitric acid and sulfuric acid, resulting in pulmonary congestion, alveolar injury, and hyaline membrane formation.

both extrapulmonary and intrapulmonary factors,[25,73] including cardiac output, mixed venous O_2 content or saturation, and shunt fraction.[27] In general, the prognosis for survival is diminished by the presence of an inhalation injury that doubles the mortality from cutaneous burns[52]; in children mortality is reported to be approximately 16%.[74]

RENAL

Renal function may be adversely affected soon after the injury, primarily as a result of myoglobinuria and hemoglobinuria but also from hypoxemia, hypotension, or inhaled toxins leading to acute tubular necrosis.[75] Myoglobinemia most commonly occurs after electrical injury,[76,77] whereas hemoglobinemia is common after severe cutaneous burns covering 40% or more of BSA. Catecholamines, angiotensin, and vasopressin production increase; and release of vasoactive peptides such as endothelin-1 cause systemic vasoconstriction, compounding the renal dysfunction.[78–81] Fluid retention is common during the first 3 to 5 days after a burn injury and is followed thereafter by a diuresis. Glomerular filtration rate (GFR) decreases soon after the injury, although 3 to 7 days after the burn injury, it actually increases pari passu with an increased cardiac output and metabolic rate, thus affecting the clearance (increased or decreased) of many antibiotics and other medications that depend on renal excretion.[82–87] Children who sustain a burn affecting 40% or more of BSA demonstrate renal tubular dysfunction with an inability to concentrate urine.[24] Even during hyperosmolar states, antidiuresis is not observed, suggesting an inadequate renal response to antidiuretic hormone and aldosterone. Thus an adequate urine output may be observed even in the presence of hypovolemia.[88] Episodic or persistent hypertension is frequent in children, in part mediated by an increase in renin and catecholamine production[89,90]; in some children treatment with propranolol may be indicated.

HEPATIC

The liver may also be damaged by hypoxemia, hypoperfusion as a result of inhaled or absorbed chemical toxins, hypovolemia, or hypotension during the early postburn phase.[91,92] Reperfusion injury may harm the liver when an adequate circulation is reestablished. Hepatic dysfunction may also result from drug toxicity, sepsis, the hypermetabolic response to burns, or blood transfusions.[19] Studies in adults and animal models have found increased hepatic blood flow, increased protein synthesis and breakdown, and increased hepatic gluconeogenesis during the hypermetabolic phase of burn injury.[93] Sustained increases in hepatic blood flow deliver more drug to the liver; this effect, combined with drug-induced enzyme induction, may increase the clearance of drugs.[94] Although all studies of animals suggest decreased clearance of drugs after burn injury, clinical studies of the capacity of the liver to metabolize drugs are conflicting, even for the same class of drugs.[95–100] The magnitude of the burn, the time after injury, and the effects of coadministered drugs, alone or in combination, as well as alterations in protein binding and volume of distribution, may have contributed to the conflicting reports regarding drug half-lives. With the onset of sepsis, hepatic glucose output and alanine uptake may decrease sharply but hepatic blood flow and O_2 usage can remain increased.[91,101] Fatty infiltration of the liver has also been reported.[102]

CENTRAL NERVOUS SYSTEM

The central nervous system (CNS) may be adversely affected by inhalation of neurotoxic chemicals or by hypoxic encephalopathy; other contributing factors include sepsis, hyponatremia, and hypovolemia.[103] CNS dysfunction includes hallucinations, personality changes, delirium, seizures, abnormal neurologic symptoms, and coma,[104] which may be due to the burn injury or to the drugs necessary for sedation, anxiolysis, and analgesia[105]; these effects usually clear after several weeks. Abnormalities of CNS neurotransmitters have been postulated to mediate the anorexia associated with extensive burn injury.[106] The possibility of cerebral edema and increased intracranial pressure must also be considered during the initial phases of burn injury. Under such circumstances, the usual measures for treating increased intracranial pressure would be instituted (see Chapter 26). Rapid overcorrection of hyponatremia also may be associated with cerebral injury.[107]

HEMATOLOGIC

The hematopoietic system is also adversely affected after burn injury. Blood viscosity may increase with hemoconcentration secondary to fluid shifts and alterations in plasma protein content.[108] Ongoing microangiopathic hemolytic anemia is common.[109] An inhibitor of erythroid stem cells may contribute to the anemia of burns, but burned patients have a normal erythropoietin response to anemia.[110] The half-life of red blood cells is diminished and multiple blood draws further contribute to the development of anemia.[111,112] The possible role of recombinant erythropoietin in the care of children with burns has yet to be defined.[113–116] One study in adults reported no reduction in either mortality or blood transfusion requirements in patients who received recombinant erythropoietin compared with controls.[117] However, evolving evidence suggests that recombinant erythropoietin may promote skin and burn wound healing when administered systemically or locally injected.[118–121]

In the early stage, thrombocytopenia secondary to increased platelet aggregation with a nadir at approximately 3 days and trapping of platelets in the lungs is followed by an increase in platelet count 10 to 14 days after the burn injury. A prolonged period of thrombocytopenia and reduced nadir in platelet count compared with survivors are both associated with sepsis and increased mortality.[122,123] In some patients, thrombocytopenia may persist for several months.[112,122] An increase in fibrin split products (disseminated intravascular coagulopathy), which lasts for 3 to 5 days, may also occur.[85] Factors V, VII, and VIII and fibrinogen are increased several-fold over baseline for the first 3 months after severe injury uncomplicated by sepsis.[124,125] Children with increased platelet counts (thrombocytosis) (>1 million/mm^3) who then developed sepsis in our unit experienced a marked decrease in the platelet count; the sudden onset of thrombocytopenia should prompt an evaluation of the child for sepsis.[122,123,126] Likewise, large swings in the fibrinogen concentration can occur (up to 2 g/dL),[127] although these do not appear to herald an increase in the incidence of thrombotic events.

GASTROINTESTINAL

Gastrointestinal function is diminished immediately after thermal injury secondary to the onset of gastric stasis and intestinal ileus.[128] Because of the risk of pulmonary aspiration of gastric contents during this time, the stomach should be adequately vented and appropriate gastric acid ulcer prophylaxis instituted. At 48 to 72 hours after a burn injury, when generalized edema is resolving, gastrointestinal function usually resumes. Enteral feeding should be established at this time to provide calories, to blunt the hypermetabolic response, and to attenuate gluconeogenesis and stress ulceration.[108,129–132] Early enteral feeding has the added

advantages of diminishing muscle catabolism, reducing bacterial translocation through the intestinal mucosa, and being associated with reduced mortality.[133–136]

In children who do not tolerate enteral feeding, parenteral nutrition must be initiated.[129,132,137,138] Stress ulcers (Curling ulcers) are associated with any burn injury and may be life-threatening, although the incidence has decreased in critically ill patients because of better management of systemic hypoperfusion, early gut feeding, and improved pharmacologic control of gastric acidity.[139] Prospective studies of pediatric and adult burn patients and patients in intensive care indicate that cimetidine or ranitidine in the usual doses does not adequately protect critically ill patients from increases in gastric acidity.[83,84] The increased requirement for drugs is due to alterations in their pharmacokinetics.[83] Therefore frequent feedings when tolerated and the liberal use of antacids, combined with larger or more frequent doses of H_2-receptor antagonists (or proton pump inhibitors), may be required to prevent stress ulcers.[83,108,128,140]

ENDOCRINE

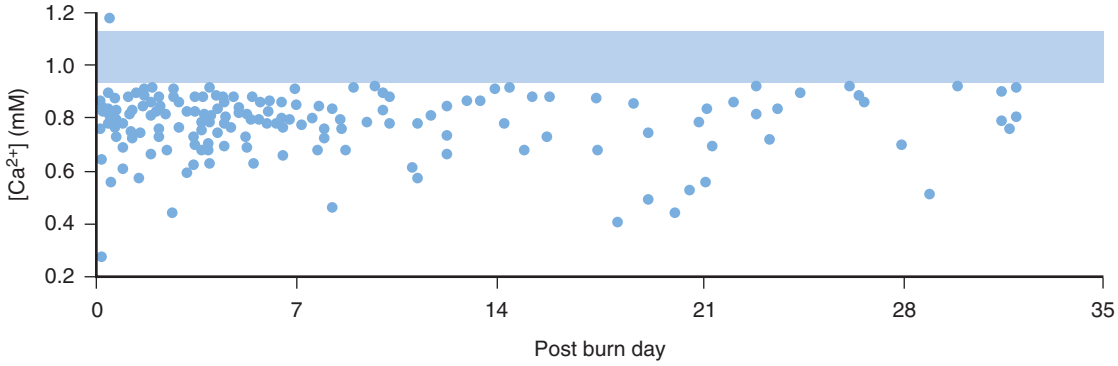
The endocrinologic response to acute thermal injury involves most organ systems. Stimuli that trigger endocrine responses include the thermal injury itself, type of burn (scald vs. flame) and subsequent fluid shifts, as well as the stress responses associated with critical illness.[141,142] These may include decreased circulating hormone concentrations (e.g., triiodothyronine, dehydroepiandrosterone, and testosterone), as well as increased concentrations of other hormones (antidiuretic hormone, catecholamines, renin, angiotensin II, and cortisol).[143] Replacement therapy with synthetic androgenic steroids (e.g., oxandrolone) reduces acute hospital stay, improves body composition (lean body mass), muscle protein deposition,[144] and hepatic protein synthesis.[145,146] A 5-year follow-up study found that oxandrolone-treated children had improved height percentile, bone mineral content, and improved cardiac function and muscle strength; no adverse effects from long-term administration were noted.[147] Glucose control may be poor, owing to the increased levels of cortisol and insulin resistance; abnormal glucose control may persist for up to 36 months after the burn injury.[148–151] Tight control of hyperglycemia may improve mitochondrial oxidative capacity,[152] reduce protein turnover,[153] decrease the incidence of urinary tract infection, and improve the survival of critically ill burn patients, although the last finding resulted from a single study.[154,155] However, this needs to be balanced with the increased likelihood of hypoglycemic events, which in turn are associated with increased mortality.[153,156] Avoiding hyperglycemia may attenuate the risk of cerebral injury from hypoperfusion states (see Chapters 26 and 39); one group recommends a target blood glucose level of 130 mg/dL.[155] Blocking the renin-angiotensin system may improve the insulin response after burn injury.[45–47,157]

SKIN

Extensive skin destruction, proportional to the number of layers of tissue damaged, results in the inability to regulate body heat, conserve fluids and electrolytes, and protect against bacterial invasion.[158] Because children have a much greater BSA/weight ratio compared with adults, they are more likely to become hypothermic (see Fig. 36.1). Thus it is important to keep children covered as much as possible, to increase the environmental temperature, and to use radiant warmers, plastic wrap around extremities, reflective insulated blankets, artificial "noses" (in-line moisture and heat exchangers), and hot-air heating blankets. Late complications affecting the skin include progressive scar formation, which results in movement-restricting contractures.[29,159] Topical antibiotic and antibacterial therapy are necessary to prevent burn wound sepsis.[160–165] There is evolving evidence and intensive investigation regarding the role of stem cell therapy that may improve burn would healing and reduce scar formation.[166–174]

METABOLIC

Many metabolic changes follow extensive burn injury.[175] Increased use of glucose, fat, and protein (particularly muscle breakdown)[176] results in greater O_2 demand and increased carbon dioxide (CO_2) production.[a] Mediators that have been implicated in these metabolic changes include interleukin-1, tumor necrosis factor, catecholamines, prostanoids, and other stress hormones.[2,184] Centrally mediated or sepsis-induced hyperthermia also increases O_2 consumption and CO_2 production. Some of these abnormalities may persist even after complete closure of burn wounds, when metabolic demand is already reduced.[b] Intravenous (IV) alimentation, particularly with increased glucose concentrations, may also increase CO_2 production and therefore increase ventilatory requirements.[137] The increase in O_2 demand[186] and CO_2 production must be compensated for during controlled mechanical ventilation; treatment of fever reduces metabolic demand.[187]



CALCIUM HOMEOSTASIS

The ionized calcium concentrations in acutely burned patients are dramatically decreased. Marked abnormalities of calcium and magnesium metabolism, including hypoparathyroidism in both acute and recovery phases, may persist for weeks after injury (E-Fig. 36.1).[188,189] Increased bone resorption with failure of bone calcium uptake, as well as low levels of vitamin D and a markedly reduced conversion in burned skin of dehydrocholesterol to previtamin D, result in bone density loss.[190–192] Treatment with pamidronate, a drug that inhibits bone resorption, conserves bone mass and reduces muscle protein turnover after burn injury in children.[193–195] Hypophosphatemia and hypermagnesemia revert toward normal during the latter phase of recovery from the acute injury. The usual reciprocal relationship between calcium and inorganic phosphate is not evident in those with major burns. Therefore supplemental calcium therapy is extremely important, particularly when rapid intraoperative colloid and fresh frozen plasma (FFP) infusions are required, because ionized hypocalcemia dramatically impairs cardiovascular homeostasis. Frequent small boluses of calcium are safer and more effective than intermittent large boluses (see also Figs. 12.8 and 12.9).[196] Doses of 5 mg/kg calcium chloride or 15 mg/kg calcium gluconate ionize at equivalent rates and produce equivalent increases in serum calcium concentration. During and after recovery from burn injury, high-dose vitamin D supplements are strongly recommended to offset the decreased conversion of 7-dehydrocholesterol to previtamin D_3.[197–199]

NEUROPSYCHIATRIC

It is imperative to recognize that physical trauma is not the only trauma sustained by the pediatric burn patient; psychological trauma and its associated long-term sequelae are also common.[200,201] A large percentage of acutely burned children and their parents present with acute stress or develop posttraumatic stress disorders[200–204];

[b]References 15, 18, 19, 44, 46, and 185.

E-FIGURE 36.1 Ionized calcium values from burned children and adults are plotted for the first 35 days after burn injury. Note that the majority of values are abnormally low; the *shaded blue area* shows the range of normal values. (From Szyfelbein SK, Drop LJ, Martyn JA. Persistent ionized hypocalcemia during resuscitation and recovery phases of body burns. *Crit Care Med*. 1981;9[6]:454–458.)

risk factors include the size of burn, the degree of pain, the pulse rate, and parental issues.[205] Treatment with fluoxetine or imipramine may ameliorate these stress disorders,[206–208] although one randomized controlled study found no difference from placebo.[209] Another study found risperidone to be of value in reducing stress symptoms.[210] There is an increased incidence of attention-deficit disorders in pediatric burn patients, likely owing to impulsivity.[211,212] Another concern is that sleep efficiency with markedly decreased rapid eye movement time persists for years in children after burn injury, which might necessitate consultation with a sleep specialist.[213] A study of the pharmacokinetics of zolpidem prescribed to reduce sleep fragmentation and insomnia reported an increased frequency or dose may be required for children with large burns.[214] Furthermore, after a burn injury, obese children are at significant risk for obstructive sleep apnea, abnormal respiratory disturbance index, episodes of desaturation, and apneic events.[215] Additionally, a normal psychosocial support network may be impaired in the families of burn patients, even before the burn injury.[216–218]

Pharmacology

Burn injury induces many physiologic changes that affect drug pharmacokinetics and pharmacodynamics. During the hypovolemic period, uptake and clearance of drugs may decrease because of impaired organ perfusion.[2,94–97,219] During the hypermetabolic phase, the activity of organs that clear drugs from the circulation (e.g., the liver and kidneys) are enhanced because of enzyme induction and increased blood flow.[a] Massive edema and loss of drugs through burn wounds increase the volume of drug distribution.[226]

Many drugs are highly bound by plasma proteins, rendering only a small unbound fraction that determines the drug activity. The two major binding proteins, α_1-acid glycoprotein and albumin, increase and decrease, respectively, after a burn injury. These changes exert substantive effects on the free fractions of the drugs they bind.[94,223,227] For example, the clearance of morphine and meperidine is enhanced or impaired, depending on the size of the burn, with a trend to reduced morphine or meperidine clearance after large burns compared with moderate burns. In general, burned children clear drugs more readily than those without burn injuries.[96–98,226,228,229] Similarly, pharmacokinetic studies of lorazepam and diazepam indicate that the clearance of the former is increased, whereas that of the latter is decreased.[99,100] In the case of oral ketamine, the clearance was unaffected in children with small burns, although gastric absorption of the oral formulation was delayed.[230]

Evidence indicates that burn injury, with its complications and hormonal responses, may affect the number of receptors in tissues.[99,106,219,223,231–238] Therefore reports of aberrant responses to drugs acting on adrenergic and cholinergic receptors are not surprising. These include altered sensitivity to succinylcholine at the neuromuscular junction, increased sensitivity to dopamine in the pulmonary circulation, and decreased sensitivity to nondepolarizing neuromuscular blocking drugs (NDBDs).[94,231,233–235,239–241] Other examples of drugs affected by burn-induced kinetic and dynamic changes include aminoglycoside antibiotics, diazepam, and cimetidine. Burn-induced alterations in kinetics and dynamics make the clinical response to any medication unpredictable. Therefore clinical effects should always be closely monitored and plasma concentrations, protein binding, and clearance evaluated when possible.[83,86,94,242–246] Dexmedetomidine (see later discussion) also may have altered pharmacodynamics in the burned child; because of the known hypotensive effects of the α_{2a}-adrenoceptor agonists, particular attention to limit the dose and to ensure euvolemia may minimize the hemodynamic consequences.[247]

Resuscitation and Initial Evaluation

Resuscitation of children with a burn injury requires a clear and secure airway, as well as maintenance of adequate oxygenation, perfusion, and circulating blood volume. The diagnosis and evaluation of associated injuries also must be considered.

AIRWAY AND OXYGENATION

Every burn patient, especially those with inhalation injuries, must be considered hypoxemic and exposed to CO. Therefore during transport to the hospital and on admission, administration of high inspired concentrations of O_2 is mandatory, pending evaluation of the severity of CO poisoning and pulmonary injury (see later discussion).[246] Direct injury to the airway and alveoli occurs in children with inhalation of smoke, flames, superheated air, noxious gases, or steam.[b] When a child is burned in an enclosed space (house, automobile) or if thermal burns or carbonaceous materials are evident about the mouth and nose, inhalational injury is probable.[258,276] Upper airway obstruction caused by edema of the lips, nose, tongue, pharynx, glottis, and subglottis is very common. The resultant airway obstruction can be compared with the combined effects of acute macroglossia, epiglottitis, macro uvula, and laryngotracheobronchitis. The decreasing patency of the airway resulting from rapidly increasing edema, beginning in the first hours after the injury and lasting several days, makes delayed intubation hazardous if not impossible (Fig. 36.4). Prophylactic intubation should be performed in any case of severe facial burns or when pulmonary burn and upper airway inhalation injury are suspected. Mortality is related to the presence or absence of inhalation injury.[71,74,265–275,277]

Control of the airway in children is usually accomplished with the child under general anesthesia. Our early clinical experience showed that tracheal tubes could be left in place in these children for weeks with fewer risks than the alternative, tracheostomy.[278,279] Tracheostomy in thermally injured children was associated with high mortality rates; in one pediatric series the death rate approached 100%.[280] However, in recent years and with the development of superior antibiotics, there has been a move back to performing tracheostomy for children expected to require long-term ventilation, although one review of burn centers in North America found that the practice of performing a tracheostomy in burned children varied.[281] Some report that an early tracheostomy reduces the risk of subglottic stenosis[282,283]; the duration of tracheostomy is related to BSA burn and not age.[284] When early airway instrumentation is indicated, a cuffed tracheal tube is preferred to reduce the need for changing the tube to deliver high peak inspiratory pressures should they be required.[285] We routinely use cuffed tracheal tubes, appreciating the added flexibility they offer as airway edema recedes, and it is common to allow permissive hypercarbia to reduce barotrauma.[286] Tracheal tubes with a more distal cuff and made of thinner material may reduce the potential for airway injury (see also Figs. 14.15 and

[b]References 53, 71, 74, 159, 184, and 248–275.

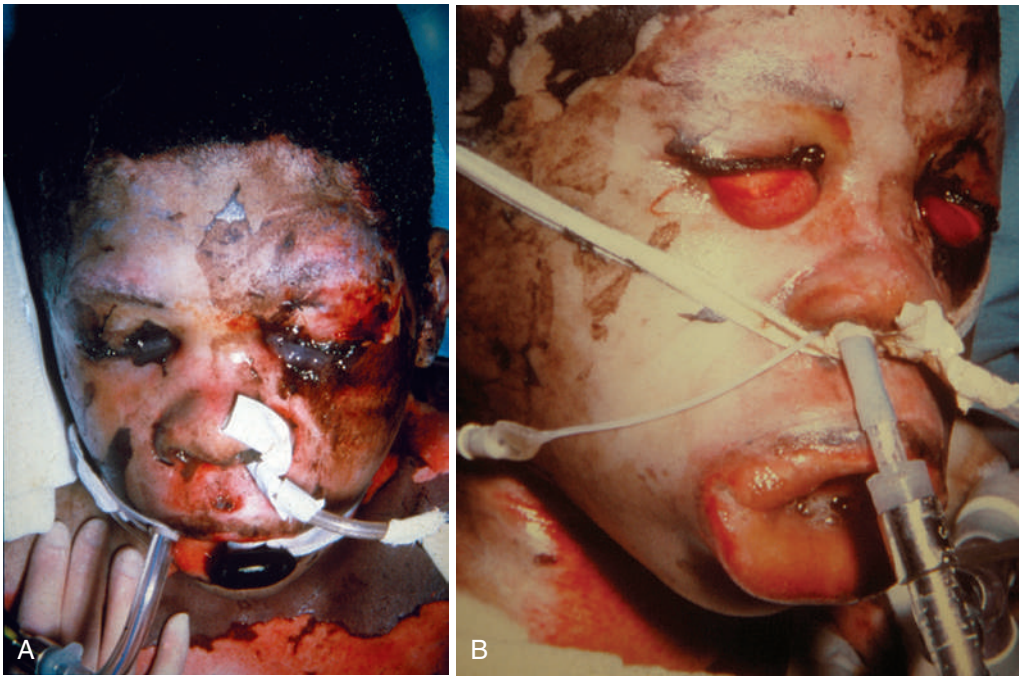

FIGURE 36.4 **A**, A young child who had just sustained a facial burn in a closed space. Note the early onset of facial edema. **B**, Several hours later there is massive edema that extends into the oropharynx, larynx, and trachea (similar to the combined effects of macroglossia, epiglottitis, and laryngotracheobronchitis). Early prophylactic intubation is mandatory in any facial burn or in any child when there is potential for inhalation injury. Note that the cuffed endotracheal tube was changed from an oral to a nasal position and that it is secured with cloth tape rather than adhesive tape.

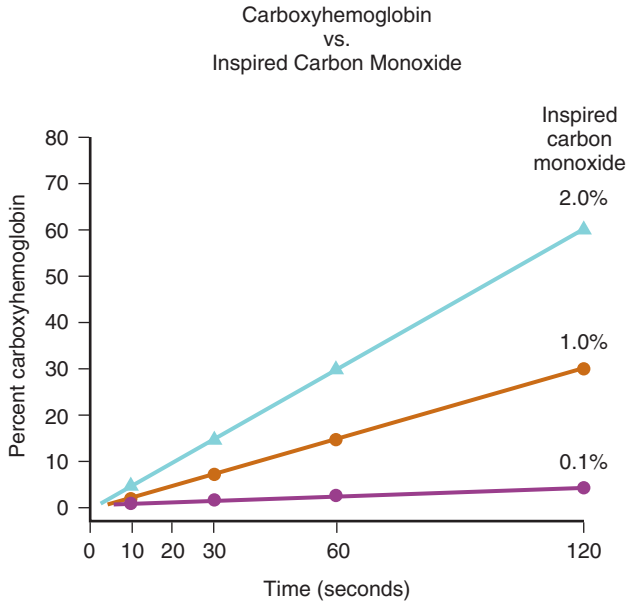
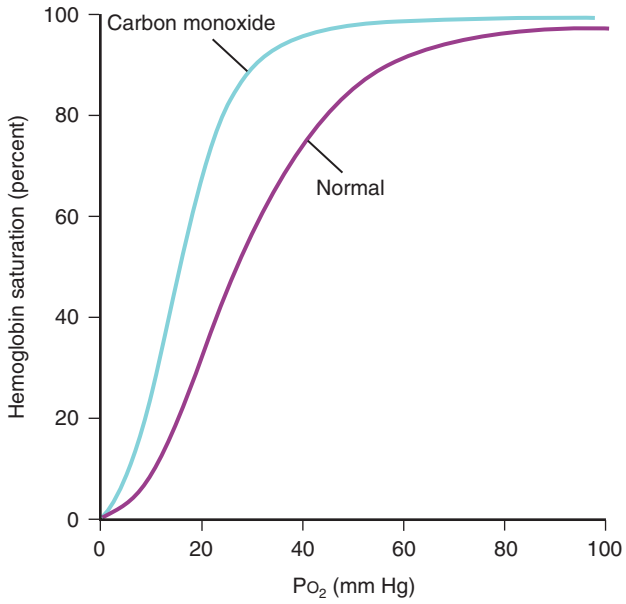
14.17), but in the hot environment of a burn unit, they may have a greater tendency toward kinking.[287–293]



CARBON MONOXIDE AND CYANIDE POISONING

Most smoke inhalation victims have CO poisoning; direct measurement of COHb is important to guide treatment. Estimates of COHb concentrations may be derived by measuring (not calculating) O_2 saturation or arterial O_2 content. The half-life of COHb is approximately 5 hours when the patient is breathing room air but decreases to 90 minutes when 100% O_2 is administered.[294,295] Immediate administration of O_2 is essential to achieve the maximum possible Pa_{O_2}. Positive-pressure ventilation[296–298] and hyperbaric O_2 may also be indicated (see later discussion).



Standard pulse oximeters cannot accurately monitor oxygen saturation in patients with CO poisoning because COHb produces an overestimation of O_2 saturation; the photodetector is "fooled" into interpreting COHb as oxyhemoglobin.[299–301] An eight-wavelength pulse oximeter is capable of measuring COHb and methemoglobin, but the sensors are quite expensive.[302–305] Concern arose from a study of 1363 patients that compared the Rad-57 device with cooximetry (Masimo Corporation, Irvine, CA), which reported a 9% incidence of false-positive values and an 18% incidence of false-negative values. The authors concluded that pulse oximetry with eight-wavelength sensors yields both greater and lesser values than standard measures of carboxyhemoglobin and that it should not be used for patient management decisions.[306] It is important to be aware that in neonates and young infants, the presence of fetal hemoglobin will result in a false increase in COHb.[307,308]

COHb is produced by the combination of CO with the iron of the heme radical at the O_2-binding site. CO combines more slowly with hemoglobin than O_2 but is bound 200 times more firmly.[309,310] Inhalation of 1% CO for just 2 minutes can result in COHb values of 30% (E-Fig. 36.2).[311] The toxic effects of CO poisoning are due to tissue, organ, and cellular hypoxia from decreased O_2 delivery because CO reduces O_2 binding capacity to the hemoglobin molecule at the tissue level and to cytochromes in the respiratory chain at the cellular level; even in small amounts, COHb shifts the O_2 dissociation curve to the left (E-Fig. 36.3), reducing release of O_2 from hemoglobin.[53,246,296,310–314] For example, if an individual had 40% COHb, this would reduce the O_2-carrying capacity from 20 mL/100 g of hemoglobin to 12 mL/100 g with the leftward shift, further compromising O_2 delivery.

Evidence supporting the use of hyperbaric oxygenation (HBO) therapy as an adjunct therapy for burns remains controversial.[108,315–319] A Cochrane review concluded that insufficient data exist to demonstrate reduced adverse neurologic outcomes with HBO therapy and that additional research is needed to "better define the role, if any, of HBO in the treatment of patients with CO poisoning."[320] The most common indication for hyperbaric therapy in burned children is concomitant CO poisoning.[53,321–325] Children with significant CO exposure are at risk of developing both acute and delayed neurologic sequelae. The pathophysiology of neurologic sequelae is unknown, although imaging studies suggest a potentially reversible demyelinating process.[326,327] The important practical question is whether hyperbaric treatment will decrease the frequency and severity of delayed neurologic sequelae in children with CO poisoning. This is a difficult question because

E-FIGURE 36.2 Note the rapid rise in carboxyhemoglobin values when just 1% carbon monoxide is inhaled.

E-FIGURE 36.3 The changes in the oxygen-hemoglobin dissociation curve that occur with carbon monoxide poisoning. The oxygen-hemoglobin dissociation curve is altered in shape and shifted to the left. Therefore less oxygen is available for delivery to tissues and the oxygen carried by hemoglobin is more tightly bound. (Modified from Douglas CG, Haldane JS, Haldane JBS. The laws of combination of hemoglobin with carbon monoxide and oxygen. *J Physiol*. 1912;44[4]:275–304.)

the incidence of delayed sequelae is unknown and determining the severity of the CO poisoning is difficult to pinpoint because there is a poor correlation between serum COHb and degree of CO exposure.[328,329] One study suggests that prolonged loss of consciousness and rescue by ventilation are major indicators for later neurologic sequelae.[330] Another study suggests that increased blood concentrations of lactate at the time of admission may provide additional guidance regarding duration of loss of consciousness.[331] Some clinicians believe that a history of unconsciousness indicates that an exposure has been severe enough to warrant treatment.[330–335] However, the relatively few randomized prospective studies evaluating this have returned conflicting results.[336,337] Hyperbaric O_2 treatment is not without expense, inconvenience, and risk, and the indications for treatment of burned children with concomitant CO poisoning are debated.[325,338] One study described complications during treatment of a heterogeneous group of patients: emesis (6%), seizures (5%), agitation requiring restraints or sedation (2%), cardiac dysrhythmias or cardiac arrests (2%), arterial hypotension (2%), and tension pneumothorax (1%).[325] Complications may be expected more frequently in the critically ill.[339]

The severity of delayed neuropsychological sequela do not seem to be related to the COHb concentration at the time of presentation.[340] Delayed sequelae include headaches, irritability, personality changes, confusion, memory loss, and gross motor deficits; a symptom-free interval of several days is commonly reported. Delayed hyperbaric treatment may relieve symptoms, and spontaneous resolution of delayed sequelae may be expected in up to 75% of patients within 1 year.[332,341–346] Data supporting the use of hyperbaric O_2 to prevent and treat these complications may be weak[336,337,347–352] but cannot be discounted given the seriousness of these sequelae.[317,318,353,354] Hyperbaric O_2 treatment is probably appropriate in burned children with documented or strongly suspected serious CO poisoning who are hemodynamically stable, not requiring ongoing burn resuscitation, and not wheezing or showing evidence of air trapping and in whom such treatment does not require interfacility transport.

Cyanide toxicity is another complication associated with inhalational burn injuries.[355] If cyanide poisoning is confirmed, administration of hydroxycobalamin or sodium thiosulfate, alone or in combination, is warranted (see Chapter 12).[57,356] HBO therapy has been shown to facilitate movement of cyanide out of tissues and into blood, thereby potentially facilitating treatment,[355] although the use of HBO for cyanide poisoning remains investigational.

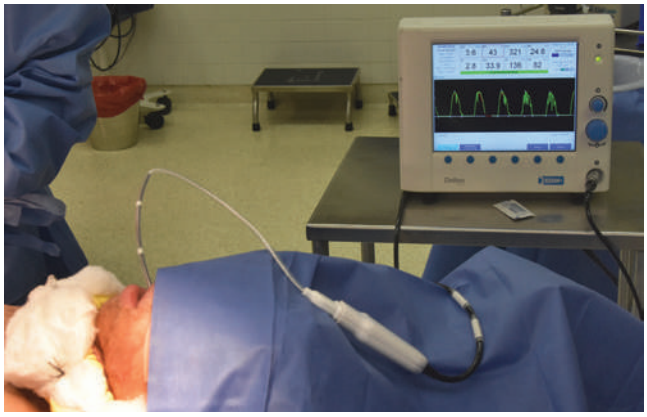
ADEQUACY OF CIRCULATION

The various formulas for determining fluid replacement are estimates and often need modification, depending on clinical and laboratory findings.[a] The most widely accepted fluid protocols in current use are the Parkland (Baxter) and Brooke formulas. Both formulas provide estimates of the fluid volume required for resuscitation, in addition to the calculated normal maintenance fluid requirement for each day. *These formulas are of great value in guiding the fluid resuscitation of older children; however, serious underestimation of the fluid volume may occur if applied to infants weighing less than 10 kg.* In such infants, it is reasonable to estimate the normal hourly maintenance fluid requirements and then add to this the fluid volume of the Parkland or Brooke formula.[2,369] Alternatively, the crystalloid fluid regimen for resuscitation can be increased to 6 mL/kg × the percent surface area burn per 24 hours.[370,371] All formulas and guidelines for fluid therapy require modification according to the individual child's response (Table 36.1)[7]; the most important metric of fluid homeostasis remains a good urine output (0.5 to 1 mL/kg per hour).

TABLE 36.1 Parkland and Brooke Formulas

Formula	FLUID THERAPY Crystalloid (mL/kg)	Colloid (mL/kg)	
Parkland	4.0	+0	× Percent burn × wt (kg)
Brooke	0.45	+1.5	× Percent burn × wt (kg)

NOTE: Half this volume is administered during the first 8 hours and the remainder during the next 16 hours. **Infants who weigh less than 10 kg may have even greater fluid requirements (see text).**



Goal-directed fluid therapy, using a noninvasive or a minimally invasive monitor, may be beneficial for tailoring fluid administration.[372] The development of continuous noninvasive cardiac output monitors may soon be routinely used in the fluid and inotropic management of burn victims. These devices include Fick calculation using expired carbon dioxide rebreathing, esophageal Doppler, pulse contour analysis, thoracic impedance, and bioreactance.[373–381] We are currently investigating esophageal Doppler monitors (EDMs) for our pediatric burn patients (Deltex Medical, Chichester, West Sussex, England; see E-Fig. 36.4), which are approved by the U.S. Food and Drug Administration (FDA) for use in children weighing 3 kg or more. The EDM measures blood flow velocity in the descending aorta via a soft Doppler probe placed in the esophagus at approximately the thoracic fifth vertebral level. Based on the flow velocity and diameter of the aorta (estimate based on a normogram of age, weight, and height), a cardiac output is calculated. The advantage of this technology is that it can be used in children with burn injuries of the chest and neck, which precludes the use of other devices that require placement of skin electrodes (bioimpedance and bioreactance require this). One of these latter devices, ICON (Cardiotronic-Osypka, La Jolla, CA), is FDA approved for use even in neonates and could be used in infants and children whose airways are unintubated and who are without injury to the left chest and left neck (E-Fig. 36.4).

The degree of edema depends on the volume and composition of the resuscitation fluid administered. Consequently, colloids or hypertonic saline solution (with or without albumin) are used in some burn centers during early burn wound resuscitation; these modified regimens are purported to be particularly effective in the very young and the elderly, resulting in less tissue edema.[b] A Cochrane review of 15 studies using hypertonic saline solution found that less IV fluid was needed for resuscitation and greater sodium concentrations occurred, although the overall morbidity and mortality was unchanged.[384] Further work is required before advocating hypertonic fluid regimens in burned children routinely.[385]

A growing practice in burn programs has been to begin the fluid resuscitation with colloid, usually 5% albumin, early during resuscitation of seriously burned children[386–388]; however, no consensus has been reached on colloid protocols.[383] In seriously burned children, we begin with 5% albumin at a maintenance

[a]References 2, 6, 20, 108, 181, 184, and 357–368.

E-FIGURE 36.4 This illustrates the easy placement of an esophageal Doppler for continuous cardiac output assessment (Deltex Medical, Chichester, West Sussex, England). It is ideal for intubated children with extensive burns that preclude the use of less invasive continuous cardiac output devices that require adhesion of electrocardiographic pads of specially designed adhesive systems. This figure shows an esophageal Doppler monitor placed in an 8-year-old, 41-kg boy, after an approximately 40% total body surface area burn having a neck release. The monitor displays cardiac output (CO), cardiac index (CI), and stroke volume/stroke volume index (SV/SVI). If mean arterial pressure and central venous pressure are known, it will also calculate systemic vascular resistance (SVR).

rate immediately upon admission. We administer an amount equal to that of their calculated crystalloid requirements, tapering the crystalloid first and continuing the albumin infusion for 48 hours.

The syndrome of hyperosmolar hyperglycemic nonketotic coma (severe dehydration, marked hyperglycemia, serum hyperosmolality, and coma in the absence of ketoacidosis) may be associated with burns. Avoiding this syndrome is critically important because it carries a high mortality.[357] Glucose-containing solutions should be restricted at all times, particularly during the initial volume resuscitation. Serum glucose concentrations should be measured frequently during this period; we recommend administering insulin as indicated to maintain a target blood glucose of approximately 130 mg/dL.[155]

The general appearance of the child and his or her sensorium provide important guides to the effectiveness of the resuscitative therapy. In addition, urine output is a useful metric to determine the need for additional fluid administration, recognizing that antidiuretic hormone secretion may be increased and renal tubular dysfunction may be present.[24,220] Every effort must be made to protect kidney function by providing adequate perfusion and fluid replacement.[2,385] Renal failure in the presence of a major burn is usually lethal.[26] However, overly aggressive fluid administration may induce pulmonary and tissue edema. Therefore, when a burned child is volume resuscitated, the fluids we administer to replace the circulating blood volume must be carefully titrated. Commonly used endpoints of satisfactory fluid resuscitation include heart rate, systemic arterial blood pressure, urinary output, central venous pressure (CVP), arterial oxygenation, and pH. Echocardiography may be of great value in critically ill patients but, as described earlier, methods of continuous cardiac output assessment may provide better goal-directed fluid resuscitation than clinical assessments alone regarding the decision to use a vasopressor or provide additional volume loading.

The evaporative fluid losses in a child exceed 4000 mL/m^2 of burn surface each day, compared with only 2500 mL/m^2 in an adult.[362] Concomitantly, for each square meter of burn surface, 2500 to 4000 kcal of heat is lost each day. Minimizing caloric expenditure and providing caloric supplementation simultaneously are the only ways to minimize catabolism of body tissues. The tendency for children to be poikilothermic, particularly in the absence of protective skin as a result of the burn injury, causes profound temperature derangements. Efforts to maintain a normal body temperature are essential in both the operating room and the intensive care unit. These measures are especially important during the initial volume resuscitation and in the operating room when dressings are removed for examination and excision (Fig. 36.5).

FIGURE 36.5 Children with extensive burn injury can be kept warm by having the extremities wrapped with sterile plastic bags. Covering the head is also an important method of heat preservation.

ASSOCIATED INJURY

Associated injuries such as a tension pneumothorax, a ruptured spleen or liver, long-bone fractures, or head injury may be missed, especially during the initial assessment and early phase of burn wound fluid resuscitation. Taking a detailed history, especially from the emergency medical personnel and family, combined with a careful physical examination, is mandatory during the initial resuscitation because such injuries may compound or be hidden by the need for an increased volume of resuscitation fluids. The type of burn injury (e.g., explosion, electrical) may trigger concerns for associated injuries (e.g., shrapnel wounds).

CIRCUMFERENTIAL BURNS

Adverse cardiovascular and respiratory responses are immediate consequences to circumferential burns of the chest, abdomen, and extremities.[2,29,159,262] Circumferential burns of the thorax can restrict respiratory effort, resulting in respiratory failure from decreased chest wall compliance; functional residual capacity is reduced with airway closure and atelectasis, resulting in profound hypoxemia.[53,159,249–253,256–263,389] Deep circumferential burns of the chest and abdomen may generate excessive intrathoracic and intraabdominal pressure, which, in addition to restricting movement of the thorax and diaphragm, may further reduce the already decreased cardiac output by impairing venous return (Fig. 36.6).[29,159,262] When this occurs, both extrapulmonary and intrapulmonary factors can contribute to arterial desaturation.[73]

The edema of damaged tissues also can generate severe compressive forces, restricting or occluding the blood flow to burned extremities. The net result may be ischemia of the limb, which if left untreated, may lead to partial or total amputation. Escharotomies of circumferential burns of the chest, abdomen, and extremities must be performed urgently because impaired hemodynamics and respiratory mechanics can cause irreversible damage within hours of the burn injury. Escharotomy is often undertaken without the need for general anesthesia because a full-thickness burn usually destroys skin innervation. Abdominal compartment syndrome may develop in children who require large-volume resuscitation. To detect any evolving compartment syndrome, some burn centers advocate routine monitoring of bladder pressure.[389,390]

ELECTRICAL BURNS

Electrical burns occur with household voltage (electric cords and sockets) and non-household high-voltage current (power line or lightning). Children often disconnect extension cords by stabilizing one end in their mouths and pulling the other end with a hand, resulting in circumoral and lingual burns.[5,76,391,392] High-voltage injuries are often associated with loss of limbs and other injuries that are not immediately obvious.[393–396] The extent of this injury is unpredictable. The surface injury is often small, but the extent of underlying tissue damage and necrosis is massive. Such an injury is a combination of electrical and thermal damage.[396,397] Victims often have concurrent injuries such as fractures of vertebrae or long bones, ruptured organs, myocardial injury, or numerous contusions. Even children with low-voltage injuries may have abnormalities of cardiac conduction.[394] Children with electrical burns may be comatose or have sustained seizures at the time of admission to the hospital. Muscle tissue adjacent to bone is usually more damaged than superficial muscles because bone is a poor conductor of electrical current, and therefore heats up when high currents are passed through it, resulting in damage

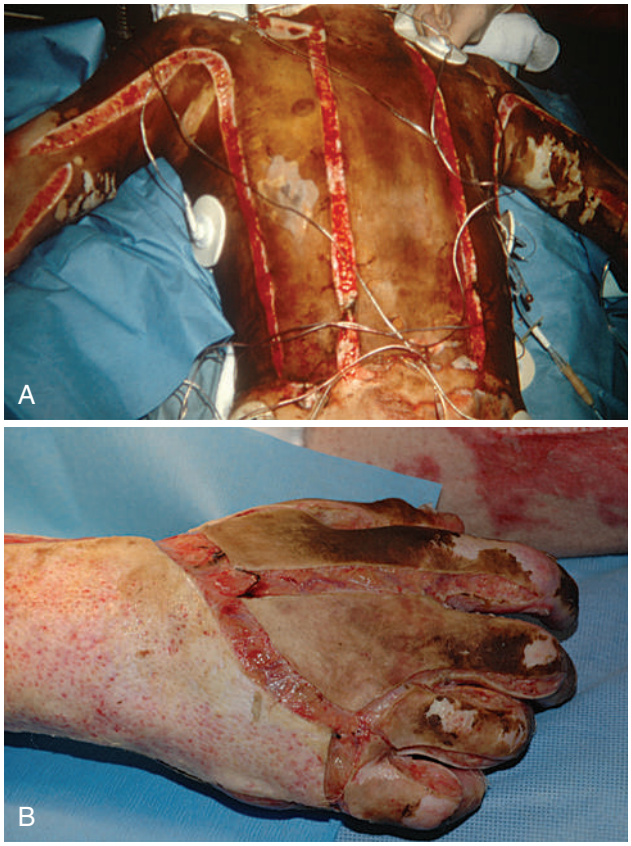

FIGURE 36.6 **A**, Circumferential chest burns result in severe impairment of respirations secondary to the tourniquet effect of the shrinking eschar and subcutaneous edema. The widely separated escharotomy lines indicate the severity of the constriction. **B**, Similar effects occur in circumferentially burned extremities. Early escharotomy may help to preserve blood flow and obviate amputation.

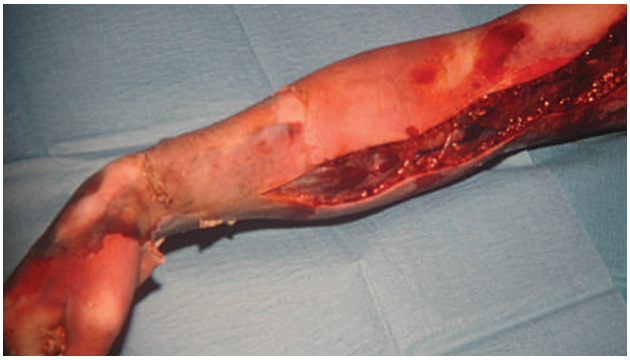

FIGURE 36.7 Electrical injuries tend to follow neurovascular structures and have an entry as well as an exit wound. The skin might appear normal but the underlying structures may have had extensive injury. These children require a fasciotomy rather than just a simple escharotomy to preserve blood flow to the deep structures. In general, this is required on the first day of injury for best results in tissue preservation.

to the surrounding muscles. Early fasciotomy may be needed to preserve the blood flow to extremities (Fig. 36.7). Myonecrosis necessitates general anesthesia during the first day of injury at the time when fluid shifts, hyperkalemia, and myoglobinuria are maximal. Massive myonecrosis and hemolysis may result in hyperkalemia, as well as myoglobinuria and hemoglobinuria. In the presence of hemoglobinuria or myoglobinuria, increased fluids and mannitol will ensure a continuous urine output (>1 mL/kg per hour).[398,399] Alkalization of the urine may prevent these proteins from precipitating in the renal tubules. Follow-up of patients with electrical injuries often reveals unpredictable sequelae, which may manifest months to years later. These injuries may occur in organs or areas that do not appear abnormal during the acute course of illness. These late complications most frequently include neurologic dysfunction, ocular damage, damage to the gastrointestinal tract, circumoral strictures, changes in the electrocardiogram, and delayed hemorrhage from large vessels.[397,399]

Guidelines to Anesthetic Management

Anesthetic management of children with severe thermal injury begins with the initial resuscitation and continues for many years through reconstructive surgery.[400] Knowledge and understanding of the pathophysiology of burn injury enable anesthesiologists to plan appropriate anesthetic management and recognize and treat complications arising as a result of burn injury or its therapy (Table 36.2).[2,13,23,401]

Children who require surgery for burn wound excision and grafting must be properly prepared physiologically and psychologically, and specific equipment must be available in the operating room. Children who have not had surgical debridement and have had the burn for a week or longer must be considered septic. Such children often demonstrate severe cardiovascular instability during burn wound excision, likely because of acute bacteremia. In such cases, it is advantageous to have infusions of dopamine, epinephrine, or norepinephrine prepared for administration before induction of anesthesia.

Psychological support must be provided by parents, nurses, physicians, and trained psychologists. It is important for anesthesiologists to understand that the families of children who have sustained a severe burn injury feel a great deal of psychological stress and guilt. This stress may be manifested as anger towards the physicians, nurses, and other members of the burn care team. The parents are angry that their child has sustained a devastating injury and occasionally vent their anger and frustration. It is therefore vital that the entire burn care team understand this response, that they spend as much time as possible listening to the parents' concerns, and that they emphasize all that is being done to ensure the very best care for their child. Specific nurses and physicians should be designated to communicate with the family to avoid any misunderstandings and confusion about issues of patient care that result if disparate information comes from multiple sources. The anesthesia care team, while explaining the risks of anesthesia, must emphasize the extensive monitoring and the central role that anesthesiologists have in ensuring the well-being of their child. Special emphasis must be placed on methods for minimizing physical and psychological pain during transport to the operating room, in the operating room, and postoperatively.

Keeping children with severe burn injuries on nothing by mouth (NPO) status for 8 hours or longer before sedation for a dressing change or anesthesia for a surgical procedure severely compromises caloric intake; therefore we advocate the use of continuous orojejunal or nasojejunal alimentation. Generally children can receive calories up to about 4 hours before

TABLE 36.2 Systemic Effects of Burn Injury

System	Early Effects	Late Effects
Cardiovascular	↓ CO as a result of decreased circulating blood volume, myocardial depressant factor	↑ CO as a result of sepsis ↑ CO 2 to 3 times > baseline for months (hypermetabolism) Hypertension secondary to vasoactive substances such as renin
Pulmonary	Upper airway obstruction as a result of edema Lower airway obstruction as a result of edema, bronchospasm, particulate matter, sloughing of airway mucosa ↓ FRC ↓ Pulmonary compliance ↓ Chest wall compliance	 Bronchopneumonia Tracheal stenosis, vocal cord granuloma ↓ Chest wall compliance
Renal	↓ GFR secondary to ↓ circulating blood volume Myoglobinuria Hemoglobinuria Tubular dysfunction	↑ GFR secondary to ↑ CO Tubular dysfunction
Hepatic	↓ Function as a result of ↓ circulating blood volume, hypoxia, hepatotoxins	Hepatitis ↑ Function as a result of hypermetabolism, enzyme induction, ↑ CO ↓ Function as a result of sepsis, drug interactions
Hematopoietic	↓ Platelets ↑ Fibrin split products, consumptive coagulopathy, anemia	↑ Platelets ↑ Clotting factors
Neurologic	Encephalopathy Seizures ↑ ICP	Encephalopathy Seizures ICU psychosis
Skin	↑ Heat, fluid, electrolyte loss	Contractures, scar formation, difficult IV access, difficult intubation
Metabolic	↓ Ionized calcium	↑ Oxygen consumption ↑ Carbon dioxide production ↓ Ionized calcium
Pharmacokinetics	Altered volume of distribution Altered protein binding Altered pharmacokinetics Altered pharmacodynamics	Tolerance to opioids, sedatives Enzyme induction, altered receptors Drug interaction

sedation or induction without fear of significant gastric residual fluid volumes. Some continue these jejunal feeds throughout the perioperative period but insert a nasogastric tube to monitor whether feeds are present in the stomach. If feeds are detected in the stomach, then jejunal feeds are interrupted perioperatively. Feeding can be resumed almost immediately after the procedure. In children with large injuries who will quickly develop a negative nitrogen balance with cessation of enteral feedings, short-term use of parenteral protein-sparing support is justified and safe.[402]

Adequate sedation and pain control are necessary before moving children to the operating room; IV fentanyl and midazolam are particularly helpful to provide analgesia and amnesia. Drug doses should not be based on standard doses used in children without thermal injury because burned children rapidly develop tolerance to most opioids and sedatives, thus requiring increasing doses over time to achieve a satisfactory clinical response.[403,404] The dose of sedative or opioid should be titrated to effect while the child is carefully observed and monitored. It is not unusual for children with burns in excess of 25% of the body surface area to require 1 to 3 mg/kg per hour of both morphine and midazolam to provide adequate analgesia and sedation. However, we believe that opioid-sparing techniques including regional anesthesia and infusions of dexmedetomidine should be employed before such large doses are used.

Correction of intravascular volume before induction of anesthesia may require fluid boluses during and after sedation and before transport. Establishing adequate IV access preoperatively may be especially difficult in children with large burns. We use both topical anesthetic creams and needle-free subcutaneous local anesthetics to help make this process painless and stress free.

It is critically important to minimize heat loss and maintain normothermia. This is may be difficult to achieve because of the massive evaporative heat loss that occurs through open wounds. Operating room temperatures during extensive excisions are commonly maintained near 98.6°F (37°C).[184] Attention must be paid to minimize heat loss both during transport and in the operating room. Multiple blankets or thermal reflective covers are helpful. Special equipment is used to maintain body temperature, including a warming blanket, radiant warmer, blood warmer, and heat/moisture exchangers and forced hot air warmers. Simply wrapping the extremities in sterile plastic bags and covering the head with plastic or thermal insulation material markedly reduces heat and fluid losses (see Fig. 36.5). Although a hot operating room is uncomfortable for staff, maintaining the child's temperature is essential for maintaining normal blood clotting and reducing

loss of valuable calories on thermogenesis. Each calorie saved is one more that can be used for tissue healing.

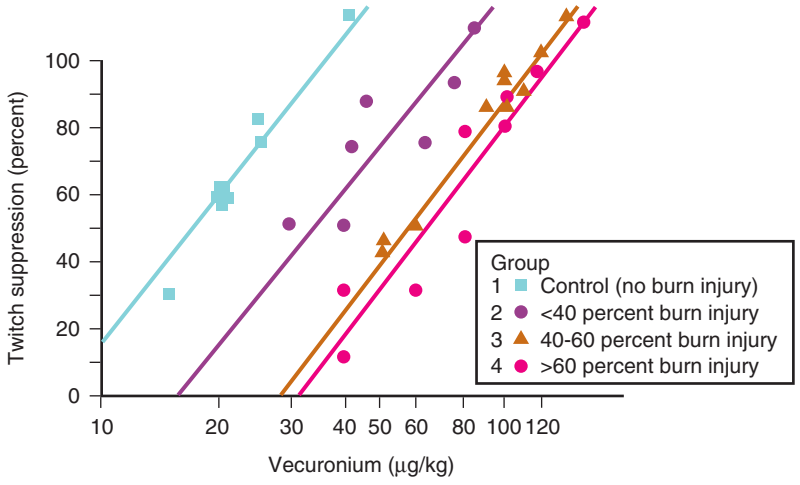
Adequate monitoring for major blood loss and fluid shifts includes arterial and central venous cannulas, a urinary catheter, an electrocardiograph, a pulse oximeter, a capnograph, and an esophageal stethoscope; continuous noninvasive cardiac output monitoring may be indicated in some children. A secure IV route for volume infusion is essential. If the potential for rapid blood loss exists, multilumen catheters may not be adequate because of their high-flow resistance. Rapid infusion devices may be particularly helpful (see Chapter 52).[405–407] The femoral vein is an alternative cannulation site, in addition to the internal jugular and subclavian veins (see Chapter 49). Sterilized laryngoscope blades, tracheal tubes, airways, and blood pressure cuffs are indicated.

Invasive arterial and CVP monitoring may be established after induction of anesthesia in most children. Propofol, thiopental (if available), or ketamine in incremental doses is usually well tolerated, provided the children are not hypovolemic (onset of effect is noted by lateral nystagmus (see Video 7.1). Studies in children long recovered from acute burn injury found a 40% increase in the thiopental dose needed to ablate the lid reflex, compared with children without burn injury (E-Fig. 36.5).[408] Our experience suggests that the clinical response to propofol appears to be equally shifted to the right; however, clinical studies are lacking. Ketamine may, on occasion, be preferred if the adequacy of intravascular volume is in question or if invasive monitoring lines must be inserted before anesthetic induction; tolerance to ketamine with repeated administration has been reported.[409] High-dose fentanyl or morphine combined with nitrous oxide (N_2O) for those children who will undergo ventilation postoperatively is also an acceptable anesthetic technique. In general, an inhalation agent is titrated to clinical effect to supplement the opioid-based anesthetic. A slow inhalation induction is preferable for children with a compromised airway, bearing in mind the potential for cardiovascular depression[410]; a difficult airway cart with appropriate advanced airway adjuncts should be in the operating room.

Succinylcholine is contraindicated in burned children because of a potentially lethal efflux of potassium from muscle.[231,234,237] However, within the first 24 hours after a burn, succinylcholine can be used without triggering a hyperkalemic response. This abnormal response first appears 24 to 48 hours after the burn and continues for an indeterminate, but prolonged, period. Because the endpoint for succinylcholine-induced hyperkalemia is unknown, we advise avoiding succinylcholine in children with large burns (≥40% BSA) for at least 1½ years. The smallest burn reported to trigger a hyperkalemic response was a 9% BSA burn. This abnormal response occurs because the entire muscle membrane, rather than just the myoneural junction, is occupied by acetylcholine receptors. The muscle tissue of burn victims also demonstrates resistance to nondepolarizing muscle relaxants (NMBD).[234,411] We observed a child who demonstrated marked resistance to NMBDs 463 days after burn injury. This response indirectly suggests that the hyperkalemic response may persist long after the acute injury phase of the burn[412]; nondepolarizing NMBDs are therefore the relaxants of choice in burned children.

Early studies reported that both the total dose of *d*-tubocurarine and the serum concentration necessary to attain a given degree of muscle twitch depression in children with burns in excess of 25% of their BSA are three to five times greater than in children without burn injury.[94,219,222,234,244,245] Although *d*-tubocurarine is no longer used, similar observations have been made with the current NMBDs (Fig. 36.8). If rapid intubation is needed and it is clear that the child's lungs can be ventilated, large doses of rocuronium (1.2–1.5 mg/kg) can be used; because 1.2 mg/kg may not provide adequate conditions for rapid intubation, larger doses may be indicated (Fig. 36.9).[413] Even with these large doses of rocuronium, the onset time is prolonged compared with that in nonburned children.[414] Pharmacologic reversal of neuromuscular blockade, however, poses no special problem in burned children.

Recovery from neuromuscular blockade has been observed at serum concentrations that would cause 100% twitch depression in children without burn injury. Studies with nondepolarizing NMBDs indicate that the hyposensitivity correlates well with the



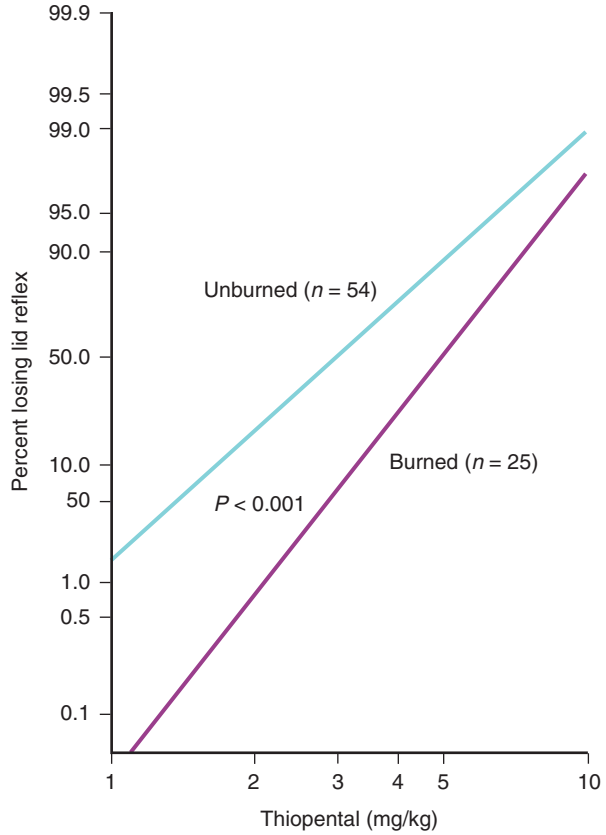


FIGURE 36.8 Logarithm of dose versus twitch suppression for vecuronium in control subjects and burned children. In the presence of acute injury, the vecuronium effective dose values increased with increasing burn size. The slopes of the curves were not different, but the intercepts were significantly different ($P < 0.01$). *Solid squares,* children without burn injury; *purple circles,* children with less than 40% burn injury; *triangles,* children with 40% to 60% burn injury; *pink circles,* children with greater than 60% burn injury. (From Mills AK, Martyn JA. Neuromuscular blockade with vecuronium in paediatric patients with burn injury. *Br J Clin Pharm.* 1989;28[2]:155–159.)

E-FIGURE 36.5 The percentage of children (burned and unburned) who lost the lid reflex is compared with the intravenous bolus dose of thiopental. Note the marked shift in the dose-response curve. (From Coté CJ, Petkau AJ. Thiopental requirements may be increased in children reanesthetized at least one year after recovery from extensive thermal injury. *Anesth Analg* 1985;64;1156–1160.)

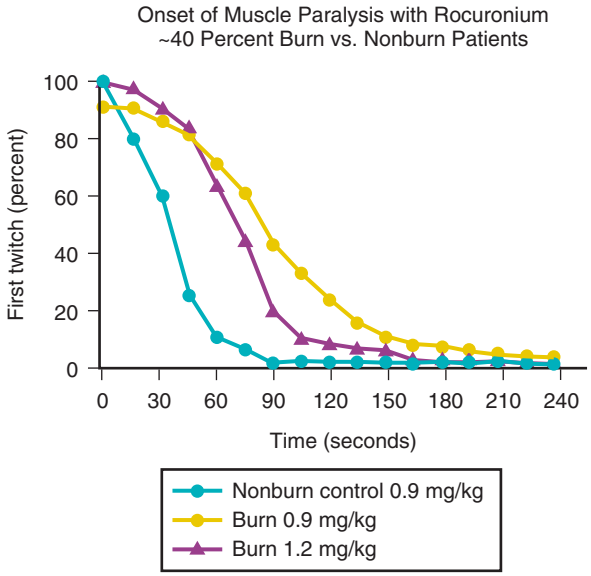

FIGURE 36.9 This dose escalation study of rocuronium in burned adults (approximately 40% BSA) demonstrated severe resistance to the onset of neuromuscular blockade (percent of train-of-four first twitch). The time of onset could be reduced with higher doses; however, a dose of 1.2 mg/kg did not achieve complete paralysis until longer than 2 minutes had elapsed. These data suggest that if a rapid sequence induction were needed in patients with severe burns, an even greater as yet undefined dose would be required to shorten the time to complete relaxation. (Modified from Han TH, Kim HS, Bae JY, et al. Neuromuscular pharmacodynamics of rocuronium in patients with major burns. *Anesth Analg.* 2004;99[2]:386–392.)

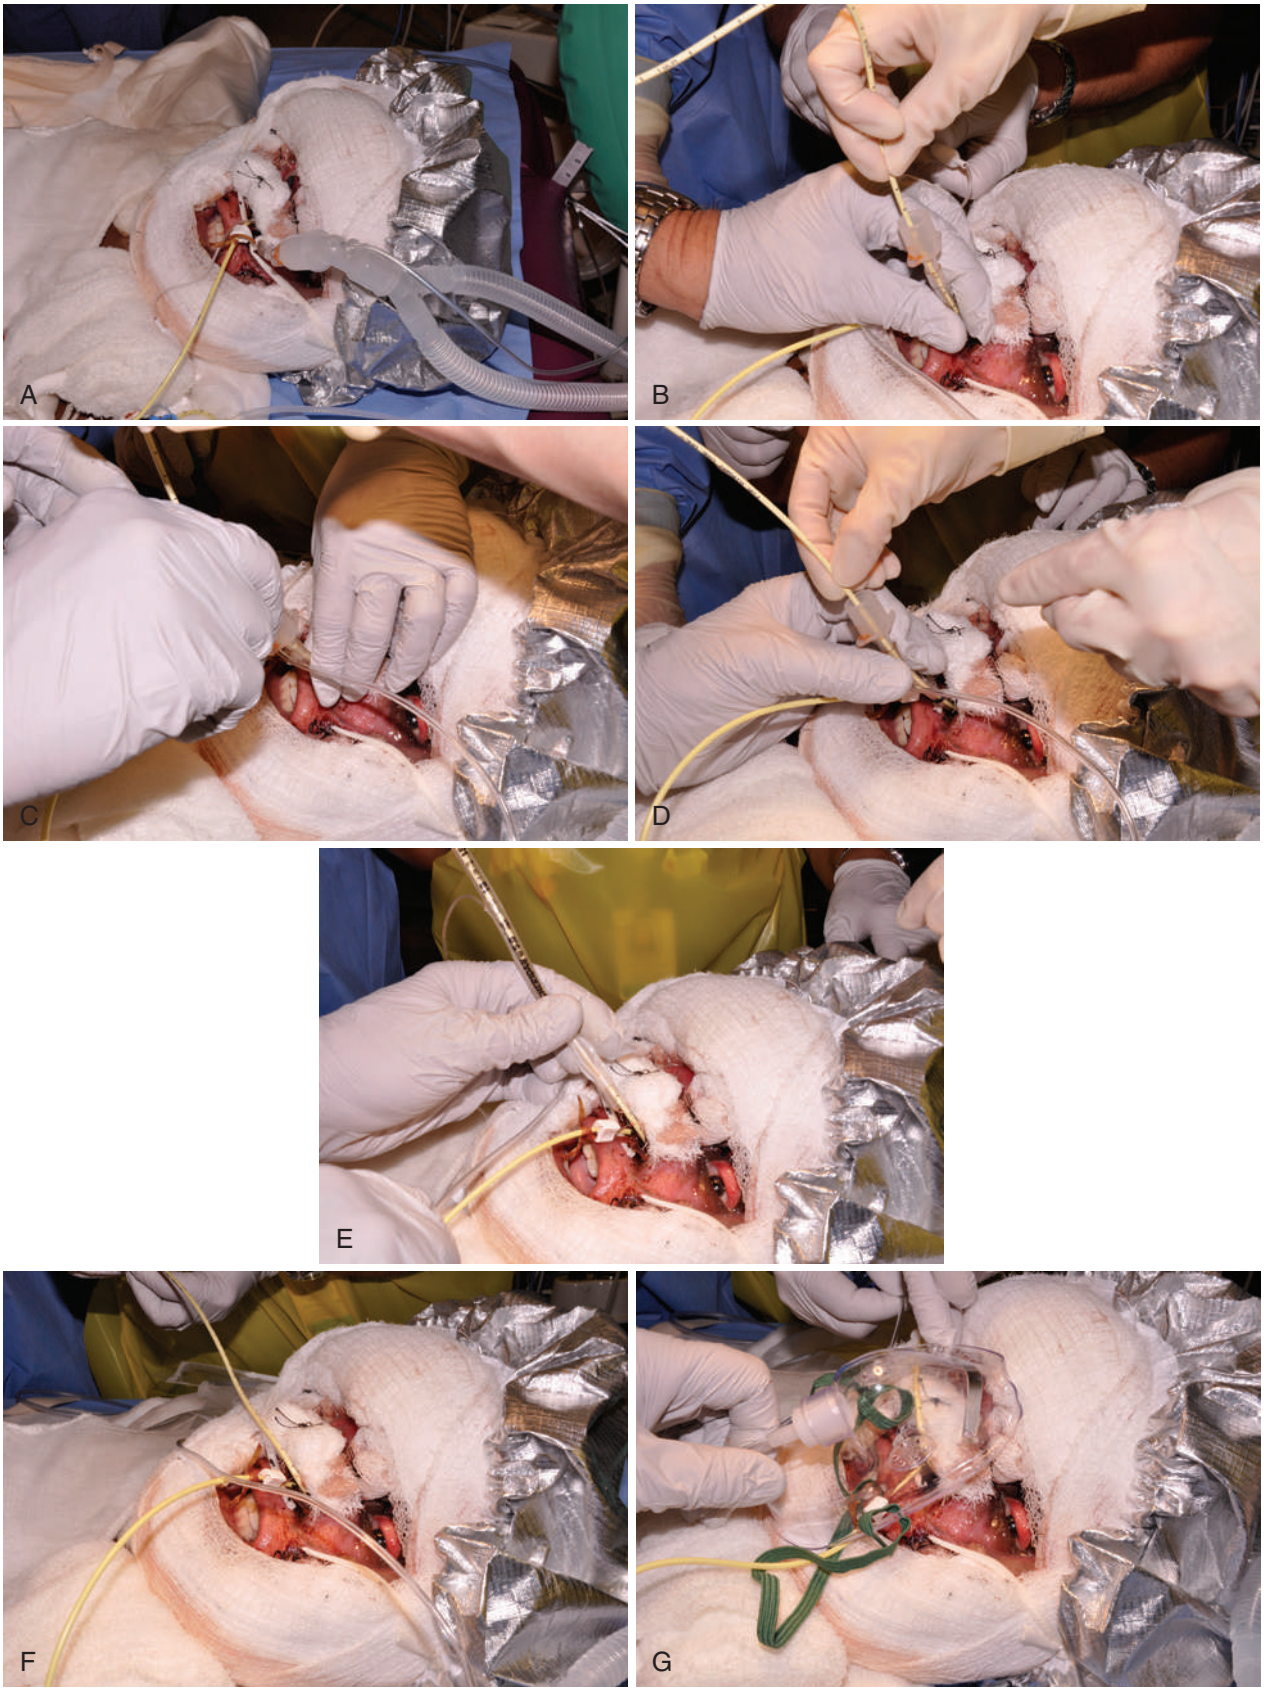
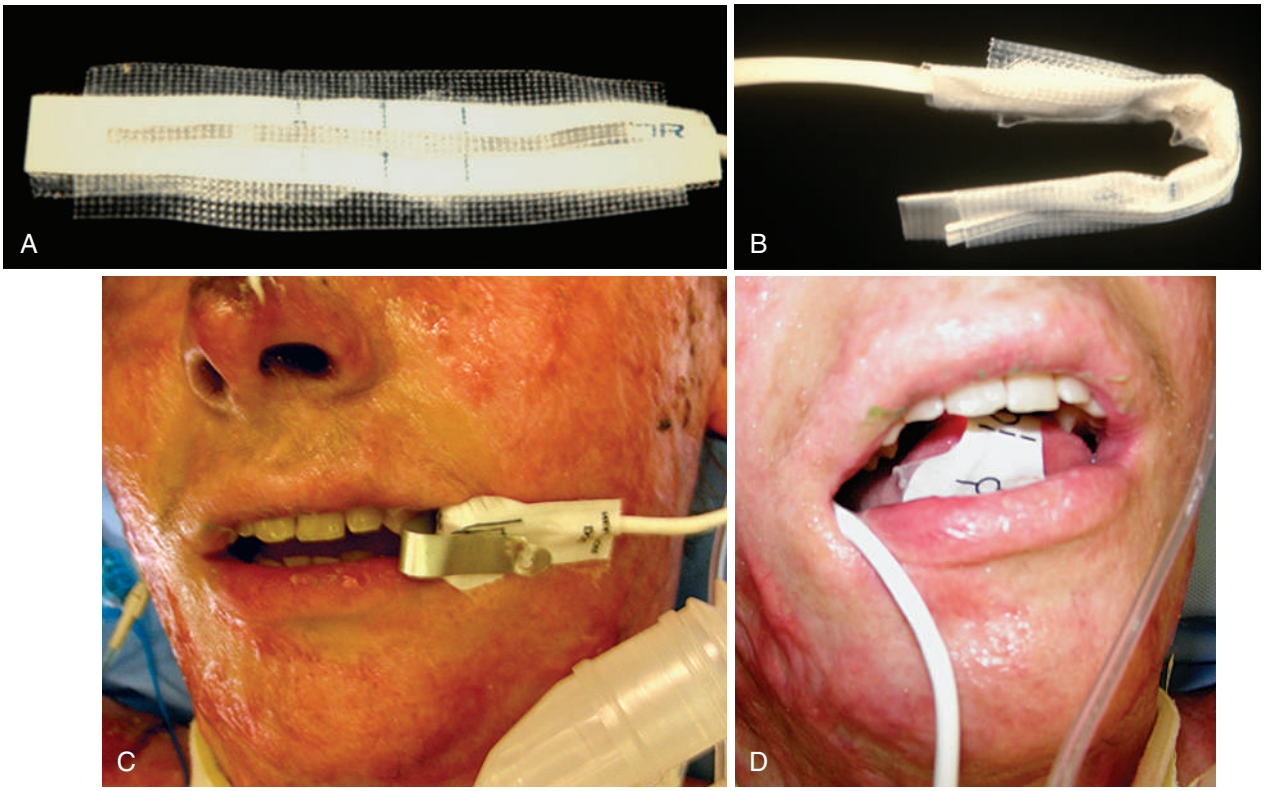


magnitude of burn ($r = 0.88$).[245,415–417] Protein binding and pharmacokinetic studies with *d*-tubocurarine indicate that these two factors contribute little to the enhanced requirements.[94,219,222,234] An increase in the number of acetylcholine receptors at junctional and extrajunctional areas and an altered affinity for the NMBD by those receptors have a major role in the elevated demand for nondepolarizing NMBDs.[233,239,411]

Maintenance of anesthesia is usually accomplished with N_2O, O_2, an NMBD, and an opioid or inhalation agent; all potent anesthetic agents can be safely administered to burned children. Sevoflurane offers an advantage of smooth inhalation induction; isoflurane, desflurane, or halothane can be used for maintenance. There is no evidence that repeated halothane anesthetics in burned children cause hepatotoxicity. All anesthetics cause concentration-dependent depression of cardiac output. In very ill children, anesthetic doses, but not NMBD requirements, are drastically reduced. In this injury, high-dose fentanyl-O_2-N_2O/air anesthesia is well tolerated. Ketamine may be the anesthetic agent of choice in specific circumstances, including those in which we wish to avoid airway manipulation after application of fresh facial grafts; for very brief procedures; or for children who are unable to open their mouth for a standard laryngoscopy. Ketamine may also be used along with midazolam for sedation before a trial of extubation. E-Fig. 36.6 illustrates extubation of a child with a severe facial burn with the use of an airway exchange catheter to provide a ready means for possible reintubation should the trial fail. Some burn centers use ketamine as the sole anesthetic and find it quite satisfactory.[418] The postoperative analgesia and somnolence for prolonged periods produced by high-dose ketamine may be considered an advantage in some instances in which postoperative agitation might dislodge fresh skin grafts.[419] However, prolonged somnolence will delay reinstitution of critical enteral nutrition. Low-dose ketamine may be used postoperatively for its opioid-sparing effects.[420,421] Ketamine, either alone or with propofol, is commonly used for burn dressing changes.[418,422] An emerging experience with dexmedetomidine appears to demonstrate safety and efficacy in reducing otherwise common opioid tolerance and dose escalation.[423]



The inspired O_2 concentration is regulated according to the arterial blood gases and O_2 saturation. A pulse oximeter may not function properly on tissue discolored with silver nitrate; scraping the fingernail and cleaning the skin allow proper transmission and reception of the pulse oximeter light.[424,425] A pulse oximeter probe generally can function even on burned digits; however, if a child's digits are swollen or in the presence of severe vasoconstriction, alternative sites such as the earlobe, nasal septum, or tongue must be sought. We have found the tongue to be particularly valuable[312]; a sealed oximeter probe that prevents electrical current leakage can be easily modified (E-Fig. 36.7).[426,427] Reflectance oximeters may also be valuable in the care of burned children.[428,429]

The combination of increased metabolic rate–induced CO_2 production and inhalation injury often necessitates an increase in alveolar ventilation compared with healthy children. Blood gas analysis must be assessed early and frequently throughout the anesthetic procedure. Constant monitoring of expired CO_2 is vital, but one must be cognizant of the possibility of significant differences between arterial and expired CO_2 values as a result of shunting and dead-space ventilation in children with severe pulmonary injury. *For these reasons, an expired CO_2 monitor may be used for trending and as a disconnect alarm but should not be relied on to adjust and assess ventilation until a correlation with the arterial blood gas value is assessed.* The tracheal tube must be secured with tracheostomy tape because standard adhesive tape does not stick to burned tissue and wet dressings. Electrocardiographic leads also do not adhere and are placed under dependent portions of the body or sutured or stapled onto the skin after the child is anesthetized. The standard measures for protecting the cornea from drying (including ophthalmic ointment and closing the eyelids when possible) and for positioning the limbs to prevent nerve compression must be observed.

The most important consideration of the intraoperative course is monitoring and correcting a child's blood losses. For this reason, invasive intravascular monitoring is essential. Children may lose as much as 1 to 3 blood volumes during each burn excision (this is completely surgeon dependent).[430] It is therefore necessary to be familiar with the surgical approach to burn excision. During a tangential excision (Fig. 36.10 and Videos 36.1 and 36.2), a child might lose 3 to 5 times more blood than during excisions down to fascia (Video 36.3). The liberal use of very dilute concentrations of epinephrine (500 µg/L in normal saline) injected subcutaneously in both donor and excision sites markedly reduces surgical blood loss (Fig. 36.11 and Video 36.4)[431]; our institution uses a 1:2,000,000 epinephrine-containing solution (0.5 µg/mL). Large doses of epinephrine are well tolerated and markedly diminish bleeding. In a series of 25 consecutive children undergoing extensive layered excision, we used a total dose of epinephrine averaging 25 ± 3 µg/kg without complication[431]; as much as 10 µg/kg epinephrine may be injected every 20 minutes.[238] One note of caution is that some centers use electric infusion pumps to inject dilute epinephrine-containing saline solution; such devices have been associated with complications such as acute pulmonary edema and carpal tunnel syndrome, suggesting that hand injection may

E-FIGURE 36.6 **A**, The child with a severe facial burn but no pulmonary injury requires a trial of extubation. The only approach to the airway was through the nose; therefore the decision was made to use a tube changer, which would allow administration of oxygen and provide a guide to reintubation without the need of the fiberoptic scope. The child was moderately sedated with midazolam and ketamine to maintain spontaneous respirations. **B**, After administration of tracheal lidocaine, an airway exchange catheter (Rapi-Fit, Cook Medical, Bloomington, IN) is placed within the tracheal tube after the patient had been preoxygenated with 100% oxygen. **C**, **D**, and **E**, After removal of the tracheostomy tapes that had been securing the tracheal tube, the tracheal tube is slowly withdrawn. **F**, After removal of the tracheal tube the airway exchanger is left within the trachea with the child breathing spontaneously. **G**, Face mask oxygen is applied, and after assurance of stable respirations and oxygenation of the airway, the exchange catheter was removed and the child returned to the intensive care unit.

E-FIGURE 36.7 In children with severe vasoconstriction or inadequate peripheral blood flow, a pulse oximeter probe may be modified by taping the malleable metal nosepiece from a paper operating room mask on the back side (**A**), shaping it into a horseshoe (**B**). Care must be taken not to occlude either the transmitting or receiving light module with the tape. The oximeter is then placed around the edge of the cheek (**C**) or the tongue (**D**). (*NOTE:* The manufacturer may not approve of these modifications; a sealed probe may be preferable to a standard oximeter probe because this would diminish the possibility of electrical current leakage and leaching of adhesive.)

be safer.[432] Fluid overload may not become evident until several hours after surgery if excessive clysis or tumescent fluid is injected by the surgeons to facilitate harvesting of skin (Video 36.4). We have observed a number of infants (≤10 kg) who later developed pulmonary edema; therefore the amount of fluid injected must be taken into consideration with the amount administered intravenously. Since it is difficult to estimate blood and fluid loss, other indicators of circulating blood volume, such as urine output, CVP, arterial pressure, and shape of the arterial waveform (see Fig. 12.10), must be closely monitored.

Early excision of full-thickness burns has improved survival and shortened hospital stays.[433–435] In the past, we routinely observed that 5% of the blood volume was lost for every 1% BSA excised and grafted.[436,437] This extensive blood loss was a major source of morbidity and expense.[438,439] More recently, effective blood-conserving techniques for excision have drastically reduced intraoperative blood loss. These techniques include (1) clearly planning the excision to be performed before its initiation; (2) performing all extremity excisions under pneumatic tourniquet, exsanguinating the extremity before tourniquet inflation, and wrapping the extremity in a hemostatic dressing (epinephrine/saline soaked dressings) before tourniquet deflation; (3) conducting all fascial excisions with coagulating electrocautery; (4) performing major layered excisions as soon as possible after injury, before significant wound hyperemia develops; (5) executing all layered torso excisions after subeschar epinephrine clysis; (6) maintaining normothermia, primarily through maintaining a hot operating room (near 98.6°F [37°C]); and (7) subcutaneous injection of saline diluted epinephrine (with and without dilute bupivacaine) in donor areas.[440] Based on preoperative and postoperative hematocrit and known volume of transfusion, the percent of the total blood volume lost per percent of total wound excised generated an average 0.98% ± 0.19% of the blood volume per percent of the body surface excised. This was about one-fifth of our earlier experience with this type of excision.[441,442]

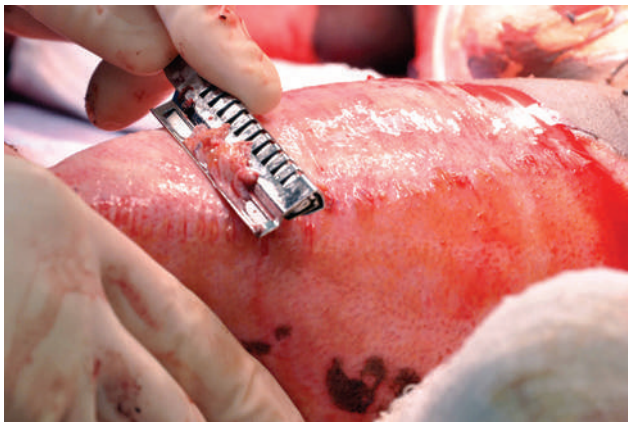


FIGURE 36.10 Tangential skin excision in which multiple thin areas of burn tissue are excised until a viable vascular bed is achieved. This is indicated by brisk bleeding. This type of excision results in less scarring because the majority of fat tissue remains intact. However, this also results in significantly greater blood loss.

Chronic ionized hypocalcemia is commonly observed with major thermal injury.[188] Prophylactic intermittent administration of calcium chloride or calcium gluconate is strongly recommended during the rapid infusion of citrated blood products.[443–446] Some children experience electromechanical dissociation or cardiac arrest during the rapid administration of FFP. This observation prompted a controlled prospective study in which a highly significant decrease in the serum calcium concentration occurred when FFP was administered at a rate of 1 mL/kg per minute or greater (see Fig. 12.9).[446] Interestingly, there was no correlation between adverse cardiovascular responses, the rate of FFP infusion, and the serum calcium concentration. A careful review of the previous cases of cardiac arrest revealed that all children were anesthetized with halothane, whereas in our prospective study most were anesthetized with "balanced" techniques. Because all inhalation agents depress cardiac function, in part through their calcium channel–blocking activity, a sudden citrate-induced decrease in ionized calcium would be expected to exacerbate the cardiac dysfunction. Studies in our laboratory have, in fact, documented this interaction.[25,446,447] Additional exogenous calcium is administered during rapid infusion of FFP or citrated whole blood, especially in infants (see Chapter 12).[446] It is our clinical impression that the rapid administration of (cold) FFP or citrated whole blood through a central line, without additional exogenous calcium, may be more likely to induce severe hypotension, bradycardia, and electrical mechanical dissociation. Our experience has been that rapid administration of citrated blood products, particularly FFP or whole blood, is safer through peripheral lines; rapid administration of packed red

FIGURE 36.11 **A**, Subcutaneous injection of normal saline with a dilute concentration of epinephrine (0.5 µg/mL) from an area to be excised. **B**, Note the blanching of the donor skin secondary to the epinephrine. This helps to greatly reduce the amount of blood loss from both the donor sites and burn wound excision. It should be noted, however, that in the case of a large quantity administered to a small patient, late absorption can result in fluid overload. **C**, Skin is now harvested with minimal blood loss owing to the vasoconstriction of the tumescence solution.

blood cells does not cause ionized hypocalcemia. However, calcium administered simultaneously in the same IV line with FFP or citrated blood products may precipitate clot formation; we recommend giving exogenous calcium through a separate rapidly running IV line or preferably through a central line.

SPECIAL CONSIDERATIONS

Pharmacologic Responses

As a general rule, children with burn injuries require larger than normal doses of all IV medications, including antibiotics, NMBDs, opioids, and benzodiazepines.[a] Cardiovascular responses to catecholamines may be attenuated because of a reduced affinity of β-adrenergic receptors for ligands and diminished second messenger production,[238] thus the need for greater than standard doses to achieve the desired clinical response. Pharmacokinetic studies in acutely burned children indicate that the increased requirement for antibiotics is due in part to leakage through the burn wound, rapid urinary excretion, and altered volume of distribution.[55] Thermal injuries greater than 30% BSA cause an upregulation of acetylcholine receptors and consequent resistance to NMBDs.[232–234,236–239,448] In addition, there appears to be increased tolerance to sedatives and opioids. In adult burn patients, the free fraction (pharmacologically active component) of diazepam was greater than in nonburned patients, whereas the clearance of free diazepam was reduced. An increased tolerance to diazepam despite a greater fraction of the pharmacologically active compounds combined with a decreased clearance suggests resistance at tissue receptors similar to that observed for NMBDs at the neuromuscular junction.[99] A similar tolerance has been observed with opioids. The persistence of such pharmacodynamic changes for both NMBDs and anesthetic drugs long after recovery from burn injury must be kept in mind and doses titrated according to patient responses.[94,242,408,412] In general, many pharmacokinetic and pharmacodynamic changes are present in this population. Furthermore, these children are frequently taking multiple medications; thus drug interactions, potentiations, and incompatibilities may occur. Of particular importance in this context are the H_2-receptor antagonists, which are commonly used in burned children and are known to inhibit the clearance of many other medications (see Chapter 7).

Methemoglobinemia

A less common, but important, source of intraoperative cyanosis and hypoxemia is the development of methemoglobinemia. When silver nitrate dressings are used on the burn sites, some strains of gram-negative bacteria are capable of reducing nitrates to nitrites, which diffuse into the bloodstream and convert hemoglobin into methemoglobin.[160,161,357] The methemoglobin decreases the available O_2-carrying capacity and increases the affinity of the unaltered hemoglobin for O_2, thereby further impairing O_2 delivery. As a consequence, the O_2-hemoglobin P50 curve is shifted to the left. Therefore methemoglobinemia should be considered in the differential diagnosis of cyanosis. Approximately 5 g of deoxyhemoglobin for each deciliter of blood is necessary to produce visible cyanosis, but a comparable skin color is produced by 1.5 to 2 g of methemoglobin for each deciliter of blood. Blood that contains more than approximately 10% methemoglobin usually appears dark red or even brown, despite a high measured PaO_2, and does not change color even with vigorous agitation in room air. Measured O_2 saturation is low; however, the decrease in saturation provides a falsely increased value.[300,301] Treatment consists of removing the toxic agent and administering methylene blue (2 mg/kg) and high inspired O_2 concentrations. Other possible sources of methemoglobinemia include excessive EMLA (eutectic mixture of local anesthetics) cream or benzocaine cream application for burn wound pruritus.[449,450]

Tracheal Tube Size

Because burned children frequently undergo multiple anesthetic procedures, special considerations must be given to the tracheal tube type and size. As mentioned previously, cuffed tracheal tubes are preferable. The size of the tracheal tube, the volume of air inflated into the cuff, and the pressure at which leakage occurs around the cuff should be recorded on each anesthetic record. It is common to note that the requirement for a smaller diameter tracheal tube as weeks go by suggests the development of a subglottic lesion (stenosis, granuloma, polyps), which should be investigated with bronchoscopy. When N_2O is used, the intraoperative cuff pressure should be checked to avoid excessive pressure on the tracheal mucosa, although Microcuff (Halyard Health, Inc., Alpharetta, GA) tubes provide a greater margin of safety than conventional tracheal tubes (see Chapter 14). We generally inflate the cuff to the minimum pressure that allows controlled ventilation and check the cuff pressure regularly.

Airway Control

The pediatric burn patient may present an especially difficult airway challenge. This may be due to external airway factors, such as temporomandibular joint limitation, macroglossia from thermal injury, and neck contractures.[13,410] It also may be due to direct thermal or inhalational injuries to the glottis and respiratory tree. A detailed history and physical examination focusing on airway injury is vital. History details such as a victim of fire in a closed space (e.g., house or automobile fire [very commonly associated with inhalational injuries]), vocal changes, stridor, and hoarseness may be important predictors of difficulty in establishing an airway.

Fiberoptic intubation is frequently used after induction when we are confident we can maintain a mask airway, as well for "awake" but sedated children who are breathing spontaneously. Recently, we have used dexmedetomidine as our sole sedative while performing fiberoptic intubations on spontaneously breathing children. Dexmedetomidine may provide a relatively stable hemodynamic environment, without respiratory depression, making it an ideal sedative when loss of respiratory drive could be catastrophic.

Fiberoptic intubation is often aided in these children with manual distraction of the tongue (especially if macroglossia is present), a stitch through the tongue, and a jaw lift (Fig. 36.12). If the tongue is difficult to grasp, moderately high suction applied to the tip of the tongue or a gauze wrapped around the tongue and then gently pulling the tongue forward facilitates visualization of glottic structures (Fig. 36.12D; see also Fig. 14.29).[451] Fiberoptic intubation sometimes is more easily performed if the bronchoscope is guided through a laryngeal mask airway (LMA) that has already been seated and used to ventilate the lungs. This can be especially advantageous if there is a great deal of perioral edema from inhalational burn injury.

In addition to direct laryngoscopy, fiberoptic intubations, and LMA-assisted intubations, the GlideScope (Verathon, Bothell, WA) has proven particularly helpful; other techniques including retrograde wires and light-wand intubations may be difficult to use in a child with a severely burned neck and contractures. In

[a]References 2, 82–84, 94, 98–100, 222, 223, 226, 228, 229, 234, 242–245, 415–417, and 440.

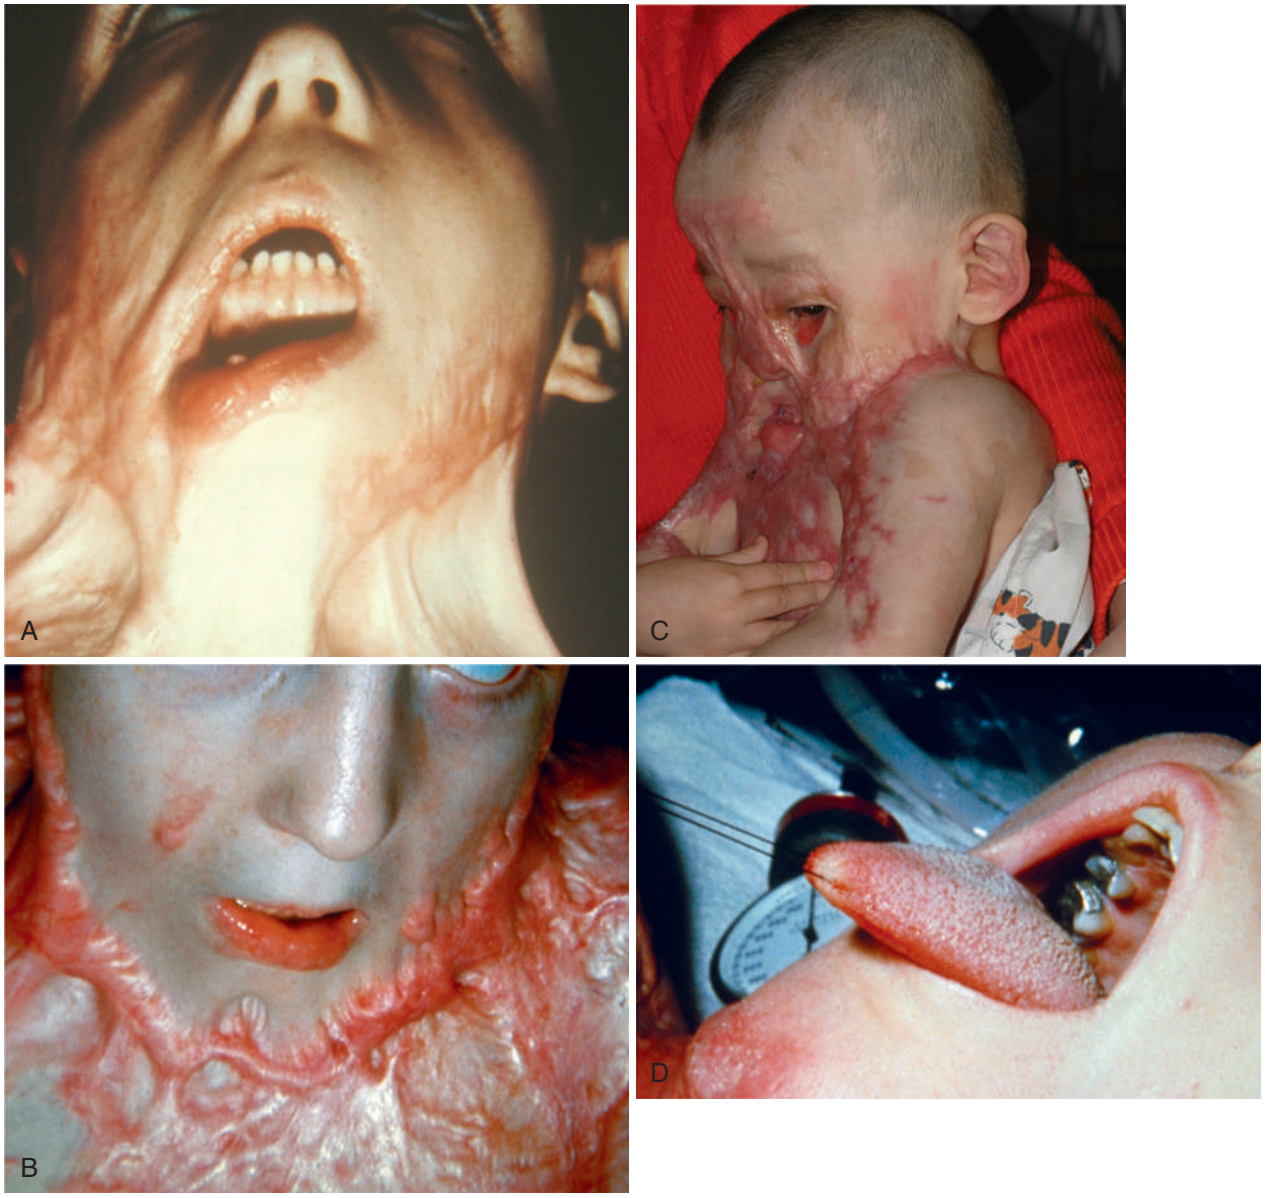

FIGURE 36.12 **A**, Child with inadequately treated facial burn. Note that skin contracture has resulted in complete distortion of the face with inability to close the right eye. **B**, Child with another example of an inadequately treated neck burn; note that her chin is fused with the sternum, resulting in very difficult airway management. **C**, An acute burn injury with an even more extreme example of inability to access the airway. To manage this child safely for the initial neck release, extracorporeal membrane oxygenation was used. This child is also unable to close her eyes. **D**, Some children with severe neck burns may have their airway visualized only by pulling back on the tongue (0 silk suture, suction applied to the tip of the tongue, or grasping forceps may be used [see also Fig. 14.29]) so as to pull the tongue and larynx cephalad.

these children, the surgeon may release the contracture during ketamine sedation and spontaneous ventilation to facilitate access to the airway (Video 7.1). The airway may then be instrumented either directly or indirectly (see Chapter 14). A useful review of airway management in pediatric head and neck burns that details successful strategies we use for securing the airway is available elsewhere.[452]

Hyperalimentation

Hyperalimentation fluids are frequently administered to burned children.[129,453] These fluids should be continued intraoperatively; however, we generally reduce the rate of infusion to half to two-thirds of the initial infusion rate because the metabolic rate is usually decreased during anesthesia. These fluids should be administered with a constant-infusion pump to avoid accidental over infusion or under infusion. If the hyperalimentation fluids must be terminated (e.g., to permit blood transfusion), monitoring of blood glucose concentration is recommended. Dangerous rebound hypoglycemia may occur if infusions are abruptly interrupted and no compensation is made with other glucose-containing solutions. Compatibility of hyperalimentation solutions with drugs, blood, and other infusions must be addressed.

Ultrasound-Guided Vascular Access, Regional Analgesia, and Cardiovascular Assessment

High-resolution portable ultrasound is exceedingly helpful in the care of the pediatric burn patient; we commonly use ultrasound as an adjunct for vascular access, regional anesthesia, and cardiopulmonary diagnosis. Placing CVP and arterial catheters in the operating room under carefully controlled conditions is associated with a low rate of acute mechanical complications and deep vein thrombosis (~1%), even in children with multiple prior cannulations, a hypercoagulable state from the burn, and long periods of being bedbound.[454] Ultrasound is useful to rapidly access arteries and veins but also to diagnose clotted vessels, reducing futile attempts at obtaining vascular access.[455] Ultrasound also helps establish the location of cannulae–for example, we use ultrasound to assist in placing peripherally inserted central catheters (PICCs), then place the probe over the internal jugular to verify that the PICC is not traveling cephalad, and then scan the subclavian vein to verify correct placement.

Ultrasound-guided regional anesthesia is also a valuable tool in children undergoing reconstructive surgery. Typically, the complaints children have after reconstructive procedures most often involve the pain of the graft donor site. For the past 10 years we have improved the postoperative experience by placing ultrasound-guided blocks of donor sites, sometimes with catheters for more prolonged postoperative analgesia. These blocks include transversus abdominal plane blocks for truncal analgesia where both single-shot blocks and catheters are used (E-Fig. 36.8). Other specific blocks we have found very useful include the lateral femoral cutaneous nerve and fascia iliaca (Fig. 36.13) to cover the most common donor site: the lateral thigh or lower abdomen. Ultrasound has greatly improved success and reliability over typical blind techniques.[456,457] Our experience is that lateral femoral cutaneous nerve or fascia iliaca blocks provide better pain control for the donor site than infiltrating the donor site with local anesthetics; more prolonged analgesia is provided by leaving a catheter in place. We usually place fascia iliaca catheters since these are easier to place with a shorter learning curve than for placement of lateral femoral cutaneous nerve catheters.[458,459]

Ultrasound is one of several strategies to rapidly assess intraoperative cardiac function during burn surgery. We have used real-time ultrasound while decompressing a spontaneous pneumothorax in a burn patient as a rapid and reliable indicator of when the lung has reexpanded (as indicated by return of the pleural "sliding" sign).[460–462] Hemodynamic measurements also can be estimated intraoperatively; we use the Bedside Assessment for Trauma/Critical Care (BEAT) examination as a quick assessment of volume status.[463,464] We also use ultrasound as a rapid method of assessing urine output by performing a bladder scan, which may avoid the need for a bladder catheter in some instances.

Awakening

In the immediate postoperative period, O_2 consumption increases even in the absence of shivering.[43] If O_2 debt develops (metabolic acidosis), appropriate measures must be taken to correct it. Special consideration also must be given to the likelihood of severe pain. Analgesic drugs should be administered in increasingly liberal doses because of increased drug tolerance. Adequacy of air exchange and patency of the airway, however, must be given first priority. It is important to assess the leak pressure at the end of the surgical procedure. Airway patency in the burned child is dynamic, and the child whose airway had minimal edema at the beginning of a procedure may have become very edematous at the end and be a poor candidate for extubation.

PAIN MANAGEMENT AND POSTOPERATIVE CARE

Treatment of burn pain, both perioperatively and in the intensive care unit, remains a major challenge. Our experience is that the pain is proportional to the size of the thermal injury. Nearly every

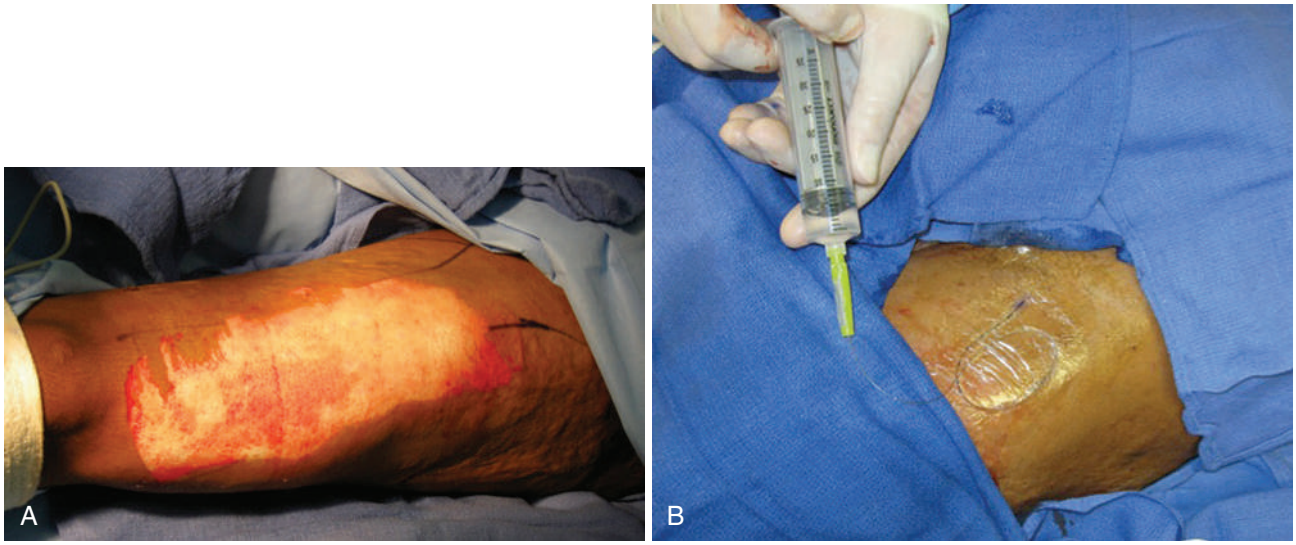

FIGURE 36.13 **A**, It is common for the thigh to be a donor site. In this case, a single-shot lateral femoral cutaneous nerve block is placed for postoperative analgesia. **B**, The fascia iliaca block will cover the distribution of the lateral femoral cutaneous nerve (lateral thigh) but also covers anterior and medial sensation (femoral and obturator nerves). In this case, the patient's legs are on the left and the lower abdomen to the right. A catheter was placed at the level just above the femoral crease allowing an infusion of low-dose local anesthetic for 2 to 4 days. Note that the catheter is secured with a coil to provide more stable placement.

E-FIGURE 36.8 The transversus abdominal plane (TAP) block is a compartmental block frequently used for abdominal/pelvic surgery. In burned children, it is for covering truncal pain from abdominal skin harvests. The block can be maintained by placing TAP block *catheters* and running a continuous infusion of local anesthetics.

maneuver involving the care of these children, including dressing changes, excision and grafting, physical therapy, weighing, and line placements, is associated with pain.

Part of the challenge in managing burn pain is due to the overlay of physiologic and psychosocial responses to thermal injury. Besides physical stimulation of nociceptors and other direct pain mechanisms, there is also the very real anticipation, anxiety, and fear associated with these procedures. Evidence suggests that skillful communication and explanations for specific treatments are necessary, despite the pain caused, and decrease analgesic requirements.[403,465–467]

Opioid administration for pain control has been an evolving science; 20 years ago there was significant fear that treatment of pain with opioids would create addictions. However, no reports of children developing opioid addiction after therapeutic uses of opioids have been published and studies in adults revealed a very low addiction rate.[468–472] This has led to liberalization of opioid dosing; it is not unusual for children to receive more than 1 to 3 mg/kg per hour of IV morphine while recovering from burn injuries. Once the thermal wounds are closed, opioid requirements rapidly decrease (Fig. 36.14).

Although the fear of postburn care addiction to opioids has never been realized, there are other reasons this class of drugs may be detrimental to the child with a burn. Animal data suggest that thermal injury itself may lead to a hyperalgesic state with both reduced effectiveness of morphine (presumably from downregulation of spinal μ receptors) and increases in *N*-methyl-D-aspartate (NMDA) receptors. The increases in NMDA receptors induced by burns provide the rationale for the widespread use of ketamine to treat pain in these children. Opioids may also increase the sensitivity to pain. In a mouse model, morphine downregulates μ-opioid receptors within the spinal cord and causes injury to spinal inhibitory interneurons.[471,472] In the same model, opioids cause postburn immunosuppression.[473] Additionally, opioid tolerance and opioid-induced hyperactive behaviors have, in a rat pup model, been exacerbated when midazolam has been concomitantly administered. This may be important as midazolam is frequently used as a clinical adjunct.[474] These potential opioid disadvantages have led to a search for alternative analgesics. Among these are potentially dexmedetomidine,[475–481] gabapentin,[482] and, until their recent withdrawal from the market, cyclooxygenase-2 inhibitors.[483–485]

Dexmedetomidine is a parenterally administered α_2-adrenoceptor agonist with good sedative and anxiolytic properties. In adults, it decreases opioid requirements postoperatively.[476–480,486] In children with burns, it has been used successfully for sedation,[423,475] although larger dexmedetomidine doses may be needed than those required in nonburned adults or nonburned children.[475] Dexmedetomidine does not appear to be a remarkable analgesic for children with burns.[487] In a prospective study of dexmedetomidine in acutely burned children,[488] a bolus dose of dexmedetomidine (1 μg/kg over 10 minutes) was followed by an ascending infusion protocol (0.7 μg/kg per hour to 2.2 μg/kg per hour).[475] We found no instances of heart block, bradycardia, or other arrhythmias, but noted a consistent and significant decrease in mean arterial blood pressure after the bolus dose (approaching 30% change in mean pressure) (Fig. 36.15). This occurred in all ages studied (2–18 years), although the decrease in the mean arterial pressure did not correlate with size of burn, time since the burn, or CVP. Given these observations, we now omit a loading dose of dexmedetomidine, although should a bolus dose be indicated, we recommend 10 mL/kg or more of balanced salt solution or mild pressor support before commencing the dexmedetomidine. Other investigators have retrospectively examined cardiovascular stability of pediatric burn patients sedated

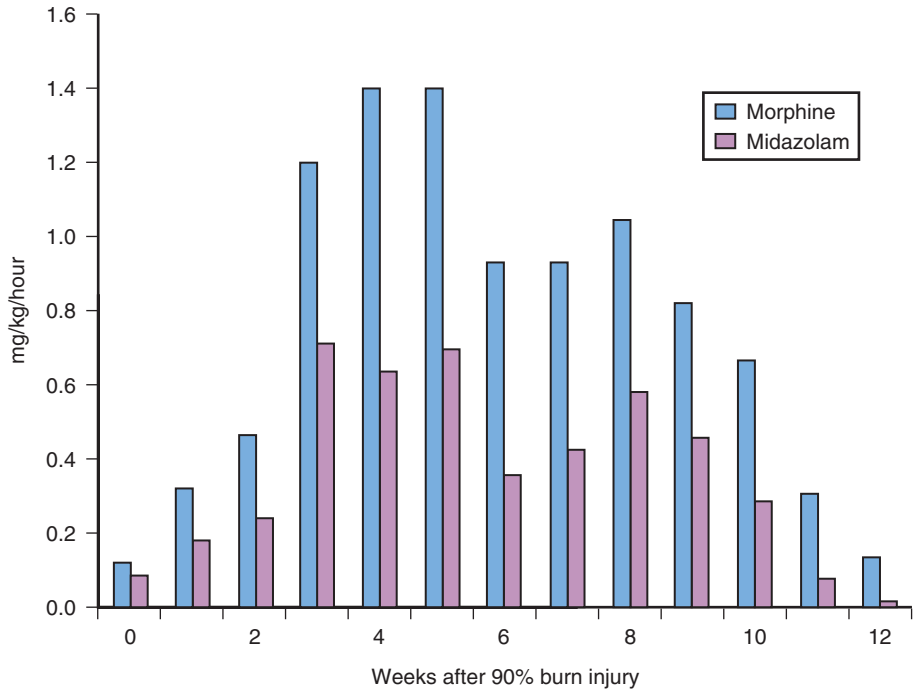

FIGURE 36.14 Morphine and midazolam requirements of a 16-year-old boy who had suffered an approximately 90% BSA burn injury. Note the marked rapid rise in analgesia and sedation requirements during the first 4 to 5 weeks after injury and then the rapid decline in requirements as his wounds were successfully grafted.

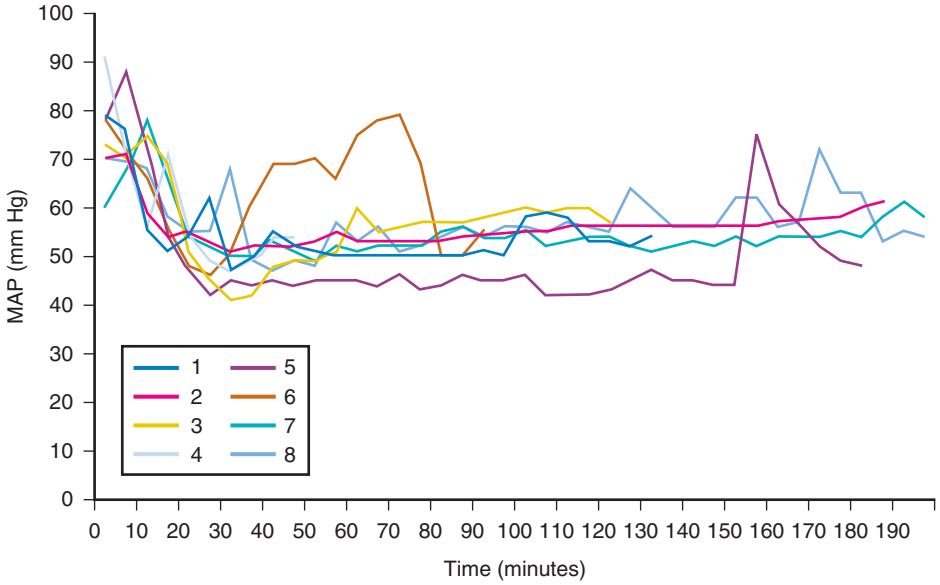

FIGURE 36.15 Change in mean arterial pressure (MAP) after bolus dose of dexmedetomidine in eight consecutive acute pediatric burn patients. *NOTE:* Given these observations, we now avoid a bolus dose; however, should a bolus dose be considered necessary, we suggest that the need for volume resuscitation (≥10 mL/kg of balanced salt solution) or mild pressor support must be anticipated. (From Shank ES, Sheridan RL, Ryan CM, Keaney TJ, Martyn JA. Hemodynamic responses to dexmedetomidine in critically injured intubated pediatric burned patients: a preliminary study. *J Burn Care Res.* 2013;34[3]:311–317.)

with dexmedetomidine and concluded that in the absence of a loading dose, blood pressure was maintained in the dexmedetomidine treatment group.[423] Dexmedetomidine pharmacokinetics in nonburned children appear similar to those in adults, but they have not been reported in pediatric burn patients.[489–491] When dexmedetomidine was compared with midazolam as an adjunct to ketamine in sedation and analgesia for burn dressing changes, the authors determined that both were effective adjuncts but that the dexmedetomidine-ketamine group had better sedation with less hemodynamic instability.[492] Dexmedetomidine has also been used in anxious children with burns as an intranasal premedication.[493] The authors concluded that dexmedetomidine (2 μg/kg) intranasally as a premedication compared with oral midazolam (0.5 mg/kg) induced preoperative sleep faster and was equally effective for induction conditions and rapidity of emergence. In our experience, the majority of our children prefer oral midazolam despite its bitter aftertaste, to intranasal dexmedetomidine. A substantial detractor from dexmedetomidine use is its cost (more than $44 for a 100-μg vial at our institution). One study in adult volunteers compared IV with intranasal dexmedetomidine; pharmacodynamic responses were similar, but the peak blood concentration occurred earlier in the IV group.[494] Bioavailability after nasal administration was 65% (range 35%–93%).

Dressing changes sometimes present one of the greatest analgesic challenges. This is because they are very painful, cause a rapid increase above baseline pain, and are associated by the child with anticipation of impending pain. Strategies to manage this pain include additional opioids and benzodiazepines, ketamine,[418] intranasal fentanyl,[495] remifentanil,[496] immersive virtual reality,[497,498] and music therapy (Video 36.5).[499] Management of the child's pain depends on physiologic and pharmacologic factors, as well as the psychological state of the child. Unfortunately, some children become so tolerant that one author observed that doses of IV fentanyl as large as 100 μg/kg administered as a bolus to a teenager did not cause respiratory depression nor did it control the pain (CJC).

When poorly controlled, pain and anxiety have adverse psychological[205,500,501] and physiologic effects.[20] Posttraumatic stress disorder occurs in up to 30% of those with serious burns[204,502,503] and may be related to both the accident and the treatment, particularly in the setting of inadequate control of pain and anxiety. An inconsistent approach to pain and anxiety will be associated with inappropriate degrees of child discomfort, nonuniform drug selection with inconsistent dosing of unfamiliar drugs, varying tolerance of child discomfort among staff members, and bedside disagreements over management of the child's distress.

To address this issue, a pain and anxiety guideline should be developed by all facilities that routinely treat burned children.[504–507] We developed one such guideline that we have followed for several years, which is summarized in Table 36.3.[404] The ideal characteristics of such a guideline include (1) safety and efficacy over the broad range of ages and injury acuities seen in the particular unit; (2) explicit recommendations for drug selection, dosing, and escalation of dosing; (3) a limited formulary that generates staff familiarity with agents used; and (4) regular assessment of pain and anxiety levels and guidance for intervention as needed through dose ranging. We have found this structured approach to be very effective over the broad range of injury severity and child ages seen in our unit. Substantial escalation of drug doses, particularly in children with large injuries, is commonly required; doses should be titrated to the child's needs. When the child is being weaned toward extubation, background medications should be tapered to yield a sensorium consistent with airway protection; many tracheas are safely extubated while the children are still receiving opioid and benzodiazepine infusions. Finally, it is essential to emphasize that the most effective of all analgesics and anxiolytics is prompt, definitive wound closure.

TABLE 36.3 Pain Treatment Plan

Clinical State	Background Anxiety	Background Pain	Procedural Anxiety	Procedural Pain	Transition to Next Clinical State
Mechanically ventilated acute burn	Midazolam infusion	Morphine infusion	Midazolam intravenous titration	Morphine intravenous titration	Wean infusions 10%–20% per day and substitute "nonmechanically ventilated acute burn guideline"
Nonmechanically ventilated acute burn	Scheduled enteral lorazepam	Scheduled enteral morphine	Lorazepam intravenous titration or enteral dose	Morphine enteral or intravenous titration	Wean scheduled drugs 10%–20% per day and substitute "chronic acute burn guideline"
Chronic acute burn	Scheduled enteral lorazepam	Scheduled enteral morphine	Lorazepam enteral dose	Morphine enteral dose	Wean scheduled and bolus drugs 10%–20% per day to outpatient requirements and pruritus medications
Reconstructive surgical patient	Scheduled enteral lorazepam	Scheduled enteral morphine sulfate	Lorazepam enteral dose	Morphine enteral dose	Wean scheduled drugs and bolus drugs to outpatient requirement

Tolerance to opioids occurs over time and must be considered so that adequate analgesia is provided throughout the recovery period. It is common to observe children who receive 1 mg/kg of morphine at the beginning of a 2-hour operative procedure not only to be ready for extubation but also to require additional opioids for continued pain relief postoperatively. Similar trends have been observed for fentanyl.[226] Thus an increased rate of excretion and degradation may attenuate the effects of some opioids. As the child recovers, the painful stimuli diminish and the opioid requirements are gradually reduced. This is generally such a prolonged process that withdrawal is not an issue. Anesthesiologists can have a key role in the treatment of thermal injury pain and, with an understanding of pharmacology, pharmacokinetics, and pharmacodynamics, are a vital resource for the care of these children (see also Chapters 43, 44, and 45).

Summary

The care of burned children involves detailed knowledge of the early and late effects of burn injury on the respiratory, cardiac, renal, central nervous, hepatic, gastrointestinal, hematopoietic, and metabolic systems. An awareness of the pharmacokinetics and pharmacodynamics of anesthetic agents, combined with an understanding of the problems of massive blood transfusion, also contribute to the safe conduct of anesthesia. Finally, the importance of adequate analgesia, sedation, and concern for the psychological well-being of these devastatingly injured children cannot be overemphasized. Knowledge of all of these factors combines to produce a successful outcome.

ACKNOWLEDGMENT

We wish to thank S.K. Szyfelbein for his previous contributions to this chapter.

ANNOTATED REFERENCES

Caruso TJ, Janik LS, Fuzaylov G. Airway management of recovered pediatric patients with severe head and neck burns: a review. *Paediatr Anaesth*. 2012;22(5):462-468.

Pediatric airways in burned children may present some of the greatest airway challenges for the anesthesiologist. This is a useful review of some of these challenges and the techniques used to meet them.

Han T, Kim H, Bae J, et al. Neuromuscular pharmacodynamics of rocuronium in patients with major burns. *Anesth Analg*. 2004;99(2):386-392.

Currently, rocuronium is the fastest-acting nondepolarizing muscle relaxant available. This paper discusses its pharmacodynamics in burn patients and in particular describes both delayed onset and resistance in burned adults with doses as great as 1.2 mg/kg.

Shank ES, Martyn JA, Donelan MB, et al. Ultrasound-guided regional anesthesia for pediatric burn reconstructive surgery: a prospective study. *J Burn Care Res*. 2016;37(3):e213-e237.

This is the first randomized, prospective study in pediatric burn patients demonstrating the efficacy of peripheral regional nerve blocks—especially in patients with continuous indwelling catheters—in the postoperative analgesic management of reconstructive surgery. This study suggests that regional anesthesia should be used for most reconstructive surgeries to minimize narcotics and optimize analgesia.

Song L, Wang S, Zuo Y, et al. Midazolam exacerbates morphine tolerance and morphine-induced hyperactive behaviors in young rats with burn injury. *Brain Res*. 2014;1564:52-61.

This animal study demonstrated that the coadministration of midazolam and morphine did exacerbate morphine tolerance and hyperactive behavior. It appears the morphine tolerance is mediated through a spinal NMDA/protein kinase C mechanism. Since it is very common to sedate pediatric burn-injured patients in the intensive care unit with both midazolam and morphine, this study may have important implications for this population.

THE PREMATURE INFANT IS DEFINED as birth before 37 weeks gestation. Premature births can be classified as low-birth-weight (LBW) infants (<2500 g), very low-birth-weight (VLBW) infants (<1500 g), and extremely low-birth-weight (ELBW) infants (<1000 g). Alternatively, they may be classified as moderate to late prematurity (32 to <37 weeks), very premature (28 to <32 weeks), and extremely premature (<28 weeks). A neonate is an infant in the first 28 days after birth. "Premies" are commonly referred to as infants rather than neonates as a group because gestation may be very short (e.g., 24 weeks) and thus even at 37 weeks postmenstrual age (PMA), they are truly infants with a postnatal age of 13 weeks (24 + 13 = 37). These infants should be labeled with both gestational age (i.e., at birth) and postnatal age (i.e., age after birth). The use of current postconception age (PCA) or PMA (approximately 10 days older) helps define maturation of physiologic processes.

Morbidity and mortality in this population has decreased considerably compared with 30 years ago, especially in ELBW infants.[1–3] This decrease is the result of many factors, including the development of specialized maternal fetal medicine and neonatal care units, antenatal corticosteroid administration, surfactant use shortly after birth, increased cesarean deliveries, and implementation of strategies to reduce lung injury, such as decreased delivery room intubations and increased use of continuous positive airway pressure (CPAP).[1,2] Although survival and morbidity-free survival rates continue to increase, the trend over the past 20 years has plateaued. The cost of care is escalating, as are the number of surgical procedures and the need for specialized care these infants require. The first part of this chapter will focus on the VLB and ELBW infant, or "micropremie," and discuss developmental physiology and its impact on anesthetic care.

Physiology of Prematurity Related to Anesthesia

RESPIRATORY SYSTEM

Airway

Anatomic Differences and Work of Breathing

The anatomic differences of the pediatric airway are detailed in Chapter 14; however, there are specific challenges unique to the airway of the premature infant that must be taken into consideration. The small airways predispose the micropremie to obstruction and difficulty with ventilation. Resistance to airflow is inversely proportional to the fifth power of the radius in the upper airway and to the fourth power of the radius beyond the fifth bronchial division (see also Fig. 14.7). As a result, insertion of an endotracheal tube (ETT) increases resistance and work of breathing far greater for the micropremie (2.5- or 3-mm inside diameter [ID]) than for

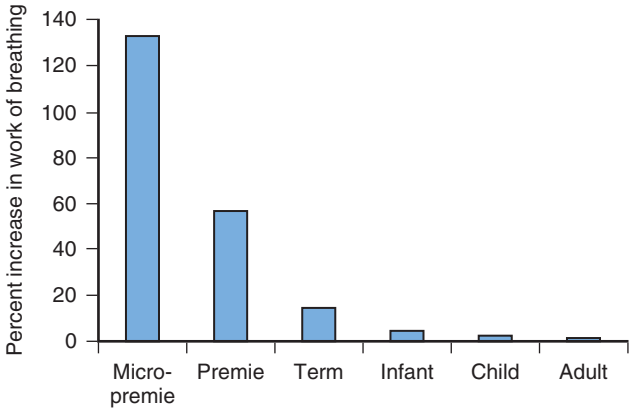

FIGURE 37.1 Change in work of breathing after placement of an appropriately sized endotracheal tube in extremely low-birth-weight infants (<1000 g), premature infants (1500 g), full-term infants, children, and adults (see text for details). a larger infant (4 mm ID), child (5 mm ID), or adult (7 mm ID) (Fig. 37.1). Similarly, partial occlusion of the ETT by secretions, blood, or kinking increases the work of breathing to a much greater extent in the micropremie. Partial occlusion of the natural airway from loss of muscle tone during anesthesia and sedation also increases the work of breathing more in the micropremie. Consequently, general anesthesia often requires placement of an ETT to ensure airway patency and provide assisted ventilation to overcome the increased work of breathing.

Diseases that narrow the airway, such as subglottic stenosis, tracheal stenosis, and tracheobronchomalacia, occur commonly in the micropremie, and the associated reduction in airway diameter further increases both resistance to airflow and work of breathing. Subglottic stenosis necessitates the placement of a smaller ETT than would otherwise be placed, further increasing airflow resistance. Although tracheal stenosis near the carina may not necessitate a smaller ETT, it still increases airway resistance from the stenosis distal to the ETT. With tracheobronchomalacia, the intrathoracic airways collapse during exhalation, again increasing resistance and the work of breathing (see also Figs. 14.10 and 33.10). Positive end-expiratory pressure (PEEP) or CPAP helps stent open the airway. Mechanical ventilation, rather than spontaneous ventilation during anesthesia, prevents fatigue from increased work of breathing, and maintains ventilation and oxygenation. During anesthesia, the use of smaller inspiratory-to-expiratory ratios prevents air trapping and hyperinflation of lung segments.

The cardiopulmonary system of the neonate is driven by the need to deliver sufficient oxygen (O_2) to maintain a high metabolic rate. The O_2 consumption of an average neonate is 5 to 8 mL/kg per minute, whereas that of an adult is 2 to 3 mL/kg per minute (Table 37.1); the O_2 consumption rate in the premature infant is nearly 3 times that in the adult. It is this enormous O_2 consumption rate that explains the rapid decrease in blood O_2 partial pressures in the neonate during periods of hypoventilation. Although ventilatory gas exchange volume is nearly 10-fold greater in adults than in neonates, the tidal volume relative to body weight for both is approximately equal (6 mL/kg). In neonates, increasing the respiratory rate facilitates the elimination of carbon dioxide (CO_2) generated by their relatively high metabolic processes; alveolar ventilation is approximately 130 mL/kg per minute in the perinatal period, compared with 60 mL/kg per minute in adulthood.

Lungs

Pulmonary Gas Exchange

The structure and function of the immature lung predisposes to alveolar collapse and hypoxia. The premature alveoli are primarily composed of thick-walled, fluid-filled saccular spaces that are surfactant deficient and require greater pressures to initially expand. Production of surfactant by type II alveolar pneumocytes begins between 23 and 24 weeks gestation, although surfactant concentrations often remain inadequate until 36 weeks gestation. These factors lead to the development of respiratory distress syndrome (RDS), which causes reduced lung volumes and lung compliance, increased intrapulmonary shunting, and ventilation-perfusion mismatch. It is clinically characterized by grunting respirations, nasal flaring, and chest retractions that develop shortly after birth. Decreased lung volumes and ventilation-perfusion mismatch may also occur as a consequence of anesthesia. The effects of immature structures, disease, and anesthesia on lung function all increase the risk of hypoxia during surgery and anesthesia.

In neonates, atelectasis might also be caused by anatomic forces that decrease lung volume. For example, the relatively large abdomen in a neonate displaces the diaphragm cephalad, placing the closing capacity within the expiratory reserve volume (see also Fig. 2.5). Moreover, increases in intraabdominal pressure from gastric distention associated with overzealous assisted ventilation with a face mask, replacement of bowel in the abdomen during repair of gastroschisis or omphalocele, or surgical retraction or manipulation of the abdominal contents also might shift the closing capacity to within the infant's expiratory reserve volume. The resulting atelectasis and intrapulmonary shunting may require controlled ventilation with PEEP to recruit closed lung units and improve oxygenation, emptying of the stomach, or changes in surgical maneuvers.

Micropremie lungs are particularly susceptible to volutrauma. Mechanical lung injury is no longer thought to be caused by the use of high peak-inspiratory pressures, but rather related to increased end-inspiratory lung volumes and frequent collapse and reopening of alveoli. A ventilation strategy using small tidal volumes (4–6 mL/kg), greater respiratory rates, PEEP sufficient to avoid alveolar collapse, and permissive hypercapnia reduces lung injury in the premature lung.[4] Permissive hypercapnia

TABLE 37.2	Severity-Based Diagnostic Criteria for Bronchopulmonary Dysplasia (BPD)
Gestational age	<32 weeks
Time point of assessment	36 weeks postmenstrual age or discharge home, whichever comes first
	Therapy with oxygen >21% for at least 28 days
Mild BPD	Breathing room air
Moderate BPD	Need for <30% oxygen
Severe BPD	Need for ≥30% oxygen and/or positive-pressure ventilation or nasal continuous airway pressure

(arterial partial pressure of CO_2 [$PaCO_2$] 45–55 mm Hg) results in smaller periods of assisted ventilation and reduced incidence of bronchopulmonary dysplasia (BPD), without an increase in adverse neurodevelopmental outcomes.[5]

Bronchopulmonary Dysplasia

BPD is an important chronic lung disease of prematurity, defined as the need for supplemental oxygen at 28 postnatal days.[6–8] Traditionally, BPD has been associated with premature infants subjected to high levels of O_2 and ventilation therapy that causes a lung injury–induced increase in cytokine activation. Other factors that increase the risk for developing BPD include chorioamnionitis and the persistence of a hemodynamically significant patent ductus arteriosus (PDA).[9]

Alveolarization begins around 36 weeks gestation. Therefore lung injury in the premature infant interrupts pulmonary maturation, resulting in larger but fewer alveoli than normal lungs. Decreased lung development in infants with BPD diminishes the surface area for pulmonary gas exchange, which increases O_2 requirements. Moreover, some infants with BPD have reduced lung compliance and increased airway resistance and hence have prolonged pulmonary time constants. Some infants with severe BPD have abnormal muscularization of the vessels in the periphery of their lungs, leading to pulmonary hypertension and right ventricular hypertrophy.

A number of strategies may be implemented to prevent the development of BPD. Modalities include antenatal corticosteroid administration to the mother and early postnatal administration to the infant, exogenous surfactant therapy, and specific ventilatory strategies, such as early and aggressive use of CPAP instead of intubation with positive-pressure ventilation. Treatment of existing BPD often requires ventilatory and medical therapies.[10] Ventilatory goals should be aimed at the avoidance of intubation if possible, and the use of permissive hypercapnia and smaller tidal volumes in those whose lungs are intubated. Infants with BPD are often treated with diuretics to decrease pulmonary alveolar and interstitial edema. As a result of chronic furosemide treatment, metabolic abnormalities may exist. Hypercalciuria from furosemide may lead to secondary hyperparathyroidism and nephrocalcinosis in some infants. Hydrochlorothiazide and spironolactone produce less severe metabolic abnormalities. Bronchodilators such as aminophylline, albuterol, or ipratropium may be beneficial in reducing airway resistance in some infants with BPD, although data are conflicting.[7] Finally, large doses of steroids, especially dexamethasone, provide relief for some infants with severe BPD that is refractory to other medical and ventilator therapies.[11,12] However, dexamethasone may cause systemic hypertension, hyperglycemia, hypertrophic cardiomyopathy, and alteration of neurologic and pulmonary development in some children.[13,14]

A severity index for BPD based on the need for supplemental oxygen and/or positive-pressure ventilation or nasal CPAP has been developed and shown to identify a spectrum of risk for adverse pulmonary and neurodevelopmental outcomes in preterm infants (Table 37.2).[15] Although this severity index has not been studied in the context of anesthetic risk, experience suggests that such infants requiring supplemental oxygen, positive pressure, or medications for reactive airways are at greater risk for perioperative pulmonary complications. Anesthetic goals include minimizing the inspired oxygen concentration and tidal volumes while maintaining adequate arterial oxygen saturation (SaO_2 90%–94%) and ventilation ($PaCO_2$ 50–55 mm Hg). The use of smaller tidal volumes decreases the risk of pneumothoraces and interstitial emphysema. Preoperative evaluation of infants with BPD requires a very careful history and physical examination, particularly focused on the pulmonary and cardiovascular systems.

Hyperoxia

Some prematurity-related diseases, such as retinopathy of prematurity (ROP) and BPD, have been associated with neonatal exposure to supplemental oxygen (hyperoxia). Oxygen toxicity from hyperoxia leads to the formation of reactive oxygen intermediaries that impair intracellular macromolecules, leading to cell death. The formation of oxygen free radicals also promotes an extensive inflammatory response, leading to secondary tissue damage and cell death. Oxygen-induced vascular endothelial growth factor (VEGF) signals disturbances associated with abnormal angiogenesis; it may be detected in both ROP and BPD.[8]

Controversy exists over the optimal oxygen saturation to target in the premature infant.[16–20] Two studies, the SUPPORT trial (**S**urfactant, **P**ositive Pressure, and Pulse **O**ximetry **R**andomized **T**rial) from the United States and the BOOST II trial (**B**enefits **O**f **O**xygen **S**aturation **T**argeting) from the United Kingdom, Australia, and New Zealand reported that a reduced oxygen saturation target range of 85% to 89% had a reduced incidence of ROP but an increased mortality compared with a target range of 91% to 95%.[21,22] However, the COT (**C**anadian **O**xygen **T**rial) and BOOST-NZ (BOOST New Zealand) trials found no significant differences in either death or disabilities among the two target ranges.[23,24]

Recent evidence suggests a more graded approach according to gestational age, with increasing oxygen saturation targets with increasing age, rather than a generalized approach that aims to target a single goal.[20] For example, one study suggested that an infant younger than 33 weeks should have an oxygen saturation target between 83% and 89%, whereas an infant between 33 and 36 weeks should have a goal between 90% and 94%.[20] However, the optimal range for the graded approach is controversial, as well. Because of the possible increase in mortality, most practitioners use the 91% to 95% target range of oxygen saturation.

Respiratory Control

Micropremies possess a biphasic ventilatory response to hypoxia. Initially, ventilation increases in response to hypoxia, but after several minutes, ventilation decreases and apnea may ensue.[25] The ventilatory response to CO_2 is decreased in the micropremie, and hypoxia further blunts this response.[26,27] Anesthetic drugs depress

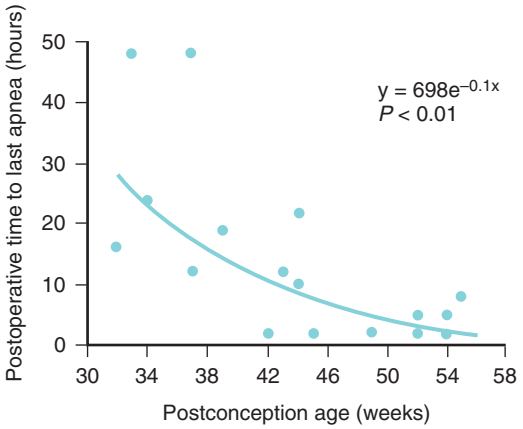

FIGURE 37.2 Time from the end of anesthesia to the last episode of postoperative apnea in prematurely born infants ($r^2 = 0.49$.) (Redrawn with permission from Kurth CD, Spitzer AR, Broennle AM, et al. Postoperative apnea in preterm infants. *Anesthesiology*. 1987;66(4):483–488.)

the ventilatory responses to both hypoxia and hypercapnia. Hypoxia and hypercapnia occur commonly as a result of apnea and hypoventilation during emergence and recovery from anesthesia. Thus the combination of anesthetic effects and an immature respiratory control system (see also Fig. 14.11), as well as immature intercostal and diaphragmatic muscles, increases the risk of hypoxia, hypercapnia, and apnea in the postoperative period (see also Figs. 4.8 and 4.9).[28,29]

Apneic episodes occur commonly in the micropremie but decrease with advancing PCA.[30] PCA is defined as the sum of the conception age and the postnatal age. These apneic episodes usually involve both a failure to breathe (central apnea) and/or a failure to maintain a patent airway (obstructive apnea). Central apnea results from decreased respiratory center output, although it may be precipitated by abrupt changes in oxygenation, pulmonary mechanics, brain hemorrhage, hypothermia, or airway stimulation. Apnea may also occur without a precipitating event (i.e., idiopathic). Preterm infants with apnea do not increase ventilation in response to hypercapnia, compared with those without apnea, thereby delaying resumption of breathing and prolonging the apneic episode.[31] During obstructive apnea, the airway becomes obstructed in the hypopharynx and larynx as a result of pharyngeal muscle incoordination. Anesthetic drugs may further decrease pharyngeal muscle tone, precipitating airway obstruction during recovery from anesthesia. The combination of anesthetic effects and immature respiratory control places the micropremie at risk for central and obstructive apnea for a prolonged period of time during recovery from anesthesia.

Not surprisingly, apnea occurs commonly after anesthesia and surgery in premature infants.[32,33] Like apnea of prematurity, postoperative apnea may be central, obstructive, or mixed in origin.[34] The term *postoperative apnea* usually means prolonged apnea (>15 seconds) or brief apnea accompanied by bradycardia (heart rate ≤80 beats/minute). Postoperative apnea typically occurs as a cluster of episodes over several minutes, with minutes of normal breathing in between the clusters. Bradycardia may occur with apnea, usually beginning at the onset of apnea and is not a response to hypoxia but likely a vagal-mediated response. Arterial oxygen desaturation usually follows the apnea, although many apneic episodes may not have any associated desaturation. Arterial desaturation is worse with obstructive apnea than with central apnea.[34]

The incidence of postoperative apnea depends on PCA, hematocrit, and the type of surgical procedure (Fig. 37.2; see also Fig. 4.7 and E-Fig. 4.5).[32–35] The most significant risk factor is the PCA; the less the PCA, the greater the risk, with the incidence of postoperative apnea in the micropremie greater than 50%.[32,33] Postoperative apnea can occur in the micropremie even without a history of apnea of prematurity.[32] After the initial decrease in postoperative apneic events in premature infants occurs at approximately 44 weeks PCA, a second significant decrease to near that of full-term infants occurs at 60 weeks PCA.[32] Therefore most centers have adopted a policy where premature infants need to be monitored for 12 continuous hours of apnea-free events after anesthesia when younger than 60 weeks PCA. Many admit these infants for overnight monitoring. Anemia (hematocrit <30%) and younger gestation increase the risk of apnea for a given PCA.[33,35] Postoperative apnea usually begins within an hour of emergence from anesthesia.[32] In the micropremie, it can continue to occur up to 48 hours postoperatively, despite the elimination of anesthetic agents (see Fig. 37.2). In fact, postoperative apnea can occur after surgery with desflurane- or sevoflurane-based anesthetics, or even after surgery for which a regional anesthetic was administered and no general anesthetic drugs were used.[36–39] Although spinal anesthesia may reduce the incidence of apnea within the first 30 minutes in PACU, the incidence of late apnea is the same as that after general anesthesia. Postoperative apnea is more common after major procedures, such as a laparotomy, compared with peripheral surgical procedures, such as inguinal hernia repair. These observations indicate that the neurohormonal response to surgery and postoperative pain may play an important role in the origins of postoperative apnea.

Management of postoperative apnea includes close observation with a cardiorespiratory monitor and pulse oximeter, administration of intravenous (IV) methylxanthines, such as caffeine and theophylline (Table 37.3), and prevention/treatment of anemia or hypovolemia. Caffeine is generally preferred over theophylline as it has a greater half-life and thus needs less frequent dosing (see also E-Fig. 4.6), its enteral absorption is more reliable, has fewer adverse side effects (tachycardia and feeding intolerance), and generally does not require serum drug monitoring. A loading dose of 10 mg/kg (IV or oral [PO]) is followed by a maintenance dose of 2.5 to 5 mg/kg daily.[40] Aminophylline 5–10 mg/kg, a predrug of theophylline, can also be used intravenously. Apnea can be exacerbated by opioids in the premature neonate, so their avoidance, if at all possible, is recommended. Obstructive apnea often responds to

TABLE 37.4 Circulating Blood Volume in Micropremies, Premies, Full-Term Neonates, Infants, and Children

	Blood Volume (mL/kg)	Weight (kg)	Total Blood Volume (mL)	25-mL Blood Loss Proportion of Total Blood Volume (%)

Child	70	20	1400	2

changes in head position, insertion of an oral or nasal airway, or placing the infant in a prone position. Nasal CPAP, high-flow nasal prongs (HFNP), or tracheal intubation and mechanical ventilation may be required for several days postoperatively if these measures fail.[32]

CARDIOVASCULAR SYSTEM

Immature Versus Adult Heart

The micropremie remains at greater risk of cardiovascular collapse during anesthesia and surgery than does the full-term infant for several reasons. The fetal heart differs from the infant heart in that it has more connective tissue, less organized contractile elements, and increased dependence on extracellular calcium concentration. In addition, the less compliant fetal heart has a flatter Frank-Starling curve (see also Figs. 18.3 and 18.4) and is less sensitive to catecholamines because of near-maximal baseline β-adrenergic stimulation (see also Chapter 18).[41,42] Consequently, cardiac output in the micropremie depends more on heart rate than it does in the term neonate. The increased resting heart rate in the micropremie also does not permit cardiac output to increase to the same extent as in an infant or child. Additionally, the vagotonic response caused by succinylcholine or its metabolites (succinylmonocholine) and synthetic opioids may lead to bradycardia. These cardiac reflexes can be offset by the vagolytic effects of pancuronium or atropine.[43,44]

The micropremie has a greater blood volume per kilogram, but it has a smaller absolute blood volume (Table 37.4). Therefore relatively little blood loss during surgery can cause hypovolemia, hypotension, and shock. Because autoregulation is not well developed in the micropremie, the heart rate may not increase with hypovolemia, and blood flow and oxygen delivery to the brain and heart may decrease with relatively little blood loss.[45] Anesthesia blunts baroreceptor reflexes in the micropremie, further limiting the ability to compensate for hypovolemia.[46] The combination of limited ventricular stroke volume reserve, an increased heart rate, small blood volume, and limited autoregulation predispose the micropremie to cardiovascular collapse during major surgery.

Transition From Fetal to Neonatal Circulation

The lungs are not required for gas exchange in utero because the placenta performs this function. The fetal circulatory pattern consists of atria and ventricles working as units in parallel (see Fig. 18.2). As little as 10% of the fetal right ventricular output may circulate through the lungs.[47] Most of the blood returned from the lower extremities and a portion of the umbilical venous blood supply passes into the pulmonary arteries and subsequently through the ductus arteriosus (DA) into the systemic circulation (see Chapters 16 and 18; Fig. 18.1). The superior vena caval blood supply circulates through the foramen ovale (FO) into the left atria and subsequently into the systemic circulation. With expansion of the lungs and increase in oxygen tension during the first breath, pulmonary vascular resistance decreases and blood flow to the lungs increases, matching perfusion with new ventilation.[47,48] The increased oxygen tension and loss of prostaglandin E_2-based relaxation are thought to result in closure of the DA. Any factor that increases pulmonary vascular resistance (e.g., hypoxia, hypercarbia, acidosis, and hypothermia) may cause the circulation to revert to a fetal circulatory pattern with shunting of deoxygenated blood from the right to the left side of the heart via a patent foramen ovale (PFO) or patent ductus arteriosus (PDA).[49–51] This right-to-left shunting of blood explains in part why some infants remain hypoxemic despite ventilation with 100% O_2 after severe desaturation.

Patent Ductus Arteriosus

In addition to aeration of the lungs, the removal of prostaglandins from the placenta and release of vasoactive substances at birth cause the DA to constrict and functionally close around 12 to 24 hours after birth, with anatomic closure in 2 to 3 weeks. Failure of the DA to close at birth occurs in 1/2000 full-term births, but affects up to 60% of ELBW infants with the incidence increasing with decreasing gestational age.[52,53] It is thought to be due to immaturity and failure of smooth muscle cells within the ductus to constrict, as well as immaturity of the lungs, which are responsible for metabolizing prostaglandins.

With the increase in systemic vascular resistance and decrease in pulmonary vascular resistance at birth, a PDA often results in significant left-to-right shunting of blood, causing excess pulmonary blood flow, congestive heart failure, and respiratory failure. Diastolic runoff of blood into the pulmonary artery leads to a widened pulse pressure (owing to low diastolic blood pressure) and risk of coronary ischemia. In a neonate with RDS or persistent pulmonary hypertension, right-to-left shunting across the PDA may occur, producing cyanosis. Paradoxical embolism is another concern with a PDA, as well as a PFO.[51] Fluid restriction and diuretic therapy, often used to treat congestive heart failure from left-to-right shunting through a PDA, further increase the risk of hypotension during surgery. The use of nonsteroidal antiinflammatory drugs to close the PDA can also cause renal compromise.[54,55]

Persistent Pulmonary Hypertension and Inhaled Nitric Oxide

Persistent pulmonary hypertension (PPHN) and refractory hypoxemia in neonates occurs in approximately 2/1000 live births.[56,57] PPHN is diagnosed when right-to-left shunting of blood occurs through a PDA and/or PFO in the absence of other congenital heart disease. Right-to-left shunting results from the failure of the pulmonary vascular resistance (PVR) to decrease at birth, thus preventing the conversion from fetal to neonatal pulmonary blood flow. The exact etiology of PPHN is not understood, but has been attributed to a variety of factors, including increased muscularization of pulmonary arterial vessels, impaired endothelial release of nitric oxide (NO), increased production of vasoconstrictors (e.g., endothelin-1), and impaired VEGF.[58] It can be associated with circumstances leading to perinatal distress (meconium aspiration, sepsis, asphyxia) or can be idiopathic, and rarely, genetic.[59]

PPHN is suspected in severely hypoxic neonates who do not have a significant increase in postductal O_2 saturation despite mechanical ventilation with an increased fraction of inspired oxygen (FIO_2). A greater preductal versus postductal O_2 saturation supports the diagnosis because it reflects the extrapulmonary right-to-left shunting of deoxygenated blood via the PDA. An echocardiogram excludes the presence of a congenital heart defect as the cause of or a contributing factor in the pulmonary hypertension and/or right to left shunt. It is imperative to diagnose and treat PPHN in a timely fashion as the morbidity, including neurodevelopmental delay, cerebral palsy, deafness, blindness, and mortality are substantive.[60,61] Premature infants tend to have worse outcomes and have more severe PPHN, requiring extracorporeal membrane oxygenation (ECMO) support earlier and more frequently than full-term neonates.[62]

The American Heart Association and American Thoracic Society have published guidelines for the diagnosis and treatment of PPHN. Treatment strategies aim to maintain adequate systemic blood pressure, maximize oxygen delivery, and optimize ventilator management to protect lung volume and function.[62] Normal lung expansion should be the goal of mechanical ventilation. Caution must be taken to avoid overdistending the lung, which can increase PVR. In cases of severe parenchymal lung disease, such as meconium aspiration, in which airway disease can lead to atelectasis and intrapulmonary shunt, PEEP and exogenous surfactant may be used to recruit alveoli. Although inspired O_2 is a potent vasodilator, maximum dilation of the pulmonary vasculature is achieved by relatively low levels of O_2, and hyperoxia can potentiate lung injury. For these reasons, increasing the FIO_2 often does not improve gas exchange in PPHN. Acidosis causes pulmonary vasoconstriction and should be avoided in patients with PPHN. This led to the practice in the past of inducing alkalosis by hyperventilation of the lungs or by infusing sodium bicarbonate. However, there is no evidence of any long-term benefit with this approach, and such management has been shown to worsen pulmonary vascular tone and lead to worse neurodevelopmental outcomes.[62,63] ECMO should be considered in those infants with severe sustained hypoxemia or compromised hemodynamic function.

Inhaled nitric oxide (iNO) is a selective pulmonary vasodilator used to treat PPHN. NO is normally produced by the endothelium and diffuses into subjacent smooth muscle cells, where it increases cyclic guanosine monophosphate (cGMP) levels that play a role in intracellular calcium levels and vasomotor protein function, leading to vascular relaxation (Fig. 37.3). iNO decreases PVR, limiting right-to-left shunting of blood, increases systemic O_2 partial pressures, and reduces the need for ECMO support in neonates with pulmonary hypertension.[62–65] However, not all infants respond to iNO, and studies have failed to demonstrate that iNO reduces mortality, length of stay in the hospital, or risk of neurodevelopmental impairment.[62,63,66] In contrast to full-term neonates, the success of iNO in the micropremie with hypoxic respiratory failure and pulmonary hypertension remains unclear.[62–64] Even among full-term neonates, some conditions such as congenital diaphragmatic hernia (CDH) do not respond well to iNO.[63,67]

When iNO is administered, the optimal initial dose is 20 ppm (Fig. 37.4). There is no advantage in terms of improvement in oxygen requirements to starting iNO at doses greater than 20 ppm. Moreover, doses greater than 20 ppm for extended periods may produce methemoglobinemia and/or nitrogen dioxide. Methemoglobin levels should be monitored if large concentrations of iNO are used. Fig. 37.4 delineates both treatment and weaning algorithms for iNO. Care must be taken to slowly wean the iNO to avoid rebound pulmonary hypertension. Weaning should cease if the oxygen requirements increase at any stage during the weaning process and resumed once the oxygen requirements stabilize. Some who encounter hypoxemia during weaning may benefit from phosphodiesterase inhibitors such as sildenafil or milrinone. Sildenafil (Revatio) is a phosphodiesterase-5 inhibitor that selectively reduces PVR. It has been recommended for PPHN that is refractory to iNO, although the US Food and Drug Administration (FDA) issued a blackbox warning in 2012 against chronic use of sildenafil in children. It may be administered orally or intravenously. Milrinone may also be added to treat infants with PPHN when left ventricular dysfunction is present. Prostacyclin-I_2 (e.g., epoprostenol IV or treprostinil oral, IV or subcutaenous) has been used to treat PPHN (as well as iNO-resistant PPHN); however, it has a very brief half-life (5 minutes) and requires permanent vascular access for continuous administration.[56,57] Any interruption in therapy will rapidly result in profound rebound pulmonary hypertension with many untoward adverse effects. Inhaled prostaglandin-I_2 analogs (e.g., iloprost) and endothelin receptor antagonists (e.g., bosentan) may also be used in iNO refractory PPHN.

NEUROLOGIC DEVELOPMENT

Immature Brain

The central nervous system (CNS) is incompletely developed at birth. Regions of the CNS develop at different times during gestation; consequently, the impact of premature birth depends on gestational age at birth and the severity of cardiovascular, respiratory, and other postnatal stressors. The area of the brain most susceptible to injury in the micropremie is the periventricular white matter.[65] The white matter consists of preoligodendrocytes, astrocytes, and neuronal axons. Late in the second trimester (24–27 weeks gestation), preoligodendrocytes and astrocytes multiply tremendously and most cortical and subcortical structures begin to develop.[65] The periventricular white matter is perfused by arteries penetrating from the cortical surface and by lenticulostriate arteries from the circle of Willis. During this period, the periventricular white matter is particularly susceptible to neurologic injury as it is a "watershed region," susceptible to poor perfusion and hypoxic-ischemic injury during hypotension, reduced cardiac output, hypoxemia, and hypocarbia.

Neural pathways responsible for the perception of pain develop during the first, second, and third trimesters (see also Chapters 2, 44, and 45).[66] During the first trimester, peripheral sensory receptors and spinal reflex arcs mature, yielding the "withdrawal reflex" to non-noxious stimuli. Neurons that transmit nociception appear in the dorsal root ganglia at 19 weeks gestation, and afferent neurons from the thalamus reach the cortical subplate and cortical plate between 20 and 24 weeks gestation. However, it is not until early in the third trimester (29 weeks) that pathways between the thalamus and somatosensory cortex are functional. Significant controversy exists regarding the exact gestational age at which perception and memory of pain occur.[68,69] The hormonal responses to pain and stress may be exaggerated in neonates, although the clinical significance of this has not been defined.[70,71] Nevertheless, our approach in the micropremie is to administer anesthesia during surgery and provide pain management postoperatively.

Glucose and the Brain

The neonatal brain requires a larger percentage of glucose production because of the greater brain weight in proportion to body weight. Multiple animal models and clinical studies implicate hyperglycemia as detrimental to the adult brain during global

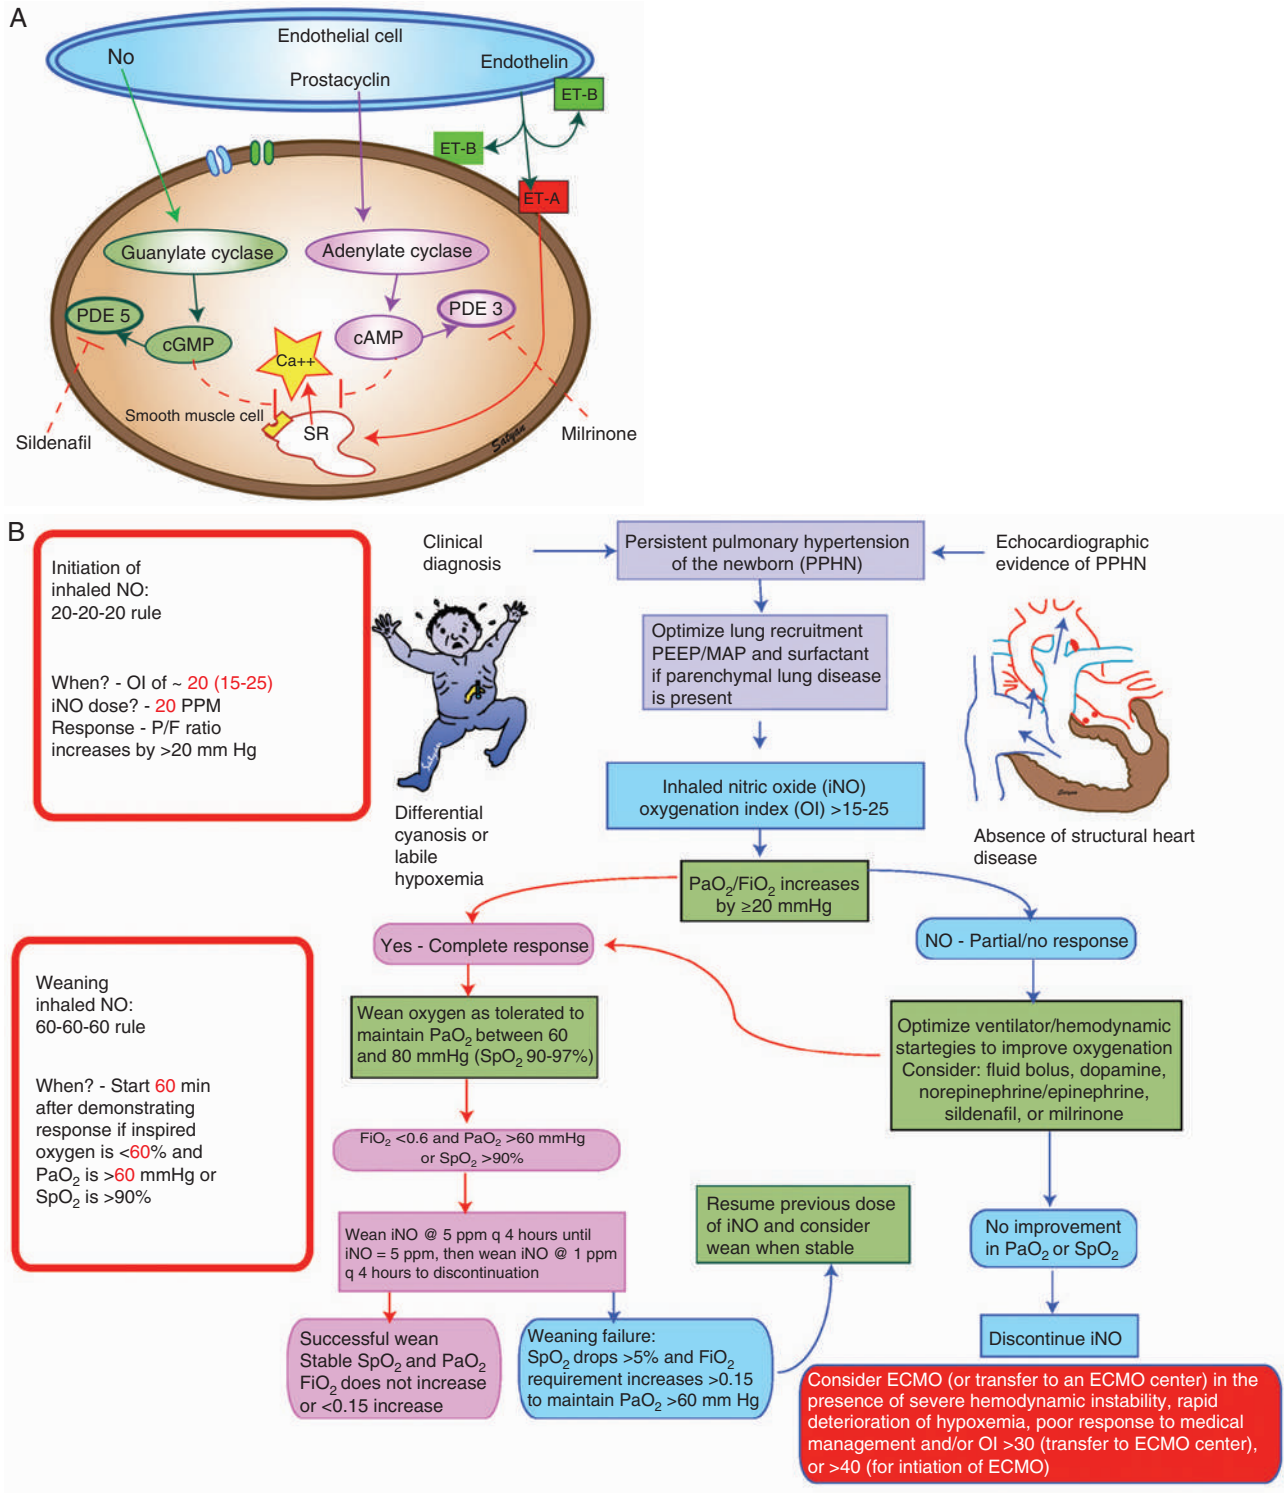

FIGURE 37.3 **A,** Nitric oxide *(NO)* produced by nitric oxide synthase *(NOS)* in endothelial cells diffuses into subjacent smooth muscle cells, interacts with soluble guanylate cyclase, and increases the concentration of cyclic guanosine monophosphate *(cGMP)* to cause vascular relaxation. and focal ischemia, such as with a cerebral or hypoxemic ischemic event and during cardiac surgery with deep hypothermic cardiac arrest.[72] In contrast, hyperglycemia in neonates appears to protect the brain from ischemic damage or at the very least be less harmful than hypoglycemia.[73,74] Studies in both neonatal rat and pig hypoxia-ischemia models observed less brain damage with greater glucose concentrations. Many mechanisms exist for this strikingly different outcome between neonates and adults.[75] Relatively mild hypoglycemia is known to cause brain damage in preterm infants.[76] Micropremies with critical illness are especially prone to hypoglycemia because they contain limited stores of glucose and consume glucose anaerobically. Thus the administration of dextrose-containing fluids (carefully controlled with an infusion pump to minimize wide serum glucose fluctuations) and close monitoring of blood glucose concentrations are vital during anesthesia. Mild or moderate hyperglycemia during surgery is best managed by reducing the rate of infusion of dextrose-containing solutions and not administering insulin, with its attendant risk of hypoglycemia.

Complications of Prematurity

Despite decreases in mortality in the micropremie, long-term neurologic and developmental disabilities remain common in this group and include cerebral palsy, cognitive deficits, behavioral abnormalities, as well as hearing and visual impairment.[65,77] In a study of ELBW infants, only 25% were classified as "normally developed" at 5 years of age. Twenty percent exhibited major disabilities.[77] Brain magnetic resonance imaging (MRI) has identified a spectrum of abnormalities in these infants. The most common abnormality is diffuse high signal intensity on T2-weighted imaging in the periventricular cerebral white matter. Diffusion-weighted imaging shows increased apparent diffusion coefficient values, indicative of increased water content and delayed white matter maturation, suggesting ischemia-reperfusion injury in periventricular white matter, which has activated microglia and damaged preoligodendrocytes.[65,78] Damage to preoligodendrocytes impairs myelination of cerebral white matter axons and accounts for many of the fine motor, speech, and cognitive deficits. On MRI, tissue volumes in the basal ganglia, corpus callosum, amygdala, and hippocampus are reduced and correlate with smaller full-scale, verbal, and performance IQ scores.[79] Collectively, these MRI findings indicate that different regions of the brain vary in their susceptibility to injury during development and that such injuries lead to specific long-term disturbances in neurocognitive function.

Intraventricular Hemorrhage

Intraventricular hemorrhage (IVH) occurs in as many as one-third of micropremie infants. Although an association has been noted between the incidence of IVH and fluctuations in blood pressure, it is difficult to confirm any causal relationship. The severity of IVH, as defined by head ultrasound, is graded as follows:

- Grade 1: hemorrhage limited to the germinal matrix
- Grade 2: hemorrhage extending into the ventricular system
- Grade 3: hemorrhage into the ventricular system and with ventricular dilatation
- Grade 4: hemorrhage extending into brain parenchyma.

Although micropremie infants with grade 3 or 4 IVH are more likely to exhibit severe long-term neurocognitive sequelae, even micropremie infants with grade 1 and 2 IVH display poorer neurodevelopmental outcomes compared with those without IVH.[79–81] Early onset of IVH appears during the first day of life. Risk factors include fetal distress, vaginal delivery, reduced Apgar scores, metabolic acidosis, severe hypercapnia, and the need for mechanical ventilation.[82,83] Late onset of IVH appears days to weeks after birth with contributing factors including RDS, seizures, pneumothoraces, hypoxemia, acidosis, severe hypercarbia, and the use of vasopressor infusions.[82,84] Lack of autoregulation leading to rapid fluctuations in cerebral blood flow, cerebral blood volume, and cerebral venous pressure, as well as fragile cerebral blood vessels, appear to play a role in the development of IVH.[45,84,85] Factors that may decrease the incidence and severity of IVH include administration of antenatal glucocorticoids or indomethacin.[86] Indomethacin helps to blunt the hyperemic response to hypoxia, improve cerebral autoregulation, and promote microvessel maturation of the germinal matrix. Although indomethacin decreases the incidence and severity of IVH, there is no evidence that long-term outcomes are improved.[86,87] Corticosteroids produce vasoconstrictive effects on fetal cerebral blood flow, protecting the fetus against IVH at rest and when challenged by conditions causing vasodilatation such as hypercapnia, leading to a significant reduction in IVH.[88]

TEMPERATURE REGULATION

The micropremie is very susceptible to hypothermia. Heat loss occurs by four possible routes: radiation (39%), convection (34%), evaporation (24%), and conduction (3%). In the micropremie, evaporative heat loss and insensible fluid loss are increased because the epidermis has less keratin.[89] Conductive and convective heat losses are also increased because the micropremie has little subcutaneous fat for insulation and a large surface area/mass ratio. Thermal regulation is not well developed in the micropremie.

Even full-term neonates do not have the capability to shiver or sweat, relying instead on nonshivering thermogenesis. Nonshivering thermogenesis, which depends on brown fat stores (which do not develop until 26–30 weeks gestation), is decreased in the micropremie and regulation of skin blood flow is less efficient.[90,91] During anesthesia, measures should be undertaken to minimize radiation and convective heat loss by warming the operating room (OR) to 80°F to 85°F (26.7°C–29.4°C) before the neonate arrives, and minimizing convective heat loss during transport (i.e., use a thermoneutral incubator or a warming mattress). The most effective means to maintain normothermia and to warm the micropremia is a forced-air warmer. Other strategies that may be useful to maintain normothermia include use of a warming pad on the operating table to reduce conductive heat loss, use of overhead heat lamps to reduce radiant heat loss, and keeping the skin dry to reduce evaporative heat loss. Additional strategies to reduce heat loss include using humidified gases in the ventilator circuit, covering the head, and warming IV and irrigation fluids before they are used. Temperature should be carefully monitored as overheating the infant may readily occur.

RENAL AND METABOLIC FUNCTION

Renal Function

The kidneys are not fully developed at birth.[92] Full-term neonates have a glomerular filtration rate (GFR) that is only 30% of normal adult rates owing to fewer nephrons and smaller glomerular size.[93–96] In fact, the GFR does not reach normal adult values until approximately 1 year of age (see Figs. 7.11 and 7.12). Maternal transplacental transfer of creatinine in utero increases the creatinine level in the neonate for the first few days of life.[97] The baseline plasma concentrations of creatinine increase with increasing prematurity and remain increased until approximately 3 weeks of age because of immature renal function and the consequent lower creatinine clearance compared with full-term infants.[98] These factors affect the metabolism of many drugs in the neonate. The renal excretion of medications such as penicillin, gentamicin, and some neuromuscular blocking drugs (NMBDs) such as pancuronium may be prolonged, resulting in increased duration of action or the development of high blood concentrations. This effect is particularly important when administering medications to an extremely premature infant. Thus the use of NMBDs that do not require renal function are most advantageous (e.g., cisatracurium).

Very premature infants easily become hyponatremic because of reduced proximal tubular reabsorption of sodium and water and reduced receptors for hormones that influence tubular sodium transport. As many as one-third of ELBW neonates develop hyponatremia.[95] Frequent assessments of the serum concentration of sodium and free water requirements are important during critical illness. Increased serum concentrations of potassium occur in premature infants during the first few days after birth. The increase results from a shift in potassium from the intracellular to extracellular spaces.[96] These increases are greater as gestational age and birth weight decrease.[99] Reduced cardiac output and urine production may further increase serum concentrations of potassium and predispose to cardiac arrhythmias.[100]

The total body water content in neonates is greater than in infants, children, and adults. In a term infant, 70% of the body weight is water (see also Figs. 7.7 and 7.8).[101] By 6 to 12 months of age, 50% to 60% of the body weight is water. In the premature infant 75% to 85% of the body weight is water. In general, the smaller the PCA of the neonate, the greater the percent of water present. Differences among the total body water, renal maturity, and serum protein concentrations in a neonate affect the volume of distribution of many medications. Because the volume of distribution of drugs confined to the extracellular fluid is increased, the initial doses of some medications (e.g., NMBDs, aminoglycosides) may be greater on a weight basis in neonates than adults to achieve the desired blood concentration. In contrast, because of immaturity of renal function, the interval between doses of these drugs must be increased.

Fluid Management

The basic principles of fluid maintenance in neonates are similar to those in older children and adults. The highly variable body fluid composition, degree of renal maturity, neuroendocrine control of intravascular fluid status, and insensible fluid loss with age make precise estimates of fluid requirements in neonates challenging.[102,103] Urine volume and concentration may be difficult to determine intraoperatively and may not always correlate with volume status. Moreover, blood pressure and heart rate may not correlate with intravascular volume status in premature infants, and anesthetics may mask subtle cardiovascular changes that occur with changes in intravascular volume. Increased insensible fluid loss, which often occurs in the OR environment, requires judicious titration of IV fluids. Congenital abnormalities (e.g., gastroschisis, omphalocele) may markedly increase insensible fluid loss through exposure of large mucosal surfaces. The use of humidified gas mixtures reduces insensible fluid loss through the respiratory tract. However, overzealous intraoperative administration of fluids can result in pulmonary complications and worsened third-spacing of fluids. It is recommended to use volume-controlled devices for fluid management, such as a Buretrol or an IV infusion pump, to ensure accurate fluid administration.

Calcium Homeostasis

During the third trimester, calcium is delivered to the fetus from the mother via placental transfer, resulting in fetal hypercalcemia. At birth serum calcium concentrations decrease with the abrupt loss of maternal calcium and reach a nadir at 2 days. By the third day of life, the combination of parathyroid hormone (PTH) secretion, dietary calcium intake, renal calcium reabsorption, skeletal calcium stores, and vitamin D allow the serum calcium concentrations in the full-term neonate to return to normal.[104]

Infants who are born prematurely do not benefit from the transfer of maternal calcium and are at greater risk for hypocalcemia after birth. In addition, premature infants experience hypocalcemia owing to hypoalbuminemia (reduces serum but not ionized calcium), limited oral intake, impaired secretion and response to PTH, increased calcitonin levels, and increased urinary losses as a result of increased renal excretion of sodium. Hypocalcemia has also been observed in nearly 40% of critically ill neonates.[105–107] Causes of hypocalcemia in the latter population include PTH insufficiency and peripheral resistance to PTH, inadequate calcium supplementation, and altered calcium metabolism caused by transfusion with citrated blood products, bicarbonate administration, or diuretics (e.g., furosemide).

Calcium exists in the serum in three fractions: protein bound, chelated to bicarbonate, phosphate, and citrate, and free or ionized calcium (iCa^{2+}). The ionized fraction is the physiologically active component; however, there is not always a clear relationship between total serum calcium and iCa^{2+}. The correlation is poor with hypoalbuminemia or acid-base disturbances, as seen in premature and critically ill neonates. Hypocalcemia is defined as a total serum calcium concentration less than 8 mg/dL (2 mmol/L)

in full-term infants and less than 7 mg/dL (1.75 mmol/L) in premature infants. An iCa^{2+} less than 4 mg/dL (1 mmol/L) defines hypocalcemia in both populations.

Hypocalcemia may be asymptomatic or accompanied by nonspecific symptoms such as neuromuscular irritability (myoclonic jerks, exaggerated startle, or seizures), tachycardia, prolonged QT interval, and decreased cardiac contractility. Diagnosis rests on the determination of total and iCa^{2+} levels. Neonatal hypocalcemia is a feature of DiGeorge syndrome (chromosome 22q11.2 deletion), also known as velocardiofacial syndrome, secondary to underdeveloped or absent parathyroid glands. The syndrome also involves abnormal facial characteristics, cardiac defects, thymic hypoplasia, and cleft palate.

Symptomatic hypocalcemia may be treated with 90 mg/kg calcium gluconate or 30 mg/kg calcium chloride[108] by slow IV infusion over 5 to 10 minutes while monitoring the electrocardiogram, as bradyarrhythmias may develop in response to rapid increases in the serum concentration of calcium.[104] The IV site must also be closely monitored for extravasation of a calcium gluconate infusion, as it may cause tissue necrosis and subcutaneous calcification deposits. Alternatively, if calcium chloride is administered, it should be infused through a central IV line.[104] If using an umbilical venous catheter (UVC), caution must be taken to ensure the tip of the catheter is in the inferior vena cava (IVC) because direct infusion into the portal system can cause hepatic necrosis. Maintenance calcium gluconate dosing is administered at 80 mg/kg per day for the first 48 hours, followed by 40 mg/kg per day for the next 24 hours, and then discontinued. The clinical response and serum iCa^{2+} concentrations should be monitored. Treatment of hypocalcemia is not effective in the presence of hypomagnesemia. In such a situation, parenteral administration of supplemental magnesium and calcium and treatment of the underlying cause of hypocalcemia are necessary.[105] Persistent hypocalcemia necessitates determination of magnesium, phosphorus, PTH, and vitamin D concentrations.

Glucose Homeostasis

Early in gestation, the fetal liver begins to store glycogen while a continuous supply of glucose is delivered by transplacental transfer from the mother. In the third trimester, glycogen stores begin to develop in fetal skeletal and cardiac muscle, as well as in the kidneys, intestines, and brain. At birth neonatal glucose concentrations decrease rapidly to 30 mg/dL within the first 1 to 2 hours, stimulating glycogenolysis and gluconeogenesis.[109,110] The glucose flux usually stabilizes at values greater than 45 mg/dL by 12 hours.[109,110] The premature infant is prone to hypoglycemia owing to immature glucoregulatory mechanisms, reduced levels of glycogen storage, increased energy demands, and limited adipose stores (reduced free fatty acids and ketones available as alternative sources of energy).[109] Full-term infants who have been excessively fasted, small-for-gestational-age (SGA) infants, and infants of diabetic mothers are also prone to develop hypoglycemia.

The definition of hypoglycemia varies in the literature and among institutions. In full-term neonates, hypoglycemia is defined as a glucose concentration less than 40 mg/dL during the first 24 hours after birth and less than 60 mg/dL at 36 hours. In premature infants or those at risk for hypoglycemia, the threshold for hypoglycemia at 24 hours is less than 45 mg/dL and at greater than 24 hours is less than 50 mg/dL.[109,111] Signs and symptoms of hypoglycemia tend to be nonspecific and many are masked under anesthesia.[109,112] Hypoglycemia may manifest as respiratory distress, apnea, cyanosis, seizures, tremors, high-pitched cry, irritability, limpness, lethargy, eye-rolling, poor feeding, temperature instability, and sweating.[112,113]

A bolus of 0.25 to 0.5 g/kg (1–2 mL/kg of $D_{25}W$ or 2.5–5 mL/kg of $D_{10}W$) and an increase in the basal glucose infusion are prudent measures to treat hypoglycemia. Full-term infants require a glucose infusion rate of 5 to 8 mg/kg per minute to prevent hypoglycemia. However, premature and SGA infants have greater glucose requirements, and thus require infusion rates of 8 to 10 mg/kg per minute. It is extremely important to reassess the blood glucose concentration after these treatments to determine the effectiveness of the therapy. A single bolus of glucose without subsequent infusion can stimulate insulin production with consequent return to the hypoglycemic state.

Infants undergoing surgical procedures often require less glucose supplementation.[114] This reduced need may be attributed to hormonal responses that decrease glucose uptake as a result of catecholamine release in excess of insulin activity, as well as a decrease in metabolic demand from the effects of the anesthetic agents.[70,71,115] Nonetheless, it is important to administer glucose-containing solutions using a constant-infusion device to avoid large fluctuations in blood glucose concentrations and to monitor blood glucose concentrations in critically ill neonates. All other fluids (e.g., to replace third-space losses, blood loss, and fluid deficits) should be glucose-free to avoid hyperglycemia.[114] Infants treated with glucose via total parental nutrition (TPN) may develop severe hypoglycemia if the infusion rate is abruptly lowered; thus it is important to continue these infusions (possibly at a slightly reduced rate) during surgery and to check the serum glucose concentrations.

GASTROINTESTINAL AND HEPATIC FUNCTION

The anatomic structures of the fetal gastrointestinal (GI) tract are formed in the second trimester; however, the functional maturation does not occur until later in gestation and continues after birth. For example, compared with adults, gastric emptying in neonates is prolonged and lower esophageal sphincters are incompetent, making reflux of stomach contents common, even in the full-term neonate.

Premature infants, however, are susceptible to a multitude of complications because of the immaturity of the GI system at birth. Intestinal motility significantly increases between 29 and 32 weeks gestation and is stimulated by enteral feeds. A full-term infant usually passes meconium within the first 48 hours; however, less than 50% of micropremies will pass meconium in that time frame, and it may be delayed by days to weeks. Intestinal motility is also important to decrease the time allowed for colonization of harmful bacteria in the GI tract.[116] Increased time for bacterial growth, coupled with decreased bactericidal gastric and pancreatic secretions and immature GI immune defenses, renders the micropremie at risk for infections and the development of necrotizing enterocolitis (NEC). Enteric feeds increase intestinal motility in premature infants. However, controversy exists over the optimal time to start enteral feeds and which type of nutrition is best (mother's milk, donated human milk, or various types of formulas).[117–119] Early feeding of premature infants with hypertonic or trophic feeds (<10–20 mL/kg per day) is well tolerated, although the volume and frequency should be increased very gradually in premature infants to limit the risk of feeding intolerance.[117,120] A recent Cochrane review failed to associate early trophic feeding with the development of NEC or other bowel difficulties in extremely premature infants compared with prolonged enteral fasting.[118,119,121]

Hepatic metabolism is immature in neonates, particularly in premature infants. Drug metabolism may be slow as a result of immaturity of enzymatic processes, reduction of hepatic proteins, and relatively low hepatic perfusion (less drug delivered to the liver). Any factor that further compromises hepatic blood flow (e.g., increased intraabdominal pressure) may have profound adverse effects on drugs with perfusion-limited hepatic clearance.[122] Therefore careful titration of these drugs (e.g., opioids, propofol) is required to optimize therapeutic effects and prevent toxicity. Just as consideration is given to immature renal function, the use of NMBDs that do not require hepatic metabolism is advantageous (e.g., cisatracurium). The use of remifentanil during the procedure followed by a small dose of longer-acting opioid or regional block at the end of the procedure might facilitate early extubation.

In addition, reduced albumin synthesis decreases albumin concentrations compared with term neonates, enhancing the free (unbound) concentration of anesthetic drugs that are highly bound to albumin. Increased concentrations of unbound serum bilirubin introduce the risk of kernicterus, particularly in infants who are premature, hypoxemic, and acidotic and have low serum protein concentrations.[123,124] Highly protein-bound agents such as furosemide, sulfonamides, ceftriaxone, and benzyl alcohol (found as a preservative in many drugs such as diazepam) may displace bilirubin and increase the possibility of kernicterus.[123] The micropremie is also at particular risk for spontaneous liver hemorrhage.[125,126] This occurs most commonly during laparotomy for NEC, is associated with large IV fluid resuscitation, and is difficult to control surgically. One case report described the apparent successful use of recombinant factor VIIa to stop liver hemorrhage when administration of other blood products had failed.[127]

HEMATOLOGIC FUNCTION

Full-term newborns are born with an average hemoglobin (Hgb) concentration of 16.8 g/dL. This increase in Hgb is the results of increased production of fetal Hgb (Hgb-F) during the second and third trimesters, as well as an increase in the production of adult Hgb (Hgb-A) between 34 and 36 weeks gestation. This prepares the infant for the physiologic anemia of the newborn that develops between 8 and12 weeks of life as the result of the fall in Hgb-F at birth and slow rise in erythropoietin (EPO) levels. The kidneys start transcribing EPO at 17 weeks gestation; however, production is not significant until around 30 weeks. At birth EPO production is initially decreased because of greater oxygen levels, and is subsequently stimulated by the anemia of the neonate. Therefore the premature infant has several reasons for being more susceptible to anemia at birth (average Hgb of 9.4 g/dL), which often occurs earlier and is more pronounced than the full-term neonate (average Hgb of 11.0 g/dL).[128] The leftward shift of the oxygen-Hgb dissociation curve resulting from the decreased affinity of Hgb-F for 2,3-diphosphoglycerate is also more pronounced in the premature infant, further contributing to the anemia.

The ideal hematocrit for the micropremie remains controversial. In the micropremie with reduced oxygen saturations and cardiac output, tissue oxygen delivery is maximized by maintaining the hematocrit between 44% and 48%. In a randomized study of liberal versus restrictive transfusion in neonates weighing between 500 and 1300 g, intraparenchymal brain hemorrhage, periventricular leukomalacia, and episodes of apnea occurred more frequently in the restrictive transfusion group.[129,130] The risks of blood transfusion in the micropremie must be balanced against the benefits of improved oxygen delivery and fewer medical complications.

Thrombocytopenia (platelet count <150,000/mm^3) occurs in as many as 70% of micropremies.[131] Although the etiology of thrombocytopenia is often unknown, pathophysiologic processes such as sepsis, disseminated intravascular coagulation, and NEC are common causes. In addition to thrombocytopenia, premature infants are at increased risk for bleeding as the result of increased capillary fragility and decreased concentration of vitamin K–dependent coagulation factors. Preoperative evaluation should include a recent platelet count and coagulation studies and the availability of platelets and fresh frozen plasma and/or cryoprecipitate for major procedures.

Anesthetics and the Neonate/Premature Infant

ANESTHETICS AND THE IMMATURE BRAIN

Research in immature animals indicates that anesthetics are both neuroprotective and neurotoxic. Inhalational anesthetics protect against hypoxic-ischemic injury in neonatal pigs and rats.[132–134] The anesthetic must be administered before and during the ischemic event at a concentration of 1 minimal alveolar concentration (MAC) to be effective. Thus for surgery in which there is a risk of brain ischemia, use of an inhalational anesthetic may afford some advantage over IV agents. Cardiac surgery, ventricular shunt insertion, and vein of Galen embolization represent examples of procedures performed in preterm infants that carry a risk of brain ischemia. The MAC for sevoflurane has not been established in premature infants, and unfortunately many sick preterm infants cannot tolerate even modest concentrations of potent anesthetic agents.

Of particular concern are the reports in immature rats and other animals, including primates, that prolonged exposure to commonly used anesthetics, such as isoflurane, ketamine, and midazolam, induces apoptosis in many regions of the brain (see Chapter 25).[135,136] If this phenomenon applies to humans, the premature infant could potentially be more susceptible to anesthetic neurotoxicity than is the full-term infant.

A confounding factor is that neurodegeneration and apoptosis is a normal developmental phenomenon in the maturing fetal brain. Furthermore, anesthesia-induced neuronal cell death in neonatal animals may not directly translate into long-term neurologic abnormalities. Indeed, evidence suggests that sevoflurane-induced cognitive impairment, in the form of short-term memory deficiency in neonatal rodents, is offset by delayed exercise.[137] Moreover, immature animals that undergo painful procedures without anesthesia experience neuronal degeneration.[138,139] Premature infants who receive anesthesia and sedation for painful procedures experience less morbidity and mortality than those who do not.[140] Curiously, the combination of surgery and anesthesia in neonatal rats produces more apoptosis than either intervention alone, suggesting that in this model, anesthetics are neither neuroprotective themselves nor do they offset the apoptotic effects of surgery.[141] In summary, the neurodegeneration precipitated by inhaled anesthetics, ketamine, and benzodiazepines depends on developmental age, brain region, and duration of exposure. Based on the animal models, the micropremie exposed to several hours of large concentrations of inhaled agents with nitrous oxide (N_2O) and midazolam is potentially at risk, as is the micropremie exposed to surgery with insufficient anesthesia. Thus our approach at the present time for surgery is to use small concentrations of inhaled agent, muscle relaxants, opioids (e.g., remifentanil), and regional anesthesia whenever possible.

Of even greater concern may be the sedatives that are administered for prolonged periods of time in the intensive care unit (ICU), although one study found "no evidence of an association between dose and duration of sedation and/or analgesia drugs given during the preoperative, intraoperative, and postoperative period and major adverse developmental outcomes" in children undergoing repair of congenital heart disease in the first 6 weeks of life.[142]

INHALATIONAL ANESTHETICS

The MAC defines the minimum alveolar concentration for inhaled agents at which 50% of patients respond to a painful skin incision with withdrawal. This measure allows comparison of the effects of inhaled anesthetics at equipotent doses. The MAC of isoflurane in the micropremie (<32 weeks PCA) is approximately 20% less than that in full-term neonates (see also Fig. 7.17), and at equipotent doses of isoflurane (1 MAC), systolic arterial pressure decreased similarly in all age groups, 20% to 30%.[143] Sevoflurane affords a rapid induction and emergence from general anesthesia. Desflurane is contraindicated for induction of anesthesia but is widely used for maintenance of anesthesia administered through an ETT. However, desflurane causes more airway irritability than isoflurane or sevoflurane, and as a result, it is not recommended for infants with severe BPD. Desflurane, sevoflurane, and isoflurane decrease arterial blood pressure in a dose-dependent manner, possibly through decreasing the systemic vascular resistance or by myocardial depression. One possible mechanism to explain the myocardial depression is that the baseline ionized calcium concentrations in premature infants, especially critically ill neonates, are less.[106,107] Premature infants may be more susceptible to the cardiodepressant effects of inhalational anesthetics because inhalational anesthetics block the calcium channels,[144] and the neonatal heart depends on the plasma ionized calcium for contractility to a greater extent than do the hearts of older children[145] (see also Chapter 7).

N_2O is not routinely used in the micropremie for several reasons. First, N_2O must be delivered in inspired concentrations ranging from 50% to 75% to reduce the MAC of other agents; therefore its role in micropremies, a group often requiring supplemental oxygen, is limited. Second, because of its blood gas solubility, N_2O rapidly enters air-filled cavities; therefore it is not recommended for use in infants with bowel obstruction, NEC, pulmonary interstitial emphysema, or pneumothoraces, pathologies that are common disorders in micropremies.[146] Third, in neonatal and young rats, N_2O demonstrates no antinociceptive effects, which contrasts with its antinociceptive effect in adolescent and adult rats.[147] This observation requires validation in humans.

INTRAVENOUS ANESTHETICS

IV agents include opioids, benzodiazepines, barbiturates, propofol, ketamine, and dexmedetomidine. Fentanyl possesses analgesic and sedative properties; however, it does not reliably produce unconsciousness or amnesia and, by itself, is not considered an anesthetic in children or adults. Nonetheless, the use of fentanyl as an anesthetic has been justified in preterm infants because they were deemed to be inherently amnestic by virtue of their age, even though the age at which consciousness and memory occurs is unknown. Premature infants (<1500 g) who receive IV fentanyl (30–50 μg/kg) and pancuronium for ligation of a PDA exhibit remarkable hemodynamic stability, with only a 5% decrease in blood pressure.[148] A dose of 10 to 12.5 μg/kg of fentanyl administered together with an NMBD maintained hemodynamic stability for 75 minutes in neonates undergoing a variety of thoracic and abdominal procedures.[149] Hypertension and tachycardia did not occur with skin incision, suggesting that analgesic concentrations necessary for surgery are achieved with this dose of fentanyl.

The pharmacokinetics of fentanyl (30 μg/kg) in premature infants yielded plasma concentrations that remained constant for up to 120 minutes, indicating a reduced clearance.[150] The elimination half-life of fentanyl ranged from 6 to 32 hours in premature infants, greater than the 2- to 3-hour half-life observed in children and adults.[150] The clearance of fentanyl is 7 mL/minute per kilogram at 25 weeks, 10 mL/minute per kilogram at 30 weeks, and 12 mL/minute per kilogram at 35 weeks PCA.[151] These studies demonstrated that the half-life and volume of distribution of fentanyl are increased, whereas the clearance is reduced in premature infants compared with adults.[122] These changes may be explained by immature CYP450 3A4, the major enzyme responsible for clearance (see also Chapters 6 and 7). In a subset of infants with increased intraabdominal pressure (after repair of a gastroschisis or omphalocele), the elimination half-life of fentanyl is 1.5- to 3-fold greater than that in other infants of the same age.[122] Fentanyl clearance may be impaired consequent to reduced hepatic blood flow as the result of increased intraabdominal pressure, although maldistribution of blood away from regions of concentrated CYP450 3A4 activity and reduced hepatic function may play a greater role.[122,152] The increased volume of distribution decreases the initial plasma concentration of fentanyl compared with that in adults.[122] These pharmacokinetic differences, combined with an increased propensity to apnea, serve to prolong analgesia and respiratory depression, increase the risk of postoperative apnea, and slow recovery of consciousness. In the micropremie, mechanical ventilation may be required for several days after large doses of fentanyl.

Similarly, the elimination half-life of morphine is markedly prolonged in premature infants compared with that in children and adults.[153–156] The elimination half-life of morphine ranges from 6 to 16 hours in the micropremie, compared with 2 to 4 hours in the adult. The clearance (normalized to a 70 kg person) of morphine increased with PMA between 23 and 35 weeks, reaching 50% of the mature clearance by 50 weeks PMA, and mature values by 80 weeks PMA.[154] The active water soluble metabolite, morphine-6-glucuronide, also has reduced elimination because of immature renal function.[157] We prefer fentanyl to large-dose morphine for anesthesia because the former has fewer hemodynamic side effects.[151,156]

Remifentanil is rapidly inactivated by plasma and tissue esterases and, because of its short half-life, is administered by continuous infusion. The half-life of remifentanil in adults is 3 to 4 minutes, independent of the duration of infusion, and similar to that in infants or children.[158] A multicenter study that compared halothane and remifentanil for maintenance of anesthesia in infants undergoing pyloromyotomy showed similar intraoperative hemodynamic stability with the two techniques, but significantly fewer "new-onset apneas" with remifentanil compared with halothane.[159,160] Interestingly, the most rapid clearance of remifentanil was in infants and children younger than 2 years of age, thus allowing an intense opioid effect intraoperatively that rapidly dissipates upon terminating the infusion.[161] Remifentanil has been used to provide anesthesia in infants weighing 400 to 580 g with apparent good hemodynamic stability.[162,163] A study examining cord blood from premature infants found high nonspecific esterase activity, comparable with that of term infants, thus suggesting

that preterm infants should be able to rapidly metabolize remifentanil.[164] If a remifentanil infusion is indicated, it is best to use a dilute concentration (5 μg/mL) piggybacked as close to the IV as possible with a continuous carrier to achieve a constant rate of administration.

Ketamine, a phencyclidine derivative, affords several advantages compared with inhaled and other IV agents. It provides analgesia, amnesia, and unconsciousness yet minimally depresses cardiovascular function (Fig. 37.4).[165] However, ketamine anesthesia depresses ventilation and airway reflexes, which predisposes to airway obstruction, apnea, and gastric aspiration. Thus we recommend the use of an ETT when ketamine is used for surgical procedures in the micropremie. In the setting of brief painful procedures, IV ketamine can be used as an anesthetic without an ETT.[166]

Other IV agents include thiopental, propofol, and benzodiazepines. These agents induce loss of consciousness but possess less analgesia than ketamine. Thiopental is a short-acting barbiturate primarily used for the induction of anesthesia. The micropremie requires less thiopental for induction than does the infant (2–3 mg/kg vs. 5–6 mg/kg, respectively), a relationship similar to the MAC of isoflurane.[167] In the past, we used only thiopental for neurosurgical procedures involving increased intracranial pressure in these infants. However, thiopental is no longer available in the United States. Propofol is primarily used to induce anesthesia and has largely replaced thiopental for this purpose. A word of caution is needed regarding the use of propofol for induction of anesthesia in neonates. Several reports highlight episodes in otherwise stable infants of protracted hypotension and low cardiac output that were associated with hypoxia after propofol boluses (1–3 mg/kg IV). The mechanism underlying these responses remains unclear, although systemic vasodilation and acute pulmonary hypertension with reversion to persistent fetal circulation remains a strong possibility.[168,169] In our experience, a propofol infusion (50–200 μg/kg per minute) supplemented with fentanyl as needed for analgesia can anesthetize the micropremie. The use of an infusion pump that accurately allows for delivery of small volumes is vital. The infusion rate of propofol in these small infants must be carefully entered and then double-checked by another provider to avoid a detrimental overdose.[170] Recovery from propofol anesthesia is delayed in micropremies compared with term infants, because micropremies have both less fat and muscle tissue to redistribute the drug, and reduced clearance. In the pediatric ICU, propofol infusions have been implicated in unexpected deaths (propofol infusion syndrome).[171] Until the safety of long-term administration of propofol has been examined in preterm infants, other alternatives for prolonged sedation should be considered.

Benzodiazepines, such as midazolam and diazepam, have been used in the neonatal intensive care unit (NICU) for sedation. As with thiopental and propofol, these drugs do not provide analgesia and are not recommended as the sole anesthetic for surgery. However, the combination of a benzodiazepine and opioid provides complete anesthesia for surgery. Midazolam clearance is markedly decreased in the micropremie compared with the term neonate or infant, and will be further prolonged in the setting of decreased liver function.[172] Midazolam can cause systemic hypotension, depress ventilation, and impair airway reflexes in preterm infants. The hypotension caused by midazolam is greater in the presence of fentanyl; thus both drugs must be titrated in small doses when administered concomitantly.[173] One study noted an 8% to 23% decrease in arterial pressure after a bolus of 0.1 mg/kg of midazolam in premature infants.[174]

REGIONAL ANESTHETICS

Regional anesthesia (see Chapter 42) is possible in premature infants and offers the advantage of the avoidance of sedative, volatile, and opioid medications that may lead to apnea, bradycardia, and hypotension. However, there is conflicting evidence of the superiority and reduction of adverse events of regional anesthesia compared with general anesthesia in this population.[175] In neonates the conus medullaris extends to a lower segment of the spine than adults; however, there does not appear to be a significant difference in location between term and premature neonates (see Fig. 42.3), thus it is generally recommended that lumbar punctures are made at L4-5 or L5-S1 interspaces in this age group.[176] Larger doses of local anesthetics per kilogram are required in infants because of their larger volume of distribution of cerebrospinal fluid (see E-Fig. 42.3), relatively increased surface area of the spinal cord and nerve roots, and increased cardiac output with proportionally greater blood flow to the spinal cord. However, faster drug distribution, uptake, and elimination of local anesthetics from the CSF also abbreviate their duration of action. Adjuncts to local anesthetics, such as clonidine, may increase the duration of the block but also increase the risk of sedation, bradycardia, apnea, and hypotension. The optimal dose, timing and, side effects of these adjuncts in this age group are controversial.[177]

Neonatal Surgical Emergencies

Neonatal emergencies can present at any time, occurring immediately at birth or within weeks after delivery. Thankfully, advances in perinatology have improved the morbidity and mortality of critically ill newborns. Nonetheless, whether acquired or congenital in nature, these emergencies can be truly life-threatening and require the skill and expertise of an anesthesiologist who is knowledgeable about the nuances of neonatal physiology. The goal of this section is to describe common neonatal surgical emergencies and the considerations important to the anesthesiologist caring for this very special population.

PREPARATION FOR SURGERY

The "Urgent" Emergency

In the past, many conditions classified as neonatal emergencies were expeditiously taken to the OR, often within hours of diagnosis. However, with newer technology and medical advances, along with better outcome data, immediate surgical intervention is not always necessary or preferable. In most circumstances, there is time to medically optimize the infants and correct any hemodynamic instability and/or metabolic derangement, although the optimal timing for surgical correction is not always straightforward and must be determined on a case-by-case basis.[178–181]

THE OPERATING ROOM

Environment

Owing to the immature and inefficient measures neonates use to regulate body temperature, precautions must be made to prevent heat loss in the OR. Warming the room to 80°F to 85°F (26.7°C–29.4°C), using radiant warming units, using forced-air heating pads, and adding humidity to the inspired gases in the circuit help maintain the neonate's temperature in the neutral thermal range (see Chapter 52).[182–184] Other methods used to prevent heat loss include using a head cover and warming IV and irrigation fluids before they are used.[185,186] Precautions should also be used during transport, such as the use of an incubator/radiant warmer or a portable heated mattress.

MONITORS

Routine standard monitoring equipment includes an electrocardiograph, chest or esophageal stethoscope, blood pressure monitor, temperature probe, pulse oximeter, and an end-tidal carbon dioxide ($ETCO_2$) and agent analyzer. Cerebral near-infrared spectroscopy (NIRS) is used increasingly in neonates (E-Fig. 42.3) with cardiac pathology, neonatal intensive care, and the OR. Noninvasive continuous cardiac output monitors may become routine in these infants in the future (see Chapter 52).[187,188]

Oxygen Saturation

It is recommended to limit the use of oxygen in neonates to maintain an oxygen saturation as measured by pulse oximetry (SpO_2) of anywhere between 83% and 95% in order to decrease oxidative stress.[16–19] However, an increased inspired fraction of oxygen (FIO_2) may be required during anesthesia and surgery owing to their deleterious effects on oxygenation, such as reduced functional residual capacity (FRC), ventilation-perfusion mismatch, and hypoventilation. Perhaps more importantly, many neonatal emergency surgeries are intrathoracic or intraabdominal in nature, further exacerbating difficulties in oxygenation with limited recruitment maneuvers available. In the event that the ductus arteriosis is still patent, it is recommended to place a preductal pulse oximeter (right hand), as well as a postductal oximeter (left hand or foot) to determine the severity of any extrapulmonary shunting of deoxygenated blood via the PDA. If the patient has a right-sided arch, the pulse oximeter should be placed on the left hand instead of the right for preductal monitoring.

End-Tidal Carbon Dioxide

$ETCO_2$ measurements have been shown to correlate generally well with $PaCO_2$, even in neonates.[187,189–191] However, most of these studies have taken place in ICUs, not in the OR, where the anesthesia circuits tend to carry significantly more dead space (VD). The increase in VD, along with a small neonatal tidal volume (VT) exacerbates the $PaCO_2$–$ETCO_2$ gradient, as evidenced by the Enghoff modification of the Bohr equation:

$$VD)/VT = (PaCO_2 - ETCO_2)/PaCO_2$$

In addition, it has been noted that the correlation of $PaCO_2$ to $ETCO_2$ in neonates with severe lung disease who demonstrate an arterial oxygen saturation (PaO_2) to FIO_2 ratio of less than 200 is not as strong.[187] Neonates presenting for emergency surgery may harbor some degree of lung disease, and most will be subject to a large VD, making it important to recognize that the $ETCO_2$ may significantly underestimate true $PaCO_2$. A more accurate estimate of $ETCO_2$ concentration may be obtained by using a special endotracheal tube with a sample port located at its tip (mainstream monitoring) or by inserting a narrow catheter through the CO_2 sampling port in the elbow and into the lumen of the tracheal tube.[191–193] Measures to limit VD include eliminating the elbow from the anesthesia circuit and shortening the ventilation circuit as much as possible.

Invasive Monitors

In neonates, changes in blood pressure, heart rate, and the intensity of heart sounds are excellent indicators of cardiac function, intravascular volume status, and depth of anesthesia. Invasive monitors may not be indicated in all cases. They can be difficult to place, lead to adverse events, and contribute to a significant decrease in hematocrit owing to multiple blood draws from a very small circulating volume. However, in cases in which major blood or fluid losses are expected, or the physiology is complicated by the presence of cardiac disease, a central venous catheter is warranted. Likewise, any neonate with significant underlying cardiovascular instability should have an arterial catheter placed for continuous monitoring of blood pressure and to provide means to obtain arterial blood samples for determination of blood pH, serum glucose, and electrolyte concentrations. Some neonates arrive in the OR with umbilical venous (UVC) and/or arterial catheters (UAC) in place. Umbilical catheters can be used during the first 5 to 7 days of life and are rarely used beyond 7 to 10 days. High-lying UACs (above the diaphragm) are associated with fewer complications, such as ischemia, thrombosis, and hypoglycemia, than low-lying catheters (above the aortic bifurcation) (Fig. 49.9).[194] UVCs should lie in the IVC at its junction to the right atrium (Fig. 49.8). A UVC that lies within the portal system or wedged within the liver will not accurately reflect central venous pressure (CVP) and can lead to hepatic necrosis with infusions of hypertonic solutions.[195] Care must be taken to verify where the tips of each of these catheters lie before using them.

Ventilator

As mentioned previously, there is often a large amount of VD from anesthesia circuits to a neonate who requires a very small TV. In addition, these infants may have intrinsic lung pathology, which when coupled with intrathoracic or intraabdominal surgery that compresses the lungs, can render it extremely difficult to ventilate with a conventional anesthesia machine. It may be necessary to manually ventilate the lungs in these infants during parts of the surgery, particularly if a primitive ventilator is used. In limited circumstances, it may be beneficial to have the ICU bring one of their ventilators to the OR for use during surgery, but this will preclude the ability to administer volatile agents.

Equipment Setup

Anesthesiologists need to be well prepared for these surgical cases. A sick neonate can have extremely labile hemodynamics even before the induction of anesthesia or surgical incision. Table 37.5 lists basic equipment for conducting emergency anesthesia in a neonate (Figs. 37.5 and 37.6).

Fluids and Medication

Particular attention must be paid to ensuring the accurate delivery of medications and fluids. These infants require only small fractions of the medications in most vials and ampules. As a result, either tuberculin syringes should be used to carefully measure the very small aliquots of medications or the medication in the vial should be diluted so that a measurable and accurate fraction of the content of the vial can be given. Tuberculin syringes present several challenges, including difficulty in removing air bubbles from the syringe, and the very small volume that will be administered. The volume of medication may be so small that it is no larger than the volume of the stem of the clave or stopcock, resulting in less drug than intended being administered to the infant. Diluting medications introduces the risk of a drug dose error that could lead to an overdose or underdose of the medication. In all instances, it is prudent to verify the dose and dilution of the medication with a colleague and carefully label the contents. To ensure the drug is not lost in the VD of the IV set, each clave or stopcock should be flushed with saline solution after the medication has been given. All medications should be administered into the IV

TABLE 37.5 Suggested Equipment for Emergency Neonatal Anesthesia

Airway Equipment	Environment	Agents	Intravenous Fluids[a]
Suction catheters	Room temperature (80°–85°F; 26.6°–29.5°C)	Gases	Lactated Ringer's solution
Oral airways	Forced warm air delivery device	Air/O_2/iNO	$D_{10}W$
Face masks	Underbody warming blanket	Volatile anesthetics	Normal saline solution
Breathing circuit	Circuit humidifier	Drugs	5% albumin
Miller 0, 1, blades and handle	IV fluid warmer	IV anesthetics	PlasmaLyte
Uncuffed endotracheal tubes (ID 2.5, 3.0, 3.5, 4.0 mm)	Infusion pumps for both maintenance fluid and for opioid or vasoactive drugs	Propofol Ketamine	
Stylet		Muscle Relaxants	
Cuffed endotracheal tubes (ID 3.0, 3.5 mm)		Succinylcholine Cisatracurium Vecuronium Pancuronium	
		Opioids	
		Fentanyl Morphine Remifentanil	
		Local Anesthetics	
		Tetracaine 1.0% Bupivacaine 0.25%	
		Emergency Drugs	
		Atropine Epinephrine (1:10,000) Dopamine Calcium Bicarbonate Isoproterenol	

ID, inner diameter; *IV,* intravenous; *NO,* nitric oxide; O_2, oxygen.
[a]Some guidelines suggest 1% glucose should be added to an isotonic fluid for maintenance during anesthesia.[301]

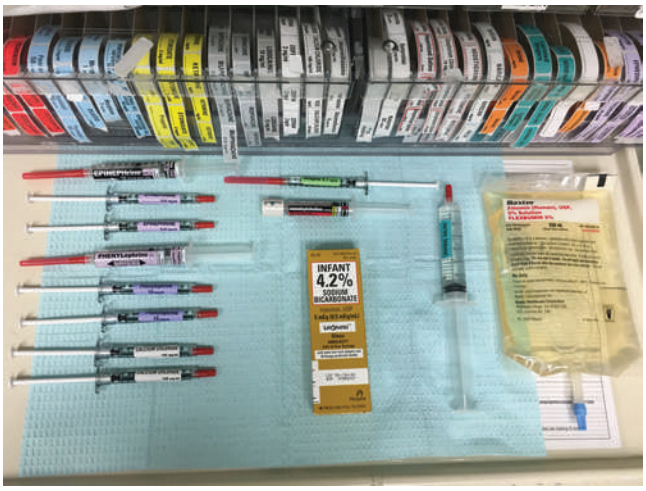

FIGURE 37.5 Example of emergency drug setup on anesthesia cart.

FIGURE 37.6 Example of neonatal airway setup on anesthesia machine.

set as close to the patient as possible to minimize the volume of fluids needed to flush the medication into the child (see Fig. 52.2).

Fluid overload is always a concern in these small infants. To minimize the fluids administered, all IV infusions should be delivered through a pump. Free-flowing IVs are dangerous sources for fluid overload, which may open a DA and cause congestive heart failure. Finally, meticulous care must be taken to remove air bubbles from all IV administration systems, solutions, and medications that are administered. See Chapter 52 for further discussion on infusion pumps and the implications of IV administration VD on drug delivery (see also Figs. 52.2 and 52.3).[196,197]

Intraoperative fluid management in micropremies should begin with continuing the solution that arrives with the infant from the NICU; usually this is a calcium- and/or glucose-containing solution. Alternatively, some infants may arrive with a hyperosmolar glucose or dextrose (10%) parenteral nutrition solution. In both cases, these solutions should not be discontinued, but rather continued at the same rate (by infusion pump) or slightly less throughout the surgery to avoid reactive hypoglycemia from increased circulating insulin concentrations. There is no evidence regarding the optimal infusion rates for these solutions during anesthesia. If no solution is being infused, a balanced salt solution (e.g., lactated Ringer's solution or PlasmaLyte) could be initiated at 4 mL/kg per hour, supplemented with the same solution for third-space loss (at least 10 mL/kg per hour), and replacement of blood loss. If a glucose solution is not being infused, then a balanced salt solution containing glucose may be administered through a pump. Serum glucose concentrations should be monitored regularly to avoid hypoglycemia. Third-space losses include evaporation and vascular leak and are replaced with a balanced salt solution.

Bedside Procedures in the ICU

Occasionally, neonates may be so critically ill that simply transporting the infant to the OR may be life-threatening. To decrease the risk, many institutions now perform surgical procedures at the infant's bedside or in a specialized surgical suite within the NICU, minimizing the period of transport and providing optimal surgical conditions. Providing surgical and anesthetic care at the bedside has its challenges. There is reduced access to the child, suboptimal lighting, reduced sterility, limited monitors (usually capnography

is absent), and an inability to control room temperature, although NICU incubators commonly include a built-in overhead radiant heater.

Adapting to the working environment requires planning and organization in concert with communication with the surgeons, neonatologists, and nurses in the NICU. If bedside anesthesia is to be provided, then appropriate IV equipment for transfusion, pumps, and monitors compatible with electrocautery and expired CO_2 monitoring should be available, just as in the OR.

THE FAMILY

Close interaction between the parents and the anesthesia, medical, surgical, and nursing staff promotes effective communication of medical concerns and continued emotional support for parents. The birth of a premature neonate or illness in a full-term infant often does not allow time for emotional preparation for or acceptance of the situation by the family. With the institution of aggressive medical and surgical interventions, parents sometimes feel excluded from the care of their infant and develop feelings of isolation and lack of control. The development of rapport between the parents of critically ill infants and hospital staff is essential to ensure adequate psychological support during this intensely anxiety-provoking event.

Emergency Surgery

RESPIRATORY PATHOLOGY

Lesions of the respiratory system can be categorized into those that involve the large and small airways and those that involve the lung parenchyma.

ABNORMALITIES OF THE AIRWAY

Airway surgery presents unique operative challenges. The airway must be shared between the anesthesiologist and surgeon, while the OR table is rotated 90 degrees, hindering immediate access to the child's airway. Bronchoscopy with a rigid scope is very stimulating and requires a deep level of anesthesia, which may lead to cardiac and respiratory depression. There is intermittent and often inadequate ventilation because of leakage around the scope or during periods where the insufflation port is removed or just the telescope is used. These factors make it difficult to maintain an adequate level of anesthesia when inhalational agents are used. It may be more prudent to provide anesthesia with IV medications, such as propofol or ketamine, with intermittent boluses or with the use of a constant infusion for longer cases together with opioids (see also Chapters 15 and 33).

Choanal Atresia

Choanal atresia is a developmental failure of the nasal cavity to communicate with the nasopharynx owing to the persistence of the nasobuccal membrane. It occurs in approximately 1/7000 live births with a female predominance.[198] Choanal atresia is often associated with other congenital anomalies, such as CHARGE syndrome (**C**oloboma, **H**eart disease, **A**tresia choanae, **R**etarded growth, **G**enital anomalies, **E**ar anomalies), Treacher-Collins, Pfeiffer, and VATER (**V**ertebral defects, **A**nal atresia, **T**racheoesophageal fistula with **E**sophageal atresia, and **R**adial and renal anomalies).[199,200] Unilateral choanal stenosis is usually diagnosed later in childhood or adulthood and is characterized by unilateral nasal discharge and persistent nasal obstruction. Bilateral stenosis, however, is considered a surgical emergency owing to the obligatory nasal breathing pattern in neonates. They often present within the first days of life with respiratory distress and cyanosis, usually while feeding, which is relieved by crying. Other diagnostic criteria include noisy breathing, difficulty feeding, and the inability to pass a 5/6F catheter into the nasopharynx. Definitive treatment involves perforation of the persistent membrane via an endoscopic transnasal approach (most common) or via a transseptal approach (usually reserved for patients with other significant craniofacial abnormalities).[199,201] Nasal stenting is often performed at the end of the procedure with stents left in place for about 4 weeks. These neonates may develop airway obstruction during anesthetic induction, therefore early placement of an oral airway may aid in airway management.

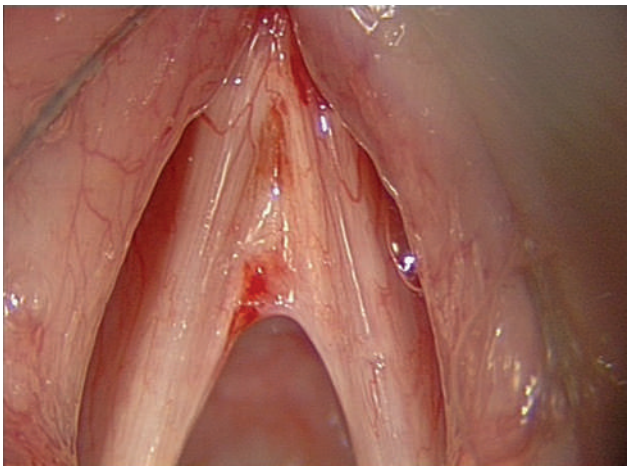

FIGURE 37.7 Laryngeal web in a neonate. (Courtesy Dr. Christopher Hartnick.)

Laryngeal and Upper Tracheal Obstruction

Because of the narrow diameter of neonatal airways, even a small obstruction can lead to significant resistance to airflow, leading to life-threatening respiratory distress. Therefore timely recognition and treatment of laryngeal and upper tracheal abnormalities, such as webs, congenital subglottic stenosis, and hemangiomas is essential in reducing morbidity/mortality. (Figs. 37.7 and 37.8 and Video 37.1; see also Videos 14.1, 14.5, and 14.18).

As resistance increases inversely with the airway radius to the fifth power, ventilatory assistance is required to overcome this substantial increase in the work of breathing. The greater time constants that result from the increased airway resistance require a greater time for expiration to avoid gas trapping. In the most severe cases of obstruction, tracheal intubation may not be possible or is unable to provide adequate ventilation past the stenosis, and a tracheostomy may have to be placed before treatment.

WEBS. Laryngeal and tracheal webs are fibrous membranes that develop as the result of incomplete recanalization of the larynx during early gestation, resulting in variable degrees of airway obstruction and acute respiratory distress or stridor shortly after birth (see Fig. 37.7).[202,203] Some infants may succumb at birth because of a complete or near-complete tracheal web if this airway defect has not been identified antenatally. If a tracheal web has been identified in utero, an ex utero intrapartum treatment (EXIT) procedure may be a lifesaving maneuver (see Chapter 38). Anterior glottic webs are associated with velocardiofacial syndrome (also known as 22q11.2 deletion or DiGeorge syndrome) in 65% of cases, and many also include concurrent subglottic stenosis.[203] Endoscopic web excision is the preferred treatment via microlaryngoscopy.

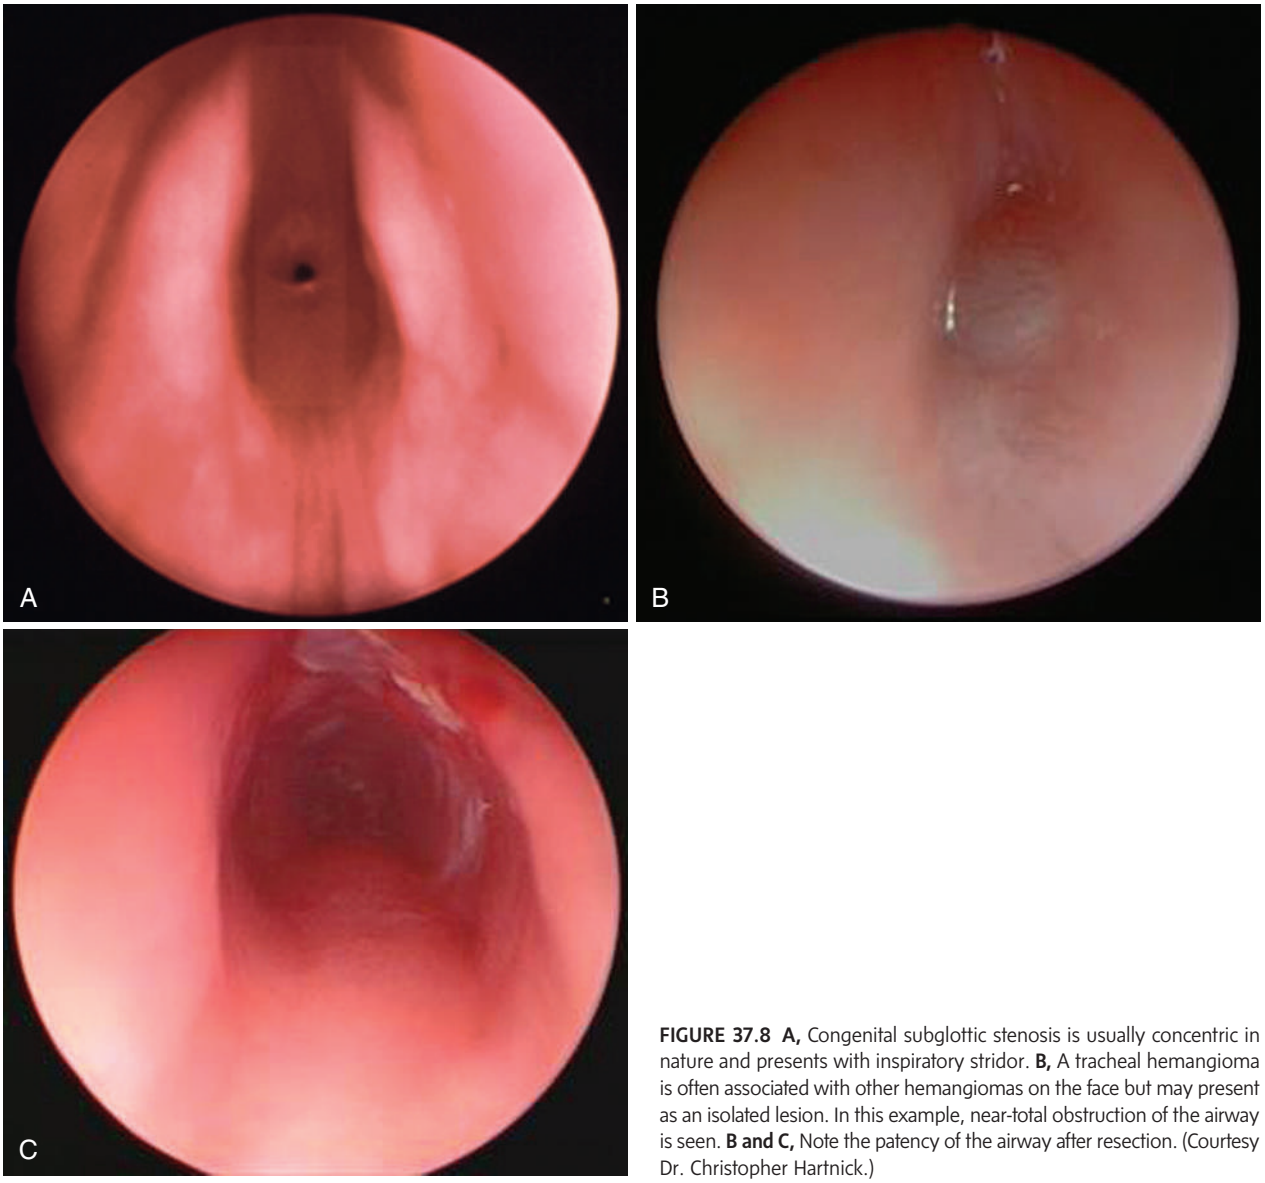

FIGURE 37.8 A, Congenital subglottic stenosis is usually concentric in nature and presents with inspiratory stridor. **B,** A tracheal hemangioma is often associated with other hemangiomas on the face but may present as an isolated lesion. In this example, near-total obstruction of the airway is seen. **B and C,** Note the patency of the airway after resection. (Courtesy Dr. Christopher Hartnick.)

Many surgeons will elect to keep the airway intubated for 24 hours after surgery to allow the raw edges to re-mucosalize.

CONGENITAL SUBGLOTTIC STENOSIS. Subglottic stenosis is the most common indication for neonatal tracheostomy placement.[204] It is thought to be the result of malformed cricoid cartilage in utero, or, in rare cases, owing to severe gastroesophageal reflux, eosinophilic esophagitis, or infection.[203] The degree of symptomatology and treatment options varies with the degree of narrowing. Lower-grade stenoses can be treated with endoscopic interventions such as balloon dilation and steroid injection. However, the more severe stenoses require more extensive surgical repair. In the past, these neonates received long-term tracheostomy placement with the expectation that they would outgrow the stenosis. Currently the surgical options include cricotracheal resection and laryngotracheoplasty, involving an anterior with or without a posterior cricoid split involving the placement of a cartilage graft, usually from the thyroid or costal cartilage, to enlarge the subglottic lumen. This may or may not include the temporary placement of a tracheostomy while the incision heals (see also Chapter 15).[204]

SUBGLOTTIC HEMANGIOMA. Infantile hemangiomas are the most common type of vascular tumor, affecting 4% to 10% of infants, and the most common tumor to involve the pediatric airway (see Fig. 37.8).[205,206] Its cause is not well understood. Any child with a cutaneous hemangioma, especially if in the V3 "beard" distribution on the face, should be evaluated for a concomitant subglottic hemangioma (20%–30% co-incidence), although they can occur anywhere in the airway.[205,207] Airway hemangiomas can also be associated with PHACES syndrome (**P**osterior fossa malformation, **H**emangioma, **A**rterial lesions of the head and neck, **C**ardiac abnormalities, **E**ye abnormalities, **S**ternal cleft or **S**upraumbilical hernia). Symptoms, which include respiratory distress and stridor, are generally absent immediately after birth but can develop quickly as the hemangioma rapidly grows between 6 and 12 weeks of life. This proliferation continues until approximately 12 to 18 months of age, and the hemangioma then gradually begins to shrink. First-line medical therapy includes oral propranolol, followed by systemic and intralesional injection of steroids. Propranolol can cause bradycardia, hypotension,

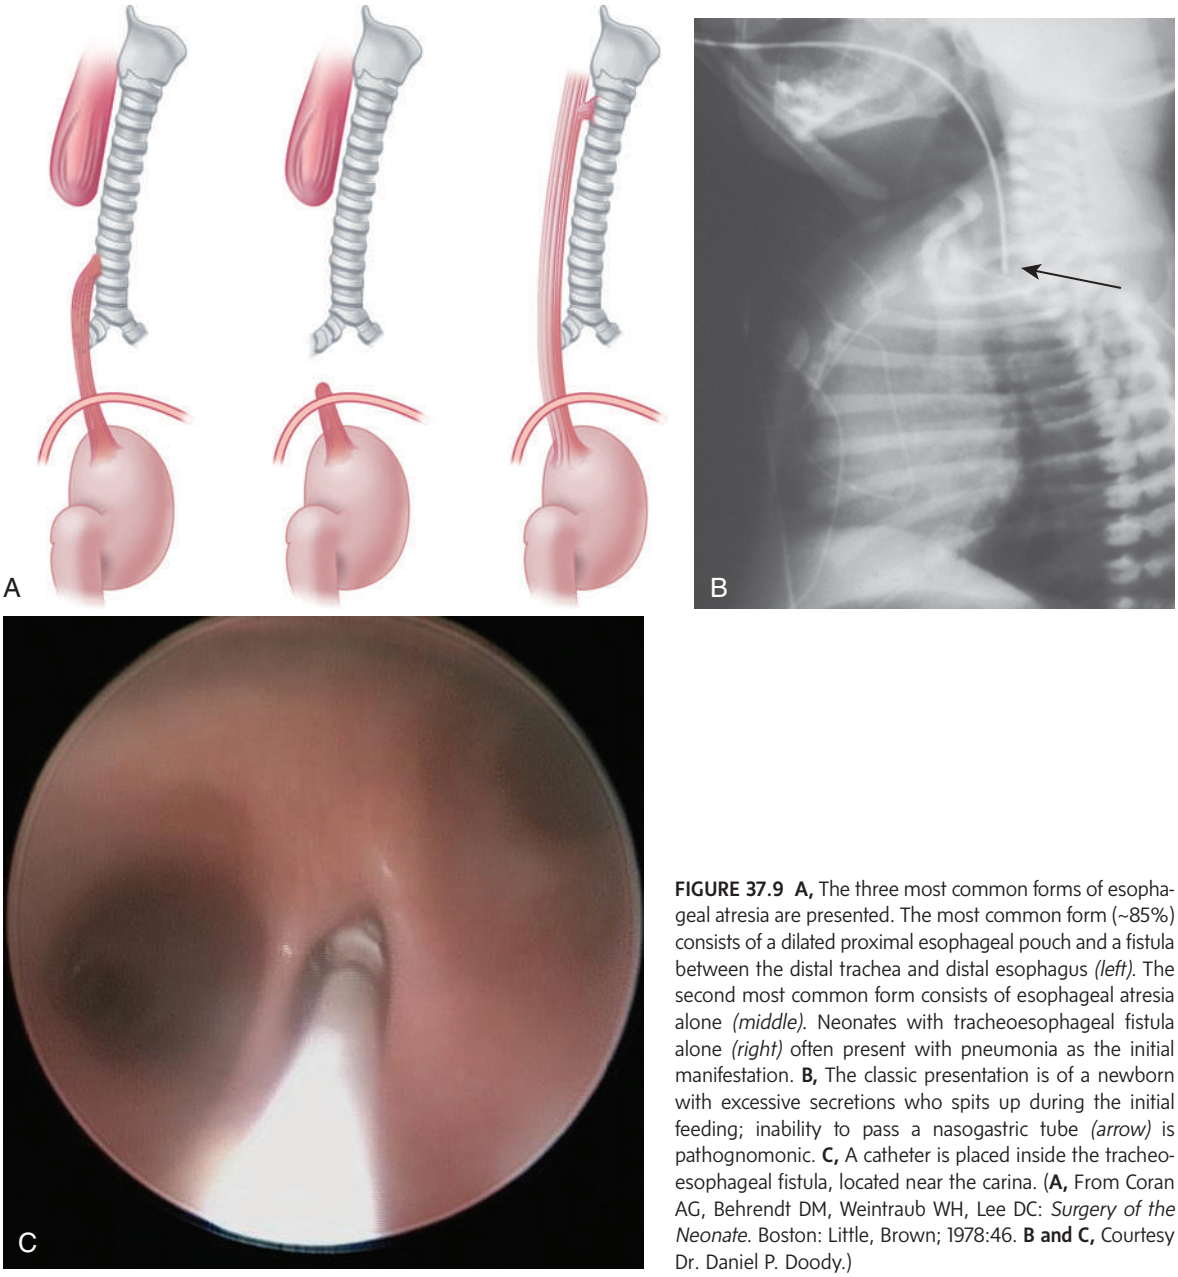

FIGURE 37.9 A, The three most common forms of esophageal atresia are presented. The most common form (~85%) consists of a dilated proximal esophageal pouch and a fistula between the distal trachea and distal esophagus *(left)*. The second most common form consists of esophageal atresia alone *(middle)*. Neonates with tracheoesophageal fistula alone *(right)* often present with pneumonia as the initial manifestation. **B,** The classic presentation is of a newborn with excessive secretions who spits up during the initial feeding; inability to pass a nasogastric tube *(arrow)* is pathognomonic. **C,** A catheter is placed inside the tracheoesophageal fistula, located near the carina. (**A,** From Coran AG, Behrendt DM, Weintraub WH, Lee DC: *Surgery of the Neonate*. Boston: Little, Brown; 1978:46. **B and C,** Courtesy Dr. Daniel P. Doody.)

hypoglycemia, and hyperkalemia. Surgical options include laser therapy or open excision and are generally offered to those in whom medical therapy with persistent airway obstruction fails. Laser therapy achieves focal tissue ablation with the use of either the yttrium-aluminum-garnet (YAG) laser or a diode laser via an endoscopic approach through direct laryngoscopy. This therapy is reserved for smaller, focal lesions. Open excision is performed via an anterior airway incision around the cricoid cartilage, which may require a rib or thyroid cartilage graft to avoid subglottic stenosis. These children will remain intubated for several days after the procedure.[203,205] Subglottic hemangiomas are easily compressed when a tracheal tube is passed to intubate the airway, although bleeding is always a possibility and should be anticipated. However, when the practitioner is unaware of the presence of a hemangioma, the first recognition of the lesion may be the absence of an air leak around an appropriately sized tracheal tube.

Tracheoesophageal Fistula/Esophageal Atresia

Tracheoesophageal fistulas (TEFs) occur in 1/3000 live births in a mostly sporadic, nonsyndromic manner with no preference for sex or race. They are due to an error in separation of the trachea from the floor of the foregut around the fourth to fifth week of gestation. They are often associated with other congenital anomalies, in particular the VACTERL association (**V**ertebral anomalies, imperforate **A**nus, **C**ongenital heart disease, **T**racheoesophageal fistula, **R**enal abnormalities, **L**imb abnormalities).[208,209] There are two main systems of classifications of TEF (Gross and Vogt) that describe the lesions in terms of whether or not esophageal atresia (EA) is present and where the tracheoesophageal connection occurs in relation to the trachea (Fig. 37.9A) (see also Fig. 15.12). The most common type (Gross classification C) consists of a blind proximal esophageal pouch with a distal TEF just above the carina (80%–90% of cases).

TEF can be diagnosed prenatally with signs of polyhydramnios (fetus cannot swallow), small or absent fetal stomach bubble, and/or blind-ending upper pouch in the fetal neck. Early postnatal signs and symptoms include excessive salivation, choking/coughing/regurgitation at the first feed leading to cyanosis and/or respiratory distress, and a distended abdomen owing to the stomach filling with air every time the baby cries, which may compress the lung and embarrass respiration. Diagnosis of TEF/EA can be confirmed by the inability to pass a nasogastric (NG) tube into the stomach, a dilated proximal esophagus with air in conjunction with air in the distal stomach on x-ray, computed tomography scan, or direct visualization via bronchoscopy/esophagoscopy (Fig. 37.9B and C, E-Fig. 37.1 and Video 37.2) (see also Fig. 15.11).

The Waterston and Okamoto classification systems use weight, congenital anomalies, and comorbidities to determine surgical risk and guide planning. This helps determine whether the child should undergo more immediate surgical correction, should undergo more extensive stabilization before correction, or requires a more drawn-out staged repair. Generally, there is enough time to stabilize and optimize the infant before surgery. This involves establishing IV access, correcting anemia and electrolyte imbalances, typing and crossmatching blood, evaluating for other anomalies (especially cardiac echocardiography), and possible placement of a gastrostomy tube, which can be completed using local anesthesia to vent the stomach.

Surgical repair has traditionally been performed with an open thoracotomy and manual lung retraction. However, in the past two decades, thoracoscopic repair has become increasingly popular.[210] Single-lung ventilation is not required, as low-flow, low pressure intrathoracic CO_2 is used instead to collapse the right lung to improve surgical exposure. The patient is placed in the left lateral decubitus position for a right thoracotomy to avoid the aortic arch. The anesthesiologist will place a nasoesophageal tube to aid the surgeon in identifying the proximal esophageal pouch. The fistula is ligated first to avoid further entrapping air into the stomach, followed by a primary end-to-end anastomosis of the esophagus.

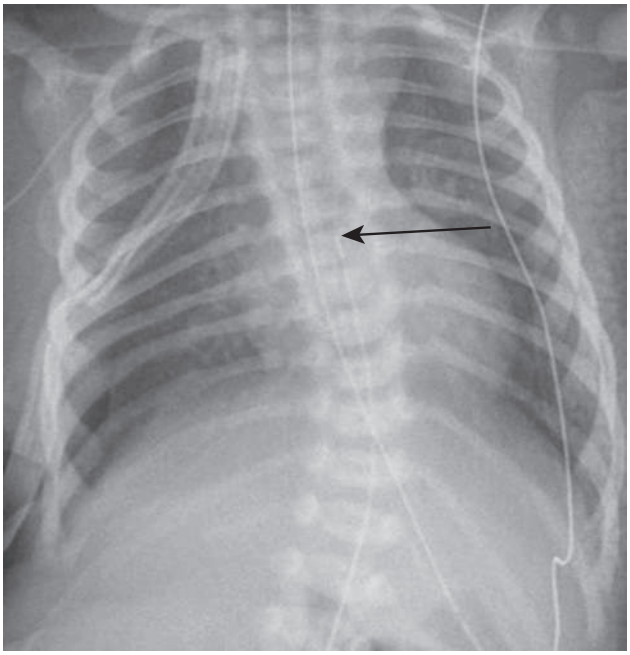
Several approaches may be used to secure the airway in these infants. One option is to keep the infant spontaneously breathing. Avoiding positive-pressure ventilation reduces the amount of gas entering the stomach, which can impede the ability to ventilate. This can be achieved by means of an awake intubation with topicalization and/or sedation, or with an inhalational induction. However, the awake approach can be traumatic and difficult, and a crying infant will only put more air into the stomach. Inhalational inductions in neonates can (but rarely do) cause major cardiovascular instability. An IV induction is quicker (less crying) and may be more stable, allowing for the use of NMBDs to optimize intubating conditions. Positive-pressure ventilation is usually successful because the compliance of the lungs is greater than that of the distended stomach. Gentle mask ventilation with low peak pressure ventilation will decrease the amount of air that enters the stomach. If a gastrostomy has been performed, a Fogarty catheter can be passed retrograde through the gastrostomy to occlude the fistula from below.[211]

Although one-lung ventilation is usually not required, the tip of the ETT must be placed above the carina but distal to the fistula. This can be achieved by purposefully placing the ETT into the right main stem (with the bevel facing anterior to block the aperture of the fistula) and then very slowly withdrawing the ETT while auscultating the left thorax until breath sounds are first heard. A fiberoptic scope can also be used to guide the ETT into position and to confirm correct placement. The ETT must be carefully secured to prevent accidental movement above the fistula. Frequent suctioning of the ETT may be required because of the accumulation of blood and secretions.

After correction of the defect, absorptive atelectasis may require ventilation with long inspiratory times to reexpand alveoli. Early extubation is desirable because it prevents prolonged pressure of the ETT on the suture line. However, many surgeons request that the airway remains intubated postoperatively for several days because the tip of the ETT may perforate the sutured trachea at the level of the fistula during an emergency reintubation or to prevent pneumonia and atelectasis. The ETT provides a means to suction and expand the lungs during the first 24 hours of greatest risk. It is important to maintain the head in a neutral position so as not to pull on the esophageal anastomosis.[212] An epidural catheter threaded from the caudal to the thoracic space may provide a postoperative analgesia and aid in successful extubation (E-Fig. 37.2). An intrapleural catheter is another means of providing analgesia after open surgery, but this may risk local anesthetic toxicity owing to rapid absorption from the pleural cavity.

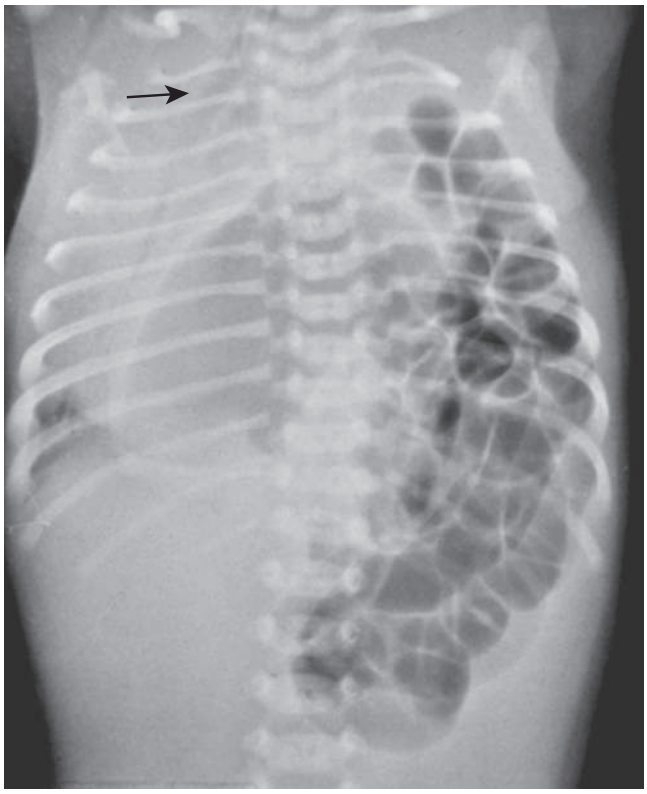
Abnormalities of the Lung

Congenital Diaphragmatic Hernia



CDH has an incidence of 1 to 2/5000 live births. It occurs around the eighth week of gestation owing to the failure of complete closure of the pleural and peritoneal canal, resulting in herniation of the abdominal organs into the thorax, inhibiting normal lung growth. This affects not only the division of the airways, but also the formation of pulmonary vasculature, leading to a decreased number of bronchi and alveoli (diminished surface area for gas exchange), as well as decreased cross-sectional area and numbers of pulmonary artery branches. This, in turn, increases the PVR and primary pulmonary hypertension. The degree of abnormality depends on the timing of the herniation in utero and the amount of abdominal contents in the thorax. The ipsilateral lung is usually the one affected, but the contralateral lung may be involved as well.

The most common type of CDH occurs at the posterolateral foramen of Bochdalek (90%) and is also the largest and is associated with the greatest degree of pulmonary hypoplasia; CDH occurs five times more frequently on the left rather than right side. Neonates with the Bochdalek hernia are more likely to have other birth defects including a 20% to 40% frequency of congenital heart defects and a 5% to 15% frequency of chromosomal abnormalities.[213] A Morgagni type of defect is reported in about 2% of CDHs with the remaining occurring through the esophageal hiatus. CDH is associated with genitourinary and GI malformations, as well as chromosomal anomalies, including trisomy 13, trisomy 18, tetrasomy, and 12p mosaicism.



Prenatal diagnosis can be made via ultrasound findings of polyhydramnios, an intrathoracic gastric bubble (stomach above the diaphragm), and mediastinal shift away from the herniation site (E-Fig. 37.3) (see also Fig. 15.10).[214] Antenatal predictors of poor outcome rely on the observed/expected lung/head ratio and the presence or absence of a thoracic liver in left-sided lesions. Lung/head ratios of <25% are associated with 25% survival, whereas those with ratios greater than 45% are associated with 100% survival.[214,215] An abdominal chest x-ray displaying intestinal loops and/or abdominal organs in the thorax and ipsilateral lung compression aids in postnatal diagnosis. Signs and symptoms are related to the degree of lung hypoplasia and pulmonary hypertension and associated defects that might be present. Owing to the increase in PVR, right-to-left shunting via the patent foramen ovale and DA may occur with hypoxemia. Infants most often

E-FIGURE 37.1 H-type tracheoesophageal fistula is most often diagnosed with a contrast study. Note the contrast material migrating from the esophagus to the tracheobronchial tree. (Courtesy Dr. Daniel P. Doody.)

E-FIGURE 37.2 Some surgeons prefer for the neonate to be extubated after tracheoesophageal fistula repair. A useful means for providing analgesia while minimizing respiratory depression is to thread a caudal catheter to the level of the surgical incision *(arrow)* and administer a continuous infusion of local anesthetic. It should be noted that even with such therapy, some infants may require reintubation to clear secretions.

E-FIGURE 37.3 Chest radiograph of a neonate with a left diaphragmatic hernia. Note shifting of the trachea and bronchi into the right chest *(arrow)*.

present with respiratory distress, and tachycardia, tachypnea, and cyanosis can be observed shortly after delivery. A scaphoid (concave) abdomen and barrel chest may also occur from displacement of the viscera into the thorax. Bowel sounds in the chest are fairly uncommon.

Emergent surgical closure of the defect used to be the standard of care because of the prevalent belief that reduction of the herniated viscera would facilitate lung growth and a return toward normal lung size and function. However, this was untrue. A thorough understanding of the specific pathophysiology of the defect prompted the application of new medical therapies and changed the timing of open surgical repair.[216] Now the focus is to stabilize these neonates medically, optimize the infant's condition before surgery, and adopt measures to improve pulmonary hypertension and reduce PVR. Respiratory support is given, as needed, which may include tracheal intubation with gentle mechanical ventilation to avoid pneumothorax or barotrauma (especially in the normal [contralateral] lung), as in the use of an oscillator or ECMO. ECMO and/or iNO should be used to bridge ventilation and oxygenation during the early postnatal life if the child is persistently hypoxic and/or acidotic despite conventional ventilation strategies. Care is provided to avoid introducing air into the GI tract via the use of an NG tube and to avoid CPAP and prolonged mask ventilation, which will only further impinge on the lungs. These infants may also need pharmacologic cardiovascular support. Timing of the procedure is uniquely variable but should be based on the individual condition of the infant and institutional experience.[217–220]

Open surgical correction is achieved with a transabdominal approach, and primary closure is usually possible. If the defect is too large, artificial tissue may be used for closure. In most instances, the abdomen is too small to accommodate the bowels when they are returned to the abdominal cavity. The net effect is a dramatic decrease in pulmonary compliance (in the good lung), desaturation, and hypercapnia. Alternately, the viscera are placed in a Silo pouch (Bentec Medical, Woodland, CA) outside the body until growth allows their return to the abdominal cavity. A chest tube may be placed on the contralateral side before surgery in the event of a pneumothorax. In the past two decades, thoracoscopic repair has been used with excellent success in infants who are medically stable.[216,217]

This approach can be performed without single-lung ventilation by use of low-flow, low-pressure CO_2 insufflation, which collapses the lung and gently allows the return of the herniated viscera back into the abdomen. The infant is positioned in the lateral decubitus, with the upper arm supported without interfering with surgical instruments. Both of these techniques can also be performed if the child requires ECMO, but in the latter case these surgeries are usually undertaken in the NICU.[216,217] The surgical timing for neonates who require ECMO remains contentious. Some believe that surgery should be either performed early, before ECMO, whereas others believe that later surgery is preferred. These arguments arise because bleeding during surgery in anticoagulated infants during ECMO can be excessive. In addition, some centers offer advanced treatment options such as fetal-based corrective surgical procedures.[218,221] Temporary fetoscopic tracheal plugging, performed between 25 and 28 weeks gestation, prevents the normal outflow of surfactant-rich fetal lung fluid.[222] The retained volume subsequently enlarges the fetal lungs, accelerates growth, and reduces the mass effect of herniated viscera.

Anesthetic management is aimed at avoiding the harmful effects of volutrauma (by maintaining frequent small TVs and limited peak inspiratory pressures) and those conditions known to increase PVR (hypoxemia, acidosis, hypothermia, hypercarbia). An NG tube should be passed before induction of anesthesia to empty the stomach while the airway is ventilated at low peak inspiratory pressures by face mask before the ETT is placed. N_2O should be avoided because it will expand air-filled cavities (bowel) and limit the inspired oxygen concentration. Postoperatively, the trachea remains intubated. The use of an epidural catheter or intercostal nerve block (thoracoscopic approach) aids in postoperative comfort.

Congenital Lung Malformations

CONGENITAL BRONCHOGENIC AND PULMONARY CYSTS. Congenital bronchogenic and pulmonary cysts result from the abnormal development of the ventral foregut and lung budding during the first trimester.[223] These cysts may be centrally located within the mediastinum and produce obstruction by a mass effect.[224] They may also be located at the carina and cause obstruction or distal gas trapping by a ball-valve effect. Those located in the hilum, in the paratracheal region, or in the lung parenchyma may lead to chronic respiratory illness from infection and abscess formation.[225,226] Congenital cysts are occasionally diagnosed only after rupture of the cyst produces hemorrhage or bronchopulmonary fistula formation.[223,226] Urgent surgical resection via thoracotomy or thoracoscopically is recommended for symptomatic cysts, and at 3 to 6 months of age for asymptomatic cysts to promote lung growth.[227–229]

The anesthetic should be designed to prevent further enlargement of the cyst because a communication may exist with the airway. Awake (sedated) intubation or intubation after an inhalation induction, followed by maintenance of spontaneous ventilation, if possible, until the thorax is opened may reduce the potential risk of a sudden expansion of the cyst. If assisted ventilation is required, low peak inspiratory pressures should be used. Should the cyst be fluid filled or infected, selective bronchial blocking may be helpful to protect the unaffected lung (see Chapter 15).[230,231] N_2O and positive-pressure ventilation without adequate expiratory time should be avoided to decrease the possibility of enlarging the cyst. If these attempts are unsuccessful and the cyst enlarges to the point of occluding the airway or compromising the circulation, needle aspiration may be required to reduce the size of the cyst and facilitate oxygenation and ventilation. If this approach is unsuccessful, emergency thoracostomy may be lifesaving.

CONGENITAL LOBAR EMPHYSEMA. Congenital lobar emphysema, also known as congenital lobar overinflation or infantile lobar emphysema, is the hyperinflation of one or more pulmonary lobes (Fig. 37.10) (see also Fig. 15.9). The incidence is approximately 1/20,000 with a 3 : 1 preference for males. The left upper lobe is most frequently involved (43%), followed by the right middle lobe (32%), and right upper lobe (20%), with bilateral involvement in 20%. In 12% to 14% of cases there is associated congenital heart disease or vascular anomaly.[232] The exact etiology is unknown; however, it is thought to result from a disruption in the development of the bronchial cartilage that causes bronchial collapse.[233,234] This lack of cartilaginous support leads to a ball-valve effect with consequent overinflation. The hyperinflated lung causes an increase in intrathoracic pressure and compression atelectasis on the ipsilateral or contralateral lung, resulting in mediastinal shift and ventilation-perfusion mismatch.[232]

Surgical lobectomy of the affected segments via an open thoracotomy or thoracoscopically is the definitive treatment. Avoiding N_2O and positive-pressure ventilation prevents the expansion of the emphysematous lobe, which could compress

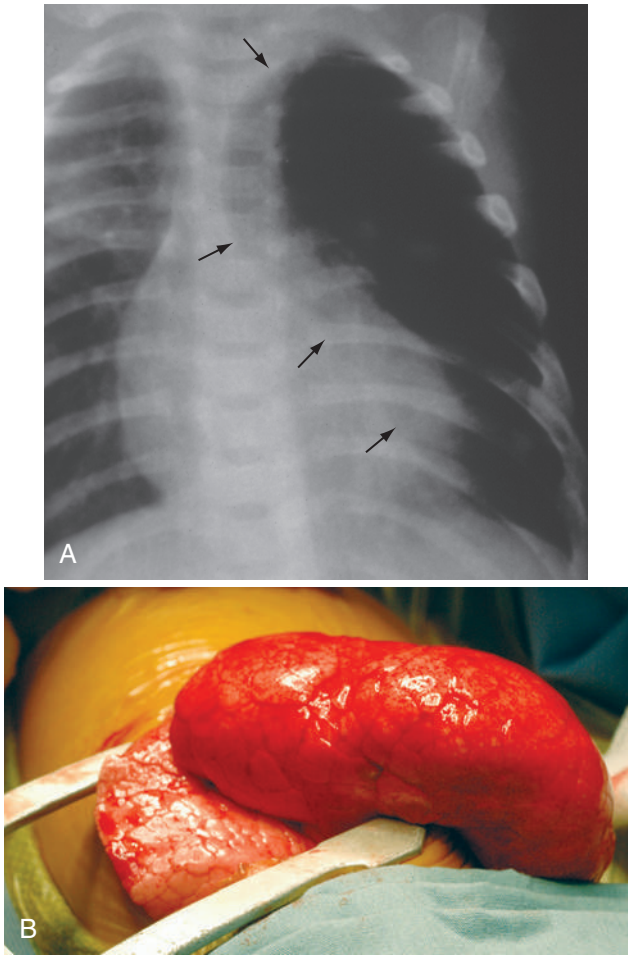


FIGURE 37.10 A, Radiograph from an infant with congenital lobar emphysema demonstrates hyperinflation of the left lung with herniation across the midline *(arrows)* and mediastinal shift. **B,** Intraoperative photograph shows the emphysematous lobe bulging through the thoracotomy incision. (From Coté CJ. The anesthetic management of congenital lobar emphysema. *Anesthesiology*. 1978;49(4):296–298.)

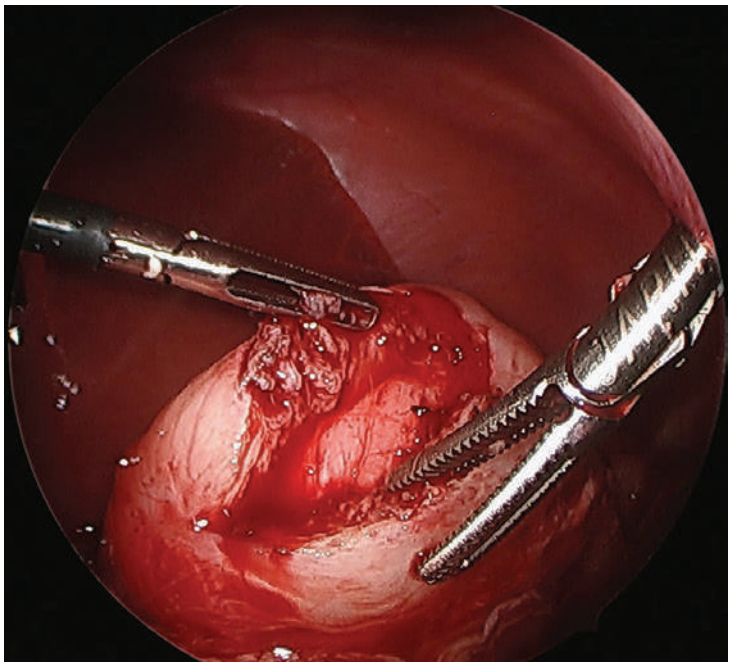
normal lung tissue.[235,236] If positive-pressure is required, low peak pressures and TVs should be used. There have been reports of using single-lung ventilation while the affected lobe is resected. Frequent ETT suctioning is suggested; an epidural catheter threaded from the caudal to the thoracic space may provide pain control.[232,234]

GASTROINTESTINAL PATHOLOGY

Emergency surgical conditions of the GI tract are most frequently due to obstructive lesions, lesions that compromise intestinal blood supply, or both.

Infants with obstructive lesions should be considered to have a full stomach, as the retention of gastric fluid increases the risk of aspiration during induction. A rapid-sequence induction (RSI) should follow suctioning of gastric contents (usually with a vented catheter in supine, right and left positions), and N_2O should be avoided to minimize intestinal distention. Desaturation after a brief period of apnea during an RSI occurs more rapidly in neonates than in older infants,[237] emphasizing the importance of preoxygenation and the rapid establishment of an airway. Some providers advocate the use of a modified RSI technique, with gentle mask ventilation before tracheal intubation.[238] Unless life-threatening compromise of organ blood flow occurs, these lesions do not require immediate surgical correction, and the priority is to correct any metabolic derangements and establish euvolemia before undergoing corrective surgery.



Infants with lesions that compromise intestinal blood supply and cause ischemia are extremely ill. They may present with hypotension, metabolic abnormalities, particularly hyperkalemia, anemia, and thrombocytopenia. Emergency surgery is required in these circumstances and is directed at removing the necrotic tissue, closing perforations, and reestablishing normal perfusion to the intestine. Blood products and emergency drugs should be readily available. Good IV access is required, and a centrally located catheter may be necessary for the administration of vasoactive drugs, as well as an arterial line for close blood pressure monitoring. Infants with compromised intestinal blood supply are usually considered to have full stomachs and N_2O is avoided, as well.

Obstructed Lesions

Hypertrophic Pyloric Stenosis

Hypertrophic pyloric stenosis is the result of hypertrophy and hyperplasia of the muscularis layer of the pylorus, causing a functional gastric outlet obstruction (Fig. 37.11). It occurs in 1/500 live births and more frequently in first-born males.[239,240] Infants usually present between 2 and 8 weeks of age with protracted nonbilious projectile vomiting, creating a hypokalemic, hypochloremic metabolic alkalosis; severe cases may progress to a metabolic acidosis. The kidneys attempt to maintain a normal blood pH by excreting bicarbonate. To maintain euvolemia and retain sodium cations, the kidneys excrete hydrogen and then potassium cations to maintain charge neutrality. Paradoxical aciduria occurs in the hypovolemic infants (after prolonged vomiting) when the urine appears acidic while the pH in the blood is alkaline. Since this is not a life-threatening emergency, time should be taken to correct the metabolic derangements and ensure proper rehydration; this may take 24 to 48 hours. Before considering an anesthetic in these infants, the skin turgor and the urine output (1–2 mL/kg per hour) should be restored, a serum sodium greater than 130 mEq/L, potassium greater than 3.0 mEq/L, and a chloride concentration greater than 85 mEq/L. Diagnosis is commonly made via ultrasonography or rarely with a barium swallow and radiographic examination.[241,242] Most infants are quickly diagnosed with pyloric stenosis today, rendering a minority who present with severe fluid and electrolyte imbalances compared with the past.[243] Treatment is surgical pyloromyotomy by means of an open periumbilical incision or laparoscopic approach (E-Fig. 37.4 and Video 37.3).[244] The laparoscopic approach speeds time to return to oral feeds, reduces hospital stay, and provides better cosmesis.[245–247] Some assert that the laparoscopic approach may have a greater rate of perforation and incomplete relief of gastric obstruction, although this is not evidence-based.[248,249] A meta-analysis has reported no difference in the rate of incomplete incision, mucosal perforation, and reoperation between open and laparoscopic groups.[250]

Most advocate a modified RSI for induction of anesthesia and tracheal intubation in these infants because of their gastric outlet obstruction, although some have performed inhalational inductions successfully.[251] The duration of surgery whether open or laparoscopic is brief (30 minutes), necessitating the use of a quick-acting inhalational anesthetic (e.g., desflurane) and propofol or a muscle relaxant; the latter is not a requirement in most cases. With postoperative pain of minimal intensity, opioids are generally not

required for this surgery. Pain is managed by the infiltration of local anesthetic into the trochar sites and a nonopioid agent such as acetaminophen or a nonsteroidal antiinflammatory agent. Specific perioperative anesthetic management is as detailed earlier for obstructed lesions.[245,246]

Duodenal Atresia and Meconium Ileus

The exact etiology of duodenal atresia is unknown; however, with its close association with multiple other congenital anomalies (50%–70%), it is believed to occur early in gestation. It is one of the more common causes of intestinal abnormalities, occurring in 1/6000 live births. Approximately 20% to 30% of these neonates also have trisomy 21, and up to 25% of these infants will have a cardiac anomaly. Diagnosis can be made prenatally with ultrasound or postnatally with an abdominal radiograph demonstrating the "double bubble" sign, formed by fluid/air seen in the dilated stomach and proximal duodenum, with the remaining bowel devoid of fluid/air (Fig. 37.12).[252] Neonates born with duodenal atresia usually present with bilious vomiting beginning within the first 24 to 48 hours after birth, leading to dehydration and electrolyte imbalances. After medical stabilization, open or laparoscopic surgical correction is required. A peripherally inserted central catheter (PICC) may be placed in the event of continued obstruction and the need for long-term total parenteral nutrition (TPN).

Meconium ileus is an intestinal obstruction of the newborn caused by inspissated meconium in the terminal ileum. Most cases are associated with cystic fibrosis (10%–15% of neonates with cystic fibrosis will have meconium ileus).[253] Other cases have been reported in premature infants, especially whose with very low birth weight and extremely low birth weight, and is thought to be due to immature intestinal function and dysmotility.[254] Failure to pass meconium within the first 24 hours of birth, abdominal distention, and bilious vomiting support this diagnosis. Abdominal radiographs reveal low small bowel obstruction with numerous air-filled loops of bowel and a soap-bubble effect of gas mixed with meconium in the right lower abdomen. Microcolon is often seen with a barium enema. Conservative management is

the initial treatment of choice, consisting of rectal stimulation with *N*-acetylcysteine (NAC) or glycerin, contrast or Gastrografin enemas, or the administration of Gastrografin or NAC via an NG tube.[252,254] Hyperosmolar enemas may result in substantial shifts in intravascular volume, leading to hypovolemia and electrolyte imbalances. If conservative management fails and persistent ileus ensues, the neonate may require surgical evacuation.

Imperforate Anus

The etiology of imperforate anus remains unclear but is thought to occur between 5 and 7 weeks of gestation. The incidence is 1/5000 births and is more prevalent in males. It is a part of the VACTERL association. The diagnosis of imperforate anus is usually made by initial physical examination or by failure to pass meconium within the first 48 hours of life. Milder cases can be treated with a perineal anoplasty, but more complicated cases may require a temporizing colostomy followed by a more definitive repair, such as a colonic pull-through or a posterior sagittal anorectoplasty.

Compromised Intestinal Blood Supply

Inguinal Hernia

Failure of the process vaginalis to close during the last few weeks of gestation can result in the protrusion of abdominal cavity and gonadal structures through the inguinal canal. Most inguinal hernias manifest within the first 6 months of life, affecting 1% to 5% of full-term infants and children, and up to 30% of premature infants. The prevalence is greater in males. In 60% of infants, the hernia occurs on the right, in 30% it occurs on the left, and in 10% there is bilateral involvement. Clinical manifestations include the visualization and/or palpation of a bulge in the inguinal or scrotal region that is more prominent when crying or straining and generally reduces while at rest.

Hernias that do not spontaneously resolve need to be surgically corrected because of the risk of incarceration; however, surgery can be performed on a semi-elective basis as an outpatient. When the contents of the hernia become incarcerated or strangulated, they are at risk for ischemia and necrosis, and emergency surgical correction is indicated. Elective repair can be performed with the infant under either general or regional anesthesia (caudal or spinal block). Premature infants less than 60 weeks PCA should be observed for 24 hours for signs of apnea before discharge. Anesthetic management for incarcerated or strangulated hernias should proceed as mentioned earlier for ischemic lesions.

Necrotizing Enterocolitis

NEC is a multifactorial disease that can lead to bowel necrosis and is a leading cause of neonatal mortality. It affects 5% to 11% of premature and low-birth-weight infants and has a mortality rate of 10% to 50%.[255–257] The pathogenesis is not completely understood, but is thought to be due to unbalanced inflammatory responses of bowel mucosa, alterations in normal intestinal flora by antibiotics and feeds, and lack of a fully developed intestinal mucosal barrier, which leads to the breakdown of the intestinal wall and bowel necrosis.[255,256,258] In addition to prematurity, NEC has also been associated with low systemic cardiac output, hypoxia, PDA, infection, red blood cell transfusion, and enteral feedings (especially formula-fed neonates).[259,260] In fact, human breast milk is now touted as the preferred strategy to prevent NEC in preterm infants.[261]

NEC can be insidious in onset or rapidly progress to multisystem organ failure or death. Early signs tend to be nonspecific and include temperature instability, poor feeding with residual volumes or vomiting, lethargy, apnea, bradycardia, mild abdominal distention, and bloody stools, although recent evidence points to specific biomarkers to facilitate early diagnosis (fecal calprotectin and S100A12, serum fatty acid–binding protein, and urine biomarkers).[262] Tachycardia, poor perfusion/hypotension, metabolic acidosis, thrombocytopenia, abdominal tenderness, and peritonitis are findings in later, more severe cases.[255,259] An abdominal x-ray may initially suggest an ileus with thickened bowel walls and dilated bowel loops and later demonstrate gas in the intestinal wall (pneumatosis intestinalis) and in the hepatobiliary tract or portal venous system (Fig. 37.13). The finding of free air in the abdominal cavity (pneumoperitoneum) warrants prompt surgical intervention (Fig. 37.14).

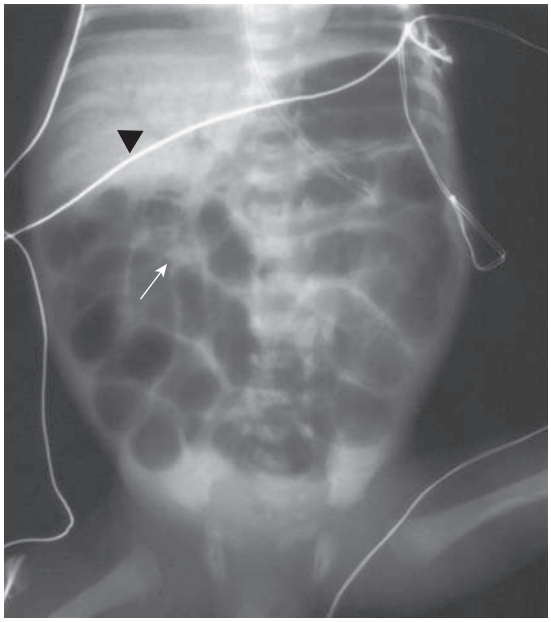

FIGURE 37.13 Abdominal radiograph of a neonate with necrotizing enterocolitis demonstrates generalized bowel distention (ileus), a small amount of pneumatosis intestinalis in the left upper quadrant *(arrow)*, and gas outlining the intrahepatic portal vein *(arrowhead)*. (Courtesy Dr. Sjirk J. Westra.)

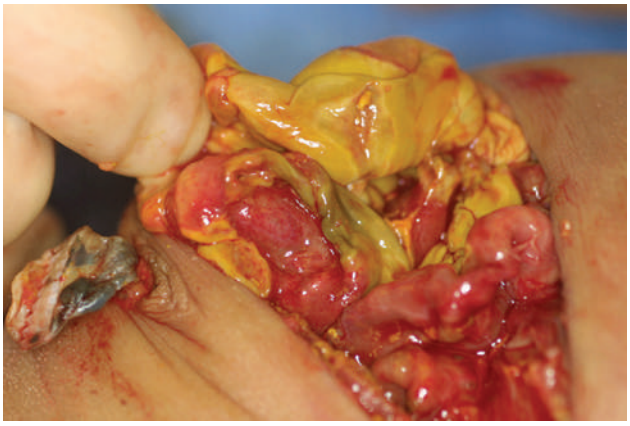

FIGURE 37.14 Early necrotizing enterocolitis with bowel perforation. Note that the perforation was diagnosed early and that there is soiling of the peritoneum but there does not appear to be any dead bowel. This type of perforation is generally associated with a positive outcome.

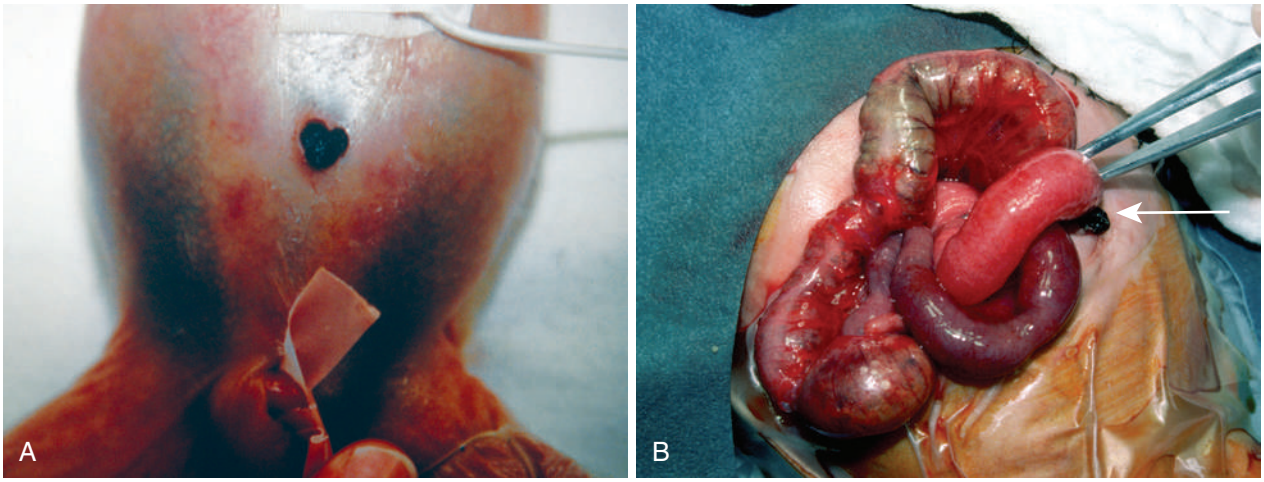

FIGURE 37.15 A preterm neonate with severe necrotizing enterocolitis and intestinal necrosis. **A,** Abdominal discoloration consistent with dead bowel. **B,** Necrotizing enterocolitis with a segment of dead bowel *(top)* and evidence of free stool in the abdomen *(arrow)*. These infants often have bowel perforation and hemorrhage from the bowel or liver. They can have severe hypotension requiring vasopressor support and enormous volume requirements. Moreover, because of hemorrhage and disseminated intravascular coagulopathy, these infants will generally require transfusions of blood, platelets, and fresh frozen plasma. Some practitioners also advocate administration of vitamin K. (Courtesy Dr. Daniel P. Doody.)

TABLE 37.6 Comparison of Omphalocele and Gastroschisis

Comparison Factors	Omphalocele	Gastroschisis
Cause	Failure of gut migration from yolk sac into abdomen	Occlusion of omphalomesenteric artery
Location	Within umbilical cord	Periumbilical
Associated lesions	Beckwith-Wiedemann syndrome (macroglossia, gigantism, hypoglycemia, hyperviscosity) Congenital heart disease Exstrophy of bladder	Exposed gut inflammation, edema, dilation, and foreshortened

Initial therapy is conservative and includes making the neonate *nil per os* (NPO), initiating broad-spectrum antibiotics, and decompression of the bowel with low continuous gastric suction. Supportive measures to correct metabolic and hematologic abnormalities, as well as fluid resuscitation, are also involved. If conservative management fails or signs of necrosis or viscus perforation appear, an exploratory laparotomy is indicated for resection of necrotic bowel (Fig. 37.15). These infants are critically ill. Preoperative preparation in a timely fashion is vital. NEC predisposes to hypovolemia, cardiovascular and respiratory failure, capillary leak syndrome, disseminated intravascular coagulation, and hypoglycemia. These infants may be septic and volume depleted with very large fluid requirements as the result of massive third-space losses. Often there is an enormous need for 5% albumin just to maintain intravascular volume (up to 1 blood volume of more) because of third spacing. There is nearly always a need for transfusion of platelets and fresh frozen plasma. Hyperkalemia with renal failure is common, and central venous access is usually required for inotropic support (dopamine or epinephrine or both).

Omphalocele and Gastroschisis

Defects in the abdominal wall can lead to herniated organs with impaired blood supply, intestinal obstruction, and major intravascular fluid defects in neonates with omphalocele and gastroschisis. The differences between omphalocele and gastroschisis are summarized in Table 37.6.

Omphalocele represents a failure of the gut to migrate from the yolk sac into the abdomen during gestation (Fig. 37.16A).[263,264] It occurs in 1/5000 births.[265] Infants with omphalocele may have associated genetic, cardiac, urologic (exstrophy of the bladder; Fig. 37.16B), and metabolic abnormalities (eg., Beckwith-Wiedemann syndrome with visceromegaly, macroglossia, hypoglycemia, and polycythemia).[266] The herniated viscera emerge from the umbilicus and are covered with a membranous sac. The bowel is morphologically and usually functionally normal.

Gastroschisis develops as a result of occlusion of the omphalomesenteric artery during gestation.[264,267] It occurs in 1/2000 births and is usually not associated with other congenital anomalies.[265] The herniated viscera and intestines are periumbilical, usually on the right, and are exposed to amniotic fluid in utero and to air after delivery, resulting in inflammation, edema, and dilated, foreshortened, functionally abnormal bowel (Fig. 37.16C).[268,269]

Management of these neonates until surgical repair is directed at maintaining perfusion to the herniated viscera and reduction of fluid loss from exposed visceral surfaces by covering the mucosal surfaces with sterile, saline-soaked dressings. A plastic wrap aids in decreasing evaporative volume losses and the tendency to develop hypothermia, which is more pronounced with gastroschisis. These defects represent a wide spectrum of pathology and require individualized assessment of associated anomalies, intravascular volume status, and fluid replacement.[270] If complete reduction is not possible, a staged reduction is carried out.[271,272] The abdominal

FIGURE 37.16 **A,** Omphalocele covered with a membranous sac; the defect arises at the umbilicus. **B,** Omphalocele with associated exstrophy of the bladder. **C,** Gastroschisis; note the absence of a membranous sac. In contrast to omphalocele, the gastroschisis anomaly is periumbilical.

contents are covered with a Silastic pouch, and the size of the pouch is subsequently reduced in stages, thus allowing the abdominal cavity gradually to accommodate the increased mass without severely compromising ventilation or organ perfusion.[273,274] Tissue expanders and skin grafting may also be necessary for closure.

Anesthetic management is directed at continued volume resuscitation and measures to prevent hypothermia. Primary abdominal closure may be associated with markedly increased intraabdominal pressure (E-Fig. 37.5). Intraabdominal pressure may be monitored by transducing either a CVP catheter or less invasively, an intragastric tube. A gastric pressure that exceeds 20 mm Hg after primary closure is likely to cause abdominal ischemia and necessitate an urgent reoperation.[275] Increased intraabdominal pressure can decrease organ perfusion and ventilatory reserve, including perfusion of the intestines, kidney, and liver as well as secondarily impaired organ function. This may lead to markedly altered drug metabolism and prolonged drug effects.[122] The bowel may become edematous, and urine output may be reduced as a result of renal congestion. Venous return from the lower body also may be reduced, resulting in lower extremity congestion and cyanosis. Blood pressure and pulse oximetry determinations from a lower extremity may be different from those in the upper extremity. Significantly decreased diaphragmatic function and bilateral lower lobe atelectasis may occur, leading to respiratory failure.[276]

Malrotation and Midgut Volvulus

Malrotation and midgut volvulus result from abnormal migration or incomplete rotation of the intestines from the yolk sac back into the abdomen.[277] It occurs in 1/500 births and 30% to 60% of affected patients have associated congenital anomalies. Rotation of the intestine around the mesentery may produce the abnormal location of the ileocecal valve in the right upper quadrant and kinking or compression of its vascular supply. If the malrotation occurs during development, atretic segments of bowel are formed. If the kinking or compression occurs after the bowel is normally developed, bowel necrosis may result.

These infants present with bilious emesis, a tender and distended abdomen, and increasing abdominal girth. Bloody stools are an ominous sign. They may have hypotension, hypovolemia, and electrolyte abnormalities. Because delay in surgery may result in necrosis of the entire small intestine, fluid and electrolyte resuscitation with stabilization should not delay surgical correction. This is a true neonatal emergency, and surgery should proceed as expeditiously as possible with ongoing perioperative resuscitation.

E-FIGURE 37.5 Closure of a large omphalocele or gastroschisis may result in a very tight abdominal closure that will require the infant to remain intubated after repair with relatively high peak end-expiratory pressure; such patients may have reduced drug clearance as a result of impaired hepatic and renal blood flow or compromise and may experience impaired venous return to the heart.

FIGURE 37.17 Toxic megacolon results in massive abdominal distention, fluid requirements, and sepsis. These infants require special consideration in airway management because of the high risk for aspiration and increased abdominal pressure.

Hirschsprung Disease

Hirschsprung disease is the absence of parasympathetic ganglion cells (Auerbach and Meissner plexuses) in the large intestine.[278,279] This deficiency creates a nonperistaltic segment of variable length, a tonically contracted anorectal sphincter, and delayed passage of meconium. Functional obstruction occurs at the level of the affected segment. Its incidence is 1/6000 with a male predominance and is relatively rare in premature infants. Approximately 60% of patients will have an associated anomaly.

Infants with Hirschsprung disease present with symptoms consistent with bowel obstruction, such as bilious vomiting and abdominal distention. However, the bowel may occasionally become distended to the point that its blood supply is compromised, leading to perforation. If left untreated, enteric bacteria may invade the bowel wall and enter the bloodstream, leading to toxic megacolon (Fig. 37.17). These infants are critically ill and may require massive volume replacement and vasopressor support. Surgical repair depends on the extent of intestinal involvement and includes anorectal myomectomy, mucosal resections, diverting colostomies, and transanal pull-throughs.

LIGATION OF PATENT DUCTUS ARTERIOSUS

Controversy exists regarding whether a PDA should be treated at all, the timing of therapy if treated, and merits of medical versus surgical therapy.[280–282] This controversy is the result of several trials that have failed to show early PDA closure leads to significant benefit in premature neonatal outcomes.[282] It is possible that although a PDA is associated with morbidity in the neonate, it is not a causative factor. Medical therapy involves the administration of a cyclooxygenase inhibitor, such as indomethacin or ibuprofen. Indomethacin therapy is less likely to close the PDA in micropremies compared with premature infants, and is more likely to produce complications, including thrombocytopenia, renal failure, hyponatremia, and intestinal perforation.[283] Ibuprofen is equally effective for PDA closure in the micropremie, with a reduced frequency of renal failure.[284] Both the probability of PDA closure and the probability of adverse effects relate to plasma nonsteroidal antiinflammatory drug concentration. The concentration achieved after a standard dose changes with PMA because clearance increases with PMA; failure to account for a changing clearance with age contributes to confusion in the literature.[285,286] More recently, paracetamol (acetaminophen) has been used with equal effectiveness in those infants in whom cyclooxygenase inhibitor therapy has failed or in whom those drugs are contraindicated, although further efficacy evidence is required.[282,285] Surgical ligation of the PDA has a low incidence of major intraoperative complications when performed by an experienced team.[287] However, as many as one-third of premature infants develop severe cardiovascular instability following PDA ligation, termed postligation cardiac syndrome (PLCS). PLCS is due to an abrupt increase in left ventricular afterload with decreased preload, leading to low cardiac output, hypotension, and myocardial dysfunction.[281,282,288] In addition, some studies show an increased risk of chronic lung disease, ROP, and neurosensory impairment after surgical ligation.[281,289]

Surgical ligation of the PDA can be performed in the OR or in the NICU (usually reserved for micropremies and ELBW neonates). It is achieved via left thoracotomy with manual retraction of the lung. The aorta and pulmonary artery lie in proximity to the PDA; thus severe bleeding may occur abruptly and unexpectedly during the procedure. Blood should be immediately available for transfusion. In addition, it can be difficult to distinguish the PDA from the aorta, as the diameter of the PDA may be the same or even greater than that of the aorta. Monitoring blood pressure and pulse oximetry on the right arm (preductal) and oximetry on the foot (postductal) will assist the surgeon to identify the correct vessel to be ligated. The surgeon will place a temporary clamp on what is believed to be the PDA. A loss in postductal oximetry indicates clamping of the aorta, whereas a decrease in both oximeters and $ETCO_2$ suggests clamping of the pulmonary artery. A successful PDA ligation results in a "step up" in mean arterial pressure owing to an increase in diastolic blood pressure with no decrease in either of the pulse oximeters

Transcatheter occlusion of the PDA can be accomplished using either coils or an occluder device in the catheterization laboratory as an alternative to surgical ligation with similar efficacy (see Chapter 22). Like the surgical option, device occlusion is performed only after failed conservative and medical attempts. In the past, the small vessel size of the extremely premature infant prevented the use of a large enough sheath to implant the device. However, advances over the past 5 to 10 years produced devices capable of transcatheter occlusion in infants weighing less than 1 kg. In some instances, they are even being deployed at the bedside using only echocardiographic guidance. In addition to avoiding the complications of a surgical repair, the transcatheter approach has shown a more rapid recovery of respiratory function. The most common complications include femoral artery thrombosis, left pulmonary artery stenosis, and aortic coarctation.[53,290–293]

RETINOPATHY OF PREMATURITY

ROP can lead to blindness if left uncorrected. The exact cause of ROP is unknown; however, it is associated with prematurity, low birth weight, supplemental oxygen therapy, postnatal hypotension, use of surfactant or inotrope, and need for mechanical ventilation.[294,295] It is thought to be initiated by oxygen-induced retinal vasoconstriction and endothelial cell death, followed by unchecked neovascularization from angiogenic factors, such as VEGF, that do not respond to normal regulation because of immaturity.[296,297] Its incidence increases with decreasing gestational age. ROP may be treated with cryotherapy, laser photocoagulation, scleral buckling surgery, and/or vitrectomy.

Cryotherapy involves applying a freezing probe under direct visualization to the avascular retina anterior to the fibrovascular ridge. It requires general anesthesia and is usually performed in the OR. Diode laser photocoagulation is typically performed at the bedside in the NICU. It has been shown to be as effective as cryotherapy for moderate ROP, and is most commonly used because the systemic side effects are significantly less, the ocular tissues are less traumatized, and it has a smaller incidence of late complications than cryotherapy. Laser photocoagulation may be performed using topical anesthesia alone, with IV sedation, or with the patient under general anesthesia. However, the incidence of cardiorespiratory complications is greater with topical anesthesia alone than with topical anesthesia with sedation or general anesthesia.[294] The procedure takes 10 to 30 minutes to perform and often involves a series of treatments every few weeks. Anesthetic goals are to provide optic analgesia and to prevent eye and head movement. Many premature infants younger than 32 weeks PCA are naturally inactive and may remain motionless with topical anesthesia alone.

Scleral buckle surgery and vitrectomy, performed for more severe ROP with retinal detachment, are less frequently used because early detection and treatment with laser photocoagulation prevents ROP progression to severe disease. It is usually performed in older infants between 6 months and 1 year of age and requires general anesthesia in the OR.

The latest form of therapy includes intravitreal injection of bevacizumab, a recombinant humanized monoclonal antibody aimed at reducing VEGF. Results are encouraging; however, more data are needed to establish safety and efficacy.[296,298,299] As discussed previously, the optimal oxygen saturation target is controversial. Hyperoxia should be avoided if at all possible, with a suggested target range of 91% to 95%. It should be noted, however, that ROP has been reported in infants with cyanotic heart disease and infants never exposed to oxygen; thus hyperoxia is but one factor associated with ROP (see also Chapter 34).[298,300]

ANNOTATED REFERENCES

Kamata M, Cartabuke RS, Tobias JD. Perioperative care of infants with pyloric stenosis. *Paediatr Anaesth*. 2015;25(12):1193-1206.

This article reviewed the current techniques in use for the perioperative management of infants with pyloric stenosis. They conclude that the optimal approach to airway management is not known, and several different techniques may be used, such as rapid-sequence induction or modified rapid sequence with gentle mask ventilation.

Sola A, Golombek SG, Montes Bueno MT, et al. Safe oxygen saturation targeting and monitoring in preterm infants: can we avoid hypoxia and hyperoxia? *Acta Paediatr*. 2014;103(10):1009-1018.

This study sought to define a more targeted range of oxygen saturations in premature infants to reduce morbidity and mortality. They concluded that there was an increase in mortality with reduced oxygen saturations, yet a greater morbidity with hyperoxia in the higher ranges, leading them to recommend a broader range of intermediate targets.

Stoll BJ, Hansen NI, Bell E, et al. Trends in care practices, morbidity, and mortality of extremely preterm neonates, 1993–2012. *JAMA*. 2015;314(10):1039-1051.

This prospective study of more than 34,000 premature infants born at the Neonatal Research Network centers looked at maternal and neonatal care, morbidities, and survival. They concluded that over the past 20 years there have been several advances in maternal and neonatal care that have contributed to improved outcomes.

Future Considerations

THE ADVENT OF FETAL intervention introduced the concept of surgically correcting or ameliorating known congenital defects in utero. With improvements in prenatal imaging and surgical techniques, fetal interventions have grown to include diagnoses associated with intrauterine demise and significant postnatal morbidity. The goal of fetal intervention is to improve the probability that the fetus will develop normally with minimal postnatal morbidity.[1] Increasingly, advances have changed some procedures from open in utero interventions, which are associated with significant maternal risk, to percutaneous or fetoscopic techniques, thus improving the maternal risk/benefit ratio while diminishing postoperative uterine contractions associated with open procedures.

Fetal surgery often requires the anesthesiologist to care for two or more patients at once, all with distinctive and, at times, conflicting requirements. The first is the mother who can express her level of discomfort, who can be monitored directly, and to whom drugs can be administered easily. The second (and possibly third) is the fetus. For the latter, detecting pain depends solely on indirect evidence, monitoring is limited at best, administering drugs is more complicated, and there is the possibility of long-term effects from procedures and drugs administered during early development. The anesthesiologist is required to provide both maternal and fetal anesthesia and analgesia while ensuring both maternal and fetal hemodynamic stability; a plan must be prepared to resuscitate the fetus if problems occur during the intervention.

A Range of Anesthetic Options for Mother and Fetus

MOTHER

Fetal interventions have been successfully performed with various anesthetic techniques; both maternal and fetal anesthetic requirements must be considered and may, in fact, be quite different.

With some endoscopic interventions, the site of surgical intervention is not innervated; thus the fetus may not sense a noxious stimulus, and its anesthetic requirements are presumably minimal. Nevertheless, fetal immobility remains essential to procedural safety and success. Other interventions may require that a needle be inserted into the fetus, which may elicit a noxious stimulus and possibly even cause pain. Open procedures can produce significant noxious stimuli. In addition to surgical demands, each mother and fetus exhibit a unique physiologic, pharmacologic, and pathophysiologic profile; the anesthesiologist must evaluate the advantages and disadvantages of each anesthetic technique and select the safest approach.[2]

Local Anesthesia (Field Block)

Local anesthesia is almost exclusively used to insert the trocar for percutaneous procedures. The most obvious advantage is maternal safety because the mother receives no intravenous (IV) medications. The disadvantages of this technique include increased risk of injury to the unanesthetized, nonparalyzed fetus, the absence of analgesia for the fetus, and no uterine relaxation. Patients who receive tocolytic therapy or those with polyhydramnios and uterine contractions may be at even further risk of worsening contractions with this approach.

Monitored Anesthesia Care

IV sedation involves the maternal administration of benzodiazepines, opioids, and occasionally low-dose hypnotic agents. Advantages include possible provision of anesthesia and analgesia to the fetus via transplacental transfer of drugs, as well as decreased maternal anxiety and pain. Depending on the amount and effect of the drugs administered, this sedation may increase the mother's risk of aspiration because of an unprotected airway; this technique is also devoid of uterine relaxation.

Regional Neuraxial Blockade

Neuraxial techniques (spinal, epidural, or combined spinal and epidural anesthesia) have been used with fetoscopic techniques and, rarely, without an adjunct general anesthetic for open techniques. A T4 sensory-level blockade is required for most surgical uterine manipulations. Neuraxial techniques provide neither uterine relaxation nor analgesia or anesthesia for the fetus.

Regional Neuraxial Blockade With Sedation

The addition of IV sedation to regional anesthesia may provide the fetus with analgesia/anesthesia via placental drug transfer. Although IV fentanyl, propofol, and benzodiazepines can be administered to patients receiving regional anesthesia, they may place the mother at increased risk of bradyarrhythmias, respiratory depression, and pulmonary aspiration; the need for a T4 sensory block may produce alterations in respiratory mechanics in addition to those associated with pregnancy. In addition, the level of sympathetic blockade is often two to six levels greater than the sensory level.[3] Hence, a T4 sensory block may completely block cardiac accelerator fibers (T1–T4); severe bradyarrhythmias and cardiac arrest have been reported.[4–6] When IV agents with vagotonic properties are administered in this clinical setting, the risk of significant bradyarrhythmias may be increased.[7]

General Anesthesia

General anesthesia with high-dose inhalational anesthetics (generally desflurane) provides both maternal and fetal anesthesia and dose-dependent uterine relaxation even in patients who have received tocolytic therapy for premature uterine contractions.[8–11] Caution must be exercised as the required depth of maternal anesthesia necessary to provide adequate uterine relaxation may produce maternal hypotension with resultant uteroplacental insufficiency and fetal cardiovascular insufficiency. Particular attention must be paid to maintenance of maternal blood pressure in the normal or perhaps slightly supranormal range.[12]

The adjunctive administration of remifentanil and propofol infusions may reduce the necessary concentration of inhalational anesthetic required without compromising uterine relaxation. With such regimens, maternal hypotension and subsequent fetal depression may be avoided.[13] An additional benefit of this combined approach may be the contribution of remifentanil and propofol to fetal anesthesia, as both readily cross the placenta without known reductions in placental blood flow.[14]

Combined Regional and General Anesthesia

A combined regional and general anesthesia technique is often used for open procedures, as well as for patients with anterior placentas, in whom externalization of the uterus for safe trocar insertion is anticipated. In addition to providing the advantages of both the regional and the general anesthetic techniques listed previously, this method allows for postoperative pain control.[15] The physical window for trocar insertion is often smaller in this patient cohort, necessitating either externalization of the uterus or extreme lateral decubitus position. Externalization of the uterus requires a larger surgical incision than for standard cesarean sections, conferring benefit from epidural anesthesia. However, perceived intraoperative benefits (e.g., reduced requirements for inhalational agents) may be offset by the necessity to provide adequate uterine relaxation.

FETUS

Maternal anesthetic techniques that do not include inhalational anesthetics may not provide adequate analgesia and/or anesthesia for the fetus. However, fetal analgesia and anesthesia may also be accomplished by delivery of anesthetics and analgesics directly to the fetus. Potential methods include transplacental, direct intramuscular, direct intravascular, and intraamniotic administration; each route of administration has advantages and disadvantages that can have a direct impact on overall outcome.

Transplacental Access

Many fetal interventions (open or endoscopic) use transplacental drug administration to provide anesthesia and analgesia for both mother and fetus (Table 38.1). Many, but not all, drugs cross the placenta in accordance with Fick's law of passive diffusion (Fig. 38.1). Lipid solubility, the pH of both maternal and fetal blood, the degree of ionization, protein binding, perfusion, placental area and thickness, and drug concentration are factors that influence the extent of transplacental drug diffusion.[16] The most obvious disadvantage with this approach is that the mother must be exposed to every drug that the fetus is intended to receive, often at large concentrations, to achieve adequate drug concentrations in the fetus. In addition, the uptake of drugs may be impaired if there is reduced placental blood flow. This has implications for successful anesthesia and analgesia both in terms of the delivered fetal dose and the time interval that must be allowed from maternal administration to the start of the fetal intervention. All inhalational anesthetics cross the placental barrier, but uptake in the fetus is slower than in the mother.[16] However, this is offset by the reduced minimum alveolar concentration (MAC) for anesthesia in the

TABLE 38.1 Placental Transfer of Common Anesthetic Drugs[a]

Drugs That DO NOT transfer	Drugs That DO transfer
Glycopyrrolate	Atropine
All neuromuscular blocking drugs	Ephedrine
Insulin	Esmolol, labetalol
Heparin	Benzodiazepines
	Propofol
	Ketamine
	Opioids[b]
	Inhalational anesthetics
	Local anesthetics[c]

[a]The major mechanism of transfer is passive diffusion of largely lipid-soluble, nonionized substances with low molecular weight (<500 D). Bulk flow, pinocytosis, and passage through the intervillous spaces are negligible sources of reliable transfer.
[b]Epidural or intrathecal opioids, to a lesser extent, generally produce minimal neonatal effects.
[c]Fetal acidosis produces higher fetal/maternal local anesthetic drug ratios because binding of hydrogen ions to the nonionized form causes trapping of the local anesthetic in the fetal circulation.

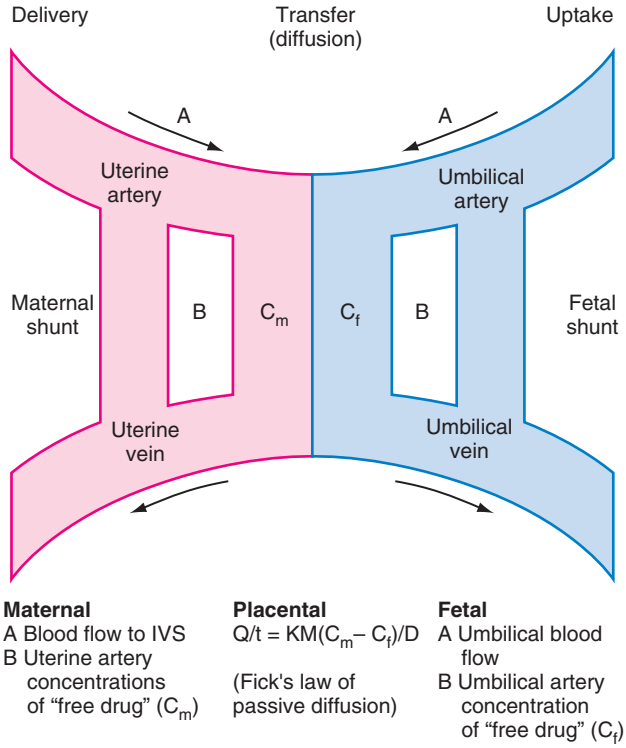

FIGURE 38.1 Fick's law of passive diffusion described at the intervillous space (*IVS*). *D,* membrane thickness; *K,* diffusion constant of the drug; *M,* membrane surface area; *Q/t,* rate of diffusion.

fetus, resulting in a similar onset of anesthesia as in the mother.[2] Fetal anesthesia is also important to reduce the fetal stress response, which, through catecholamine release, can reduce placental blood flow and exacerbate any asphyxia.[17–20]

Intramuscular Access

Intramuscular (IM) injection involves inserting a needle under ultrasound guidance into a fetal extremity or buttocks. Unlike umbilical cord injection, the noxious stimulus to the fetus by the IM injection stimulates the fetal stress response. Although the bleeding risk from an IM injection is less than that with intravascular injections, there remains a risk of bleeding and injury from the needle itself. Furthermore, if the fetus is already stressed, blood will be diverted away from muscle (the site of drug administration) and toward the fetal heart and brain. In this case, it may be impossible to estimate the time course for the drug to be absorbed from the IM site.

Intravascular Access

Intravascular fetal drug administration ensures immediate fetal drug delivery, and no additional dosing calculations are necessary because placental perfusion does not alter dosing. Intravascular access can be obtained via the umbilical cord (which is not innervated), larger fetal veins (e.g., hepatic vein), or intracardiac, as the specific intervention dictates.[21] One advantage of administering drugs via the umbilical vein is the ability to provide analgesia before the surgical insult. Neuromuscular blocking drugs (NMBDs), analgesics, and vagolytic agents, as well as resuscitation drugs, can be given with assurance of immediate access to the fetal circulation. This method is also useful when alterations in peripheral blood flow occur (i.e., a "central sparing response"), which diminishes the blood distribution to sites of potential IM access.

Establishing intravascular access in the fetus requires inserting a needle in a fetus that is often not sedated from maternally administered agents. The needle may injure the moving fetus, and there is a risk of bleeding from the fetus, umbilical cord, and placenta. Uncontrolled bleeding could impair the surgical view and it places the fetus and mother in jeopardy because an open hysterotomy may be necessary to control the bleeding. Establishing access with the umbilical cord vessels may also produce vascular spasm, potentially compromising fetal perfusion.

Intraamniotic Access

Intraamniotic fentanyl, sufentanil, thyroxine, vasopressin, and digoxin have been safely administered in pregnant large-animal models with only minimal drug detected in the mother.[22,23] If the safety and efficacy of this method of drug delivery hold true in human trials, intraamniotic drug administration may become the preferred method for fetal drug delivery; however, at present, this approach is not currently a part of routine clinical practice.

Fetal Development

PATHOLOGIC LUNG DEVELOPMENT

In the context of fetal interventions, there are two important causes of respiratory morbidity to consider: insufficient amniotic fluid and prematurity. With both, the timing of the insult in terms of the stage of lung development is critical to estimating the degree of likely morbidity. Deficiency of amniotic fluid may result from prelabor premature rupture of the amniotic membranes (PPROM), which may be spontaneous or iatrogenically induced either directly through trauma or by introducing infection into the uterus. Small amniotic fluid volume may also be secondary to reduced fetal urine output, from either poor renal function (e.g., with renal agenesis or urinary tract obstruction) or growth restriction secondary to placental insufficiency. Amniotic fluid deficiency contributes to pulmonary hypoplasia. In general, the likelihood of pulmonary insufficiency is inversely related to gestational age at membrane rupture, a long latency to delivery, and the amount of residual amniotic fluid.[24–26] The risk is relatively small if PPROM occurs after 24 weeks gestation,[27] as demonstrated

by one series of fetuses with PPROM before 26 weeks that reported pulmonary hypoplasia in 27% of fetuses.[28] In contrast, in fetuses less than 25 weeks gestation with severe oligohydramnios that persists for more than 2 weeks after PPROM, the predicted neonatal mortality exceeds 90%.[29]

Studies in sheep show that oligohydramnios causes spinal flexion, which compresses the abdominal contents, displacing the diaphragm upward and thus compressing the developing lungs.[30] This increase in the pressure gradient between the lungs and the amniotic cavity causes a net loss of lung fluid through the trachea, preventing lung expansion.[30] Lung fluid produced in the airways is thought to act as a stent for the developing lungs.[31] Normally, it passes out through the trachea and is either swallowed or passes into the amniotic cavity. Ligation of the trachea causes lung hyperplasia[32] or ipsilateral lung hyperplasia if a main bronchus is ligated.[33] Experimental drainage of amniotic fluid in animals has been shown to result in pulmonary hypoplasia.[34] Later restoration of amniotic fluid prevents the onset of pulmonary hypoplasia.[35] There is evidence to support amnioinfusion in humans to maintain fluid volumes around the fetus after PPROM in an effort to improve lung development.[29,36]

Surfactant is a complex of phospholipids secreted by type II alveolar cells that reduces lung surface air tension, thereby preventing the lungs from collapsing at low volumes. Glucocorticoids, thyroid hormone, and β-adrenergic agonists stimulate surfactant synthesis. Surfactant is first detected in the lungs around 23 weeks gestation, but mature levels necessary for unassisted ventilation are not present until about 34 weeks. The degree of lung maturity can be evaluated by amniocentesis using the lecithin/sphingomyelin ratio or, more recently, by the lamellar body count.[37] Acceleration of surfactant synthesis may be achieved with corticosteroids administered to the mother.[38]

FETAL CARDIOVASCULAR DEVELOPMENT

The differences between the fetal and postnatal circulations are complex (Fig. 38.2). In the fetal circulation, oxygenated blood returns from the placenta via the umbilical veins and ductus venosus (bypassing the liver) into the right atrium. At 20 weeks, 30% of the umbilical venous return (40–60 mL/kg per minute) is shunted through the ductus venosus.[39] This flow decreases over the second half of gestation as hepatic blood flow increases so that by term only 20% of umbilical venous return (<20 mL/kg per minute) is shunted through the ductus venosus (see Figs. 18.1 and 18.2).[39] Hypoxia and hemorrhage increase the resistance in the liver, shunting a greater proportion of blood toward the brain and heart through the ductus venosus.[40] The proportion of blood that perfuses the liver, which exits 15% less saturated in oxygen, rejoins the ductus venosus blood in the inferior vena cava. However, this deoxygenated blood has less kinetic energy and flows more slowly into the right atrium toward the right ventricle.[40] The greater-velocity oxygenated blood from the ductus venosus is preferentially directed through the foramen ovale into the left side of the heart and out through the aortic arch to the developing head and upper body. The integrity of the foramen ovale is thus imperative. Blood returning from the placenta along the umbilical vein is 80% to 85% saturated. Despite this streaming within the right atrium, some mixing does occur, resulting in blood that is 65% saturated in the ascending aorta. The blood in the left ventricle, however, is 15% to 20% more saturated than the blood in the right ventricle. Most of the deoxygenated blood in the right ventricle bypasses the high-resistance pulmonary vasculature to enter the ductus arteriosus, and from there the descending aorta to supply the lower body, or pass through the umbilical arteries for reoxygenation in the placenta. In contrast to extrauterine life, when the two ventricles function in series and thus have equal outputs, before birth they function in parallel. Their outputs, therefore, do not have to be equal and, in fact, are not. In the third trimester, the right side of the heart has a greater output, as determined by Doppler ultrasonography studies, showing a 28% greater stroke volume than the left side.[39,39]

The fetal heart rate (FHR) is maintained above the intrinsic rate of the sinoatrial node by a combination of vagal and sympathetic inputs, as well as circulating catecholamines.[41–43] FHR decreases throughout gestation,[44,45] accompanied by an increase in stroke volume as the heart grows. Hypoxic stress in late gestation produces a reflex bradycardia, with a normal heart rate or tachycardia developing a few minutes later. The chemoreceptor reflex nature of the bradycardia is demonstrated by its abolition after section of the sheep carotid sinus nerves.[46] The later tachycardia is a result of an increase in plasma catecholamines causing β-adrenergic stimulation.[47] Hemorrhage can also produce increases in FHR, probably via a baroreceptor reflex.

Cardiac output in the fetus is determined largely by heart rate.[48] The combined ventricular output of the left and right ventricles in the human fetus is 450 mL/kg per minute.[48] During development, the ability of the fetus to increase stroke volume is limited by a reduced proportion of functioning contractile tissue and a limited ability to increase the heart rate because of a relatively reduced β-adrenergic receptor density and immature sympathetic drive. If the blood volume is reduced by hemorrhage, the heart cannot compensate by increasing stroke volume, or conversely, if volume is increased, the walls are less able to distend and cardiac efficiency is reduced (although this second effect is reduced substantially by the huge, relatively compliant placental circulation). Thus the only mechanism by which the fetus can increase its cardiac output is to increase its heart rate. Despite this homeostatic limitation, the fetus is able to withstand significant hemorrhage. Studies have shown that the fetal lamb can restore arterial blood pressure and heart rate very quickly after acute loss of 20% of its blood volume, without any measurable disturbance in acid-base balance.[49] Even after a 40% reduction in blood volume, the ovine fetal blood pressure recovers to normal within 2 minutes and the heart rate within 35 minutes.[50] Oxygen delivery to the brain and heart is maintained secondary to vascular redistribution (*central sparing effect*) and blood volume replacement from the placenta and extravascular space, with 40% of the hemorrhaged loss being corrected within 30 minutes.[50] The development of acidemia indicates that the fetus is unable to compensate; acidosis shifts the oxygen dissociation curve to the right, thereby decreasing fetal hemoglobin oxygen saturation but improving release of oxygen from hemoglobin. Blood flow during periods of asphyxia increases more than 100% to the brainstem but only 60% to the cerebral hemispheres.[51]

FETAL OXYGENATION

The fetus exists in an environment of low oxygen tension, with arterial oxygen partial pressure (PaO_2) being approximately one-fourth that of the adult. The maximum PaO_2 of umbilical venous blood is approximately 30 mm Hg. The affinity of fetal hemoglobin for oxygen is modulated in utero by two principal factors: fetal hemoglobin and 2,3-diphosphoglycerate (2,3-DPG). The hemoglobin oxygen dissociation curve is shifted to the left because of fetal hemoglobin (hemoglobin F), thereby increasing the affinity for oxygen. In addition, 2,3-DPG is present and might be expected

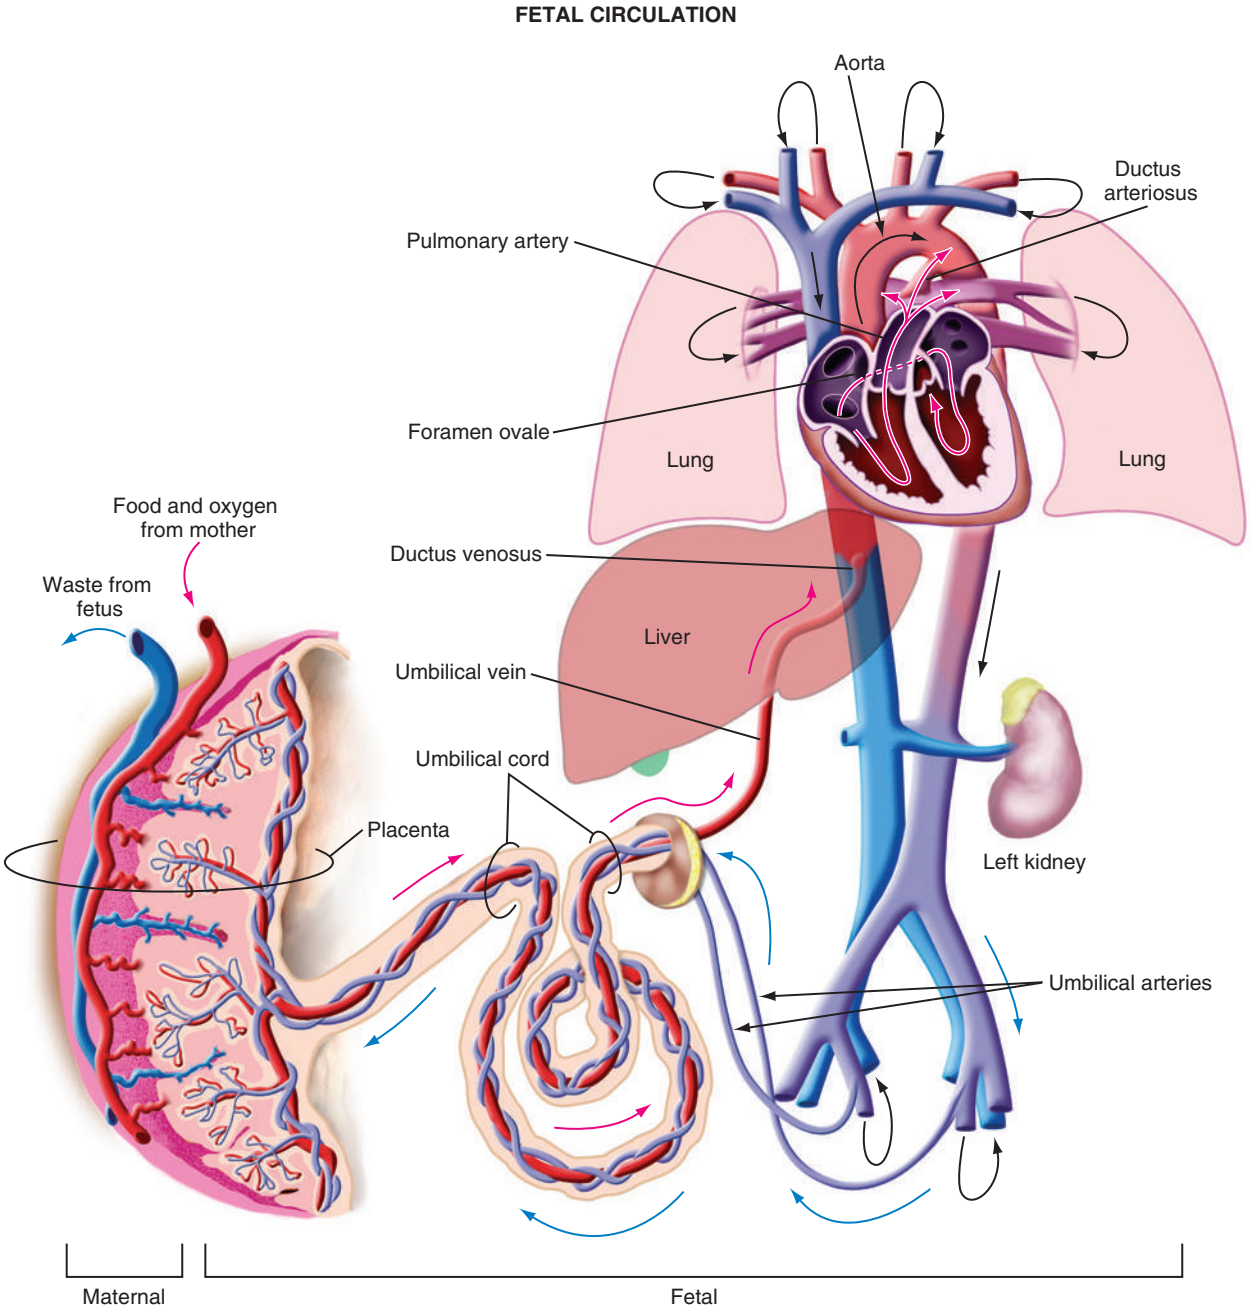

FIGURE 38.2 Fetal circulation. *Red arrows* represent flow of oxygenated blood and *blue arrows* represent flow of deoxygenated blood. *Black arrows* indicate direction of blood flow and represent travel of blood from the central circulation through capillary membranes and return to central circulation. Shading (from red to purple to blue) represents the corresponding relative oxygenation of the blood at that site, from oxygenated to deoxygenated. Note the mixing of blood as the ductus venosus delivers oxygenated blood from the placenta to the central fetal circulation and the progressive desaturation of blood in the fetal aorta secondary to shunts, consumption, and the return of deoxygenated blood from the fetal pulmonary circulation.

to shift the oxyhemoglobin dissociation curve to the right, decreasing the affinity of the fetal hemoglobin for oxygen and favoring oxygen unloading. However, 2,3-DPG appears to only exert approximately 40% of the effect on fetal hemoglobin as it does on adult hemoglobin, thereby preserving a net leftward shift on the oxyhemoglobin dissociation curve. Thus for any given PaO_2, the fetus has a greater affinity for oxygen than does the mother. The P50 (the PaO_2 at which hemoglobin is 50% desaturated) is approximately 27 mm Hg for the adult and 20 mm Hg for the fetus. The concentration of 2,3-DPG increases with gestation, as does the concentration of hemoglobin A[52]; the greater hemoglobin concentration (18 g/dL) results in a greater total oxygen-carrying capacity.

Oxygen supply to fetal tissues depends on a number of factors (Table 38.2). First, the mother must be adequately oxygenated. Second, there must be adequate flow of well-oxygenated blood

TABLE 38.2 Causes of Impaired Blood Flow and Oxygenation to Fetal Tissues

Causes of Impaired Uteroplacental Blood Flow/Oxygenation	Causes of Impaired Umbilical Blood Flow/Fetal Circulatory Redistribution
Reduced maternal oxygenation/ hemoglobin concentration	Umbilical vessel spasm
Maternal hemorrhage	Reduced fetal cardiac output
Aortocaval compression	Fetal hemorrhage/reduced hemoglobin concentration
Drugs reducing uterine blood flow	Fetal hypothermia
Uterine trauma	Impaired uteroplacental blood flow/oxygenation
Uterine contractions	Umbilical cord kinking
Placental insufficiency (PET, IUGR)	
Polyhydramnios: pressure effect	
Maternal catecholamine production increasing uteroplacental vascular resistance	Fetal catecholamine production increasing fetoplacental vascular resistance

IUGR, intrauterine growth restriction; *PET,* preeclamptic toxemia.

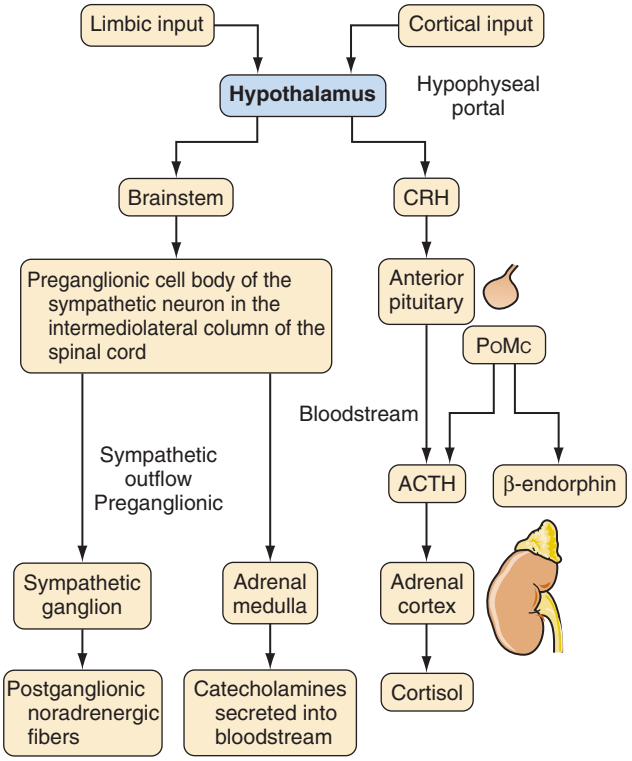

FIGURE 38.3 Human fetal endocrine responses to stress. *ACTH,* adrenocorticotropic hormone; *CRH,* corticotropin-releasing hormone; *PoMc,* proopiomelanocortin.

to the uteroplacental circulation. This blood flow may be reduced from maternal hemorrhage (reduced maternal blood volume) or compression of the inferior vena cava (reduced venous return), which increases uterine venous pressure, thus reducing uterine perfusion. Additionally, aortic compression reduces uterine arterial blood flow.[15] Care must be taken to position the mother in such a way as to prevent aortocaval compression whether by airplaning the table 15 degrees left or by turning the patient to the left decubitus position and then rolling her back to a 15 degrees left tilt.[53,54] The surgical incision of hysterotomy itself reduces uteroplacental blood flow by as much as 73% in sheep, whereas fetoscopic procedures with uterine entry have no effect.[55]

Even if the uterine circulation is adequate, the fetus still depends on uteroplacental blood flow and umbilical venous blood flow for tissue oxygenation. Care must be taken not to interrupt umbilical vessel blood flow by manipulation or kinking the cord, which can cause vasospasm. Umbilical vasoconstriction can also occur as part of a fetal stress reaction resulting from a release of fetal stress hormones (Fig. 38.3). Increases in amniotic fluid volume increase amniotic pressure and impair uteroplacental perfusion.[56,57] Placental vascular resistance may increase, thereby increasing fetal cardiac afterload via a surge in fetal catecholamine production stimulated by surgical stress.[58] Fortunately, animal studies suggest that adverse effects on the arterial blood gas in the fetus do not occur until uteroplacental perfusion has been reduced by 50% or more.[59]

Inhalational anesthetics may cause maternal vasodilatation and thus, in theory, could cause or exacerbate preexisting fetal hypoxia. Studies of anesthetics in hypoxic ovine fetuses have shown that isoflurane exacerbates preexisting acidosis.[60] Isoflurane also attenuates the usual vascular redistribution response to fetal hypoxia, but this is offset by a reduction in cerebral oxygen demand. The net effect is that the balance of cerebral oxygen supply and demand is unaffected. β-Adrenergic blockade, however, renders the fetus less able to cope with asphyxia. Compared with controls, these fetuses have a smaller increase in heart rate, cerebral blood flow, and cardiac output and recover from acidosis more slowly.[61]

CENTRAL AND PERIPHERAL NERVOUS SYSTEM DEVELOPMENT

By the beginning of the second trimester, the spinal cord is largely formed; development of the brain and spinal cord begins as early as postconception week 3. Neural crest cells migrate laterally to form peripheral nerves from about 4 weeks, with the first synapses between them forming a week later.[62] Synapses within the spinal cord develop from about 8 weeks gestation, suggesting the first spinal reflexes may be present at this time. Neuronal development is maximum between 8 and 18 weeks gestation. The first neurons and glial cells develop in the ventricular zone (an epithelial layer) along which the newly formed neurons migrate out in waves to form the neocortex. Synaptogenesis occurs after neural proliferation, first in peripheral structures and, second, more centrally from approximately 20 weeks; this process depends in part on sensory stimulation.[63]

The development of the nociceptive apparatus proceeds in parallel with the development of the basic central nervous system. The first essential requirement for nociception is the presence of sensory receptors, which develop first in the perioral area at around 7 weeks gestation. From here, they develop in the rest of the face and in the palmar surfaces of the hands and soles of the feet from about 11 weeks gestation. By 20 weeks, they are present throughout all of the skin and mucosal surfaces.[64] The nociceptive apparatus is initially involved in local reflex movements at the spinal cord level without higher cortical integration. As these reflex responses become more complex, they in turn involve the brainstem, through which other responses, such as increases in heart rate and blood pressure, are mediated. However, such reflexes to noxious stimuli have not been shown to involve the cortex and, thus, are not

thought to be available to conscious perception. The nature of fetal consciousness itself is complicated, both physiologically and philosophically, and a discussion of such is beyond the scope of this chapter. However, there is a working consensus that there must be electrical activity in the cerebral cortex for consciousness to be present.[65] It appears that, far from being "switched on" at any one moment, consciousness evolves in a gradual process that has been likened to a "dimmer switch," making attribution of fetal consciousness to any particular developmental moment a difficult undertaking.

PROGRAMMING EFFECTS

When considering the effects of noxious stimuli on the developing fetus and the rationale for fetal anesthesia and analgesia, we must consider not just the humanitarian need to alleviate the possible distress of pain sensation, but also whether being subjected to surgical stress during early development might cause permanent alterations in physiology. This concept is known as *programming*, defined as *"the process whereby a stimulus or insult at a critical, sensitive period of development has permanent effects on structure, physiology, and metabolism."*[65,66] Studies in rats and nonhuman primates have shown that the numbers of hippocampal and hypothalamic glucocorticoid receptors in the offspring of antenatally stressed animals were permanently reduced. This attenuates the negative feedback response, resulting in increased basal and stress-induced cortisol concentrations in the offspring that persist into adulthood. Behavioral changes, such as poor coping behaviors, have also been observed.[66]

Fetal Monitoring

The goal during any fetal intervention is to optimize fetal well-being by avoiding fetal hypoxia and hypothermia while optimizing stable fetal hemodynamics. It is essential that the physiologic response of the fetus to anesthetic and surgical stresses be understood and addressed to avoid the known detrimental effects of stress on an already compromised fetus. However, access to the fetus is limited at best and the technologies for continuous intraoperative and postoperative fetal vital sign monitoring are still in development.

A hysterotomy is not needed for many surgical interventions; thus the fetus remains within the uterus, often making access for direct monitoring impossible. Even for those fetuses that are partially delivered for an invasive procedure, monitoring is obtainable only intermittently and is frequently unreliable because the fetus must remain within a fluid environment during the procedure. These obstacles make it difficult to directly apply the available monitors. Current methods for assessing fetal well-being include FHR monitoring, direct measurement of fetal blood gases, fetal electrocardiography, fetal pulse oximetry (FPO), fetal echocardiography, and Doppler ultrasonography of fetal cerebral blood flow.

USE OF FETAL HEART RATE MONITORING FOR FETAL INTERVENTIONS

Currently, FHR monitoring with Doppler ultrasonography is the standard for the intrapartum assessment of fetal well-being. FHR monitoring is also used perioperatively during fetal interventions. The FHR is documented before maternal induction of anesthesia to (1) serve as a baseline for comparison and (2) reassure the perinatologist, surgeon, and anesthesiologist that the fetus is stable. The FHR may be continuously monitored intraoperatively by fetal echocardiography and with intermittent palpation of the umbilical cord in open cases. The most commonly used induction agents for anesthesia (propofol and thiopental) rapidly cross the placenta and thus also rapidly reach the fetus at appropriate doses.[67,68] The inhalational anesthetics also cross the placenta,[69] but their uptake occurs more slowly in the fetus than in the mother.[10,70] These anesthetics decrease FHR and FHR variability. Although it is reassuring if the FHR is within the normal range for the gestational age, fetal bradycardia is a reliable indicator of fetal distress that needs to be immediately addressed.

With the advent of minimally invasive fetal endoscopic surgery, new problems in monitoring have surfaced. The fetus is no longer physically accessible to the surgical team, and the trocars currently used for fetoscopic surgery prevent applying radiotelemetric probes. Currently, fetoscopic or cardiac intervention use direct visualization of the heart with fetal echocardiography, which gives an accurate estimation of the FHR. Although very beneficial, the continuous use of fetal echocardiography requires the presence of a skilled ultrasonographer working in the operative field.

USE OF FETAL BLOOD SAMPLING DURING FETAL INTERVENTIONS

In suspected cases of fetal compromise during an open intervention, fetal blood can be obtained from capillary vessels, a peripheral vein, a central vein, or a puncture of the umbilical vessels. Vascular access is difficult in the fetus because of its small size and friable tissue. Puncture of the umbilical vessels can cause umbilical cord spasm, hematoma, and even fetal death. Hence umbilical cord manipulation should be reserved for circumstances when no other options are available. During an endoscopic intervention, access to the fetal circulation is possible through puncture of the umbilical vessels. With most fetal cardiac interventions, a needle and/or catheter is placed directly through the fetal myocardium, allowing access for blood samples; only a very small sample should be withdrawn because of the small circulating fetal blood volume.

FETAL ELECTROCARDIOGRAPHY

Several groups have used fetal electrocardiography analysis to determine whether changes in time interval (PR and RR interval) and signal morphology (T/QRS ratio) correlate with fetal or neonatal outcome. Studies in animals and humans have shown that under normal conditions, there is a negative correlation between the PR interval and the FHR: as the FHR slows, the PR interval lengthens, and as the FHR increases, the PR interval shortens. *The opposite relationship occurs in acidemic infants.*[71–77] During periods of fetal compromise, it is hypothesized that the sinoatrial node and the atrioventricular node respond differently.[75] Periods of mild hypoxemia induce increases in epinephrine levels, which increase the FHR and shorten the PR interval. However, with periods of prolonged hypoxemia, the oxygen-dependent calcium channels of the sinoatrial node demonstrate reduced sensitivity to epinephrine, thus decreasing the FHR. The fast sodium channels of the atrioventricular node are unaffected by the reduction in the oxygen supply, whereas the increased levels of epinephrine shorten the PR interval. As a result, the relationship between the PR interval and FHR changes from negative to positive.[75,74] Measurements of this relationship have been divided into short-term and long-term measures.[75,76] The short-term measure or the conduction index can be intermittently positive over brief intervals without an adverse outcome. However, a prolonged positive conduction index (>20 minutes) has been associated with an increased risk of fetal acidemia.[77]

FETAL PULSE OXIMETRY

Standard pulse oximeters use the transmission and absorption of light through a vascular bed to a photodetector on the opposite side of the tissue. However, the development of reflectance oximetry allows measurement of oxygen saturation from light-emitting diodes that are positioned next to each other on the same skin surface and absorption is determined from the light that scatters back to the tissue surface[78,79]; any fetal condition that decreases vascular pulsations (e.g., hypotension, vasoconstriction, shock, or strong uterine contractions) can produce inaccurate oximetry readings.[80] Because direct contact of the oximeter must be made with the fetal skin surface, anything that interferes with light transmission or skin adhesion (e.g., fetal or maternal movement, vernix caseosa, caput succedaneum) can influence the signal quality and accuracy of the oximeter.[81–85] Oximetry readings also vary in relation to the site of sensor application; several studies have found reduced baseline oxygen saturation values with the use of the oxygen sensor on the fetal buttock compared with the fetal head.[86–89]

The development of a 735-/890-nm wavelength system (compared with the older 660-/890-nm system) has improved the accuracy in monitoring arterial oxygen saturation ($FSaO_2$) in the fetus.[90] With the normal range of $FSaO_2$ of 30% to 70% in the middle of the oxygen-hemoglobin dissociation curve, small changes in pH or oxygen partial pressure exert large changes in $FSaO_2$.[91] FPO can also identify an acidotic fetus. Increased concentrations of both the hydrogen ion and 2,3-DPG cause a rightward shift of the oxygen dissociation curve (Bohr effect) such that a chronically acidemic or hypoxemic fetus will have a reduced $FSaO_2$ even though the PO_2 is within normal limits.[91]

NEAR-INFRARED SPECTROSCOPY

Near-infrared spectroscopy is a monitoring modality for continuous measurement of mixed-vascular oxygenation of tissues. Using an optical probe to assess light wavelengths in the 650- to 1000-nm range, this tool is able to provide data about tissues several centimeters deep and as such has been particularly useful for assessing cerebral oxygenation as well as detecting changes in fetal tissue oxygenation noninvasively through the maternal abdominal wall in real time in a sheep model.[92] While this monitor has yet to gain widespread clinical use during fetal surgery, in animal models of fetal surgery, near-infrared spectroscopy measurements have been shown to correlate closely with umbilical venous oxygenation.[93]

FETAL ECHOCARDIOGRAPHY

When technically feasible, fetal echocardiography should be available to assess fetal myocardial contractility and function, heart rate, intravascular volume status, and amniotic fluid volume. We have also used echocardiography to correctly identify proper endotracheal tube placement during an EXIT procedure[94] (see later discussion); a sterile sleeve is placed over the ultrasonographic probe, which is then placed over the fetal chest.

DOPPLER ULTRASONOGRAPHY OF FETAL CEREBRAL BLOOD FLOW

Antepartum Doppler ultrasonography studies of the fetal circulation in cases of intrauterine growth restriction with presumed hypoxia have shown a compensatory redistribution, with an increase in peripheral vascular resistance in the fetal body and placenta and a compensatory reduction in peripheral vascular resistance in the fetal brain, producing a brain-sparing effect.[95] Intrapartum Doppler ultrasonography and FPO have verified the brain-sparing response in the presence of intrapartum arterial hypoxemia ($FSaO_2$ <30% for 5 minutes or more), as reflected by increased mean flow velocity in the fetal middle cerebral artery.[96] Preliminary studies of the middle cerebral artery pulsatility index in minimally invasive procedures, such as fetal blood sampling, transfusion, shunt insertion, tissue biopsy, and ovarian cyst aspiration, have demonstrated significant cerebral hemodynamic responses (decreases in the middle cerebral artery pulsatility index) in fetuses that underwent procedures involving transgression of the fetal body. This response was not noted in the fetuses undergoing procedures at the noninnervated placental cord insertion.[97]

Although not yet advocated for routine intrapartum management, it has been suggested that the combination of reduced arterial oxygen saturation and increased cerebral blood flow may indicate an ominous phase during labor. The redistribution of the fetal circulation is not an unlimited protective mechanism, and with persistent cerebral hypoxia, the active vasodilation of the cerebral vessels may fail, leading to disastrous consequences for the fetus.[98]

TABLE 38.3 Anesthetic Considerations of Respiratory Changes of Pregnancy

Decreased functional residual capacity
Faster denitrogenation
Rapidly prone to hypoxia during apnea
Faster induction and emergence of anesthesia with inhaled agents
Increased oxygen consumption
Rapidly prone to hypoxia during apnea
Capillary engorgement of the respiratory mucosa
Predisposes upper airway to trauma, bleeding, and obstruction
Laryngeal edema increases the frequency of difficult intubation
Decreased $PaCO_2$ and no $PETCO_2$-$PaCO_2$ gradient
Capnograph reading similar to $PaCO_2$
Hyperventilation may lead to a reduction in uterine blood flow

$PETCO_2$, end-tidal carbon dioxide pressure.

Physiologic Consequences of Pregnancy

RESPIRATORY AND AIRWAY CONSIDERATIONS

There is an increase in metabolic demand of both the mother and the fetus, and this, along with anatomic and hormonal influences, accounts for the changes in maternal pulmonary physiology (Table 38.3). Pregnancy results in progressive increases in maternal oxygen consumption and minute ventilation, along with a decreased residual volume and functional residual capacity.[99] The increased metabolic demands and anatomic changes can make adequate oxygenation and perfusion of the parturient and the fetoplacental unit a challenge during maternal general anesthesia. During periods of apnea or hypoventilation, the parturient is prone to rapid development of hypoxia and hypercapnia. Even after adequate preoxygenation, the PaO_2 in an apneic anesthetized parturient decreases about 8 mm Hg more rapidly per minute than in a comparable nonpregnant women.[100] Acidosis rapidly develops from hypoxia during difficult airway situations because of a decreased buffering capacity during pregnancy. The decreased pulmonary oxygen stores and increased oxygen consumption make parturients more susceptible than nonpregnant women to the consequences of airway mismanagement.

Not all physiologic changes of pregnancy are deleterious to the performance of anesthesia. For example, both the induction

TABLE 38.4 Anesthetic Considerations of Cardiovascular Changes of Pregnancy

Aortocaval compression
Supine position leads to a decline in cardiac output
May lead to supine hypotensive syndrome
Mostly prevented by left or right uterine displacement
Decreased colloid oncotic pressure
Parturient is at greater risk for developing pulmonary edema
Increased maternal blood volume
Parturient tolerates more blood loss than nonparturients
Hypotension and acidosis may develop with significant blood loss

of and emergence from anesthesia with inhalational anesthetics occur faster in parturients than in nonpregnant women because the combination of increased alveolar ventilation and decreased functional residual capacity speeds the rate at which denitrogenation occurs and at which inspired and alveolar concentrations of inhalational anesthetics reach equilibrium[101]; a faster induction, coupled with a decreased MAC, predisposes the parturients to relative anesthetic overdose and severe hypotension.[102]

CARDIOVASCULAR CONSIDERATIONS

Cardiovascular function is appropriately increased during pregnancy to meet the increased metabolic demands and oxygen requirements of the mother (Table 38.4). Cardiac output increases by 35% to 40% by the end of the first trimester and continues to increase steadily throughout the second trimester until it reaches a level 50% greater than that in nonpregnant women.[103] Heart rate increases 15% to 25% and stroke volume increases 25% to 30% compared with prepregnancy values by the end of the second trimester, after which they both remain stable until term.[104,105] Aortocaval compression by the gravid uterus can decrease cardiac output by 30% to 50%; lesser decreases occur in the sitting or semirecumbent positions. Maternal position is a major factor contributing to hypotension and fetal well-being.[106]

Maternal blood flow and pressure are directly linked to fetal perfusion via the placenta, and uterine blood flow represents about 10% of maternal cardiac output. It is imperative to prevent aortocaval compression by left or right uterine displacement. Because large doses of inhalational anesthetics are often necessary to relax the uterus during fetal intervention, prompt treatment of hypotension is vital. A decrease in maternal blood pressure eventually decreases placental blood flow and, therefore, blood flow to the fetus because uteroplacental blood flow is not autoregulated. Ephedrine (5–10 mg IV) or phenylephrine (50–100 μg IV) per dose effectively treats maternal hypotension unless contraindicated.[107]

Careful attention to the volume status of the parturient is imperative; aggressive volume hydration, the normal decrease in colloid oncotic pressure that occurs during pregnancy, and the use of tocolytic agents (e.g., magnesium or β-adrenoceptor agonists) may all predispose the parturient to pulmonary edema.

CENTRAL AND PERIPHERAL NERVOUS SYSTEMS

Pregnancy-mediated analgesia is affected by changes in spinal opioid antinociceptive pathways and peripheral processes, including the effect of ovarian sex steroids (estrogen and progesterone) and uterine afferent neurotransmission. It is thought that pregnancy-mediated analgesia increases the woman's threshold for pain during the latter stages of pregnancy before labor.[108,109] Pregnant women are more sensitive to the action of many anesthetic agents and require less local anesthetic for spinal and epidural anesthesia and less inhalational anesthetics than their nonpregnant counterparts. The MAC of inhalational anesthetics in pregnancy is approximately 30% less than in nonpregnant females, and yet recent evidence indicated that the hypnotic effects of inhalational anesthetics are similar in pregnant and nonpregnant women.[110] To preclude awareness on the one hand and uterine atony and neonatal depression on the other, the concentration of inhalational anesthetic needs to be carefully titrated.[111]

PHARMACOLOGIC CONSEQUENCES OF PREGNANCY

Physiologic changes of pregnancy alter the pharmacokinetics and pharmacodynamics of many anesthetic drugs. An increase in total body water and adipose tissue, and a decrease in plasma protein concentrations alter the volume of distribution. An increased renal blood flow and glomerular filtration rate can enhance the elimination of renally excreted drugs; hepatic metabolism of some drugs may be inhibited by competition with steroid hormones during pregnancy, whereas others may have a greater clearance associated with the increased basal metabolic rate. Therefore drug administration must consider the pharmacokinetics within the maternal-placental-fetal unit. Most drugs cross the placenta to some extent and the proportion transferred increases with the duration of gestation. The fetus has reduced plasma protein binding, producing relatively greater concentrations of free drug (i.e., unbound and available to cross biologic membranes).[112] Despite detection of oxidation and reduction reactions in the fetal liver from as early as 16 weeks, enzyme concentrations and reaction rates are minimal, exposing the fetus to more prolonged drug effects than occur in the mother.[113] Early in gestation, the primary mode of drug excretion is via blood flow to the placenta, but later, as the fetal kidneys mature, they become a route of drug excretion into the amniotic fluid for water-soluble drugs and metabolites. Amniotic fluid, however, can act as a reservoir for drugs, from which they can be reabsorbed.[112]

Induction

Pregnancy increases the parturient's sensitivity to induction agents.[114] Propofol has been safely used for induction of anesthesia for cesarean delivery in doses of 2 mg/kg, with minimal effects on the neonate.[115] Ketamine has also been used as the sole induction agent for parturients undergoing elective cesarean section; ketamine (1.5 mg/kg) has not been associated with maternal awareness or neonatal depression at delivery and parturients required fewer analgesics in the first 24 hours after delivery.[116] It is speculated that ketamine's analgesic properties may reduce the sensitization of pain pathways and subsequently confer extended benefit into the postoperative period. Induction agents decrease spontaneous uterine contractions of isolated pregnant rat myometrium, but only in concentrations greater than those seen in clinical obstetric practice.[117]

Neuromuscular Blocking Drugs

Although serum cholinesterase activity decreases 30% during pregnancy, recovery from a dose of 1 mg/kg of succinylcholine is not prolonged.[118] Succinylcholine has limited placental transfer, owing to its poor lipid solubility and high degree of ionization.[119] Similarly, *cis*-atracurium has been safely used for cesarean section without routine neostigmine antagonism, despite decreased plasma cholinesterase activity.[120] Pregnant women may be more sensitive to the action of nondepolarizing muscle relaxants, with the

administration of vecuronium resulting in a more rapid onset and delayed recovery of neuromuscular blockade compared with nonpregnant control patients. The prolonged action of vecuronium is reported in women 4 days after delivery[121]; the clinical duration of vecuronium in term and postpartum women is twice that of nonpregnant women.[122] However, in a study that compared *cis*-atracurium 0.2 mg/kg for intubation in immediate postpartum women with nonpregnant women, both the mean onset and recovery times in the postpartum women were significantly smaller.[123] Nondepolarizing muscle relaxants have no effect on uterine relaxation and, as quaternary amines, do not cross the placenta.

Inhalational Anesthetics

Pregnant women are more sensitive to the anesthetic action of the inhalational anesthetics (MAC is reduced approximately 30% from nonpregnant females).[124] This may lead to a deeper plane of anesthesia than predicted during fetal surgery and a relative overdose associated with maternal cardiac depression and hypotension. Recent evidence, however, suggests that the hypnotic effects of sevoflurane measured electroencephalographically and with a bispectral index monitor were similar in pregnant and nonpregnant women.[110] The difference in MAC between these two groups may reflect differences in spinal nociceptive responses rather than central hypnotic effects.

All inhalational anesthetics rapidly cross the placenta, but their uptake occurs more slowly in the fetus than in the mother.[125,126] At light (1.0 MAC) isoflurane or halothane anesthesia, neither maternal pulse rate, cardiac output, and acid-base status, nor fetal pulse rate, acid-base status, and oxygen saturation changed significantly.[127] During moderately deep (1.5 MAC) isoflurane or halothane anesthesia, maternal arterial pressure and cardiac output decreased. Uterine vasodilation occurred, but uteroplacental perfusion was maintained; fetal oxygenation and base excess were also maintained. However, at concentrations of inhalational anesthetics that exceeded 2.0 MAC, maternal hypotension decreased uteroplacental perfusion despite uterine vasodilation, leading to fetal hypoxia and acidosis. Inhalational anesthetics produced a dose-related uterine relaxation.[128] At 0.5 MAC of isoflurane, uterine contractility decreases 20%. whereas at 1.5 MAC, contractility decreases 60%.[129] Sevoflurane produces a dose-dependent depression in uterine muscle contractility, with complete abolition of uterine activity at greater than 3.5 MAC.[130] The large concentrations of inhalation anesthetic needed for profound uterine relaxation generally requires tracheal intubation and aggressive use of vasopressors.

Fetal Preoperative Evaluation

Prenatal imaging of all fetal anomalies, including anatomic areas of involvement, the relationship to normal structures, and tracheal location, is needed to plan the most appropriate surgical and anesthetic interventions. The accuracy and quality of preoperative fetal ultrasonography and magnetic resonance imaging (MRI) are of the utmost importance because some lesions, especially pulmonary lesions, may spontaneously regress in utero; an inaccurate diagnosis could lead to suboptimal or inappropriate intervention. In addition, extremely valuable information can be obtained that would aid in the decision-making process for a given treatment—namely, the presence of ascites, hydrops, mediastinal shift, degree of lung hypoplasia and lesion involvement, airway involvement and potential tracheal distortion, or compression from intrathoracic masses. Preoperative imaging can also determine other anticipated alterations in anatomy that may acutely alter fetal cardiopulmonary physiology (e.g., mediastinal shift and the known associated potential alterations in fetal preload). Serial radiologic examinations can also monitor the growth of certain masses, the development of hydrops, and the response to treatment medications (e.g., transplacental digoxin). Significant fetal ventricular dysfunction or heart failure should alert the anesthesiologist to the possibility of fetal cardiac arrest during a fetal intervention. Other congenital abnormalities may be detected that may render a potential fetal intervention useless.

In addition, a fetal karyotype must be obtained preoperatively to diagnose any genetic disorders that are associated with significant fetal morbidity or mortality and that would preclude further intervention. An estimated fetal weight, obtained by ultrasonography immediately before surgical intervention, allows for preparation of unit doses of fetal medications. Any previous attempts at fetal intervention should be evaluated, including the number of interventions, fetal tolerance of the procedures, transient reversal in fetal symptoms, the presence of fetal cardiac dysfunction, and the reason or reasons for failed intervention. Assuming that fetal hydrops is present, any attempts to treat this condition should also be documented, including the effectiveness of digoxin therapy, total dose administered, method of administration, and response to treatment.

Maternal Evaluation

A complete medical history and physical examination, especially a focused airway evaluation, are of the utmost importance. Details regarding fetal pathophysiology and its effects on secondary maternal morbidity should be addressed. Any patient with significant polyhydramnios and associated preterm contractions is at increased risk for preterm labor and rupture of membranes with uterine manipulation. Patients with polyhydramnios despite multiple amnioreductions require greater amounts of intraoperative tocolysis as well as greater concentrations of inhalational anesthetic to relax the uterus and ensure acceptable surgical conditions.

The presence of fetal hydrops should alert the practitioner to the possibility of maternal mirror syndrome. *Mirror syndrome* refers to characteristic maternal pathophysiologic changes associated with a variety of fetal disorders, including nonimmune hydrops, molar pregnancies, congenital cystic adenomatoid malformation (CCAM) of the lung, and sacrococcygeal teratoma (SCT). Polyhydramnios and placentomegaly are usually present. Although the etiology of this condition is unclear, the end result is a maternal hyperdynamic state with associated hypertension and total body edema.[131] Respiratory insufficiency or pulmonary edema may develop, requiring prompt and aggressive treatment. If preterm uterine contractions develop, treatment options may be limited because tocolytic agents can greatly exacerbate respiratory decompensation. Treatment is aimed at maternal supportive care; even correction of the underlying fetal pathology will not completely resolve the maternal abnormalities. Delivery of the fetus is the only sure method to completely reverse this maternal pathologic process.

The anesthesiologist should specifically investigate for the presence of placentomegaly; increased placental blood flow may alter pharmacologic treatment in both the mother and the fetus because increased drug metabolism may occur. The presence of placentomegaly may also increase the risk for acute massive intraoperative bleeding. Strategies should be in place before incision to permit rapid fluid resuscitation of the mother. Several reports describe inadvertent inclusion of the placental edge during the

hysterotomy incision, causing a sudden, massive loss of blood with a completely relaxed uterus.[132,133] Immediate surgical control of the bleeding, resuscitation of the mother with blood products, and liberal use of vasopressors that do not increase placental vascular resistance must be immediately available.

Tocolysis and Tocolytic Agents

The occurrence of contractions and preterm labor is an expectation for the first few postoperative days. Fortunately, in many cases, delivery can be postponed until after 32 weeks, giving the fetus time to heal from the procedure and allowing the lungs to mature. However, for many women, the onset of surgically induced preterm contractions heralds premature labor and delivery that, at best, eliminates the positive results of the procedure, and, at worst, ends in the loss of the pregnancy. Although most women who require fetal surgery can be successfully prevented from delivering immediately after surgery, the current generation of medications used for tocolysis have been ineffective in preventing premature labor and delivery. Preterm labor remains the single most common complication that limits the success of fetal surgery.

HORMONAL RECEPTORS IN LABOR

The adrenergic hormonal system plays a very influential part in the activity of the myometrium; several types of adrenergic receptors are found in the uterus (Fig. 38.4). Stimulation of the α-adrenergic receptor causes an increase in the rate and intensity of uterine contractions, whereas activation of the β_2-adrenergic receptors produce myometrial relaxation.[134] In addition, the term uterus is heavily populated with receptors for endogenously released oxytocin responsible for initiating uterine contractions. Prostaglandins also play a significant role in modulating myometrial tone. In general, prostaglandins are produced in or near the local environment where they exert their effect; both uterotonic and tocolytic prostaglandins have been identified. The balance of intrauterine and maternal uterotonic prostaglandins is thought to play an essential part in the preparation for both term and preterm labor. Prostaglandins, especially prostaglandin E_2, are an essential component of every aspect of natural labor.[135]

TREATMENT OF ACUTE PRETERM LABOR

Nonsteroidal Antiinflammatory Drugs

Nonsteroidal antiinflammatory drugs (NSAIDs) block the action of cyclooxygenase, preventing the formation of prostaglandins. In vitro studies of indomethacin have found consistent inhibition or complete arrest of overall myometrial activity.

β-Adrenergic–Mimetic Agents

Currently, only β_2-adrenoceptor–selective medications are routinely used for acute preterm labor. Most adverse effects result from their lack of pure specificity—that is, simultaneous stimulation of β_1- and β_2-adrenergic receptors. Adverse effects include fetal tachycardia, maternal tremors, palpitations, tachycardia, a decreased or increased blood pressure, lethargy, sleepiness, ketoacidosis, and pulmonary edema. Pulmonary edema occurs in up to 5% of patients, especially when these medications are used with other tocolytics (e.g., magnesium).[136] Because the β-adrenergic–mimetic agents are nonspecific receptor agonists, in large concentrations these agents can stimulate α-adrenergic receptors, which promotes uterine contractions, leading to treatment failure.

Magnesium

Magnesium competes with calcium for transmembrane channel entry into cells.[137] Because the myometrium depends on stores

of calcium for adequate contraction, a decrease in intracellular transport prevents the activation of the actin and myosin complex, resulting in uterine relaxation.

Nitric Oxide Donors

Nitroglycerin is an effective uterine relaxant used in select situations to rapidly relax the uterus (e.g., extraction of a retained placenta and uterine inversion). In pregnant sheep, nitroglycerin causes a decrease in mean maternal arterial pressure and increase in heart rate, without compromising uterine blood flow.[138] During fetal surgery, nitroglycerin has been used to relax the myometrium and arrest breakthrough contractions. Adverse effects include maternal hypotension, tachycardia, headache, development of tachyphylaxis, and a high incidence of maternal pulmonary edema.[139]

Calcium-Channel Blockers

Calcium-channel blockers are better tolerated than β-adrenergic–mimetic agents. Nifedipine may be more effective than β_2-adrenergic agonists in postponing delivery, especially in those women with intact membranes.[140] Neonates born to women treated with calcium-channel blockers have a reduced frequency of respiratory distress, necrotizing enterocolitis, and intraventricular hemorrhage.[141] The most serious adverse effect is maternal hypotension; the combination of calcium-channel blockers and magnesium sulfate should generally be avoided.

Pain Control

Pain control after fetal surgery is an essential component of tocolytic therapy, because it is thought that adequate pain control prevents the stress-induced hormonal impetus for preterm labor. Surgical stress elicits the release of adrenocorticotropic hormone that increases production of cortisol; cortisol production, in turn, leads to the deleterious changes in the placenta that increase fetal estrogen and prostaglandin production, promoting increased uterine activity.

Fetal Complications of Tocolytic Therapy

The adverse effects of tocolytics in the fetus present a number of problems, albeit usually less so than in the mother. Sympathomimetics that act through β-adrenoceptors cause fetal tachycardia.[142] Whereas cyclooxygenase inhibitors are more effective than other tocolytics in delaying labor,[143] the adverse effects of fetal oliguria and ductus arteriosus constriction have limited their long-term use.[144] However, after short-term use, these adverse effects are fully reversible within 72 hours from cessation of treatment.[144] Longer-term use of indomethacin has been associated with renal dysfunction and increased rates of necrotizing enterocolitis, intracranial hemorrhage, and patent ductus arteriosus in infants delivered at less than 30 weeks gestation.[145] Magnesium sulfate reduces FHR variability[139] and depresses fetal right ventricular function.[146] Because this drug rapidly crosses the placenta but is excreted more slowly by the fetal kidneys than by the maternal kidneys, there are concerns about fetal toxicity, resulting in respiratory and central nervous system depression.[147] Nitric oxide donors, such as nitroglycerin, appear to have minimal fetal side effects.[11]

POSTOPERATIVE PULMONARY EDEMA

Noncardiogenic pulmonary edema is a known complication of tocolysis. Most often, obstetric pulmonary edema is a result of increased hydrostatic pressures and resolves rapidly with diuretics, cessation of tocolytics, and fluid restriction. One study observed a prevalence of pulmonary edema of 0.5%, but that rate increased to 23% in fetal surgical patients; 93% of those with pulmonary edema required intensive care and 20% required tracheal intubation.[139] It has been hypothesized that extensive uterine manipulation during surgery may result in release of mediators that increase the permeability of lung vasculature. The class of medications most strongly associated with pulmonary edema is β-adrenergic–mimetic agents. An additional important observation is that patients receiving nitroglycerin for tocolysis have demonstrated more pronounced pulmonary edema (more severe hypoxemia, greater time to resolution, worse chest radiograph, and a greater composite lung injury scores) than those who received other tocolytics.[139]

Congenital Cystic Adenomatoid Malformation: the Open Procedure

CCAM serves as a prime example of a fetal condition that requires an open intervention. Fetuses with lung masses that present before extrauterine viability represent a complex group of congenital disorders. Before the advent of preterm fetal intervention, management of fetal lung masses had limited options that included (1) delivery with hydrops once fetal viability was determined based on lung maturity while acknowledging the potential need for emergent postpartum resuscitation, (2) transplacental digoxin therapy in an effort to treat severe forms of cardiac dysfunction,[148,149] and (3) termination of the pregnancy if the fetus was considered nonviable (Fig. 38.5). Fetuses that demonstrate in utero tumor regression documented by serial sonograms are allowed to progress to term gestation. Most infants with smaller lung masses or those with masses demonstrating in utero regression do well with standard delivery and neonatal resection.[145] However, a subset of fetuses experience fetal lung mass growth, ultimately compromising normal lung development. Treatment options for these fetuses have expanded to include cyst aspiration, thoracocentesis, double-J stents for permanent thoracic drainage, and in utero resection of the lung mass.[145,150,151] All treatment options aim to reduce the size of the lung mass to allow the remaining fetal lung to develop.

CONGENITAL CYSTIC ADENOMATOID MALFORMATION OF THE LUNG

CCAM of the lung consists of cystic masses of pulmonary tissue and bronchial structures, neither of which participate in gas exchange,[152,153] that may represent a form of pulmonary hypoplasia.[154] CCAMs can compress surrounding lung tissue and impede normal lung development, resulting in pulmonary hypoplasia.[155] Of all the fetal lung masses, CCAM is the lesion most frequently associated with hydrops fetalis that often indicates a premorbid fetal state. Although the exact mechanisms for the development of hydrops are unclear, it has been suggested that it is secondary to either cardiac compression or vena caval obstruction from the intrathoracic mass.[156,157] This condition is associated with an imbalance of fetal fluid that results in the accumulation of fetal fluid, causing increases in fetal interstitial and total body water, pericardial and pleural effusions, ascites, anasarca, polyhydramnios, or placental thickening.[158,159]

Fetal lung abnormalities themselves may lead to excessive fluid accumulation because the fetal lung is an important organ for amniotic fluid balance. The average fetus produces approximately 300 mL/day or about 4 mL/kg per hour of lung fluid[160] and approximately 700 mL/day of urine output, and swallows approximately

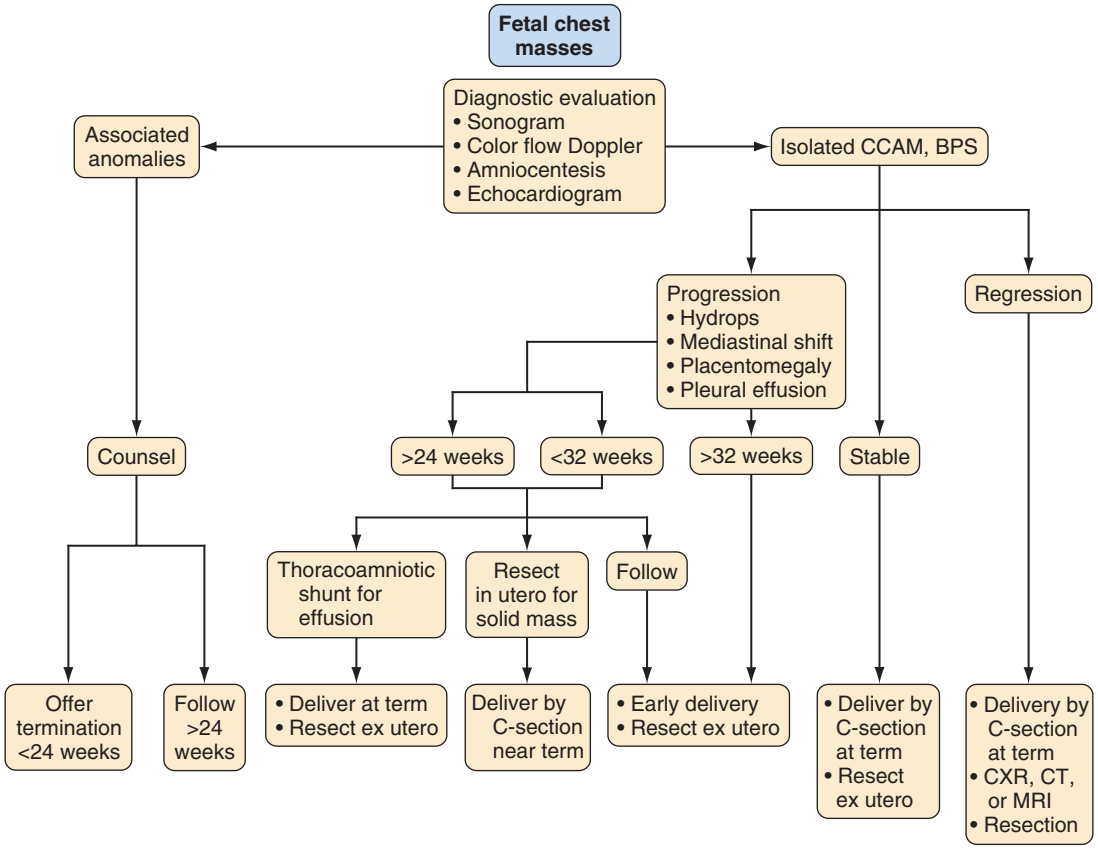

FIGURE 38.5 Algorithm for the management of fetal chest masses. *BPS,* bronchopulmonary syndrome; *CCAM,* congenital cystic adenomatoid malformation; *CT,* computed tomography; *CXR,* chest radiography; *MRI,* magnetic resonance imaging. 700 mL/day of amniotic fluid. The remaining 300 mL/day is postulated to exit the amnion through the chorioamnionic membrane. CCAMs may impair fetal swallowing via esophageal obstruction and therefore disrupt the normal fluid balance. Fetal swallowing is the major route by which amniotic fluid is returned to the fetal vascular compartment. A second possibility is hypersecretion or transudation of fluid from the CCAM itself.

Management

Experts have formulated guidelines for the fetal surgical management of fetuses diagnosed with CCAM lesions; overall prognosis depends on the size of the lung mass and the presence of secondary physiologic derangements.[145] Special consideration is given to fetuses that exhibit signs of hydrops fetalis, especially those who are less than 32 weeks gestation.[150] Although these conclusions were based primarily on the experience with CCAM infants, it might be appropriate to extend this experience to the management of fetuses with other lung lesions. The primary goal of treatment is to reduce lesion size so that the fetal lung has an improved chance of normal development.

Operating Room Preparation

As with all other types of fetal intervention, ultrasonography should be performed before the induction of anesthesia to assess fetal well-being and to obtain an estimated fetal weight. In addition to the normal preanesthesia preparation checklist, additional maternal airway equipment, resuscitation drugs, and tocolytic agents should be prepared and immediately available. The availability of type-specific packed red blood cells (PRBCs) for the mother and O-negative irradiated PRBCs, divided into 50-mL aliquots for the fetus must be confirmed. The operating room temperature should be warmed to at least 80°F (26.7°C) to prevent hypothermia of the partially exposed fetus during thoracotomy. Resuscitation drugs for the fetus (atropine 10–20 μg/kg, epinephrine 1–10 μg/kg), as well as an NMBD (e.g., vecuronium 0.2 mg/kg or pancuronium 0.1 mg/kg), and fentanyl (10 μg/kg) are prepared under sterile conditions, thus making them available during the procedure.[51] A rapid infusion system with warmed isotonic saline solution is used to replace amniotic fluid loss during fetal lung resection, and is ready to administer onto the surgical field via a sterile tubing system. A pulse oximeter with a sterile extension cord should be available for application to the upper extremity of the fetus.

Induction

The preferred method of maternal anesthesia for these cases is general anesthesia with tracheal intubation and neuromuscular blockade. IV access is established and sedation is administered as needed before entering the operating room. If the mother has not received indomethacin (50-mg rectal suppository) for tocolysis before arrival, it is administered after induction of general anesthesia. Indomethacin is used in conjunction with magnesium in the postoperative period for tocolysis but does not play a significant

tocolytic role in the intraoperative period. After placement of standard monitors, a lumbar epidural catheter may be inserted for postoperative pain management. With the exception of a test dose, most practitioners avoid local anesthetic administration through the epidural catheter until the fetal intervention is completed. This is done to avoid possible decreases in maternal mean arterial pressure from an epidural-associated sympathectomy. The mother is then positioned in a uterine displacement position, preoxygenated, and a rapid-sequence induction is performed with an induction agent, succinylcholine (and subsequently followed with a short-acting nondepolarizing agent), and a rapid-acting opioid. Anesthesia is maintained with 1 MAC of the inhalational anesthetic of choice (usually sevoflurane or desflurane should a rapid reinstatement of uterine tone be required) in 100% oxygen (with remifentanil and propofol as possible adjuncts), while an ultrasonographic examination maps out surface anatomy with respect to the placenta and fetus, as well as reassuring fetal well-being after anesthetic induction. A second large-bore peripheral IV catheter, radial arterial catheter, urinary catheter, and nasogastric tube are then inserted. Because the maternal anesthesia induction is the same as a standard cesarean section, invasive blood pressure monitoring is not necessary until the inhalational anesthetic (or inhalational plus intravenous equivalent) is increased to 2 to 3 MAC. Fetal hemodynamics (heart rate, right ventricular contractility) are monitored intraoperatively by continuous fetal echocardiography.[51]

Alternatively, if the interval between induction of anesthesia and the hysterotomy is expected to be prolonged, a substitution or combination with an IV anesthetic (typically propofol and remifentanil) may reduce fetal cardiac acidosis that has been reported with greater concentrations of inhalational anesthetics (most notably desflurane).[160] In the past, large concentrations of inhalational anesthetics would be reinstituted before uterine incision to ensure adequate relaxation of the uterus. An alternative approach is to use total IV anesthesia techniques that may include remifentanil, nitrous oxide, midazolam as general anesthetic agents with IV nitroglycerin for uterine relaxation.[12–14,161] Remifentanil, which moves across the placenta freely, has also been described as an agent for fetal immobilization under combined spinal epidural anesthesia.[162]

Maintenance

Historically, the concentration of inhalational anesthetic (typically desflurane) would be increased to 2 MAC before hysterotomy to ensure myometrial relaxation and tocolysis.[51,163] However, as discussed previously,[12–14] a recent trend is to reduce the use of large concentrations of inhalational anesthetics and substitute these with remifentanil and propofol infusions to achieve similar goals. In either case, satisfactory uterine relaxation can be achieved, but these techniques may variably decrease maternal arterial pressure, uteroplacental perfusion, and fetal oxygenation and may require pressor support.[51,164] Although only small increases in fetal PaO_2 occur with maternal inspired oxygen concentrations of 100%, this small increase may be advantageous. Furthermore, the increased concentration of inhalational anesthetic needed for uterine relaxation dictates that only medications that augment uterine relaxation be administered.[165] Given that nitrous oxide does not affect the uterine tone to any measurable degree and thus provides no direct surgical benefit, it seems best to omit it and administer 100% oxygen. However, eliminating nitrous oxide from the anesthetic prescription has given rise to an increase in the incidence of perioperative awareness that should be anticipated and prevented.[166] Maternal eucapnia ($PaCO_2$ of 31–33 mm Hg) is the physiologic goal,[158] because maternal hyperventilation may lead to decreases in fetal PaO_2.[167,168] Some have suggested that maternal hypercarbia can, in fact, increase fetal PaO_2.[169] At this time, however, extrapolation of these conclusions to fetal intervention cases should be undertaken with caution.

When recovery from the short-acting nondepolarizing agent has been achieved, additional doses of NMBD should be titrated as needed. If preoperative tocolytic agents were administered, combined with the anticipated administration of magnesium sulfate during the abdominal closure, long-acting NMBDs are best avoided to ensure that neuromuscular blockade can be antagonized at the end of the surgery.

Meticulous attention to maternal blood pressure is essential to ensure adequate uterine blood flow and uterine perfusion; maternal systolic pressure is maintained at 110% of mean awake values with IV ephedrine or phenylephrine. Total IV fluids are limited unless blood loss is excessive to minimize the risk of postoperative maternal pulmonary edema.[170]

Once the uterus has been completely exposed, the surgeons assess uterine tone. Because there is no objective method to assess the degree of uterine relaxation, surgical palpation remains the standard. The concentration of inhalational anesthetic is adjusted as needed, with bolus doses of nitroglycerin administered followed by an infusion to diminish uterine tone. Any attempted surgical manipulation before complete uterine relaxation may increase uterine vascular resistance, reduce uterine perfusion, and place the fetus at risk for hypoxia.

After adequate uterine relaxation, the hysterotomy site is prepared by placement of two sutures parallel to the proposed incision site and through the full thickness of the uterine wall. A hemostatic uterine stapling device is inserted. Once the stapler is deployed, the amniotic membranes are secured to the uterine wall, effectively minimizing excessive maternal bleeding. However, if the stapling device misfires or if the placental edge is mistakenly incorporated into the hysterotomy, significant hemorrhage may occur.

Intervention

The fetal hemithorax and upper extremity are delivered through the hysterotomy. Warm fluids are continuously infused into the uterine cavity from a high-volume fluid warmer to replace amniotic fluid losses, provide a thermoneutral environment for the fetus, and prevent umbilical cord kinking or stretching. Limiting the size of the uterine incision helps prevent fetal evaporative fluid loss, uterine hemorrhage, and postoperative uterine contractions. Once the fetal hemithorax and upper extremity have been delivered into the operative field, fentanyl (5–20 μg/kg), atropine (20 μg/kg), and an NMBD (usually vecuronium 0.2 mg/kg or pancuronium 0.1 mg/kg) are given IM as a single injection into the exposed shoulder of the fetus.[51] Fentanyl is administered for intraoperative and postoperative fetal analgesia and to suppress the fetal stress response, atropine ablates the expected bradycardic response with fetal surgical manipulation, and an NMBD will ensure an immobile fetus during surgery. Although the fetus receives anesthesia from transplacental transfer of maternal inhaled anesthetic, these additional IM medications augment fetal anesthesia and ensure fetal analgesia before thoracotomy.

A pulse oximetry probe can be applied to the exposed fetal extremity. Fetal echocardiography provides information about FHR and ventricular filling, which is particularly useful in those procedures in which fetal blood loss is anticipated (Fig. 38.6). Fetal lung lesions, especially if composed of multiple tissue types,

may have a very irregular vascular supply, and significant fetal hemorrhage is possible. Direct vascular access in the exposed upper extremity allows immediate resuscitation and blood administration as needed. Even surgical manipulations alone can lead to hemodynamic instability, requiring urgent resuscitation. This may be secondary to mediastinal torsion, resulting in a sudden loss of cardiac preload.

Intraoperative Fetal Resuscitation

Fetal bradycardia (FHR <100 beats/minute) usually results from hypoperfusion with low cardiac output, umbilical cord kinking, or surgical manipulation, but it may also be a result of increased uterine vascular resistance or unrecognized bleeding from the tumor site. Other expected surgery-related complications include blood loss from the tumor, hypothermia, dehydration, and unintended delivery of the fetus. Despite identification and correction of precipitating factors, the fetus may remain severely bradycardic and require resuscitation. Efforts should be made to maximize fetal perfusion and ensure adequate fetal intravascular volume. Maneuvers include confirming maternal F_IO_2 of 100%, increasing maternal mean arterial pressure to 15% to 25% above awake values, increasing the concentration of the inhalational anesthetic to minimize the resistance of the uterine vessels, confirming adequate intrauterine volume with warmed replacement Ringer's lactate solution, and identifying the umbilical cord via ultrasonography to verify that twisting or kinking has not occurred are essential to avoiding untoward events. Pharmacologic support may also be needed. In cases with no fetal intravascular access, IM epinephrine (1–2 μg/kg) and atropine (20 μg/kg) can be administered and repeated if necessary. If intravascular access is available, pharmacologic resuscitation should be administered via this route to guarantee immediate effect. In addition, blood transfusions (5–10 mL/kg O-negative irradiated PRBCs) can be administered in cases of severe fetal hypovolemia, by either an upper extremity intravascular route or by percutaneous access to the umbilical vein with ultrasound guidance.

Closure

Once the lung lesion has been resected and fetal well-being is confirmed, the fetus is returned to the intrauterine environment and the hysterotomy incision closed. Closure consists of two separate layers, thus minimizing the risk for postoperative amniotic fluid leak and uterine wall dehiscence (Fig. 38.7). It is important to maintain complete uterine relaxation during closure, because uterine manipulation can alter blood flow and place the fetus at risk of hypoperfusion. Before the last uterine stitches, intraamniotic volume is assessed via ultrasonography and any deficit is replaced with warmed Ringer's lactate solution.

Once the uterine incision is closed, the surgeon begins to close the maternal abdominal wall. At this time, a loading dose of magnesium sulfate (6 g) is administered IV over 20 minutes, followed by an infusion (3 g/hour) that is continued postoperatively. The epidural catheter can be dosed with local anesthetic (15–20 mL of 0.25% bupivacaine) and an opioid (e.g., fentanyl 1–2 μg/kg) as the inhalational anesthetic is decreased or discontinued. Careful attention to the degree of neuromuscular blockade is needed, as magnesium sulfate potentiates the action of the muscle relaxants. Tracheal extubation occurs as soon as the usual criteria for extubation are met.

Postoperative Management

As soon as the procedure is completed, the mother should be monitored by experienced staff with necessary equipment to immediately address any complications that might occur. Ultrasonography is performed in the immediate postoperative setting and frequently over the subsequent week to monitor fetal hemodynamic stability. Tocodynamometers to assess the degree of uterine activity and irritability are used to guide tocolytic therapy.

Serious postoperative complications include premature labor, pulmonary edema, amniotic fluid leak, wound seroma, infection, and fetal demise.[15,51,158,171–173] Virtually all patients experience premature uterine contractions in the immediate postoperative period, thereby necessitating a continuous magnesium sulfate infusion until premature labor risk is significantly diminished. In some instances, additional tocolytic agents may be necessary. Despite maximal tocolytic therapies, continued uterine irritability may result in premature delivery. Amniotic fluid leak can lead to oligohydramnios and significant reductions in amniotic fluid volume that may necessitate replacement. In refractory cases, the mother may need to return to the operating room for reclosure of the hysterotomy incision.

The etiology of fetal demise after open fetal surgery is usually secondary to a primary complication (see earlier discussion). As such, every effort is made to minimize and promptly treat potential postoperative complications to ensure a positive fetal intervention and to provide an environment for a successful term gestation. Surgical stress and pain can lead to release of cortisol and inflammatory cytokines in both the mother and the fetus, which, in turn, may lead to premature uterine maturation and contractions.[174] Maternal pain control can be provided by patient-controlled analgesia and epidural or spinal analgesia. One disadvantage of epidural analgesia is that the systemic opioid concentrations are reduced; therefore less is transferred to the fetus for postoperative analgesia. Maternal IV analgesia improves the likelihood of fetal analgesia. However, IV analgesia does not reliably prevent a maternal stress response. To address this, the optimal choice for epidural analgesia may be a reduced concentration of the local anesthetic with a high concentration of a fat-soluble opioid, such as fentanyl (e.g., bupivacaine [0.05%] and fentanyl [10 µg/mL]).[171]

Other Diseases Eligible for Open Procedures

PULMONARY SEQUESTRATION

Pulmonary sequestration, also known as bronchopulmonary sequestration, accessory lung, or bronchopulmonary foregut malformation, represents 0.5% to 6% of congenital lung disease (0.15% and 1.7% of live births).[33–35] Pulmonary sequestrations consist of nonfunctional lung tissue that does not communicate with the normal tracheobronchial tree and hence does not participate in gas exchange.[34] Pulmonary sequestration may be differentiated from CCAM by investigation of its blood supply. Unlike pulmonary sequestrations, CCAMs derive their blood supply and venous drainage from the pulmonary circulation. A multitude of somatic anomalies have been associated with sequestration, most commonly diaphragmatic hernia. If not treated in utero, these lesions often present as respiratory distress in the neonatal period or as chronic respiratory infections in older children.

BRONCHOGENIC CYSTS AND MIXED OR HYBRID PULMONARY LESIONS

Bronchogenic cysts are embryonic abnormalities considered to be a type of bronchopulmonary foregut malformation.[156] These cysts are thought to result from an abnormal budding of the primitive bronchial tree between weeks 4 and 8 of gestation, thus representing abnormal lung development at an early stage of ontogeny.[175] In most cases, bronchogenic cysts are asymptomatic in the first months of life. A notable exception is a mediastinal cyst that usually manifests as stridor.

Although in utero complications are less likely than with the other fetal lung lesions previously described, the propensity of these lesions to cause life-threatening postnatal complications warrants close attention throughout the prenatal period. Fetal intervention with intermittent or continuous drainage of cysts can prevent the secondary morbidity; definitive fetal surgery with thoracotomy has also been successful.[176]

SACROCOCCYGEAL TERATOMA

SCTs (Fig. 38.8) are one of the most common congenital neonatal tumors (1 per 40,000 live births).[177] A variety of tissues from the three primary germ layers are usually found, and the size of the tumor is quite variable.[178,179] Most SCTs are external, usually protruding from the perineal region. The majority include both solid and cystic components, with only 15% being entirely cystic.[180,181] Although usually benign, SCTs can cause significant secondary morbidity in selected cases because of the tumor's mass effect and vast blood supply.[182] With smaller tumors, complete surgical resection usually occurs after delivery under elective, controlled conditions. In extreme cases, the tumor can cause fetal congestive heart failure (usually high output failure), and even fetal demise if no treatment is performed.[131] Death is usually secondary to an enlarged tumor mass and associated polyhydramnios, resulting in preterm labor and delivery, with ultimate survival dependent on fetal lung maturity. Massive hemorrhage into the tumor with fetal exsanguination may occur spontaneously in utero or be precipitated by labor and delivery. Prenatal intervention may be necessary, including intrauterine transfusion or fetal surgery for those fetuses that develop significant secondary morbidity (e.g., hydrops).

Hypoplastic Left Heart Syndrome: Percutaneous and Fetoscopic Procedures

A variety of congenital heart defects (CHDs) may be considered for fetal intervention. To date, the most studied defects include severe aortic stenosis with evolving hypoplastic left heart syndrome (HLHS) and pulmonary valve atresia with an intact ventricular septum with evolving hypoplastic right heart syndrome.[183–187] HLHS and critical aortic stenosis with severely restricted or intact foramen ovale are associated with high neonatal mortality and poor long-term outcome. Prenatal relief of left atrial and pulmonary hypertension may promote normal pulmonary vascular and parenchymal development and improve short- and long-term outcomes. Fetal atrial balloon septostomy, laser perforation, and stenting of the foetal interatrial septum are the current options for fetal therapy.[188]

RATIONALE FOR FETAL CARDIAC INTERVENTION

Most CHDs can be safely repaired in infancy, with excellent surgical survival and long-term prognosis. For these defects, there would be no need for in utero intervention; and for many defects, in utero intervention would not be technically possible (e.g., arterial switch procedure for transposition of the great arteries). For other

defects, surgical correction itself may not be possible and the only option is staged surgical palliation, which is often associated with significant surgical morbidity and mortality.[183,189,190] As such, the risk of performing any fetal intervention must be balanced against the potential benefits of improving the anticipated outcome of surgery performed in the neonatal period to correct the specific cardiac defect. It is the intention of prenatal intervention for certain types of CHDs to reverse the pathologic process in an attempt to preserve cardiac structure and function and, thus, it is hoped, prevent serious postnatal disease. A secondary aim of prenatal intervention is to modify the severity of the disease and improve postnatal surgical outcomes.

DEFECTS AMENABLE TO IN-UTERO REPAIR

Certain CHDs cause aberrations in blood flow, which are usually secondary to valvular stenosis or regurgitation. Regardless of the etiology, the end result is often an abnormally developed ventricle.[3] Several case reports have characterized the progression of valvular stenosis to ventricular hypoplasia from reduced flow through the chamber during gestation.[128,191,192] It has been hypothesized that relief of valvular stenosis in utero could reverse the progression toward ventricular hypoplasia. In these cases, there may be a window of opportunity in which ventricular growth can be salvaged. Because most routine prenatal ultrasonographic screening is performed between 16 and 24 weeks gestation, the window of opportunity for prenatal intervention is likely between 20 and 26 weeks gestation.

To date, the defect most amenable to correction is severe aortic stenosis with evolving HLHS.[128,191–193] Without prenatal intervention, severe aortic stenosis can lead to marked left ventricular dysfunction, diminished flow through the left heart, arrest of left ventricular growth, ventricular fibroelastosis, and, consequently, HLHS. Aortic valve dilation may be performed percutaneously with ultrasound guidance. Optimal fetal positioning, placental location, or maternal habitus may require exposure of the uterus through an abdominal incision to obtain ideal access to the fetal thorax. These procedures have been performed with both maternal regional and general anesthesia, although general anesthesia is often preferred to obtain optimal uterine relaxation and an anesthetized fetus. Preliminary results are promising, but larger prospective investigations are warranted to determine long-term outcomes.[48]

TECHNICAL ASPECTS OF FETAL CARDIAC INTERVENTIONS

Open cardiac surgery on the fetus is not presently technically possible.[194–198] In humans, all of the reported procedures to date have been attempted using the transcutaneous or transuterine approach with ultrasound-guided access into the fetal heart.[185–187] Although hysterotomy would provide means for more direct fetal access (e.g., femoral artery, transumbilical or carotid artery access), maternal morbidity would be significantly increased and postoperative premature labor certain. After valvuloplasty, the fetus requires time for the ventricle to recover. Therefore any procedure that substantially increases the likelihood of early delivery would likely be counterproductive.

Although initial percutaneous techniques for fetal cardiac valvuloplasty were performed with only the mother receiving sedation,[185,186] recent advances in surgical techniques have led to the provision of maternal and fetal analgesia and anesthesia.[199] The mother usually receives general anesthesia. After ultrasonographic confirmation of placental location, the maternal abdomen and uterus are punctured with a 22-gauge spinal needle. An IM injection of fentanyl, atropine, and a NMBD is delivered to the fetus. A 19-gauge needle is subsequently directed into the fetal thorax, and access to the fetal heart is obtained. A small coronary balloon-tipped catheter is threaded over a guidewire through the needle, and passed through the stenotic valve or closed septum. The catheter balloon is then dilated, and blood flow is confirmed using Doppler ultrasonography (Fig. 38.9). The technique has been modified in certain cases, such that a laparotomy to expose the uterus is performed. Using this technique, better ultrasonography and ideal fetal positioning are possible to achieve optimal access to the fetal thorax.

ANESTHETIC MANAGEMENT FOR THE MOTHER

Fetal cardiac interventions are performed using a percutaneous technique or through a laparotomy incision with direct uterine exposure. The surgical approach will vary according to maternal habitus, placental position (anterior vs. posterior), and fetal position. For the less invasive percutaneous approach, the choice of a regional anesthetic accompanied by IV sedation for the mother is preferable for its favorable maternal hemodynamic profile. However, it must be remembered that although the placental transfer of sedative drugs administered to the mother may sedate the fetus, an anesthetized or immobile fetus is not guaranteed and in most cases direct delivery of medications to the fetus will be required. Excessive fetal movement makes most cardiac interventions impossible and even dangerous to both the fetus and mother.

Patients who received an epidural anesthetic technique required significantly more IV fluids but less IV opioid. The administration of large amounts of crystalloid and tocolytics during fetal surgery increases the risk of maternal pulmonary edema.[139,170] Neuraxial techniques (e.g., spinal, epidural, and combined spinal-epidural anesthesia) have been used in other percutaneous and fetoscopic procedures; a T4 sensory-level blockade is required. Neuraxial anesthesia provides no uterine relaxation and no analgesia or anesthesia to the fetus unless supplemented with IV maternal analgesics and sedatives (e.g., fentanyl, benzodiazepines, propofol) or otherwise delivered directly to the fetus. If there is a high suspicion of performing a laparotomy, spinal morphine may be delivered to the mother before the anesthetic induction for postoperative pain relief and resultant suppression of myometrial contractility after laparotomy.[191,192]

ANESTHETIC MANAGEMENT FOR THE FETUS

Anesthesia for percutaneous and fetoscopic interventions, of which fetal cardiac interventions are a significant subset, pose several unique challenges for the anesthesiologist. The combination of immature organ systems and the underlying cardiac anomaly places the fetus at considerable anesthetic risk. Unlike adults and older children, fetal cardiac output depends more on heart rate than on stroke volume. Because fetal myocardial contractility is likely maximally stimulated, the fetus has a limited ability to increase stroke volume. Therefore it is plausible that fetal patients with congenital heart disease and evidence of failure (i.e., hydrops) will exhibit more pronounced physiologic limitations. Notably, anesthetic-induced decreases in contractility, combined with intracardiac catheter manipulation in a structurally compromised heart, can result in fetal hypotension, bradycardia, and eventual cardiac collapse and death. It is generally accepted that neonates manifest a greater degree of hypotension in response to isoflurane and halothane at equipotent anesthetic concentrations compared with older children.[200,201] Because direct exposure of the fetus is not warranted during most cardiac interventions, intraoperative

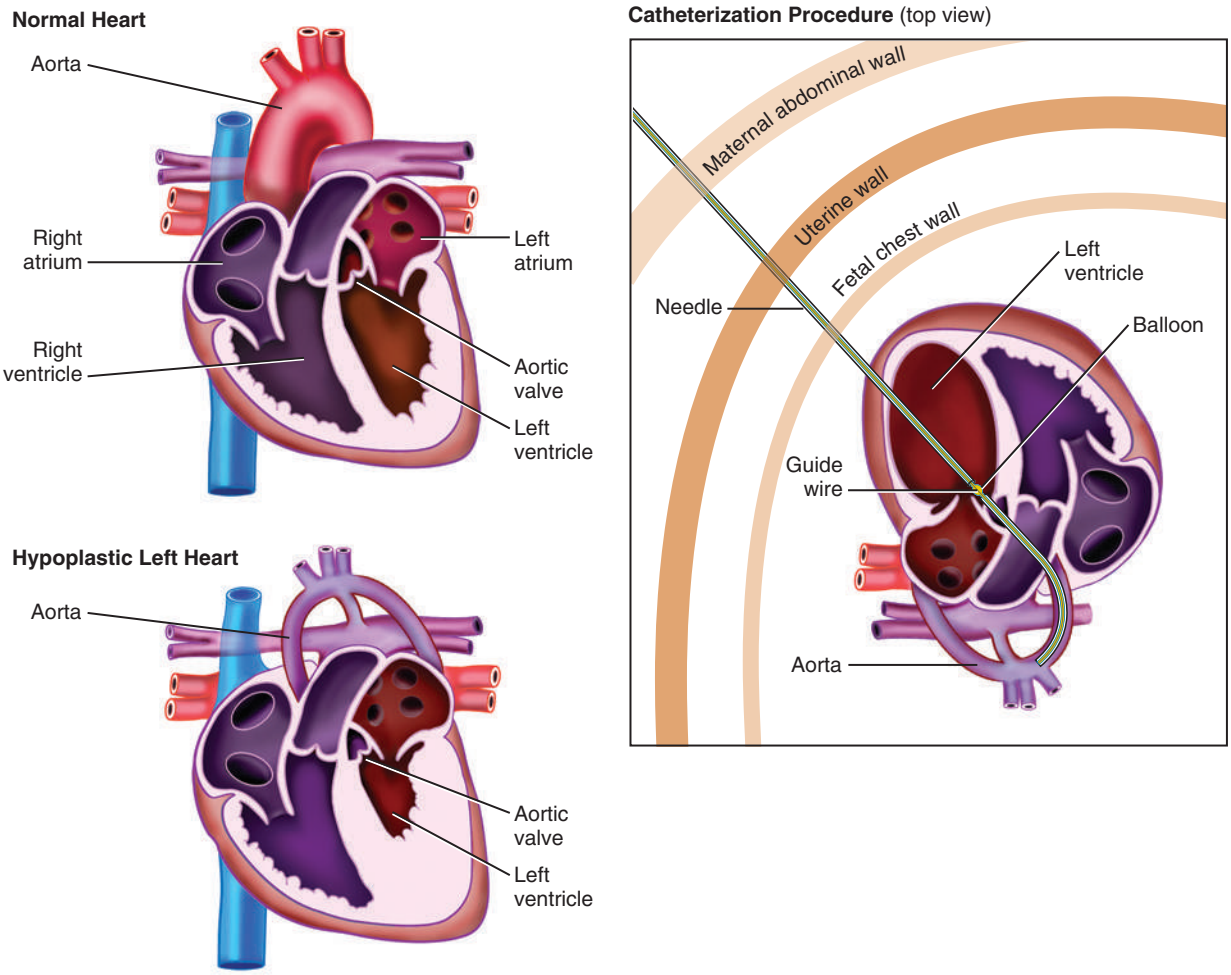

FIGURE 38.9 Technique for balloon dilation of a stenotic aortic valve in a fetus with hypoplastic left heart syndrome. (Reproduced with permission from *Dream Magazine*, Spring/Summer 2002. Boston: Children's Hospital Boston; 2002:20.)

monitoring is limited to echocardiography. An ultrasonographer continually monitors the fetal heart during placement of the intracardiac needle and during catheter balloon inflation. A continuous echocardiogram is also useful for measuring FHR, contractility, and volume status.

INTRAOPERATIVE FETAL RESUSCITATION DURING PERCUTANEOUS INTERVENTIONS

If fetal bradycardia (heart rate <100 beats/minute) or significantly reduced ventricular function develops, resuscitation proceeds immediately. Because direct vascular access to the fetus may not be immediately available, several other treatments can be used. Intracardiac and IM administration of epinephrine (1–2 µg/kg) may be used to treat severe sustained bradycardia. Other maneuvers improve uterine perfusion and hence fetal oxygenation and include increasing maternal mean arterial pressure to 15% to 25% above awake values with volume loading and ephedrine or phenylephrine, and decreasing uterine vascular resistance by ensuring adequate uterine relaxation. Occasionally, pericardial tamponade may impair cardiac function; needle drainage of the effusion may be necessary if the fetus is to survive. If fetal echocardiography indicates a decreased ventricular volume, an intracardiac blood transfusion with O-negative irradiated blood (5–10 mL/kg) may be indicated.

POSTOPERATIVE CONSIDERATIONS

The fetus is monitored postoperatively with intermittent ultrasonographic examinations. The incidence of premature contractions and labor is less after fetoscopic surgery than after open hysterotomy.[37,38] Fetoscopic intervention also appears to have reduced requirements for tocolysis and a reduced rate of premature delivery.[38] (If early delivery should occur, many of these fetuses are considered nonviable owing to their young gestational age [usually <24 weeks gestation] and serious cardiac disease.)

Other Diseases Eligible for Fetoscopic Procedures

TWIN–TWIN TRANSFUSION SYNDROME

Twin–twin transfusion syndrome (TTTS) is a serious complication occurring in 10% to 15% of monozygotic monochorionic twin pregnancies.[202] Although all monochorionic twin pregnancies demonstrate one or more placental vascular anastomoses, TTTS represents a pathologic form of circulatory imbalance between the monochorionic twin fetuses.[203] As a result of this imbalance, a net fetofetal transfusion occurs, from one twin (the donor) to the other (the recipient) (Fig. 38.10). Symptoms develop rapidly and,

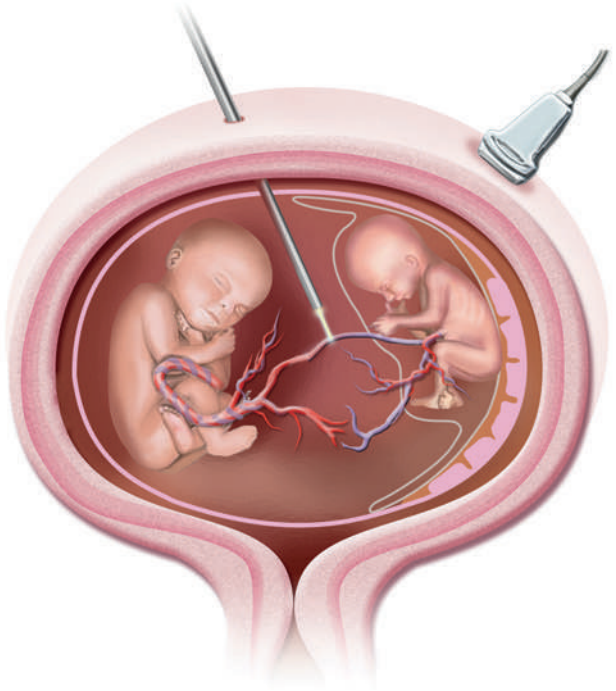

FIGURE 38.10 Schematic representation of umbilical cord ligation in twin reversed arterial perfusion sequence. (Courtesy T.M. Crombleholme, MD.)

in the donor twin, include hypovolemia, oliguria, oligohydramnios, and growth retardation. In turn, the recipient twin develops hypervolemia, polyuria, polyhydramnios, and signs of circulatory volume overload, resulting in congestive heart failure.[202–206] In severe cases, untreated TTTS may result in intrauterine fetal death and miscarriage. Even if twins with TTTS survive, there remains a high incidence of secondary neurologic and pulmonary morbidities.

Fetoscopic laser photocoagulation of the communicating vessels associated with TTTS is based on three fundamental assumptions: (1) the syndrome occurs in the presence of vascular communications between fetuses in a monochorionic gestation, (2) obliteration of these vessels can halt the pathophysiologic process, and (3) both deep and superficial communications can be interrupted at the surface of the placenta.[207] Fetoscopic laser surgical occlusion of superficial communicating vessels is associated with a reported survival rate of 55% to 83% and a reduced neurologic complication rate (5%) among survivors.[202,204]

There are few data on the reported anesthetic techniques used for fetoscopic laser ablation. The procedure has been performed with local, general, epidural, and combined general and epidural anesthesia.[8,208–210] Factors that may influence the anesthetic technique include (1) the planned surgical approach and probability of converting to open fetal surgery; (2) the likelihood of surgical perturbation of innervated fetal tissues; (3) maternal preference; and (4) a history of prior uterine activity. The surgical approach for fetoscopic laser photocoagulation is determined by (1) the location of the placenta (anterior vs. posterior), (2) the position of the fetuses, and (3) the potential window(s) for trocar insertion.[211]

TWIN REVERSED ARTERIAL PERFUSION SEQUENCE

Twin reversed arterial perfusion (TRAP) sequence denotes a common pathophysiology of several different conditions, all of which describe a twin pregnancy in which one twin is normal and the second twin exhibits multisystem malformations, including anencephaly or acardia. The twin with the hemodynamic advantage is denoted as the "pump" twin, perfusing deoxygenated blood in a retrograde direction to the other twin, "the recipient twin." The term *reversed perfusion* is used to describe this scenario because blood enters the acardiac or anencephalic twin through its umbilical artery and exits through the umbilical vein. This eventually places the normal or "pump" twin at a hemodynamic disadvantage because this normal twin provides cardiac output to both itself and the nonviable sibling. This anomaly places the pump twin at risk of cardiac overload and congestive heart failure, often with associated hepatosplenomegaly.

Perinatal complications with TRAP sequence range in severity, with reported death rates for the pump twin ranging from 39% to 59% in untreated pregnancies.[212] Treatment options include observation, medical therapy with digoxin and indomethacin, selective delivery, umbilical cord blockade with a coil, and fetoscopic cord ligation. Although all endoscopic procedures have the primary aim of interrupting umbilical cord blood flow to the nonviable twin, this invasive technique is generally used after failed medical therapy or after signs of cardiac failure in the viable twin.[213,214]

NEEDLE ASPIRATION AND PLACEMENT OF SHUNTS

A variety of fetal disorders may benefit from in utero needle aspiration or shunt placement. These disorders include posterior urethral valves, aqueductal stenosis, fetal hydrothorax, ovarian cyst, and fetal ascites. Various shunts have been attempted to provide long-term decompression, with variable results.[209]

The EXIT Procedure

EX utero **I**ntrapartum **T**reatment, or the EXIT procedure, was initially described as a method for reversal of tracheal occlusion in fetuses with prenatally diagnosed severe congenital diaphragmatic hernia that had undergone in utero tracheal clip application.[215] Although these infants demonstrated no reduced morbidity compared with those who underwent conventional treatment, this novel technique provided a new therapeutic option for fetuses with a variety of potentially fatal diseases. Improvements in prenatal imaging and widespread use of prenatal ultrasonography have increased the identification of potentially lethal fetal structural malformations, which has had a direct impact on perinatal management and outcomes.

Also referred to as the OOPS procedure (**O**peration **O**n **P**lacental **S**upport),[216] the EXIT procedure allows for a controlled delivery and intrapartum assessment strategy to treat fetuses with certain life-threatening diseases. By maintaining uteroplacental circulation with only partial delivery of the infant, crucial time is provided to perform procedures critical to infant survival. These procedures include direct laryngoscopy, bronchoscopy, intubation, tracheostomy, tumor decompression and resection, and extracorporeal membrane oxygenation (ECMO) cannulation before exteriorizing the entire infant and clamping the umbilical cord (Fig. 38.11). In this way, continuous oxygenation is maintained at all times to the threatened infant, thereby improving the chances of overall survival. The EXIT procedure is now used for infants in whom prenatal imaging suggests a very low probability of survival with conventional treatment methods. This group includes fetuses with known tracheal obstruction and other life-threatening airway abnormalities, as well as those who will likely require

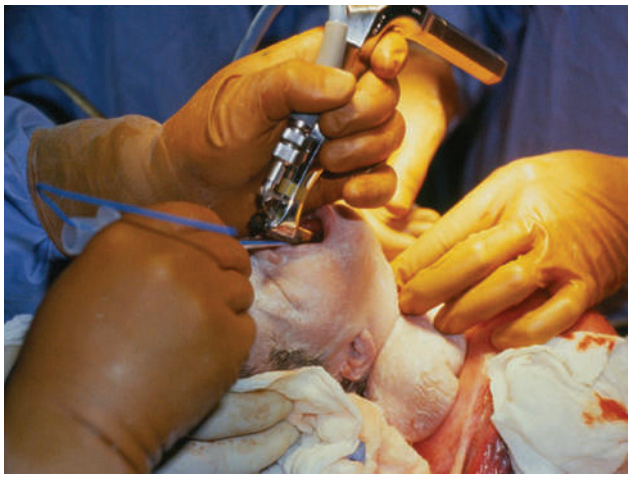

FIGURE 38.11 Fetal rigid bronchoscopy during an ex utero intrapartum treatment procedure. (Courtesy N. Scott Adzick, MD, Children's Hospital of Philadelphia.)

FIGURE 38.12 Newborn with a massive oropharyngeal cervical teratoma immediately after ex utero intrapartum treatment was performed to secure the airway. Immediate resection of the teratoma followed in an adjacent operating room.

extracorporeal membrane oxygenation (ECMO) support (i.e., congenital cardiac disease and diaphragmatic hernia).

Unlike many other fetal interventions, however, a planned delivery of the infant is the end result of these interventions. This unique difference creates significant increases in maternal morbidity because these procedures require complete uterine relaxation and serious maternal hemorrhage can occur.[132] An intimate understanding of the EXIT procedure, the fetal pathophysiology involved, and pregnancy-induced alterations directly affecting anesthesia care is required to minimize maternal and fetal morbidity and mortality.

FETAL DISEASES ELIGIBLE FOR THE EXIT PROCEDURE

Cervical Teratoma

Cervical teratomas are rare (1 per 20,000–40,000 live births) and can extend from the mastoid process to the sternal notch inferiorly and to the trapezius muscle posteriorly. They can also invade the oral floor and extend into the anterior mediastinum. Many of the larger teratomas diagnosed prenatally cause maternal polyhydramnios, which is secondary to esophageal compression by the tumor and impaired fetal swallowing. Most of these tumors are benign but are associated with substantial mortality caused by airway compression and difficulty in establishing an adequate airway after delivery (Fig. 38.12).[94] Of neonates with cervical teratomas, 30% die of airway obstruction shortly after delivery[217,214]; for infants whose tumors are not diagnosed prenatally, mortality rates are even greater.[133,159] In addition, some larger tumors may interfere with normal delivery methods and necessitate emergent alterations in maternal care, placing the mother at increased risk.[94,218]

Until recently, treatment options for infants with cervical teratomas who survived the intrauterine period were limited. The standard of care incorporated scheduled cesarean section followed by various airway maneuvers, including the establishment of a surgical airway. Even with skilled help immediately available, dismal outcomes were common.[94,159,217] Despite securing the airway, critical time is needed to perform this task, often at the expense of neonatal oxygenation. With the introduction of the EXIT procedure, precious time is provided to locate the trachea and provide a definitive airway before clamping the umbilical cord, thereby maintaining continuous fetal oxygenation and decreasing morbidity and mortality.

FIGURE 38.13 Fetus (with a cystic hygroma) that underwent ex utero intrapartum treatment to establish a surgical airway before delivery. (Courtesy N. Scott Adzick, MD, Children's Hospital of Philadelphia.)

Cystic Hygroma

Cystic hygromas arise from the failure of the jugular lymph sacs to join the lymphatic system early in fetal development, resulting in the development of endothelium-lined cystic spaces that eventually compress normal surrounding structures. This compression may result in fetal hydrops, including skin edema, ascites, and pleural or pericardial effusions (Fig. 38.13).[133,159] In infants with isolated cervical cystic hygroma and no evidence of hydrops, airway compromise at birth or shortly thereafter is the

main therapeutic concern; these infants are candidates for EXIT procedures.

Congenital High Airway Obstruction Syndrome

Congenital **H**igh **A**irway **O**bstruction **S**yndrome (CHAOS) is a clinical syndrome consisting of extremely large echogenic lungs, flattened or inverted diaphragms, a dilated tracheobronchial tree, ascites, and evidence of nonimmune hydrops, including fetal ascites, placentomegaly, and pleural or pericardial effusions.[219–221] Airway obstruction may be because of laryngeal atresia, laryngeal cyst, or tracheal atresia. Diagnosis of prenatal CHAOS is confirmed by ultrasonographic evidence of complete or near-complete upper airway obstruction. Most diagnostic findings result from increased intratracheal pressure and distention of the tracheobronchial tree secondary to the accumulation of fluid in the lungs. Cardiac changes include the appearance of an elongated heart, septal shift, and small, compressed heart chambers.[159]

Management guidelines for fetuses with CHAOS are not definitive. In third-trimester fetuses with a diagnosis of CHAOS and no evidence of hydrops, there is most probably incomplete airway obstruction, and management is aimed at establishing an airway before complete delivery. This subset of fetuses would likely benefit from an EXIT procedure.[159,222] Those fetuses with a diagnosis of CHAOS made in the second trimester and those with evidence of complete airway obstruction and/or nonimmune hydrops present a dilemma, because insufficient data exist to determine their best treatment options.

Congenital Goiter

Congenital goiter is associated with fetal hypothyroidism, euthyroidism, or hyperthyroidism. Goiter associated with fetal hypothyroidism is almost always associated with the transplacental passage of a thyroid-stimulating immunoglobulin G antibody from the mother. Such antibodies are present in 90% of women with Graves disease. These antibody levels may not reflect maternal thyroid status, making the fetus of any woman with Graves disease at increased risk for fetal goiter. Less common causes include iodine deficiency, iodine intoxication, congenital metabolic disorders of thyroid hormone synthesis, or hypothalamic-pituitary hypothyroidism.

Ultrasonographic findings of fetal hyperthyroidism include cardiac hypertrophy, tachycardia, or nonimmune hydrops fetalis. Fetal hypothyroidism may be associated with fetal cardiomegaly and heart block. Fetal blood sampling is required to determine the fetal thyroid status.[159,223,224] The possibility of significant airway compression immediately after delivery is similar for all fetuses with goiter. In severe cases, even the presence of experienced personnel in the delivery room may not ensure prompt ability to secure the airway. These infants may benefit from the EXIT procedure; it can provide time to identify and secure the compromised airway.

EXIT TO ECMO

In addition to airway management, the EXIT procedure may be considered for other instances in which separation from uteroplacental support is expected to cause critical cardiac or pulmonary compromise. Fetuses with congenital heart disease who are expected to need emergent ECMO at birth and fetuses with poor-prognosis congenital diaphragmatic hernias may benefit from the "EXIT to ECMO" strategy.[132,225] Neonates undergoing this procedure are partially delivered via the EXIT procedure, and arterial and venous cannulas are inserted while uteroplacental perfusion is maintained. Although congenital diaphragmatic hernia remains the most common disease entity considered for potential EXIT to ECMO therapy, this technique has been used for neonates with other disease processes associated with almost certain chance of immediate cardiorespiratory collapse after conventional delivery.

Intraoperative Considerations

A multidisciplinary team consisting of an obstetrician, pediatric surgeon, ultrasonographer, anesthesiologist, neonatologist, scrub nurses, and technicians provides the expertise in each respective field to aid in the overall success of the procedure. In cases in which immediate surgical intervention is planned (e.g., resection of a neck mass), a prepared adjacent operating room with separate personnel should be available. A meeting of the entire team is held before the start of the case to clearly identify individual roles and to discuss any concerns or questions. This is also a good opportunity to address any clinical changes, either in radiographic findings or in fetal position, or other factors that may alter the surgical plan.

Uterine Relaxation and Perfusion

To preserve maternal-fetal gas exchange at the placental interface, ensure fetal oxygenation, and avoid life-threatening hypoxemia, it is of primary importance to ensure complete uterine relaxation throughout the duration of fetal uteroplacental support. Factors affecting uterine blood flow include, but are not limited to, anesthetic induction agents, maternal hyperventilation, maternal hypotension, maternal catecholamine release, and other causes of increased noradrenergic activity and uterine tone. Any increase in uterine vascular resistance decreases uterine perfusion, in the same way as uterine contractions do. Of all factors ensuring the overall success of the EXIT procedure, minimal uterine vascular resistance is the most important because decreases in uterine blood flow will cause fetal hypoxemia, acidosis, and, potentially, fetal demise.[51]

Surgical Procedure

After the hysterotomy site has been created and hemostasis achieved, the fetal head, neck, and shoulders are delivered. Because many of these procedures involve large neck masses, a generous hysterotomy incision is needed to partially deliver the fetus without injury to the mass or fetus. Furthermore, if a uterine contraction occurs at this time, inadvertent expulsion of the fetus could occur, interrupting the fetoplacental unit and thus critically jeopardizing the viability of the fetus. In some cases, a fetal extremity may be delivered to apply a pulse oximetry probe and to obtain IV access.[174,226] Although the fetus is anesthetized via placental transfer of maternally administered inhalational anesthetics in most cases, additional analgesia and paralytics are administered (e.g., fentanyl, atropine, muscle relaxant). The additional medications may be given as a single IM dose in an upper extremity or can alternatively be delivered under ultrasound guidance before hysterotomy. An advantage to earlier administration is increased time for fetal absorption via the IM route. If peripheral IV access is obtained, additional medications can be given through this route.

ACCESS TO THE FETAL AIRWAY

Most EXIT procedures are currently performed to access a compromised fetal airway before delivery; successful access depends on meticulous preoperative evaluation and careful preparation.[227,228] Portions of the trachea can be completely compressed and distorted such that even successful intubation may result in an inability to achieve adequate ventilation. For this reason, most surgeons perform

a direct laryngoscopy and rigid bronchoscopy to examine the status of the fetal airway. In one series, successful tracheal intubation by conventional means was reported in 77% of cases.[132] In those cases in which tracheal intubation is impossible, a surgical tracheostomy can be performed as soon as the trachea is identified. The trachea can be located with the aid of preoperative radiographic studies, often identifying the tracheal location relative to fixed external anatomic landmarks. Gentle surgical palpation may also aid in the identification of cartilaginous tracheal rings. In cases in which the former options have failed, ultrasonography with the sterile probe inserted directly into the surgical incision may help to locate the trachea.[229] When tracheal rings are identified, the trachea may be accessed directly with a tracheal tube by tunneling through the fetal soft tissue, or with the aid of a retrograde wire inserted by the Seldinger technique. The trachea, exposed through a neck incision, may be incised via a temporary tracheotomy to allow passage of a feeding tube or wire from the trachea to the mouth or nose. The guidewire is then attached to the tracheal tube, which is then pulled down into the proper position. After suturing the tracheal tube securely to the mouth, the tracheotomy can then be closed.

Regardless of the method used to secure the trachea, the anesthesiologist must be prepared to control ventilation in the fetus. In some institutions, an anesthesiologist may be scrubbed at the operative field to assume this responsibility. In other institutions, one of the surgeons or neonatologists assumes this role. Adequate ventilation may be difficult to achieve for several reasons. Certain types of tumors–specifically cervical teratomas–may secrete thick mucus into the trachea and this must be aggressively removed before ventilation. As soon as the airway is satisfactorily cleared, surfactant should be administered via the tracheal tube to diminish expected airway resistance. Surfactant is provided for two principal reasons. First, the majority of infants treated for such lesions are delivered at some point before term and their pulmonary development (considered both by gestational age and underlying pathophysiology) cannot be assumed to be normal. Second, the thick mucoid secretions and the aggressive lavage necessary to clear them may interrupt the normal surfactant layering and functionality, suggesting that surfactant therapy may provide a benefit if administered before lung ventilation. These steps should result in increases in fetal oxygen saturation to greater than 90%. If this does not occur, the position of the tracheal tube should be rechecked and the lungs should be auscultated with a sterile stethoscope. Ultrasound examination for the presence of air bronchograms may also be used to confirm tracheal intubation. Ventilation occurs most commonly with the aid of a sterile Jackson-Rees circuit. When adequate ventilation has been established, the fetus can be delivered.

Delivery of the Infant and Maternal Management

Before umbilical cord clamping and delivery, coordination between the surgery and anesthesia teams is crucial to prevent uterine atony and excessive maternal hemorrhage. Because a decrease in the tocolytic agent, whether it is an inhalational or an IV agent, would increase uterine vascular resistance and decrease fetal oxygenation, reversal of the tocolysis must not occur before the umbilical cord is clamped. However, at clamping, a near-total reversal of tocolysis is required to limit uterine bleeding. This is best achieved with an inhalational anesthetic with a low-solubility (e.g., desflurane). As the cord is clamped, the anesthetic is immediately discontinued and oxytocin is administered as a bolus followed by a continuous infusion and titrated to uterine response (e.g., 40 units oxytocin in 500 mL of normal saline solution over 30 minutes, followed by 20 units over 8 hours). Additional uterotonic medications may be necessary and must be immediately available should uncontrolled maternal hemorrhage occur.[230] These medications include methylergonovine, carboprost, and calcium carbonate. Anticipation of massive and rapid maternal hemorrhage is essential. Appropriate IV access (e.g., rapid infusion catheters, introducer sheaths) with a rapid infusion device in place for blood product administration may be lifesaving, should uncontrolled and persistent bleeding occur. In cases of uncontrolled hemorrhage despite maximal drug therapy, a hysterectomy may be necessary. When maternal hemostasis has been achieved, uterine tone restored, and the placenta delivered, then a low-dose inhalational anesthetic and nitrous oxide can be administered, provided that the mother is hemodynamically stable.

A separate team of neonatologists, anesthesiologists, and nurses should be available for the neonate because additional medications, blood products, and vascular access may be needed. A brief physical examination, confirmation of bilateral breath sounds, and hemodynamic stability must be ensured soon after delivery. In some instances, immediate surgical intervention is planned, necessitating entirely separate anesthetic, surgical, and nursing teams in an adjacent OR as the maternal abdomen is closed.

Postoperative Considerations

Mothers recovering from an EXIT procedure differ from those who undergo standard cesarean deliveries. Potential postoperative complications include wound dehiscence, infection, bleeding, and urinary retention.[132] Although every attempt is made to place the hysterotomy incision in the lower uterine segment during EXIT procedures, those patients with anterior placentas may require incisions in different areas of the uterus. As a result, these patients are at increased risk of uterine rupture in any subsequent pregnancy. Practitioners should also consider the fact that, unlike with a standard cesarean section, the parents cannot immediately interact with or even view their neonates after delivery. Because many of these neonates undergo immediate surgical intervention, the parents' first glimpse of their child will be of an intubated, sedated child with monitors, invasive catheters, and swollen, distorted facies. Continued emotional support, social services, and education will help ease this transition.

Movement Toward Intervention for Non–Life-Threatening Diseases: Myelomeningocele

At present, nearly all human fetal interventions are performed to prevent almost certain fetal demise secondary to a known congenital defect or pathophysiologic process. Myelomeningocele (MMC) is the first nonfatal birth defect to be treated in utero. MMC affects 0.5 to 1 per 1000 live births annually, with variations in both population and geography.[231–233] At least 75% of affected individuals reach early adulthood; most deaths occur during infancy and the preschool years secondary to respiratory and neurologic complications.[234] There is significant risk associated with this early fetal intervention. Many infants with MMC may be delivered prematurely as a direct result of intrauterine intervention, further adding to the risks of an already compromised infant.[233] Some have argued that because MMC is a nonlethal defect, intrauterine intervention for potential reduced secondary morbidity may not justify the significant maternal morbidity or fetal mortality

associated with this procedure. However, the severe morbidity associated with MMC combined with the promising results of animal research have led to prenatal intervention for this disorder. Initial human outcomes demonstrated some improvement in secondary morbidity.[233,235,236] The Management of Myelomeningocele Study (or the MOMS trial) demonstrated a reduced need for placement of cerebrospinal fluid shunts and improved motor outcomes (e.g., earlier ambulation) at 30 months in the fetal intervention group, compared with infants whose repairs were deferred until after delivery. Nevertheless, significant maternal and fetal morbidities were reported.[237]

Future Considerations

With the advances in surgical and anesthetic techniques and technologies, significant progress may be made in mid-gestation fetal intervention, and in moving from treatment of only life-threatening fetal pathologic processes toward preemptive management of fetal disorders that are not necessarily life-threatening but have significant, disabling postpartum morbidities. However, these benefits may have to be balanced against the possibility of long-term neurocognitive disorders in anesthetized fetuses, particularly in those fetuses undergoing prenatal repair of anomalies that are not life-threatening, that have been demonstrated in rodents and animals but not in humans.[238–242]

The particular challenges for anesthesiologists are to develop methods to provide selective fetal anesthesia and analgesia, and techniques of targeted uterine relaxation such that safer, specifically tailored anesthesia may be provided to all patients involved in the fetal intervention. Furthermore, techniques and technologies that will enhance tocolysis and retard PPROM and preterm labor will allow increased time for fetuses to heal and mature in utero, while reducing the incidence of postoperative pulmonary edema in mothers. Finally, enhanced fetal monitoring will help the anesthesiologist provide better care for the fetus both in utero and in the postoperative period. With such advances, the provision of fetal anesthesia may become a more routine part of pediatric surgical and anesthetic practice, bringing with it new opportunities for practice and research, and new problems to be solved.

ANNOTATED REFERENCES

Boat A, Mahmoud M, Michelfelder EC, et al. Supplementing desflurane with intravenous anesthesia reduces fetal cardiac dysfunction during open fetal surgery. *Paediatr Anaesth*. 2010;20(5):748-756.

In a retrospective study, Boat and colleagues found that early institution of high concentrations of volatile agents for extended periods before hysterotomy resulted in the development of intraoperative fetal bradycardia, most notably when desflurane was used as the maintenance agent. Based on their findings, they suggest alternative utilization of supplemental IV anesthesia with propofol and remifentanil until just before the hysterotomy incision is made, at which point high volatile-anesthetic concentrations may be used to achieve the desired uterine relaxation.

Fink RJ, Allen TK, Habib AS. Remifentanil for fetal immobilization and analgesia during the ex utero intrapartum treatment procedure under combined spinal-epidural anaesthesia. *Br J Anaesth*. 2011;106(6):851-855.

The authors report three cases of ex utero intrapartum treatment performed under neuraxial anesthesia, with maternal administration of remifentanil used to provide fetal immobilization and analgesia via placental transfer. No clinically significant maternal sedation or respiratory depression were observed. In all cases, the authors argue, remifentanil provided adequate fetal immobilization and obviated the need to administer other analgesics or NMBDs.

Ngamprasertwong P, Michelfelder EC, Arbabi S, et al. Anesthetic techniques for fetal surgery: Effects of maternal anesthesia on intraoperative fetal outcomes in the sheep model. *Anesthesiology*. 2013;118(4):796-808.

Using an instrumented mid-gestational ewe model, the authors compared maternal and fetal hemodynamics, acid-base status, and left ventricular function in the setting of both high-dose desflurane anesthesia and lower-dose desflurane anesthesia with supplemental infusions of propofol and remifentanil. In this crossover design study, high-dose desflurane resulted in more maternal hypotension, reduced uterine blood flow, and greater fetal acidosis when compared with the lower-dose desflurane/intravenous agent technique.

Ngan Kee WD, Khaw KS, Tan PE, et al. Placental transfer and fetal metabolic effects of phenylephrine and ephedrine during spinal anesthesia for cesarean delivery. *Anesthesiology*. 2009;111(3):506-512.

The authors randomly assigned 104 healthy parturients undergoing elective cesarean section under spinal anesthesia to receive infusions of either phenylephrine or ephedrine, titrated to maintain approximate baseline systolic blood pressure. The authors found that, although ephedrine crosses the placenta to a greater extent and undergoes less early metabolism (or redistribution) in the fetus compared with phenylephrine, its associated increased fetal concentrations of lactate, glucose, and catecholamines may favor phenylephrine as the preferred vasopressor for such indications, despite historical evidence suggesting uteroplacental blood flow may be better maintained with ephedrine.

Tran KM, Maxwell LG, Cohen DE, et al. Quantification of serum fentanyl concentrations from umbilical cord blood during ex utero intrapartum therapy. *Anesth Analg*. 2012;114(6):1265-1267.

The authors quantified the concentration of fentanyl in umbilical vein blood drawn following IM injection from 13 human fetal subjects undergoing EXIT procedures. The median dose of fentanyl was 60 μg (range, 45-65 μg) for fetuses with a mean weight at delivery of 3000 g. The median time between IM administration of fentanyl and collection of the sample was 37 minutes (range, 5-86 minutes). Fentanyl was detected in all of the samples, with a median serum concentration of 14.0 ng/mL (range, 4.3-64.0 ng/mL).

Summary

ANESTHESIOLOGISTS COMMONLY PROVIDE CARE TO CHILDREN who have suffered traumatic injuries of varying complexity. They range from the healthy, older child with an isolated elbow fracture to the infant with a life-threatening epidural hematoma. The anesthesiologist should view the management of children with traumatic injuries as a continuum of care that may originate in the prehospital setting with emergency medical services (EMS), progress to the emergency department, and continue to the operating room, the postanesthesia care unit (PACU), and the intensive care unit (ICU). Anesthesiologists should be integrated into all phases of care of the injured child, with the possible exception of the prehospital setting. The care required to properly manage the injured child may be complex but can be effectively accomplished in a collaborative environment incorporating a standardized process for initial evaluation and management.[1] Anesthesiologists should be familiar with these processes to effectively continue this care into the perioperative setting.

Anesthesiologists provide much needed expertise in the care of injured children. Operative interventions demand the full involvement of the anesthesiologist. In many institutions, anesthesiologists also provide emergency airway and critical care management. In addition, anesthesiologists are highly skilled in airway management, ventilation, hemodynamic resuscitation, metabolic management, and control of pain, all of which can be important in the care of the injured child. Despite major reductions in the overall mortality rate for pediatric trauma within recent years, unintentional injuries remain the leading cause of death and disability in the pediatric population of the United States.[2] Injury has also emerged as the most common public health threat to children around the world.[3]

This chapter reviews the key principles of anesthesia management for children with traumatic injuries. This discussion is intended to augment the principles established in the widely accepted Advanced Trauma Life Support (ATLS) program, which is produced by the American College of Surgeons Committee on Trauma.[4] Additional resources for the management of the pediatric trauma patient include the Advanced Pediatric Life Support (APLS) course administered by the American Academy of Pediatrics and the American College of Emergency Physicians.[5] Many of the topics discussed in this chapter are currently being investigated to determine the most effective strategy, including fluid resuscitation, evaluation of the cervical spine, and prehospital tracheal intubation.

Epidemiology of Pediatric Trauma

Injuries are the most common cause of death within the United States for children older than 1 year of age[6]; road injuries are the leading cause of death among adolescents globally.[7] Approximately 20,000 children die annually in the United States as a result of trauma. Most traumatic injuries in children result from motor vehicle accidents (the leading cause of death), falls, nonaccidental trauma, drowning, and extremes of temperature. The epidemiology of trauma reflects its continued growth as a significant health risk for children of the world. Table 39.1 lists the death rates for traumatic causes of childhood death within the United States in 2013.[2] Motor vehicle trauma is a major threat to the health of children in the United States. This has spurred research to identify methods to enhance prevention strategies.[8–10] Unintentional injuries consistently rank as the leading causes of death among children older than 1 year of age.[11]

Pediatric and adult injury patterns and their corresponding treatment protocols differ.[12] Head injuries are the leading cause of death among children. One explanation for this is the proportionately larger (and heavier) head of children compared with adults. Thoracic injuries are the second leading cause of death for pediatric trauma patients. Because of increased rib cage pliability from a lack of bony calcification and the presence of a flexible cartilaginous component, severe internal thoracic and upper abdominal injuries can occur in children without obvious external signs such as rib fractures. Blunt abdominal trauma frequently can be treated with close observation, avoiding operative intervention. Penetrating abdominal trauma usually requires surgical exploration. However, diagnostic laparoscopy is being used in

lieu of exploratory laparotomy in hemodynamically stable children to evaluate and repair many types of abdominal injuries.[13]

Nonaccidental Trauma

Nonaccidental trauma, also referred to as shaken baby syndrome or child abuse, is an epidemic that continues to grow in virtually every part of the world. Although 3 million reports of nonaccidental trauma are filed every year in the United States, most experts believe that this represents less than one-third of the actual number of cases as many go unreported.[14,15] The youngest children, particularly infants, are the most vulnerable to mistreatment (Fig. 39.1). Every state has stringent laws for reporting nonaccidental trauma. These laws are designed to assist the health care provider who suspects mistreatment and to punish health care providers who do not appropriately report potential abuse and neglect. It is the responsibility of every physician who is involved in a child's care, including the anesthesiologist, to be aware of the potential for nonaccidental trauma in all infants and children and to report all suspicious observations to the appropriate authorities.[16]

Characteristics of nonaccidental trauma include a history inconsistent with the characteristics and extent of the injuries as well as a delay in obtaining medical care.[17,18] Children experiencing nonaccidental trauma have a greater level of injury severity on average when compared with children sustaining injuries from accidental trauma.[19,20] Nonaccidental trauma should be considered when the history appears suspicious. Funduscopic examination may disclose retinal hemorrhages or papilledema, which suggests forceful shaking of the head or increased intracranial pressure (ICP), respectively. Examination of the skin may show bruises, burns, or other injuries in several stages of healing (Fig. 39.2). A skeletal survey may reveal multiple fractures of various ages occurring typically at the metaphysis of long bones. Occasionally, a child who has previously been silent in the company of the parents or caregiver reveals details to operating room or recovery room personnel about the events surrounding his or her injuries. These reports should be carefully documented and conveyed to the appropriate personnel. Mistreated children are often terrified of painful procedures, and the need for sensitivity as well as reassurance in these settings cannot be overemphasized.

The anesthesiologist encountering a potential victim of nonaccidental trauma may be in a position to provide the first impartial assessment of the child's status.[21] Physicians, nurses, and other professionals who provide initial resuscitation may be preoccupied with treating the child's life-threatening injuries. Historical data associated with the event may be inaccurate or fictitious at the time of initial presentation. A careful evaluation by the anesthesiologist in preparation for operative intervention may reveal the first objective evidence of nonaccidental trauma. Indications of mistreatment may be subtle, ranging from lack of parental availability for perioperative evaluation to the irrational refusal of consent for a necessary operative intervention.[22,23]

TABLE 39.1 Death Rates for Traumatic Causes of Childhood Death in the United States (2013)[a]

	AGE (years)				
Cause of Death	**1–4**	**5–9**	**10–14**	**15–19**	**Overall (1–19)**
Unintentional/ Accidents	8.3	3.6	3.8	17.3	8.3
Assault/homicide	2.1	0.6	0.7	6.6	2.6
Intentional/Self-harm or suicide			1.9	8.3	2.7

Prehospital Care of the Pediatric Trauma Patient

TRAUMA SYSTEMS

The evolution of pediatric trauma systems has significantly improved outcomes and quality of life for trauma victims.[24,25] Countries such as the United States have a trauma system philosophy more in line with the military approach in which prehospital personnel, such as paramedics, are the first team summoned to make rapid assessments, initiate efforts at stabilization, establish radio contact with the medical facility, and transport the child to the trauma center as rapidly as possible.[26] This philosophy of minimizing the time on the scene and emphasizing prompt transport to the closest trauma center is termed *scoop and run*.

In parts of Canada and several European countries, initial resuscitation of injured children is commonly performed by physicians who are charged with evaluating the child at the scene, securing the airway, initiating resuscitative measures to maintain hemodynamic stability, and transporting the child to an appropriate trauma center. Instituting these management procedures may result in additional time on the scene. This approach has been termed

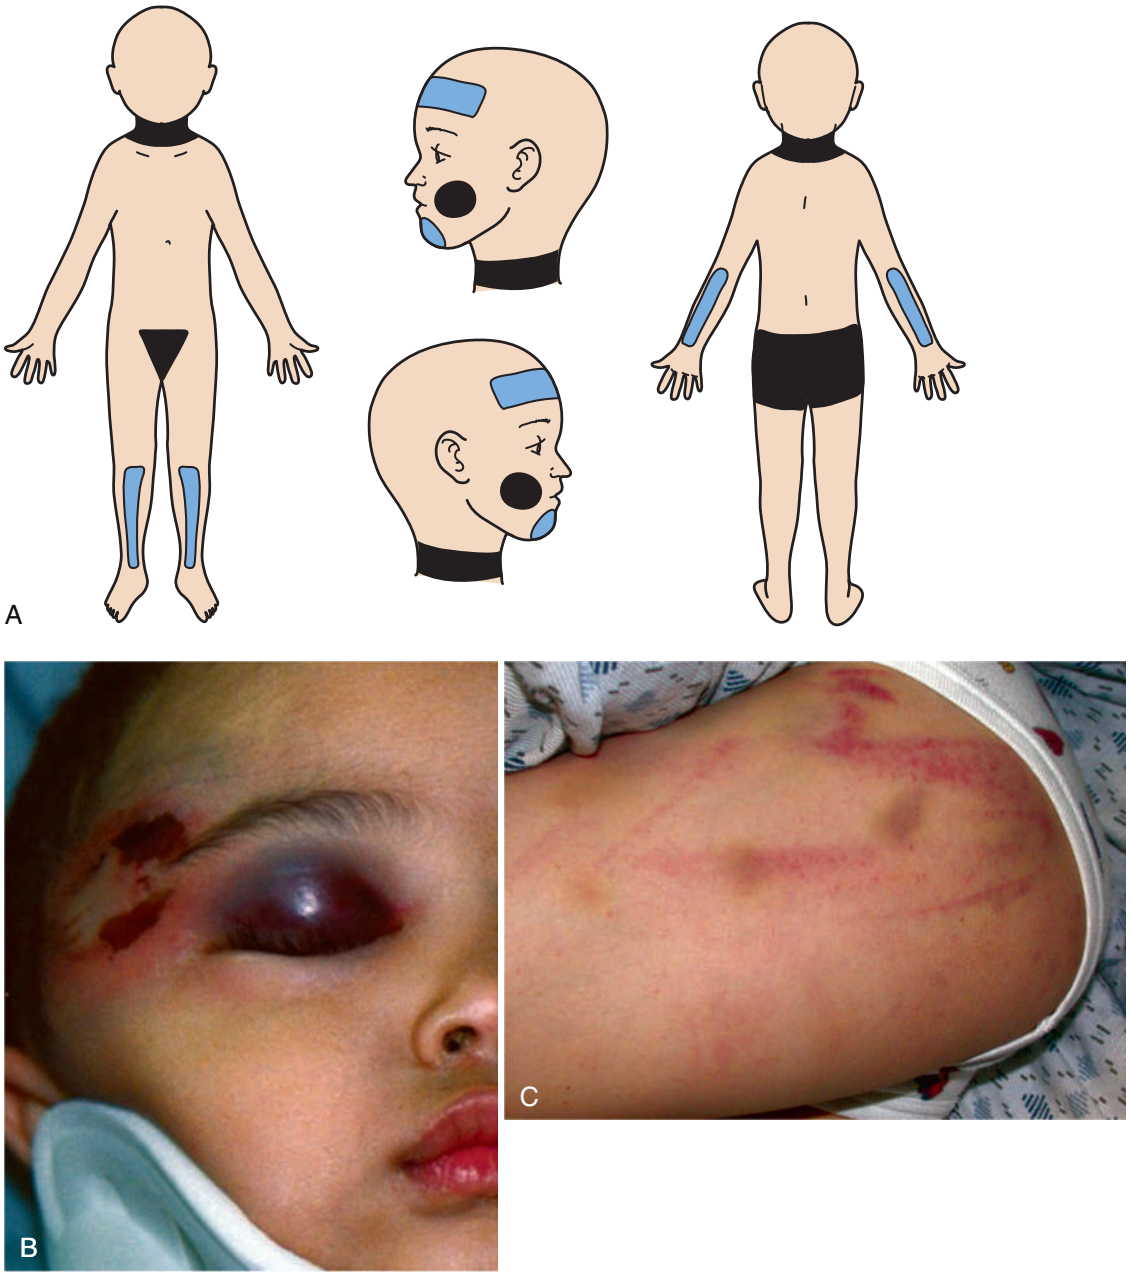

FIGURE 39.2 Common examples of child abuse, also referred to as nonaccidental trauma, are shown. **A**, Typical areas on children where bruising can be detected. The *blue areas* indicate regions where normal bruising may occur. The *black areas* are regions of unusual bruising. Any bruise in the black areas must be considered for possible nonaccidental trauma. **B**, A child with obvious facial trauma. **C**, A whipping injury from a belt plus additional bruises.

stay and play. Many aspects of this system are being integrated into existing American trauma systems as part of mass casualty disaster management plans.[27,28] The ideal approach is to minimize time on the scene and initiate resuscitation while en route to the hospital.[29]

Developing a systematic approach to the care of the pediatric trauma patient is crucial. This includes acquiring age- and size-appropriate equipment. Broselow and Luten developed a system that provides immediate guidance to identify appropriately sized equipment and drug doses for the trauma victim whose age and

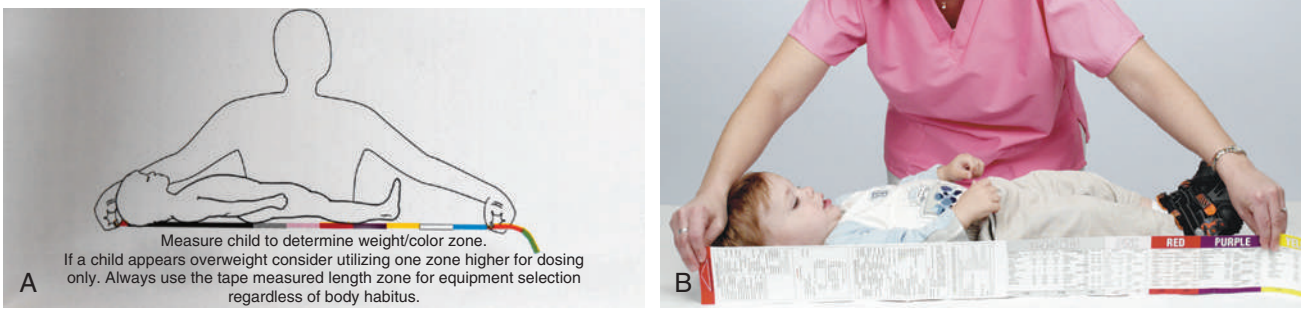
TABLE 39.2 Modification of the Glasgow Coma Scale for Pediatric Patients

Type of Response	Score[a]	AGE-RELATED RESPONSES		
		>1 Year	<1 Year	
Eye-opening response	4	Spontaneous	Spontaneous	
	3	To verbal command	To shout	
	2	To pain	To pain	
	1	None	None	
		>1 Year	<1 Year	
Motor response	6	Obeys commands	Spontaneous	
	5	Localizes pain	Localizes pain	
	4	Withdraws to pain	Withdraws to pain	
	3	Abnormal flexion to pain (decorticate)	Abnormal flexion to pain (decorticate)	
	2	Abnormal extension to pain (decerebrate)	Abnormal extension to pain (decerebrate)	
	1	None	None	
		>5 Years	2–5 Years	0–2 Years
Verbal response	5	Oriented and converses	Appropriate words, phrases	Babbles, coos appropriately
	4	Confused conversation	Inappropriate words	Cries but is consolable
	3	Inappropriate words	Persistent crying or screaming to pain	Persistent crying or screaming to pain
	2	Incomprehensive sounds	Grunts or moans to pain	Grunts or moans to pain
	1	None	None	None

[a]The total GCS score is determined by adding scores for each of the three sections to predict the extent of neurologic injury: severe, <9; moderate, 9–12; mild, 13–15.
Modified from James HE, Trauner DA. The Glasgow Coma Scale. In: James HE, Anas NG, Perkin RM, eds. *Brain Insults in Infants and Children*. Orlando: Grune & Stratton; 1985;179–182.

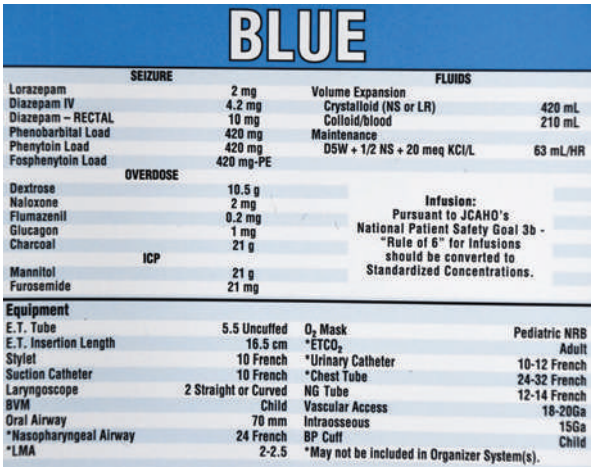
weight are unknown (https://www.ebroselow.com/php/static/home.php).[30–33] A folded color-coded tape can be placed next to the child and the height of the child is matched to the color panels on the front and back of the tape (E-Figs. 39.1 and 39.2). The color panel provides weight-based drug doses and other information regarding tracheal tube size and laryngoscope blade size (E-Fig. 39.2). A corresponding color-coded wristband identifies the weight/height category to which the child is assigned. A similarly color-coded crash cart contains appropriately sized airway devices, tracheal tubes, syringes, intravenous (IV) catheter start kits, and other supplies (E-Fig. 39.3). This system is designed to minimize delays, medication errors, and equipment errors.

Dramatic advances in the capability of prehospital providers to initiate resuscitation of pediatric trauma patients have occurred over the past two decades. Part of this progression has been attributed to the development of trauma systems and the commitment of trauma centers to provide more effective medical direction to prehospital providers. Effective management for the continuum of care in trauma patients is optimized if the prehospital personnel communicate the details regarding the child's injuries directly to the responsible hospital-based personnel. This information may include details about the mechanism of injury, traumatic forces involved, time elapsed from the event, loss of consciousness, estimated blood loss, treatment given (e.g., IV access, airway management), and a summary of suspected injuries.



As trauma systems have evolved and emergency departments have become overwhelmed by larger patient volumes, effective triage for the pediatric trauma patient has become increasingly important. Care of traumatically injured children requires the use of personnel and resources from many services, including the operating room and many ancillary services such as diagnostic imaging and transfusion medicine.[34] Inappropriate triage may waste precious time and resources and limit access to patients most in need if every patient with traumatic injuries, regardless of their severity, is sent to a trauma center. Conversely, failure to recognize a child who needs the resources of a trauma center may increase morbidity and result in preventable deaths.[35–37]

The Glasgow Coma Scale (GCS) and the modified GCS for children (Table 39.2) are the most common scales used to estimate the severity of neurologic injury. The GCS assigns a total score with a range of 3 to 15 that quantifies eye opening, verbal response, and motor function; a GCS score of 8 or less implies severe neurologic injury and the need for placement of an advanced airway. The Pediatric Trauma Score (PTS) was developed to facilitate the initial assessment and triage of injured children by categorizing the overall severity of their injuries (Table 39.3). As trauma systems have matured and prehospital providers have become more experienced with assessment and field management, the GCS and PTS have emerged as effective tools for determination of the need for direct transfer to a trauma center.[38,39]



PREHOSPITAL AIRWAY MANAGEMENT

Providing effective airway management within the prehospital environment has many challenges, including poor access to the child, unavailability of pharmacologic agents, inclement weather, trauma to the face, and demanding environments such as within an ambulance. Several studies of adult patients undergoing tracheal intubation in the prehospital setting have reported an increased incidence of difficult tracheal intubation,[40] the need for multiple attempts,[41] and undiagnosed esophageal intubation. These events have been reported by all levels of providers, including anesthesiologists,[42] although anesthesiologists have more success and fewer complications when performing tracheal intubation compared with other providers.[43–45]

Unsuccessful prehospital airway management in children may be due to a combination of training, experience, equipment, and environmental issues. A significant proportion of the unsuccessful prehospital tracheal intubations results from ineffective operator

training and lack of professional experience. Most prehospital providers such as paramedics receive minimal dedicated training in pediatric airway management, insertion of supraglottic airway devices, and tracheal intubation.[46] These providers may not have had an opportunity to either acquire or maintain the necessary skills. Over time, the psychomotor skills required for pediatric tracheal intubation decay, which likely contributes to the increased complication and failure rates associated with tracheal intubation in children.[47]

Guidelines that recommend that instrumentation of the airway be avoided in the prehospital setting may yield similar outcomes to those that recommend intubating the trachea for pediatric trauma patients.[48] For example, the 2015 American Heart Association Pediatric Advanced Life Support (PALS) guidelines state that "*Bag-mask ventilation can be as effective, and may be safer, than endotracheal tube ventilation for short periods during out-of-hospital resuscitation.*"[49] The guideline further states that "*The likelihood of successful endotracheal tube placement with minimal complications is related to the length of training and supervised experience in the operating room and in the field.*"[50] However, if tracheal intubation is performed, it is strongly recommended to utilize carbon dioxide detection devices. The current PALS guidelines state that *"When available, exhaled CO_2 detection (capnography or colorimetry) is recommended as confirmation of tracheal tube position for neonates, infants, and children with a perfusing rhythm in all settings … and during intrahospital or interhospital transport"* (E-Fig. 39.4). Thus many EMS agencies have developed policies based on a scoop-and-run philosophy for pediatric trauma patients that avoid definitive airway management if the transport time is brief and bag-mask ventilation is effective. Several investigators have also questioned whether prehospital tracheal intubation is the best approach in children who require positive-pressure ventilation. The infrequent need for tracheal intubation in pediatric trauma patients has created obstacles for members of the emergency medical teams to maintain their skills. Multiple studies have demonstrated an increased mortality rate or worsening neurologic outcomes for adult patients who received prehospital tracheal intubation compared with those who received standard bag-mask ventilation.[51,52] Several studies focused on children also reported increased complication rates associated with prehospital tracheal intubation,[53–56] particularly in infants.[48]

There is a trend toward using alternative airway devices in the field for adult and pediatric trauma patients. Among the devices that have found support, supraglottic airway devices have proved easy to use with high reliability in the field. Although these devices do not protect the airway from gastric regurgitation and pulmonary aspiration, they may provide adequate oxygenation and ventilation during transport, particularly if traditional bag-mask ventilation is inadequate. One meta-analysis of prehospital alternative airway devices in adults and children indicated that airways (LMAs) were very successful in the hands of anesthesiologists and nonphysician flight crews (success rate 96%) and slightly less successful in the hands of nonphysician clinicians (83%).[57] However, there is no evidence for placement of an LMA in pediatric trauma unless it is used as a rescue device.

Emergency Department Evaluation and Management of the Pediatric Trauma Patient

Anesthesiologists should familiarize themselves with the initial management of pediatric trauma patients in the emergency department because they may be asked to assist in emergency airway management and provide intraoperative care. Rapid establishment of provisional diagnoses and priorities of care is essential in the emergency department management of trauma victims.[58] Most trauma centers use a multilayered assessment system consisting of a primary survey with resuscitation and a secondary survey, followed by definitive management.[1]

Anesthesiologists can provide more effective intraoperative management if they understand the care that pediatric trauma patients commonly receive in the emergency department. During initial resuscitation, a team member should attempt to obtain a history from the parents, the prehospital personnel, and the child if possible. The history should include the usual questions about drug allergies, medications, and past illnesses, as well as inquiries about loss of consciousness, estimated blood loss, and treatment rendered before arrival at the emergency department.

Based on the ATLS program, evaluation of the trauma patient occurs in three progressive steps: primary survey, secondary survey, and definitive care.[4] The initial evaluation of all trauma patients begins with the primary survey. The sequence of the primary survey can be remembered as "ABCDE": **A**irway (A), **B**reathing (B), **C**irculation (C), **D**isability (D), and **E**xposure or environment (E). Many trauma centers have the personnel and resources to concurrently perform several activities and have rooms to accommodate multiple patients simultaneously. In this circumstance, it would be acceptable for the primary and secondary surveys to occur simultaneously–that is, the primary survey (e.g., volume resuscitation) can occur when a part of the secondary survey is being performed (e.g., drawing blood samples).

The primary survey always starts with assessment of the airway. The airway (A) should be evaluated for patency and opened using a jaw-thrust technique if airway obstruction is suspected. Immobilization of the cervical spine should be maintained. The child's breathing (B) and ventilation should be evaluated, and immediate intervention should take place if they are inadequate. Circulation (C) is evaluated by palpation of peripheral or central pulses, blood pressure values, level of sensorium, and degree of skin turgor.

E-FIGURE 39.4 Verification of endotracheal tube placement can be confirmed by measurement of exhaled carbon dioxide. When a capnograph is unavailable, portable carbon dioxide colorimetric detection devices, such as the Easy Cap II (Medtronic-Covidien-Nellcor; Minneapolis, MN) for patients weighing more than 15 kg, or the Pedi-Cap (Medtronic-Covidien-Nellcor) for children who weigh 1 to 15 kg, may be used.

TABLE 39.4 The Advanced Trauma Life Support Primary Survey Management Priorities

Priority Level	Management
Highest	Airway and cervical spine immobilization
	Breathing and ventilation
	Circulation and hemorrhage control
	Disability and neurologic status
Lowest	Exposure and environmental

Control of external hemorrhage by the application of direct pressure is also part of the circulation phase. Disability (D) is evaluated by examining the child for neurologic injuries and commonly using a neurologic scoring system such as the GCS. A GCS score of 8 or less implies severe neurologic injury (see Table 39.2), and immediate tracheal intubation (with in-line cervical spine immobilization) is strongly recommended (see further). Exposure (E) of the whole child is essential for a complete examination. The environment (E) should consist of a heated treatment area that is ideally prepared in advance of the child's arrival and environmental threats should be determined (i.e., need for chemical decontamination). The ATLS Primary Survey management priorities, listed in order from top (first priority) to bottom, are shown in Table 39.4.

The importance of obtaining an adequate and secure airway cannot be overemphasized. All trauma patients should initially receive 100% supplemental oxygen. The trachea should be intubated in most children with major traumatic injuries using a rapid-sequence induction (RSI) technique with manual in-line stabilization as necessary and appropriate medications or, when it is unclear whether the airway can be secured, while the child remains awake. When increased ICP is suspected, measures to prevent increases in ICP during tracheal intubation should be undertaken. Regardless of the site or mode of tracheal intubation, proper position and patency of the tracheal tube must be confirmed as soon as the child's airway is intubated and again on arrival in the emergency department.[59] Techniques to verify correct tracheal tube position may initially include chest auscultation, direct laryngoscopy, determination of the tracheal tube length from the lips, and the detection of end-tidal carbon dioxide. All children should be monitored with frequent blood pressure measurements as well as continuous electrocardiography and pulse oximetry.

Shock is most commonly the result of hypovolemia in trauma patients. Cardiogenic shock, although rare in children, may also be associated with chest trauma or preexisting cardiovascular disease. Attempts should be made to place two large-bore IV lines that are appropriate for age; if two attempts fail, including femoral access, then intraosseous access is indicated (see also Chapter 49).[60] For the child who is hypotensive, administer a bolus of 20 mL/kg of an isotonic crystalloid solution such as lactated Ringer's solution or normal saline. Fluid administration may be repeated with additional boluses of isotonic crystalloid as required to stabilize the blood pressure within the normal range. Blood products should be considered when the volume of isotonic crystalloid exceeds 40 to 60 mL/kg and the blood pressure remains unstable. Glucose-containing solutions typically are avoided (in the absence of hypoglycemia) because they may lead to hyperglycemia and potentially worsen neurologic outcome.

For traumatic injuries that are primarily located in the abdomen, preference should be made to place vascular access in the upper extremities. Traumatic chest injuries should have vascular access placed in the upper and lower extremities to account for disruption of a major vessel above or below the right atrium.

When the primary survey and initial resuscitation have been completed, a secondary survey is initiated. The secondary survey is a complete head-to-toe examination designed to identify additional injuries not recognized during the primary survey. Frequent reassessment of the vital signs is critical during this phase. If clinical deterioration occurs during the secondary survey, the primary survey and initial resuscitation should be resumed. Head examination should include visual inspection, palpation, assessment of pupillary size and reactivity, and a funduscopic examination. The cervical spine, chest, and abdomen should be evaluated in detail. Chest examination should involve inspection for wounds, palpation for tenderness and crepitus, and auscultation for bilateral breath sounds. The abdomen should also be examined carefully for tenderness, firmness, and external lesions (e.g., gunshot wounds). In children, the physical signs of intraabdominal injuries can be subtle, especially in sedated or neurologically depressed children. The extremities should be inspected for tenderness, bruising, deformities, and vascular insufficiency.

Diagnostic testing is completed during the secondary survey.[61,62] Imaging studies, including computed tomography (CT) scans of the brain, neck, chest, abdomen, and pelvis, may be obtained along with a bedside **f**ocused **a**bdominal **s**onography for **t**rauma (FAST) examination, which is principally used to detect intraperitoneal free fluid but can also be used to identify other life-threatening lesions such as a pneumothorax[63] or pericardial effusion. Standard radiographs of the chest and extremities may also be obtained during the secondary survey. Laboratory studies, including blood cell count, electrolytes, and blood product crossmatching, are completed during this phase. If the child remains unstable despite aggressive resuscitation, the child should be considered for emergent transfer to the operating room for surgical intervention. After the child has been stabilized and all injuries have been identified, plans for definitive care can be made. Disposition options from the emergency department may include admission to the ICU, an acute care bed, an observation unit, discharge home with outpatient follow-up, or transfer to the operating room.

Anesthesia Management of the Pediatric Trauma Patient

Anesthesiologists, surgeons, and other personnel should work as a coordinated team when managing children with traumatic injuries. This collaborative approach can optimize the prompt and reliable identification of suspected injuries so that the anesthesiologist can more effectively anticipate the magnitude of bleeding, physiologic effects, and nature of the surgical procedures. By understanding the appropriate evaluation and initial management of the pediatric trauma patient, the anesthesiologist can recognize injuries that might have been undiagnosed and anticipate the resultant effects intraoperatively.[6]

The approach to diagnosis of and treatment for the pediatric trauma patient is dictated by the degree of urgency. A diagram of the management priorities for pediatric trauma patients appears in Fig. 39.3. For critically ill and hypotensive children who need immediate surgical intervention, resuscitation and the administration of anesthesia may need to be provided simultaneously. The recommended equipment for the management of the pediatric trauma patient is listed in Table 39.5. Basic principles are applied in this circumstance, including establishment and protection of

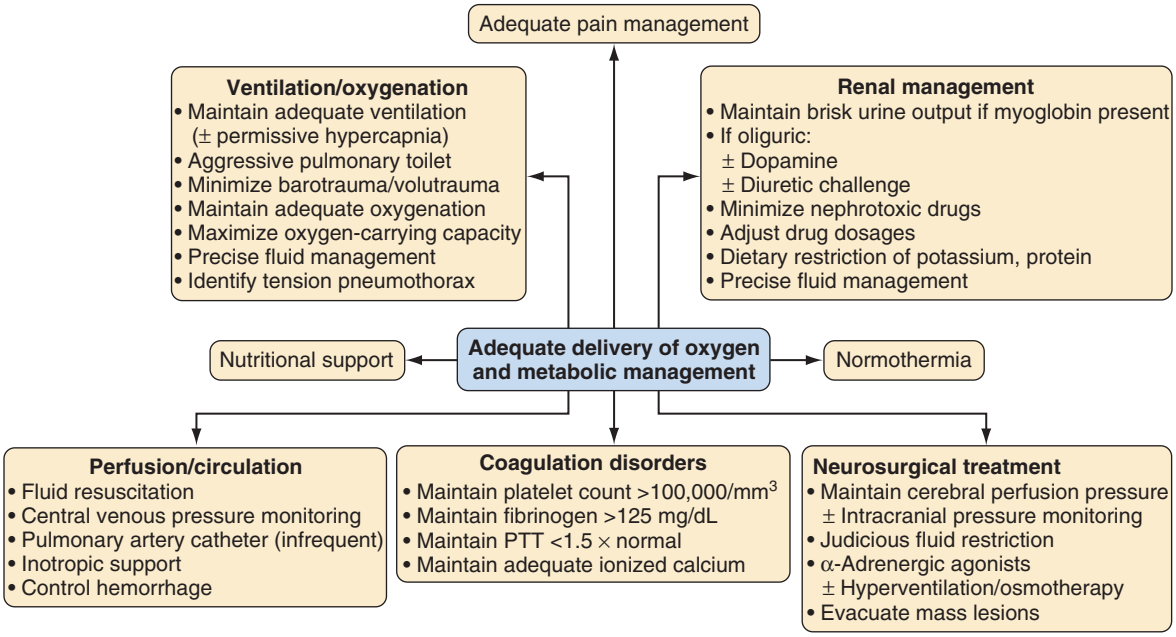

FIGURE 39.3 Diagram of the management priorities for pediatric trauma patients. The primary goals are delivery of oxygen, appropriate ventilation, perfusion to vital organs, maintenance of normothermia to mild hypothermia, stability of renal and neurologic function, correction of coagulopathies, avoidance of overhydration, and meticulous management of metabolic demands. *PPT,* partial thromboplastin time. (Modified from Todres ID, Fugate JH, eds. *Critical Care of Infants and Children.* Boston: Little, Brown; 1996:17.)

the airway, maintenance of adequate ventilation, and support of hemodynamics with fluids, blood products, and vasoactive medications. Establishment of generous vascular access is recommended in the critically injured child; this may necessitate a vascular cutdown or placement of an intraosseous needle (Figs. 49.6 and 49.7) to be used for volume resuscitation. Anesthetic medications should be cautiously administered by carefully titrating the dose to the child's hemodynamic status.

For the child who requires emergent transfer to the operating room, does not have a secure airway in place, and is believed to have a normal airway, induction of anesthesia should begin with preoxygenation followed by IV medications and an RSI technique. If the child is thought to be hypovolemic, a preoperative fluid bolus of an isotonic crystalloid solution (20 mL/kg) should be administered before induction of anesthesia with medications that maintain circulatory homeostasis. If concern exists regarding a possible cervical spine injury, which applies to most trauma patients, the practitioner should also incorporate in-line immobilization of the cervical spine during airway management and all patient transfers (Fig. 39.4).[64] Arterial and central venous line placements should be selected on a case-by-case basis. The anesthesiologist should be vigilant for undiagnosed traumatic injuries that may manifest in the operating room. For a child who is critically ill, surgery should proceed without delay; monitoring may initially include only a blood pressure cuff, pulse oximeter, expired carbon dioxide, and electrocardiogram.

As conditions permit, hemodynamic monitoring with arterial and central venous catheters may be established (see also Chapter 49). Arterial catheters for trauma patients may be helpful in some situations, including concern about the adequacy of ventilation and the need to frequently sample arterial blood gases, the need for frequent and repeated blood sampling (i.e., severe hemorrhage or metabolic derangements), hemodynamic instability, and the need to alter the blood pressure rapidly. In a setting with significant actual or anticipated blood loss, establishment of large-bore venous access is of much greater priority than obtaining arterial access. Establishment of central venous access may be delayed until hemodynamic stability is established since peripheral venous lines typically can be obtained quickly and can provide effective volume resuscitation. Rotating the neck to place an internal jugular central line in a trauma patient with a possible cervical spine injury should be avoided. Alternative sites should be selected to establish central venous access.

After oxygenation, ventilation, and circulation have been stabilized, the anesthesiologist may need to address additional concerns. If it has not been possible to administer acceptable doses of anesthetic medications, they are administered in stepwise increments after hemodynamic stability has been achieved. Evidence from adult victims of major trauma indicates that recall is more common in these cases. It is reasonable to assume that a similar risk holds true in children.[65–67] IV administration of midazolam is strongly recommended,[68] although a single dose may be insufficient to guarantee amnesia and may contribute to cardiovascular instability. If inhalational anesthetics produce hemodynamic instability, the anesthesiologist may administer a ketamine infusion (titrated to the child's hemodynamic responses), or a total IV anesthetic technique (e.g., high-dose fentanyl and benzodiazepine and vasoactive infusions).

An important principle of trauma anesthesia management is the maintenance of body temperature. Hypothermia occurs commonly in victims of major trauma, especially burn patients, beginning before the child arrives in the emergency department. Hypothermia may potentiate neuromuscular blockade, exacerbate coagulopathy, and contribute to delayed emergence. The evidence

TABLE 39.5	Recommended Equipment for Resuscitation of a Pediatric Trauma Patient

that moderate hypothermia (34.5°C) might be protective in children with traumatic brain injury[69] is poor.[70,71] Measures to warm the child should be instituted immediately on arrival in the emergency department. These measures include warming all IV fluids and blood products, using forced-air warming devices and heat lamps, wrapping the head and extremities in plastic bags, and increasing the temperature of the operating room. Ideally, the operating room should be warmed in advance of the child's arrival to minimize radiation heat loss.

The features and mechanisms of trauma are different in children than adults. In children, abdominal trauma is more common than thoracic trauma, and blunt traumatic injuries are more common than penetrating traumatic injuries. In thoracic trauma, hemothorax and pneumothorax are common; needle decompression followed by chest tube placement may be lifesaving for a tension

FIGURE 39.4 Cervical spine control must be maintained during tracheal intubation. The child with a known or suspected cervical spine injury requiring a definitive airway should be intubated under controlled circumstances. A dedicated person should immobilize the head and neck during intubation. Oral intubation is the preferred route. Cervical in-line immobilization before attempts at laryngoscopy should occur so that the head is stabilized and prevented from rotating side to side and into flexion or extension.

pneumothorax. Strong consideration should be given to needle decompression or the placement of a chest tube before instituting positive-pressure ventilation in a child with a tension pneumothorax. Chest injuries in children may be overlooked because rib fractures are less common than in adults.[72]

Head injury is the most common cause of traumatic death in children.[73] Although the principles of managing head injuries in polytrauma patients are, for the most part, similar in adults and children, there are some noteworthy differences. In neonates and infants, unlike adults, intracranial bleeding can lead to hypovolemic shock because the head is a significantly larger fraction of the body and the vessel-rich organs receive a substantially greater fraction of the cardiac output in infants and children. The open fontanels in children may provide greater compliance and a potential space for a proportionately larger amount of blood to accumulate. However, the open fontanels may also provide additional protection against initial increases in ICP. A key goal for children with neurosurgical emergencies is maintenance of hemodynamic stability to preserve cerebral perfusion pressure and avoid the development of secondary brain injury. A child with suspected intracranial hemorrhage is at risk for increased ICP. Acute treatment for increased ICP caused by intracranial hemorrhage includes hyperventilation, IV administration of hyperosmolar medications such as hypertonic saline or mannitol, cerebrospinal fluid drainage, raising the head of the bed, and surgical removal of an intracranial hematoma.[74,75]

PREOPERATIVE EVALUATION

Advances in health care have produced an increased patient population with significant preinjury comorbid conditions. For example, children with repaired congenital heart disease may be victims of a traumatic injury. It is common for an acutely injured child to have a preexisting diagnosis of a medical condition such as asthma, developmental delay, seizure disorder, obesity, obstructive sleep apnea, and significant psychosocial issues exacerbated by an unstable home environment. Each of these issues must be carefully considered when planning appropriate anesthesia management and postoperative care.

Emergency surgery can be a large source of fear and anxiety for children and their parents.[76] The suddenness of the event provides little time for the child and family to adjust to the crisis and often limits the time the anesthesiologist has to develop rapport with the child and parents. The calm and reassuring anesthesiologist is of great benefit to all parties.

If the child's condition permits, the preoperative evaluation should include a complete assessment. Vital signs should be stable and appropriate for age. Sensorium, urine output, skin turgor, and vital signs can be used to evaluate and estimate the child's preoperative volume status. A comprehensive airway examination should be completed, including assessment of the cervical spine. The past medical and surgical histories, medications, and allergies are recorded when feasible. A list of known injuries and interventions taken up until now should be acquired before entering the operating room. Special attention to fluid management helps to estimate preoperative volume status and assist with intraoperative fluid administration. Assessment should include review of available laboratory reports such as hemoglobin, electrolytes, coagulation studies, and arterial blood gas results. Results from diagnostic imaging studies, including plain radiographs and CT scans, should also be obtained. The suggested items for emphasis during the preoperative evaluation of the pediatric trauma patient are shown in Table 39.6.

Evidence suggests that the gastric residual volume in children undergoing emergency surgery is greater than in those undergoing elective surgery.[77,78] In emergency cases, the size of the gastric residual volume (measured in milliliters per kilograms) depends, in part, on the time interval between the last food ingestion and the injury.[78] There is some reassurance in these numbers, but the anesthesiologist should consider acutely injured children to have full stomachs and take appropriate measures to reduce the risk of pulmonary aspiration of gastric contents.[79–82] The possible value of H_2-blocking agents, metoclopramide, and clear antacids may be considered, although their use in these circumstances is not evidence based.

Premedication for emergency procedures, if indicated, usually is administered by the IV route. Benzodiazepines, such as midazolam, may help to reduce preoperative anxiety. If pain is present, opioids may be beneficial for children who are hemodynamically stable and have no airway compromise. Other than ketamine, anesthetics rarely cause profuse secretions, and the use of antisialagogues before induction should be reserved for specific indications. The administration of premedications to alleviate pain or control anxiety must be balanced against their disadvantages, including the potential for respiratory compromise, increased sedation, or hemodynamic instability.

Fasting time

CERVICAL SPINE EVALUATION

Cervical spine injuries occur less often in children than in adults and typically at different spinal levels.[83] Cervical spine injuries in children tend to be located at a more cephalad spinal level than in adults, usually at or above C_3. In contrast to actual injuries, pseudosubluxation of the cervical spine may also be present but is a common and benign finding in children. Pseudosubluxation of the cervical spine usually occurs as the anterior displacement of C_2 on C_3. The physician may need to differentiate benign pseudosubluxation from a true cervical spine injury in the pediatric trauma patient.[84] After consultation with the surgeon, pseudosubluxation can be excluded by placing the child's head in the sniffing position and repeating the radiograph; pseudosubluxation is reduced with this maneuver. In older children, an odontoid or open mouth view can also be considered to evaluate the superior cervical vertebrae. The physician must assume a cervical spine injury exists if the child complains of tenderness in response to palpating the spinous processes of the cervical spine, if the sensorium is decreased, or if neurologic deficits are present. Any of these findings demand a neurosurgical consultation and cervical spine immobilization.

Injury to the cervical spine is less common in children than in adults because the child's spine is more elastic and mobile, and their incompletely calcified vertebrae are less likely to fracture with minor trauma. Nevertheless, the risk of spine injury is increased when the child is subjected to a substantial force from a fall or the considerable forces associated with motor vehicle crashes.[8] Any child with a suspected neck injury should have cervical spine precautions implemented (e.g., placement of a cervical collar). Cervical spine immobilization (see Fig. 39.4) should always be maintained when airway management is attempted. Airway management in a child with a cervical fracture may require up to four individuals: one person to provide in-line immobilization, a second person to perform tracheal intubation, a third person to perform cricoid pressure, hold the tracheal tube, and retract the cheek if needed, and a fourth person to administer the medications (Fig. 39.5).

Challenges in obtaining plain radiographs of the cervical spine include difficulty in obtaining a complete view of the cervical spine below C_6 and the odontoid process. As CT technology has advanced to more rapid and precise imaging, most centers have replaced

FIGURE 39.5 Intubation of a child with a cervical fracture may require up to four individuals: one person to provide in-line immobilization, a second person to perform tracheal intubation, a third person to perform cricoid pressure, hold the endotracheal tube, and perhaps retract the cheek, and a fourth person to administer the medications.

standard radiographic examinations with CT scans for evaluation of the cervical spine in the trauma patient. The American College of Surgeons updated the ATLS guidelines, stating that a CT scan of the neck can be substituted for a cervical spine radiograph.[4] Replacing plain films with CT scans resulted in a doubling of the rate of cervical spine fractures identified in one study.[85]

It is challenging to rule out spinal cord injuries in children by standard radiography alone because up to 50% of spinal cord injuries may exist without positive radiographic findings. **S**pinal **C**ord **I**njury **W**ithout **R**adiographic **A**bnormality (SCIWORA) has been estimated in as many as 25% to 50% of children with spinal cord injuries.[86,87] These occult cases may reflect ligamentous damage that cannot be detected with standard radiographic examinations or CT scans; however, this ligamentous injury can be visualized using magnetic resonance imaging (MRI), which may require anesthesia care and be performed at a later time because of patient instability.

Imaging must be used in conjunction with the physical examination to evaluate the cervical spine, but the cervical spine cannot be considered cleared of pathology only on the basis of diagnostic imaging studies.[88,89] Appropriate spine immobilization should continue during the intraoperative and postoperative periods if a cervical spine injury cannot be excluded by negative results on an imaging study[90] combined with negative findings on physical examination. The cervical spine cannot be considered cleared if the child is not alert, is nonconversant, has positive neurologic deficits, has midline cervical tenderness, or has a painful, distracting injury. If the cervical spine cannot be clinically cleared in the postoperative period, MRI of the spine should be considered after the child is hemodynamically stable.

AIRWAY MANAGEMENT

Children undergoing emergency surgery are assumed to have full stomachs. They often have considerable gastric contents because of a recent meal,[79] increased acid secretion, delayed gastric emptying caused by pain, trauma, as well as the previous administration of opioids. Many experts recommend using an RSI technique to secure the airway to minimize the risk of pulmonary aspiration of gastric contents. However, evidence-based data supporting this approach are lacking.[91] The anesthesiologist must balance the risks of the RSI technique against the risks of other airway management techniques. RSI may result in the inability to intubate the trachea and rapid oxygen desaturation during periods of apnea.[92] The risks of using this approach must be weighed against the benefit of reducing the risk for pulmonary aspiration. The decision to use an RSI technique assumes that the anesthesiologist has completed an airway evaluation and predicts that the intubation will be uncomplicated and that if mask ventilation is required with cricoid pressure, it will be possible as a backup measure.[93]

In the operating room, induction of anesthesia depends on the child's injuries, condition at the time of presentation, whether the airway has been secured, and anticipated airway difficulty. The most common approach to the initial airway management is to follow a protocol for RSI technique.[94,95] Awake intubation is another approach for airway management but usually is reserved for those with severely depressed consciousness, cardiac arrest, or a suspected difficult airway. The selection of medications depends on individual circumstances (e.g., head injury, hypovolemia, contraindication to succinylcholine) and preferences of the anesthesiologist. Table 39.7 lists the dosages, advantages, and disadvantages of common anesthetic medications used to perform a RSI. Fig. 39.6 presents an algorithm for management of children with multiple traumatic injuries but without a suspected traumatic brain injury. Specific considerations for children with multiple trauma that includes traumatic brain injury are outlined in Fig. 39.7.

Before RSI is performed, the anesthesiologist must ensure that the proper equipment is present and functioning, including laryngoscope blades and handles, suction, a leak-free anesthesia circuit, an anesthesia machine, monitors, tracheal tubes of appropriate sizes, tracheal tube stylets, and backup equipment such as appropriately sized supraglottic airway devices. If a difficult intubation is suspected, a videolaryngoscope should be present. With the availability of sugammadex (2–16 mg/kg IV), it is reasonable to perform RSI with high-dose rocuronium (1.2 mg/kg) should a cannot intubate/cannot ventilate situation arise.[96] All monitors should be properly functioning, and at a minimum, the pulse oximeter and blood pressure cuff should be applied before induction, even though these monitors may not function properly in a moving, uncooperative child until after induction of anesthesia.

After properly functioning IV access is confirmed, the child's lungs are denitrogenated with 100% oxygen for several breaths (as tolerated). Studies of adult patients demonstrate that oxygen saturation remains greater than 95% for 6 minutes after only four vital capacity breaths of 100% oxygen.[97] Similar studies have not been performed in children, although the rates at which the PaO_2 decreases[98] and the SaO_2 decreases to 95%[99] in infants and younger children after breathing 100% oxygen through a tracheal tube and then performing an apnea maneuver were more rapid than in older children and adults.[100] Even with an uncooperative child, it is possible to increase the PaO_2 by enriching the immediate environment around the child's face with high flows of 100% oxygen. Preoxygenation should not involve forcefully holding the face mask on the awake child; this will likely result in increased anxiety, increased oxygen consumption, and decreased effectiveness of denitrogenation. Premedication (e.g., 0.05–0.1 mg/kg of IV midazolam) in divided doses is one strategy that may alleviate fear and anxiety before induction. All medications intended for use during the RSI should be prepared and labeled along with the doses predetermined for the child's weight and hemodynamic status.

The RSI technique consists of preoxygenation with 100% oxygen and application of cricoid pressure, followed by the bolus administration of an induction agent such as ketamine (2 mg/kg), etomidate (0.2–0.3 mg/kg), or propofol (1–3 mg/kg), as well as atropine (20 μg/kg) if succinylcholine is selected and a neuromuscular blocking agent such as succinylcholine (2 mg/kg) or high-dose rocuronium (1.2 mg/kg). This is followed by laryngoscopy and tracheal intubation. We also recommend the administration of 1 mg/kg of IV lidocaine, before administering the induction agents, to reduce pain from the injection of propofol or etomidate as well as the blunting of hemodynamic responses from airway instrumentation. Positive-pressure ventilation before tracheal intubation is avoided during a "classic" RSI, although many use a "modified" RSI for younger children, which differs from a classic RSI in that it includes manual ventilation at low peak inspiratory pressures before tracheal intubation. Cervical spine immobilization is typically indicated for most trauma patients during RSI (see Fig. 39.4) and requires an assistant dedicated to perform cervical in-line stabilization during laryngoscopy (see Fig. 39.5).

RSI can be a considerable risk for children with cardiovascular problems such as hypovolemia or congenital heart disease. When performing RSI, it may be difficult to select the appropriate anesthetic dose for the child's needs because it may lead to profound hypotension owing to myocardial depression and vasodilation.

TABLE 39.7 Medications, Dosages, Advantages, and Disadvantages of Common Medications Used to Perform a Rapid-Sequence Induction (RSI) in Pediatric Trauma Patients

Medication	Intravenous Dose (mg/kg)	Advantages	Disadvantages
Atropine	0.01–0.02	Attenuates vagal response	Flushed skin, tachycardia, mild hyperpyrexia; possible sedation/agitation
Glycopyrrolate	0.01	Attenuates vagal response and antisialagogue; lacks sedation/agitation	Longer acting than atropine
Lidocaine	1–1.5	Attenuates hemodynamic and intracranial responses to airway management	Can cause toxicity in large doses (e.g., >5 mg/kg)
Fentanyl	0.001–0.003	Analgesic and attenuates hemodynamic and intracranial responses to airway management	Can cause bradycardia, chest wall and glottic rigidity
Midazolam	0.05–0.2	Sedation, amnesia, anxiolysis, increases seizure threshold, minimal respiratory depression	May cause hypotension when combined with opioids in hypovolemic patients; rarely may cause paradoxical agitation
Ketamine	1–2	Sympathomimetic, used when hypovolemia is suspected, bronchodilation	Increases oral secretions (administer with atropine or glycopyrrolate to reduce secretions), may increase intracranial pressure if $Paco_2$ is uncontrolled, hypotension possible if catecholamine depleted, causes nystagmus
Propofol	1–3	Sedative-hypnotic, some neuroprotective properties, antiemetic, lower intracranial pressure	May cause hypotension especially if hypovolemia present; painful on injection
Etomidate	0.2–0.3	Hemodynamic stability, some neuroprotective properties, used in patients with hypovolemia and cardiac instability	Possible adrenal suppression; painful on injection
Rocuronium	0.6–1.2	Rapid onset/long duration (with high doses), vagolytic properties; is an acceptable substitute for succinylcholine	Intermediate to long duration depending on dose
Succinylcholine	1–2 (precede with atropine or glycopyrrolate)	Rapid onset and ultra-short duration	May cause bradycardia if not preceded by an anticholinergic; may cause hyperkalemia, malignant hyperthermia, and rhabdomyolysis in susceptible children (muscular dystrophy, crush injury, prolonged immobilization, burns, intraabdominal sepsis, and upper and lower motor neuron lesions); may increase intracranial, intraocular, intragastric pressures
Sugammadex	2–16 **2 mg/kg:** **4 mg/kg:** **16 mg/kg:**	Dosing to antagonize rocuronium or vecuronium: At least 2 twitches present with train-of four (TOF) At least 1–2 posttetanic counts but no twitches to TOF No twitches including posttetanic are present; antagonism of neuromuscular blockade quickly, (approximately 3 minutes) after administration of 1.2 mg/kg of rocuronium	Most commonly reported adverse reactions include nausea, vomiting, headache; bradycardia, anaphylaxis, and increases in coagulopathy parameters; not indicated for use in patients with severe renal failure

Strategies for dosing IV induction agents in a child with presumed hypovolemia include reduced doses of propofol (e.g., 1 mg/kg) or using agents that are less likely to produce hypotension (e.g., etomidate, ketamine). Conversely, severe hypertension and tachycardia are also possible owing to inadequate dosing during airway management procedures such as prolonged direct laryngoscopy.

Succinylcholine is the neuromuscular blocking agent of choice for an RSI technique because of its rapid onset and short duration of action. A Cochrane review concluded that succinylcholine created superior intubating conditions compared with rocuronium using doses of less than 1.2 mg/kg.[101] However, high-dose rocuronium may also be effectively used as an alternative to succinylcholine for RSI in children.[102] If large doses of rocuronium (e.g., 1.2 mg/kg) are used in infants and children, the time to achieve a train-of-four recovery to 25% from baseline averages about 45 minutes but can be as long as 75 minutes.[102] It is possible that the duration of action of rocuronium may exceed the planned procedure. Moreover, if the child is unable to be intubated or adequately ventilated, the situation may become life-threatening. The use of high-dose sugammadex (8–16 mg/kg),[103] will reduce the duration of neuromuscular block in these situations, but anesthesiologists should also be aware of several reports of the development of associated hypersensitivity reactions (see Table 39.7).[104] The routine use of succinylcholine for elective tracheal intubation in children has lost popularity among pediatric anesthesiologists because of reports of hyperkalemia-induced cardiac dysrhythmias and cardiac

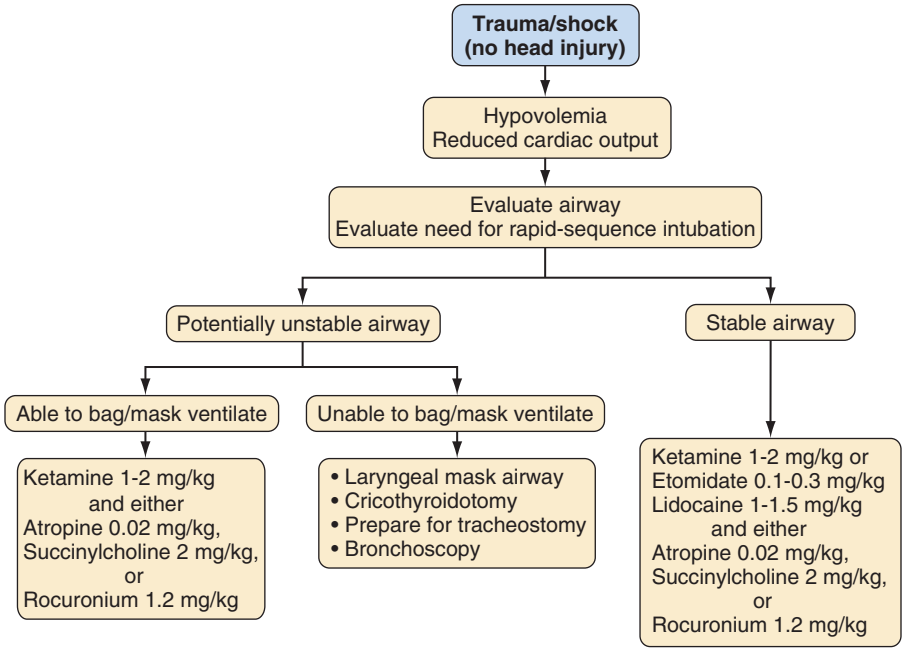

FIGURE 39.6 A proposed algorithm for airway management in children with traumatic injuries but without traumatic brain injury. The selection of medications and airway management techniques should be individualized to each patient. (Modified from Todres ID, Fugate JH, eds. *Critical Care of Infants and Children*. Boston: Little, Brown; 1996:36.)

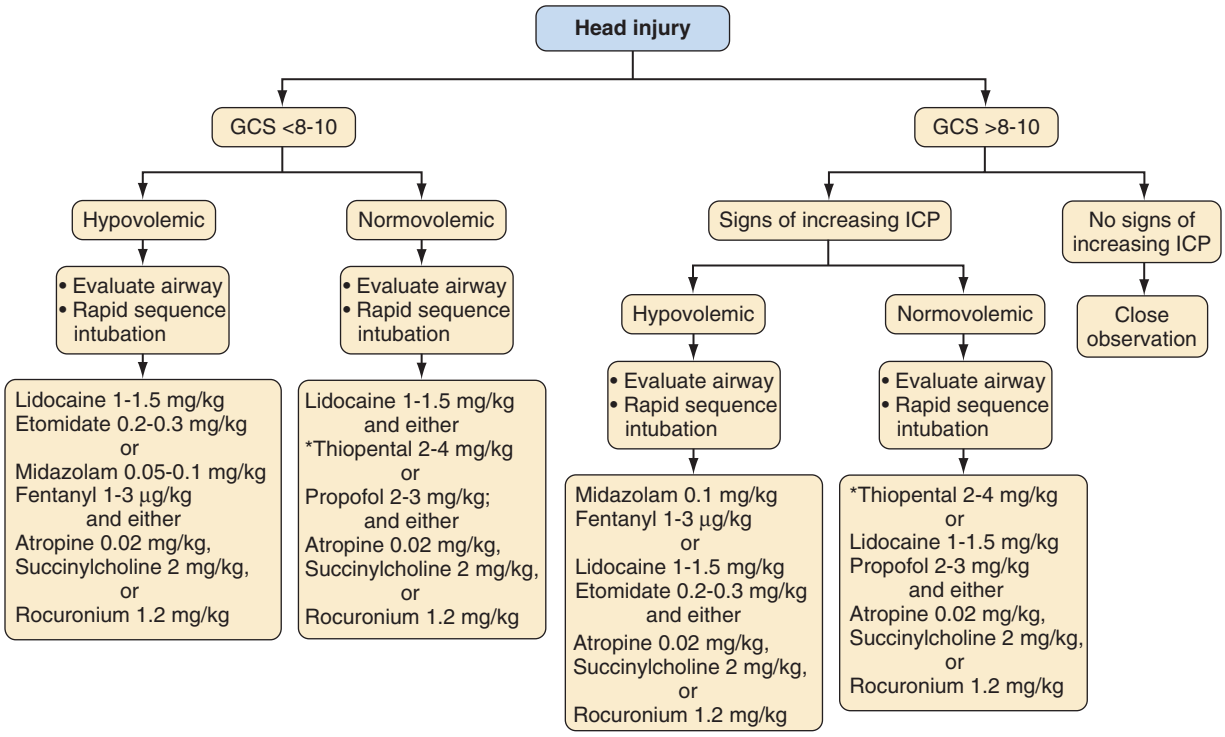

FIGURE 39.7 A proposed algorithm for airway management in children with traumatic injuries including known or suspected traumatic brain injury (TBI). The selection of medications and airway management techniques should be individualized to each patient. *GCS*, Glasgow Coma Scale score; *ICP,* intracranial pressure. *Thiopental is no longer available in the United States. arrest, which led the U.S. Food and Drug Administration to issue a black box warning about the use of succinylcholine in children undergoing elective surgery.[105] Many of the male children who developed hyperkalemic cardiac arrest were subsequently diagnosed with various forms of muscular dystrophy (mostly Duchenne muscular dystrophy, which may manifest with few clinical signs in boys 8 years of age or younger) (see also Chapters 7 and 24). Whenever succinylcholine is considered, it is imperative to ensure that IV calcium chloride or calcium gluconate is immediately available to antagonize the cardiac manifestations of hyperkalemia should it occur.

Establishing a definitive airway may be required for children with a suspected difficult airway as the result of facial, laryngeal, or thoracic trauma. Alternative approaches for airway management should be considered when difficult intubation or ventilation is anticipated.[106,107] In these situations, the urgency of securing the airway takes priority over the increased risk of pulmonary aspiration of gastric contents. These cases can be typically managed by using an awake intubation approach, which commonly includes topical anesthesia and sedation combined with one of the following airway techniques:

- Direct laryngoscopy or rigid bronchoscopy
- Indirect laryngoscopy using a fiberoptic bronchoscope (FOB) or video laryngoscope
- Supraglottic airway device–assisted tracheal intubation with or without an FOB
- Awake tracheostomy

In the nonemergent situation, the FOB is the gold standard approach to manage a difficult airway. An FOB can be a very effective technique, especially in children with limited mouth opening, restricted neck movement (common in the trauma patient with a cervical collar in place), or associated congenital syndromes that make direct laryngoscopy difficult or impossible.[108,109] Use of a video laryngoscope is also an acceptable alternative. These alternative approaches are advantageous because their main goals are to maintain spontaneous ventilation, to maintain oropharyngeal reflexes to prevent pulmonary aspiration if gastric regurgitation occurs, and to allow the option of aborting the procedure if the airway cannot be secured (see also Chapter 14). However, these airway techniques can be challenging in small children, in those whose airway anatomy is severely distorted, and in those with copious secretions such as blood in the pharynx. Large amounts of sedation to achieve effective patient cooperation during airway interventions may approach levels of general anesthesia and produce significant respiratory depression as well as airway obstruction.

Another strategy for airway management in the child with a suspected difficult airway is to anesthetize the child using a face mask with an inhalational anesthetic agent such as sevoflurane in 100% oxygen combined with gentle cricoid pressure. After the child is effectively anesthetized, airway management can now be performed using any of the previously mentioned techniques with the child breathing spontaneously. In addition to or instead of using an inhalational anesthetic, total IV anesthesia (TIVA) can be used with medications such as propofol and/or dexmedetomidine while maintaining spontaneous respirations during instrumentation of the airway. Alternatively, an infusion of ketamine can provide sedation and analgesia while maintaining spontaneous respirations, although glycopyrrolate may be required to attenuate increased production of oral secretions.

In emergency situations, blind placement of a supraglottic airway device such as an LMA is recommended as part of the American Society of Anesthesiologists' Difficult Airway Algorithm.[110] The LMA does not protect the airway from tracheal aspiration of gastric contents, but it may be used as a conduit to facilitate blind or fiberoptic intubation of the trachea as well as providing reestablishment of adequate oxygenation and ventilation.[111] The development of an LMA ProSeal (Teleflex Medical Inc., Research Triangle Park, NC) with a modified cuff and drainage tube that is available in sizes 1 to 5 may increases the safety of this process by facilitating the evacuation of gastric contents and providing an improved airway seal than earlier LMA devices.[112,113] The Fastrach LMA (Teleflex Medical Inc.) is another type of supraglottic device that is useful when direct visualization of the laryngeal inlet is not possible. This device has been designed to blindly place a tracheal tube into the trachea from within the supraglottic airway.[114] However, this device is only available for children who weigh more than 30 kg.[115]

CRICOID PRESSURE

Cricoid pressure, popularized for RSI by Sellick in his seminal report in 1961,[116] described the position of the head and neck during this maneuver. In the original description, the Sellick maneuver was performed with the patient in the supine position, with the neck fully extended, in a slight head-down tilt, and the nasogastric tube, if present, removed. The concavity of the cervical neck is maintained during cricoid pressure using a firm support placed under the cervical spine. Cricoid pressure is applied by an assistant using the thumb and second finger; the first finger stabilizes the thumb and finger on the cricoid ring. Pressure is applied firmly as consciousness is lost and released only after the tracheal tube cuff has been inflated.

In current practice, the head and neck are often not positioned as described by Sellick. Although Sellick's preliminary evidence suggested that his technique was very effective for occluding the esophagus, no randomized, controlled trials have confirmed its effectiveness or its superiority over other techniques in preventing aspiration during RSI.[117,118] A recent Cochrane review[119] in adults was unable to reach a conclusion regarding the effectiveness of cricoid pressure to prevent regurgitation. Radiologic evidence suggests that cricoid pressure may not completely occlude the lumen of the esophagus because the contours of the vertebral bodies are asymmetric and the esophagus is not aligned directly over the vertebral bodies.[120] The application of cricoid pressure in children may result in even further lateral displacement of the esophagus than in adults.[121] Sellick never described the amount of force required to occlude the lumen of the esophagus, although in adults, a force of 30 to 40 N (equivalent to a 3- to 4-kg mass) is considered sufficient to occlude the esophagus. In a study of the force required to occlude the esophagus in infants, investigators determined that a force of only 5 N distorts the airway in infants weighing less than 5 kg and that a force of only 12 N produces the same distortion in 15-year-old adolescents.[122] This raises the question of how much force is required to reliably occlude the esophagus without distorting the airway.

Many assistants who perform cricoid pressure apply insufficient force,[123] apply force at an incorrect location,[124] or use excessive force that may distort the larynx and make tracheal intubation more difficult. One study found that correctly applied cricoid pressure in children 2 weeks to 8 years of age with or without paralysis resulted in no leak of air into the stomach with up to 40 cm H_2O of peak inflation pressure.[125]

In children, the application of cricoid pressure has been viewed with some skepticism because the force required has been considered excessive in younger children. However, in the current

medicolegal climate, many providers have perceived an obligation on their part to perform this technique. In support of this perception, the results of a survey documented that even though 71% do not believe cricoid pressure occludes the esophagus, 90% use it when there is an increased risk for pulmonary aspiration.[126]

VOLUME ADMINISTRATION

Better understanding of the mechanisms of the stress response, and particularly of the factors that contribute to sepsis and ongoing proliferation of proinflammatory cytokines, has helped redefine the immediate and long-term goals of acute resuscitation as well as the definitive management for the unstable trauma patient.[127] The original concept of resuscitation was restoration of adequate circulating volume with appropriate red blood cell mass and adequate oxygenation, but this has evolved to focus on restoration of total body homeostasis. The initial priority is focused on stabilizing the circulation and should progress seamlessly to the aggressive management of metabolic derangements. The anesthesiologist who is involved in immediate resuscitation of the severely injured child should focus on these initial hemodynamic goals.

The preservation of intravascular volume is a primary priority during the initial resuscitation of the severely injured child. When immediate surgical intervention in the operating room is not necessary, it is advisable to replace fluid deficits as much as feasible before induction of anesthesia. Mild to moderate deficits can be replaced with isotonic crystalloid solutions. In severe hypovolemia with ongoing blood loss, colloids such as 5% albumin can be considered for use as an intravascular volume expander along with packed red blood cells. If time permits and if clinically indicated, crossmatched blood products should be administered, starting with an initial dose of 10 mL/kg of packed red blood cells. Type-specific uncrossmatched blood has a very low incidence of transfusion reactions and is typically available before crossmatched blood.[128] In an emergency situation requiring the immediate transfusion of blood products, type O negative packed red blood cells should be administered if the ABO blood type of the child has not been determined. Treatment strategies for managing hemodynamically unstable and actively bleeding adult trauma patients emphasizes rapid transport to definitive care, limits initial surgical interventions and supports the damage control model, uses crystalloid as the initial fluid of choice, and follows an empiric 1 : 1 : 1 approach to transfusion with red blood cells, plasma, and platelets.[129] However, the optimal fluid management strategy for trauma resuscitation in pediatric patients has not been established (see also Chapter 12).[130]

Life-threatening exsanguination is most commonly caused by a massive disruption of solid viscera or major vascular structures within the abdomen and chest. External blood loss, typically from the groin, neck, or scalp, can also lead to exsanguination. The most important part of this resuscitation process is restoration of adequate red blood cell mass and circulating volume to promote effective tissue perfusion and oxygenation. Evaluation of 103,434 cases in phases II and III of the National Pediatric Trauma Registry study suggests that massive exsanguination is relatively uncommon.[131] Children who sustain massive exsanguinating injuries typically die at the scene.

There is significant evidence that utilization of massive transfusion protocols (MTPs) improves mortality outcomes and reduces the overall usage of blood products.[132,133] Improvement is likely due to a number of factors relating to human factor behaviors during a crisis,[134] a combination of best evidence practices to reduce the likelihood of coagulopathy,[135] and system organization in reducing delays in blood product delivery.[136,137] Several MTPs have been developed for use in children (see E-Fig. 12.1 and see Chapter 12).

If volume resuscitation is vigorous and large volumes of crystalloid solutions are administered, hemorrhage-induced red blood cell loss may be further exacerbated by dilution. Overzealous fluid resuscitation may worsen bleeding by abruptly increasing the systolic blood pressure that, in turn, disrupts clots from injured vessels. Clinical evidence for this principle has been limited to the assessment of penetrating injuries in adults and elective cardiac surgery, emphasizing the necessity of a proper balance between restoration of adequate peripheral perfusion and avoidance of gross fluid overload.[138,139] Effective circulatory resuscitation of the injured child requires a combination of clinical data, anticipation of future physiologic challenges, and coordination of planned operative interventions by all specialists involved in the child's acute care. Large-volume transfusions without consideration of coagulation status, electrolyte shifts, or critical serum protein depletion may produce coagulopathy. Injudicious or inadequate crystalloid infusions may worsen capillary leak locally within injured organs and remotely in the interstitium of lung and brain. It is postulated that the concentrations of systemic inflammatory mediators increase after traumatic injuries. Increased serum secretory phospholipase A_2 levels have been associated with traumatic injuries.[140] Increased plasma high-mobility group box 1 (HMGB1) levels have also been identified after traumatic injuries, although clear correlations with patient outcomes have not been established.[141]

Injured children tend to be reasonably free of the acquired cardiovascular diseases that complicate the care of injured adults. However, transient myocardial ischemia can quickly undermine contractility of even the healthiest heart. In the presence of cardiovascular collapse from massive or ongoing hemorrhage, this can rapidly lead to cardiac failure and peripheral hypoperfusion. Children who are resuscitated from major hemorrhage and who have been exposed to prolonged low flow states may require inotropic support to maintain adequate perfusion. Since an accurate definition for what was previously referred to as myocardial contusion is not easily quantifiable, a high index of suspicion based on an understanding of the child's mechanism of injury is the best guide to preemptive management, especially if rhythm disturbances or refractory hypotension are observed.[142,143]

Studies are being conducted to determine the ideal products and dosing schedules for fluid resuscitation of injured children; it is possible in the near future that noninvasive continuous cardiac output will provide immediate feedback regarding adequacy of volume resuscitation and/or the need to supplement with inotropic agents[144] (see also Chapter 52 and Fig. 52.9). Several studies have evaluated hypertonic saline for use as a resuscitation solution and for the management of traumatic brain injury[145–147]; recommendations cannot be made at this time since no fluid product has been proven superior.[148–150] However, children with evidence of hypovolemia who are bleeding significantly and receiving isotonic crystalloids probably should be initially resuscitated with lactated Ringer's solution because of its pH of 6.5, compared with a pH of 5.0 for normal saline; solutions such as PlasmaLyte should also be considered since they have a physiologic pH (7.4). The critical objectives during volume resuscitation are immediate control of the sources of hemorrhage, restoration of red blood cell mass to ensure adequate oxygen delivery, and appropriate rheology to enhance tissue microperfusion.

VASCULAR ACCESS

Vascular access can be improperly disregarded as one of the more important priorities in the initial care of injured children. In some circumstances, placement of two large-bore IV lines may be very challenging in the hypovolemic child. In other situations, the child arrives at the emergency department with no vascular access. In the setting of the emergency department or operating room, adequate vascular access can usually be readily obtained by a standard percutaneous approach through a peripheral vein (see Fig. 49.1) or perhaps by direct percutaneous cannulation of the femoral vein (see Fig. 49.5). These two methods are consistently successful in achieving rapid vascular access without resorting to invasive techniques. The success rate for percutaneous femoral catheterizations using a Seldinger technique (see Fig. 49.2) is so high that using a cutdown approach is rarely required. If the child is severely exsanguinated and percutaneous femoral vascular access is unsuccessful, surgical exposure through an incision 1 cm below the inguinal ligament can expose the saphenous vein at the saphenofemoral junction. This provides immediate access to large-caliber venous vessels and also facilitates the placement of a femoral arterial line for ongoing management.

Ultrasound-guided vascular access techniques may also be used to place peripheral and central catheters within the venous and arterial systems.[151,152] Many trauma centers no longer routinely use subclavian or internal jugular veins for vascular access during acute resuscitation. Personnel responsible for airway management usually obstruct access to the neck, as does the cervical collar that should be in place as part of standard prehospital management protocols. In an orchestrated approach, during the primary survey, one individual or group of individuals should concentrate fully on securing adequate access to the vascular system.

Intraosseous infusion devices are being increasingly used in adults and children for whom percutaneous vascular access is unavailable or unsuccessful,[153] particularly within the prehospital setting.[154] In the pediatric population, intraosseous needles are usually placed in the tibial plateau medial to the tibial tuberosity approximately 3 to 5 cm below the knee. These devices can be lifesaving and usually are inserted after several attempts at venous access have failed (see also Chapter 49 and Figs. 49.6 and 49.7). If appropriately placed, they are useful conduits for infusion of all medications, crystalloids, and blood products.[155] Intraosseous needles should be replaced by effective and reliable venous access as soon as possible. One type of intraosseous infusion device, the EZ-IO (Teleflex Medical Inc.) operates like a battery-powered drill and is relatively simple to train providers in its operation and is associated with rare complications (see Fig. 49.7).[156,157]

DAMAGE CONTROL SURGERY

Children with massive anatomic derangements associated with uncontrollable hemorrhage usually require emergent operative intervention. In many trauma centers, these hemodynamically unstable children are initially treated using *damage control surgery*,[158] which is based on the premise that rapid control of abdominal bleeding by placing abdominal packing and immediate coverage of the open abdomen enables more effective resuscitation before exposing the child to a more prolonged definitive repair.

Over the past decade, the use of damage control surgery for the initial stabilization rather than definitive repair has moved the focus of resuscitation away from simple circulatory volume management to a need for immediate correction of whole-body metabolic derangements associated with the stress response.[159] Acute abdominal packing and coverage avoids the development of abdominal compartment syndrome, allows reevaluation of the injured tissue, and provides access for repeated lavage of contaminated spaces. Although there have been concerns that this approach may be used more often than necessary,[160] the risks of leaving an abdomen open are minimal compared with the ventilatory and circulatory consequences that may develop from an abdominal compartment syndrome. Damage control surgery has proved to be a lifesaving technique in isolated circumstances by allowing an unstable child to receive comprehensive resuscitation in a more controlled environment.[161]

PAIN MANAGEMENT

Acute pain that occurs as a result of traumatic injuries is one of the most common adverse sequelae experienced by children.[162] Some practitioners fear that if they treat the pain that follows a traumatic injury, they may mask the symptoms of injury. Historically, adults have received significantly more analgesia after injuries than children.[163] As a result, many physicians withhold significant pain relief, especially opioids, because they fear opioid-related sequelae including respiratory depression or hypotension. All medications used for analgesia and sedation in children can have significant adverse effects; however, careful titration to the desired effect along with appropriate monitoring should ensure their safe administration.

The management of acute pain in the injured child can be accomplished by using nonpharmacologic interventions and pharmacologic therapies. Nonpharmacologic interventions include positive reinforcement, distraction, hypnotherapy, acupuncture, massage and touch relaxation, and guided imagery.[164] Pharmacologic therapies include oral and IV acetaminophen and nonsteroidal antiinflammatory drugs for mild to moderate pain[165] and oral and IV opioids for moderate to severe pain.[166]

Injured children are often in pain at the time of arrival at the emergency department. For unstable children and those with evolving neurologic dysfunction, opioids must be used with caution. In many circumstances, injured children are sufficiently stable to allow judicious administration of opioids. Opioids free of histamine release (e.g., fentanyl) are preferable to those that release histamine (e.g., morphine), especially for children who are potentially hypovolemic. Fentanyl should be titrated in small increments (e.g., 0.5–1.0 μg/kg) to reduce the risk for respiratory depression and side effects such as chest wall or glottic rigidity.

An alternate route to deliver medications, especially when venous or intraosseous access is not initially present, includes the nares. This route can be used until other routes for drug administration are established or in lieu of IV catheters placed solely for minor procedures (i.e., fracture reductions in the emergency department). Nasal diamorphine,[167] sufetanil, ketamine, and fentanyl[168] are commonly used. Improved nasal delivery systems provide accurate dosing and broaden the drug choices (e.g., ketorolac[169]). Drug combinations may show benefits over single-drug therapy. Formulations containing two drugs may improve analgesia by additivity while decreasing adverse effects.[170]

In many cases, regional anesthesia can be used to provide analgesia in the emergency department, as the primary anesthetic in a cooperative or older child to avoid the risks associated with general anesthesia such as pulmonary aspiration, and as a supplement to general anesthesia for postoperative analgesia.[171,172] For example, analgesia for children with midshaft fractures of the femur can be provided by a traditional femoral nerve block or fascia iliaca compartment block, diminishing pain from the femur and quadriceps muscle spasm (see also Chapters 42 and 43). Similarly, an axillary or supraclavicular nerve block may be used

in children with forearm fractures.[173] Central neuraxial techniques, such as epidural analgesia, can be useful for children with major thoracoabdominal trauma, including rib fractures, provided no contraindications to regional anesthesia are present.[174] Precise transfer of relevant information with the surgical team is advised so that there are no miscommunications about the ability to perform sensory and motor examinations as well as coordination for the administration of additional analgesic medications.

Future Directions in Pediatric Trauma

As traumatic injuries have become recognized as a significant public health threat, numerous initiatives have emerged to improve prevention of this hazard, management of its victims, and measurement of system performance and outcomes. Exciting areas of investigation continue to emerge in aspects of clinical management, systems development, patient safety, and injury prevention.[175–177]

Prevention and public education are important areas of ongoing research in pediatric trauma. There has been great progress in educating the public that many injuries are avoidable, but there are still many factors that undermine the best intentions to produce a safe and nurturing environment for children. A significant advance in effective prevention and public education has occurred through the Injury Free Coalition for Kids sponsored by the Robert Wood Johnson Foundation.[178–180] This coalition has evolved into a network of more than 30 institutions throughout the country, and each focuses on specific areas of enhanced public education to define opportunities for improvement within the environment of children. Although there is no such thing as a completely risk-free environment, ongoing and effective public awareness campaigns can enhance the likelihood that risks to children throughout the world will diminish.[181,182]

As the transition from fluid resuscitation to metabolic management has evolved, there has been increasing interest in identifying tissue-specific biomarkers that reflect the severity and prognosis of injury.[183,184] The efficacy of resuscitation may be enhanced by the routine assay of biomarkers that accurately reflects the levels of physiologic derangements or effective restoration of homeostasis. Numerous studies are focusing on identification of various components of neuronal tissue markers that reflect the presence and severity of traumatic brain injury.[185]

The combination of hypovolemia, coagulopathy, hypothermia, and acidosis are associated with increased morbidity and mortality. There have been many efforts to control these issues,[186] and most significant has been the evolution of damage control surgery. There is growing laboratory animal evidence that hypothermia, if induced in a rapid and controlled fashion, is cytoprotective.[69,187–189] However, a recent meta-analysis found no benefit from therapeutic hypothermia in children with traumatic brain injury.[190] This is an area that must make the transition from animal observations in the basic science laboratory to well-designed, randomized, controlled trials involving prehospital providers and established trauma programs. Emerging evidence also suggests that premature death in bleeding patients with severe trauma may be attenuated by administering antifibrinolytics, such as tranexamic acid.[191–193] Institution of tranexamic acid within 3 hours of the insult, particularly in countries with low to middle incomes, is likely to have the greatest impact on outcome. However, there is insufficient evidence to recommend antifibrinolytics in patients with traumatic brain injury,[194] although clinical research has demonstrated a reduction in mortality with early use of tranexamic acid in adult trauma patients.[195] Randomized, controlled trials enrolling traumatized children are warranted to identify a possible role for antifibrinolytics to prevent premature death.

Summary

Trauma remains the most common cause of death for children older than 1 year of age. Pediatric patients develop unique traumatic injuries compared with adults, resulting in the need for specific knowledge and specialized anesthesia management. Anesthesiologists may function in several essential roles in the perioperative management of the pediatric trauma patient. They may provide emergent airway management in the emergency department, intraoperative care in the operating room, and anesthesia and pain control in the ICU. The transition from acute resuscitation to definitive care should be a seamless continuum focusing on immediate recognition of threats to life, rapid restoration of homeostasis, definitive treatment of injuries, and effective rehabilitation and convalescence.

Care of the trauma patient is a perfect example of a team-driven approach that requires thoughtful coordination and adherence to established protocols. The investment of time necessary to master this level of multidisciplinary, comprehensive care produces immense returns in diminished mortality and enhanced quality of life for all children.

ACKNOWLEDGMENT

We thank J. Tepas, MD, and H. DeSoto, MD, for their prior contributions to this chapter.

The 2015 AHA Pediatric Advanced Life Support Guidelines Update

THE PEDIATRIC ANESTHESIOLOGIST must be prepared to resuscitate a child who suffers a cardiac arrest in the course of a routine elective anesthetic, during a high-risk surgery, or outside the operating room (OR) during the delivery of an anesthetic or as a vital part of the "code team." The goal of this chapter is to provide pediatric anesthesiologists with an in-depth understanding of cardiopulmonary-cerebral resuscitation physiology and the current recommended resuscitative strategies.

Historical Background

In 1814, a description in poetical form of the Rules of the Humane Society for recovering drowned persons included the following description of mouth-to-mouth resuscitation[1]:

Let one the mouth, and either nostril close
While through the other the bellows gently blows.
Thus the pure air with steady force convey,
To put the flaccid lungs again in play.
Should bellows not be found, or found too late,
Let some kind soul with willing mouth inflate;
Then downward, though but lightly, press the chest.
And let the inflated air be upward prest.

External cardiac massage was successfully performed more than 100 years ago in two children (ages 8 and 13 years) after circulatory arrest precipitated by chloroform anesthesia during a surgical procedure.[2] In 1904, Crile described the effectiveness of external cardiac compressions in maintaining the circulation of dogs.[3]

After multiple reports that attested to the effectiveness of mouth-to-mouth resuscitation,[4–6] in 1958 the National Academy of Sciences National Research Council recommended mouth-to-mouth resuscitation with maximum backward tilt of the head as the preferred technique for all individuals requiring emergency artificial ventilation. In 1960, external cardiac compression was revived as a resuscitation technique when its effectiveness[7] was demonstrated when combined with artificial respirations. Many of the patients had sustained cardiac arrest during anesthesia. Before this study, internal cardiac compression was the accepted technique, with its effectiveness demonstrated by experience in cardiac bypass surgery. In 1947, the first successful internal defibrillation of a human heart was performed,[8] and in 1956, the first successful external defibrillation was performed.[9]

Epidemiology, Prevention, and Outcome of In-Hospital Cardiopulmonary Arrest

A 2009 review of cardiac arrest events submitted to the National Registry of Cardiopulmonary Circulation included 3342 pediatric events, excluding events in a delivery room or neonatal intensive care unit (NICU).[10] Seventy-three percent of the inpatient cardiac arrests had occurred in an ICU, 7% in a general inpatient area, 11% in an emergency department, and 3% in an OR or postanesthesia care unit. Return of spontaneous circulation (ROSC) was achieved in 65%, 24-hour survival occurred in 47%, and 30% of children survived until hospital discharge. Other large series of in-hospital pediatric cardiac arrest reported that between 14% and 44% survived until hospital discharge[11–14] with the 44% survival rate from cardiac arrests that had occurred in a pediatric cardiac ICU. In another multicenter cohort study of in-hospital pediatric cardiac arrest,[15] 48.7% of the 353 children survived until hospital discharge. Survivors had greater body temperatures, greater pH values, and reduced serum lactate concentrations compared with nonsurvivors. Nonsurvivors were more likely to have had a tracheal tube before the arrest and to have received sodium bicarbonate, calcium, and vasopressin during the arrest. In this study, postoperative cardiopulmonary resuscitation (CPR) was associated with decreased mortality. In a retrospective review of more than 29,000 discharges with in-hospital cardiac arrest between 1997 and 2012 revealed a discharge survival of 54% overall, having increased from 49% in 1997 to 60% in 2012.[16] The incidence of in-hospital cardiac arrest was greater for males, neonates and infants, African American children, and children from metropolitan regions and from families with lower median incomes. Survival rates were less for teenagers, African American and Hispanic children, and children from metropolitan regions.

Inpatient quality improvement and patient safety-focused programs have identified interventions and recognized risks that may prevent cardiac arrest events. Rapid response teams and early warning screening scores have become mainstays that reduce the prevalence of cardiac arrest.[17–20] Perioperative physicians have spearheaded the development of risk-stratification instruments for assessing patient's risk of morbidity and mortality such as the American Society of Anesthesiology Classification physical status and airway visualization scoring methods.[21] These screening and stratification instruments identify necessary resources and help to develop plans for high-risk patients.[22–27] In addition, the perioperative physician should identify potential risks to the patient and consult closely with surgical and subspecialty colleagues. The increased survival of children with uncommon chronic morbidities, syndromes, and metabolic illness requires consultation from a host of specialists as the breadth of knowledge and experience required for their safe, effective care is extensive and complex. In complex cases, broad consultation may be necessary before an anesthesia plan is formulated. The operative and anesthesia plan along with potential risks should be conveyed to the patient as well as a management plan for their chronic conditions.

Diagnosis of Cardiac Arrest

For the child who suffers a cardiac arrest in the OR, electronic monitoring usually alerts the anesthesiologist to an actual or impending cardiac arrest. The electrocardiogram (ECG) may indicate nonperfusing rhythms such as ventricular fibrillation (VF), pulseless electrical activity (PEA), and asystole; end-tidal carbon dioxide ($ETCO_2$) may decrease precipitously, reflecting a decrease in cardiac output as a result of a decreased delivery of carbon dioxide (CO_2) to the lungs; and a pulse oximeter may lose its regular waveform in the absence of pulsatile blood flow. Despite the importance of these monitors, the diagnosis of cardiopulmonary arrest still rests on the absence of a pulse in a major artery (e.g., carotid, femoral, or brachial artery) that is determined by palpation in the presence of unconsciousness and apnea.

In the early minutes of CPR, the reason for the cardiac arrest should be sought. A blood gas analysis and serum electrolyte concentrations (ideally as point-of-care testing) may prove helpful in determining the cause of the arrest. In many instances, resuscitation will not be successful without identification and correction of the underlying cause. A focused physical examination should be conducted and a brief history elicited if it is not already known. If not present, a cardiorespiratory monitor should be placed and the ECG examined. In an intraoperative arrest, the surgeon may be able to provide clues to the diagnosis, such as excessive blood loss, compression of major blood vessels, decreasing venous return to the heart, manipulation of anatomic structures (e.g., manipulation of the peritoneum resulting in a severe vagal bradycardia or asystole), or air embolism. Equipment malfunction must always be considered as a potential cause of arrest.

Mechanics of Cardiopulmonary Resuscitation

CPR should follow the airway, breathing, circulation (ABC) algorithm with the exception that the child with VF or pulseless ventricular tachycardia should receive electrical defibrillation without delay. Airway access in children with VF or pulseless ventricular tachycardia should be performed secondarily. CPR should continue without interruption until a shock can be delivered.

AIRWAY

Before tracheal intubation, the child's airway can be managed effectively with bag-valve-mask (BVM) ventilation with proper head positioning and jaw thrust. Although tracheal intubation ensures optimal control of the airway for effective ventilation, multiple attempts at tracheal intubation by an inexperienced operator may seriously compromise the airway and increase the cumulative duration of "no flow" (i.e., no CPR).

In the child without an artificial airway and proper application of the jaw thrust, the use of BVM devices may cause significant gastric inflation that leads to regurgitation and pulmonary aspiration of gastric contents.[28] Abdominal distention (gastric and bowel) can compromise oxygenation; therefore the stomach should be vented when excessive gastric inflation occurs. In one study, the incidence of pulmonary aspiration in a series of failed resuscitations was 28%.[29] For this reason as well as the risk of barotrauma and volutrauma, excessive inflation pressures should be avoided. Visualizing bilateral chest excursions and listening to the quality of the breath sounds rather than setting a preset maximal inflation pressure best judges effective bilateral ventilation. Placement of a supraglottic device such as a laryngeal mask airway (LMA) may serve as a bridge to establishing a more definitive airway in the hands of those inexperienced in airway management.

Tracheal intubation should be performed as soon as appropriate personnel and equipment are available. Some centers advocate placement of an LMA owing to the delay and technical challenge of direct laryngoscopy and endotracheal tube placement. However,

this is not a universally reported practice in the care of pediatric cardiac arrest.[30,31] The $ETCO_2$ is a valuable method of confirming correct placement of the tracheal tube. In the absence of capnography, a disposable colorimetric $ETCO_2$ device may be substituted (E-Fig. 39.4). However, it is important to appreciate that $ETCO_2$ measurements are meaningful only in the presence of effective pulmonary circulation, such that a lack of color change may reflect either improper placement of the tube or a lack of pulmonary blood flow resulting from ineffective chest compressions or a massive pulmonary embolism. It is also essential to use the proper size colorimetric device for the child's weight because the adult size may not detect the presence of CO_2 and may lead the user to misdiagnose a successful intubation as unsuccessful.

BREATHING

Equipment to artificially ventilate the lungs should be readily available for all inpatients. The anesthesiologist needs to be familiar with the available equipment in different locations within the hospital because equipment for emergency ventilatory support may differ from standard equipment in the OR. Anesthesiologists are skilled providers of ventilatory support, but in the context of a cardiac arrest, must return to the basics and remember that *if there is no chest movement, there is no ventilation.* If no chest movement occurs during BVM ventilation despite an apparently good seal between the mask and the child's face, the underlying cause, be it upper airway obstruction, whether anatomic or caused by the presence of a foreign body, bilateral tension pneumothoraces, or severe bronchospasm, must be considered.

Overventilation is common during CPR, resulting in greater mean intrathoracic pressures than required, which decreases venous return and reduces cardiac output.[32] In cardiopulmonary arrest, less than normal minute ventilation may be appropriate, because cardiac output and delivery of CO_2 to the lungs are diminished. If an artificial airway is not in place for single-person rescue, two breaths should be given for each 30 chest compressions. If an artificial airway is not in place for two-person rescue, two breaths should be given after each 15 chest compressions. Once an artificial airway is in place, a ventilator rate of 8 to 10 per minute *without* pausing during rapid chest compressions should be used (Table 40.1).

CIRCULATION

During cardiac arrest, chest compressions provide the sole pump to perfuse a child's vital organs; therefore optimal performance of CPR is critical. Key elements to providing quality chest compressions include (1) ensuring an adequate rate (100 compressions per minute), (2) ensuring adequate chest wall depression (one-third to one-half of the anteroposterior chest diameter), (3) releasing completely between compressions to allow full chest wall recoil, (4) minimizing interruptions in chest compressions, and (5) ensuring that the child is on a sufficiently hard surface to allow effective chest compressions.[33] The strategy for successful CPR is to push hard and push fast, release completely, and do not interrupt compressions unnecessarily. Be mindful that incomplete recoil during CPR is associated with greater intrathoracic pressures and significantly decreased venous return, and coronary and cerebral perfusion.[34]

If the child is younger than 6 months, the person performing chest compressions can comfortably encircle the chest with his or her hands. Chest compressions should be performed using the circumferential technique; with thumbs depressing the sternum and the fingers supporting the infant's back and circumferentially squeezing the thorax (Fig. 40.1). In larger infants, the sternum can be compressed using two fingers; and in the child, either one or two hands can be used, depending on the size of the child and of the rescuer.[34] Whichever method is used, focused attention must remain on delivering effective compressions with *minimal interruptions.*[35] In all cases other than circumferential CPR, a backboard should be used. Properly delivered chest compressions will quickly fatigue the provider. To maintain effective CPR, providers should rotate approximately every 2 minutes to prevent fatigue and deterioration in the quality and rate of chest compressions.[34]

Mechanisms of Blood Flow

External chest compressions generate cardiac output via two mechanisms: the cardiac pump and the thoracic pump. The cardiac pump mechanism generates cardiac output by squeezing blood

TABLE 40.1 Ventilation and Chest Compressions During Pediatric Cardiopulmonary Pulmonary Resuscitation (all ages)

	Respirations	Chest Compressions	Notes
Bag-mask ventilation	2 respirations after each 15 chest compressions (if one rescuer only, 2 respirations after each 30 compressions)	100/minute	Aspirate (vent) the stomach if gastric inflation interferes with ventilation.
Endotracheal intubation	8–10/minute	100/minute	Do not pause compressions during ventilation.

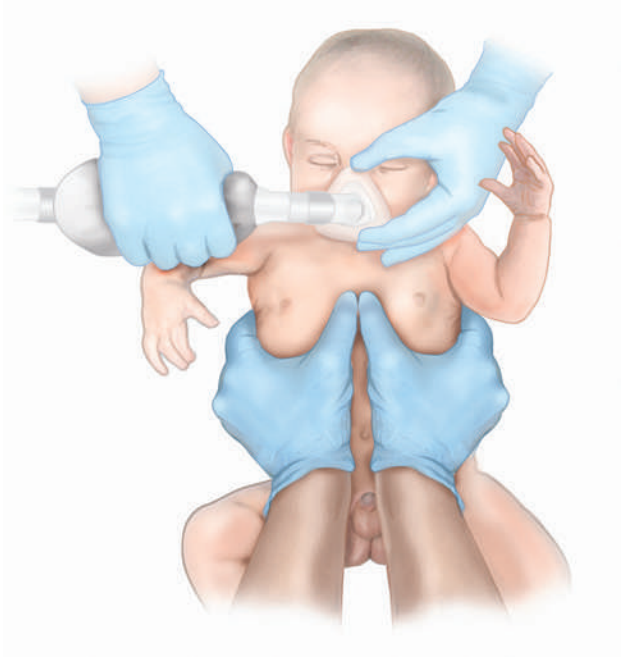

FIGURE 40.1 Chest-encircling method for cardiac compressions in a neonate: thumbs are placed one finger's breadth below the nipple line. (Modified from Todres ID, Rogers MC. Methods of external cardiac massage in the newborn infant. *J Pediatr.* 1975;86:781–782.)

out of the heart when it is compressed between the sternum and the vertebral column. Blood exits the heart in an anterograde direction because the atrioventricular valves close during ventricular compression. Between compressions, ventricular pressure decreases below atrial pressure, allowing the atrioventricular valves to open and fill the ventricles. This sequence of events resembles the normal cardiac cycle. Although the cardiac pump is likely not the dominant mechanism that generates cardiac output during most closed-chest CPR, specific clinical situations have been identified in which the cardiac pump mechanism is more prominent. For example, a smaller, more compliant chest may allow for more direct cardiac compression (Fig. 40.2). Increasing the applied force during chest compressions also increases direct cardiac compression and emptying of the ventricles.

Several observations suggest that the cardiac pump is not the primary mechanism of generating cardiac output during CPR. Angiographic studies show that blood passes from the vena cava through the right heart into the pulmonary artery and from the pulmonary veins through the left heart into the aorta during a single chest compression.[36,37] Echocardiographic studies show that the atrioventricular valves are open during blood ejection.[36,38,39] Without closure of atrioventricular valves during chest compression, the cardiac pump mechanisms cannot account for anterograde movement of blood during CPR.

The thoracic pump mechanism is the second mechanism by which cardiac output is generated during CPR. In 1976, several patients who developed VF during cardiac catheterization were noted to produce enough blood flow to maintain consciousness by repetitive coughing.[40] The increase in thoracic pressure with coughing produced anterograde blood flow without direct cardiac compression. This describes the thoracic pump mechanism, in which the heart acts a passive conduit for blood flow. The intrathoracic pressure is greater than the extrathoracic pressure during the compression phase of CPR, at which time blood flows out of the thorax, with venous valves preventing excessive retrograde blood flow (Fig. 40.3). Experimental and clinical data support both mechanisms of blood flow during CPR in human infants.

Rate and Duty Cycle

The recommended rate of chest compressions for all children is 100 per minute, with great care taken to minimize interruptions in chest compressions and to ensure adequate compression depth.[35] This rate represents a compromise that attempts to maximize contributions from both the thoracic pump and cardiac pump mechanism of blood flow.

Duty cycle is defined as the percent of the compression-relaxation cycle devoted to compression. If blood flow is generated by direct cardiac compression, then the force of compression determines the stroke volume. Prolonging the compression (increasing the duty cycle) beyond the time necessary for full ventricular ejection should not affect the stroke volume. Increasing the rate of compressions should increase cardiac output because a fixed volume of blood is ejected with each cardiac compression. In contrast, if blood flow is produced by the thoracic pump mechanism, the volume of blood that is ejected comes from a large reservoir of blood contained within the capacitance vessels in the chest. With the thoracic pump mechanism, flow is enhanced by increasing either the force of compression or the duty cycle but is not affected by changes in the compression rate over a wide range of rates, given a set duty cycle.[41]

Animal models yield conflicting results as to the optimal compression rate and duty cycle. However, a rate of compressions during conventional CPR of 100 per minute satisfies both those who prefer the faster rates and those who support a longer duty cycle. This is true because it is easier to produce a longer duty cycle when compressions are administered at a faster rate.[42,43]

Defibrillation and Cardioversion

In children with VF or pulseless ventricular tachycardia, the immediate management should be defibrillation, without delay to secure an airway.

ELECTRIC COUNTERSHOCK

Electric countershock, or defibrillation, is the treatment of choice for VF and pulseless ventricular tachycardia. Defibrillation should not be delayed to secure an airway, because the likelihood of restoring an organized rhythm decreases as the duration of fibrillation increases. VF is terminated by simultaneous depolarization and sustained contraction of a critical mass of myocardium,[44] allowing return of spontaneous, coordinated cardiac contractions, assuming the myocardium is well oxygenated and the acid-base status is relatively normal. Drug treatment may be required as an adjunct to defibrillation, but by itself cannot be relied on to terminate VF.

An older generation of defibrillators still present in many hospitals delivers energy in a monophasic damped sinusoidal waveform (Fig. 40.4A). This type of instrument delivers a single, unidirectional current with a gradual decrease to zero current. By contrast, the newer generation of biphasic defibrillators delivers a current in a positive direction for a set period, followed by a reversal in current (Fig. 40.4B). Biphasic defibrillators are more effective than monophasic defibrillators for terminating VF in adults; therefore their use is recommended where possible. Pediatric attenuator pads or a pediatric mode on the automated external defibrillator (AED) should be used in children 1 to 8 years of age if it is available, but if it is not (and a standard defibrillator is similarly unavailable), an unmodified AED can be used.

In the majority of adult cases, energy levels of 100 to 200 J are successful when shocks are delivered with minimal delay.[45,46] The goal of defibrillation is to deliver a minimum amount of electrical energy to a critical mass of ventricular muscle while avoiding excessive current that could further damage the heart.

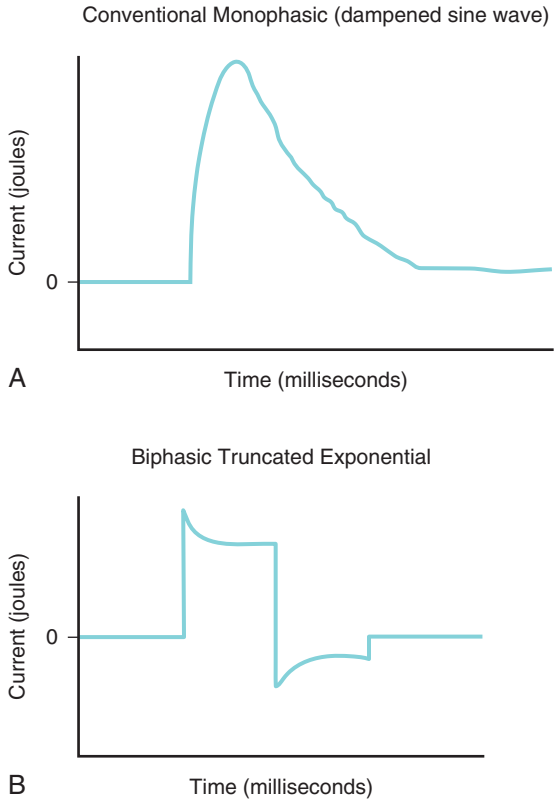

FIGURE 40.4 Energy delivery during conventional monophasic **(A)** and biphasic truncated exponential **(B)** defibrillation.

The most reliable predictor for success of defibrillation is the duration of fibrillation before the first countershock.[47] Acidosis and hypoxemia also decrease the success of defibrillation.[47]

PRACTICAL ASPECTS OF DEFIBRILLATION IN CHILDREN

Correct paddle size and position are critical to the success of defibrillation. The largest paddle size appropriate for the child should be used because a larger size reduces the density of current flow, which in turn reduces myocardial damage. In general, adult paddles should be used in children weighing more than 10 kg and infant paddles should be used in infants weighing less than 10 kg. Paddle force is important as well. If the entire paddle does not rest *firmly* on the chest wall, a current of increased density will be delivered to a small contact point. Paddles should be positioned on the chest wall so that the bulk of myocardium lies directly between them. One paddle is placed to the right of the upper sternum below the clavicle; the other is positioned just caudad and to the left of the left nipple. For children with dextrocardia, the position of the paddles should be a mirror image. An alternative approach is to place one paddle anteriorly over the left precordium and the other paddle posteriorly between the scapulae.

The interface between the paddle and chest wall can be gel pads, electrode cream, or electrode paste. The electrode cream produces less impedance than the paste. *Electric current follows the path of least resistance, so care should be taken that the interface material from one paddle does not touch that of the other paddle. This is especially important in infants, in whom the distance between paddles is small.* If the gel is continuous between paddles, a short circuit is created and an insufficient amount of current will traverse the heart. Use of bare metal paddles increases the risk of arcing and worsens cutaneous burns from defibrillation. The use of self-adhesive pads is preferable when feasible.

In the past, sparking from poorly applied defibrillator paddles has been a fire risk. All sources of free-flowing O_2 were maintained at a distance of at least 1 m from the child. However, the use of pads rather than paddles has reduced the risk of fire, allowing the nasal oxygen or mask oxygen supply to remain in place during defibrillation. It is not necessary to disconnect the ventilator from the child's tracheal tube, but if the ventilator is disconnected, the fresh gas flow should be turned off.

For children with in-hospital VF or pulseless ventricular tachycardia, defibrillation should be attempted as soon as possible, with optimal CPR until the defibrillator is ready to deliver a shock. For the first defibrillation, 2 J/kg of delivered energy should be administered (Fig. 40.5). After delivery of the shock, CPR should resume immediately with chest compressions for five duty cycles (2 minutes). If the first shock fails to restore normal sinus rhythm, the incremental benefit of a second immediate shock is small. Resumption of CPR is likely to confer a greater benefit than a second shock. CPR may restore coronary perfusion, increasing the likelihood of defibrillation with a subsequent shock. It is important to minimize the time interval between chest compressions and delivery of the shock and between delivery of the shock and resumption of post-shock CPR.[35] Approximately 2 minutes of CPR should be delivered before a second shock is delivered at twice the original energy level (4 J/kg).[35]

If VF or pulseless ventricular tachycardia persists beyond the second defibrillation, standard doses of epinephrine should be administered (with subsequent doses every 3 to 5 minutes during persistent cardiac arrest). After 2 minutes of CPR, another defibrillation should be attempted, followed by amiodarone (5 mg/kg)

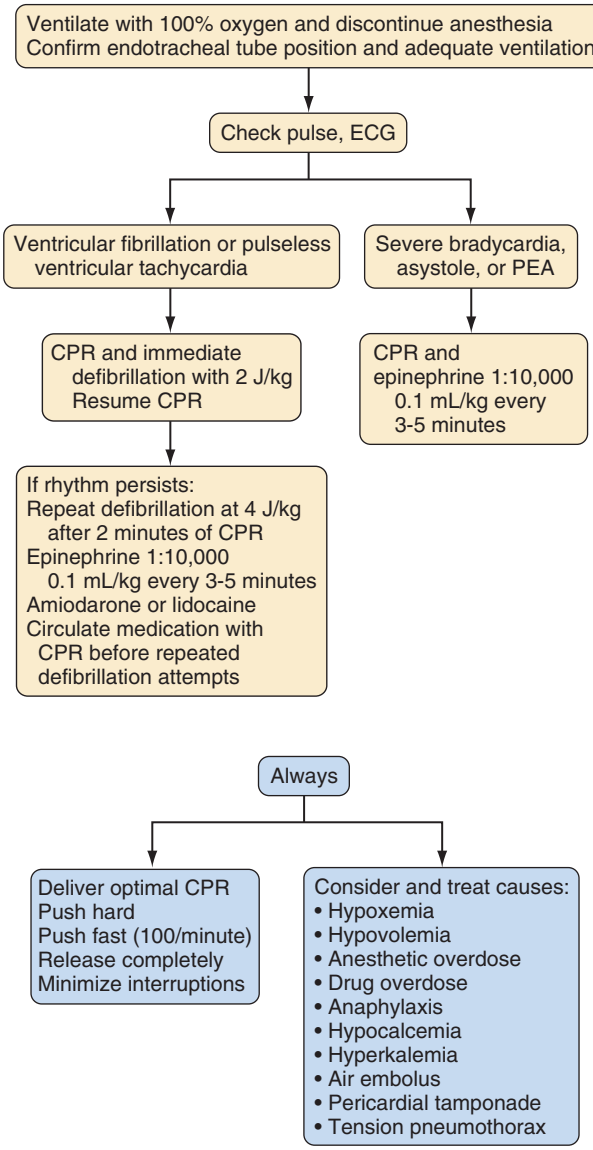

FIGURE 40.5 Algorithm for diagnosis and treatment of acute cardiac dysfunction in the operating room. *CPR,* cardiopulmonary resuscitation; *ECG,* electrocardiogram; *PEA,* pulseless electrical activity.

or lidocaine (1 mg/kg) intravenously, with subsequent defibrillation attempts. It is not necessary to increase the energy level on each successive shock after the second attempt. However, successful defibrillation has been reported with currents in excess of 4 J/kg, up to a maximum dose not exceeding 10 J/kg or the adult level, whichever is less, without adverse sequelae.[35] This sometimes occurs when a fixed energy level, adult AED is used in a small child.

OPEN-CHEST DEFIBRILLATION

If the chest is already open in the OR or easily opened as in a postoperative cardiac patient, VF should be treated with open-chest defibrillation, using internal paddles applied directly to the heart. These should have a diameter of 6 cm for adults, 4 cm for children, and 2 cm for infants. Handles should be insulated. One electrode is placed behind the left ventricle and the other over the right ventricle on the anterior surface of the heart. The energy level used should begin at 5 J in infants and 20 J in adults.

AUTOMATED EXTERNAL DEFIBRILLATION

The use of AEDs is now standard therapy in out-of-hospital resuscitation of adults.[34,45] AEDs are now deemed appropriate for use in children older than 1 year. If available, pediatric attenuator pads or a pediatric mode on the AED should be used in children 1 to 8 years of age, but if unavailable (and a standard defibrillator is similarly unavailable), an unmodified AED should be used.

TRANSCUTANEOUS CARDIAC PACING

In the absence of in situ pacing wires or an indwelling transvenous or esophageal pacing catheter, transcutaneous cardiac pacing (TCP) is the preferred method for temporary electrical cardiac pacing in children with asystole or severe bradycardia. TCP is indicated for children whose primary problem is impulse formation or conduction, with preserved myocardial function. It is most effective in those with sinus bradycardia or high-grade atrioventricular block, with slow ventricular response but adequate stroke volume. TCP is not indicated for children during prolonged arrest, because in this situation it usually results in electrical but not mechanical cardiac capture and its use may delay or interfere with other resuscitative efforts.

To set up pacing, one electrode is placed anteriorly at the left sternal border and the other posteriorly just below the left scapula. Smaller electrodes are available for infants and children, but adult-sized electrodes can be used in children weighing more than 15 kg. ECG leads should be connected to the pacemaker, the demand or asynchronous mode selected, and an age-appropriate heart rate used. The stimulus output should be set at zero when the pacemaker is turned on and then increased gradually until electrical capture is identified on the monitor. After electrical capture is achieved, whether an effective arterial pulse is generated must be determined. If not, additional resuscitative efforts should be initiated.

The most serious complication of TCP is the induction of a ventricular arrhythmia. Fortunately, this is rare and may be prevented by pacing only in the demand mode. Mild transient erythema beneath the electrodes is common. Skeletal muscle contraction can be minimized by using large electrodes, 40-msec pulse duration, and the smallest stimulus required for capture. If defibrillation or cardioversion is necessary, a distance of 2 to 3 cm must be allowed between the electrode and paddles to prevent arcing of the current.

Vascular Access and Monitoring During Cardiopulmonary Resuscitation

VASCULAR ACCESS AND FLUID ADMINISTRATION

One of the key aspects of successful CPR is the early establishment of a route to administer fluids and medications. If intravenous (IV) access cannot be established rapidly, the intraosseous or endotracheal route should be used (see Chapter 49 and Figs. 49.6 and 49.7).

Intravenous Access

Many children who suffer an in-hospital cardiac arrest will already have established vascular access. For children with impending cardiac arrest and no vascular access, a brief attempt should be made to establish peripheral IV access. If access is not achieved quickly, an intraosseous needle should be placed. For young children in cardiac arrest without vascular access, an intraosseous needle should be placed immediately to avoid any delay from repeated attempts to establish IV access.

Intraosseous Access

The intraosseous route can be used to administer all medications and fluids used during CPR, including whole blood. It may also be used to obtain initial blood samples, although acid-base analysis will be inaccurate after administration of sodium bicarbonate through the intraosseous needle. Intraosseous access should be considered a temporary measure during emergencies when alternate access is not available. Placing an intraosseous needle in an older child (older than 10 years) and adult, although possible, is more difficult because of the thicker bony cortex. Nonetheless, the success rate establishing intraosseous access in these age groups is 50%.[48]

The technique of establishing intraosseous access is straightforward. An intraosseous needle or, if unavailable, a standard 16- or 18-gauge needle, a spinal needle with stylet, or bone marrow needle may be inserted into the anterior surface of the tibia 1 to 2 cm below and 1 cm medial to the tibial tuberosity (avoiding the epiphyseal plate). The needle is directed at 90 degrees to the anteromedial surface of the tibia, just distal to the tuberosity (see Figs. 49.6 and 49.7). When the needle passes through the cortex and into the marrow, a sudden loss of resistance is sensed. If the needle has reached the marrow cavity, it will remain upright without support. If, however, the needle is in the subcutaneous tissue, it cannot remain upright without support. The free flow of infusate without significant subcutaneous infiltration confirms that the tip of the needle is in the bone marrow. Intraosseous access has a small complication rate,[49] although the complications could include osteomyelitis, fat and bone marrow embolism, and compartment syndrome. To avoid these complications, IV access should replace intraosseous access as soon as possible. The onset of action and concentration of most drugs after intraosseous administration are comparable with venous administration.[50] The EZ-IO system (Vidacare, Shavano Park, TX) provides a rapid means to establish intraosseous access (see Fig. 49.7).

ENDOTRACHEAL MEDICATION ADMINISTRATION

In the absence of other vascular access, medications including lidocaine, atropine, naloxone, and epinephrine (mnemonic LANE or LEAN; vasopressin is occasionally used in adults with the mnemonic NAVEL) can be administered through the endotracheal tube.[51,52] Ionized medications such as sodium bicarbonate and calcium chloride should not be administered through the tracheal tube. The peak concentration of epinephrine or lidocaine administered through the endotracheal tube, at similar doses, may be less than that through the IV route.[53] For example, the peak drug concentration of epinephrine after endotracheal administration was only 10% of that after IV administration in anesthetized dogs. The recommended dose for endotracheal epinephrine is 10 times the IV or intraosseous dose or 0.1 mg/kg for bradycardia or pulseless arrest.

The volume and the diluent in which the medications are administered through an endotracheal tube may be important. When large volumes of fluid are used, pulmonary surfactant may be altered or destroyed, resulting in atelectasis. The total volume of fluid delivered into the trachea with each drug administered should not exceed 10 mL in children and 5 mL in infants and neonates.[54] However, administering an adequate volume of a drug is important to reach a large surface area beyond the tip of the endotracheal tube to achieve rapid absorption. Absorption into the systemic circulation may be further enhanced by deep intrapulmonary administration by passing a catheter beyond the tip of the tracheal tube deep into the bronchial tree. The duration of effect of lidocaine, epinephrine, and atropine administered via the tracheal tube is prolonged compared with the same drugs given by the IV route. This "depot" effect is due to both a slower absorption from the lung and the larger drug doses used via this route.[53]

MONITORING DURING CARDIOPULMONARY RESUSCITATION

A basic clinical examination is vital during cardiac arrest. The chest is carefully observed for adequacy of bilateral chest expansion with artificial ventilation and for equal and normal breath sounds. In addition, the depth of compression and the position of the rescuer's hands should be constantly reevaluated while performing chest compressions by palpation of a major artery. Palpation of an artery is essential for both confirming the absence of a pulse and for assessing the adequacy of blood flow during chest compressions. Palpating the peripheral pulses may be inaccurate, especially during intense vasoconstriction associated with the use of epinephrine, so it is prudent to palpate only large arteries such as the brachial, femoral, or carotid artery.

An indwelling arterial catheter is a valuable monitor to assess the arterial blood pressure. Specific attention should be paid to diastolic blood pressure as it relates directly to adequacy of coronary perfusion during CPR. In addition, arterial access allows for frequent blood sampling, particularly for measurement of arterial pH and blood gases. Pulse oximetry can be used during CPR to determine the O_2 saturation and may be of value in assessing the adequacy of cardiac output, as reflected in the plethysmograph. The ECG can suggest metabolic imbalances and diagnose electrical disturbances.

The $ETCO_2$ monitor provides important information during the course of resuscitation. Capnography confirms correct placement of the endotracheal tube, monitors the quality of CPR, and provides an early indicator of ROSC.[55] Because the generation of exhaled CO_2 depends on pulmonary blood flow, $ETCO_2$ can provide a useful indicator of the adequacy of cardiac output generated by chest compressions. As the cardiac output increases, the $ETCO_2$ increases and the difference between end-tidal and arterial CO_2 becomes smaller.[56] In animal models, $ETCO_2$ during CPR correlates with coronary perfusion pressure and with ROSC.[57,58] A reduced $ETCO_2$ may occur transiently in the presence of adequate chest compressions after administration of epinephrine owing to an increase in intrapulmonary shunting. The International Liaison Committee on Resuscitation (ILCOR) acknowledges that small values of $ETCO_2$ are associated with small probability of survival. The committee believes, however, that there are insufficient data to support or refute a specific cutoff value of $ETCO_2$ as a prognostic indicator of outcome during adult cardiac arrest.[59] $ETCO_2$ monitoring may be considered to evaluate quality of chest compressions, but there is no pediatric evidence that it improves outcomes after cardiac arrest.[60] However, we strongly advocate the use of $ETCO_2$ monitoring as a surrogate to monitor effective chest compressions.

Temperature should be monitored during and after CPR. The resuscitation of the child with hypothermia as the cause of cardiac arrest must be continued until the child's core temperature exceeds 95°F (35°C). A glass bulb thermometer measures the temperature to very low values. Repeated measurements of core body temperature should be made at several sites (rectal, bladder, esophageal, axillary, or tympanic membrane) where possible to avoid misleading temperature readings from a single site, because local body temperature may vary with changes in regional blood flow during

CPR. Hyperthermia should be aggressively treated in the periarrest period, because postarrest hyperthermia is associated with worse outcomes in children.[61] Data suggest a benefit to induced hypothermia after resuscitation from cardiac arrest in adults[62,63] and after perinatal hypoxic or ischemic injury,[64] although recent evidence supports a temperature of 36°C rather than 33°C. The recent Therapeutic Hypothermia After Pediatric Cardiac Arrest (THAPCA) study concluded that therapeutic hypothermia did not confer a significant benefit over therapeutic normothermia for survival with good functional outcome at 1 year.[65]

Medications Used During Cardiopulmonary Resuscitation

α- AND β-ADRENERGIC AGONISTS

In 1963, only 3 years after the original description of closed-chest CPR, early administration of epinephrine in a canine model of cardiac arrest was shown to improve the success rate of CPR.[66] In addition, the administration of α-adrenergic agonists increased the aortic diastolic pressure, which improved the success of resuscitation. The evidence suggested that vasopressors such as epinephrine were valuable during resuscitation because they increased peripheral vascular tone and, hence, coronary perfusion pressure. The relative importance of α- and β-adrenergic agonist actions during resuscitation has been widely investigated. In a canine model of cardiac arrest, only 27% of dogs that received a pure β-adrenergic receptor agonist along with an α-adrenergic antagonist were resuscitated successfully, compared with 100% of dogs that received a pure α-adrenergic agonist and a β-adrenergic antagonist. Others demonstrated that the α-adrenergic effects of epinephrine resulted in intense vasoconstriction of the resistance vessels of all organs of the body, except those supplying the heart and brain.[67] Because of the widespread vasoconstriction in nonvital organs, adequate perfusion pressure and thus blood flow to the heart and brain could be achieved despite the fact that cardiac output was poor during CPR.[67–69]

The increase in aortic diastolic pressure associated with epinephrine administration during CPR is critical for maintaining coronary blood flow and enhancing the success of resuscitation.[70,71] Even though the contractile state of the myocardium is increased in the presence of β-adrenergic agonists in the spontaneously beating heart, β-adrenergic agonists may actually decrease myocardial blood flow by increasing intramyocardial wall pressure and vascular resistance during CPR.[72] By its inotropic and chronotropic effects, β-adrenergic stimulation increases myocardial O_2 demand, which, when superimposed on low coronary blood flow, increases the risk of ischemic injury.

Any medication that causes systemic arterial vasoconstriction can be used to increase aortic diastolic pressure and resuscitate the heart. For example, pure α-adrenergic agonists can be used in place of epinephrine during CPR. Phenylephrine and methoxamine, two α-adrenergic agonists, have been used in animal models of CPR with success equal to that of epinephrine. Their use results in a greater O_2 supply to demand ratio in the ischemic heart and at least a theoretical advantage over the combined α- and β-adrenergic agonist effects of epinephrine. These agonists, as well as other classes of vasopressors such as vasopressin, have been used successfully for resuscitation.

The merits of using a pure α-adrenergic agonist during CPR have been questioned by some investigators. Although the inotropic and chronotropic effects of β-adrenergic agonists may have deleterious hemodynamic effects during CPR for VF, increases in both heart rate and contractility will increase cardiac output when spontaneous coordinated ventricular contractions are achieved.

EPINEPHRINE

Epinephrine (adrenaline) is an endogenous catecholamine with potent α- and β-adrenergic stimulating properties. The β-adrenergic property increases systemic (both systolic and diastolic blood pressures) and pulmonary vascular resistance. The increase in diastolic blood pressure directly increases coronary perfusion pressure, thereby increasing coronary blood flow and increasing the likelihood of ROSC.[70,71] The β-adrenergic effect increases myocardial contractility and heart rate and relaxes smooth muscle in the skeletal muscle vascular bed and bronchi. Epinephrine also increases the vigor and intensity of VF, increasing the likelihood of successful defibrillation.[73]

Larger than necessary doses of epinephrine may be deleterious. Epinephrine may worsen myocardial ischemic injury secondary to increased O_2 demand and may result in postresuscitative tachyarrhythmias, hypertension, and pulmonary edema. Epinephrine causes hypoxemia and an increase in alveolar dead space ventilation by redistributing pulmonary blood flow.[56,74] Prolonged peripheral vasoconstriction by excessive doses of epinephrine may delay or impair reperfusion of systemic organs, particularly the kidneys and gastrointestinal tract.

Routine use of large-dose epinephrine in in-hospital pediatric cardiac arrest should be *avoided.* The use of high-dose epinephrine children with in-hospital cardiac arrest refractory to initial standard-dose epinephrine has not been encouraging. Survival was reduced at 24 hours compared with those given standard-dose epinephrine, with weak evidence of decreased survival to hospital discharge in the children who received large doses of epinephrine.[75] Despite these data, large doses of epinephrine may be considered in special cases (e.g., β-blocker overdose), particularly when diastolic blood pressure remains low despite excellent chest compression and several standard doses of epinephrine.

VASOPRESSIN

Vasopressin is a long-acting endogenous hormone that causes vasoconstriction (V1 receptor) and reabsorption of water in the renal tubule (V2 receptor). In experimental models of cardiac arrest, vasopressin increases blood flow to the heart and brain and improves long-term survival compared with epinephrine.[76,77] In a randomized trial of epinephrine and vasopressin in shock-resistant out-of-hospital VF in adults, vasopressin produced a greater rate of ROSC.[78] In a study of in-hospital adult cardiac arrest, epinephrine and vasopressin produced similar rates of survival to hospital discharge.[79] A recent meta-analysis of vasopressin for cardiac arrest did not demonstrate any overall benefit or harm.[80]

In a pediatric porcine model of prolonged VF, the combination of vasopressin and epinephrine resulted in greater left ventricular blood flow than either drug alone, and both vasopressin alone and vasopressin plus epinephrine increased cerebral blood flow more than epinephrine alone.[81] By contrast, in a pediatric porcine model of *asphyxial* cardiac arrest, ROSC was more likely in piglets treated with epinephrine than in those treated with vasopressin.[82] Pediatric[83–85] case series and reports suggested that vasopressin[83] or its long-acting analog, terlipressin,[84,85] may be effective in refractory cardiac arrest. In the 2009 National Registry of Cardiopulmonary Resuscitation (NRCPR) review, vasopressin was associated with reduced ROSC and weak evidence for reduced 24-hour

and discharge survival. There was insufficient evidence to make a recommendation for its routine use during cardiac arrest.[35]

ATROPINE

Atropine, a parasympatholytic agent, blocks cholinergic stimulation of the muscarinic receptors in the heart, increasing the sinus rate and shortening atrioventricular node conduction time. Atropine may activate latent ectopic pacemakers. Atropine has little effect on systemic vascular resistance, myocardial perfusion pressure, or contractility.[86]

Atropine is indicated for the treatment of bradycardia associated with hypotension, second- and third-degree heart block, and slow idioventricular rhythms. Atropine is no longer recommended for asystole or PEA.[87] Atropine is particularly effective in clinical conditions associated with excessive parasympathetic tone. *However, for children with asystole or symptomatic bradycardia associated with severe hypotension, epinephrine is the medication of choice and atropine should be regarded as a second-line drug.*

A dose of 0.02 mg/kg with no minimum dose may be considered when atropine is recommended as a premedication for emergency intubation.[60] Although a minimum dose of 0.1 mg of atropine has been entrenched in the pediatric literature, this dose was not evidence-based.[88,89] There is no minimum dose of atropine in young infants and children.[90] Atropine may be given by any route, including IV, intraosseous, endotracheal, intramuscular, or subcutaneous. After IV administration, its onset of action is within 30 seconds and its peak effect occurs in 1 to 2 minutes. The recommended adult dose is 0.5 mg every 3 to 5 minutes until the desired heart rate is obtained, up to a maximum of 3 mg.

SODIUM BICARBONATE

The routine use of sodium bicarbonate during CPR remains controversial, and it remains American Heart Association Class Indeterminate. Acidosis may depress myocardial function, prolong diastolic depolarization, depress spontaneous cardiac activity, decrease the electrical threshold for VF, and reduce the cardiac response to catecholamines.[91–93] Acidosis also vasodilates systemic vessels and attenuates the vasoconstrictive response of peripheral vessels to catecholamines,[94] which is the opposite of the desired vascular effect during CPR. In children with a reactive pulmonary vascular bed, acidosis causes pulmonary hypertension. Therefore, correction of even mild acidosis may help to resuscitate children with increased pulmonary vascular resistance. In addition, the presence of severe acidosis may increase the threshold for myocardial stimulation in a child with an artificial cardiac pacemaker.[95] Bicarbonate may also be indicated in tricyclic antidepressant overdose, hyperkalemia, hypermagnesemia, and sodium channel blocker poisoning.

Potentially deleterious effects of bicarbonate administration include metabolic alkalosis, hypercapnia, hypernatremia, and hyperosmolality. The use of sodium bicarbonate was associated with increased mortality in a multicenter cohort study of in-hospital pediatric cardiac arrest.[15] Alkalosis causes a leftward shift of the oxyhemoglobin dissociation curve and thus impairs release of O_2 from hemoglobin to tissues at a time when O_2 delivery may already be reduced.[96] Alkalosis also can result in hypokalemia by enhancing potassium influx into cells and in ionic hypocalcemia by increasing protein binding of ionized calcium. The marked hypercapnic acidosis that occurs during CPR in the venous circulation, including the coronary sinus, may be exacerbated by the administration of bicarbonate.[97] Myocardial acidosis during cardiac arrest is associated with decreased myocardial contractility.[93] Hypernatremia and hyperosmolality may decrease tissue perfusion by increasing interstitial edema in microvascular beds.

Paradoxical intracellular acidosis after bicarbonate administration can occur with the rapid entry of CO_2 into cells with a slow egress of hydrogen ions out of cells; however, in neonatal rabbits recovering from hypoxic acidosis, the administration of bicarbonate increased both arterial pH and intracellular brain pH as measured by nuclear magnetic resonance spectroscopy.[98,99] Likewise, in rats, intracellular brain adenosine triphosphate concentration did not change during severe intracellular acidosis in the brain produced by extreme hypercapnia.[99] In a separate animal study, bicarbonate slowed the rate of decrease of both arterial and cerebral pH during prolonged CPR, suggesting that the blood-brain pH gradient is maintained during CPR.[100] Given the potentially deleterious effects of bicarbonate administration, its use should be *limited to cases in which there is a specific indication*, as discussed earlier.

CALCIUM

Calcium administration during CPR should be restricted to those with a specific indication for calcium (e.g., hypocalcemia, hyperkalemia, hypermagnesemia, and calcium channel blocker overdose). These restrictions are based on the possibility that exogenously administered calcium may worsen ischemia-reperfusion injury. Intracellular calcium overload occurs during cerebral ischemia by the influx of calcium through voltage-dependent and agonist-dependent (e.g., *N*-methyl-D-aspartate [NMDA]) calcium channels. Calcium plays an important role in the process of cell death in many organs, possibly by activation of intracellular enzymes such as nitric oxide synthase, phospholipase A and C, and others.[101]

The calcium ion is essential in myocardial excitation-contraction coupling, in increasing ventricular contractility, and in enhancing ventricular automaticity during asystole. Ionized hypocalcemia is associated with decreased ventricular performance and the peripheral blunting of the hemodynamic response to catecholamines.[102,103] Severe ionized hypocalcemia has been documented in adults suffering from out-of-hospital cardiac arrest[103] and in animals during prolonged CPR.[104] Children at risk for ionized hypocalcemia should be identified and treated as expeditiously as possible. Both total and ionized hypocalcemia may occur in children with either chronic or acute disease. Ionized hypocalcemia also occurs during massive or rapid transfusion of blood products (particularly whole blood and fresh frozen plasma, see Fig. 12.9) because citrate and other preservatives in stored blood products rapidly bind calcium. Because of this effect, ionized hypocalcemia is a known cause of cardiac arrest in the OR and should be treated immediately with calcium chloride or calcium gluconate (see Chapter 12 and Figs. 12.8 and 12.9). The magnitude of hypocalcemia in this setting depends on the rate and volume of blood products administered and the hepatic and renal function of the child. Administration of fresh frozen plasma at a rate in excess of 1 mL/kg per minute decreases the ionized calcium concentration in anesthetized children.[105]

The pediatric dose of calcium chloride for resuscitation is 20 mg/kg and of calcium gluconate is 60 mg/kg with a maximum dose for both of 2 g. Calcium gluconate is as effective as calcium chloride in increasing the ionized calcium concentration (see Fig. 12.8).[106,107] Calcium should be given slowly through a large-bore, free-flowing IV cannula, or preferably a central venous line. When administered too rapidly, calcium may cause bradycardia, heart block, or ventricular standstill. Severe tissue necrosis occurs when calcium infiltrates into subcutaneous tissue. Calcium administration is not recommended for pediatric cardiopulmonary arrest in the

absence of documented hypocalcemia, calcium channel blocker overdose, hypermagnesemia, or hyperkalemia (Class III, level of evidence B). Routine calcium administration in cardiac arrest provides no benefit and may be harmful.[95,108]

GLUCOSE

The administration of glucose during CPR should be restricted to children with documented hypoglycemia because of the possible detrimental effects of hyperglycemia on the brain during or after ischemia. The mechanism by which hyperglycemia exacerbates ischemic neurologic injury may be caused by an increased production of lactic acid in the brain by anaerobic metabolism. During ischemia under normoglycemic conditions, brain lactate concentration reaches a plateau. In a hyperglycemic milieu, however, brain lactate concentration continues to increase for the duration of the ischemic period.[109]

Clinical studies have shown a direct correlation between the initial serum glucose concentration after cardiac arrest and poor neurologic outcome,[110–113] although the greater glucose concentration may be a marker rather than a cause of more severe brain injury.[111] However, given the likelihood of additional ischemic and hypoxic events in the postresuscitation period, it seems prudent to maintain serum glucose concentrations within the normal range. Additional studies are needed to determine if the benefit from tight control of serum glucose after cardiac arrest outweighs the risk of iatrogenic hypoglycemia. Some groups of children, including preterm infants and debilitated children with small endogenous glycogen stores, are more prone to developing hypoglycemia during and after a physiologic stress such as surgery. Bedside monitoring of the serum glucose concentration is critical during and after a cardiac arrest and allows for the opportunity to administer glucose before the critical point of small substrate delivery has been reached. The dose of glucose generally needed to correct hypoglycemia is 0.5 g/kg given as 5 mL/kg of 10% dextrose in infants or 1 mL/kg of 50% dextrose in an older child. The osmolarity of 50% dextrose is approximately 2700 mOsm/L and has been associated with intraventricular hemorrhage in neonates and infants; therefore the more dilute concentration is recommended in infants.

AMIODARONE

Amiodarone was established for the treatment of cardiac arrest after several studies demonstrated that it was more effective than lidocaine in the management of refractory tachyarrhythmias in adults. Compared with lidocaine, amiodarone increases survival to hospital admission of patients with shock-resistant out-of-hospital VF.[114]

Early reports on the use of oral amiodarone in children were favorable.[115–117] Recent data on amiodarone use in children have been limited to case reports and descriptive case series. Nevertheless, it is now used widely for serious pediatric arrhythmias in the nonresuscitation environment. It appears to be effective, with an acceptable short-term safety profile.

The pharmacology of amiodarone is complex and may explain its wide range of usefulness. It is primarily classified as a Vaughn-Williams class III agent that blocks the adenosine triphosphate–sensitive outward potassium channels, causing prolongation of the action potential and refractory period; however, this effect requires intracellular accumulation. After IV loading, the antiarrhythmic effects of amiodarone are primarily due to noncompetitive α- and β-adrenergic receptor blockade, calcium channel blockade, and effects on inward sodium current, causing a decrease in anterograde conduction across the atrioventricular node and an increase in the effective atrioventricular refractory period. The α-adrenergic blockade leads to vasodilation, which may increase coronary blood flow. It is poorly absorbed orally, requiring IV loading in urgent situations. The full antiarrhythmic impact requires a loading period of up to 1 to 3 weeks to achieve intracellular concentrations and full potassium channel–blocking effects.

Hypotension is commonly reported with IV administration and may limit the rate at which the drug can be given. However, the development of hypotension is less common with the aqueous formulation.[118] The overall hemodynamic impact of IV administration will depend on the balance of its effect on rate control, myocardial performance, and vasodilation. Dosage recommendations for children are based on limited clinical studies. The dose is extrapolated from data on adults; 5 mg/kg intravenously is used for life-threatening arrhythmias. This dose can be repeated if necessary to control the arrhythmia. IV loading doses are followed by a continuous infusion of 10 to 20 mg/kg per day if there is a risk that the arrhythmia will recur. The ideal rate of a bolus administration of amiodarone is unclear; once it has been diluted, it is given as an IV push in adults. Amiodarone is best administered over 20 to 60 minutes to avoid profound vasodilation. We recommend a slow IV push (2 to 3 minutes) for pulseless ventricular tachycardia or VF until the arrhythmia is controlled and then a slower bolus (up to 10 minutes) for the remainder of the dose. An alternative dosing regimen for children is a 1 mg/kg IV push every 5 minutes up to 5 mg/kg. The use of the small aliquot bolus technique may be particularly appropriate for infants younger than 12 months of age.

Amiodarone-induced torsades de pointes has been described.[119] The use of amiodarone should be avoided in combination with other drugs that prolong the QT interval, as well as in the setting of hypomagnesemia and other electrolyte abnormalities that predispose to torsades de pointes. Severe bradycardia and heart block have also been described, especially in the postoperative period, and ventricular pacing wires are recommended in this setting. Both amiodarone and inhalation anesthetic agents prolong the QT interval; however, no specific data exist to evaluate the use of amiodarone for ventricular arrhythmias in children receiving inhalation anesthetics. It would seem prudent to be especially vigilant for this adverse effect in this circumstance.

Noncardiac adverse effects are often seen, especially with chronic dosing.[120] The most serious of these is interstitial pneumonitis seen most commonly in patients with preexisting lung disease.[121] The incidence in children is unknown. Rarely, an acute illness similar to acute respiratory distress syndrome illness has been reported in both infants and adults at the initiation of treatment.[122] The lung disease may remit with early discontinuation of the drug. Hypothyroidism, hepatotoxicity, photosensitivity, and corneal opacities are also common side effects with chronic use.[120]

The 2005 and 2010 Pediatric Advanced Life Support guidelines recommend administering amiodarone in place of lidocaine to manage VF and pulseless ventricular tachycardia. Paradoxically, an observational study demonstrated that the ROSC after lidocaine was superior to that after amiodarone.[123] There was no association between lidocaine or amiodarone use and survival to hospital discharge. Consequently, the 2015 Pediatric Cardiac Arrest Algorithm[60] reflects the change in recommendation that either lidocaine or amiodarone can be used for refractory VF or pulseless VT.

LIDOCAINE

Lidocaine is a class IB antiarrhythmic that decreases automaticity of pacemaker tissue that prevents or terminates ventricular arrhythmias as a result of accelerated ectopic foci. Lidocaine

abolishes reentrant ventricular arrhythmias by decreasing the action potential duration and the conduction time of Purkinje fibers and increases the effective refractory period of Purkinje fibers, reducing the nonuniformity of contraction. Lidocaine has no effect on atrioventricular nodal conduction time, so it is ineffective in the treatment of atrial or atrioventricular junctional arrhythmias. In healthy adults, no change in heart rate or blood pressure occurs with lidocaine administration. In patients with cardiac disease there may be a slight decrease in ventricular function when a lidocaine bolus is administered intravenously.

In children with normal cardiac and hepatic function, an initial IV bolus of 1 mg/kg of lidocaine is given, followed by a continuous IV infusion at a rate of 20 to 50 μg/kg per minute. If the arrhythmia recurs, a second IV bolus at the same dose can be given. In children with severely decreased cardiac output, a bolus of no greater than 0.75 mg/kg may be administered followed by an infusion at the rate of 10 to 20 μg/kg per minute. In children with severe hepatic disease and reduced hepatic blood flow, dosages should be decreased by 50%. Children with renal insufficiency have normal lidocaine pharmacokinetics; however, the toxic metabolite (monoethylglycinexylidide) may accumulate in children receiving infusions over a long period and affect sodium channels. In children with hypoproteinemia, the dose of lidocaine also should be reduced because of the increase in free fraction of the drug.

Toxic effects of lidocaine may occur when the serum concentration exceeds 7 to 8 μg/mL. These effects include seizures, psychosis, drowsiness, paresthesias, disorientation, agitation, tinnitus, muscle spasms, and respiratory arrest. The treatment of choice for lidocaine-induced seizures is a benzodiazepine (midazolam or lorazepam) or a barbiturate (e.g., phenobarbital; chronic therapy also increases the hepatic metabolism of lidocaine).[124] Conversion of second-degree heart block to complete heart block has been described,[125] as has severe sinus bradycardia.

Special Cardiac Arrest Situations

PERIOPERATIVE CARDIAC ARREST

The incidence, causes, and risk factors associated with anesthesia- and operative-related cardiac arrest have been evaluated by the Pediatric Perioperative Cardiac Arrest registry.[126,127] Cardiovascular causes of cardiac arrest were the most common (41% of all arrests), with hypovolemia from blood loss and hyperkalemia from transfusion of stored blood the most common identifiable cardiovascular causes. Among respiratory causes of arrest (27%), airway obstruction from laryngospasm was the most common cause. Vascular injury incurred during placement of central venous catheters was the most common equipment-related cause of arrest. The cause of arrest varied by phase of anesthesia care.

Cardiac arrest in the OR should have the greatest potential for a successful outcome, because it is a witnessed arrest with virtually instantaneous availability of skilled personnel, monitoring equipment, resuscitative equipment, and drugs. Whenever a cardiac arrest occurs in the OR, the circumstances causing the arrest should be rapidly determined. The circumstances of the arrest may provide a clue as to the cause, such as hyperkalemia after succinylcholine administration or rapid blood transfusion; hypocalcemia during a rapid infusion of fresh frozen plasma or large blood transfusion; or a sudden fall in $ETCO_2$ indicating air, blood clot, or tumor embolism. The most important causes of bradyarrhythmia are first, hypoxemia, second, an anesthetic overdose (real or relative), and third, a vagal reflex caused by surgical or airway manipulation. Administering 100% O_2 and establishing adequate ventilation should be the first maneuvers to implement, regardless of the cause of the bradycardia. In reflex-induced bradycardia, atropine may be the first drug of choice, but in extreme cases of bradycardia, whatever the mechanism, epinephrine is preferred in place of atropine. Hypotension and a low cardiac output state must be rapidly corrected by administration of IV fluids, vasopressors, and adequate chest compressions to circulate drugs to have the desired clinical effect. Once chest compressions are required, the standard American Heart Association recommendations for CPR apply and these include the frequent administration of epinephrine. Fig. 40.5 presents an algorithm for the differential diagnosis and treatment of the more common causes of acute OR-associated cardiac dysfunction.

HYPERKALEMIA

A child with a hyperkalemic cardiac arrest may be identified by history, by the progression of ECG changes leading up to the arrest (Fig. 9.7), or by initial laboratory results. A high index of suspicion must be maintained for hyperkalemia as a cause of cardiac arrest because it requires specific therapy. Along with the usual resuscitation algorithms, immediate therapy to antagonize the acute effects of the increased serum potassium concentration on the myocardial cells is necessary in order to reestablish sinus rhythm. Calcium gluconate or calcium chloride antagonizes the effects of hyperkalemia on the myocardial cell membrane by increasing the threshold potential so that the gap between the threshold potential and the resting membrane potential is reestablished, curtailing the depolarization of random myocardial cells. Sodium bicarbonate and hyperventilation increase the serum pH and shift potassium from the extracellular to the intracellular compartments. and insulin (with concomitant dextrose) shifts potassium intracellularly (0.1 U/kg of insulin with 0.5 g/kg of dextrose; 2 mL/kg of dextrose 25%). The serum potassium concentration must be monitored frequently during this treatment, preferably by point-of-care testing. Because these therapies simply shift potassium intracellularly, therapy to remove potassium from the body (furosemide, hemodialysis, sodium polystyrene sulfonate) should be instituted (see Chapter 28, Table 28.6).

ANAPHYLAXIS

Anaphylaxis is a rare, but usually reversible, cause of cardiac arrest. Classic anaphylaxis is defined by the triad of dermatologic (usually flushing, pallor, or urticaria), respiratory (airway edema and possible obstruction and bronchospasm), and cardiovascular signs. Anaphylaxis may be particularly severe in situations of decreased endogenous catecholamines, such as in a child taking β-blockers or in children receiving spinal or epidural anesthesia.

Resuscitation of the child with anaphylaxis rests on reversing airway obstruction and restoring intravascular volume and vascular tone. In the child with mild anaphylaxis (as manifested by mild bronchospasm and hypotension), epinephrine 1 to 2 μg/kg IV in repeated doses should be given until signs abate. In the child in cardiac arrest from anaphylaxis, the dose of epinephrine should be 10 μg/kg or 0.01 mL/kg of IV or subcutaneous epinephrine (1 : 1000 concentration). Children with anaphylactic shock have profound intravascular depletion requiring rapidly administered, large-volume fluid resuscitation (20-mL/kg boluses of balanced salt solutions). In addition to the usual resuscitation medications, treatment should include an antihistamine and corticosteroid, such as diphenhydramine (Benadryl), 1 mg/kg, and methylprednisolone (Solu-Medrol), 2 mg/kg. Inhaled bronchodilators such as albuterol

may relieve the bronchospasm. If severe airway obstruction occurs, tracheal intubation or even cricothyroidotomy may become difficult or impossible. Therefore the airway should be secured by a skilled practitioner early in the course of the reaction.

SUPRAVENTRICULAR TACHYCARDIA

Supraventricular tachycardia (SVT), despite being a common arrhythmia in infants and children, is uncommon during the intraoperative period in children without cardiac disease.[128] SVT may be associated with severe circulatory compromise or even cardiac arrest. Therapy for this arrhythmia should be based on the child's hemodynamic status. SVT associated with inadequate circulation should be treated immediately with synchronized cardioversion beginning at a dose of 0.5 J/kg. If IV access is available, adenosine can be administered while cardioversion is being prepared; however, cardioversion should not be delayed to establish IV access.

Adenosine is the medical treatment of choice for SVT. The underlying mechanism in children is usually a reentry circuit involving the atrioventricular node. Adenosine causes a temporary block in the atrioventricular node and interrupts this reentry circuit. The initial dose is 0.1 mg/kg given as a rapid IV bolus. Central venous administration is preferable because the drug is rapidly metabolized by red blood cell adenosine deaminase and therefore has a half-life of only 10 seconds. When the drug is given peripherally, the IV line should be immediately and rapidly flushed with 10 mL of saline. If there is no interruption in the reentry circuit, successive doses of 0.2 and 0.4 mg/kg should be given. In neonates, a smaller initial dose of 0.05 mg/kg is given and increased by 0.05 mg/kg per dose until termination of the arrhythmia up to a maximum dose of 0.3 mg/kg.[129] When SVT appears without any circulatory compromise, conversion of the arrhythmia may first be attempted with a vagal maneuver such as ice to the face. If this is ineffective, then adenosine should be used. Note that the denervated transplanted heart is extremely sensitive to the AV blockade and that half the normal starting dose is recommended.

Other medications used to treat SVT have a greater incidence of adverse effects than adenosine. Digoxin is often ineffective and causes frequent arrhythmias. Verapamil should be avoided in infants because of its association with congestive heart failure and cardiac arrest because of its negative inotropic effects.[130] Flecainide is effective in treating SVT but has many cardiac and noncardiac adverse effects[131]; its role for hemodynamically unstable SVT remains to be established. Other therapies include β-adrenergic blockers, edrophonium, and α-agonists. If SVT persists despite medical therapy and the child progresses to circulatory instability, electrical cardioversion should proceed immediately.

PULSELESS ELECTRICAL ACTIVITY

PEA is defined as organized ECG activity, excluding ventricular tachycardia and fibrillation, without clinical evidence of a palpable pulse or myocardial contractions. It may occur spontaneously after cardiac arrest or as an intervening rhythm associated with treatment for cardiac arrest. The causes of PEA are divided into primary (cardiac) and secondary (noncardiac) causes. Primary PEA, associated with cardiac arrest, is due to depletion of myocardial energy stores and responds poorly to therapy. Drugs used to treat primary PEA include epinephrine, atropine, calcium, and sodium bicarbonate.

The causes of secondary PEA are often remembered using the 4 Hs and 4 Ts mnemonic: **H**ypovolemia, **H**ypoxia, **H**ypothermia, and **H**ypo- or **H**yper-electrolytemia (hyperkalemia, hypocalcemia), **T**ension pneumothorax, pericardial **T**amponade, **T**hromboembolism, and **T**oxins (anesthetic overdose). In secondary PEA, intervention is directed at the underlying disorder and usually results in a successful resuscitation. When the cause of PEA is unknown and the child does not respond to medications, giving a fluid bolus and inserting needles into the pleural space to rule out pneumothorax and into the pericardial space to rule out cardiac tamponade are recommended.

Adjunctive Cardiopulmonary Resuscitation Techniques

OPEN-CHEST CARDIOPULMONARY RESUSCITATION

The use of open-chest cardiac massage, although generally replaced by closed-chest CPR, still has an active role in the OR and ICU, especially during and after thoracic surgery. Compared with closed-chest CPR, open-chest CPR generates greater cardiac output and vital organ blood flow. During open-chest CPR, the intrathoracic, right atrial, and intracranial pressures increase to a lesser extent, resulting in greater coronary and cerebral perfusion pressure and greater myocardial and cerebral blood flow compared with closed-chest CPR.[132,133,134]

Typically, in the OR and ICU, open-chest CPR is preferable to closed-chest CPR in the child who has had a recent sternotomy. Open-chest CPR is also indicated for selected children when closed-chest CPR has failed, although exactly which children should receive this method of resuscitation under this condition is controversial. When initiated early after failure of closed-chest CPR, open-chest CPR may improve outcome.[135–137] When performed after 15 minutes of closed-chest CPR, open-chest CPR significantly improves coronary perfusion pressure and the rate of successful resuscitation.[138]

EXTRACORPOREAL MEMBRANE OXYGENATION

Extracorporeal cardiopulmonary bypass (CPB) may be considered for refractory pediatric cardiac arrest when the condition leading to arrest is reversible and when the period of no flow (cardiac arrest without CPR) was brief. This intervention depends on the institution's ability to rapidly mobilize an extracorporeal circuit. Survival with a good neurologic outcome is possible after more than 50 minutes of CPR in selected children by using extracorporeal CPB.[139,140] Emergency extracorporeal membrane oxygenation (ECMO) in children with in-hospital CPR 10 minutes or longer in duration has been associated with improved survival to hospital discharge and survival with favorable neurologic outcome compared with failed conventional CPR.[141] CPB techniques such as ECMO require major technical support and sophistication but can be rapidly implemented in hospitals set up to do so. However, absence of a formal rapid deployment ECMO team does not preclude resuscitation with ECMO in pediatric cardiac patients with good results.[142]

ACTIVE COMPRESSION-DECOMPRESSION

Active compression-decompression CPR uses a negative-pressure "pull" on the thorax during the release phase of chest compression using a handheld suction device. This technique improves vascular pressures and minute ventilation during CPR in animals and humans.[143–147] The hemodynamic benefit of this technique is attributed to increased venous return by the negative intrathoracic pressure generated during the decompression phase. When this

technique was used with a device adding impedance to inspiration, vascular pressures and flow increased further.[148] Its effectiveness in adults shows promise, with increased survival and weak evidence for neurologic improvement in prehospital victims.[149–151] However, larger trials did not demonstrate improved survival in in-hospital or prehospital victims of cardiac arrest, nor did any subgroup demonstrate benefit from active compression-decompression CPR.[152–154] The complication rate, including fatal rib and sternal fractures, may be greater with this technique.[155]

Postresuscitation Stabilization (Post–Cardiac Arrest Care)

The goals of postresuscitation care are to prevent secondary organ injury, preserve neurologic function, diagnose and treat the cause of the illness, and prevent a recurrence of the arrest. Respiratory support should be tailored to minimize the risk of oxidative damage while maintaining adequate O_2 delivery. FIO_2 should be limited to the minimum necessary to maintain an adequate saturation. Ventilation should be closely monitored because both hypercarbia and hypocarbia may confer deleterious effects.

Mitigation of neurologic injury after cardiac arrest has been a goal of many investigator groups. In adult patients with out-of-hospital VF and in asphyxiated newborns,[64] therapeutic hypothermia was believed to offer some benefit. However, the effectiveness of hypothermia therapy was neither supported nor refuted in a retrospective study.[156] A target temperature of 36°C proved better than 33°C in adults.[157] Similar results have been reported in children. Therapeutic hypothermia in children did not confer a significant benefit in survival with a good functional outcome at 1 year.[65]

The 2015 AHA Pediatric Advanced Life Support Guidelines Update[60]

Cardiopulmonary resuscitation of children with a nonnative airway should use $ETCO_2$ carbon-dioxide monitoring as a surrogate for effective compressions. This is of particular relevance for the perioperative physician as patients should have $ETCO_2$ monitoring as part of their routine anesthetic care. Attention should focus on an adequate depth and frequency of compressions with sufficient recoil. The compressor should be monitored for fatigue and rapid change of practitioners (every 2 minutes) should be instituted if compressions are judged to be inadequate because of poor technique. Examination of patients for successful ROSC should not occur within the 2-minute epochs of compression as the quality of compressions could be compromised. Compressions should be extended 2 minutes after the confirmation of the ROSC.

Nadkarni VM, Larkin GL, Peberdy MA, et al. First documented rhythm and clinical outcome from in-hospital cardiac arrest among children and adults. *JAMA*. 2006;295:50-297.

In this multicenter registry of in-hospital cardiac arrest, the first documented pulseless arrest rhythm was typically asystole or pulseless electrical activity in both children and adults. Because of improved survival after asystole and pulseless electrical activity, children had better outcomes than adults despite fewer cardiac arrests resulting from ventricular fibrillation or pulseless ventricular tachycardia.

Perondi M, Reis A, Paiva E, et al. A comparison of high-dose and standard-dose epinephrine in children with cardiac arrest. *N Engl J Med*. 2004;350:1722-1730.

This blinded, randomized controlled trial compared high-dose and standard-dose epinephrine as rescue therapy in children with in-hospital cardiac arrest. No benefit of high-dose epinephrine was detected. The data suggest that high-dose therapy may be more deleterious than standard-dose therapy.

Summary

MALIGNANT HYPERTHERMIA (MH) is a pharmacogenetic disease of skeletal muscle that may precipitate a potentially fatal sequence of metabolic responses in the presence of triggering anesthetics. The primary triggers for MH–inhalational anesthetics and succinylcholine–induce an uncontrollable release of intramyoplasmic calcium (Ca^{2+}) that results in sustained muscle contractures, which produce a hypermetabolic response. The hypermetabolic response manifests with hypercarbia, hyperpnea, tachycardia, and if not treated early, a mixed metabolic and respiratory acidosis. An acute reaction is usually accompanied by muscle rigidity either as isolated muscle rigidity (e.g., masseter muscle tetany in the temporomandibular joint) or total body muscle rigidity (e.g., sustained contraction of major peripheral muscle groups).

MH was first described by Denborough and Lovell in 1960, who reported a 21-year-old man who was hesitant to undergo general anesthesia to repair his leg fracture because family members had died under anesthesia.[1] After 10 minutes of halothane anesthesia, he became hemodynamically unstable with hypotension, tachycardia, and mottled skin that was hot to the touch. The soda lime canister was found to be hot and was changed because it appeared to be exhausted. The anesthetic was discontinued, the patient was packed in ice, and he recovered without sequelae. Postprocedural examination did not reveal any known medical condition. A careful family history disclosed that 10 blood relatives had previously died after ether anesthesia, suggesting an autosomal dominant inheritance pattern. This patient required a subsequent operation and was administered a spinal anesthetic without incident.[2] Subsequent reports from around the world established this disorder as a familial entity that was potentially fatal.[3,4] The term *malignant hyperpyrexia* (later changed to *malignant hyperthermia*) was coined in 1967 at the first international meeting on this disorder in Toronto, Canada.

The incidence of MH based on the frequency of MH reactions has been reported to be 1 case per 50,000 to 100,000 adults and 1 case per 3000 to 15,000 children.[5,6] Regional differences in the prevalence of MH may account for an even greater frequency of reactions (of all levels of severity) in some jurisdictions–for example, 1 case per 16,000 anesthetics in adults in Denmark and 1 case per 4200 adults when an inhaled anesthetic and succinylcholine were combined.[7] A recent review of discharge diagnoses from New York state ambulatory centers reported a prevalence of MH of 1:500,000,[8] a frequency that may reflect the reluctance of these centers to handle patients with MH. A survey in a pediatric hospital in the United States during the halothane era revealed an MH incidence of 1 case per 20,000 to 40,000 children, almost one-half of that reported previously.[9] The incidence of fulminant MH (defined as a rapid increase in temperature accompanied by life-threatening metabolic changes, arrhythmias, and increased serum creatine kinase level) was far less frequent: 1 case per 250,000 general anesthetics in Denmark[7] and 1 case per 200,000 in the United Kingdom.[10] The Danish survey found an incidence of 1 case of masseter muscle spasm per 12,000 anesthetics among children who received succinylcholine, whether in combination with inhalational or intravenous (IV) anesthetics.[7] Clinically, the demographic data suggested that the incidence or suspicion of MH was greater among children than adults and that the incidence was even greater among children in whom succinylcholine was used.

Genetic testing has become sufficiently pervasive to permit estimation of the prevalence of MH based on genetic mutations.[11] On the basis of genetic testing, the prevalence has been estimated between 1:3000 and 1:8500, although some estimates have reached 1:400.[11] The frequency of MH reactions is greatest in childhood (up to 52% of reactions), with a peak age of 3 years, and the

youngest confirmed cases in early infancy, 2 months of age.[12] In one case, a known genetic mutation (G2434R) consistent with the diagnosis of MH was identified in the cord blood of a neonate born to an MH-susceptible (MHS) parturient with the same mutation.[13]

Many believe the incidence of MH reactions has decreased in the past 2 decades, although some have challenged this notion.[14] Two reasons for this notion are that (1) families with a genetic predisposition to MH have been identified and patients bring it to the attention of their surgical and anesthetic care providers preoperatively and (2) the routine use of succinylcholine has decreased dramatically as a result of concerns of rare complications, such as hyperkalemic cardiac arrest. The latter has resulted in a black box warning admonishing against the routine use of succinylcholine in children, particularly male children younger than 8 years of age in the United States who may have unrecognized muscular dystrophy or other myopathy.[15,16]

All inhalational anesthetics (except xenon) and succinylcholine trigger MH reactions in susceptible patients[17–23]; no other drugs used for IV or regional anesthesia trigger MH reactions. A comprehensive list of triggering and nontriggering drugs is available from the Malignant Hyperthermia Association of the United States (MHAUS; http://www.mhaus.org/).

The mortality rate from MH has decreased dramatically from more than 80% in the 1960s to 1.4% more recently (Fig. 41.1).[14,24–26] For children, the mortality rate from MH, 0.7%, is 20-fold less than that for adults, 14% based on an inpatient database.[14] The overall decrease in mortality may be attributed to several factors: better identification of MH-susceptible individuals; the routine use of capnography and pulse oximetry, facilitating early identification of the signs and symptoms of an acute MH reaction[27,28]; a better understanding of the pathogenesis of MH; and the widespread availability of dantrolene.[29]

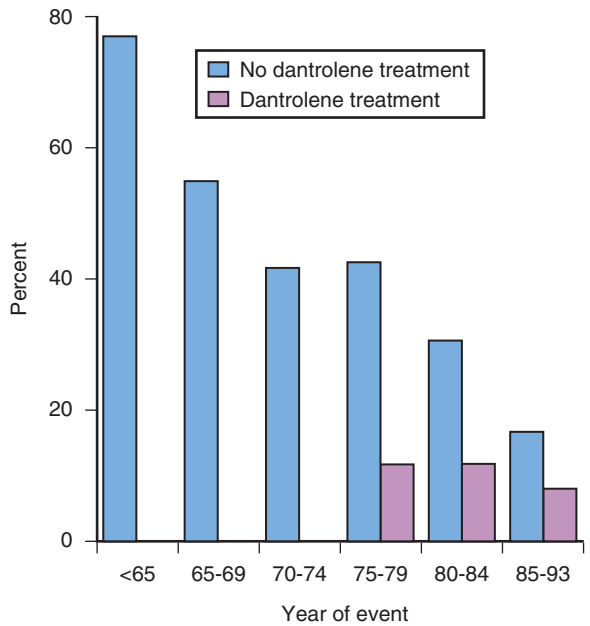

FIGURE 41.1 The trend in fatality rates from malignant hyperthermia is shown over time. The *blue bars* represent data from 361 patients, and the *magenta bars* represent data from 142 patients. Notice the marked decrease in mortality with dantrolene treatment. (Modified from Strazis KP, Fox AW. Malignant hyperthermia: a review of published cases. *Anesth. Analg.* 1993;77[2]:297–304.)

Clinical Presentation

The most common presentation of MH is a hypermetabolic response to the inhalational anesthetics, with or without succinylcholine (Table 41.1). Among the earliest clinical signs is a marked increase in the end-tidal carbon dioxide ($ETCO_2$) that resists control by either mechanical ventilation or an increase in minute ventilation when the patient is breathing spontaneously.[25,30] Other nonspecific early signs include tachycardia and hemodynamic instability with a trend toward hypertension. Severe masseter muscle spasm (i.e., masseter tetany) refers to the inability to insert a laryngoscope blade into the mouth—the so-called jaws of steel—even with no twitches evident on a blockade monitor after administration of succinylcholine. It strongly indicates MH susceptibility (Fig. 41.2). The differential diagnosis of severe masseter spasm should include the possible presence of the ultra-rapid polymorphism of pseudocholinesterase, the C5 (E Cynthiana or Neitlich) variant (see Chapters 6 and 7), which terminates the action of succinylcholine more rapidly than usual.[31] In vitro live muscle biopsy testing revealed a 28% to 50% incidence of MH susceptibility among children with jaws of steel, with an extensive differential diagnosis (Table 41.2).[32–34] Generalized muscle rigidity develops as a result of the excessive accumulation of myoplasmic Ca^{2+} concentrations in MHS skeletal muscle, causing sustained muscle contractures.[30] This occurs even in the presence of neuromuscular blockade with nondepolarizing neuromuscular blocking drugs (NMBDs).

Hyperthermia, often a late sign, results from the greatly increased aerobic and anaerobic metabolic activity of triggered skeletal muscle; the overlying skin soon becomes hot to the touch. In

TABLE 41.1 Clinical and Laboratory Findings Associated With Malignant Hyperthermia

Clinical Findings	Laboratory Findings
Tachycardia, tachypnea, and hypertension	
Hypercarbia ($ETCO_2$)	Increased $PaCO_2$
Greatly increased minute ventilation	Acidosis (mixed respiratory and metabolic)
Hemoglobin desaturation	Relative hypoxia, increased alveolar to arterial partial pressure gradient for oxygen
Generalized muscle rigidity (unresponsive to nondepolarizing muscle relaxants)	Hyperkalemia Increased CPK level (usually a late sign) Increased plasma lactate concentration
Skin mottling	
Hyperthermia (late sign)	
Cardiac arrhythmias (hyperkalemia-induced: PVC, VT, VF)	
Cola-colored urine (late sign)	Myoglobinuria, myoglobinemia
Disseminated intravascular coagulation (late)	Abnormal coagulation studies (late sign)

CPK, creatinine phosphokinase; *$ETCO_2$*, end-tidal carbon dioxide; *$PaCO_2$*, arterial partial pressure of carbon dioxide; *PVC*, premature ventricular contraction; *VF*, ventricular fibrillation; *VT*, ventricular tachycardia.
Data from Malignant Hyperthermia Association of the United States. Available at http://www.mhaus.org (accessed July 2012).

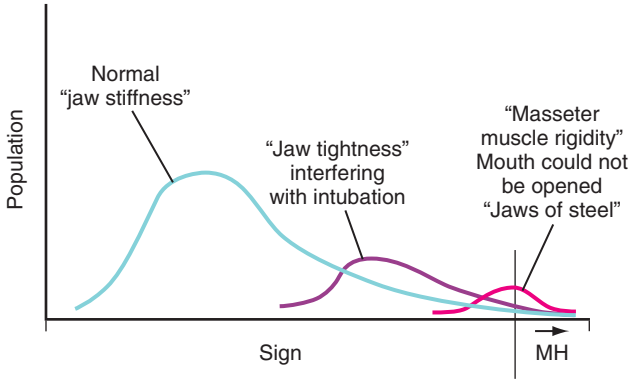

FIGURE 41.2 The spectrum of masseter muscle responses to succinylcholine varies from a slight jaw stiffness that does not interfere with endotracheal intubation to the extreme "jaws of steel," which is masseter muscle tetany that does not allow the mouth to be opened. The latter response is likely highly associated with malignant hyperthermia (MH). Even with the inability to open the mouth, the child's lungs should still be able to be ventilated by bag and mask because all other muscles are relaxed. (From Kaplan RF. Malignant hyperthermia. Annual refresher course lectures. Washington, DC: American Society of Anesthesiologists; 1993.)

TABLE 41.2 Limited Excursion of the Mandible: Differential Diagnosis

Temporomandibular joint dysfunction: congenital, inflammatory/infectious, trauma, neoplasm, collagen vascular disease (rheumatoid arthritis)
Muscle disease: malignant hyperthermia, Duchenne or Becker muscular dystrophy, myotonia congenita
Integumentary disease: inflammatory or infectious disease, neoplasm, radiation effects, collagen vascular disease (scleroderma)
Neurologic injury
Ultra-rapid metabolizer of succinylcholine (Neitlich or E Cynthiana [C5 enzyme] variant of pseudocholinesterase) (see Chapters 6 and 7)
Ineffective succinylcholine

many instances, the large muscle groups such as calf or thigh muscles feel tight or knotted. This is accompanied by exaggerated carbon dioxide (CO_2) production, which usually is the first sign of an evolving MH reaction, and the accumulation of lactate fueled by markedly increased glycogenolysis and glycolysis (i.e., mixed respiratory and metabolic acidosis).[35,36] If an acute MH reaction is diagnosed and treated early in its evolution, before the body becomes unable to maintain this exaggerated aerobic metabolism, arterial blood gases may show an almost pure respiratory acidosis, which can make the diagnosis of MH difficult (Table 41.3). A mixed venous or peripheral venous blood gas analysis can be helpful in establishing the presence of hypermetabolism because it is more likely to demonstrate an increased partial pressure of CO_2, significant oxygen desaturation consistent with increased oxygen consumption ($\dot{V}O_2$ <40 mm Hg, despite administering supplemental oxygen for which the expected $\dot{V}O_2$ is >60 mm Hg), and a possible increased lactate concentration.

In fulminant cases, untreated MH may increase the temperature as rapidly as 1C° every 10 minutes.[30] In one case, the temperature reached 43.8°C (110.8°F) within 18 minutes.[37] In addition to the profound hypercarbia and tachycardia, severe hypoxia, skin mottling, exuberant metabolic acidosis, rhabdomyolysis, coagulopathy, and hyperkalemia may follow unless the reaction is aborted

TABLE 41.3 Arterial Blood Gas Data From a Child in Early Malignant Hyperthermia

	TIME AT MEASUREMENT			
Data	***08:52***	***08:59***	***09:05***	***09:27***
pH[a]	7.34	7.03	7.29	7.39
P_{CO_2} (mm Hg)	46.3	109.4	47.9	42.7
P_{O_2} (mm Hg)	236	159	589	635
Base excess	–1	–2	–3	1
(mmol/L)	25.1	29	23.1	25.6

[a]Notice the pure respiratory acidosis in this patient from Fig. 41.3 and the rapid decrease in P_{aCO_2} after dantrolene administration between 08:59 and 09:05. *P_{aCO_2}*, arterial partial pressure of carbon dioxide; *P_{O_2}*, partial pressure of oxygen.

following the administration of dantrolene. Unstable hemodynamics and ventricular arrhythmias inevitably follow. Intractable ventricular arrhythmias, pulmonary edema, disseminated intravascular coagulation, cerebral hypoxia or edema, and renal failure as the result of myoglobin deposition in the renal tubules are often associated with fatal outcomes.

In the early years of treating acute MH reactions, before dantrolene was identified as the specific antidote, symptomatic treatment was the mainstay of therapy. This included treatment of the acidosis and hyperkalemia with bicarbonate, and insulin with glucose, respectively; active cooling with iced saline solution gastric lavage; infusion of cold IV saline solution; and infusions of procainamide (a drug that was later shown to be ineffective). These interventions helped to reduce the mortality rate to about 50%, but with the availability of dantrolene, the mortality rate decreased dramatically, to 1.4% to 2.9% based on an MH database and an inpatient pediatric database.[38,39]

The presenting signs of MH vary (see Table 41.1). The syndrome may be fulminant or indolent, not all features of a classic MH reaction may be immediately evident, and it may occur intraoperatively or postoperatively, although the frequency of MH reactions occurring postoperatively is only ~2%.[30,40] The latest that an MH reaction has occurred postoperatively is 11 hours, although a review of reports of postoperative MH from the North American Malignant Hyperthermia Registry failed to find any cases that occurred beyond 40 minutes after the end of the anesthetic.[40,41] The likelihood that an MHS patient will develop MH in the presence of inhalational anesthetics is exasperatingly unpredictable. In one study, 50% of susceptible individuals reported two or more uneventful general anesthetics before an MH reaction was triggered.[25,42] Only 6.5% of probands in a retrospective review reported a family or personal history of MH.[42] A negative personal or family history is insufficient to conclude that a child is not susceptible to MH. Other disease states may be confused with MH (Table 41.4) and must be distinguished from it to provide correct therapy.

Given the variability of the clinical presentation of MH and the dearth of pathognomonic signs for this syndrome, establishing the diagnosis can be difficult. In response to the need for an objective measure to verify a clinical episode of MH, a retrospective, multivariable clinical grading scale was developed.[43] This grading scale was devised to clarify the cutoff value for a positive muscle caffeine halothane contracture test (CHCT) result. It was not intended to be a clinical guide in the operating room. Despite recommendations not to use this scale to guide treatment and to be more conservative in its application, E-Tables 41.1A and 41.1B

E-TABLE 41.1A Clinical Indicators for Determining the Malignant Hyperthermia Raw Score

Process	Indicator	Points
Rigidity	Generalized muscular rigidity	15
	Masseter spasm	15
Muscle breakdown	Creatine kinase >20,000 IU after succinylcholine	15
	Creatine kinase >10,000 IU with no succinylcholine	15
	Cola-colored urine in perioperative period	10
	Myoglobin in urine >60 μg/L	5
	Myoglobin in serum >170 μg/L	5
	Blood, plasma, or serum K^+ >6 mEq/L, no renal illness	3
Respiratory acidosis	P_{ETCO_2} >55 mm Hg with controlled ventilation	15
	Arterial Pa_{CO_2} >60 mm Hg with controlled ventilation	15
	P_{ETCO_2} >60 mm Hg with spontaneous ventilation	15
	Arterial Pa_{CO_2} >65 mm Hg with spontaneous ventilation	15
	Inappropriate hypercarbia, anesthesiologist's call	15
	Inappropriate tachypnea	10
Temperature increase	Inappropriately rapid increase	15
	Inappropriately increased temperature >38.8°C (101.8°F)	10
Cardiac involvement	Inappropriate sinus tachycardia	3
	Ventricular tachycardia or fibrillation	3
Family history	Positive family history for first-degree relative	15
	Positive family history for more distant relative	5
Others	Arterial base excess more negative than −8 mEq/L	10
	Arterial pH <7.25	10
	Rapid reversal of malignant hyperthermia (MH) signs after intravenous administration of dantrolene	5
	Positive MH family history with another indicator from the patient's anesthesia experience other than increased creatine kinase level	10
	Elevated creatine kinase level and a family history of MH	10

Pa_{CO_2}, arterial partial pressure of carbon dioxide; *P_{ETCO_2}*, end-tidal pressure of carbon dioxide.

E-TABLE 41.1B Malignant Hyperthermia Clinical Grading Scale

Raw Score Range	Rank	Likelihood
0	1	Almost never
3-9	2	Unlikely
10-19	3	Somewhat less than likely
20-34	4	Somewhat greater than likely
35-49	5	Very likely
≥50	6	Almost certain

Modified from Larach MG, Localio AR, Allen GC, et al. A clinical grading scale to predict malignant hyperthermia susceptibility. *Anesthesiology.* 1994;80:771–779.

TABLE 41.4 Differential Diagnosis of Malignant Hyperthermia

Diagnosis	Distinguishing Traits
Hyperthyroidism	Patients often present with similar symptoms and physical findings; blood gas abnormalities gradually evolve; creatine phosphokinase value does not increase substantively. Unresponsive to dantrolene.
Sepsis	Usually, blood gases are normal early, and metabolic acidosis occurs late; creatine phosphokinase remains normal.
Pheochromocytoma	Similar to malignant hyperthermia (MH), except for marked blood pressure swings, hypercarbia, and venous desaturation
Metastatic carcinoid	Flushing, diarrhea, hypotension
Cocaine intoxication	Fever, rigidity, rhabdomyolysis similar to NMS
Heat stroke	Similar to MH, except that the patient is outside the operating room
Masseter muscle rigidity (MMR)	May progress to MH; total body spasm more likely than isolated MMR
Neuroleptic malignant syndrome (NMS)	Similar to MH but evolves over weeks; usually associated with the use of antipsychotics
Serotonergic toxicity	Similar to MH and NMS; associated with the administration of mood-elevating drugs (e.g., selective serotonin reuptake inhibitors)
Nonmalignant hyperthermia syndrome	Reported only once; severe hyperthermia seemingly associated with fentanyl

are provided to help clinicians identify true MH reactions. Although these clinical grading scales are somewhat cumbersome and have not been prospectively validated in clinical settings for use by nonexperts, they do provide a useful guide for the clinician.

Patient Evaluation and Preparation

Optimal treatment begins with prevention and preparation. Obtaining an accurate family history of suspicious or unusual reactions to general anesthesia in blood relatives, unexpected admissions to intensive care after surgery, or unexplained sudden death during or immediately after general anesthesia should signal to the surgeon and anesthesiologist to consider MH or another problem related to anesthesia. These questions assume the patient is part of a classic nuclear family, but with increasing levels of adoption, artificial insemination, surrogate motherhood, and egg donations, standard probing may not elicit clear family histories. The anesthesiologist must be sensitive but decisive in determining the true genetic relationship between the guardians and the child. Despite attempts to obtain an accurate history, misinterpretation of the questions may occur. In one case, an adopted child died of succinylcholine-induced hyperkalemic cardiac arrest, even though the parents denied that anyone in the family had anesthesia problems or muscle disease during the preoperative assessment. Only immediately after the event did the parents reveal that the child had been adopted and that the child's birth uncle had muscular dystrophy.

If the anesthesiologist is informed that the child has a blood relative who had an MH reaction or who has a myopathy with high concordance with MH, the most prudent course of action is to schedule the case for the first of the day to minimize exposing the children to inhalational anesthetics in the operating or recovery room.[44–47] With the abundance of evidence that stress alone can trigger an MH reaction, preoperative anxiolytics such as midazolam are warranted in these children, except for the most minor procedures (e.g., myringotomy and tubes). Prophylactic dantrolene is not warranted in MH patients who receive a trigger-free anesthetic as the frequency of MH reactions is very small.[48–50] The anesthetic prescription must include nontriggering agents such as total IV or regional anesthetics, or both. In the rare circumstance in which triggers must be used (and these are rare), extreme vigilance and anticipation to treat an acute MH reaction are of the utmost importance, although in a recent case of acute epiglottitis, the airway was secured with a total intravenous anesthesia (TIVA) technique rather than an inhalation technique.[48,49,51] When a child with a known susceptibility to MH is scheduled for general anesthesia, the anesthesia machine (i.e., anesthetic workstation [AWS]) must be prepared to preclude the delivery of triggering agents. First, succinylcholine should be removed from the local vicinity to avoid inadvertent administration. Second, all vaporizers should be physically disengaged from the AWS, which is preferable because they can leak trace concentrations of inhalational anesthetics even in the off state, or if they cannot be removed from the AWS, tape should be placed across them in the off position to avoid accidentally turning them on.[52] Third, to accelerate the washout of anesthetics, the CO_2 absorbent should be replaced, a new anesthetic breathing circuit installed, and the ventilator bellows flushed and left operating.[52–54] Fourth, to eliminate inhalational anesthetics from the AWS, many clinicians follow a standardized protocol of flushing the workstation with 10 L/minute of oxygen for 10 to 20 minutes, depending on the AWS manufacturer and age of the machine.[55] However, the assumption that one protocol fits all to reduce the anesthetic concentration to less than 10 ppm, which is assumed to be the threshold below which an MH reaction cannot be triggered,[56] may not hold true for every AWS. This is particularly an issue with the newer AWS, which are more complex in construction and more likely to contain internal working parts made of plastic, which act as sumps for inhalational anesthetics.[57] To address the various types of AWS, the duration of flushing with large fresh gas flows (Table 41.5) and the need to exchange contaminated internal components with clean versions must be determined for each AWS. For some types of AWS, more than 60 minutes may be required to reach anesthetic concentrations less than 10 ppm.[55,57–59] To achieve an anesthetic concentration of 10 ppm or less in the Dräger Primus, Fabius, and Zeus machines (Drägerwerk AG & Co. KGaA, Lübeck, Germany) in a timely manner, the ventilator diaphragm and integrated breathing system should be replaced with autoclaved components and then flushed for 20 minutes at a fresh gas flow of 10 L/minute.[58,59] Table 41.5 lists the published times required to reach an anesthetic concentration of less than 10 ppm without replacing any AWS components.[55,57,59–61] These data support the notion that the previously held protocols to wash out inhalational anesthetics from older AWSs do not hold true for the newer AWSs. The need for a single protocol or intervention that consistently achieves an anesthetic concentration of less than 10 ppm in all AWSs is of even greater importance because none of the available anesthetic agent analyzers is capable of measuring anesthetic concentrations in the 10-ppm range to confirm adequate removal of inhalational anesthetics.

After the AWS has been flushed with 10 L/minute of an air and oxygen mixture, most anesthesiologists reduce the fresh gas flow during anesthesia. However, evidence has shown that

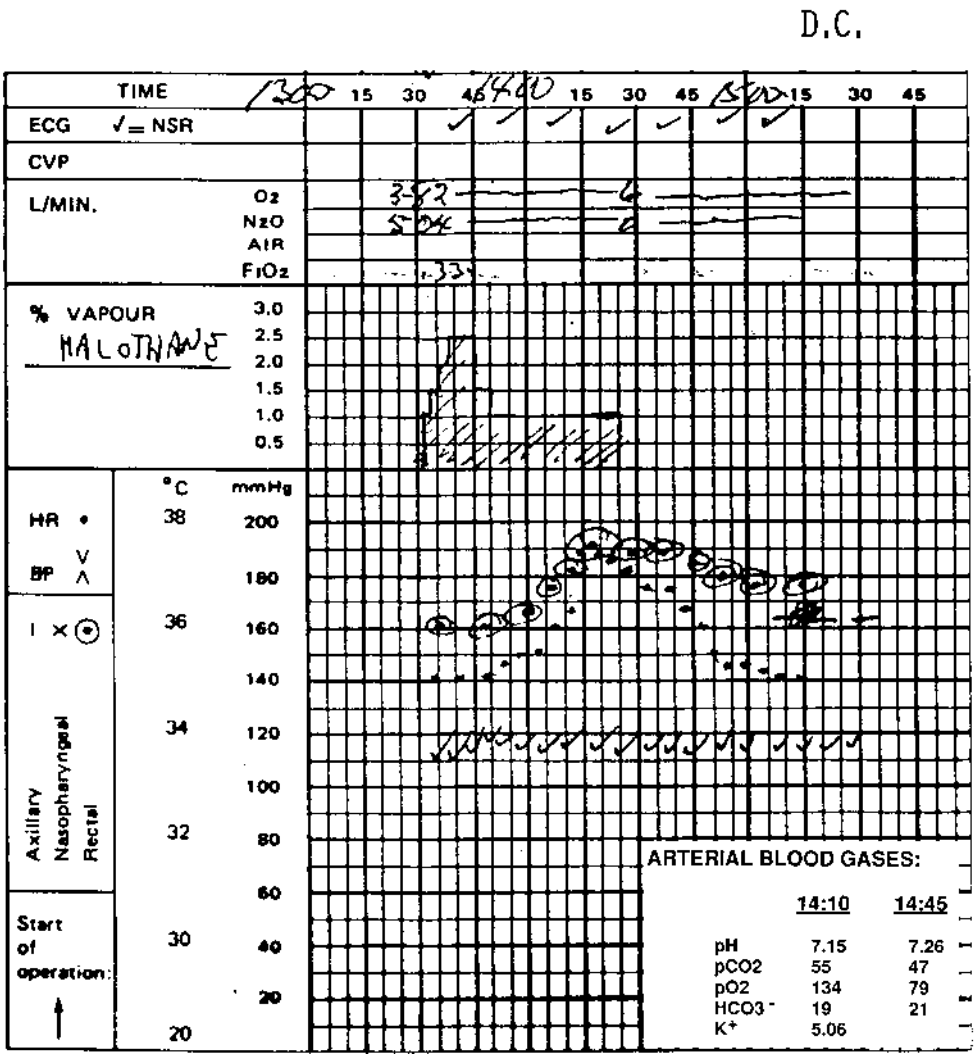
the concentration of inhalational anesthetic surges (≥50 ppm) when the fresh gas flow is reduced, and the magnitude of the rebound directly depends on the fresh gas flow rate.[60,62] Those who reduce the fresh gas flow after purging the AWS may be exposing their patients to concentrations of inhalational anesthetics that may trigger an MH reaction, although no MH reactions have been reported in patients in whom a reduced fresh gas flow was used in an AWS that had been purged using a large (>10-L/minute) fresh gas flow. To avoid confusion, a single, consistent, effective, and reliable intervention is required to prevent MH reactions in patients exposed to trace gases from a previously contaminated AWS.

A commercially available charcoal filter (Vapor-Clean, Dynasthetics, LLC, Salt Lake City, UT) fitted to the expiratory and inspiratory limbs of the AWS reduces the concentration of inhalational anesthetics to less than 5 ppm within several minutes.[63] These filters are sold in pairs. The manufacturer recommends that a filter be inserted into both the inspiratory and expiratory limbs of the anesthesia breathing circuit just distal to the valves, which is reasonable during an acute MH reaction. However, when only the machine is contaminated with inhalational anesthetic (e.g., after flushing the AWS for elective MH cases), we apply a single filter in the **inspiratory limb** and keep the second of the pair to replace the first after 60 to 90 minutes, since it may become expended by that time.[63] Another alternate approach is to replace the breathing circuit and carbon dioxide absorber with new equipment and then insert a filter into the inspiratory limb.



Ambulatory surgery has rapidly expanded to include most pediatric surgery. Consequently, the safety of discharging children with a personal or family history of MH after an uneventful, trigger-free anesthesia on the day of surgery has raised concerns. Several studies demonstrated that the risk of developing an MH reaction after an uneventful, trigger-free anesthesia was exceedingly small.[48–50] Postoperative monitoring for an MH reaction while in the hospital has gradually been reduced from 6 hours to 2 hours or less before discharge.[64–66] For MHS children, parents should be provided with a written description of the signs and symptoms of an MH reaction and the direct phone number to reach the on-call anesthesiologist for further advice and management. Families should contact an anesthesiologist rather than return to the emergency department because the emergency physician may be unfamiliar with MH, particularly in children. Additional advice for the parents should include the use of an oral antipyretic drug (e.g., acetaminophen) to treat a mild fever. If the fever abates after a dose or two of acetaminophen, the fever was not caused by MH. If the fever persists despite acetaminophen and sponge baths and is accompanied by tachycardia and tachypnea, the parents should notify the on-call anesthesiologist and immediately return the child to the hospital.

Monitoring

Capnography and pulse oximetry, key monitors for early signs of an MH reaction, are required for all children who receive general anesthesia, irrespective of the duration of the procedure. Measurement of the body temperature is recommended for all children who undergo general anesthesia when fluctuations may be anticipated, according to the American Society of Anesthesiologists standards for basic anesthesia monitoring, last updated in 2015 (www.asahq.org/quality-and-practice-management/standards-and-guidelines). Monitoring the axillary temperature site (opposite the extremity with the IV line) is recommended rather than a core site for early detection of an MH reaction because the axillary region and the venous drainage thereof may reflect the increased metabolism from sustained contractures of the pectoral shoulder girdle, a large muscle bulk. Although most consider an increasing temperature a late sign of an MH reaction, a retrospective review suggested that an increasing body temperature may occur early in an evolving MH reaction.[42,67] Moreover, data from a retrospective review of MH deaths suggested that the risk of dying during an MH reaction was 14-fold greater if the core temperature was not measured and that the risk of any complication increased 2.9-fold for every 2°C increase in body temperature.[38] Evidence also suggests that crystalline skin temperature tapes may not reliably track temperature changes during MH reactions.[42]

Diagnosis

Because the underlying disorder in MH is a hypermetabolic reaction (i.e., increased CO_2 production and oxygen consumption), massive volumes of CO_2 are released into the circulation, which rapidly increase the partial pressure of CO_2 ($PaCO_2$) and respiratory rate in the unparalyzed child. The cardiovascular response is an increased cardiac output, heart rate, and in some cases, blood pressure (E-Fig. 41.1). The first clinical signs and symptoms of this hypermetabolic reaction in a spontaneously breathing patient are hypercapnia, sinus tachycardia, and tachypnea (see Table 41.1).[42]

E-FIGURE 41.1 Malignant hyperthermia reaction in a 5-year-old child undergoing ptosis surgery. After an inhalational induction with halothane and establishment of intravenous access, anesthesia was maintained with an inhalational induction and spontaneous respiration. After 30 minutes of halothane, heart rate and temperature increased from 140 to 190 beats/minute and 36°C to 37.5°C, respectively. Arterial blood gases showed a combined metabolic and respiratory acidosis. After 55 minutes of halothane, anesthesia was discontinued, and 100% oxygen and dantrolene 2.5 mg/kg IV were administered. Vital signs returned to normal within 25 minutes. By 75 minutes after induction of anesthesia, the severity of the acidosis was resolving.

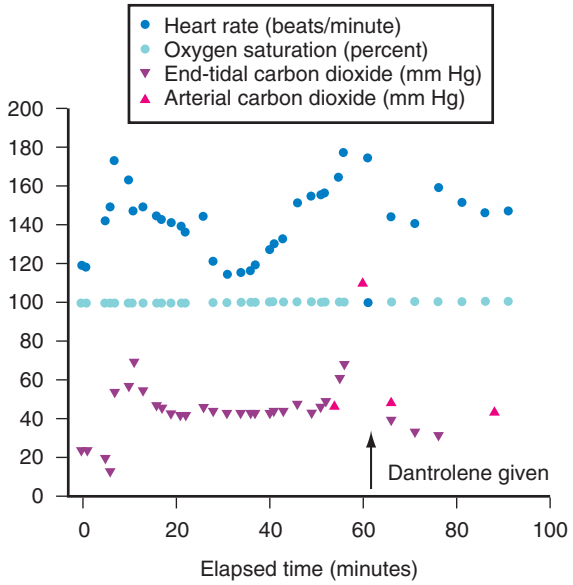


FIGURE 41.3 Response of physiologic parameters to dantrolene during an apparent intraoperative episode of malignant hyperthermia. Notice the rapid decrease in arterial and end-tidal carbon dioxide pressures after dantrolene (2.5 mg/kg) administration (*arrow*). (Courtesy Steven C. Hall, MD.)

In a retrospective review of 264 children in the North American MH Registry, the most common signs of an MH reaction were sinus tachycardia in 73% and hypercarbia in 69%, which were most common in adolescents.[68] Hyperthermia appeared in fewer than half (48%) of the children.[68] Greater temperatures and peak potassium concentrations were present more commonly in adolescents, whereas greater peak lactic acid concentrations and reduced peak creatine kinase concentrations were present in the younger children (<2 years).[68] A steady and relentless increase in the end-tidal CO_2 ($P_{ET}CO_2$) is the earliest sign of a reaction and is usually evident regardless of whether respirations are spontaneous or controlled. In some instances, the increase in $P_{ET}CO_2$ and heart rate occur contemporaneously, alerting the clinician to consider an evolving MH reaction (Fig. 41.3). Sudden unexpected cardiac arrest is a very rare presentation of MH and suggests a disease process other than MH, such as acute rhabdomyolysis and hyperkalemia after succinylcholine in a (male) child with an undiagnosed myopathy.

The presenting signs of an MH reaction are nonspecific and may suggest several possible disease states or equipment problems. The earliest sign of an MH reaction, an increase in $P_{ET}CO_2$, may result from one or more of three factors from the CO_2 mass balance equation:

$$P_{CO_2} = (\dot{V}_{CO_2} / \dot{V}_A) + F_{ICO_2} \qquad \text{Eq. 41.1}$$

The circulating P_{CO_2} depends on the production of CO_2 ($\dot{V}_{CO_2}$), the elimination of CO_2 (i.e., alveolar ventilation ([$\dot{V}_A$]), and the fraction of inspired concentration of CO_2 (F_{ICO_2}). The differential diagnosis of an increased P_{CO_2} can be analyzed by considering the causes for each of these three factors: $\dot{V}_{CO_2}$, $\dot{V}_A$, and F_{ICO_2}. Causes of an increased $\dot{V}_{CO_2}$ include fever, MH, thyroid storm, and sepsis. This may pose a particular challenge to diagnose during laparoscopic surgery.[69,70] Causes of a decreased $\dot{V}_A$ include a deep level of anesthesia, endobronchial intubation, bronchospasm, and a kinked tracheal tube or airway breathing circuit. Causes of increased F_{ICO_2} include an incompetent expiratory valve, exogenous source of CO_2, low fresh gas flows with a partial or nonrebreathing circuit, and expired CO_2 absorbent. The initial evaluation should include a rapid assessment of the integrity of the breathing circuit, the presence of bilateral breath sounds and absence of wheezing, and examination of the CO_2 absorbent.

During airway obstruction and hypermetabolic states such as thyrotoxicosis and sepsis, an increased $P_{ET}CO_2$ can be readily corrected with mild to moderate hyperventilation. During MH reactions, however, it is very difficult to restore the $P_{ET}CO_2$ to the normal range, even with vigorous mechanical hyperventilation.[28] The CO_2 production is sometimes so great that the in-circuit CO_2 absorbent rapidly becomes exhausted in an exothermic reaction, and the absorbent container becomes hot to touch. Thyrotoxicosis can be distinguished from an acute MH reaction by the absence of general muscle rigidity, less severe metabolic acidosis and peak creatine kinase (CK) level, and the absence of an effect by dantrolene on the course of the disease in thyrotoxicosis.

A child's response to surgery during light anesthesia often includes tachycardia and may sometimes include bronchoconstriction. However, a dramatic and unexpected increase in heart rate from 120 to 180 beats/minute in a healthy, 7-year-old child (or an increase from 70 to 120 beats/minute in an adult) strongly suggests a pathologic process, and a differential diagnosis beyond light anesthesia should be seriously considered. Before intervening, it is important to quickly scan all the monitors to determine whether the aggregate indexes point to a specific diagnosis. If tachycardia is associated with an increase in body temperature, a differential diagnosis of fever and tachycardia under anesthesia should be considered. Fever related to sepsis or viral infection usually has a slow onset, whereas fever from an MH reaction typically has a rapid onset. The differential diagnoses include iatrogenic external overheating and an MH reaction (see Table 41.4). A rapid increase in the inspired concentration of desflurane and isoflurane, but not sevoflurane, may cause a sympathetic-based tachycardia that in isolation should not suggest a diagnosis of MH because the $P_{ET}CO_2$ remains unchanged.[71,72] Of the inhalational anesthetics, halothane appears to be the most likely to trigger an MH reaction and the best discriminator for the CHCT. Enflurane provides the smallest trigger, sevoflurane and isoflurane are intermediate, and preliminary data suggest that xenon does not trigger MH reactions.[23,56,73–75] If none of these factors appears to be causative and a deeper level of anesthesia (achieved with propofol with or without an opioid) fails to abate the signs, simultaneous venous and arterial blood gases should be analyzed to determine whether the patient has or is developing a hypermetabolic state.

Rhabdomyolysis can occur during an acute MH reaction, but it usually occurs later in the course of an incompletely treated reaction compared with anesthesia-induced rhabdomyolysis (AIR), which is the presenting finding after the administration of succinylcholine with or without an inhaled anesthetic to a young child with an often undiagnosed myopathy (e.g., Duchenne muscular dystrophy).[76] The presenting features of MH and AIR are contrasted in Table 41.6. Note that MH rarely presents with isolated rhabdomyolysis; however, in contrast to AIR, it is responsive to dantrolene.

A moderate but gradual increase in body temperature may occur in children excessively draped, those with forced-air warming devices, those with bilateral limb tourniquets, and those covered with plastic occlusive wrap. However, the sudden onset of a high fever must be more thoroughly investigated because it may result from several potentially fatal causes (see Table 41.4).[77–80]

TABLE 41.6 Differences Between Malignant Hyperthermia and Anesthesia-Induced Rhabdomyolysis

		Anesthesia-Induced Rhabdomyolysis	Malignant Hyperthermia
Early Signs	Clinical		Rigidity Masseter spasm
	ECG	Peaked T waves Bradycardia, dysrhythmia, ± cardiac arrest	Tachycardia
	Oxygen saturation Airway gas monitoring	Normal until arrest	Decreasing ↑ $ETCO_2$ ↑ Oxygen consumption[a]
	Blood results	Marked hyperkalaemia Increased creatine kinase (CK)	Hyperkalaemia
Late Signs		Acidosis ↑ $ETCO_2$ ± ↑ Temperature (rare) Myoglobinemia/urea CK > 1000/μL (may increase to >40,000)	Acidosis ↑ Temperature Myoglobinemia/urea Ventricular arrhythmia Cardiac arrest Bleeding diathesis
Timing (unless succinylcholine has been given)[b]		May occur at any time, particularly later in the anesthetic or in recovery room	Any time
Treatment Priority		CPR Stop halogenated agent Reduce plasma potassium "Clean" source of oxygen	Stop halogenated agent Dantrolene "Clean" source of oxygen

CPR, cardiopulmonary resuscitation; *ECG*, electrocardiogram; *$ETCO_2$*, end-tidal carbon dioxide.
[a]Represented by widening inspired to expired oxygen concentration in the face of unchanged fresh gas flows.
[b]If succinylcholine has been given, malignant hyperthermia or anesthesia-induced rhabdomyolysis may happen precipitously.

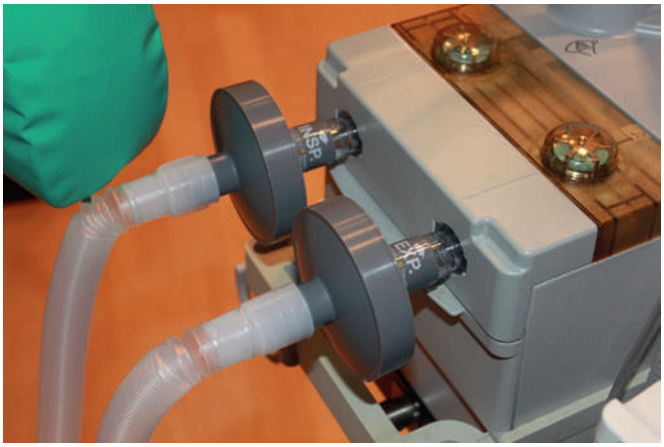
Management, Susceptibility Screening, and Counseling



TREATMENT

Management of an acute MH reaction is the model for which anesthetic crisis resource management (ACRM) was developed. The decision-making process for every aspect of managing the MH reaction (from differential diagnosis to counseling for MedicAlert bracelets [MedicAlert Foundation, Salida, CA] http://www.medicalert.org) together with excellent communication and human resource management ensure an optimal outcome after the reaction.[81] Given the rarity of these reactions, ACRM can be built into the simulation scenario for MH to teach leadership and decision making in the time of crisis (see Chapter 53).

If the anesthesiologist suspects that a child is experiencing an MH episode, the inhalational anesthetic should be immediately discontinued, 100% oxygen administered at a large fresh gas flow rate (≥10 L/minute), and the surgeon informed; if surgery cannot be aborted, it must be completed expeditiously. Charcoal filters should be inserted into both limbs of a new and previously unused breathing circuit (E-Fig. 41.2). The filters prevent the child from being contaminated by residual anesthetic in the AWS and to prevent the AWS from being contaminated by anesthetic in the patient.[63] The MH cart and additional personnel to assist in dissolving the dantrolene (see later text) should be brought to the operating room immediately (Table 41.7). Minute ventilation should be increased to control the partial pressure of carbon dioxide ($PaCO_2$) and $PETCO_2$.

The anesthesia technique should be converted to total IV anesthesia (TIVA), and if charcoal filters are not available, hyperventilation should be continued using an external self-inflating or anesthesia-type bag with an exogenous source of oxygen that is uncontaminated by inhalational anesthetics. If the airway was not intubated, tracheal intubation should be performed and ventilation controlled mechanically to achieve a normal $PETCO_2$.

Because native dantrolene is quite insoluble in water, several strategies have been developed to speed its solubility. The current formulation (Dantrium, Par Pharmaceutical, Par Sterile Products, Chestnut Ridge, NY) is packaged as a lyophilized yellow powder (E-Fig. 41.3) with constituents that contain mannitol and an alkaline pH to speed the dissolution of dantrolene in water (Table 41.8). Warming the 60 mL of sterile water speeds dissolution.[82] Most of the dantrolene dissolves within 60 seconds of adding the water, turning the solution orange; vigorously shaking the vial quickly dissolves any residual crystals. The solution should be withdrawn immediately and administered intravenously as rapidly as possible. Given the extreme alkaline pH of the dantrolene solution, it should be infused into a large vein to reduce the risk of phlebitis. Extravasation of dantrolene into interstitial tissues may cause tissue necrosis. Prolonged continuous infusions of dantrolene may cause thrombophlebitis or thrombosis of large and small veins.[83–85] Some have recommended continuous infusions of small doses of dantrolene in adults after the initial bolus, although the risk/benefit ratio of this practice is unproved in adults and untested in children.[86] A new formulation of nanocrystalline dantrolene (Ryanodex, Eagle Pharmaceuticals, Woodcliff Lake, NJ) approved in the United States in 2014 rapidly dissolves in a much greater

E-FIGURE 41.2 Charcoal filters should be inserted into both the inspiratory and expiratory limbs of the anesthesia breathing circuit during an acute malignant hyperthermia (MH) reaction to remove inhalational anesthetic from the anesthesia workstation and to prevent the patient from being exposed to additional inhalational anesthetic. They can also be used preoperatively to rapidly prepare an anesthesia workstation for use with an MH-susceptible patient in the event a "clean machine" is not available, although only a filter on the inspiratory limb would be required in such a case. These filters are effective within a few minutes and reduce the anesthetic concentration to 2 to 3 ppm, well below the theoretical threshold to trigger an MH reaction.

E-FIGURE 41.3 Dantrolene for intravenous treatment of an acute malignant hyperthermia reaction. This formulation is lyophilized for storage, stability, and reconstitution. Each bottle contains 20 mg of dantrolene. The dantrolene is reconstituted by injection of sterile water 60 mL per bottle, producing an orange-colored solution. Dissolution may be accelerated by shaking the bottle or by injecting warmed sterile water. An initial dose of 2.5 mg/kg IV dantrolene should be administered as quickly as possible. If the reaction does not abate, further dantrolene should be administered 1 mg/kg IV until the reaction stops.

TABLE 41.7 Contents of a Pediatric Malignant Hyperthermia Emergency Cart

Fluids			
3 L cold normal saline or Lactated Ringer's solution			
Number of Containers	**Drug**	**Concentration**	**Container**
	Dantrolene IV[a]		
36	Dantrium or Revonto (see Table 41.8)	20 mg in 60 mL of sterile water (0.33 mg/mL)	1 vial
3	Ryanodex	250 mg in 5 mL of sterile water (50 mg/mL)	1 vial
25	Sterile injectable water		100 mL
4	Sodium bicarbonate	1 mEq/mL	50-mL vial
2	50% dextrose	500 mg/mL	50-mL vial
1	Regular insulin	100 units/mL	10-mL vial
2	Calcium gluconate or chloride (10%)		10 mL
3	Lidocaine (2%)[a]	20 mg/mL	5 mL
10	20- and 22-gauge IV catheters		
10	18- and 20-gauge needles		

IV, intravenous; *TB*, tuberculin.
[a]Avoid lidocaine if wide QRS complex is present.
Charcoal filters should be immediately available if they are not on the malignant hyperthermia cart.

TABLE 41.8 Characteristics of Three Formulations of Dantrolene IV

	Dantrium[a]	Revonto[b]	Ryanodex[c]
Dose (mg)/vial	20	20	250
Volume of diluent (mL)	60	60	5
Mannitol content (mg)	3000	3000	125
Time to dilute (seconds)	20 or "until solution is clear"[a]	20 or "until solution is clear"[a]	<10
	"Shake the vial to ensure an orange-colored uniform suspension. Visually inspect the vial for particulate matter and discoloration prior to administration."		
pH of reconstituted solution	9.5	9.5	10.3
Number of vials recommended by MHAUS (for a 70 kg patient)	36	36	3 (equivalent to ~720 mg dantrolene)
Shelf-life (years)	3	3	2
Acquisition cost (USD wholesale)	4028	3192	8280

[a]Dantrium (Par Pharmaceutical Companies Inc., Spring Valley, NY).
[b]Revonto (dantrolene sodium; DSM Pharmaceuticals Inc., Greenville, NC); package insert revised November 2016.
[c]Ryanodex (dantrolene sodium; Eagle Pharmaceuticals, Inc., Woodcliff Lake, NJ); package insert revised July 2014.
Data were summarized in part from *Cleveland Clinic Clinical Rx Forum*, 2016:4(5);4–5.

concentration formulation (5 mL of sterile water yielding 250 mg/5 mL) than the previous formulations (http://www.ryanodex.com/wp-content/uploads/2014/09/ryanodex-mh-white-paper.pdf [accessed May 16, 2017]).[87,88] This preparation contains more dantrolene (250 mg) than the standard preparation (20 mg) and less mannitol (125 mg) versus 3 g per vial (see Table 41.8) and requires only 5 mL instead of 60 mL of bacteriostatic water per vial to dissolve the dantrolene.[88] Preliminary evidence suggests that the blood concentration of dantrolene from Ryanodex reaches its maximum concentration (C_{max}) more rapidly (smaller T_{max}) than that from the previous dantrolene formulations.[89] The shelf life of Dantrium is 3 years, whereas that of Ryanodex is only 2 years.[88] Table 41.8 compares and contrasts the characteristics of the three current formulations of dantrolene.

The pharmacokinetics of IV dantrolene have been studied in MHS children 2 to 7 years of age.[90] A loading dose of 2.5 mg/kg produced predictable blood concentrations (≥3 μg/mL) for about 6 hours after the loading dose (Fig. 41.4).[90] Based on these pharmacokinetic data, if half of the loading dose of dantrolene were repeated at 6 hours after the loading dose, therapeutic blood concentrations of dantrolene would be maintained for a total of 15 hours and possibly prevent a recrudescence.[90]

An initial bolus dose of 2.5 mg/kg controls most MH reactions if the dantrolene is administered as soon after the onset of the reaction as possible (see Fig. 41.3).[91] Delay in instituting dantrolene therapy increases the probability of failed therapy and death.[42] For a 70-kg patient, this initial dose requires 8 vials of Dantrium or 1 vial of Ryanodex. Since the likelihood of successfully aborting the MH reaction depends on the speed of administering the dantrolene, we recommend that Ryanodex be used despite its added cost and reduced shelf life. The response to dantrolene should be evident within minutes, with a marked reduction in

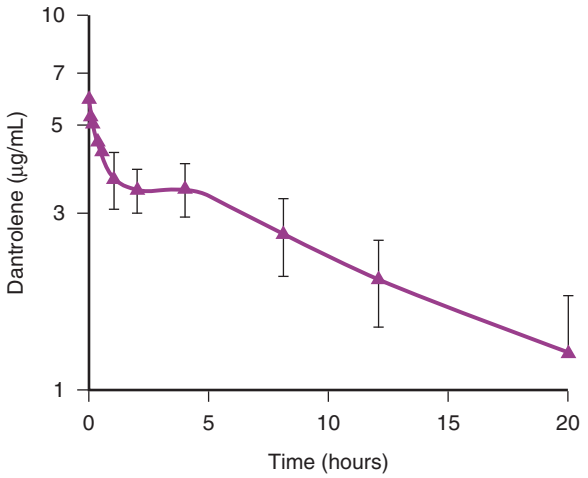


FIGURE 41.4 Pharmacokinetics of dantrolene in children. (From Lerman J, McLeod ME, Strong HA. Pharmacokinetics of intravenous dantrolene in children. *Anesthesiology* 1989;70[4]:625–629.)

P_{ETCO_2}, heart rate, and respiratory rate (see Fig. 41.3). If there is no response within 3 to 5 minutes, the initial dose should be repeated until signs that the physiologic variables are abating. The clinical end points include resolution of the hypercapnia, tachypnea, and tachycardia; resolution of muscle rigidity; restoration of clear urine output; return of normal consciousness when sedation is discontinued; self-correction of blood gas abnormalities; and resolution of electrolyte disturbances. If these do not occur or are incomplete, additional doses of dantrolene should be administered until all signs and symptoms of the MH reaction have abated or the diagnosis is reevaluated.[91] There is no upper limit to the amount of dantrolene that can or should be given acutely to stop an MH reaction. In rare instances of persistent MH or recrudescence, a cumulative dose of up to 40 mg/kg has been required.[92] Dantrolene is a fairly potent muscle relaxant, and a child with an unintubated airway (particularly one with respiratory disorders) may become weak and require controlled respirations.

Although dantrolene is effective in terminating acute MH reactions, this effect may wane as the blood concentration of dantrolene decreases and a recrudescence may occur. The prevalence of recrudescence may be as great as 20% and associated with several predictive factors, including muscular body type and a greater time interval between induction of anesthesia and the development of the initial reaction.[93] However, the first episode of recrudescence may occur any time after the initial reaction was successfully treated, up to and as late as 36 hours.[94] The possibility of recrudescence must always be considered during the first 2 to 3 days after an MH reaction has occurred. Because recrudescence cannot be predicted, all children who experience an MH reaction must be admitted to the pediatric intensive care unit or a monitored bed until the reaction resolves and the child's metabolic indices return to and remain normal for 2 to 3 days. MHAUS recommends that 1 mg/kg of dantrolene be administered intravenously every 6 hours for 24 to 48 hours after an MH reaction to prevent recrudescence. This recommendation remains empirical because there are no data to support the effectiveness of dantrolene in preventing recrudescence, although these dosages are consistent with pharmacokinetic data in children.[90] We recommend continued vigilance, frequent physical examinations for muscle tightness (every 30 minutes), repeated laboratory tests (e.g., blood gas analyses), and monitoring of vital signs, particularly heart rate, respiratory rate, and expired CO_2 tension for evidence of a recrudescence during the first 48 hours after an MH episode. If recrudescence does occur, additional IV dantrolene should be administered until the reaction again abates.

There have been no reports of acute dantrolene toxicity, although acute administration of dantrolene may result in side effects that include skeletal muscle weakness (15%), phlebitis (9%) and gastrointestinal upset (4.3%).[84] Respiratory failure was reported in 3.8% of patients who received dantrolene, although distinguishing the cause of the failure to the underlying MH or the dantrolene has proven difficult.[84] Extravasation of dantrolene into subcutaneous tissue may cause necrosis.[88] Not surprisingly, neostigmine is ineffective in reversing the effects of dantrolene because the latter acts intracellularly, not at the neuromuscular junction (see the section on molecular mechanisms of dantrolene). It may be advisable to maintain control of the airway (combined with IV sedation) until there is no further need for dantrolene. Preoperative, orally administered dantrolene, initially recommended in MH-susceptible children 2 decades ago, caused skeletal muscle weakness, dysarthria, sialorrhea, and diplopia and was ineffective in preventing MH reactions.[48] As a result, this practice was discontinued.[48] Long-term use in the treatment of chronic skeletal muscle spasticity has been reported to cause liver dysfunction and fatal hepatitis in about 1% and 0.1% of patients, respectively.[95] Given the risks of an MH reaction, there seems little downside to treating a child with dantrolene before the diagnosis is certain, provided all the necessary blood work and laboratory tests have been collected, because early treatment reduces mortality and morbidity (see Fig. 41.1).[42] The probability of developing a complication from an MH reaction increases almost threefold for every 2C° increase in body temperature and 1.6-fold for every 30-minute delay in administering IV dantrolene during a reaction.[42] Cardiac arrest and death during an MH reaction correlate with a muscular physique and greater time intervals between induction of anesthesia and the maximal value of P_{ETCO_2}.[26] Other possible diagnoses should continue to be considered while the treatment for the suspected MH reaction is organized (see Table 41.4). A positive response to dantrolene is not pathognomonic of an MH reaction, because other conditions may respond with resolution of their signs.

Moderate external cooling measures may be instituted to control a rapidly increasing temperature, although ice should never be applied directly to the skin because it may cause tissue injury and intense cutaneous vasoconstriction. The latter may decrease heat loss further by accelerating acidosis and pyrexia. It is important to avoid overshooting with cooling measures (i.e., stop aggressive cooling at a temperature of about 38.5°C), because hypothermia may ensue, particularly if dantrolene has been administered. A urinary catheter should always be inserted during an MH reaction to identify myoglobinuria and to facilitate bladder emptying because 0.375 g of mannitol/kg body weight is given as part of the initial (2.5 mg/kg) loading dose with the older dantrolene formulations.

Initial laboratory assessments should be obtained before the bolus dose of dantrolene, and in addition to arterial and venous blood gases, determinations should include electrolyte, glucose, blood urea nitrogen, and creatinine levels; a complete blood cell count with platelets; prothrombin and partial thromboplastin times; CK concentrations; and serum and urine myoglobin levels. Because CK concentrations peak 12 to 24 hours after the onset of an MH reaction, it is prudent to obtain a baseline blood sample as soon as an MH reaction is suspected. The provider should be especially aware of the potential for hyperkalemia as the result of muscle breakdown and for acute renal failure as a late complication. Placing an arterial catheter facilitates continuous monitoring of blood pressure and for serial determinations of arterial blood gases, electrolytes, and CK.

The potential for life-threatening acidosis–a pure respiratory acidosis early in the syndrome, followed later by a mixed metabolic/respiratory acidosis–always exists. Metabolic acidosis should be treated with sodium bicarbonate (1–2 mEq/kg IV initially), as would be done for any acutely acidotic child, and continue treatment guided by pH and base deficit, although if hypercapnia persists despite aggressive hyperventilation, administration of sodium bicarbonate should be reconsidered since the severity of the respiratory acidosis may increase. Because an acute MH episode is associated with catecholamine stress, hemodynamic instability, particularly owing to dysrhythmias, may develop and should be treated according to Advanced Cardiac Life Support protocols. Calcium channel blockers must be avoided when treating MH reactions because they may cause cardiovascular collapse or acute hyperkalemia in the presence of dantrolene.[96–98] Acute

hyperkalemia is common in patients with MH complicated by rhabdomyolysis and acidosis. Glucose and insulin should be immediately available and combined with the judicious use of exogenous IV calcium for treatment (see also Chapter 9). There is no evidence that the use of calcium in this setting exacerbates an MH reaction but it would be effective in opposing the cardiac effects of hyperkalemia.[99,100]

After the acute crisis has been treated, late complications, including severe rhabdomyolysis, are possible. It is important to follow serial serum concentrations of CK; if they are greater than 10,000 IU or urinary myoglobin concentrations increase, the urine should be alkalinized, and forced diuresis (>2 mL/kg per hour) with mannitol should be induced to prevent myoglobin from precipitating in the renal tubules, causing acute myoglobinuric renal failure. The enormous fluid requirements and edema associated with rhabdomyolysis may produce a compartment syndrome, which requires immediate surgical treatment.

Other organ systems may be affected after an acute episode of MH. It is common for markers of liver function to increase 12 to 36 hours after the crisis; some liver enzymes, including lactate dehydrogenase, aspartate aminotransferase, and alanine aminotransferase, can also originate from muscle. A concomitant increase in CK to more than 10,000 IU strongly suggests a severe and acute muscle disorder. Accompanying increases in γ-glutamyltransferase and bilirubin suggest liver involvement. Disseminated intravascular coagulation as part of multisystem organ failure is an ominous late complication.[101] Coagulation profiles should be followed serially to guide treatment appropriate to the case.

When necessary, the MH treatment algorithm should be accessed, available on the MHAUS website (www.mhaus.org/). We recommend attaching an updated MH treatment algorithm to every MH cart and anesthesia machine and that operating room personnel hold practice drills for the treatment of an MH crisis (see "Emergency Therapy for Malignant Hyperthermia" on the inside back cover of this text and at ExpertConsult.com). If the patient experiences what is believed to be an MH reaction, the care provider should call the MH emergency response line (1-800-644-9737 or 001-1-315-464-7079 if calling from outside the United States) for consultation with experienced anesthesiologists who are available 24 hours every day. We strongly encourage completion of an adverse metabolic reaction to anesthesia (AMRA) report by members of the team who provided anesthesia and postoperative care to the child. These forms can be downloaded (www.mhreg.org), sent by the hotline consultant, or obtained from the MHAUS office through regular mail. The data contained in the completed AMRA forms allow the North American Malignant Hyperthermia Registry (NAMHR) and MHAUS to produce better data regarding the variability of MH crises and the effectiveness of treatment. Because anesthesiologists should take a leading role in managing these patients, the families should be strongly encouraged to register the proband before leaving the hospital for MedicAlert identification (www.medicalert.org) that provides critical health information, such as "malignant hyperthermia susceptible, avoid inhaled anesthetics and succinylcholine."

STRESS-TRIGGERED MALIGNANT HYPERTHERMIA

In 1974, Wingard described an MHS family with a history of exercise- and emotion-induced fevers and sudden death not associated with anesthesia or surgery; he considered the possibility that MH was part of a spectrum of human stress syndromes.[102] Likewise, the porcine model of MH, also known as porcine stress syndrome, was first described as an awake, stress-induced syndrome brought about by tightly packing pigs in a train, car, or truck for shipment.[103] Dantrolene-responsive cases of awake and heat stroke–induced MH have been reported.[104,105] Heat stress–induced MH also seems to be characteristic of susceptible animal models.[106–108] A fatal case of exercise-induced MH in a 12-year-old boy who had previously survived a suspected episode of MH during general anesthesia to set a fractured humerus has been reported.[109] Eight months after surgery, while playing a game of football, the child became hyperthermic, collapsed, and died. Postmortem DNA testing revealed an MH-associated *RYR1* mutation in the child and his surviving father.[109] More cases of stress-induced MH have been reported, substantiated by genetic testing and in vitro contracture testing (IVCT).[110,111]

Screening for MH susceptibility in heat stroke patients and those suffering postexercise cramps or rhabdomyolysis using the in vitro CHCT has led to the laboratory diagnosis of MH susceptibility in some patients.[45,112–115] Although there is laboratory evidence of similarities in skeletal muscle metabolism in exertional heat stroke and MH,[116] and one of the mouse MH knock-in models exhibits environmental heat triggering,[67] there is as yet little evidence that these are anything more than clinically similar presentations.[45] For this reason, dantrolene has rarely been an effective treatment for heat stroke.[117] Nonetheless, it seems reasonable to suggest that subsets of MHS patients may be more sensitive to heat stroke. Therefore it may be helpful to test children with exertional heat illness for MH susceptibility.[118]

MH reactions have been reported infrequently in susceptible patients who received a nontriggering anesthetic.[49,119,120] Of 2214 patients who presented for muscle biopsy for MH susceptibility, 5 (0.46%) of 1082 who had MH-positive biopsy results developed MH reactions in the recovery room. None of the patients with negative biopsy results developed MH reactions. There is a small incidence of MH reactions among susceptible individuals that may occur despite a safe anesthetic regimen. Whether this is caused by stress or trace anesthetic concentrations that were inhaled is unclear. Massive rhabdomyolysis has been reported on rewarming from cardiopulmonary bypass despite the patient having received a nontriggering anesthetic.[119,120] The mechanism of these responses may be stress, but evidence is lacking.

POSTEPISODE COUNSELING

Ideally, after treating a child for MH, the anesthesiologist should arrange for referral of the child and first-degree relatives to an MH diagnostic biopsy center. It is only at such centers that the CHCT can be performed in adults. The CHCT is the only test that can produce a true negative diagnosis (i.e., not MHS),[121] but the sensitivity and specificity of this test are less than 100%. False-negative test results may occur, albeit rarely.[122] When the anesthetic management of a small number of MH biopsy-negative patients was reviewed, more than one-half were given inhalational anesthetics, although the biopsy results for the remainder may not have been known at the time of anesthesia because they were given trigger-free anesthetics.[123]

Because there are no control muscle biopsy data for prepubescent children, contracture testing is not performed in this age group. Instead, children are more often fitted with MedicAlert bracelets, and the parents are counseled regarding their own need for biopsies. The children may be reconsidered for muscle biopsy upon reaching puberty.

Many persons suspected of having MH have normal muscle responses on the CHCT. In the event that an adult who experienced an MH reaction has a normal CHCT result, he or she should be

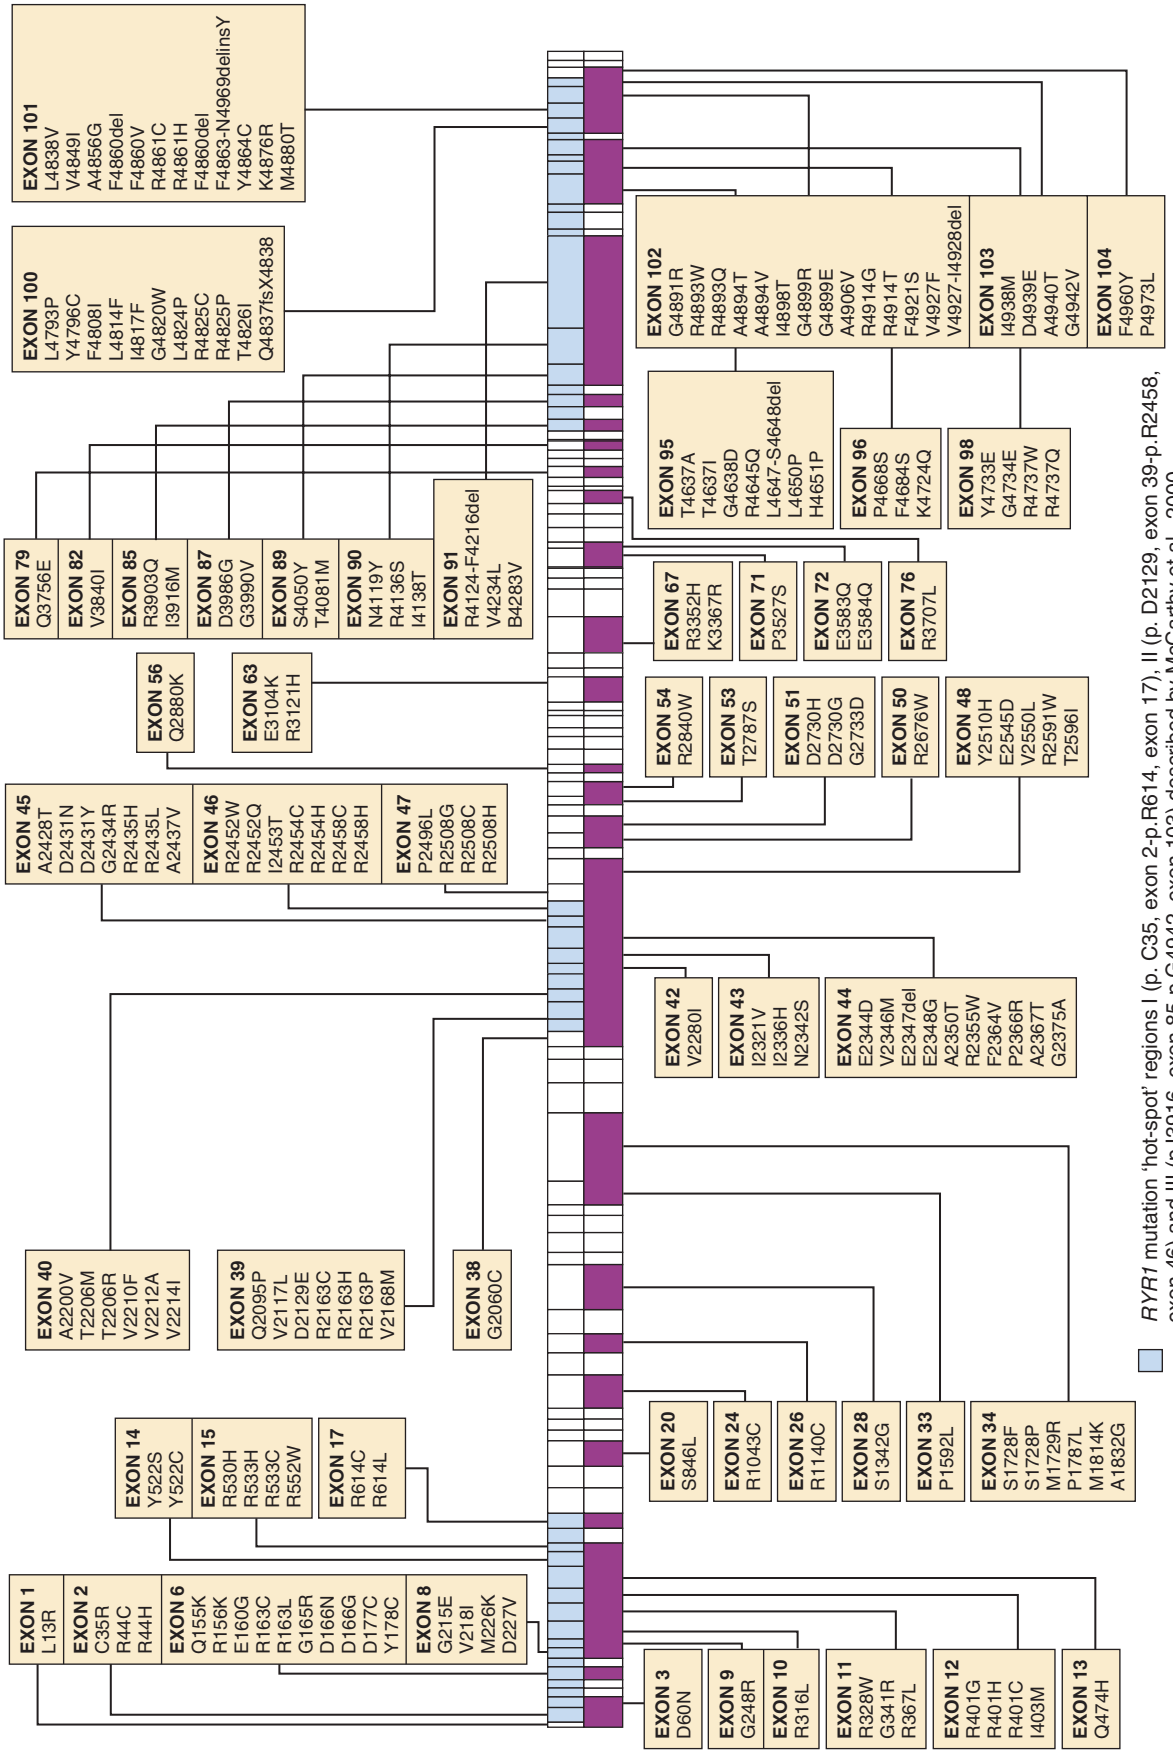
referred to a neurologist with an interest in muscle diseases to determine whether an occult myopathy is responsible for the clinical events. Alternatively, the diagnosis may be incorrect, and other diagnoses should be considered (see Table 41.4). Individuals suspected of being MHS should undergo CHCT; the family should also be evaluated and counseled accordingly.

Patients with strongly positive CHCT results should undergo screening for the ryanodine receptor 1 gene *(RYR1),* because mutations in this gene have been found in about 60% of family members who had an MH episode (conversely, this means that ~40% test negative genetically but are clinically MH positive). However, if neither an MH reaction nor a positive CHCT result has occurred, DNA testing for *RYR1* gene mutations based on a vague history offers such a poor yield of positive results that it cannot be justified at the present time.[124] If an MH-associated mutation (discussed later) is found in *RYR1,* first-degree relatives have a 50% probability of having a similar defect. Diagnostic testing for *RYR1* is performed on DNA obtained from a blood specimen, obviating the need to travel to an MH diagnostic biopsy center or undergo muscle biopsy for the genetic test. Genetic testing of relatives can be undertaken through the office of the primary care physician or by the anesthesiologist, a process that will simplify evaluation of the family. Failure to identify an MH-causative *RYR1* mutation (E-Fig. 41.4) does not confirm a negative diagnosis (i.e., not MHS) because more than one gene is associated with MH susceptibility, and not all are known.

Genetic testing and counseling can be arranged by the anesthesiologist or primary care physician by scheduling an appointment; one such center is located at the Center for Medical Genetics & Genomics at the University of Pittsburgh. The genetic counselors have extensive experience in counseling patients on the utility of the ryanodine receptor gene test for evaluation of MH susceptibility. The center currently screens 12 exons of genomic *RYR1* that commonly contain MH mutations (exons 6, 9, 11, 14, 17, 39, 40, 44, 45, 46, 101, and 102). A private commercial laboratory that also offers *RYR1* testing is Prevention Genetics (www.preventiongenetics.com), which screens for MH mutations. It has adopted a two-tiered approach: tier 1 involves bidirectional sequencing of exons 2, 6, 8, 9, 11, 12, 14, 15, 17, 39, 40, 41, 44-47, 95, and 100-104. These 22 exons contain most of the conclusively documented MH and central core disease causative mutations in the *RYR1* gene (European Malignant Hypothermia Group, www.emhg.org/genetics/). If the first tier is uninformative, their second-tier screen covers the remaining 84 exons of the 106 making up the human *RYR1* gene. The Prevention Genetics company corresponds only with physicians and does not provide patient or family counseling.

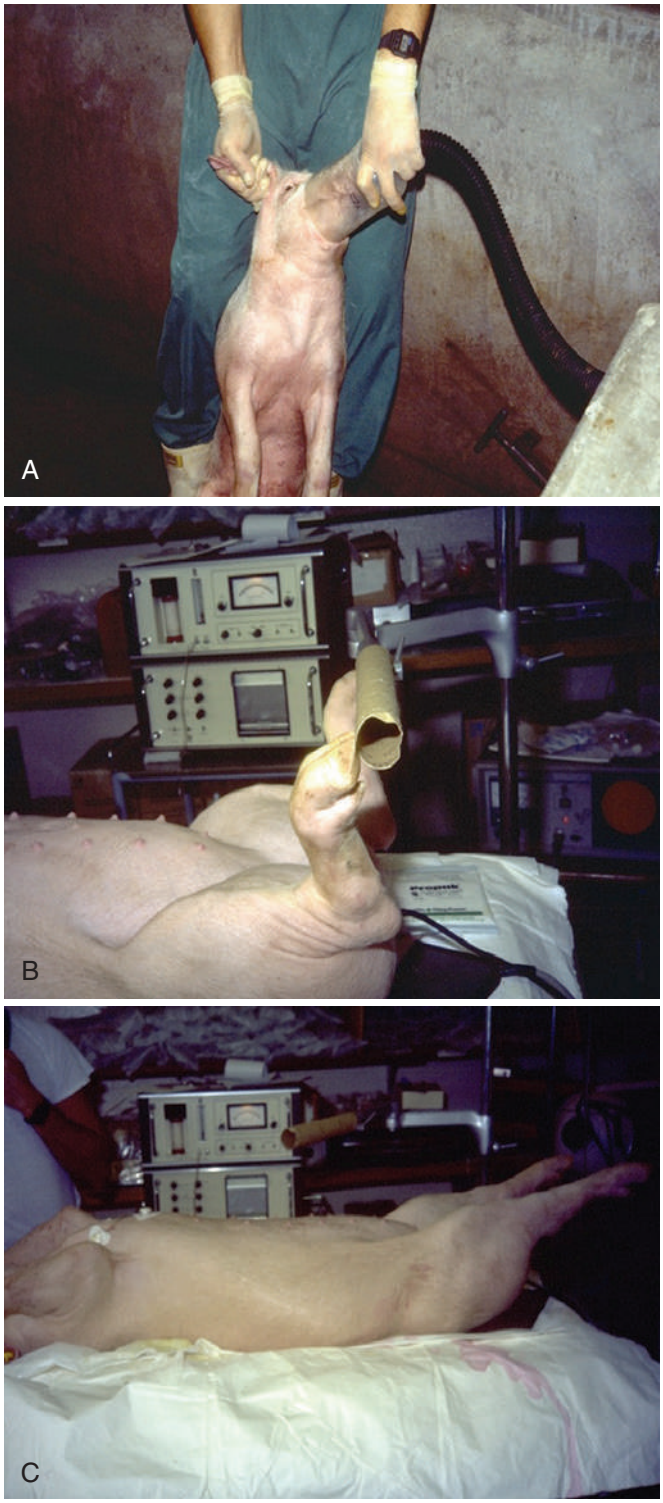
As DNA sequencing has become more automated and the cost has drastically declined, many private companies have arisen that purport to diagnose the entire panoply of human genetic diseases and resultant predispositions, including MH. We have no information about the reliability of their screening or the recommendations based on their findings. If no causative *RYR1* mutations are found, nothing more can be determined from genetic testing about susceptibility, because more than one mutated gene is linked to MH.

Genetics



MH in humans follows an autosomal dominant inheritance pattern with incomplete penetrance and variable expressivity.[30,125,126] In the context of MH, incomplete penetrance means that there are fewer patients with MH susceptibility than would be predicted by simple autosomal dominant inheritance. Variable expressivity means that the presence of a genetic mutation defining susceptibility is documented, but it does not mean that a patient will have an MH reaction when exposed to triggering agents. One patient in the NAMHR received 30 anesthetics before an MH reaction was triggered.[42] Another was discovered to be MHS by IVCT during screening of a proband's family and later was inadvertently anesthetized with succinylcholine and isoflurane, but these drugs did not trigger a reaction.[127] However, it seems that once an MH reaction has been triggered, a reaction will always occur when the patient is exposed to the trigger agents.

The molecular and cellular bases of these phenomena remain unknown. Naturally occurring susceptibility to MH seems to follow autosomal dominant inheritance patterns in dogs[128] and horses[129] but follows a recessive inheritance pattern in pigs.[130] This suggests that other genetic and epigenetic factors may play a role in determining the degree and timing of MH susceptibility.



The first breakthrough in finding a gene that predisposed to MH was the serendipitous finding of a similar syndrome in pigs.[131,132] When anesthetized with halothane and succinylcholine or with halothane alone, the pigs developed full-blown MH reactions (E-Fig. 41.5). The pig model has been a primary pathophysiologic, genetic, and pharmacologic model for the study of MH over the past 5 decades. A second serendipitous event introduced a South African anesthesiologist, G.G. Harrison, to dantrolene, and he successfully tested it in his pig model of MH.[133,134] This observation was quickly followed by the successful treatment of a patient with dantrolene.[135] An interview about Harrison's discovery of dantrolene is available from the Wood Library-Museum of the American Society of Anesthesiologists (www.woodlibrarymuseum.org/library/media).

One of the most surprising findings was that six separate breeds of pigs at different locations worldwide shared this MH susceptibility to inhalational anesthetics and succinylcholine. All reactions were treated successfully with dantrolene, and all were determined to have an autosomal recessive inheritance pattern. It was established that MH was associated with an uncontrolled increase in intramyoplasmic Ca^{2+}, presumably the result of an exaggerated release of Ca^{2+} from the sarcoplasmic reticulum (SR).[136,137] Much effort has been expended in understanding the physiologic basis of excitation–Ca^{2+}-release coupling (ECRC) as part of the general mechanism of skeletal muscle excitation-contraction coupling.

By the mid-1980s, a large channel in the SR membrane, now known as the ryanodine receptor (RyR1), was identified by its ability to bind a plant toxin, ryanodine. It was discovered to have properties consistent with being a Ca^{2+} channel.[138–140] In 1988, this presumed primary Ca^{2+}-release channel of the SR was found to have gap junction–like channel properties.[141] It was hypothesized that the ryanodine receptor might be the site of mutations that caused MH. Within a year, the complementary DNA (cDNA) for the skeletal muscle ryanodine receptor was cloned.[142] In 1990, both porcine and human MH were linked to the same region on chromosome 19q12-13.2 at the glucose phosphate isomerase locus, suggesting that MH in both species was due to mutations in homologous genes.[143] Concurrently, a linkage study in eight families demonstrated that RYR markers cosegregated with MH phenotypes, providing compelling evidence that mutations of *RYR* determine MH susceptibility.[144] Two years after the initial cloning of *RyR1*, the identical single amino acid mutation (Arg615Cys) was discovered in this channel in all six breeds of MH susceptible pigs.[145]

E-FIGURE 41.4 Distribution of known mutations associated with malignant hyperthermia and central core disease in the *RYR1* gene, which consists of 106 exons. Reported mutations are summarized in exon-specific text boxes. The current distribution of mutations spans more than the putative mutation hot-spot regions of the gene first described by McCarthy and colleagues. (From Robinson R, Carpenter D, Shaw MA, et al. Mutations in *RYR1* in malignant hyperthermia and central core disease. *Hum Mutat.* 2006;27[10]:977–89; McCarthy TV, Quane KA, Lynch PJ. Ryanodine receptor mutations in malignant hyperthermia and central core disease. *Hum Mutat.* 2000;15[5]:410–417.)

TABLE 41.9 Malignant Hyperthermia Loci

Designation	Chromosome Locus	Gene
Ryanodine receptor 1 (skeletal) (formerly malignant hyperthermia susceptibility 1 [MHS1])	19q13.1	*RYR1*
Malignant hyperthermia susceptibility 2	17q11.2-q24	*MHS2*
Malignant hyperthermia susceptibility 4	3q13.2	*MHS4*
Calcium channel, voltage-dependent, L-type, α-1S subunit (formerly malignant hyperthermia susceptibility 5 [MHS5])	1q32	*CACNA1S*
Malignant hyperthermia susceptibility 6	5p	*MHS6*

Detailed genetic evaluations have linked MH susceptibility to chromosome 19q12-13.2, the location of the human *RYR1* gene (19q13.1), in MHS families. This is the locus for malignant hyperthermia susceptibility type 1, symbolized by *RYR1* (formerly designated MHS1) (Table 41.9).[125,146,147] Of the more than 400 variants identified in *RYR1* (ClinVar-National Center for Biotechnology Information; http://www.ncbi.nlm.nih.gov/clinvar/), only about 30 have been shown to cause MH (www.emhg.org provides a comprehensive list of known causative mutations in *RYR1*). *RYR1* mutations account for 50% to 70% of MHS individuals. Not all MHS families have disorders linked to this chromosome (see Table 41.8), indicating that this syndrome is genetically heterogeneous.

The second gene mutation associated with MHS, *MHS5,* codes for the α1 subunit of skeletal muscle dihydropyrimidine receptor L-type calcium channel. This gene, *CACNA1S,* codes for 1% of MHS subjects.

Several additional loci have been mapped to MH susceptibility, although the genes have not been identified. These include *MHS2*, linked to chromosome 17q11.2-q24 in North Americans; *MHS3* locus, located on 3q13; *MHS3* located on 7q21-q22; and *MHS6* located on 5p.[11]

Complicating the potential of genetic testing for MH even further is the phenomenon of gene silencing. This phenomenon mimics a recessive mutation in heterozygous individuals by allowing expression of only the affected allele while silencing the other, normal, allele.[148] Because MH is an autosomal dominant susceptibility, it is conceivable that a mechanism underlying the variability in MH triggering seen in patients with identical, monoallelic *RYR1* mutations results from skeletal muscle–specific silencing of the affected gene. It follows that inhalational anesthetics or succinylcholine, after multiple exposures, may release a gene from the silenced state, allowing triggering to occur. This may be an explanation for discordance among genetics, linkage analysis, and trait expressivity.

Although the inheritance of human MH is described as autosomal dominant, there are a few individuals who are allelically homozygous for an *RYR1* mutation,[149,150] intra-allelically heterozygous for two different *RYR1* mutations, or compound heterozygotes containing one mutation in *RYR1* and a second mutation at another locus for MH susceptibility.[151] Surprisingly, no overt myopathies have been reported in these affected individuals.

Physiology

NORMAL SKELETAL MUSCLE: EXCITATION-CONTRACTION COUPLING

The neurochemical signal that triggers excitation-contraction coupling begins with the release of acetylcholine from the motor nerve terminal at the skeletal muscle nicotinic synapse, resulting in depolarization of the surface membrane, the sarcolemma. Sarcolemmal membrane depolarization is transmitted into the interior of the muscle cell by specialized invaginations of the surface membrane known as transverse tubules (TTs), which occur at regular intervals along the muscle cell (Fig. 41.5). The TT membrane is studded with the skeletal muscle isoform of the voltage-dependent Ca^{2+} channel known as the dihydropyridine receptor (DHPR). In skeletal muscle, this channel does not transmit Ca^{2+} in response to sarcolemmal depolarization, rather, it functions as a sarcolemmal voltage sensor.

In response to depolarization, intrachannel charge movement across the TT membrane results in a conformational change of the DHPR. The TT is surrounded by specialized portions of the cellular organelle (i.e., SR) responsible for maintaining the cellular Ca^{2+} store, and the SR contains a high-capacity Ca^{2+} storage protein called calsequestrin, which regulates the ability of the RyR1 channel to open.[152] The face of the SR junctional membrane apposing the TT contains a packed, regular array of RyR1 proteins in close apposition to the DHPR. Physically, the DHPR and RyR1 receptor proteins overlie each other in a unique arrangement of four DHPRs (tetrad) per one RyR1, with every other RyR1 lacking a tetrad (Fig. 41.6).[153] Physical interaction of the DHPR with RyR1 after depolarization causes the RyR1 channel to open, and SR-stored Ca^{2+} is released into the myoplasm. Orthograde and anterograde communication between the DHPR and RyR1 results in reciprocal regulation of both entities[154,155]

In the myoplasm, the troponin C subunit of the troponin complex is bound to tropomyosin, which in the resting state inhibits myosin interaction with actin and maintains a relaxed muscle. Ca^{2+} binding to troponin C causes a conformational change in troponin and allows the complex to move away from tropomyosin, which rotates along the actin filament in a way that permits myosin head interaction with this fibrous protein. Fiber shortening and muscle contraction then occur in a myosin-ATPase–driven ratcheting reaction. The muscle relaxes when the SR membrane–bound Ca^{2+}-ATPase transports free myoplasmic Ca^{2+} back into the SR against its concentration gradient in an energy-dependent reaction, thereby driving myoplasmic Ca^{2+} concentrations down to resting levels. Troponin I, with its bound Ca^{2+} removed, moves back to block the myosin interaction with actin, thereby preventing muscle contraction and inducing its relaxation. Although a detailed description of the complexity of this process is beyond the scope of this chapter, reviews of excitation-contraction coupling are available.[156,157]

PATHOPHYSIOLOGY OF MALIGNANT HYPERTHERMIA

Advances in the pathophysiology of MH have been reviewed in great detail elsewhere.[158–161] In brief, at the cellular level, MH is characterized by an inhalational anesthetic–induced, uncontrolled increase in intramyoplasmic Ca^{2+} levels,[162,163] which precedes the metabolic and clinical signs of this syndrome[164] (see Fig. 41.6). Increased intramyoplasmic Ca^{2+} has been demonstrated by directly measuring intracellular Ca^{2+} in anesthetic-triggered pigs[162] and by substantiating the sensitivity of stored Ca^{2+} release by isolated SR from MHS pigs.[136,137,165,166] There is also a significant loss in the

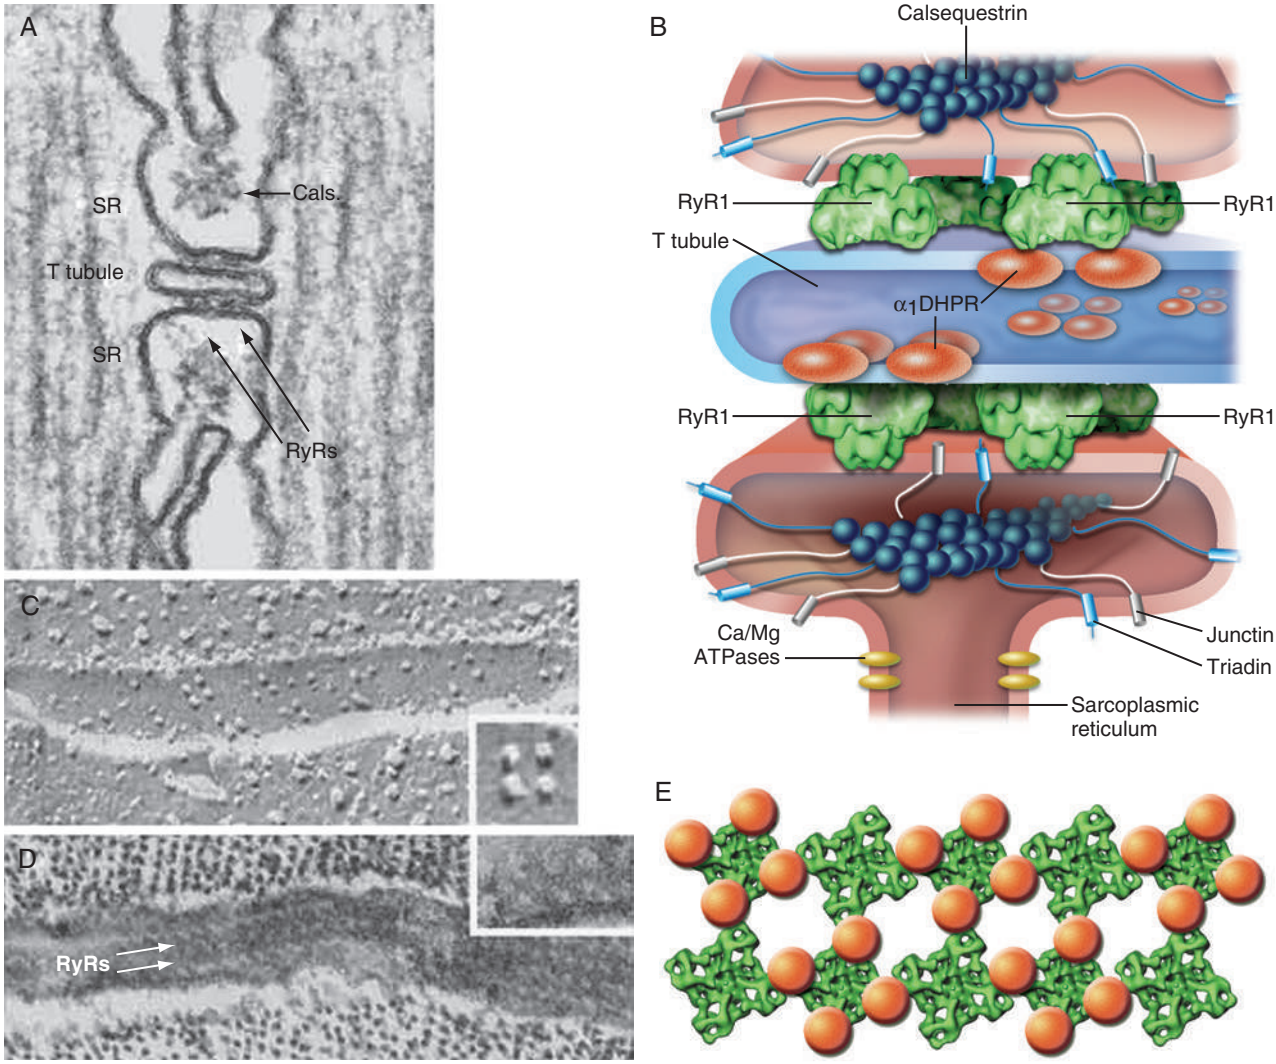

FIGURE 41.5 Structure of calcium release units in adult skeletal muscle fibers. In adult skeletal muscle, junctions are mostly triads: two sarcoplasmic reticulum (*SR*) elements coupled to a central transverse tubule (*T tubule*). **A,** A triad from the toadfish swimbladder muscle in thin-section electron microscopy shows the cytoplasmic domains of the SR Ca^{2+} release channel (*RyR1*), or feet, and calsequestrin (*Cals.*), the SR Ca^{2+} storage protein. **B,** A tridimensional reconstruction of a skeletal muscle triad shows the ultrastructural localization of ryanodine receptors (RyRs), dihydropyridine receptors (*DHPRs*), calsequestrin, triadin, junctin, and Ca^{2+}/Mg^{2+}-ATPases. Notice the localization of DHPRs in the T-tubule membrane; DHPRs are intramembrane proteins that are not visible in thin-section electron microscopy but can be visualized by freeze-fracture replicas of T tubules (in C). **C,** DHPRs in skeletal muscle form tetrads, a group of four receptors (*inset*), that are linked to subunit of alternate RyRs (in **B** and **E**). **D,** In sections parallel to the junctional plane, RyR feet arrays *(white arrows)* are clearly visible in toadfish swimbladder muscle; the feet touch each other close to the corner of the molecule (*inset*). **E,** The model summarizes the findings of **C** and **D:** RyRs (*green*) form two (rarely three) rows, and DHPRs (*orange*) form tetrads that are associated with alternate RyRs. The T tubule is shown in *blue* in **B,** and sandwiched between two portions of the SR in **A**. (**A,** Courtesy Clara Franzini-Armstrong; **B,** courtesy T. Wagenknecht; from Protasi F. Structural interaction between RYRs and DHPRs in calcium release units of cardiac and skeletal muscle cells. *Front Biosci.* 2002;7:d650–d658.)

ability of magnesium (Mg^{2+}), the natural inhibitory divalent cation that competes with Ca^{2+} for binding sites on RyR1, to inhibit Ca^{2+} release in MHS skeletal muscle.[167–169] RyR1 isolated from MHS pigs demonstrate greater open probabilities, greater sensitivity to Ca^{2+} activation, less sensitivity to Ca^{2+} inactivation, and reduced inhibition by Mg^{2+}. As a result, the affected RyR1 channels spend more time in the open state and less time in the closed state than normal channels.[170–174] Although not formally confirmed, this mechanism presumably underlies the sensitivity of RyR1 channels to volatile anesthetics and to the increase in intramyoplasmic Ca^{2+} seen in MHS skeletal muscle.

Similar single-channel studies of the Ca^{2+} responsiveness of human MHS RyR1 channels have yielded more equivocal results,[175] presumably because of the genetic heterogeneity of the human MHS population. Even within a single individual, heterozygosity for an MH mutation permits a given RyR1 channel that is supposed to be made up of four identical subunits to contain any combination of zero to four MHS subunits in combination with wild-type,

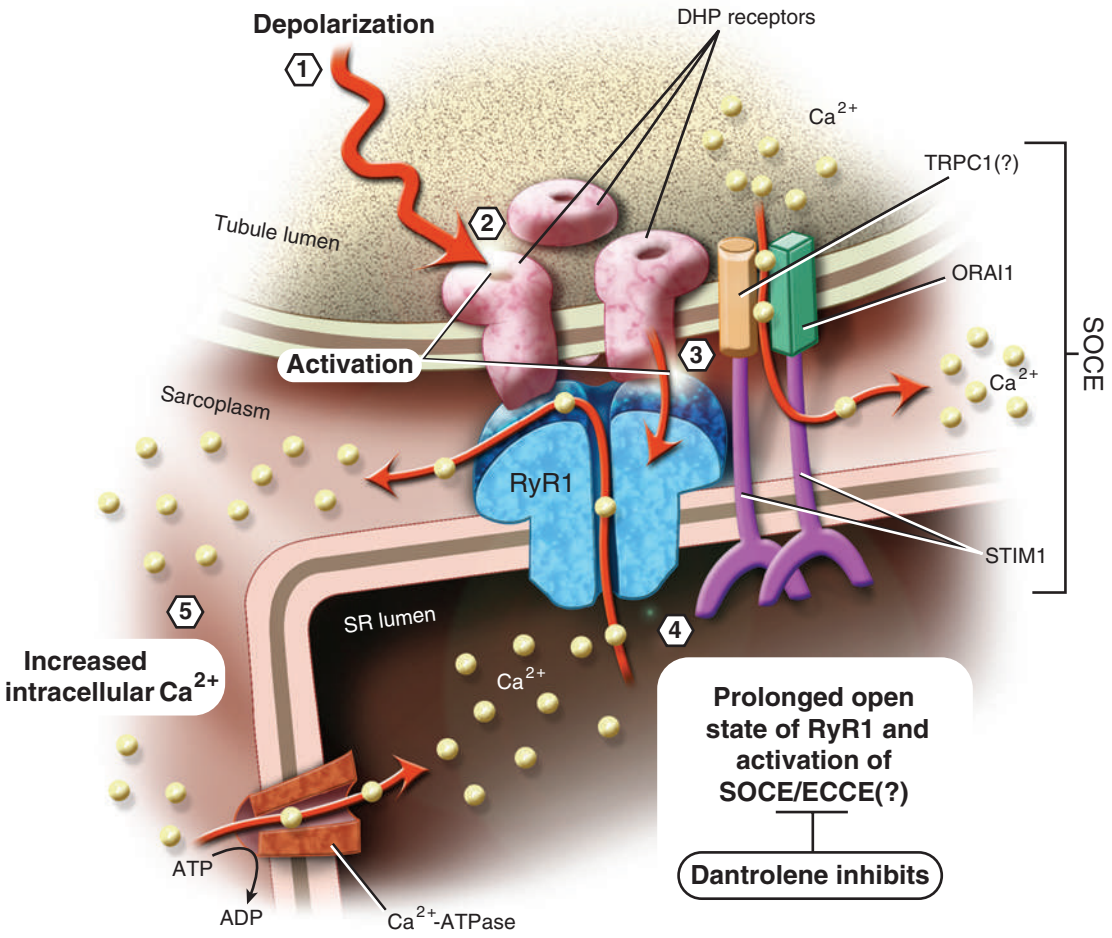

FIGURE 41.6 Schematic of the known pathophysiology of malignant hyperthermia (MH). Exposure of an individual who has a genetic susceptibility because of a ryanodine receptor (*RyR1*) or dihydropyridine (*DHP*) receptor mutation to an anesthetic triggering agent may result in MH. Normally, muscle cell depolarization (**1**) is sensed by the DHP receptor (**2**), which signals RyR1 opening by a direct physical connection (**3**). The conventional view of the genesis of MH is that RyR1 opening is easier and more sustained in the presence of volatile anesthetics (**4**), allowing a sustained rise in the Ca^{2+} concentration in the myoplasm (**5**) that surpasses the sarcoplasmic reticulum Ca^{2+} reuptake activity of the Ca^{2+}/Mg^{2+}-ATPase. This results in unrelenting muscle contraction and uncontrolled anaerobic and aerobic metabolism, which translate into the clinical manifestations of respiratory and metabolic acidosis, muscle rigidity, and hyperthermia. If the process continues unabated, adenosine triphosphate (*ATP*) depletion eventually causes widespread muscle fiber hypoxia with resultant cell death and rhabdomyolysis. Rhabdomyolysis manifests clinically as hyperkalemia and myoglobinuria and an increase in the serum creatine kinase level. Dantrolene sodium binds to RyR1, presumably causing it to favor the closed state and stemming the uninhibited flow of calcium into the myoplasm. The contributions of store-operated Ca^{2+} entry (*SOCE*) to myoplasmic Ca^{2+} fluxes and its inhibition by dantrolene suggest that MH may have a significant component from SOCE or excitation-coupled Ca^{2+} entry (*ECCE*), or both, and dantrolene may inhibit the RyR1-dependent activation of SOCE or ECCE. TRPC1, ORAI1, and STIM1 are proteins involved in calcium transport. *ADP*, adenine diphosphate; *SR*, sarcoplasmic reticulum. (Modified from Litman RS, Rosenberg H. Malignant hyperthermia: update on susceptibility testing. JAMA 2005;293[23]:2918–2924.)

normal RyR1 subunits. When examining single channels from a population of channels isolated from a heterozygous, MHS patient, the clinician can expect a wider range of channel responses than in the homozygous, inbred, porcine population used for MH models.

Several laboratories have reported the creation of knock-in mice containing one of two known MH-related RyR1 mutations: Tyr522Ser and Arg163Cys.[107,108] In contradistinction to the pig model, and like their MHS human counterparts, the knock-in MH mice are heterozygous. Their homozygous littermates die in utero on day 17. These heterozygous mice become rigid, hyperthermic, and hypermetabolic, die after exposure to inhalational anesthetics or heat stress, and respond therapeutically to dantrolene. They display exaggerated responses to the RyR1 agonists caffeine and 4-chloro-*m*-cresol and to potassium depolarization. As with MHS humans and pigs, their muscle is less sensitive to inhibitory

Mg^{2+} and possesses greater resting Ca^{2+} concentrations than wild-type animals. These experimental animals display a physiologic MH phenotype remarkably similar, if not identical, to the human syndrome and should prove extraordinarily useful in working out the details of MH pathophysiology.

Development of MH seems to require some form of neural input to muscle, because epidural anesthesia in the porcine MH model completely inhibits expression of MH.[176] However, complete inhibition of neural input into skeletal muscle in this model by the use of competitive, nondepolarizing, nicotinic cholinergic receptor antagonists such as D-tubocurarine, pancuronium, and vecuronium before a halothane challenge does not inhibit development of MH.[177,178] Together, these results suggest that a neurologically significant contribution to MH arises from the central nervous system by means of sympathetic outflow or the neuroendocrine axis, rather than direct skeletal muscle stimulation. This theory is consistent with the awake or stress-related episodes of MH described earlier.

MOLECULAR MECHANISMS AND PHYSIOLOGIC EFFECTS OF DANTROLENE

Dantrolene (Fig. 41.7) is a hydantoin derivative originally synthesized as part of an effort to examine the muscle relaxant properties of a series of substituted furan derivatives.[179] Thinking that they might have an NMBD, scientists investigated its mechanism of action but found that it differed from the known skeletal muscle relaxants. Dantrolene affected the intrinsic properties of skeletal muscle without affecting the central nervous system, neuromuscular transmission, electrical properties of the sarcolemma or the T tubule, electromyogram, or train-of-four method for testing neuromuscular blockade. Its action was intracellular (Fig. 41.8).[180] Indirect evidence pointed to dantrolene interfering with Ca^{2+} fluxes that were intrinsic to skeletal muscle contraction.[181–183] Direct observations[184,185] demonstrated that dantrolene suppressed the rate and amount of Ca^{2+} released from the SR without completely abolishing it. Subsequently, it was demonstrated that dantrolene inhibited halothane-induced Ca^{2+} release from the isolated SR of MHS pigs,[165,186,187] but was devoid of any effect on calcium reuptake into the SR.[188,189]

After SR Ca^{2+} release was identified as the likely target of dantrolene's activity, several attempts to identify a dantrolene binding partner in the SR proved unsuccessful, primarily because of the difficulties of conducting detailed pharmacologic receptor analyses with a drug as hydrophobic as dantrolene.[190,191] In 1995, an assay for radioactively labeled dantrolene helped to elucidate specific binding sites in porcine skeletal muscle SR.[192] Dantrolene inhibits RyR1-dependent cellular Ca^{2+} fluxes in skeletal muscle,

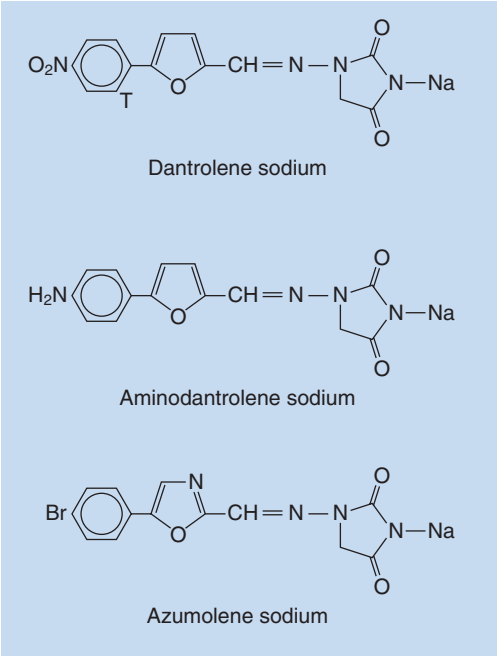

FIGURE 41.7 Dantrolene and its congeners. Dantrolene and azumolene are equipotent drugs, but azumolene is far more water soluble. Only dantrolene is approved by the U.S. Food and Drug Administration for treatment of malignant hyperthermia. Aminodantrolene is a poorly active congener, demonstrating how small changes in drug structure can result in large changes in activity. (Modified from Parness J, Palnitkar SS. Identification of dantrolene binding sites in porcine skeletal muscle sarcoplasmic reticulum. *J Biol Chem.* 1995;270[31]:18465–18472.)

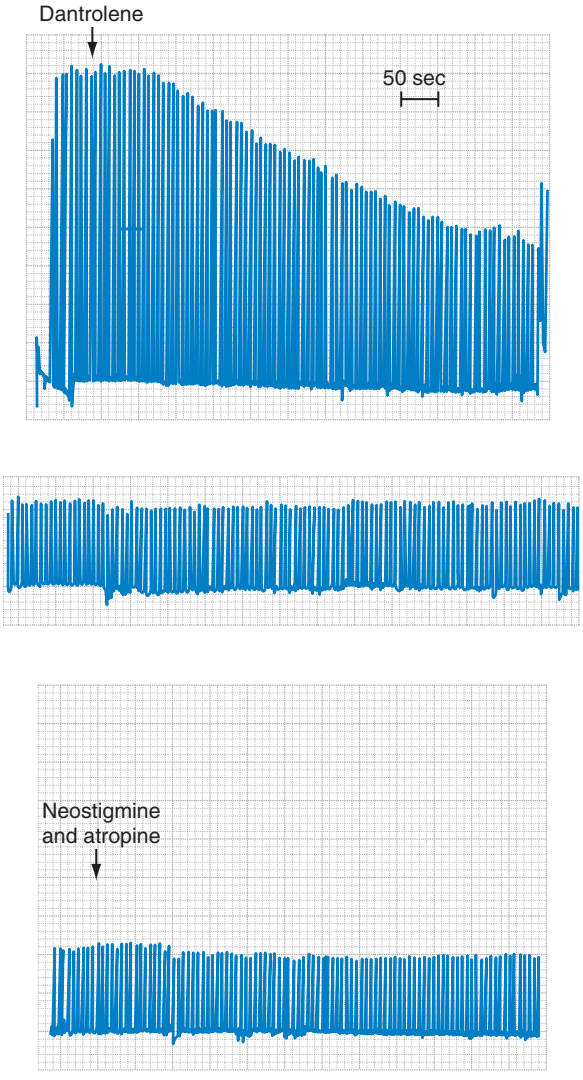

FIGURE 41.8 Intraoperative electromyogram of a child given intravenous dantrolene (2.4 mg/kg). The twitch tension decreased about 75% after dantrolene but was not reversed by administration of neostigmine, demonstrating the lack of involvement of the neuromuscular junction in the action of dantrolene.
